The relationship between sleep in the supine position and augmentation of snoring and sleep apnea in some patients is apparent. It has been hypothesized that the effects of gravity in promoting posterior movement of the tongue with apposition against the posterior pharyngeal wall are magnified in the supine position. Although manipulation of the sleeping position is not an effective therapy for the majority of patients with sleep-disordered breathing, it may be all that is needed in selected patients. It has been suggested that there may be a decreased incidence of sleep-disordered breathing events during sleep in the lateral decubitus position. Position therapy can be accomplished by sewing pockets for one or two tennis balls in the back of patients' sleeping attire in an attempt to prevent them from assuming the supine position. Devices to train people to sleep in the lateral position have been described.

Devices That Maintain Upper Airway Patency CPAP administered through a nasal mask has become the most common treatment for OSA. Nasal CPAP also effectively reduces or eliminates mixed apneas, including both the central and obstructive components. A continuous flow of air is delivered from a blower unit to a tightly fitting nasal mask held in place by head straps. Nasal CPAP acts as a pneumatic splint preventing collapse of the upper airway in all phases of respiration. The device is used for the entire sleep period every night. The optimal CPAP pressure is determined by technologists during polysomnography. Typically, 5 to 20 cm H_2O is the pressure needed to abolish apneas, snoring, and oxyhemoglobin desaturations in all positions and during REM sleep. Although CPAP use is associated with few serious complications, it does elicit a number of complaints. Minor adverse effects of CPAP include feelings of suffocation, nasal drying or rhinitis, ear pain, difficulty in exhaling, mask and mouth leaks, chest and back pain, and conjunctivitis. Most of these can be alleviated.

Newer automatic CPAP devices continuously adjust the positive pressure to the required levels. In the automatic CPAP mode, the positive pressure is maintained as long as ventilation remains stable; however, any respiratory disorder results in a progressive increase in the pressure. If a breathing disturbance has not occurred for more than 4 minutes, the positive pressure decreases again. For many patients who use it at home regularly, CPAP quite dramatically eliminates apneas and hypopneas, improves sleep architecture, and reduces daytime sleepiness, even for those with mild sleep apnea. The effectiveness of CPAP is limited, however, by incomplete patient compliance.

Oral Appliances Oral appliances are an effective noninvasive alternative to CPAP in patients with mild to moderate sleep apnea. Although oral appliances are effective in some patients with OSA, they are not universally effective. There are major design differences in the numerous oral appliances that are now available, and this may have an impact on their success and compliance rates. A novel anterior mandibular positioner has been developed with an adjustable hinge that allows progressive advancement of the mandible. This appliance may be an effective first-line treatment for the patient with mild to moderate OSA and may be associated with greater patient satisfaction than CPAP. For these devices to treat sleep apnea effectively, the mandible should be advanced to 50% to 75% of the maximal forward protrusion of the jaw. In most patients, dental appliances lessen but do not abolish OSA and snoring. In many patients treated with an oral appliance, the RDI still remains high, with more than 20 events per hour after treatment. The side effects of oral appliances include excessive salivation, dental misalignment, and pain in, or damage to, the temporomandibular joint. Several pulmonologists believe that oral appliances are just as effective as CPAP in treating sleep apnea.

Surgical Management

Surgery for OSA is designed either to bypass the obstructing region of the upper airway or to modify the upper airway in such a fashion that it is less likely to lose patency. The obstruction may result either from a wide variety of structural aberrations, such as nasal deformity, nasal polyps, hypertrophic tonsils and/or adenoids, craniofacial disproportion, neoplasms, or, as in most cases, no detectable anatomical abnormalities. Accordingly, a variety of surgical procedures have been applied to the management of these patients.

Extensive excision of soft tissue in the oropharynx, termed *uvulopalatopharyngoplasty* (UPPP), was developed to improve pharyngeal function during sleep. The procedure involves a bilateral tonsillectomy and a submucosal resection of redundant tissue. A variable portion of the posterior margin of the soft palate and the uvula is also removed and the palatopharyngeus muscle may also be resected. In the absence of weight gain or other confounding factors, a success rate of 50% has been sustained for at least 1 year postoperatively. However, even OSA patients who are UPPP failures often have substantial reduction in snoring after surgery, despite persistent apnea. A repeat polysomnogram is necessary to assess the therapeutic outcome of surgery. The success rate in patients undergoing UPPP appears to be partly related to the location of the obstructing tissue: Patients with retropalatal obstruction removal experience better results than those with retroglossal obstruction removal. The preoperative presence of tonsils has been associated with improved success of UPPP.

The patient undergoing surgical reconstruction of the airway for OSA, such as UPPP, often has coexisting medical problems, especially cardiovascular disease, which can complicate treatment. The uncertainty regarding the proper predictive parameters for surgical success greatly limits optimal patient selection. Further, a significant number of patients have difficulty at induction and intubation for general anesthesia. Men with increased neck circumference and associated skeletal deformities should be evaluated carefully and considered for fiberoptic intubation.

Laser-assisted uvulopalatoplasty is a procedure to treat snoring in the outpatient setting. The procedure entails reshaping the palate and tonsillar pillars in one to seven serial sessions under local anesthesia. Each session lasts approximately 15 minutes and is generally well tolerated; the incidence of complications is low. The procedure is successful in reducing snoring in 90% of patients. However, the success rate in patients with OSA is not yet clear.

A variety of maxillofacial and nasal surgical procedures may be performed to normalize the bony relationships of the maxilla and mandible to minimize the likelihood of airway collapse during sleep. Many of these procedures are preceded by UPPP and, if the results are unsatisfactory, a second stage involving mandibular advancement is undertaken. These procedures require a great deal of surgical and orthodontic expertise, along with careful consultation with anesthesia services and pulmonary medicine.

Nasal surgery has been performed on patients with OSA in an effort to reduce the predisposition to collapse during sleep. A nasal septoplasty is performed if gross nasal septal deformity is present. The definitive therapy is a tracheostomy. Because of the drastic nature of this procedure, it is limited to patients with life-threatening arrhythmias or severe disability who have not responded to conservative therapy.

Central Sleep Apnea

Medical treatment is ineffective in the patient with central sleep apnea. Implantation of a diaphragm-pacing device is an aggressive measure, the efficiency of which has not been proven by long-term clinical trials. Diaphragm pacing may precipitate upper airway occlusion during sleep due to dyssynchrony between activation of the diaphragm and the upper airway and laryngeal dilators. Thus, tracheostomy is often performed concomitantly with diaphragm pacing. These difficulties, in conjunction with the resource-intensive nature of the procedure and subsequent care, have made this technique one that is infrequently employed in the clinical setting of central sleep apnea.

The use of a timed bi-level system (BiPAP) device is able to normalize blood gases during sleep. The BiPAP prevents development of severe pulmonary artery hypertension during sleep. BiPAP delivers a higher airway pressure during inspiration (when the airway is most likely to be occluded) and a lower airway pressure during expiration (patient exhales against less resistance). Cardiac dysrhythmias decrease significantly. Improvement of the respiratory situation and of the hemodynamics using a timed BiPAP device may reduce the mortality rate in these patients. Bilevel systems are more expensive than conventional CPAP systems, however, and the algorithms to adjust the inspiratory and expiratory pressures are essentially empiric. Consequently, bi-level systems are typically reserved for patients who cannot tolerate CPAP, especially for those who experience difficulties with exhalation or chest pain as a result of the hyperinflation produced by the applied positive pressure.

Follow-up and Referral

In recent years, COPD and sleep apnea syndrome have been found to coexist in many patients, who are at increased risk of respiratory insufficiency. The detection of small airway disease may be difficult in OSA patients because this syndrome is associated with various pulmonary function abnormalities resulting from obesity and upper airway obstruction. Both of these factors can be responsible for airway obstruction. Patients with both disorders frequently have marked hypoxemia, hypercapnia, and pulmonary hypertension, so they should be referred for investigation of both COPD and sleep apnea. The patient with this so-called "overlap syndrome" is at a higher risk of developing respiratory insufficiency and pulmonary hypertension than the patient with "pure" OSA. Finally, hypoxemic stress is placed on the coronary circulation during sleep that may contribute to nocturnal mortality in the patient with COPD.

Patient Education

Because CPAP is a safe and effective treatment of OSA, it is important to improve patient compliance with regular CPAP use. Only 75% of patients continue to use

CPAP after 1 year, citing the noise, interference with positioning, and complaints of bed partners. Systematically collected data on family members' learning needs and descriptions of the psychosocial impact of CPAP technology treatments on family function and quality of life are essential to developing a comprehensive protocol for teaching and counseling for CPAP therapy. The effect of group patient education sessions on compliance with CPAP therapy has proved to be a simple and effective means of improving treatment of OSA. Nasal discomfort and lack of perceived benefit are possible characteristics of patients with poor compliance; these patients might benefit from education sessions and emotional support. The personal contact and teaching, along with interaction with other OSA patients, may provide an atmosphere of encouragement and support.

Counseling may be needed concerning the potential loss of employment because of poor performance or poor decision making related to profound fatigue from sleep deprivation. Problems of depression, extreme sleepiness, and the effects of hypoxia on cognition pose special difficulties for teaching these patients; their family members must be educated. Family problem-solving skills for managing equipment, overcoming psychosocial barriers to regular nightly use, and eliminating the physiological side effects of CPAP such as oral dryness are important skills and knowledge for this patient population. Home follow-up programs could help patients to eliminate reported physiological adverse effects of CPAP treatments, monitor cardiac stability, and provide ongoing education and family function assessment as evidenced in other follow-up programs. A follow-up program would be cost-effective when quality of life is considered or when compared with hospital admissions for traffic accidents or the severe cardiovascular sequelae associated with OSA.

Teaching must include nutrition counseling. Weight loss may be curative, but because 10% to 20% of body weight loss is required, many patients give up. Strict avoidance of alcohol and hypnotic medications must also be stressed. One of the developmental objectives from *Healthy People 2020* is to reduce the proportion of vehicular crashes caused by persons with excessive sleepiness. Educating patients to be aware of this and to take corrective action is an important role of the health-care provider.

SMOKING ADDICTION

A pack-a-day smoker takes more than 70,000 puffs per year. Each puff delivers a rich assortment of chemicals into the lungs and blood. Each puff also reinforces the habit a little more and augments the establishment of secondary reinforcers, such as the sight and smell of cigarettes, the lighting procedure, and the milieu and context of a meal with a cup of coffee or a cocktail. Nicotine fulfills all the criteria of a drug addiction: compulsive use, psychoactive effects, withdrawal symptoms, and drug-reinforcing behavior. Tolerance and physical dependence, manifested by an abstinence-mediated withdrawal syndrome, contribute to the strong control exerted by nicotine on smoking behavior. Although nicotine is the most popular suspect for the reinforcing agent in tobacco, there are other possibilities. Tar and carbon monoxide are the two most likely contenders. Tobacco use is the leading preventable cause of disease, disability, and death in the United States, particularly cardiovascular disease, cancer, and lung disease. Cigarettes are responsible for one in every five deaths in the United States. In addition, 8.6 million people suffer with a serious illness caused by smoking. For every person who dies from smoking, 20 more suffer from at least one serious tobacco-related illness. Besides the loss of life and the reduction in the quality of life, billions of dollars in medical expenses a year can be directly attributed to cigarette smoking.

There are hazards for nonsmokers who breathe the smoke of others' cigarettes (passive smoking or environmental tobacco smoke). *Environmental tobacco smoke* (ETS) is defined as a combination of the smoke emitted by a burning cigarette, cigar, or pipe and the smoke exhaled by smokers. Passive smoking is associated with a modestly increased risk of lung cancers and possibly other cancers and has been classified by the Environmental Protection Agency as a known human carcinogen. Exposure to ETS causes about 3,000 deaths from lung cancer per year in nonsmoking U.S. adults and damaging the respiratory health of hundreds of thousands of children who live in homes with a parent who smokes cigarettes. It has been estimated that between 150,000 and 300,000 cases of respiratory illness occurring in infants and children up to 18 months of age may stem from exposure to ETS, which increases the risk of lower respiratory tract infections.

Epidemiology and Causes

Substantial gains have been made in reducing smoking prevalence in the United States, although still almost one in four Americans smoke. More than 430,000 deaths per year in the United States are attributed to tobacco use. At the current rate, an estimated 5 million persons younger than age 18 will die prematurely from a disease related to smoking. At the cost of $50 billion per year for medical expenses, this problem is epidemic in proportion. The initiation of smoking by adolescents is now of great concern, but smoking also has become an important issue of women's health. Despite the publicizing of health risks, women continue to start smoking and to persist at high rates.

Although the reduction in overall smoking prevalence represents a major victory for public health, there are many groups within the population that have not experienced these gains. For example, low socioeconomic status and low educational attainment are now the primary predictors of smoking status in the United States and

Canada. Although there have been some important strides made in the reduction of smoking among the U.S. population, there are important target groups that continue to smoke at disproportionately high rates. These groups have been less likely to experience the benefits of tobacco control efforts.

Some forms of smokeless tobacco (plug, leaf, and snuff) have increased. "Dipping snuff," the placing of a coarse, moist powder between the cheek and gum, which results in the direct absorption of nicotine and other carcinogens through the oral tissue, has caused great concern. Oral cancer occurs more frequently among snuff dippers, as well as among pipe and cigar smokers, compared with nonusers of tobacco.

The use of tobacco products is a complex, learned behavior that is woven into the fiber of daily life and is linked to how the smoker deals with the world. Numerous daily activities, thoughts, and emotions serve as powerful cues to smoke. Such conditioned ties become paired with positive neuroregulatory effects of nicotine to reinforce the addictive process. Personal characteristics such as education level, belief in one's ability to change, and coping skills are determinants of tobacco use. Similarly, environmental factors such as the level of acceptance of smoking in the home, peer group, workplace, and community norms influence smoking behavior.

The tobacco industry's drive for profits is the root cause of why cigarette smoking continues to thrive in the United States despite towering and irrefutable evidence that it is a health hazard and a form of drug addiction. Legislative initiatives to control cigarette smoking in the United States are appreciated but not as stringent as they should be. Millions of dollars are spent every day on tobacco advertising. The estimated 3,000 children and youths who become regular smokers each year suffice to ensure an enduring supply of adult smokers. Bans on smoking in the workplace and in some restaurants have done little to discourage smokers from smoking.

Pathophysiology

When cigarettes are smoked, approximately 4,000 chemicals and gases are inhaled into the lungs. Many carcinogens have been isolated from cigarette smoke; 3,4-benzpyrene is the most dangerous. At least 43 other components have been identified as carcinogens, cocarcinogens, tumor promoters, tumor initiators, and mutagens. The primary active (and addictive) ingredient in tobacco is nicotine. In its purest state, nicotine is an extremely toxic, clear, oily liquid with a characteristic odor. At low doses, it acts as a stimulant; at high doses, it depresses the central nervous system (CNS).

Nicotine enters the body through a variety of routes. Inhalation of smoke from a cigar, cigarette, or pipe is perhaps the most common route. During smoking, some absorption of nicotine occurs through the membranes of the mouth, throat, and bronchi, as well as the alveoli of the lungs. In the case of snuff and chewing tobacco, nicotine reaches the bloodstream by absorption through the mucous linings of the mouth, nose, and throat.

Inhalation is the quickest and most effective delivery method. It is estimated that 90% of the nicotine that reaches the alveoli of the lungs in each breath is absorbed into the blood. Although an average cigarette contains from 15 to 20 mg of nicotine, only 1 to 2 mg from each cigarette smoked is actually delivered to the mouth. About 25% of the nicotine is immediately carried to the brain, where it easily crosses the blood–brain barrier and interferes with normal brain biochemistry. In humans, 60 mg of nicotine is a lethal dose.

Acute Effects of Nicotine Use

Outside the CNS, nicotine affects the transmission of nerve signals by mimicking acetylcholine. It occupies receptor sites at the synapses and prevents the transmission of nerve impulses from neuron to neuron and from neuron to muscle cells. Smoking exerts its deleterious effects primarily on the cardiovascular and pulmonary systems (Table 9.24). Nicotine, a direct adrenergic agonist, causes the release of epinephrine, which increases heart rate, systemic vascular resistance, and blood pressure. Smoking directly increases coronary vascular resistance, especially at sites of atherosclerotic plaques and stenosis. Inhaled cigarette smoke also exerts a negative inotropic effect on the myocardium, possibly due to the binding of carbon monoxide (CO) to cytochrome oxidase and myoglobin, resulting in increased myocardial oxygen consumption and decreased oxygen delivery. These changes are accompanied by the constriction of the blood vessels beneath the skin, a reduction in the motility in the bowel, and a loss of appetite.

CO, a component of tobacco smoke, is present in cigarette smoke in similar concentrations as in automobile exhaust. CO has a binding affinity for the hemoglobin molecule 250 times greater than that of oxygen, thereby reducing the smoker's oxygen-carrying capacity. In heavy smokers, as much as 15% of circulating hemoglobin may be bound to CO, reducing the oxygen-carrying capacity of the blood. In addition, CO shifts the oxyhemoglobin dissociation curve to the left, inhibiting the release of oxygen. The half-life of the COHb complex is 4 hours when the individual is breathing room air. The heart's need for oxygen is increased because of the sympathetic stimulatory effect of nicotine. Because the blood's oxygen-carrying capacity is reduced, the heart must pump more rapidly to adequately supply tissues with oxygen.

The effects of smoking on the respiratory system are diverse. The irritating effect of the smoke causes hyperplasia of cells, including goblet cells, which subsequently results in increased mucus production. Hyperplasia reduces airway diameter and increases the difficulty in clearing secretions. Smoking is known to disrupt mucociliary function and its ability to clear particles from

Table 9.24 Effects of Tobacco Smoke

Cardiovascular Effects	Respiratory Effects
Increased myocardial oxygen consumption	Decreased mucociliary clearance
Increased heart rate	Bronchospasm
Increased systemic vascular resistance	Cough
Decreased myocardial inotropic activity	Sputum accumulation
Decreased myocardial oxygen supply	Decreased circulating immunoglobulin levels
Carboxyhemoglobin (reduced available hemoglobin)	Decreased neutrophil chemotaxis
Coronary artery vasospasm	Decreased pulmonary macrophage count and adherence
Oxyhemoglobin dissociation curve shifted to the left	Altered T-lymphocyte immunoregulatory activity
	Decreased natural killer lymphocyte activity
	Decreased function of $alpha_1$-antitrypsin

the peripheral airways before any abnormality in pulmonary function is measured; smoking may cause actual loss of ciliated cells. Smoking also produces abnormal dilation of the distal air space, with destruction of alveolar walls. Many cells develop large, atypical nuclei, which is considered a precancerous condition. Smoking also alters pulmonary immune defense mechanisms by depressing neutrophil chemotaxis, decreasing immunoglobulin levels, reducing natural killer lymphocyte activity, decreasing macrophage adherence, and altering immunoregulatory T-lymphocyte activity.

In the CNS, nicotine activates receptors within the brain. Stimulation of the brain is seen by changes in EEG patterns, reflecting an increase in the frequency of electrical activity. This is part of a general arousal pattern signaled by the release of the neurotransmitters norepinephrine, dopamine, acetylcholine, and serotonin. Heavy tobacco use, resulting in high levels of nicotine in the bloodstream, eventually produces a blocking effect, as more and more receptor sites are filled. The result is a generalized depression of the CNS. When the blood levels of nicotine reach a critical point, the brain's vomiting center may be activated.

Chronic Effects of Nicotine Use

The chronic effects of nicotine include the development of tolerance and chemical dependence. These phenomena cause the user to consume greater quantities of nicotine for longer periods than the user had originally planned and thus endanger the user's health. Dependence on nicotine is quickly established in the majority of those who use it. Although psychological dependence may occur as well, the development of physical dependence, the establishment of tolerance, and the presence of withdrawal symptoms have all been demonstrated. Nicotine withdrawal symptoms include dysphoric or depressed mood, insomnia, irritability, frustration, anger, anxiety, poor concentration, restlessness, decreased heart rate, and increased appetite.

To understand better the neuropsychopharmacological basis of why people smoke, researchers performed positron emission tomography scans on smokers and abstainers and found that smokers had 40% less of a brain enzyme known as monoamine oxidase B (MAO B). The mechanisms of MAO inhibition by cigarette smoke are not known. The enzyme breaks down dopamine, a neurotransmitter associated with feelings of pleasure. Given that nicotine stimulates dopamine release and that dopamine produces pleasurable effects, it is significant in reinforcing and motivating smoking behavior. Therefore, smoking seems to create a self-perpetuating cycle: Less MAO B leads to more dopamine, which leads to more pleasure, which leads to more smoking, which leads to less MAO B, and so on. The researchers proposed that reduction of MAO B activity may synergize with nicotine to produce the diverse behavioral and epidemiological effects of smoking. The myriad of diseases associated with cigarette smoking are shown in Table 9.25.

Clinical Presentation

Subjective

Demographic, anthropometric, physiological, and laboratory features that distinguish cigarette smokers from nonsmokers reflect both baseline differences between these groups and the effects of smoking. Smokers drink more alcohol, coffee, and tea than do nonsmokers. Their weight and BP are slightly lower and their heart rate is slightly faster than those of nonsmokers. Women who smoke are at increased risk for early menopause, decreased bone density, and osteoporosis. Smoking has also been shown to decrease fertility in those attempting pregnancy and to impair uteroplacental function, which adversely affects the fetus during pregnancy. Further, sudden infant death syndrome is two to four times more common in infants whose mothers smoked during pregnancy. Smokers have impaired maximum exercise performance and impaired immune systems compared with nonsmokers. A markedly increased number of pulmonary alveolar macrophages is present in smokers, and the function and metabolism of these cells are abnormal.

Table 9.25 Diseases Associated With Cigarette Smoking

Cardiovascular	• Atherosclerotic cardiovascular disease (CAD; carotid vascular disease; mesenteric, renal, iliac disease; abdominal aortic aneurysm) • Coronary artery spasm • Arrhythmias • Peripheral vascular diseases (thromboangiitis obliterans, deep vein thrombosis, pulmonary embolus)
Endocrine	• Altered hormone secretion • Graves' disease • Antidiuresis • Goiter
Gastrointestinal	• Peptic ulcer disease (gastric, duodenal) • Gastroesophageal reflux disease • Chronic pancreatitis • Crohn's disease • Colic adenomas
Genitourinary	• Glomerulonephritis • Benign prostatic hypertrophy
Immune/musculoskeletal	• Rheumatoid arthritis • Osteoporosis
Infectious	• Tuberculosis • Pneumococcal infection • Meningococcal infection
Integumentary	• Skin wrinkling • Psoriasis
Malignancies	• Respiratory tract malignancies • Lung cancer (squamous-cell, adenocarcinoma, large-cell, small-cell) • Laryngeal cancer • Oral cancer • Others (esophagus, pancreas, bladder, uterine, cervical, breast, kidney, anus, penis, stomach, liver, leukemia)
Pediatric	• Effects on children of parental smoking (asthma, rhinitis, otitis, pneumonia, increased risk for child to begin smoking)
Psychiatric	• Depression • Schizophrenia
Reproductive	• Premature ovarian failure • Decreased sperm quality • Pregnancy-related diseases (prematurity, premature rupture of membranes, spontaneous abortion) • Fetal-/infant-related diseases (low birth weight, impaired lung growth, sudden infant death syndrome, febrile seizures, reduced intelligence, behavioral disorders, atopic disease or asthma)
Respiratory	• COPD • Asthma • Eosinophilic granuloma of the lung • Respiratory bronchiolitis • Goodpasture's syndrome • Sleep apnea • Pneumothorax
Sensory and head and neck	• Loss of olfaction • Loss of taste • Cataracts • Periodontal disease

In smokers, the ratio of high-density lipoprotein cholesterol to low-density lipoprotein cholesterol is reduced.

A causal association is present between smoking and coronary heart disease, atherosclerotic peripheral vascular disease, cerebrovascular disease, lung and laryngeal cancer, oral cancer, esophageal cancer, COPD, intrauterine growth retardation, and low-birth-weight babies. In addition, smoking is considered by many to be the probable cause or a contributing cause for other conditions such as unsuccessful pregnancies; increased infant mortality; peptic ulcer disease; and cancers of the bladder, breast, pancreas, uterus, and kidney (see Table 9.25). Smokers are at risk for increased fractures, premature wrinkling, gingival recession, dental caries, periodontal disease, cataracts, and glaucoma. Depression is twice as common among those who smoke than in people who have never smoked and has been linked to increased smoking initiation and to failures in smoking cessation efforts. A strong association also exists between smoking and other substance abuse disorders, especially alcohol. Clinical manifestations of these specific diseases, though beyond the scope of this chapter, are all clinical manifestations, directly or indirectly, of cigarette smoking.

Objective

The smoker usually demonstrates many observable signs of tobacco addiction. The smell of tobacco smoke lingers on the individual's clothing and on his or her skin and hair. The breath and sputum often smell of stale tobacco and the fingers and nails are often stained from tobacco use. Use of smokeless tobacco may manifest in periodontal disease, a gum disease that may result in the loss of teeth, abrasive damage to the enamel of the teeth caused by the tobacco during processing, and oral cancer. The patient may also have lumps in the jaw or neck area; color change in lumps inside the lips; or white, smooth or scaly patches in the mouth or throat or on the lips or tongue. A patient who smokes may present with a red spot or sore on the lips or gums or inside the mouth that does not heal or difficulty or abnormality in speaking or swallowing.

Signs of cardiopulmonary disease often accompany tobacco addiction. A productive cough, dyspnea, wheezing, and fatigue should alert the clinician to respiratory problems related to smoking. Frequent bouts of pneumonia, influenza, and bronchitis, as well as chronic diseases such as emphysema, interstitial lung disease (ILD), or chronic airway obstruction, often result from cigarette smoking. Cardiovascular signs of smoking including tachycardia, cardiac dysrhythmias, increased blood pressure, decreased peripheral blood flow, and angina must all be assessed to determine the risk for and extent of cardiovascular disease.

Nicotine dependence is related to the amount and duration of smoking and manifests as withdrawal symptoms. These signs and symptoms begin within a few hours of the last cigarette, peak 48 to 72 hours later, and return to baseline within 3 to 4 weeks of quitting. Criteria for nicotine dependence disorder are published in the *Diagnostic and Statistical Manual of Mental Disorders.* They include dysphoric or depressed mood, insomnia, irritability or anger, frustration, anxiety, concentration difficulties, decreased heart rate, and increased appetite or weight gain.

Diagnostic Reasoning

Asking the patient about smoking status and recording this information in the medical record takes only an additional 15 seconds and serves as a reminder to the practitioner to discuss the problem with each smoker. In spite of this, only 20% of smokers receive any medical quitting advice during visits to health-care providers. All patients should be asked if they use tobacco and should have their tobacco-use status documented on a regular basis as a new vital sign. It is unfortunate that teens generally do not seek medical care, because they would benefit the most from hearing about smoking cessation. This is the age-group that all providers should try to reach with this information. Several questionnaires measuring self-reported tobacco dependence have been used. The six-question Fagerstrom Test for Nicotine Dependence (FTND) predicts the level of nicotine dependence and may help predict smoking cessation success, as well as influencing nicotine replacement dosages. The FTND can be accessed at www.outcometracker.org/library/FTND.pdf.

Diagnostic Tests

Laboratory assays of smoking-related biochemical compounds such as thiocyanate, cotinine, nicotine, and carboxyhemoglobin (COHb) can be performed to verify smokers' reports of smoking status or abstinence. There are four potential sources of objective information to determine whether or not a person has smoked: urine, blood, breath, and saliva.

A urine sample can be assayed for the constituents of the cigarette smoke itself or for excretion products that are associated with the physiological effects of smoking. Nicotine excretion in smokers correlates well with the number of cigarettes smoked and inversely with pH of the urine. Urine metabolites of epinephrine can also be measured; however, a potential for false-positive results related to severe anxiety exists.

Carbon monoxide (CO) is found in the blood of those who smoke and combines to form COHb. A value of 2% suggests that smoking has occurred. However, one must take environmental and occupational sources of CO into account. Although COHb increases proportionately with number of cigarettes and varies with nicotine content, discretion is necessary in interpreting the data.

The determination of mean alveolar CO partial pressure makes it possible to determine the COHb levels of the blood with a high degree of correlation. Also, by

subtracting expired CO from inspired CO, it is possible to determine if a smoker is an inhaler. Smokers have higher levels of both expired CO and thiocyanate. To measure CO, the patient is instructed to inhale deeply and to hold his or her breath for 10 to 15 seconds before expiring with full force through the inflow valve of the monitor (EC_{50} monitor). Levels of 9 parts per million (ppm) or lower are considered to indicate nonsmoking status.

Cotinine is a major metabolite of nicotine and is a useful marker. A sample of at least 3 mL of unstimulated saliva is collected in a plastic cup. The presence of nicotine (as reflected in cotinine levels) in saliva can be determined by gas chromatography and an alkali flame ionization detector, but it is difficult to distinguish a pattern of smoking. Moreover, nonsmokers who have ingested cigarette smoke passively may also have nicotine in their saliva.

Differential Diagnosis

The best way to rule out differential diagnoses is to ensure that, for every patient at every clinic visit, tobacco-use status is queried and documented. The cause of a smoker's cough and dyspnea must be explored to rule out other explanatory causes such as lung cancer, ILD, allergies, and infections. Unfortunately, many patients with symptoms of cough, dyspnea, sputum production, and changes in pulmonary function testing not only are smokers but also suffer from some form of lung disease or disorder. Smokers tend to have unique laboratory findings such as increases in Hct, total white blood cell count, and platelet count. They may also have decreases in leukocytes, vitamin C levels, serum uric acid, and albumin.

Management

The changing face of health-care delivery in the United States indicates the need to incorporate smoking cessation as a regular part of clinical care, particularly in the current managed care environment. The Agency for Healthcare Research and Quality (AHRQ) has an extensive review and synthesis of the outcome of smoking cessation strategies, as well as recommendations for the delivery of smoking interventions in clinical practice (Level I; Agency for Healthcare Research and Quality). The Practice Guideline's key findings emphasize the importance of offering cessation treatment to every smoker at every office visit. Patients who are counseled to quit are 1.6 times as likely to attempt quitting as those who receive no counseling. The Guideline proposes a series of recommendations for primary-care clinicians, smoking cessation specialists, and health-care administrators and purchasers of health insurance, as well as specific strategies for carrying out each of the recommendations (http://www.ahrq.gov/professionals/clinicians-providers/guidelines-recommendations/tobacco/clinicians/references/quickref/index.html). Clinicians aiding patients in smoking cessation should remember the Five A's: **A**sk, **A**dvise, **A**ssess, **A**ssist, and **A**rrange, as shown in Treatment Flowchart 9.4.

The goal of every practitioner ought to be to change clinical culture and practice patterns to ensure that every patient who smokes is offered treatment. It is essential to provide a brief but effective smoking cessation intervention for all tobacco users at each clinical visit.

Initial Management

Smoking Cessation Programs Once the patient has been identified as a smoker, it is important to advise him or her of the need to quit. This should be done after the patient's chief complaint has been addressed. The patient's response will determine the proper strategy to pursue. The patient must be informed of how unhealthy smoking is. Pregnant smokers should be strongly encouraged to quit throughout pregnancy. Because of the serious risk of smoking to the pregnant smoker and fetus, pregnant smokers should be offered intensive counseling treatment. Patients should choose a quit date, usually within a month. This will provide a chance to develop effective alternative behaviors to smoking. Periods of extreme stress or depression are not optimal times to attempt smoking cessation.

Before initiating a smoking cessation program, the clinician must know which state of smoking cessation the client is in at that time. This is the first step of the provider-initiated smoking cessation program. Most smokers transition through five stages of behavioral change in their attempts at cessation—precontemplation, contemplation, preparation, action, and maintenance. By understanding the smoker's stage of behavior and readiness to change, the clinician can better assist him or her to achieve a successful cessation.

Smokers in the *precontemplation stage* have no desire to quit in the next 6 to 12 months. These individuals usually benefit from motivational interventions that increase awareness of the adverse affects of smoking. Smokers who are giving serious thought to and are interested in quitting but are not yet ready to do so are in the *contemplation stage.* These smokers also will benefit from motivational counseling emphasizing the negative effects of smoking. Smokers who are serious about quitting and have taken the initial steps toward cessation are in the *preparation phase.* Individuals in this stage benefit from interventions that assist them in quitting. These interventions include providing information about nicotine replacement and developing behavior modification skills.

During the *action stage,* the smoker quits smoking. The action stage lasts from several weeks to 6 months after cessation, which is a common time of relapse. Because of the likelihood of relapse during this stage, interventions should address relapse prevention, including congratulating successes and rewarding positive behavioral changes with more frequent contacts by the clinician. When a smoker has abstained from cigarettes for

Treatment Flowchart 9.4 Smoking Cessation Strategies

6 months, the *maintenance stage* begins. Most successful quitters relapse and recycle through these stages three or four times before attaining long-term abstinence; some may take several years to move through these stages until abstinence can be maintained.

Effective smoking cessation requires behavior modification. The behavior of smoking is usually linked to a variety of triggers (e.g., stress, foods or beverages, driving). When a patient is able to recognize the triggers, healthy alternative behaviors can be substituted. It is crucial to develop alternative coping strategies to overcome the urge to smoke. Such strategies include deep breathing and relaxation exercises, chewing gum, exercise, drinking water, sucking on a piece of sugarless candy, and eating carrots or celery sticks.

Patients with any chronic health problem need support from their clinicians, their families, and other persons. The clinician can help the patient handle particularly difficult triggers and can treat any underlying behavior problems, such as anxiety or depression. The family can provide invaluable positive reinforcement to the patient during this time. If there are other smokers in the patient's household, the clinician should encourage them to quit smoking at the same time as the patient. It is very difficult for a person to refrain from smoking in the long term when a spouse or a family member continues to smoke. Many patients benefit from the support of groups such as Nicotine Anonymous, the American Lung Association's Freedom from Smoking program, and the American Cancer Society's Freshstart program.

Hypnosis The goal of hypnosis in smoking cessation is to enable the smoker to achieve an altered state of consciousness that enhances the ability to quit. However, the hypnotic trance is generally not measurably different from deep muscle relaxation. The effects of hypnosis are often short-lived. Controlled trials of hypnosis have generally not documented long-term efficacy for smoking cessation. Hypnosis is of low reliability, with published quit rates ranging between 0% and 88%. Although it is of uncertain value, hypnosis remains a commercially popular stop-smoking method. The primary advantage of hypnosis is that it may be an attractive alternative for people who have failed to quit with other methods.

Aversion Conditioning Aversion conditioning is based on the premise that smoking is a learned response that can be extinguished by creation of an association between smoking and a negative sensation. Among the aversion techniques utilized for smoking cessation are electric shock; nausea-inducing drugs; hot, smoky air treatments; and rapid smoking. High quit rates were reported in some of the early smoking cessation trials using aversion conditioning; however, these high rates may be attributed, in part, to factors related to patient selection, because arguably only the most highly motivated persons are willing to undergo therapies such as electric shock or the breathing of hot, smoky air. In addition, aversion conditioning techniques may represent a health hazard.

Subsequent Management

Pharmacological Approaches Although some smokers may need antidepressants or anxiolytics, it is difficult to predict who will benefit from these adjunctive therapies. Bupropion (Zyban) is an antidepressant and smoking deterrent. Bupropion is a weak inhibitor of the neuronal uptake of norepinephrine and dopamine but has no effect on serotonin. Its dopaminergic and noradrenergic activities are responsible for its efficacy in smoking cessation, with the dopaminergic activity affecting areas of the brain having to do with the reinforcement activity affecting nicotine withdrawal. Bupropion appears to have no effect on patient depression scores, so it is unlikely that the mechanism for the efficacy of bupropion is through its antidepressant effects. Bupropion is well tolerated, with the most frequent adverse effects being headache, insomnia, and dry mouth. Antidepressants are associated with a small risk of seizure. Moreover, patients with a history of severe head trauma, eating disorders, recent myocardial infarction, unstable heart disease, or active alcoholism should not take bupropion.

The dosage of 300 mg per day (150 mg per day for 3 days followed by 150 mg twice a day) is begun 1 to 2 weeks before smoking cessation. It is important for the steady-state plasma levels of bupropion to be reached (usually within 8 days) before smoking cessation is begun. This dosing schedule has been found to lead to less weight gain during the medication phase. The duration of treatment is usually 7 to 12 weeks. For maintenance therapy, bupropion SR 150 mg twice a day for up to 6 months should be considered. As with the nicotine replacement products, behavioral modification therapy should coexist. For heavily addicted smokers, nicotine replacement therapy and bupropion can be coadministered concurrently.

Varenicline (Chantix) is a nicotinic acetylcholine receptor partial agonist used as a smoking cessation aid, and it is also recommended that therapy begins 1 week before a target quit date is set. Smoking cessation aids are listed in Drugs Commonly Prescribed 9.3.

Health-care providers need to be aware of the nuances of smoking cessation. For example, individuals often experience constipation during cessation, as the gastrointestinal system adjusts to withdrawal from the stimulating effects of nicotine. The use of a bulk-forming agent such as Metamucil, increased dietary fiber, and increased fluids will alleviate the problem. A form of exercise, such as walking, is an excellent, affordable stress reliever. A walking program also assists with reducing the expected mean weight gain of 5 to 7 pounds that occurs with smoking cessation. Nicotine is an appetite depressant, and once its effects have cleared from the body, food tastes better.

Drugs Commonly Prescribed 9.3 Therapies for Smoking: Prescribing Considerations

Drug	Dosage	Advantages	Disadvantages
Transdermal Patch		**Continuous Delivery**	**Expensive**
Nicoderm CQ (worn 24 hr/day)	21 mg/day for 4–6 weeks, then 14 mg/day for 2–4 weeks, then 7 mg/day for 2–4 weeks	Less instruction required than gum	Risk of insomnia or nightmares
Gum (nicotine polacrilex)		**Useful on "As Needed" Basis**	**Requires Good Dentition**
Nicorette	2 mg/piece; max 30 pieces/day 4 mg/piece; max 24 pieces/day	Provides oral gratification Patient control Delayed weight gain	Risk of mouth irritation Dyspnea, nausea Risk of developing dependence
Nasal Spray		**Useful on "As Needed" Basis**	
Nicotrol (10-mL bottle)	0.5 mg/spray; 2 sprays; maximum 40 doses/day for 3 months	Rapid delivery	Risk of nasal and throat irritation Runny nose Watery eyes
Inhaler			
Nicotrol inhaler	13 mcg/puff; 6–16 cartridges/day for 3 months	Mimics smoking behavior	Risk of cough, irritation of mouth and throat
Lozenge			
Commit	2 mg (if first cigarette smoked >30 min after waking) 4 mg (if first cigarette smoked within 30 min of waking) max. 20 lozenges/day, dissolve over 20–30 min; minimize swallowing		May cause hiccoughs, heartburn.
Other			
Bupropion hydrochloride (Zyban)	150 mg/day for 3 days, then 150 mg bid for 7–12 weeks (possibly up to 6 months)	Nonnicotine, less weight gain	Risk of seizures, headache, dry mouth, insomnia
Varenicline (Chantix)	0.5 mg/day for 3 days, then 0.5 mg bid for 4 days, then 1 mg bid for 12 weeks, take with a glass of water after eating	Nonnicotine	Nausea Risk of serious neuropsychiatric symptoms including depression, altered mood and behavior, and suicidality

Nicotine Replacement Therapies Nicotine is the drug of choice to assist smoking cessation. The nicotine patch, gum, and lozenges are available over the counter (OTC), and nicotine nasal spray and inhalers are available by prescription (see Drugs Commonly Prescribed 9.3).

Increased access through OTC availability has substantially increased the number of quitters in the United States. Evaluations of the efficacy of nicotine gum through 12-month follow-up suggest that the gum improves smoking cessation rates by approximately 40% to

60% compared with control interventions. Efficacy is increased when nicotine gum use is combined with an intensive psychosocial intervention. The efficacy of the nicotine patch overall appears to be somewhat stronger than that for the gum. The patch has been found to double the 6- to 12-month abstinence rates over those yielded by placebo interventions.

The cost of the patch remains relatively high, however, which places this cessation strategy out of the reach of some smokers. Although the manufacturer of nicotine gum has developed a series of strategies for increasing access to nicotine replacement therapy among underserved populations, it is not clear if the penetration of such programs can match the need for an effective strategy among lower-income and other underserved groups.

The gum must be correctly chewed to a softened state and then placed in the buccal mucosa. Clients should not eat for 15 minutes before or during use of the nicotine gum. A piece of gum should be chewed intermittently over a 30-minute period. Initially, one piece is chewed every 1 to 2 hours over 6 weeks with a maximum of 24 pieces in 24 hours. Time intervals for gum use are gradually increased to 2 to 4 hours for 3 weeks, then every 4 to 8 hours for 3 weeks. Fewer than 10% of patients will become dependent on the gum although many will require long-term use (1–2 years) to maintain abstinence. Nicotine absorption is decreased by acidic foods and beverages, which should be avoided during use. Irritation and trauma to the oral mucosa, teeth, and dental work can occur. Many patients experience jaw ache, gastrointestinal discomfort, hiccups, and cardiostimulation.

Nicotine patches are applied every morning and worn for 24 hours per day. Patches are usually indicated for 8 to 12 weeks to promote long-term abstinence. Patients should be instructed to change the application site daily to minimize skin irritation. The highest-dose patch should be considered if the patient smokes more than 20 cigarettes per day and has no active cardiovascular disease. Because a dose–response effect has been found, researchers recommend that a higher nicotine dose is more effective for smoking cessation. The adverse effects of the patches include skin reactions, insomnia, vivid dreams, and myalgias. If vivid dreams or insomnia occur, the patient should be instructed to remove the patch before going to bed and then to apply a new patch on arising.

The nicotine nasal spray (Nicotrol nasal spray) delivers nicotine in a more rapid manner and thereby serves as a better substitute than nicotine gum or a nicotine patch. The device is similar to nasal antihistamine sprays. The nasal spray delivers 0.5 mg of nicotine per spray. Smokers are instructed to use one to two doses per hour for 3 months for up to 40 doses per day. The nasal spray delivers nicotine more rapidly than gum, patch, or inhaler but less rapidly than cigarettes. Peak levels occur within 4 to 15 minutes and are about two-thirds of those associated with cigarettes. Patients initially experience nasal and throat irritation, rhinitis, sneezing, coughing, and watering eyes. Tolerance to these effects develops in the first week. The spray may cause serious dysrhythmias, elevated blood pressure, and angina in post–myocardial infarction patients. Use of the spray is not recommended in patients with several other chronic diseases, including asthma, peptic ulcer disease, chronic nasal disorders, severe renal impairment, liver disease, diabetes, and hyperthyroidism.

Researchers have found that the use of a nicotine patch with a nicotine nasal spray is significantly more effective for long-term smoking cessation than with either alone. The results suggest an increased efficacy in prevention of relapse with more intake of nicotine or by combining different types of nicotine replacement therapies. The combination of a nicotine patch and nicotine nasal spray may be successful not only because of the high level of substitution but also because of the opportunity to respond quickly to the smoker's need. Researchers have suggested that using a patch for 5 months with a nicotine nasal spray for 1 year provides a more effective means of stopping smoking than using a patch alone.

The nicotine inhaler (Nicotrol inhaler) is a plastic rod with a nicotine plug that provides a nicotine vapor when puffed on. Each active cartridge contains approximately 10 mg of nicotine and 1 mg of menthol. The menthol is added to decrease the throat irritation caused by the nicotine. Although the device is designed as an inhaler, this label is a misnomer because the device does not deliver a significant amount of nicotine to the lungs; rather, the device delivers nicotine buccally. This occurs whether smokers use deep or shallow puffs. Each cartridge lasts about 20 minutes and provides the nicotine equivalent of about two cigarettes. Patients use 6 to 16 cartridges per day for 3 months, then taper for 6 to 12 weeks as needed. The most common adverse effects are cough and irritation in the mouth and throat. The inhaler has the potential to assist in the smoking cessation process not only by providing nicotine replacement but also by mimicking the behavioral aspects of smoking. Such a device clearly blurs the line between cigarette and nicotine-delivery device, however. In effect, the patient is brand switching (i.e., switching from his or her usual brand of cigarette to a smoke-free nicotine-delivery device) even though the effort required to obtain nicotine from the inhaler is greater than that required from a cigarette. Combining the nicotine inhaler with the nicotine patch may increase the efficacy over using the patch alone because the inhaler would serve to supplement the nicotine provided by the patch and mimic smoking behavior.

Follow-up and Referral

As with any serious medical problem, follow-up is essential after the initial intervention. A supportive phone call the week after the quit date can be made by a healthcare worker with the reinforcement of the self-help materials that have been provided. Office follow-up by the

clinician at 1 and 3 months after the quit date can help the patient who has quit smoking to cope with persistently difficult triggers or situations; this support can help the patient who may have relapsed get back on the right track. In the case of relapse, the client should be assisted to set another quit date, revisit the reasons for quitting, and begin the process again. Assure patients that stable abstinence is commonly achieved only after five or six attempts.

Patient Education

For years, cigarette smoking was viewed as largely a social or psychological habit. As such, the ability to quit was considered a measure of personal motivation and willpower. Motivation to stop smoking, combined with sufficient psychological resources, was seen as a driving force behind successful cigarette abstinence. Thus, if smokers could be educated about the health risks of cigarette smoking, they could theoretically become sufficiently motivated and psychologically empowered to quit. Unfortunately, the anticipated benefits of achieving smoking cessation through education were overoptimistic and simplistic. More than 80% of current smokers indicate they would like to quit but cannot. Educational programs to aid smoking cessation have produced disappointing results and high long-term failure rates. Only about 4% of smokers are able to quit each year. Nonetheless, it is helpful to give the patient some age-specific smoking cessation literature.

It is important to understand the meaning of smoking to the individual patient, to hear the "patient's voice" (see The Patient's Voice 9.1). Assisting the patient in ceasing smoking involves an empowerment process that enhances the patient's motivation and self-esteem. The provider can facilitate this process by providing available cessation information to both the patient and the family. There must be a family-focused emphasis, with shared commitment and participation. Providers can encourage patients to identify daily stressors and assist them to reframe situations and develop alternative coping strategies. Equally important is developing an enhanced self-efficacy, which includes accepting and believing in the ability to succeed. Providers need to ask how the patient usually deals with stress and give simple, usable alternative coping strategies. A telephone hotline with recorded messages that empower and encourage can be an effective way to manage and overcome the desire to smoke. Information about the rewards of smoking cessation, such as improved health with lower blood pressure and improved circulation and lung functioning, should be provided. Individuals who cease smoking report more energy, enhanced taste and smell, money saved, freedom from addiction, feeling better about oneself, and better performance in sexual and sports activities. Smokers older than age 55 years should be informed that despite many years of smoking, smoking cessation will improve their health. They will enjoy a better quality of life as ex-smokers and their risk for lung and other smoking-associated cancers will be reduced. Smokers die 5 to 8 years earlier than persons who have never smoked. Additional rewards for older adults can be the satisfaction of being a positive role model for other family members and making a contribution to the improved health of their grandchildren. To enhance recovery from nicotine addiction and prevent relapse, both individual and group cessation counseling and education must include a family focus.

The Patient's Voice 9.1

Battleground

"What is it with you and your cigarettes, anyway?" I angrily thought to myself after yet another heated debate with my father about smoking. As usual, he had been defending cigarettes as a source of pleasure, saying he always enjoyed smoking. He was against federal attempts to regulate levels of nicotine or restrict access. After smoking for 60 years, he quit last year, when the severity of his lung disease nearly took his life. Why couldn't I make him understand that cigarettes were killing people?

He must have sensed my frustration or read my mind, because as his O_2 concentrator clicked off and on, he looked at me and said softly, "You know, Snicklefritz, it was cigarettes that saved my life many times during the war." My father rarely talks about THE WAR. He was a combat infantryman, a machine gunner, part of the Fifth Division known as "Roosevelt's Red Devils." He started slowly . . .

"At night we were the point. Machine gunners never got relieved. The cold was the worst. You couldn't imagine the cold. Raining—below freezing. We would take turns sleeping. You couldn't sleep for more than an hour. You had to rely on your buddies to wake you up. You had to keep moving to keep from freezing. Many only lasted one night and had to be sent back because their feet were frozen. I think we lost more men to cold that winter than from enemy fire.

"I remember standing up one night with tracers going by my head, yelling 'Go ahead and shoot me—put me out of my misery!' My buddy had to pull me down. He said. 'Have a cigarette—calm yourself!' We had to cover our heads with raingear to keep anyone from seeing to light up and give away our positions. You can't imagine the warmth and comfort in one cigarette. We were worried about living through the night.

"There were times warmth of a cigarette was the only thing that kept us alive. We were short of supplies that winter, but they always kept us in cigarettes. Even our K-rations came with a pack—I'll give them that."

As he talked, I tried to imagine, to understand, the inhuman conditions he was describing and the meaning cigarettes held for him. As I listened to my father's

story and watched him pull his arms to his chest and cup his hands to his face, as if he were holding something as precious as life itself, I finally heard what he had been saying for years. I began to feel my anger slipping away—anger with my father for smoking all those years and for nearly dying before my 3-year-old son had a chance to come to know him.

I felt my eyes fill with tears, not for the suffering my father had experienced during the war, but for the suffering he experienced because his daughter, the nurse, never understood.

Chapter 10

Cardiovascular Problems

Kathryn B. Keller, PhD, RN • Denese Sabatino, MSN, APRN, NP-C, CCRN • Jill E. Winland-Brown, EdD, APRN, FNP-BC • Brian Oscar Porter, MD, PhD, MPH • Michael B. Keller, MD, MS

COMMON COMPLAINTS

CHEST PAIN

Although chest pain is often associated with cardiovascular problems, it may also have pulmonary, gastrointestinal, musculoskeletal, neurological, psychogenic, or idiopathic causes. If the chest pain is related to coronary artery disease, the incidence increases after age 35 in men and after menopause in women. See Nursing Research-Based Practice Box 10.1 for a discussion of women's decisions to seek treatment for the symptoms of potential cardiac illness. In individuals up to 50 years of age, chest pain occurs more frequently in men, and then equally in men and women older than 50 years.

Differential Diagnosis

Obtaining a focused health history and physical exam is essential for accurate assessment and appropriate treatment for a patient with chest pain (see Differential Diagnosis Flowchart 10.1). Critical components of the history include appraisal of the major symptoms of heart disease, including chest pain, dyspnea, syncope, and heart failure. The clinician should ask patients in all age-groups about tolerance of exercise, especially whether exercise provokes any of the aforementioned complaints. The history of the present illness of the person with chest pain should focus on personal risk factors for cardiovascular disease.

The clinician should obtain a complete chest pain symptom analysis including location, quality, duration, aggravating or relieving factors, and associated symptoms or signs. In particular, localized, fleeting, and moving pain is rarely indicative of serious cardiac pathology. Anxiety and bereavement can cause diffuse pain and chest tenderness lasting for hours. Costochondritis is often described as localized, and it can be replicated with arm movement or pressing on the area of tenderness.

In contrast, the discomfort of angina pectoris is classically described as a diffuse, retrosternal sensation, often with radiation, and a heavy, burning sensation, usually lasting more than 1 minute but less than 10 minutes. Exertional symptoms are usually more common in individuals with fixed atherosclerotic lesions. In assessing the person with known angina pectoris, it is critical to ascertain if there has been a change in the symptom pattern because this may indicate an alteration in vessel patency such as that found in accelerated atherosclerosis or vessel spasm. The word "pain" should be used with caution in taking the history of a person with suspected myocardial ischemia because the patient may deny that pain is present but may agree that tightness, burning, fullness, or other sensations more aptly describe the complaint.

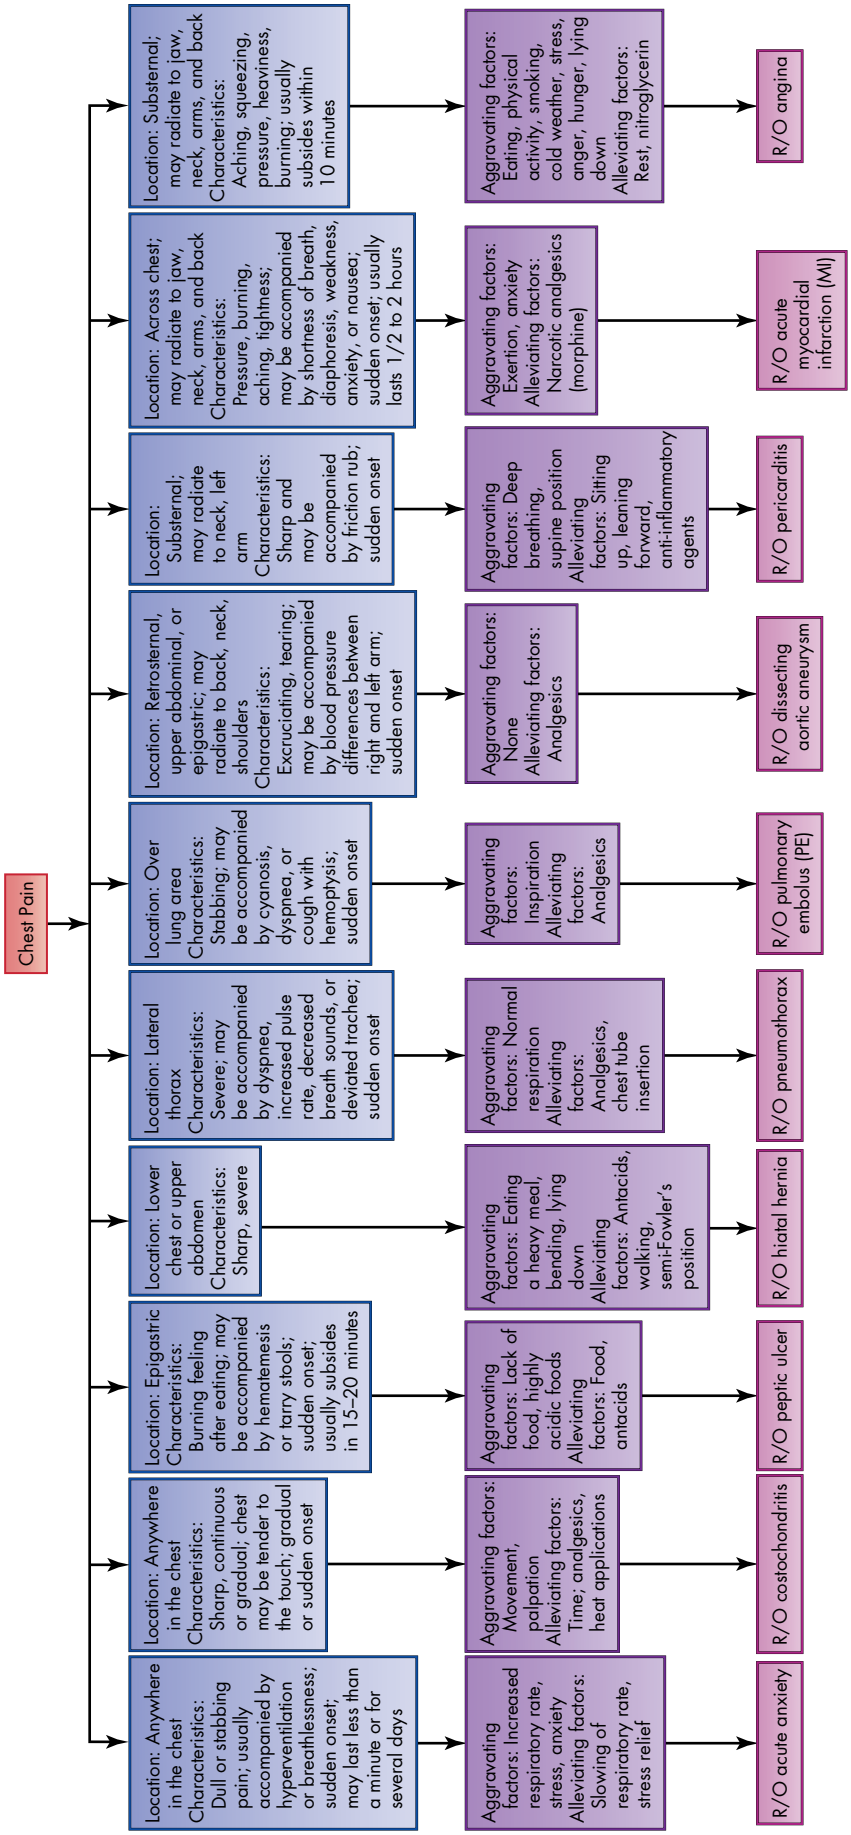
The terms *unstable angina, preinfarct angina,* and *crescendo angina* are synonyms used to describe the condition in which there is a new onset of cardiac ischemic chest pain at rest but without evidence of acute myocardial infarction (MI). Reports of symptoms at rest are

Nursing Research–Based Practice 10.1

Turris, SA. Women's decisions to seek treatment for the symptoms of potential cardiac illness. *J Nurs Scholars* 41(1):5–12, 2009.

Cardiac disease is the number one killer of Canadian women, and therapies are often highly time dependent. Consequently, understanding the forms of knowledge that women draw on to understand and interpret their symptoms of a potential cardiac event may be important in relation to efforts to reduce treatment-seeking delay. Data for this grounded-theory study were drawn from in-depth interviews with 16 women who went to one of two emergency departments for the treatment of symptoms indicating potential cardiac illness. The basic social process of maintaining integrity explained the women's interpretations of, and actions in relation to, their symptoms. Decisions about treatment seeking were influenced primarily by the context of the women's lives as mothers, daughters, and wives and only secondarily by the women's interpretations of and conclusions about their symptoms. Four ways of knowing are shared to explain their decisions to seek treatment.

Differential Diagnosis Flowchart 10.1



more likely to be associated with coronary artery vasospasm, a condition usually seen in patients with coronary atherosclerosis. The combination of two mechanisms of lumen narrowing leaves the patient at considerable risk for an acute coronary syndrome; in these cases, rapid and accurate assessment is vital to ensure appropriate disposition and treatment.

About one-third of patients with angina pectoris will have simultaneous dyspnea caused by transient increase in pulmonary venous pressures that accompanies ventricular stiffening during an episode of myocardial ischemia. The presence of diaphoresis with chest pain is particularly worrisome, often indicating a significant drop in cardiac output during the episode of pain and subsequent decreased perfusion of the skin. In contrast to the patient who complains of anginal pain, the patient who is experiencing an acute MI often complains of anginal-like chest pain that lasts in excess of 20 minutes but occasionally waxes and wanes during that period. The pain is frequently accompanied by dyspnea, diaphoresis, nausea, and dizziness. The pain may radiate to the neck, jaw, shoulder, or arm (left side more than right). Patients show extreme variation in the amount of pain experienced with an MI, from complaining of a "vise around the heart" to apologizing for seeking assistance with "just a bit of indigestion that will not clear up." In particular, women, older adults, and people with diabetes mellitus are likely to have minimal or atypical symptoms with an acute MI. A more detailed discussion of the pain of angina and MI is provided in the sections on treatment of those conditions later in the chapter.

PALPITATIONS

Palpitations are commonly reported by the individual who has or is at risk for heart disease. *Palpitations* are defined as the awareness of the beating of one's heart and may be benign or pathological in nature. When questioning the patient with palpitations, the clinician should obtain a detailed description of the sensation. If the patient reports a sensation of a strong but regular rhythmic beating of the heart after stress or exertion, this likely indicates a normal physiological response to the increased catecholamine production. If there is a report of skipped or missed beats, particularly with the sensation that the heart "stopped" momentarily, this may indicate the presence of an atrial or ventricular ectopic beat.

Differential Diagnosis

Atrial ectopic beats are most often benign, occurring with excessive caffeine, alcohol, or tobacco use. On occasion, atrial ectopic beats occur with cardiac pathology, sometimes as a precursor to a supraventricular rhythm such as multifocal atrial tachycardia or atrial fibrillation. This is most likely in the patient with chronic obstructive pulmonary disease (COPD) or rheumatic heart disease and valvular dysfunction.

Ventricular ectopic beats are somewhat more likely to indicate cardiac pathology than atrial ectopy. If the patient is at high risk for or has known heart disease, the clinician must carefully assess the complaint of palpitations because ventricular ectopy may indicate increased risk for sudden cardiac death.

Another variation on the presentation of palpitations is the patient who complains of a sudden onset of a very rapid heartbeat or fluttering of the heart. The etiology may be a supraventricular or ventricular tachycardia, often with equally rapid and unpredictable cessation of the rhythm, or a rhythmic paroxysm. Although this type of rhythmic sensation is usually regular, such as in paroxysmal supraventricular tachycardia or ventricular tachycardia, it may also be irregular, such as in intermittent atrial fibrillation. In any case, the clinician should query the patient carefully about cosymptoms such as chest pain related to decreased coronary artery filling and increased myocardial oxygen demands, as well symptoms associated with low cardiac output.

Diagnostic testing should be directed by information obtained in the health history and physical exam. As with cardiac-related syncope, thyroid function (thyroid-stimulating hormone), blood chemistries, hemoglobin, and hematocrit should be evaluated to help rule out thyroid disorder, electrolyte imbalance, or anemia as a possible, though less common, cause of palpitations. Ambulatory cardiac monitoring (Holter monitoring) until at least one event is recorded is most helpful in ascertaining the presence of a potentially lethal cardiac rhythm disturbance. Echocardiography may be necessary to assess cardiac outflow tract patency and to help rule out valvular stenosis or hypertrophic cardiomyopathy.

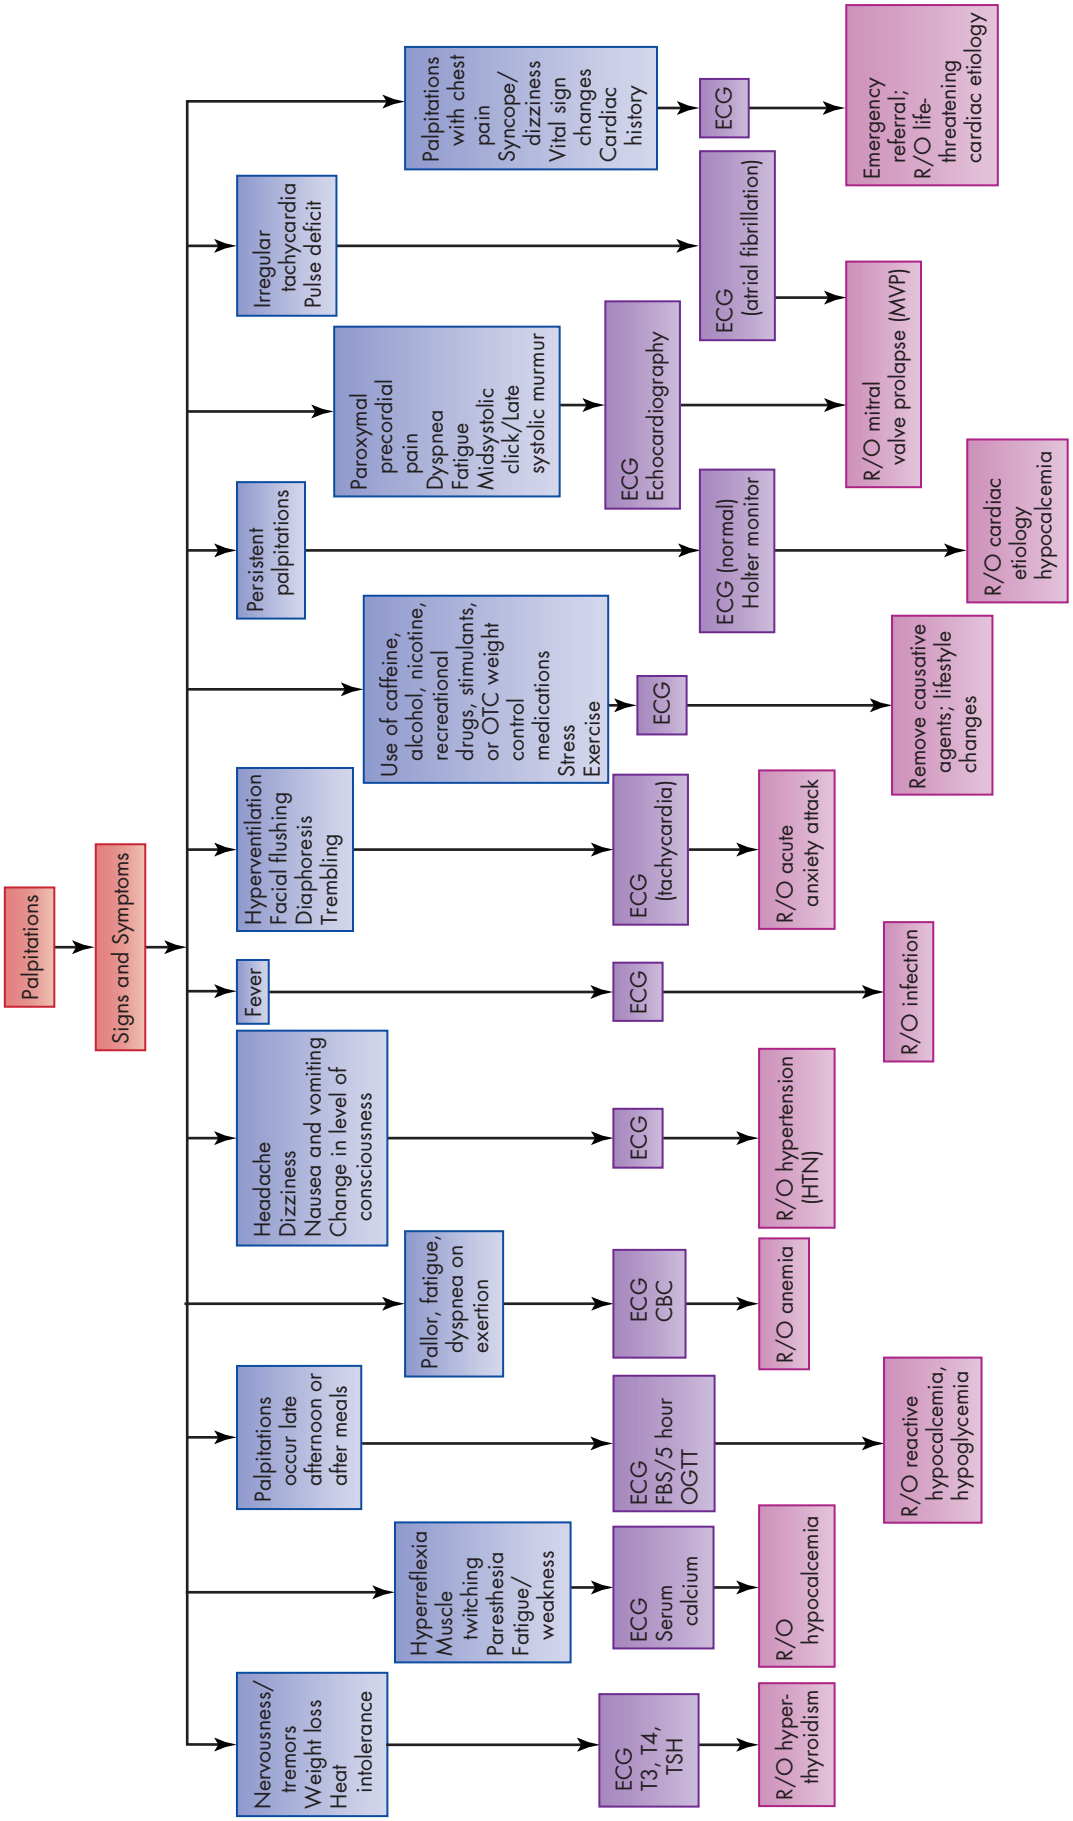
Intervention should be directed at the underlying cause of the palpitations. For example, if a rhythm disturbance such as recurrent supraventricular or ventricular tachycardia is the cause, treatment directed at eliminating this is warranted. In any event, the clinician should consult with a physician or cardiologist who has expertise in this area to ensure patient safety and optimal outcome.

Differential diagnoses of palpitations are presented in Differential Diagnosis Flowchart 10.2.

SYNCOPE

Syncope is loss of consciousness that occurs abruptly as a discrete episode and usually lasts for a short period of only a few minutes. The implied pathology is decreased cerebral blood flow caused by a marked decrease in cardiac output. Approximately one million people are affected by syncope in the United States every year. Whereas some of these episodes are explainable and of noncardiac origin (e.g., fluid loss, dehydration, emotional stress), the vast majority of these episodes are cardiovascular in origin. Cardiac-related syncope is an ominous sign associated with high rates of mortality. A syncopal episode may be the only warning sign of impending sudden death. One of the most common cardiac causes of

Differential Diagnosis Flowchart 10.2



syncope is cardiac arrhythmias (Level I; Heart Rhythm Society, 2013). A wide range of conduction disturbances can precede a syncopal event and may include tachycardia-bradycardia syndrome (sick sinus syndrome), supraventricular and ventricular tachycardias, heart blocks, and bradycardia.

Differential Diagnosis

Cardiac outflow tract blockage, such as the obstruction that may occur in hypertrophic cardiomyopathy and aortic valve stenosis, can also produce syncope. This is most often seen in response to increased activity or stress when the outflow tract blockage impedes the increase in cardiac output needed to meet the increased demands for oxygen. This leads to syncope that typically lasts for a few seconds and ends when the "rest" of the syncopal episode helps balance supply and demand.

Presyncope, a state of light-headedness, feeling faint, and muscular weakness, is most often cardiovascular in origin. The etiology is usually the same as for syncope. In contrast, *vertigo* is when the person has the sensation of staggering or veering in a certain direction or of spinning. The sensation can often be reproduced by a change in head position. In vertigo, the cause is usually something other than decreased cerebral blood flow, often an inner ear disturbance, for example.

Diagnostic testing for cardiac-related syncope should be directed by the information obtained in the health history and physical exam. Blood chemistries, thyroid-stimulating hormone, hemoglobin, and hematocrit should be checked to help rule out electrolyte imbalance, thyroid disorder, or anemia as a possible, though less common, cause of syncope. Ambulatory cardiac monitoring until at least one event is recorded is most helpful in ascertaining the presence of a potentially lethal cardiac rhythm disturbance. Echocardiography may be necessary to assess cardiac outflow tract patency and to rule out valvular stenosis or hypertrophic cardiomyopathy. A tilt-table test may be performed to assess for orthostatic syncope.

Intervention in cardiac-related syncope should be directed at the underlying cause. If a rhythm disturbance (as described previously) is the cause, treatment should be directed at eliminating the conduction disorder. Ablation, an internal cardiac defibrillator, and/or a permanent pacemaker may be indicated depending on the type of arrhythmia. In any event, the clinician should consult with a cardiologist to ensure patient safety and an optimal outcome.

DYSPNEA: SHORTNESS OF BREATH

Dyspnea, or shortness of breath, is a highly subjective complaint, yet it is one of the most common cardiac symptoms. The challenge to the clinician is to determine its etiology. As with any complaint, the patient with dyspnea should be asked about precipitating factors, quality, duration, alleviating factors, and the length of time needed to relieve the symptom after discontinuing the precipitating event. In addition, dyspnea may be an anginal equivalent, especially in older adults and individuals with diabetes.

Patients with a chief complaint of dyspnea vary markedly in presentation; however, because this is a subjective complaint, the patient's report should be taken as fact. As with the complaint of pain, the discomfort and degree of dyspnea represents the patient's reality; however, correlating the complaint with physical findings may help to establish the cause of the dyspnea, thus leading to an effective plan of intervention (Level I; Institute for Clinical Systems Improvement, 2012).

Differential Diagnosis

Dyspnea has a number of possible causes. With left-sided cardiac outflow tract blockage, such as in severe aortic stenosis or obstructive cardiomyopathy, dyspnea likely arises from the decrease in cardiac output. When dyspnea is associated with recurrent myocardial ischemia, as in angina pectoris, the shortness of breath is likely caused by an increase in pulmonary vascular pressure, coupled with a transient decrease in cardiac output. In right-sided cardiac problems, such as tricuspid and pulmonic valvular dysfunction, the complaint of dyspnea usually arises from increased pulmonary pressures and resistance to cardiac emptying of the right ventricle. Another common cause of dyspnea is pulmonary disease, such as COPD, asthma, pleural effusion, pneumothorax, pulmonary embolus, or pulmonary hypertension secondary to interstitial lung disease or pulmonary fibrosis. Other noncardiac causes of dyspnea are severe anemia and metabolic acidosis (i.e., Kussmaul's respirations), obesity, physical deconditioning, and anxiety or emotional distress.

The patient's assessment of the severity of dyspnea may differ from the objective findings. For example, some patients who have been observed to have rather marked difficulty breathing have little complaint of breathlessness, whereas other patients who have few objective findings will describe marked difficulty breathing. In addition, when asked about difficulty breathing, one patient may admit to feelings of suffocation, in that getting sufficient air in and out of the lungs is a problem, whereas others will describe a need to take deep breaths.

Dyspnea is a poorly sensitive and nonspecific marker for cardiovascular disease. Factors contributing to the complaint of breathlessness in the absence of heart disease include poor conditioning and exercise intolerance related to inactivity and obesity. The patient usually reports that the onset of this type of dyspnea accompanies increased activity and resolves rapidly when the activity ceases. In any event, in cardiovascular disease, dyspnea is usually a result of increased stiffness in the lungs caused by increased pulmonary blood volume or pulmonary congestion. This is usually found in conditions with poor cardiac output, such as heart failure (HF),

recurrent myocardial ischemia, poorly controlled hypertension, valvular dysfunction, and heart disease.

When dyspnea is the complaint, it is essential for the clinician to assess the change in the patient's ability to perform average daily activities. In particular, dyspnea often is first detected by the patient as the inability to talk during exertional activities. Pinpointing the onset of the symptoms and concurrent events may be helpful in determining its etiology. In addition, asking about cosymptoms such as wheezing and weight gain is crucial because dyspnea is the most common presenting complaint in HF.

Orthopnea is shortness of breath that begins when the patient has been in a supine position. The patient usually compensates for this sensation by sleeping on an increased number of pillows, hence the use of the qualifying term *three-pillow orthopnea.* When the person slides off the pillows, shortness of breath reoccurs, causing the person to awaken. Orthopnea is usually caused by HF as a result of increased right-sided heart pressure, which increases after the patient has been supine for a few hours, mobilizing fluid that pooled in the extremities during the waking, more active hours.

Paroxysmal nocturnal dyspnea is shortness of breath that occurs 1 to 2 hours into sleep, concurrent with redistribution of body fluids and a subsequent rise in left atrial pressure. The person awakens suddenly with significant difficulty breathing. He or she usually stands or sits up until symptoms are relieved in about 10 to 30 minutes. As with orthopnea, the diagnosis of HF should be considered.

LEG ACHES

Leg aches associated with peripheral vascular disorders are caused by impaired blood flow to the extremities. Peripheral vascular disease (PVD) affects the arteries and veins. When the disease is arterial, it is usually the result of accumulated fatty streaks and fibrous plaques (high levels of low-density lipoproteins). Venous problems relate to venous incompetence secondary to valve obstruction, leading to chronic venous insufficiency and varicose veins.

Differential Diagnosis

Patients presenting with leg aches may have a number of disorders other than PVD, so a thorough history and physical exam must be performed to rule out thrombosis, phlebitis, polycythemia, anemia, Raynaud's disease, and Buerger's disease. Because some of the contributing factors to PVD may be smoking, high blood pressure, and diabetes, these problems must be addressed and underlying conditions managed. Both peripheral arterial disease and peripheral venous disease are discussed in more detail later in the chapter.

PERIPHERAL EDEMA

Peripheral edema is the accumulation of fluid within the interstitial spaces of the extremities. When the edema involves the lower extremities, it is a symptom of an underlying disorder; it may be caused by cardiac conditions (e.g., heart failure, chronic venous insufficiency, or thrombophlebitis); by renal or hepatic disease; or by trauma, tumors, or inflammation. Peripheral edema occurs equally among men and women.

Differential Diagnosis

Peripheral edema is usually diagnosed via the history and physical exam, although laboratory findings assist in determining the cause of the edema. Specific diagnostic tests the clinician should order include complete blood count, urinalysis, serum chemistries, and a thyroid profile. X-ray studies may be ordered if trauma or osteomyelitis is suspected, and a chest x-ray film should be ordered to assess the heart and lungs. A computed tomography scan may help to assess the edema distribution and pinpoint the extent of venous and lymphatic obstructions. An electrocardiogram is essential for assessing cardiac function, and Doppler studies may be ordered to evaluate for deep vein thrombosis. It is essential that the underlying cause be identified and treated, or the peripheral edema will remain, possibly causing tissue ischemia from compressed and diminished arterial circulation. Differential diagnoses of peripheral edema are presented in Differential Diagnosis Flowchart 10.3.

COMMON PROBLEMS

HYPERTENSION

Hypertension (HTN) is one of the most common chronic health problems seen in the primary-care setting, with approximately one in three adults affected. Treatment thresholds for HTN vary in different demographics, such as adults aged 18 to 59 years without major comorbidities or patients 60 years or older who have diabetes, chronic kidney disease (CKD), or both conditions. See Table 10.1 for the breakdown of HTN per the Joint National Committee (JNC 8) guidelines.

The JNC 8 guidelines provide updated recommendations on the thresholds used to initiate pharmacological treatment for hypertension. Under the most recent guidelines, in adults over 60 years of age, pharmacological treatment is initiated to lower blood pressure to a systolic blood pressure of less than 150 or a diastolic blood pressure of less than 90 (Grade A). In adults younger than 60 years of age (including those with diabetes), pharmacological treatment is initiated at a systolic blood pressure of greater than 140 or a diastolic blood pressure of greater than 90. The initial pharmacological agent used in the general non–African American population may be a thiazide diuretic, an angiotensin-converting enzyme (ACE) inhibitor, an angiotensin receptor blocker (ARB), or a calcium channel blocker. In the African American population, initial treatment may consist of either a calcium channel blocker or a thiazide diuretic (ACE inhibitors

Differential Diagnosis Flowchart 10.3

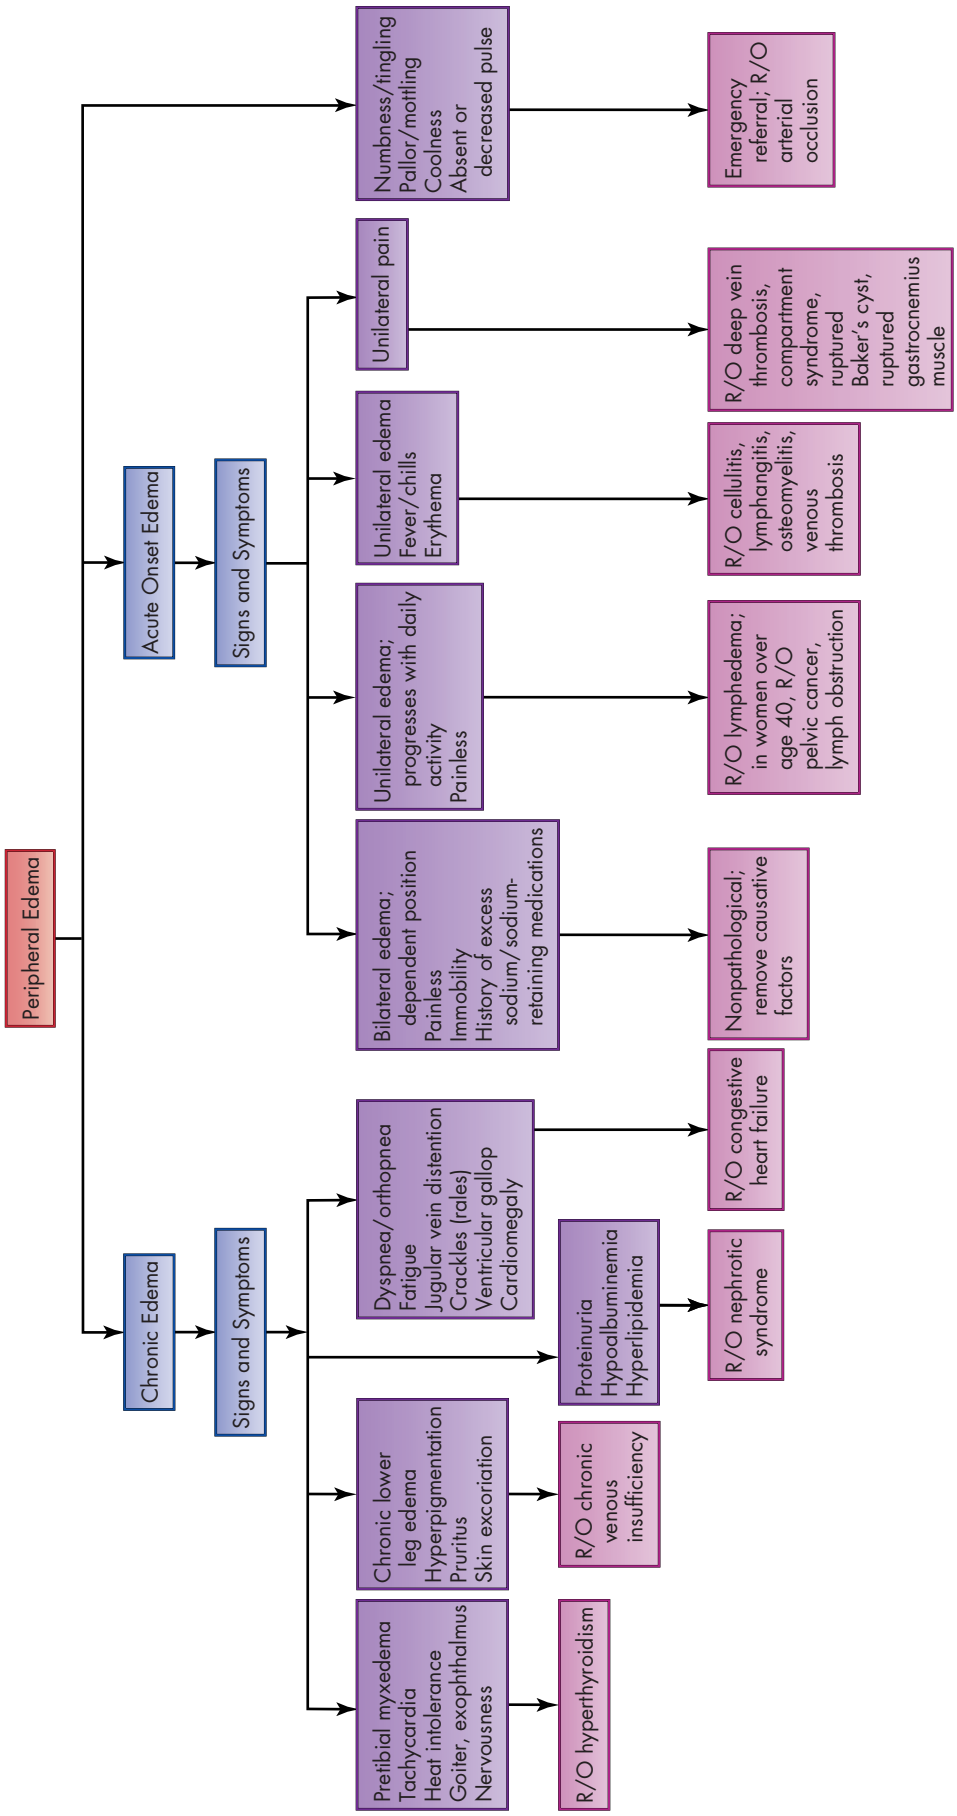


Table 10.1 Classification of Blood Pressure for Adults Aged 18 Years or Older

JNC 8 Guidelines suggest several new recommendations as to goal BP:

- In patients aged <60 years, treatment initiation and goals should be 140/90 mm Hg
- In patients aged >18 years with either chronic kidney disease or diabetes, goal should be goal of 140/90 (ADA cites goal of 140/80).
- In patients aged 60 years and over, start treatment when SBP > or equal to 150/ DBP >or equal to 90 and treat to under thresholds.
- In nonblack patient with HTN, initial treatment can be a thiazide-type treatment, CCB, ACE inhibitor or ARB; in the black population, initial therapy should be a thiazide-type diuretic or CCB.
- In patient aged 18 years or more with CKD, initial or add-on therapy should be an ACE inhibitor or ARB, regardless of race or diabetes status.

A key point to note in the JNC 8 is that although the targets have been loosened, the new guidelines do not mean that providers should ease up on treatment for patients who are doing very well based on JNC 7 guidelines. If JNC 7 is working, clinicians do not have to necessarily change the treatment plan and allow higher BPs. The study simply notes that if treatment can consistently get patients' SBP below 150, health outcomes are improved.

Additional interesting treatments to possibly speak to may include renal denervation as a promising therapy in the treatment of resistant HTN.

have been shown to be less effective in this population). In patients with chronic kidney disease, pharmacological treatment should be initiated to lower blood pressure to a systolic blood pressure of less than 140 and diastolic blood pressure less than 90. The initial agent of choice in patients with CKD should be an ACE inhibitor or ARB.

After the initiation of pharmacological treatment, the blood pressure should be reevaluated within a month. If the goal blood pressure is not attained, up-titration of the dose of the current pharmacological agent may be required. Alternatively, the addition of a pharmacological agent from another class may be added. If blood pressure goals are not obtained with the use of two blood pressure agents, a third agent may be added. Failure to respond to a triple-therapy regimen may require a referral to a hypertension specialist. Of note, beta blockers are no longer recommended as initial pharmacological agents in the primary treatment of HTN. In addition, ACE inhibitors and an ARB should not be used together in combination therapy.

More than 95% of patients with elevated blood pressure (BP) have primary, or essential, HTN, with no single identifiable cause; this type of HTN results from the interplay of multiple genetic and environmental factors, including lifestyle influences. Less than 5% of patients, therefore, have secondary HTN, a specific, possibly reversible, cause of elevated BP such as certain cardiac, renal, and endocrinological problems or the use of vasoconstricting medications.

After decades of a steady reduction in rates of HTN-related diseases, researchers have reported a recent leveling off of coronary heart disease rates, coupled with a slight increase in end-stage renal failure and age-adjusted stroke rates. These changes are likely caused by a number of factors, including a growing aging population; however, the role of undetected untreated and inadequately controlled HTN contributes significantly. Considering this, the clinician should be committed not only to the detection and treatment of HTN but also to its prevention. When a patient develops HTN, primary prevention measures have not been successful. The clinician must aggressively monitor the patient and encourage his or her participation in the management.

There is a specific listing for Heart Disease and Stroke in the *Healthy People 2020* objectives, because cardiovascular disease is so prevalent in our population. The goal is to improve cardiovascular health and quality of life through the prevention, detection, and treatment of risk factors; early identification and treatment of heart attacks and strokes; and prevention of recurrent cardiovascular events. These objectives have been modified and new ones developed. The clinician is strongly encouraged to review the U.S. Department of Health and Human Services Web site for the most up-to-date *Healthy People 2020* information cited in the bibliography. There are 23 total objectives, out of which 6 relate to BP.

Epidemiology and Causes

HTN occurs in one out of three Americans or 31% of the population of the United States (about 67 million persons). Historically, HTN has been more prevalent in males and particularly black males. However, this gender gap is narrowing and appears to be influenced by age. For persons under 45 years of age, men are affected more than woman, whereas in persons 65 years of age and older, more woman than men have HTN. Recent statistics show that among African Americans more women than men are hypertensive and that black women are more hypertensive than black men. African Americans continue to experience HTN more often and at an earlier age than whites or Latinos. The prevalence of hypertension continues to increase with age. Results from the Framingham Heart Study

demonstrate that among middle-aged and elderly persons the residual lifetime risk of developing HTN is 90%. HTN can lead to ischemic heart disease, heart failure, diabetic hypertension, chronic kidney disease, and cerebrovascular disease. An increase in body mass index (greater than 30 kg/m^2) contributes to high BP and cardiovascular disease. Today, 122 million Americans are considered overweight or obese, a situation that is reaching epidemic proportions. Although this is dismal news, a study from the National Health and Nutrition Examination Survey (NHANES) demonstrates an improvement in BP control by 50% among Americans with HTN.

The onset of diastolic HTN, with or without systolic elevation, after age 60 is unusual. If this is found, the diagnosis of new-onset secondary HTN should be considered. In particular, renovascular disease is a common cause of new-onset diastolic HTN in this age-group.

Primary HTN is a result of the interplay of a number of genetic, environmental, and lifestyle issues. HTN is more common among individuals whose parents or other close family members have HTN. In these individuals, diminished ability to excrete excessive sodium, coupled with long-term high dietary sodium intake, appears to be a predisposing factor to increased peripheral vascular resistance and rise in BP.

Pathophysiology

Pathophysiology of Essential Hypertension

The term *essential hypertension* describes high BP that has no identifiable etiology after thorough clinical examination excludes possible secondary causes. Although etiology is unknown, endothelial dysfunction is the key pathophysiological process involved in essential HTN. The arterial endothelium is an important regulator of vascular tone, vascular structure, thrombosis, and inflammation. Endothelial dysfunction is central to a wide array of cardiovascular disorders, including HTN, atherosclerosis, and myocardial ischemia. Vascular tone is maintained by endothelium-derived mediators such as nitric oxide, endothelin-1, and angiotensin II. Nitric oxide, a major vasodilator, counteracts the potent vasoconstrictors endothelin-1 and angiotensin II, which regulate normal vascular tone. In essential HTN, there is an imbalance in the vasodilator and vasoconstrictive substances secreted by the endothelium. Plasma levels of nitric oxide are diminished, whereas levels of endothelin-1 and angiotensin II are elevated. Reasons for this imbalance have not been elucidated, and it is not clear whether endothelial dysfunction precedes or is the result of HTN.

Other investigations have found that renin levels are markedly abnormal in some hypertensive individuals, despite normal renal function. Renin oversecretors experience constant cycling of the renin-angiotensin-aldosterone cascade, which raises blood volume and BP. Low renin secretors, in general, are salt-sensitive hypertensive individuals. Ingestion of sodium increases water reabsorption into the bloodstream, which raises blood volume and BP. The cause of renin imbalance in some persons with essential HTN is unknown. Measuring plasma renin levels in patients with refractory hypertension may assist in clinical diagnosis and treatment.

HTN is a common disorder that occurs with aging in industrialized societies. Data from the Framingham Heart Study suggest that even individuals who are normotensive at 55 years of age still have a 90% lifetime risk of developing HTN. There is a particular rise in systolic BP that progresses throughout life, with a difference of 20 to 30 mm Hg between early and late adulthood. Worldwide epidemiological evidence demonstrates that age-related HTN is uncommon in societies where individuals maintain lower body weight, consume less sodium and more potassium, and engage in greater levels of physical activity. These findings indicate that high BP is influenced by environmental and lifestyle factors and is not an inevitable consequence of aging. Smoking, obesity, and stress are examples of modifiable lifestyle factors that raise BP.

Genetic and ethnic influences also play a role in the development of HTN. Persons with a family history of HTN are four times more likely to suffer HTN than those with no family history of the condition. Studies show that the genetic contribution to essential HTN is complex, and multiple genes are likely involved. Most genetic effects involve gene–gene interactions and gene–environment interactions. Genes that encode components of the renin-angiotensin-aldosterone system are being extensively studied. Results of this line of investigation have implicated mutations in the angiotensinogen gene and angiotensin-converting enzyme (ACE) gene.

Studies of HTN in African Americans demonstrate that ethnicity is related to HTN susceptibility and plays a role in the efficacy of specific types of drugs. Morbidity and mortality due to HTN and HTN-related disorders are more common in blacks than in Caucasians and non-Hispanic Americans. HTN also seems to follow a more malignant course in African Americans. Compared to whites with HTN, African Americans have an increased risk of left ventricular hypertrophy, heart failure, and renal failure.

HTN has localized and systemic adverse effects. Locally, high BP creates a shearing force against the arterial walls, which injures the endothelium and accelerates development of atherosclerosis. Endothelial injury initiates a detrimental localized reaction of vasoconstriction, inflammation, platelet aggregation, and fibrin and lipid deposition—the rudiments of arteriosclerotic plaque formation. Target organs that are damaged by HTN include the heart (left ventricular hypertrophy and coronary artery disease resulting in angina or acute myocardial infarction), the kidneys (chronic renal insufficiency), the brain (transient ischemic attacks [TIAs], cerebrovascular accidents [CVAs], and increased risk of dementia), the eyes (retinal hemorrhages and hypertensive retinopathy), and the peripheral arteries (peripheral vascular disease).

The role of altered sodium excretion by impaired epithelial cells in the kidney may be a factor in the development of HTN. Other contributors include aging, sympathetic nervous system overactivity, toxins, and low nephron numbers.

Metabolic syndrome with its resultant insulin resistance and increased insulin levels may lead to increased sympathetic activity and hypertensive states. An additional overlooked cause of essential HTN is sleep apnea with its associated activation of sympathetic and renin-angiotension systems.

In summary, the etiology and pathophysiology of essential HTN are incompletely understood. It is a complex, multifactorial disorder that involves genetic and environmental factors, diet and lifestyle practices, imbalances in vasoactive substances, and dysfunction of the arterial endothelium.

Pathophysiology of Secondary Hypertension

Secondary HTN is elevated BP due to an identifiable, underlying condition. Detection of secondary HTN is critical in order to reverse the source of the pathological process and prevent hypertensive target organ damage. Less common than essential HTN, secondary HTN has an overall frequency of 5% to 10% in primary-care practices. Secondary HTN is often distinguished from essential HTN by certain assessment findings, such as age at onset younger than 30 years or older than 50 years, BP higher than 180/110 mm Hg at diagnosis, significant target organ damage at diagnosis, hemorrhages and exudates on funduscopic examination, renal insufficiency, left ventricular hypertrophy, accelerated or malignant HTN, and poor response to therapy. Resistant HTN is often due to unexplored, reversible secondary causes.

Reversible causes of secondary HTN include obesity, obstructive sleep apnea, renovascular disease, chronic steroid therapy, Cushing's syndrome, primary hyperaldosteronism, pheochromocytoma, coarctation of the aorta, thyroid disease, parathyroid disease, and excess alcohol intake. Secondary HTN can also be drug induced, and a thorough history of the patient's medications, including herbal supplements, over-the-counter (OTC) agents, and any illicit drug use is essential. Common drugs that can cause HTN include NSAIDs, cyclooxygenase-2 (COX-2) inhibitors, sympathomimetics such as decongestants and anorectics (diet pills), oral contraceptives, erythropoietin, cocaine, amphetamines, steroids, tacrolimus, cyclosporine, and herbal ephedra supplements. Licorice, smoking, and chewing tobacco also raise BP.

"White Coat" Hypertension

"White coat" HTN with a prevalence of 12% to 18% is a transient rise in BP experienced by a patient when in the clinical or hospital setting, most likely due to anxiety. This condition of "pseudohypertension" is common in primary-care practice. The "white coat" effect can lead to overestimation of BP and prescribing of unnecessary antihypertensive treatment. In addition, the patient's transiently high BP can be misinterpreted as ineffectiveness of antihypertensive therapy. Care must be taken to use the appropriate sized BP cuff. If too small a cuff is used, this will artificially increase the readings. Obese patients or those with large arms need to have a cuff that is large enough to measure BP accurately. Patients with "white coat" HTN are more accurately assessed through the use of ambulatory BP monitoring, which provides an automated 24-hour recording of the patient's BP during normal daily activities that can be reviewed by the clinician. Alternatively, the patient may be instructed to measure and record intermittent BP readings over several weeks with reliable, consistent equipment for later review.

Masked Hypertension

Masked hypertension is defined as HTN that is present during daily life and yet absent in clinical assessment. Studies conducted by the National Institutes of Health state that masked hypertension may be present in as high as one out of every seven to eight individuals with normal clinical or office BPs.

Risk factors identified for masked hypertension are smoking, alcohol use, lack of physical activity, and work-related and physiological stressors. Clients who are at high risk for masked hypertension have a higher incidence of cardiovascular events and subsequently a higher risk of mortality and morbidity due to missed opportunities to treat.

Ambulatory blood pressure monitoring (ABPM) or home BP self-monitoring by the client who is at high risk is a cornerstone to optimizing outcomes. Without active patient participation and buy-in, this prognostically challenging condition will go untreated.

Pathophysiology of Malignant Hypertension (Hypertensive Emergency)

Malignant HTN has been noted in up to 1% of patients diagnosed with central hypertension. Malignant HTN is diagnosed when a patient presents with severely elevated BP in the range of ≥180 mm Hg/110 mm Hg and evidence of acute target organ damage. Although the terms are often used interchangeably, *hypertensive emergency* or *hypertensive crisis* denotes this process acutely. If not treated with immediate parenteral antihypertensive therapy in an acute-care setting, a hypertensive emergency may prove fatal. In contrast, a significantly elevated BP alone with *no evidence* of target organ damage does *not* constitute an emergency and is classified as *hypertensive urgency.* Hypertensive urgencies may be treated with oral agents over a period of 24 to 48 hours to achieve stabilization. An isolated finding of severely elevated BP can be reduced over the course of hours with oral medications in an outpatient setting. In hypertensive emergency, acute target organ damage most commonly

involves the neurological, cardiac, or renal systems. Acute cerebrovascular events, papilledema, acute myocardial ischemia or infarction, pulmonary edema, aortic dissection, acute renal failure, epistaxis, states of catecholamine excess, and preeclampsia/eclampsia are conditions associated with severely elevated BP. A patient presenting with acutely severe BP elevation requires a thorough clinical examination that includes funduscopy, electrocardiogram (ECG), urinalysis, serum creatinine measurements, and chest x-ray study. A computed tomography scan of the head to rule out stroke may be necessary. Evidence of target organ damage includes the following:

- Papilledema, hemorrhages, or exudates on funduscopic examination
- Change in mental status or neurological deficits on physical examination
- Dementia
- ECG consistent with myocardial ischemia or infarction
- Chest x-ray film showing heart failure or aortic dissection
- Renal dysfunction evidenced by hematuria, proteinuria, and elevated serum creatinine

The primary-care provider should refer patients with hypertensive emergency to an acute-care setting for appropriate diagnostic testing, monitoring, and treatment.

Clinical Presentation

Subjective

Typically the diagnosis of HTN is made after several routine office visits with the patient complaining of no symptoms. Occasionally, if the BP is extremely elevated, the patient may present with a headache that occurs on awakening and is located in the occipital area.

Objective

A systematic approach should be used when assessing the person with or at risk for HTN. The assessment should include two measurements of BP in both arms, with the patient preferably seated with both feet on a flat surface (crossing legs may increase the systolic blood pressure (SBP) by 2–8 mm Hg), back supported with the arm at heart level (may increase the diastolic blood pressure [DBP] up to 6 mm Hg). Avoid conversation with the patient during the reading, and use the appropriate size cuff (too large will provide a falsely low BP, too small will provide a falsely elevated BP). When elevated BPs are obtained, a bilateral assessment for confirmation should be obtained when not contraindicated (e.g., by the presence of an atrioventricular shunt, postmastectomy status, etc.). BP should be taken again after the patient has stood for at least 2 minutes. The higher readings should be recorded. In groups such as the elderly, the obese, and patients with arrhythmias, certain criteria should be noted. In the elderly, the clinician should note that an auscultatory gap is common; this is usually associated with vascular disease and results in an underestimation of SBP. The obese client will often have short upper arm length relative to upper arm width; in this instance a wrist cuff may be used. Place the wrist at heart level to avoid the potential for error. In clients with very irregular arrhythmias such as atrial fibrillation, the BP varies beat to beat, so the provider should measure the BP several times and average the readings. In the client with severe bradycardia, the provider should deflate the cuff more slowly to prevent underestimating SBP and overestimating DBP.

The National Institute for Health and Clinical Excellence (NICE) guidelines state that a diagnosis of primary HTN should be confirmed with 24-hour ABPM or sequential home BP readings. Twenty-four–hour ABPM is indicated to rule out "white coat" or "masked" hypertension, to uncover apparent drug-resistant hypertension, and to identify hypertensive symptoms while the patient is being treated with hypertensive medication.

When a person has been diagnosed with or is suspected to have HTN, assessment should include a focused health history and physical exam, staging of BP elevation, and investigation for evidence of hypertensive target organ damage (TOD). This exam should include funduscopic examination, palpation of the chest for point of maximal impulse (PMI) or auscultation of the heart, abdominal assessment for bruits or widened aortic diameter and enlarged kidneys, examination of the carotid arteries for bruits, palpation of peripheral pulses, and a neurological examination (Level I; Calhoun et al, 2008). See Advanced Assessment 10.1 for assessment areas to evaluate in persons with HTN. Evidence of TOD includes retinopathy, which may appear as arteriolar narrowing, arteriovenous nicking, hemorrhages, or exudates. A bruit may be auscultated over either carotic artery, indicating stenosis. The chest may demonstrate a displaced PMI and/or an S_4 heart sound indicating left ventricular hypertrophy (LVH). Auscultation of an S_4 heart sound is associated with decreased elasticity of the left ventricle that occurs in LVH. The patient should also be evaluated for the presence of heart failure, a known sequela of longstanding HTN. An S_3 gallop, pulmonary crackles, jugular venous distention, and peripheral edema are signs of heart failure. A bruit heard in the abdomen may indicate an aneurysm or renal artery stenosis. Palpation of a widened aortic pulsation is associated with abdominal aortic aneurysm. Diminished peripheral pulses and sensation in the lower extremities can indicate peripheral arterial disease. Neurological exam can reveal deficits associated with TIAs or a CVA.

The history should include a thorough investigation of cardiovascular risk factors such as age, gender, postmenopausal status, diet, activity level, alcohol and caffeine use, smoking, dyslipidemia, diabetes, family history of heart disease, and current medications. Some medications, such as NSAIDs or OTC cold remedies, may exacerbate BP elevation. Excess use of alcohol is often the source of

Advanced Assessment 10.1 Hypertension

Assessment	Common Findings
Blood Pressure Measurement	
Proper technique:	SBP >140 mm Hg (see Table 10.1 for specifics) (depends on age)
Cuff size has a bladder length of 80% and a width of at least 40% of arm circumference Rest for 5 minutes before measurement.	DBP >90 mm Hg
Patient in a sitting position, arm resting at level of the heart with feet on flat surface, legs uncrossed. Average 2 readings at least 2 minutes apart (if >5 mm Hg difference, obtain additional readings)	
Physical Exam	
Height, weight, BMI	Obesity (BMI >27), especially with central or truncal pattern
Waist measurement	Men: >39 inches Women: >34 inches
Funduscope	Hypertensive retinopathy (arteriolar narrowing, arteriovenous nicking, hemorrhages, exudates, papilledema)
Carotid arteries	Bruits
Neck veins	Distention
Thyroid	Enlargement Nodules
Cardiac	PMI and apex displaced laterally; greater than one intercostal space S_3, S_4 heart sounds Murmur or mitral regurgitation
Lungs	Crackles Bronchospasm
Abdomen	Bruits, masses, abnormal aortic pulsations Enlarged kidneys
Extremities	Absence of peripheral arterial pulsations Bruits Edema
Diagnostic Tests	
Urinalysis	Proteinuria
BUN/Creatinine	Increased
CBC	May show anemia
Potassium	Increased or decreased
Blood glucose	May be increased
Triglycerides, HDL, LDL	Increased
12-lead ECG	May show target organ damage
BNP	Hormone released by the ventricle indicative of increased myocardial demands

refractory HTN. Culture and ethnicity should be assessed within the history as well. Compared with Caucasians, African Americans have a higher risk of HTN, diabetes mellitus, and renal impairment, which requires aggressive management of BP and specific drug therapy.

Particular care must be taken when assessing an older patient with HTN. If severe vessel rigidity is present in the brachial artery, the BP cuff may be unable to compress the calcified vessel well, leading to a falsely high pressure. This phenomenon is known as *pseudohypertension.* Although it may raise the BP by 30 mm Hg or more, it does not by itself represent a disease state.

Diagnostic Reasoning

Diagnostic Tests

Diagnostic testing of a patient who has or is suspected of having HTN should focus on the evaluation of target organs and concurrent conditions, as well as on excluding certain causes of secondary HTN. Additional testing may be indicated, particularly when concurrent diseases such as diabetes mellitus or hyperlipidemia are present.

The ECG is an important screening tool to assess for cardiac target organ damage in the hypertensive patient. It can be used to assess the presence of left atrial enlargement, left ventricular hypertrophy, myocardial ischemia or infarction, premature ventricular contractions, and atrial fibrillation. Left atrial enlargement is one of the earliest ECG findings associated with HTN. An echocardiogram is useful to detect the presence of increased left ventricular wall thickness and hypertrophy.

Differential Diagnosis

The key to differential diagnosis is to determine the underlying etiology of the HTN, whether it is essential or secondary, for instance, and to assess the degree of HTN (prehypertension, HTN, malignant or benign, etc.). A presumptive diagnosis is made if the average of at least two seated BP measurements on at least two or more visits exceeds either 90 mm Hg DBP or 140 mm Hg SBP in adults older than age 18.

Management

The key to HTN management is not only the reversal of HTN-related disease trends but also the prevention of target organ damage. The following are public health approaches to achieve a downward shift in the distribution of a population's BP, thus potentially reducing morbidity, mortality, and the lifetime risk of an individual becoming hypertensive.

- Develop community health programs to stress reducing calories, saturated fat, and salt in processed foods.
- Encourage food manufacturers and restaurants to reduce the sodium in the food supply by 50% over the next decade.
- Increase community/school opportunities for physical activity.
- Address the diversity of racial, ethnic, cultural, linguistic, religious, and social factors in the delivery of community services to increase the community's receptiveness to use of public health services.
- Improve opportunities for treatment and control of HTN. Health-care providers can help break down barriers to the diagnosis and treatment of HTN. Examples include nursing and work-site clinics and offering health services on evenings and weekends, which increase the likelihood of those who work during the weekday hours having access to care.

Patient-specific goals include the following:

- An awareness regarding the risks involved in prehypertension. Teens and young adults with high normal BP are at markedly increased risk of developing HTN in their fourth and fifth decades of life. Behavioral therapies such as a program of regular aerobic exercise and a diet that is lower in fat and sodium and higher in potassium should be initiated to help avoid HTN.
- Knowing one's own body mass index. This should serve as a guide to weight loss rather than just looking at ideal body weight.
- Improving HTN control in persons already diagnosed. Many with HTN have a BP greater than 140/90 mm Hg (see Table 10.1 for specifics), demonstrating inadequate control.
- Reducing cardiovascular risks. Many patients with HTN will have additional modifiable cardiovascular disease risk factors such as diabetes mellitus, hyperlipidemia, tobacco use, and inactivity; therefore, a comprehensive plan to treat HTN must also address these issues.

The use of lifestyle modifications (Table 10.2) should be a part of every patient's regimen to prevent or treat elevated BP (Level I; Calhoun et al, 2008). The clinician should work with the patient on a plan of lifestyle modification and medications as needed to lower the BP as much as is tolerated without symptoms. In patients with diabetes mellitus, the American Diabetes Association shares a target SBP of less than 140 mm Hg and has a target DBP of less than 80 mm Hg. Note that this diastolic threshold differs from the JNC 8 guidelines' goal DBP of less than 90 based on the lack of quality randomized control trials supporting the benefit of a goal DBP less than 90 in patients with diabetes. For patients with CKD and proteinuria, the therapeutic plan should be very individualized with attention to balancing side effects of medications (hypotension or worsening renal disease) with BP goals. Renal impairment should compel the clinician and patient to work together to maintain meticulous BP control to minimize the development of nephropathy. In addition to public health programs, community-affiliated programs, including parish-based programs and neighborhood and work-site health promotion events, should be utilized to assist patients.

Table 10.2 Lifestyle Modifications to Manage Hypertension

- **Weight reduction:** Maintain normal body weight (BMI, 18.5–24.9 kg/m^2) (weight reduction lowers BP by 5–20 mm Hg).
- **Adopt DASH (Dietary Approaches to Stop Hypertension) eating plan:** Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat (DASH diet lowers BP by 14–18 mm Hg).
- **Dietary sodium reduction:** Reduce dietary sodium intake to no more than 100 mmol (2.4 g sodium) per day (lowers BP by 2–8 mm Hg).
- **Physical activity:** Engage in regular aerobic physical activity such as brisk walking (at least 30 minutes per day, most days of the week) (lowers BP by 4–9 mm Hg).
- **Moderation of alcohol:** Limit consumption to no more than two drinks (1 oz. or 30 mL of ethanol, e.g., 24 oz beer, 10 oz wine, or 3 oz 80-proof whiskey) per day for most men and to no more than 1 drink per day for women and lighter weight persons (lowers BP by 2–4 mm Hg).
- **Stop smoking and/or use of other tobacco products.**
- **Understand hot-tub safety:** When combined with heat, antihypertensive drugs may cause vasodilation resulting in dizziness, light-headedness, fainting, reduction of cerebral blood flow, with the potential for falling and risk of injury.
- **Maintain adherence to pharmacotherapeutic plan:** When medication regimen is not adhered to, BP will rise.
- **Monitor for drug-induced hypertension:** Drugs that may induce HTN include NSAIDs, antidepressants, glucocorticoids, oral contraceptives, hormone replacement therapy, and OTC medications that contain decongestants.

Special Considerations for Older Adults

Nearly one-half of all adults aged 65 years and older develop isolated systolic hypertension (ISH), defined as an SBP above 160 mm Hg with a normal DBP (86 or below) as a consequence of atherosclerotic thickening of the vessels. More than two-thirds of persons older than age 65 develop HTN in general. Given its frequency, the development of ISH is often viewed as an unavoidable part of aging, but clinicians should be aware that behavior-based therapies used to avoid and treat HTN can also help minimize age-associated increases in BP. Historically, older adults with HTN have not received the emphasis on treatment that was merited. Present-day guidelines now stress the importance of treating HTN in older adults. Older adults benefit greatly from the treatment of ISH, yielding significant reduction in congestive heart failure and cardiovascular and cerebrovascular disease.

Even in persons older than 50 years of age, SBP greater than 140 mm Hg is a much more important cardiovascular disease risk factor than DBP. Even patients with a normal BP at age 55 still have a 90% lifetime risk for developing HTN. In a patient with a BP of 115/75 mm Hg, the risk of cardiovascular disease doubles with each incremental increase of 20/10 mm Hg.

Pharmacological Therapy

Lifestyle modifications should be used for patients at risk for HTN. No antihypertensive drug therapy is indicated if there is no compelling indication other than potential risk factors. Monitoring for drug-induced hypertension is essential before the initiation of pharmaceutical therapy. Pharmaceuticals such as NSAIDs, glucocorticoids, antidepressants, oral contraceptives, hormone replacement therapy, and OTC medications must be investigated before treatment. The use of alcohol and tobacco must be reviewed. The presence of sleep apnea must be assessed. For most patients with newly diagnosed HTN, therapeutic lifestyle changes should be tried for 1 month. If not effective in lowering the BP after 1 month, add pharmacological therapy. In the general nonblack population, including those with diabetes, initial antihypertensive treatment should include any one of four classifications of HTN medications—a thiazide-type diuretic, calcium channel blocker, ACE inhibitor, or angiotensin receptor blocker. Any of these may improve cardiovascular outcomes.

When it comes to thiazide diuretic therapy, use chlorthalidone 12.5 to 25 mg/day. A second choice is hydrochlorothiazide. These both have been shown to improve cardiovascular outcomes. Thiazide diuretics are first-line proven antihypertensive drugs. These agents are useful in the presence of ISH, as well as being inexpensive and efficacious. They are also helpful for patients with osteoporosis because they help preserve bone density. Thiazide diuretics are well documented for reducing stroke and cardiovascular-related mortality and morbidity; however, the clinician should choose antihypertensive therapy with concurrent disease or comorbid conditions in mind.

Beta blockers are no longer used as initial treatment for the hypertensive patient.

Examples of antihypertensive drugs that can be used in patients with concurrent diseases include choices from the following groups:

- **Angiotensin-converting enzyme inhibitors** (ACEIs—drugs with generic names ending in *-pril,* such as captopril, enalapril, and lisinopril) are effective in the presence of heart failure and myocardial infarction (MI) with systolic dysfunction to help limit myocardial remodeling. These should be ordered when certain comorbid conditions including renal insufficiency and diabetes mellitus are present and may assist in preserving or enhancing renal function (Level I; Michigan Quality Improvement Consortium, 2011).

- **Angiotensin II receptor blockers** (ARBs) are helpful in antihypertensive individuals with comorbid conditions such as heart failure and type 2 diabetes. Because they have a higher cost than ACEIs and because long-term research is lacking, ARBs should be reserved for patients who develop a cough when taking ACEIs.
- **Beta blockers** (drugs with generic names ending in *-lol,* such as metoprolol) are no longer commonly recommended for the primary management of HTN but may be used in the presence of angina, post-MI (to reduce cardiac workload and enhance rhythm stability), atrial tachycardia (to blunt tachycardia response), migraine headache (nonselective for reduction in frequency and severity of headache), and essential tumor (nonselective). These drugs may help to reduce the tremor resulting from blockage of beta-2 receptor sites.
- Long-acting dihydropyridine (DHP) **calcium channel blockers** (CCBs) are suggested for black clients of African or Caribbean descent who are younger than age 55, for patients with ISH, and for patients with HTN and stable angina pectoris.
- **Alpha-adrenergic antagonists** (alpha blockers) are usually effective in patients with benign prostatic hyperplasia because they facilitate bladder emptying by decreasing prostate size.

Additional drugs may include combination drugs, such as ACEIs and CCBs, ACEIs and diuretics, ARBs and diuretics, centrally acting drug and diuretics, and diuretics and diuretic agents. (See Drugs Commonly Prescribed 10.1.)

Initial therapy should consist of a low dose of the agent chosen. If the agent is well tolerated but BP control has not been achieved, the dose should be increased.

Small doses of two agents from different classes may have a synergistic effect in lowering BP while avoiding the problems of higher doses of either agent given alone and may possibly give additive therapeutic benefit (see Drugs Commonly Prescribed 10.1). These combination products may be appropriate for first-line antihypertensive therapy. In particular, a very low dose (12.5 mg) of chlorthalidone has the ability to potentiate the effect of other agents without producing negative metabolic effects.

If treatment continues to be ineffective, substitute another drug from a different class or add a second agent from a different class. If the desired effect has still not been achieved, continue to add drugs from other classes. A cardiologist should be consulted if the HTN remains uncontrolled.

Choosing the Best Drug Certain patient characteristics, including ethnicity, may influence the choice and efficacy of an antihypertensive agent. A common perception is that the best antihypertensive effect for African Americans and older adults with HTN can be achieved by using a combination of diuretics and CCBs. This should not be viewed, however, as a contraindication to using ACEIs or ARBs. Indeed, these drugs may offer significant benefit when concomitant disease is present or poses significant risk. ACEIs and ARBs may be used in all groups; however, when these drugs are used in older adults and African Americans, higher doses may be needed, and a longer period of time may elapse before the onset of action is seen. ACEIs and ARBs should not be prescribed together.

An agent with once daily dosing (24-hour activity with at least 50% of action in the last 12 hours) is recommended. (See Drugs Commonly Prescribed 10.1.) The clinician should prescribe a once-daily dose, especially if patient adherence is a problem. This provides the patient with persistent, smooth control of HTN, and adherence to drug therapy is improved. In addition, with longer-acting formulas, there is less risk of hypertensive rebound resulting from a missed dose, providing protection against risk of stroke, MI, or sudden death from cardiac arrest induced by a dramatic increase in BP.

In certain clinical situations, some medications should be used with caution or are contraindicated because they may have unfavorable effects on comorbid conditions. (See Drugs Commonly Prescribed 10.1.) The JNC 8 guidelines stress that if the patient's medications are working, they should not be changed just because new guidelines are in place.

Age-Related Concerns Certain age-related physical changes predispose older adults to difficulty with HTN drug therapy. Because this group benefits significantly from control of HTN, the appropriate drug should be chosen with care and with consideration of particular factors including loss of baroreceptors, which increases the risk for postural HTN. As a result, BP should be measured with the patient in both standing and sitting positions. In addition, older adults should be instructed to change position slowly while on antihypertensive medication.

The Beers criteria is a clinical tool developed to assist clinicians in improving medication safety in older adults. The clinician should consult the Beers criteria for potentially inappropriate medication use in older adults (see www.americangeriatrics.org/health_care_professionals/clinical_practice/clinical_guidelines_recommendations/2012).

The force of myocardial contractility decreases with age, leaving older adults more sensitive to hypertensive medications with negative inotropic effects, such as beta blockers. Because of lower circulating volume, diuretics, which are particularly effective antihypertensive agents for this age-group, should be used in lower doses. Older adults usually have decreased renal excretory capacity; therefore, smaller doses of medications are required. The adage "Start low and go slow" should be followed. The dose titration of antihypertensive drugs should be monitored closely with every dose adjustment.

Concurrent Use of Select Medications Through their sodium-retaining effect, NSAIDs can negate the BP-lowering effects of select antihypertensive medications

Drugs Commonly Prescribed 10.1 Hypertension

Medications Preferred in Specific Comorbid Conditions

Diabetes*	ACEI or ARB For metabolic syndrome, ACEI or ARB or CCB
Chronic kidney disease	ACEI or ARB
Heart failure	ACEI or ARB, mineralocorticoid receptor antagonist, beta blocker, diuretic (loop preferred) For LVH, ACEI or ARB, CCB
High-risk CAD	Beta blocker or CCB for angina ACEI or CCB for asymptomatic atherosclerosis
Post-MI	ACEI or ARB, beta blocker
Recurrent stroke prevention	Any effective antihypertensive

*To reduce risk for major CV events and slow progression of CKD in adults with diabetes not on dialysis with urine albumin <30/24 hour, the blood pressure goal is <140/90. If urine albumin is >30/24 hour, the goal is ≤130/80.
†Initial combined therapy should be used cautiously in those at risk for orthostatic hypotension.

Drug Classification	Indication	Adverse Reactions and Prescribing Considerations
Diuretics		
Thiazide diuretics (e.g., chlorthalidone)	First-line diuretic to treat hypertension. Thiazide diuretics are indicated in the management of hypertension, either as the sole therapeutic agent or to enhance the effect of other antihypertensive drugs in more severe forms of hypertension.	Use with caution in severe renal disease, which may precipitate azotemia, and in patients with impaired hepatic function. Contraindicated in patients with anuria, hepatic coma, or precoma; or known allergy or hypersensitivity to these products or other sulfonamide-derived drugs. Hypokalemia, hyperuricemia, and rise in blood lipids may occur. Occasional urticaria and skin rash; postural hypotension; gastrointestinal (GI) distress; loss of appetite; impotence; vertigo. Thiazide diuretics are less effective when creatinine is ≥1.8.
Loop diuretics furosemide (Lasix)	Loop diuretics are more potent than thiazides in promoting diuresis; however, they are less effective than thiazides in BP management. Indicated for the treatment of mild-to-moderate hypertension and in the management of edema associated with congestive heart failure. Also beneficial in the management of HTN associated with hepatic and renal disease, including the nephritic syndrome. Will likely remain effective in patients who have creatinine ≥1.8.	May cause hypokalemia, hyponatremia, low magnesium, dehydration, postural hypotension, tinnitus, hyperuricemia leading to gout, increased sensitivity to sunlight. Hypertensive patients who cannot be adequately controlled with thiazides will probably also not be adequately controlled with furosemide alone.
Aldosterone receptor blockers spironolactone (Aldactone)	Weak antihypertensives. Potassium-sparing diuretics are indicated for the treatment of HTN or edema in patients who develop hypokalemia. Aldosterone antagonists block the effects of serum aldosterone and therefore are better at regulating Na^+ and water homeostasis and maintaining stable intravascular volume.	The use of potassium-sparing agents is often unnecessary in patients receiving diuretics for uncomplicated essential HTN when such patients have a normal diet. May cause nervousness, skin rash, increased sensitivity to sunlight, confusion, irregular heart rhythm, shortness of breath, lethargy, and weakness. Hyperkalemia risk is increased with the use of ACE/ARB. Use with caution in cases of renal impairment.

Drugs Commonly Prescribed 10.1 Hypertension—cont'd

Drug Classification	Indication	Adverse Reactions and Prescribing Considerations
Beta-Adrenergic Blockers		
carvedilol, metoprolol (Toprol XL)	Not indicated as first-line management of hypertension unless compelling indications such as acute coronary syndrome or heart failure is present. May be used in combination with other antihypertensive agents, especially thiazide-type diuretics. Beta blockers are a component of core measures in the client after an ACS.	May cause sinus bradycardia, atrioventricular block, hypotension, shortness of breath, depression, dizziness, fatigue, vivid dreams, diarrhea, nausea/vomiting, increased triglycerides, increased sexual dysfunction, pruritus, skin hyperpigmentation, alopecia, xerosis, and urticaria. Use with caution in patients with COPD, asthma, and PVD. May increase the risk of developing type 2 diabetes.
Angiotensin-Converting Enzyme Inhibitors		
enalapril, lisinopril (Zestril)	Use alone or in combination with thiazide diuretics. Effective for the patient with comorbidities of heart failure, MI, left ventricular dysfunction, renal insufficiency, glomerulosclerosis. Diabetes with nephropathy may likewise benefit. May be effective in the prevention of stroke. ACEIs are a component of Core Measures in the client after an ACS.	May exacerbate hyperkalemia and increase the risk of angioedema. Avoid in pregnancy. May cause a chronic cough. When dosed with aldosterone receptor blocker, may cause orthostatic hypotension, sinus tachycardia, fatigue, dizziness, syncope, headache, hyperkalemia. Renal adjustment is indicated in renal insufficiency. Do not dose in the presence of bilateral renal artery stenosis.
Angiotensin II Receptor Blockers		
losartan (Cozaar)	Most potent antihypertensive agent routinely utilized. May be useful for the treatment of stable angina pectoris, especially the dihydropyridines. CCBs may be effective in the management of angina from coronary artery spasm. Effective in reducing cardiac muscle burden and lessens myocardial demand for oxygen.	Use with caution in HF and 2nd- and 3rd-degree heart block (unless pacer in place). All CCBs potentiated with grapefruit juice. May cause lower extremity edema. Avoid in patients with recent MI. May cause peripheral edema, headache, dizziness, flushing, palpitations, fatigue, nausea/vomiting, abdominal pain, and drowsiness. Caution in acute heart failure, renal, or hepatic impairment.
Calcium Channel Blockers		
Nondihydropyridines—diltiazem, verapamil (Calan) Dihydropyridines—amlodipine, felodipine (Plendil)		
Alpha-Adrenoceptor Blockers		
prazosin, doxazosin, terazosin (Hytrin)	Use with comorbidities of benign prostatic hyperplasia, prostatism, as well as in dyslipidemia. May be used alone or in combination with diuretics, beta-adrenergic blocking agents, calcium channel blockers, or ACEIs.	Do not use as first-line or "solo" agents. A higher rate of stroke and heart failure is associated (ALLHAT). Alters lipid metabolism by decreasing LDL-C and VLDL-C. May cause mild sexual dysfunction, dizziness, light-headedness, headache, drowsiness, fatigue, nausea/vomiting, peripheral edema, nasal congestion, palpitations. May cause complication years later during cataract surgery by leading to floppy iris syndrome during eye surgery.
Centrally Acting Agents		
clonidine, methyldopa, reserpine (Catapres)	Effectively lower BP by decreasing central sympathetic outflow.	May cause drowsiness, impotence, dry mouth, increased respirations, increased GI motility, miosis, decreased LVRL. Less common effects are depression and Coombs-positive anemia (with alpha-methyldopa). Abrupt withdrawal may lead to a rebound HTN.

Drugs Commonly Prescribed 10.1 Hypertension—cont'd

Drug Classification	Indication	Adverse Reactions and Prescribing Considerations
Direct Vasodilators		
hydralazine, minoxidil, isordil	Good for hypertension in pregnancy. Injectable hydralazine is used as a first-line agent in the treatment of hypertensive emergencies. Direct vasodilators play an important role in the treatment of severe heart failure.	May cause peripheral edema, headache, tachycardia, angina, hirsutism, mastalgia, and bullous rash, as well as orthostatic hypotension.
Combination Drug Therapy		
ACE/CCB amlodipine + benazepril (Lotrel) enalapril-felodipine (Lexxel) trandolapril-verapamil (Tarka)	Effective with atrial tachycardia or fibrillation, especially the nondihydropyridines, diabetes type 1 and 2. CCBs may be useful in Raynaud's syndrome, as well as ISH, and those at high risk of CAD. The nondihydropyridines such as verapamil and diltiazem have been shown to reduce CV mortality, proteinuria, and diabetic nephropathy progression independent of ACEI use.	
ACE/Diuretics benazepril-hydrochlorothiazide (Lotensin HCT) captopril-hydrochlorothiazide (Capozide) enalapril-hydrochlorothiazide (Vaseretic) fosinopril-hydrochlorothiazide (Monopril/HCT) lisinopril-hydrochlorothiazide (Prinzide)	As above.	See above.
ARBs/Diuretics candesartan-hydrochlorothiazide (Atacand HCT) eprosartan-hydrochlorothiazide (Teveten HCT) irbesartan (Avalide) losartan + hydrochlorothiazide (Hyzaar) olmesartan-medoxomil (Benicar)	Use alone or in combination with other antihypertensive agents. ARBs are an alternative to ACEIs in patients who develop a chronic cough secondary to ACE inhibitor usage. Attention must be paid to the exact cause of the cough and assessment as to etiology to identify possible worsening of heart failure. As above.	Avoid use in pregnancy. May exacerbate hyperkalemia, angioedema, renal impairment. Diarrhea, dyspepsia, orthostatic hypotension, syncope, dizziness, insomnia, angioedema, vasculitis, hyperkalemia, hyponatremia, elevated hepatic enzymes, hyperbilirubinemia, decreased hematocrit and hemoglobin. See above.

Continued

Drugs Commonly Prescribed 10.1 Hypertension—cont'd

Drug Classification	Indication	Adverse Reactions and Prescribing Considerations
telmisartan-hydrochlorothiazide (Micardis) valsartan-hydrochlorothiazide (Diovan HCT)		
Centrally Acting Drugs and Diuretic methyldopa-hydrochlorothiazide (Aldoril) reserpine-chlorthalidone (Diupres)	As above.	See above.
Diuretic Combination spironolactone-hydrochlorothiazide (Aldactazide) combination HCTZ and triamterene (Dyazide)	Used to treat fluid retention and hypertension.	May exacerbate hyperkalemia, metabolic acidosis, gynecomastia, gout, renal and hepatic impairment. May cause GI disturbances. Useful in patients with refractory HTN. Use in patients with need for potassium-sparing diuretic. Do not use potassium supplements or other diuretics. Advise patients to obtain emergency medical help if any signs of an allergic reaction occur: hives; difficulty breathing; swelling of face, lips, tongue, or throat. May cause numbness, muscle pain or weakness; uneven heartbeat; drowsiness, restless, or light-headedness; changes in urination pattern; shallow breathing; tremors, confusion; nausea, stomach pain, low fever, loss of appetite, dark urine, clay-colored stools, jaundice.

such as ACEIs and diuretics. In addition, use of vasoconstricting medications such as decongestants (e.g., pseudoephedrine, phenylpropanolamine, caffeine) and drugs of abuse (e.g., cocaine, amphetamines) can cause persistently elevated BP readings in spite of intervention. Excessive alcohol use may also prevent many antihypertensive medications from achieving full therapeutic effect. In addition, one of the first manifestations of alcohol withdrawal is BP elevation. Nicotine and many of the chemically active, vasoconstricting substances ingested with cigarette smoke can also contribute to inadequate BP control.

On occasion, a given clinical condition necessitates the use of a drug such as cyclosporine, erythropoietin, or certain antidepressants known to cause BP elevations. In this case, the antihypertensive therapeutic agent must be chosen with care and an adequate dose prescribed.

Concurrent health problems that are inadequately treated may also affect the BP. The normal pain response includes vasoconstriction; therefore, inadequate control of both acute and chronic pain can cause a rise in BP.

Follow-up and Referral

For the patient on lifestyle modification, a follow-up visit should be scheduled every 3 to 6 months to determine effectiveness and adherence to the regimen. If ineffective, pharmacological therapy should be initiated. HTN can be controlled only if the patient is motivated. Using the *Circle of Caring* model and involving the patient in his or her own care may assist in increasing motivation.

After initiation of antihypertensive therapy, a follow-up visit should be scheduled in 2 to 3 weeks for a BP check or even in 1 to 2 weeks for an electrolyte or side-effect check. Once the BP goal is reached, visits can be scheduled every several months. More frequent visits may be needed if comorbid conditions exist. Serum

potassium and creatinine levels should be monitored several times per year. Lifestyle modifications need to be stressed at each visit, particularly with vigorous promotion of tobacco avoidance. Low-dose aspirin therapy should be initiated when BP control is achieved. If aspirin therapy is started when the patient is still hypertensive, there is a potential risk of hemorrhagic stroke. Because the majority of MIs occur in the morning, aspirin should be administered at night. If a patient is on two HTN medications, one should be given in the morning and one in the evening.

Patient Education

A patient-directed interdisciplinary team approach is critical to successful HTN care. This team should include representatives from nursing, pharmacy, medicine, and nutrition for the continued education of the patient and family and therapeutic monitoring during antihypertensive therapy. Education is stressed to improve patient adherence to behavioral and pharmacological therapy.

Numerous factors influence the efficacy of HTN therapy. Certain issues should be considered when HTN persists. Nonadherence to therapy is the most common reason for persistent HTN. The most common reasons for nonadherence are (1) lack of perceived benefit of the intervention, (2) difficulty with provider follow-up, and (3) adverse effects of medication. The clinician must work with the patient to develop a plan of care that will meet therapeutic goals and fit with the patient's needs. Choosing well-tolerated drugs for intervention and continually acting as the patient's advocate and coach for lifestyle changes are critical.

Using the *Circle of Caring,* the patient will be involved with the clinician in addressing diet, exercise, tobacco use, and every modifiable risk factor that may be positively changed. Family may be an important component of the *Circle of Caring* and should be present when patient teaching occurs. Many times a successful regimen is spearheaded by a conscientious family member.

The Framingham Scoring System is helpful to the clinician to evaluate the risk of patients for having an acute coronary event in the next 10 years. At a patient's annual visit, this risk assessment may be done by the clinician as a teaching tool to encourage patients to change behaviors such as smoking, exercise, and diet. The clinician can "plug in" the patient's numbers and discuss the results with the patient. The scoring system is found at www.nhlbi.nih.gov/guidelines/cholesterol/risk_tbl.htm. Note that this scoring tool takes into consideration neither persons over age 79 years nor family history.

Also recommended is the Clin Calc Pooled Cohort Risk Assessment equation to predict the 10-year risk for a first atherosclerotic cardiovascular disease (ASCVD) event. If a patient's assessed risk is greater than 7.5%, it is recommended that the clinician initiate lipid-lowering therapy. This calculator is found at http://clincalc.com/Cardiology/ASCVD/pooledCohort.aspx. Clinicians might want to use both assessment tools with patients to gain their commitment to make changes.

Oral contraceptives may increase BP, and the risk of HTN increases with the length of use. BP should be monitored regularly in women taking oral contraceptives. If a woman becomes hypertensive while taking oral contraceptives, the clinician should advise the patient to consider other forms of birth control.

The frequency of erectile dysfunction (ED) is significantly higher in men who are hypertensive than in men who are normotensive. If ED occurs, the antihypertensive medication should be discontinued and treatment restarted with another agent. Hypertensive men should be advised that there is a lower risk of ED in men who are physically active, not obese, and nonsmokers. Therefore, these lifestyle modifications should be encouraged for all men to forestall ED.

Because some older adults develop postural hypotension with hypertensive drug therapy, the clinician must insist that these patients change position slowly while on HTN medication and that they sit on the edge of the bed for several minutes before standing. In addition, patients with postural hypotension should be urged to avoid volume depletion by drinking adequate quantities of water. Lifestyle modifications cannot be stressed enough. Teaching at every visit should reinforce the suggestions listed in Table 10.2.

DYSLIPIDEMIA

Dyslipidemia, also referred to as *hyperlipidemia,* is a general term for elevated concentrations of any or all of the lipids in the plasma. A major risk factor for cardiovascular disease (CVD), increased lipid levels positively correlate with a growing risk of acute coronary syndrome (ACS). In 2013, the American College of Cardiology (ACC) and the American Heart Association (AHA) released guidelines recommending consideration of statin therapy to those millions of Americans who do not currently have CVD but who have a 7.5% or greater risk for stroke or heart attack. This risk is calculated using an updated equation from the AHA/ACC panel that includes race, gender, age, total cholesterol, high-density lipoprotein, blood pressure (BP), use of BP meds, diabetes mellitus (DM), and smoking. The risk calculator may be found at http://myamericanheart.org/cvriskcalculator.

The AHA/ACC recommend that the clinician begin a discussion determining the best therapy for each unique patient situation. These recommendations from the AHA/ACC are changing the way clinicians view traditional treatment guidelines. Previously, clinicians focused on achieving a target low-density lipoprotein (LDL). However, there have been no clinical trials that have supported using LDL levels as an indication for prescribing statins.

Epidemiology and Causes

The correlation between dyslipidemia and coronary events is well documented. Elevated lipid levels present

the greatest risk factor for the development of coronary artery disease (CAD). In the United States, CVD claims the lives of approximately 815,000 men and women each year. The Framingham Heart Study (the largest ongoing cohort study of heart disease in the United States) has documented that 40% of participants who developed a myocardial infarction (MI) had a total cholesterol (TC) level between 200 and 250 mg/dL. A patient with a TC level greater than 259 mg/dL is three times more likely to develop CAD than a patient with a level less than 200 mg/dL. It is important to recognize that dyslipidemia is only one of the many factors that increase the risk of developing CAD. The greater the number of risk factors present, the greater the probability of developing clinically significant CAD.

Pathophysiology

Dyslipidemia is a heterogeneous metabolic disorder that involves levels of lipids and lipoproteins that increase risk of atherosclerosis. Lipoproteins are molecules that carry cholesterol in the bloodstream. Lipoproteins differ in size, density, and atherogenicity and are divided into several classes—very low density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), low-density lipoprotein (LDL), lipoprotein (a) (Lp[a]), and high-density lipoprotein (HDL). Atherogenesis is mediated by the lower density lipoproteins: Lp(a), VLDL, IDL, and LDL. These small LDL particles migrate into the inflamed region of the blood vessel wall where they are oxidized and phagocytosed by macrophages to form foam cells, ultimately leading to the formation of fatty streaks and atherosclerotic plaques. LDL cholesterol (LDL-C) is the specific type of cholesterol that constitutes the lipid core of arteriosclerotic plaque deposits. In clinical analyses, Lp(a), LDL, IDL, and VLDL are combined into the single fraction of LDL. Desirable levels of LDL are dependent on the existence of other CVD risk factors. (See Table 10.3 for all lipid levels.) Triglycerides (TGs) are large lipid molecules formed from dietary fats that also contribute to atherogenesis. To prevent cardiovascular disease, the desirable TG level is less than 150 mg/dL.

Atherogenic forms of cholesterol–lipoprotein complexes include all types of non-HDL cholesterol- and triglyceride-transporting proteins: LDL, IDL, Lp(a), and VLDL. Total cholesterol in the blood arises both from ingested fats and from synthesis in the liver. The measurement of total blood cholesterol is based on LDL-C, TG, and HDL-C. The following equation is used to calculate total cholesterol: TC = LDL-C + TG/5 + HDL-C. The desirable level of total cholesterol in the blood is less than 200 mg/dL.

HDL cholesterol (HDL-C) is excreted from the body and not deposited on the arterial walls. HDL removes excess cholesterol from blood vessels and delivers it back to the liver through reverse cholesterol transport. Once in the liver, cholesterol is excreted into the intestine as bile. HDL also plays a protective role by blocking the oxidation of LDL, which, in turn, inhibits atherogenesis. A low HDL level (≤40 mg/dL) is considered a cardiovascular risk factor, whereas a high level of HDL-C (≥60 mg/dL) is considered cardioprotective. An HDL-C level less than or equal to 60 mg/dL is a negative cardiovascular risk factor, subtracting one factor from the total number of CVD risk factors.

Table 10.3 Serum Lipid Levels

Classification Level	Laboratory Value
Total Cholesterol (mg/dL)	
Desirable	<200 mg/dL
Borderline high	200–239 mg/dL
High	>240 mg/dL
Triglycerides (mg/dL)	
Normal	<150 mg/dL
Borderline high	150–199 md/dL
High	200–499 mg/dL
Very high	>500 mg/dL
HDL (mg/dL)	
Low	<40 mg/dL
High (optimal: cardioprotective)	>60 mg/dL

Primary goals of treatment of dyslipidemia are (1) lowering elevated LDL, (2) lowering elevated TG, and (3) raising suboptimal levels of HDL in order to prevent CVD development. Table 10.3 shows lipid values and classifications according to the Guidelines of the National Cholesterol Education Program, National Institutes of Health, and the National Heart, Lung, and Blood Institute. Dyslipidemia can also arise as a result of a genetic disorder, such as familial hypercholesterolemia. Behavioral factors, such as dietary consumption of fats and a lack of physical activity, also play a role. Moreover, dyslipidemia can be part of a constellation of abnormalities known as metabolic syndrome. Metabolic syndrome is characterized by abdominal obesity, glucose intolerance, insulin resistance, hyperinsulinemia, dyslipidemia, and hypertension (HTN).

It is important to assess patients for secondary causes of dyslipidemia before instituting lipid-lowering treatment. Treatment of the primary disorder can correct the dyslipidemia. Secondary causes of dyslipidemia include obesity, diabetes mellitus, hypothyroidism, nephrotic syndrome, end-stage renal disease, hepatic disorders, excessive alcohol consumption, estrogen administration, Cushing's syndrome, and glycogen storage disease. Certain drugs can cause lipid abnormalities such as thiazide diuretics, steroids, beta blockers, HIV protease inhibitors, isotretinoin, and growth hormone.

Clinical Presentation

Subjective

Typically, the patient may present without symptoms when diagnosed with dyslipidemia. Often, however, concurrent problems such as HTN or CAD exist.

Objective

The clinician, on noting an abnormal lipid profile, may be the first to diagnose dyslipidemia in the unsuspecting patient. Physical examination may reveal a carotid bruit and corneal arcus. In some forms of dyslipidemia, yellowish skin deposits of cholesterol called xanthomas may occur. These deposits commonly occur around the eyelids (xanthelasma) and extensor tendons. Interestingly, even with effective lipid-lowering therapy, these deposits tend not to regress.

Diagnostic Reasoning

Diagnostic Tests

The fourth Adult Treatment Panel guidelines from the National Cholesterol Education Program (ATP IV NCEP) of the National Heart, Lung, and Blood Institute was released in November 2013. Previous guidelines recommended specific LDL and non-HDL cholesterol targets for patients with CVD to maintain, with some suggesting LDL levels lower than 100 mg/dL and others proposing levels less than 70 mg/dL. The latest ACC/AHA guidelines state that there is no evidence from trials to support treatment to a specific LDL target. These guidelines identify four groups of primary and secondary prevention patients on whom to concentrate efforts aimed at reducing CV events:

- Patients with atherosclerotic cardiovascular disease (ASCVD)
- Patients with LDL levels greater than or equal to 190 mg/dL such as those with familial hypercholesterolemia
- Patients with diabetes aged 40 to 75 years with LDL between 70 and 189 mg/dL and without evidence of ASCVD
- Patients without evidence of CVD or DM but who have LDL levels between 70 and 189 mg/dL along with a 10-year risk of ASCVD greater than or equal to 7.5% as determined by the CV risk calculator

It is recommended that the first two groups use high-intensity statins and the last two groups use moderate-intensity statins.

Differential Diagnosis

Some potential causes of secondary dyslipidemia are listed in Table 10.4. Elevated TC levels may be present in CAD, type II familial hypercholesterolemia, idiopathic hypercholesterolemia, obstructive jaundice, biliary cirrhosis, hypothyroidism, von Gierke's disease, pregnancy, uncontrolled DM, other pancreatic disease, chronic nephritis, glomerulosclerosis, and obesity. Decreased TC levels may be present in malabsorption, starvation, anorexia nervosa, liver disease, severe cell damage, HTN, chronic anemia, and drug therapy with agents such as adrenal corticotrophic hormones and antibiotics.

Elevated TG levels may be present in liver disease, alcoholism, nephrotic syndrome, renal disease, hypothyroidism, uncontrolled DM, pancreatitis, gout, glycogen storage disease, MI (increased levels may last for 1 year), metabolic diseases related to endocrinopathies, von Gierke's disease, stress, high-carbohydrate diet, and HTN. Decreased triglyceride levels may be present in malnutrition, hyperthyroidism, exercise, and malabsorption syndrome.

Table 10.4 Potential Causes of Secondary Hyperlipidemia

Causes	Lipid Abnormality
Inactivity	HDL ↓
Alcohol abuse	TG ↑, HDL ↑, LDL ↑
Diabetes mellitus	TG ↑, HDL ↓, TC ↑
Hypothyroidism	TG ↑, TC ↑
Thiazide diuretic use (high dose)	TC ↑, LDL ↑, TG ↑
Beta blocker use (high dose)	LDL ↑, HDL ↓
Chronic renal insufficiency	TC ↑, TG ↑

An elevated HDL level may be associated with chronic liver disease or chronic intoxication, long-term aerobic exercise or other vigorous exercise, and estrogen and birth control pills. A decreased HDL level may be caused by hypertriglyceridemia, hypothyroidism, end-stage liver disease, diabetes mellitus, obesity, chronic inactivity, uremia, and homozygous Tangier disease.

An increased LDL level may be the result of familial hypercholesteremia and secondary causes such as a diet high in cholesterol and saturated fat, nephrotic syndrome, chronic renal failure, pregnancy, porphyria, diabetes mellitus, multiple myeloma, steroids, and estrogens. A decreased LDL level may be the result of malnutrition and malabsorption syndromes.

An increased VLDL level may be caused by familial hyperlipidemia and secondarily by alcoholism, obesity, diabetes mellitus, chronic renal disease, pancreatitis, pregnancy, estrogen, birth control pills, and progestins. A decreased VLDL level may be the result of malnutrition and malabsorption syndromes.

Management

To determine if a patient should be on a statin, the clinician should ask the following four questions; if any response is *yes,* the patient is a potential candidate (Page, 2013):

1. Does the patient have a history of any of the following?
   a. ACS
   b. MI
   c. Stable or unstable angina
   d. Coronary or arterial revascularization
   e. Stroke, transient ischemic attack
   f. Peripher arterial disease of artherosclerotic origin
2. Does the patient have an LDL level of greater than or equal to 190 mg/dL? (indicative of familial hypercholesterolemia)
3. Is the patient 40 to 75 years of age with DM?

4. Is the patient 40 to 75 years of age with a CV risk score of greater than or equal to 7.5%?

For patients with ASCVD who are under age 75 years, high-intensity statin therapy should be used to reduce their LDL-C levels by 50%. For patients older than 75 years, use moderate-intensity therapy. A moderate-intensity statin therapy should be used for patients with DM aged 40 to 75 years, because the goal is to reduce their LDL-C levels by 30% to 49%. If these patients have a 10-year CV risk greater than 7.5%, use high-intensity therapy. In addition, for patients aged 40 to 75 years without CVD or DM, but who have a CV risk score greater than 7.5% and an LDL level anywhere from 70 to 189 mg/dL, moderate-intensity therapy is also acceptable. See Drugs Commonly Prescribed 10.2 for classifications and dosages of statins.

If patients do not fall into any of the previous categories, additional factors should be considered, such as family history of premature ASCVD in a first-degree relative; high-sensitivity C-reactive protein greater than 2 mg/dL; presence of calcification on a coronary artery calcium scan; and an ankle-brachial index less than 0.9.

Diet

A cholesterol-lowering diet is recommended for all Americans. Diets very low in total fat or in saturated fat, however, may lower HDL-C as much as they do LDL-C. A sensible nutritional approach is the best recommendation. Most nutritionists advocate reducing total fat to 25% to 30% of daily calories and saturated fat to less than 7% of daily calories. Dietary cholesterol should be limited to less than 200 mg/day. This regimen will replace fat, particularly saturated fat, with carbohydrate, usually resulting in fewer total calories consumed and facilitating weight loss in overweight patients. The Mediterranean diet has been shown to decrease cholesterol levels in some patients.

Pharmacological Therapy

For years, diet has been the cornerstone of treatment for hyperlipidemia; however, recent studies have demonstrated that diet alone is often insufficient in lowering cholesterol.

The 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (medications with generic names ending in *-statin*) are the first-line drugs of choice in the majority of patients.

Baseline liver function tests (LFTs) should be done before prescribing statins. There is no evidence from the Food and Drug Administration to support routine monitoring of LFTs during statin therapy unless clinically indicated. The clinician should caution patients about use of statins with other hepatotoxic drugs and alcohol. Other adverse effects include muscle weakness and, in extreme cases, rhabdomyolysis with significant elevations in serum creatine phosphokinase (creatine kinase) levels. Gastrointestinal complaints include dyspepsia and abdominal pain.

Once the initial dose of statin medication is prescribed, the clinician considers whether to increase the dose or add another agent if the statin does not seem to be effective. Although some practitioners recommend them, there is lack of evidence to support the use of fibrates, niacin, and fish oil to treat hyperlipidemia. Lifestyle counseling should occur at the initial and follow-up visits as the foundation for statin therapy and may improve the patient's overall risk.

Drugs Commonly Prescribed 10.2 presents information on the different levels of statin therapy along with specific dosages. Therapies are either categorized as low, moderate, or high intensity.

Follow-up and Referral

The clinician should be very well equipped to treat the patient with hyperlipidemia. If treatment goals are not reached, consultation with a cardiologist may be indicated. Consultation with a nutritionist may be recommended if the patient cannot follow or understand a cholesterol-lowering diet.

Patient Education

It is important for the clinician to provide ongoing support and reinforcement to patients undertaking both dietary and pharmacological therapy for dyslipidemia. Many patients do not like to take medications and feel that diet alone is sufficient to keep them "under control." Sometimes, showing the patient the lab results and having a discussion about what the numbers mean, especially the ratio of HDL to TC, in terms of the risk of having an MI, is an effective way to get the patient to take a hard look at potential benefits of combined therapy. Calculating the patient's CV risk score will facilitate the conversation about the possible need for statin therapy. In addition, discussing the patient's Framingham Heart Score to predict the risk of having an acute coronary event might help to motivate a patient in adhering to a diet, exercise, and drug treatment program. Using the *Circle of Caring* model, patients can be encouraged through the highs and lows that typically occur when initiating long-term changes.

METABOLIC SYNDROME

Metabolic syndrome refers to a cluster of specific cardiovascular disease (CVD) and diabetes risk factors where the underlying pathophysiology is thought to be related to insulin resistance. Because the term *metabolic syndrome* has been imprecisely defined, clinicians should evaluate and treat all CVD risk factors without regard to whether a patient meets the criteria for diagnosis of the metabolic syndrome. The clinician needs to be cognizant of new information pertaining to this syndrome, because a new definition typically appears every few years. Metabolic syndrome has been characterized by a combination of atherogenic and diabetogenic factors. Increased body mass index (BMI), elevated systolic blood pressure (BP),

Drugs Commonly Prescribed 10.2 Hyperlipidemia

Drug	Effect on Lipids	Adverse Reactions and Prescribing Considerations
HMG-CoA Reductase Inhibitors (Statins)		
High-Intensity atorvastatin (Lipitor) 40–80 mg rosuvastatin (Crestor) 20–40 mg	Decreases LDL. Increases HDL. Decrease TGs.	May cause myositis (especially in patients taking fibrates or niacin). Do not use with gemfibrozil. Take in the evening.
Moderate-Intensity rosuvastatin 10 mg (Crestor) atorvastatin 10–20 mg (Lipitor) pravastatin (Pravachol) 40 mg simvastatin (Zocor) 20–40 mg lovastatin (Mevacor) 40 mg		Do not give to patients with active or chronic liver disease. Monitor LFTs before initiating therapy.
Bile Acid Sequestrants		
cholestyramine (Questran and Questran Light) colesevelam (WelChol) colestipol (Colestid)	Decreases LDL anywhere from 10%–25%. Increases HDL 5%–10%. TG: Same or increased.	Mix with liquids. GI symptoms are common, with constipation and gas. Use psyllium to prevent. Contraindicated with dysbeta-lipoproteinemia. Do not give with TG >400 mg/dL.
Cholesterol Absorption Inhibitor		
ezetimibe (Zetia)	Decreases LDL 15%–20%.	May be given with a statin or fenofibrate. May cause back pain, arthralgia, diarrhea, abdominal pain, fatigue, cough. Give 2 hours before or 4 hours after bile acid sequestrants. Monitor warfarin.
Combination Therapy		
Statin plus calcium channel blocker atorvastatin + amlodipine (Caduet)	All lower LDL, increase HDL, and lower TGs.	May cause edema, dizziness, palpitations, flushing, fatigue, constipation, dyspepsia, abdominal pain, drowsiness, myopathy, elevated liver enzymes, rhabdomyolysis with renal dysfunction. Monitor liver function before start of therapy. May increase serum levels of digitalis, BCP.
Statin plus cholesterol absorption inhibitor simvastatin + ezetimibe (Vytorin) Statin plus niacin lovastatin + niacin (Advicor) simvastatin + niacin (Simcor)	All lower LDL, increase HDL, and lower TGs.	Caution with moderate to severe liver disease. May cause headache, myalgia, extremity pain, myopathy, rhabdomyolysis, elevated serum transaminases. Avoid fibrates, alcohol, grapefruit juice. May potentiate vasoactive drugs; monitor warfarin, antidiabetics. May cause flushing, headache, pain, pruritus, dyspepsia.
liptruzet (ezetimibe/atorvastatin)	Lowers LDL by approximately 10% more than atorvastatin, but this may not translate to better patient outcomes.	Muscle pain, tenderness for weakness, increased fatigue, or elevations of liver enzymes.

hypertriglyceridemia, hyperglycemia, and low levels of protective high-density lipoprotein cholesterol are found in affected persons. Any three of these conditions occurring together usually establish the diagnosis (see Table 10.5). The etiology is unknown; however, environmental, genetic, and behavioral factors contribute to the development of metabolic syndrome, particularly physical inactivity and excess body fat. Elevated BMI is apparent as central obesity, with the affected individual demonstrating an "apple shape" or high waist circumference. Metabolic syndrome is also a proinflammatory and prothrombotic disorder causing endothelial injury, as evidenced by elevations of the inflammatory marker C-reactive protein, increased platelet aggregation, and increased fibrinogen levels. In addition to hyperglycemia and deranged lipid metabolism, peripheral tissues are resistant to insulin. The pancreas oversecretes insulin to overcome tissue resistance, which results in hyperinsulinemia. Obesity enhances insulin resistance and predisposes the individual to type 2 diabetes mellitus.

Obesity is believed to contribute significantly to the development of metabolic syndrome. The National Cholesterol Education Program (NCEP) recommends obesity as the primary target for intervention. Abdominal obesity is defined as a high waist-to-hip ratio. Weight loss improves serum lipid profiles, reduces BP, decreases insulin resistance, and ameliorates glucose intolerance.

CORONARY HEART DISEASE (ATHEROSCLEROTIC CORONARY ARTERY DISEASE)

Coronary heart disease (CHD), also referred to as coronary artery disease (CAD), is the leading cause of death in the United States, responsible for more than one in four, or approximately 600,000, deaths per year. Mortality from CAD has declined over the years because of patient education regarding risk factors and early recognition and treatment of symptoms; management of existing problems such as hypertension (HTN), dyslipidemia, and diabetes; and improved technologies such as thrombolytic drugs.

Table 10.5 Components of Metabolic Syndrome

Risk Factor (three required for diagnosis)	Defining Level
Abdominal Obesity	*Waist Circumference*
Men:	>40 inches
Women:	>35 inches
Triglycerides HDL-C	*>150 mg/dL*
HDL-C (cardioprotective)	
Men:	<40 mg/dL
Women:	<50 mg/dL
Blood Pressure	*≥130/ ≥85 mm Hg*
Fasting Glucose	*>110 mg/dL*

Adapted from www.americanheart.org/presenter.jhtml?identifier=456

Epidemiology and Causes

Risk factors for CAD are classified as nonmodifiable, modifiable, or contributing and are listed in Risk Factors 10.1. Nearly 13 million Americans have CAD, and the incidence increases with age. More than 10 times the number of women die from atherosclerotic cardiovascular disease each year than from breast cancer.

Angina is the number one symptom of CAD. The narrowing of the coronary arteries as a result of atherosclerosis causes angina. A thrombus, coronary artery vasospasm, aortic stenosis, aortic insufficiency, severe HTN, or idiopathic subaortic hypertrophic stenosis may also cause angina. Angina is the presenting symptom in CAD in 38% of men and 61% of women. Middle-aged and older men and postmenopausal women are most prone to developing angina. Variant angina may occur in patients with normal coronary arteries who have cyclically recurring angina at rest that is unrelated to effort. The pain of unstable angina tends to last longer and have greater intensity than the pain of stable angina.

Pathophysiology of Arteriosclerosis and Coronary Artery Disease

The coronary arteries provide arterial blood flow that supplies oxygen and nutrients to afford optimal myocellular function of the heart. The coronary arteries dilate via release of vasoactive substances to further augment oxygen delivery to keep pace with changing metabolic demands.

Risk Factors 10.1 Coronary Artery Disease (CAD)

Category	Risk Factors
Nonmodifiable	Male gender Increasing age Family history of CAD African American ethnicity
Modifiable	Hypertension (>140 mm Hg SBP and/or ≥90 mm Hg DBP, depending on age) Smoking Sedentary lifestyle Hyperlipidemia For women: natural or surgical menopause without estrogen replacement therapy; oral contraceptive use combined with cigarette smoking
Contributing	Diabetes mellitus Obesity Stress

In addition, the lumen of each coronary artery needs to be patent in order to maintain optimal tissue perfusion. In CAD, arteriosclerotic plaque hinders optimal blood flow and dilation of the coronary arteries. Coronary arteries become obstructed and incapable of vasodilation, which severely impedes perfusion of the myocardium. During physical exertion, when increased blood flow is required, coronary artery blood flow becomes insufficient for the oxygen demands of the myocardium.

This coronary insufficiency, in turn, leads to ischemia of heart muscle. Ischemia creates anaerobic conditions for the myocardium, particularly if acute occlusion results. Anaerobic metabolism yields inadequate energy (approximately 5% of normal) for myocardial demand, allowing for less than a 20-minute period of tissue viability after occlusion. Lactic acid is created as a waste product, leading to localized tissue acidosis. Because lactic acid is irritating to muscle tissue, lactic acid buildup is the source of chest pain in ischemic heart disease. The term *angina pectoris* means chest pain due to ischemia of the heart muscle. If myocardial ischemia is prolonged, myocardial infarction (MI) ensues. Thus, if untreated, CAD progresses to ischemia of the heart muscle or angina pectoris, which can then lead to MI.

Atherosclerosis (arteriosclerosis) is a systemic disease affecting all arteries of the body. If CAD is diagnosed, it is likely that arteriosclerosis is present throughout all arterial systems. Likewise, if vascular disease is identified in target end-organs, CAD is likely to already be present. The process of arteriosclerosis begins with endothelial injury, which can be incited by a number of etiological agents. Free radicals, HTN, hyperglycemia of diabetes, and hyperlipidemia have been found to be agents of injury to arterial endothelial cells. Endothelial injury provokes an inflammatory reaction that attracts T cells, macrophages, monocytes, and platelets to the site. White blood cells secrete mediators, such as interleukins, tumor necrosis factor–alpha, and C-reactive protein (CRP), which perpetuate the inflammatory reaction. Platelets aggregate and form microthrombi. Inflammation is now thought to be the major force that drives atherosclerosis. This idea is supported by findings of elevated levels of *high-sensitivity C-reactive protein (hs-CRP),* an inflammatory marker, in individuals with coronary arteriosclerosis.

Inflammation of the endothelium depletes nitric oxide, a major vasorelaxant of the arterial muscle wall. This depletion results in a net vasoconstrictive effect. Other pro-inflammatory mediators stimulate proliferation of vascular smooth muscle within the arterial wall, which intensifies the vasoconstrictive effect further. Concurrently, macrophages within the vessel wall engulf and ingest low-density lipoproteins, forming "foam cells." Disruptions of the arterial endothelium by inflammation, lipid-laden macrophages, platelets, and vasoconstricting mediators are the initiating events of arteriosclerosis or atherogenesis.

In the process of atherogenesis, an initial fatty streak on the arterial wall evolves over time, serving as a nidus for fibrin deposition to become a fibrous, calcified plaque. *Arteriosclerosis* means "hardened arteries," which is an apt term for the rigid arteries resulting from long-term plaque formation. Arteries lose significant vasodilation capacity and are lined by calcified arteriosclerotic plaque. The lipid-rich, calcified plaque becomes brittle and unstable, easily rupturing with mechanical stress. When disruption of the plaque occurs, this induces platelet aggregation and activation of the coagulation cascade. A thrombus forms at the site that can embolize, lodge in, and obstruct the lumen of narrowed arteries. In patients who die of unstable angina or MI, pathological studies find that death occurs as a result of ruptured plaque with associated thrombosis. Obstruction due to thrombosis is the most common cause of ischemia in *any* arterially supplied region of the body. Common sites of arteriosclerosis are the coronary arteries, cerebral arteries, and peripheral arteries of the lower extremities. Consequently, ischemia-prone regions of the body are the myocardium, brain, and lower extremities. Prolonged, severe episodes of ischemia can lead to acute coronary syndrome, ischemic stroke, and peripheral arterial insufficiency.

Clinical Presentation

Subjective

In most patients, CAD develops many years before the patient is aware of its existence. Because collateral circulation develops, the patient is usually unaware that anything is wrong unless other concomitant conditions are present, such as dyslipidemia or HTN. Typically, symptoms of CAD are not reported until 75% of the coronary artery is narrowed. Eventually, if CAD is uncorrected, the patient will usually present with exertional angina, which should lead the clinician to suspect CAD. Associated symptoms may include radiation of the discomfort to the left arm and jaw, nausea, shortness of breath, and lightheadedness (syncopal episodes). It should be noted that not all patients present with these "typical" symptoms. Please review the differential diagnosis section.

Objective

The clinician should note all the peripheral pulses; auscultate for carotid bruits; note jugular venous distention; take the blood pressure sitting, lying, and standing; and examine the skin condition for evidence of decreased perfusion. The history should include a detailed description of other risk factors that are present, which will guide further assessment for resultant problems such as angina. (Pertinent questions related to angina are covered later in this chapter.) Because atherosclerosis is a widespread problem, patients with CAD also have a much higher incidence of peripheral vascular disease and cerebrovascular disease than other individuals. The clinician should assess for other symptoms that suggest vascular insufficiency such as intermittent claudication or transient ischemic attacks.

Diagnostic Reasoning

Diagnostic Tests

An electrocardiogram (ECG), stress test, nuclear scanning, and angiography may be ordered to determine the extent of the CAD and to identify which vessels are affected. ECGs are discussed in detail in the section on MI.

An exercise ECG, or a stress test, may be ordered to detect and evaluate CAD. Carefully controlled and supervised exercise increases the myocardial oxygen demands, which assists in evaluating the coronary arteries' ability to meet the increased demands successfully. When the patient is unable to achieve a vigorous level of exercise, a dipyridamole thallium-201 test may be used. It may produce false-positive readings, especially in women, and in cases of certain drugs and electrolyte imbalances. A stress test is contraindicated in acute cardiovascular disease (CVD) (e.g., MI, unstable angina, or heart failure) because the heart cannot respond to an increased demand for oxygen.

Nuclear scanning (technetium-99m ventriculography) studies the motion of the left ventricular wall and measures the ventricle's ability to eject blood, referred to as the ejection fraction (normally 55%–75%). When ischemia is present because of a narrowed coronary artery, the segment of the myocardium that artery serves exhibits diminished wall motion (hypokinesis) or contractility that is represented as pooled blood within the ventricular and atrial chambers.

Contrast-enhanced computed tomography (CT) scan imaging is a noninvasive imaging method of assessing overall "plaque burden," the extent to which atheromatous plaque undermines the integrity of an artery wall. Estimating "plaque burden" can assess the risk of atheromatous plaque rupturing and causing ischemia. This CT scan, also termed *CT calcium scoring,* can evaluate the overall burden of calcified atherosclerotic plaque.

A cardiac catheterization with angiography for coronary artery visualization is performed, commonly after the patient is stabilized in acute coronary syndrome (ACS) or if there is high suspicion of ACS. Visualization of the coronary arteries confirms diagnosis of CAD and can evaluate the extent of stenosis of coronary arteries.

Ultrasonography can be used with cardiac catheterization to add diagnostic information. Intravascular ultrasonography (IVUS) used during cardiac catheterization measures "plaque burden" through real-time intraluminal imaging of vessel walls. IVUS can also be used to assess plaque regression when the patient is on antilipemic drug therapy.

Because arteriosclerosis is a chronic inflammatory condition, the biomarker CRP is commonly elevated in individuals with CAD. CRP is an acute-phase inflammatory protein produced by the liver and by the smooth muscle cells within arteriosclerotic coronary arteries. An elevated level of hs-CRP has been shown to be an independent predictor of risk of MI, stroke, peripheral arterial disease, and sudden cardiac death. Measurement of hs-CRP adds to the total cardiac risk assessment of the patient and should not be solely relied on as a confirmatory test.

Epidemiological studies show that an elevated level of the amino acid homocysteine is an independent risk factor for arteriosclerosis and CAD. Homocysteine requires folic acid, vitamin B_6, and vitamin B_{12} for its metabolism. This amino acid accumulates in the blood and injures the endothelium when there are inadequate levels of the B vitamins and folate for its proper metabolism. Therefore, elevated serum homocysteine levels add to the cardiac risk assessment of a patient. Research has shown that reducing homocysteine levels with vitamins does not reduce the risk of heart disease.

Differential Diagnosis

Differential diagnoses for CAD include gastrointestinal, pulmonary, or cardiac problems that are not related to ischemia. Gastroesophageal reflux disease, esophageal spasm, or biliary colic can present with symptoms similar to MI or angina. Patients with CAD or MI often present with epigastric pain that is misinterpreted as "heartburn" or related pain. This misinterpretation is often the reason for a patient's delay in obtaining prompt medical evaluation.

Patients with anxiety or panic attacks often present to the emergency department with symptoms that mimic angina or MI. Extreme stress can precipitate chest pain, dizziness, dyspnea, and hyperventilation, all of which mimic the symptoms of angina or MI. Costochondritis, a musculoskeletal problem, can also present as chest pain that may be misinterpreted as CAD by patients. The pain of costochondritis can usually be reproduced by pressing on the sternum and costochondral regions of the chest.

Persons with diabetes may experience angina or silent MI with minor symptoms or no symptoms at all. Diabetes causes nerve related damage that blunts heart pain. Patients with CAD may experience nausea and vomiting, dyspnea, epigastric pain, diaphoresis, or dizziness with no complaint of chest pain. These symptoms are referred to as "anginal equivalents." Women experiencing angina or MI commonly present with "anginal equivalents" rather than with chest pain. Historically, clinicians have underestimated the risk of CVD in women. Atypical presentation of ACS in women contributes to lack of early recognition of cardiac symptoms by both patients and clinicians. Women classically delay seeking medical care for ischemic symptoms, which contributes to their overall higher morbidity and mortality with cardiac events.

Pneumothorax, pneumonia, pericarditis, pulmonary embolism, mitral valve prolapse, and aortic dissection are other less common causes of chest pain. The diverse causes of ischemic chest pain (angina) must be determined. Because chest pain is so often the impetus to the diagnosis of CAD, the pain characteristics that drive the differential diagnoses need to be carefully assessed. In a young, otherwise healthy adult, reproducible point tenderness is likely musculoskeletal chest wall pain and not ischemic.

Pleuritic pain worsens on inspiration and is likely from lung pathology such as pneumonia, especially if accompanied by fever and productive cough. Clinicians need to have a high level of suspicion and to complete a thorough cardiac risk assessment to rule out MI in all patients complaining of chest pain or "anginal equivalents."

Management

The principles of management include establishing the diagnosis, controlling the symptoms, and preventing the disease progression that may lead to MI or sudden death. During a cardiac catheterization, fibrinolytic agents may be infused directly into an occluded coronary artery in an attempt to restore coronary blood flow. Other therapeutic approaches may include balloon angioplasty, stent placement, and coronary artery bypass graft. Presently there are two types of stents in use—bare-metal stents (BMS) and drug-eluting stents (DES). With both types of stents, anticoagulation is begun immediately. DES require a longer duration of anticoagulation therapy than BMS (Level II; Brar et al, 2008).

Risk-Factor Modification

Risk-factor modification is essential to stop the progression of CAD. This involves aggressive lowering of lipid levels (which is discussed in the Dyslipidemia section), strict glycemic control in patients with diabetes (see Chapter 16), aggressive antihypertensive therapy (discussed in the Hypertension section), smoking cessation (see Chapter 9) and cessation of all tobacco use, and modifying the lifestyle to include regular exercise, stress reduction, and a heart-healthy diet (less than 300 mg cholesterol/day and 7% or less of total calories from saturated fatty acids).

Complementary Therapies 10.1 presents suggested vitamin, mineral, and herbal supplementation for various cardiovascular disorders.

Complementary Therapies 10.1 Cardiac Conditions

Agent	Indication	Adverse Reactions and Considerations*
Hawthorn	Angina, CHF, CAD, functional cardiovascular disorders, hypertension (in diabetes), orthostatic hypotension	May cause abdominal discomfort, agitation, arrhythmia, diaphoresis, dizziness, dyspnea, fatigue, headache, palpitations, sleeplessness, rash. Caution with: HTN medications (may increase risk of hypotension); antilipemic agents (additive effects); calcium channel blockers (additive vasodilation); cardiac glycosides and vasodilators (additive vasodilation). Monitor BP, coagulation panel, heart rate, lipid profile.
Magnesium	Arrhythmia, acute MI, CAD, HTN, mitral valve prolapse	May cause areflexia, asthenia, cardiac arrhythmias, cardiac arrest, drowsiness, hypermagnesemia, hypotension, loss of tendon reflexes, polydipsia, respiratory paralysis. Caution with aminoglycosides (increased risk of muscular weakness and paralysis); antibiotics (decreased effects); antidiabetic agents (increased absorption); antihypertensive agents (additive effects). Monitor alkaline phosphatase, blood glucose, BP, calcium levels, coagulation panel, cortisol, LFTs, ECG, parathyroid hormone.
Beta-glucan	Antioxidant, CVD, heart protection during CABG, hyperlipidemia, HTN	May cause dizziness, flushing, headache, hypertension or hypotension, inflammatory airway disease, keratoderma, nausea, polyuria, urticaria, vomiting. Caution with diabetic agents (additive effect); antihypertensive agents (additive effect); antilipemic agents (additive effect). Monitor blood glucose, BP, lipid profile, WBC count.
Selenium	Antioxidant, cardiomyopathy, CVD prevention, circulation	May cause digitalis dysfunction, garlic-like breath odor, hepatorenal dysfunction, irritability, loss or thickening of hair and nails, metallic taste, muscle tenderness, nausea/vomiting, nervous system abnormalities, skin lesions, thrombocytopenia, tremor, weakness. Caution with barbiturates (increased sedation); HMG-CoA reductase inhibitors and niacin (decreased efficacy).

Continued

Complementary Therapies 10.1 Cardiac Conditions—cont'd

Agent	Indication	Adverse Reactions and Considerations*
Vitamin B_6	Angioplasty, CVD, CHD risk reduction, coronary restenosis, homocysteine reduction	Prolonged excessive use may cause neuropathy. Monitor vitamin B_6 levels.
Vitamin B_{12}	Angioplasty, CHD, coronary restenosis, homocysteine reduction, orthostatic tremor (restless legs syndrome)	Monitor vitamin B_{12} levels.
Vitamin C	Atherosclerosis, circulation, ischemic heart disease, MI risk reduction	In large doses may cause abdominal cramps, diarrhea, nausea, skin rashes. In diabetics, may cause falsely elevated blood glucose readings. Caution with iron (increased iron levels); warfarin (in high doses, lowers prothrombin time). Monitor vitamin C levels.
Vitamin E	Angina, arterial elasticity, atherosclerosis, CVD, CHF, dyslipidemias, intermittent claudication, DVT	May cause abdominal pain, blurred vision, diarrhea, fatigue, headache. Increased risk of mortality with high doses with history of severe CVD (CVA or MI). Caution with anticoagulants/antiplatelets (increased risk of bleeding); chemotherapy (interfere with effectiveness). Monitor coagulation panel (with high doses), vitamin E levels. Discontinue use 2 weeks before dental or surgical procedures.
Flaxseed Oil	CVD, HTN, hyperlipidemia	May cause abdominal discomfort, anaphylaxis, bleeding, bowel obstruction, constipation, diarrhea, dyspnea, hypoglycemia, hypotension, mania, nausea/vomiting, increased risk of prostate cancer, pruritus, skin rash, sneezing, stuffy nose, seizures, watery eyes. Contraindicated with hypertriglyceridemia. Caution with anticoagulants/antiplatelets (increased risk of bleeding); antidiabetic agents (increased risk of hypoglycemia); antihypertensives (increased risk of hypotension); antilipemic agents (decreased effects on triglycerides); furosemide (decreased absorption of furosemide). Monitor alkaline phosphatase, blood glucose, coagulation panel, inflammatory markers, lipid profile, prostate-specific antigen (PSA), red blood cells, triglycerides.
Garlic	Anticoagulant, atherosclerosis, familial hypercholesterolemia, hyperlipidemia, HTN, prevention of MI, PVD	May cause anorexia, bleeding, burning inside the mouth, chills, constipation, diarrhea, dizziness, diaphoresis, dyspepsia, dyspnea, fever, flatulence, halitosis, hyperglycemia or hypoglycemia.
	#24- NNRTI is Non-Nucleoside Reverse Transcriptase Inhibitor	Contraindicated with concurrent use with isoniazid, NNRTIs, or protease inhibitors, inflammatory bowel disease, pregnancy, and lactation. Caution with anticoagulants/antiplatelets (increased risk of bleeding); antidiabetic agents (altered effects); antihypertension agents (additive effect); antilipemic agents (additive effect); contraceptives (decrease effectiveness); some HIV/AIDS meds (decreased levels of NNRTIs and PIs).
	#25 Protease Inhibitors	Monitor blood glucose, coagulation panel, lipid profile, urinary allylmercapturic acid.
Lycopene	CAD, HTN	May cause abdominal pain or cramps, anorexia, diarrhea, flatulence, nausea/vomiting. Monitor androgen, lipid profile, PSA.

Complementary Therapies 10.1 Cardiac Conditions—cont'd

Agent	Indication	Adverse Reactions and Considerations*
Coenzyme Q10	Adjunct to statin therapy, angina, cardiomyopathy, cardioprotection during surgery, CHF, CAD, hyperlipidemia, HTN, MI	May cause bleeding, diarrhea, dizziness, dyspnea, fatigue, flu-like symptoms, GI upset, headache, heartburn, hyperglycemia or hypoglycemia, hypotension, insomnia, irritability, loss of appetite, nausea/vomiting, photosensitivity, pruritus, rash, thrombosis, thyroid hormone alterations. Caution with antidiabetic agents (altered effects); antihypertensives (additive effect); antilipemic agents (additive effects); corticosteroids (decreased effects); warfarin (decreased anticoagulant effects). Monitor blood glucose, BP, coagulation panel, LFTs, lipid profile, T_4/T_8 ratio.
Calcium	HTN	May cause abdominal pain, arrhythmias, calcium deposits in heart and kidney, chalky taste, confusion, constipation, GI irritation, headache, irritability, MI, nausea/vomiting, nephrotoxicity, polydipsia, polyuria, renal calculi, skin reactions, urinary incontinence. Caution with calcium channel blockers (decreased effects); levothyroxine (decreased effectiveness of levothyroxine). Monitor bone mineral density, calcium levels, renal function tests.
Red Yeast Rice	CHD, hyperlipidemia	May cause bloating, dizziness, flatulence, GI discomfort, headache, kidney damage. Caution with alcohol (increased risk of liver damage); gemfibrozil and niacin (increased risk of myopathy); HMG-CoA reductase inhibitors (increased risk of adverse effects); protease inhibitors (altered effects). Monitor LFTs, kidney function.

*Chart does not list all information. For an extensive review, see Ulbricht, C. *Davis's pocket guide to herbs and supplements.* FA Davis, Philadelphia, 2011.

Pharmacological Therapy

Pharmacological agents are used to control the symptoms of angina and to prevent subsequent events (see discussion in the Acute Coronary Syndrome section). Most clinicians recommend low-dose daily aspirin (81–325 mg) to decrease the incidence of a first MI in middle-aged men and women. Coated aspirin is recommended for individuals with gastric problems. The dose should be decreased if there is a tendency to bruise. There is still controversy regarding dosage and concomitant use if patients are on other anticoagulants.

Follow-up and Referral

Patients need to understand the chronicity of this disease and be committed to frequent follow-ups for control of risk factors. The clinician should refer the patient to a cardiologist for a stress test and for any further cardiac work-up indicated by the results.

Patient Teaching

On each visit, the clinician should stress risk-factor modification. The lifestyle modifications listed in Table 10.2 for managing hypertension are good activities for overall cardiovascular health.

ACUTE CORONARY SYNDROME

Acute coronary syndrome (ACS) is a term used for the disorders of myocardial ischemia—stable angina, unstable angina, variant angina (Prinzmetal's), or myocardial infarction (MI). ACS refers to acute conditions; however, stable angina is covered in this section. Although angina pectoris (chest pain related to ischemia of the myocardium) is described as chest discomfort, the pain may radiate elsewhere. *Stable angina* (chronic exertional) is a diagnosed condition of myocardial ischemia that is predictable in pattern and frequency and controlled with medication.

Unstable angina is myocardial ischemia that is newly diagnosed or previously diagnosed angina that has changed in pattern, frequency, or severity. Unstable angina is commonly a forerunner of acute MI. Table 10.6 presents the types of angina and their characteristics.

A *myocardial infarction (MI)* is necrosis or death of part of the myocardium as a result of prolonged ischemia

Table 10.6 Types of Angina

Type of Angina	Characteristics
Stable	Chest pain: Transient episodes related to activities that increase myocardial oxygen demand. Duration: Typically lasts 3–15 minutes. Associated signs and symptoms: Nausea, vomiting, shortness of breath. Relief: Rest and/or nitroglycerin tablets.
Unstable	Chest pain: More severe and brought on with less exertion; may occur at rest. Duration: Prolonged. Associated signs and symptoms: Nausea, vomiting, shortness of breath, diaphoresis. Relief: Not relieved by rest and/or nitroglycerin tablets; relieved by morphine.
Variant (Prinzmetal's)	Chest pain: Episodes unrelated to activities that increase myocardial oxygen demand. Duration: Cyclic; often occurs during sleep (most common in early morning hours); pain intensifies quickly and lasts longer than that of stable angina. Associated signs and symptoms: Palpitation, syncope, bradycardia. Relief: May subside with exercise.

(an insufficient supply of oxygenated blood). The location and extent of the infarction determines the prognosis in addition to the speed with which reperfusion is supplied to "cut-off" areas. Because the use of early reperfusion therapy increases the likelihood of survival and improves left ventricular function, the patient with a suspected MI should be assessed rapidly and prompt, appropriate care provided. The Iceberg of Myocardial Infarction figure explores many facets involved with a patient with an MI.

Epidemiology and Causes

Each year, an estimated 640,000 Americans have a new coronary attack (defined as first hospitalized MI or coronary heart disease death) and almost 280,000 have a recurrent attack. It is estimated that an additional 150,000 persons have a silent MI every year. Approximately every 34 seconds, an American has a coronary event; every minute, an American will die of one.

The mortality rate is approximately 30% for a severe MI. More men than women experience MIs; however, after menopause this gap dramatically closes. The majority (55%) of MIs occur in individuals who are older than 65 years of age. Eighty percent of patients who die from an MI are older than age 65. Men have about a 20% chance of having an MI or coronary artery disease (CAD). MIs are more common in Western societies. African Americans have a higher incidence of MI due to the higher incidence of hypertension (HTN) in that population.

The contributing factors for an MI include the same risk factors as for CAD (see Risk Factors 10.1), as well as tachycardia, left ventricular hypertrophy (LVH), anemia, increased platelet aggregation, and abuse of illegal substances.

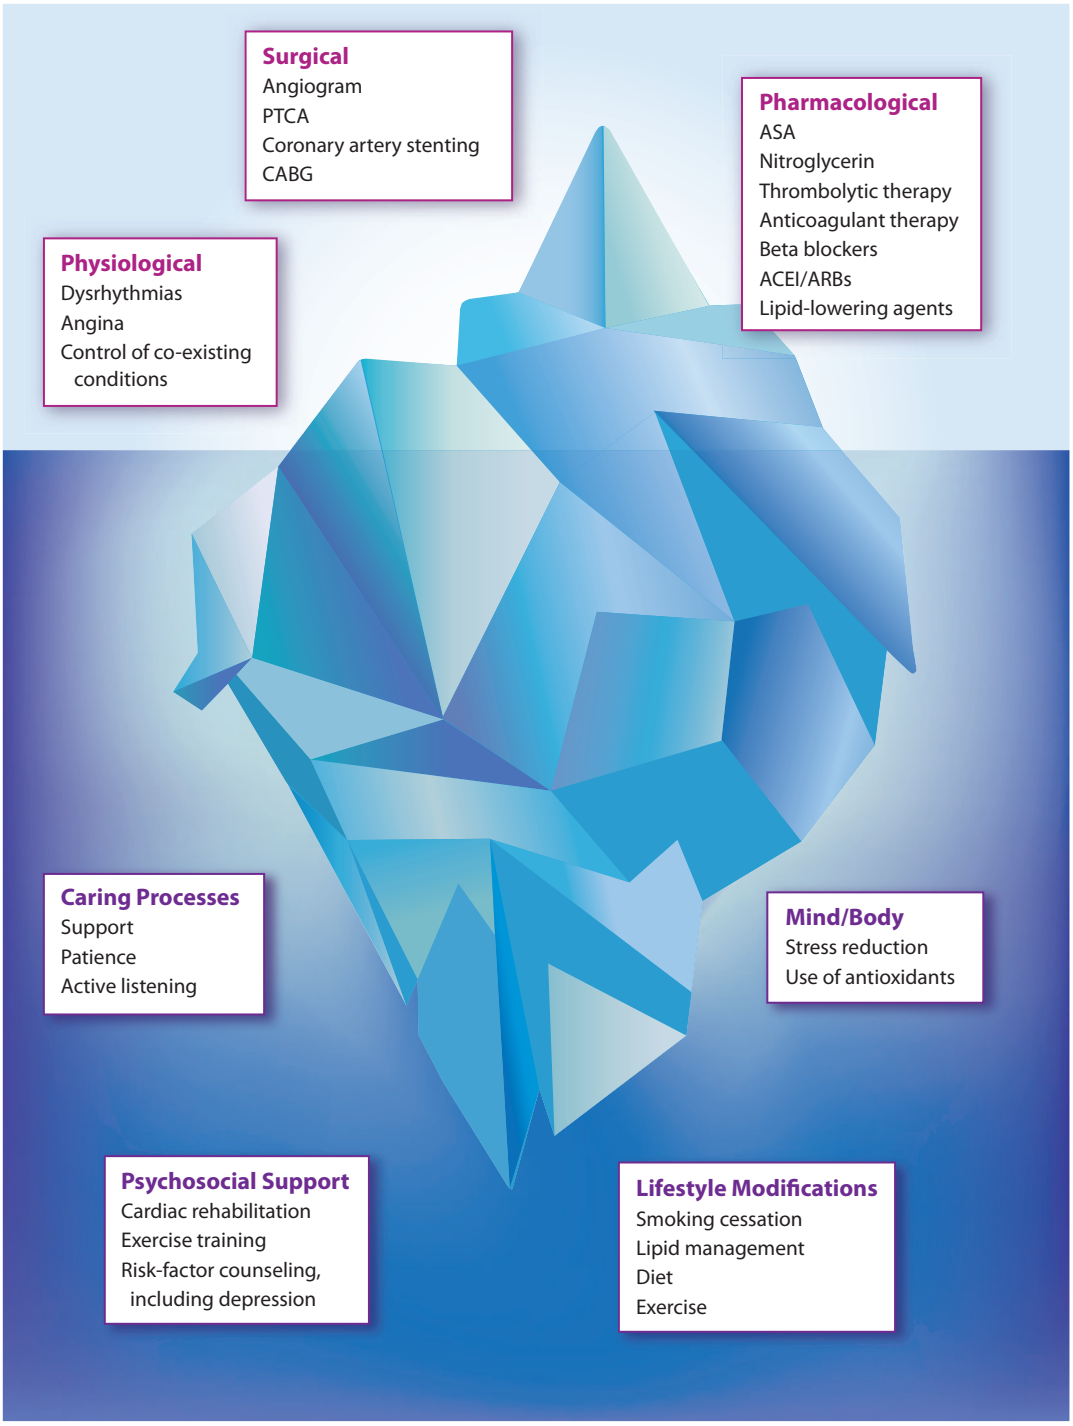
Pathophysiology

Acute coronary syndrome (ACS) is a broad term to describe a continuum of disorders that arise from coronary artery occlusion. ACS is either an episode of angina pectoris or an MI. In both angina and MI, decreased myocardial perfusion occurs because of coronary artery narrowing caused by thrombus formation subsequent to rupture of atherosclerotic plaque. In stable angina, coronary occlusion causes a brief ischemia that is treatable and reversible. In unstable angina, coronary occlusion leads to ischemia with high risk for MI. When ischemia is prolonged, MI occurs. The two types of MI are classified according to their electrographic changes—non–ST-segment elevation MI (NSTEMI) and ST-segment elevation MI (STEMI). NSTEMI indicates an infarction caused by a *nonocclusive* thrombus that *partially* interrupts perfusion of the myocardium and results in an infarction affecting only part of the myocardial wall, rather than full thickness. STEMI is caused by an *occlusive* thrombus that leads to complete *transmural* MI—an infarction of the full thickness of the myocardial wall. The majority of MIs are due to nonocclusive thrombi that cause partial wall infarctions.

After myocardial ischemia occurs, anaerobic metabolism becomes the predominant form of energy production in the affected cardiac tissue. Anaerobic metabolism yields low energy that can sustain the heart tissue only for a maximum of 20 minutes. Death of myocardial tissue (infarction) occurs as energy requirements are not met, thus underscoring the importance of acute beta blocker therapy in the management of MI to decrease cardiac workload and myocardial oxygen demand. Moreover, lactic acid, a waste product of anaerobic metabolism, is noxious to surrounding cells, further disrupting cell function.

The pharmaceutical treatment of ACS is directed primarily at dissolution of the intracoronary thrombus by antiplatelet therapy (e.g., aspirin, glycoprotein IIb/IIIa receptor antagonists), anticoagulant therapy (e.g., heparin), and relief of symptoms by antianginal (e.g., nitroglycerin, beta blockers, supplemental oxygen therapy) and analgesic (morphine sulfate) medications. After MI

The Iceberg of Myocardial Infarction



is confirmed, urgent evaluation for salvage of viable myocardial tissue is initiated through reperfusion treatments based on coronary angiographic studies.

An infarcted region of the myocardial wall is an area of necrosis that disrupts the conduction system and decreases the strength of the heart muscle as a mechanical pump. Arrhythmias and heart failure are common sequelae of MI. The more damage to the heart muscle, the greater the risk of heart failure. *Papillary muscle rupture* is also a common complication that results from MI. Heart valve leaflets are attached to papillary muscles via stringlike membranous attachments called chordae tendineae. Disrupted papillary muscles and ruptured chordae tendineae cause valvular dysfunction that may

manifest as a heart murmur due to turbulent blood flow. MI of the left ventricle (LV) with papillary muscle rupture can cause dysfunction of the mitral valve, and mitral regurgitation is a common complication of left ventricular MI.

Clinical Presentation

Subjective

With angina, the patient will complain of chest discomfort that may be described as pressure, tightness, burning, or heaviness. The pain may radiate to the arms, chest, back, neck, jaw, or teeth. Patients frequently describe the discomfort as indigestion because it may be accompanied by nausea or vomiting. Shortness of breath and diaphoresis may also be present, either at rest or with physical activity. The patient may also be anxious, light-headed, and tachycardic. The pain may frequently occur after meals because of increased oxygen consumption during the meal, or it may be brought on by psychological stress. Rest and nitroglycerin, either sublingual (SL) or spray, may relieve the symptoms of stable angina. The patient may be in denial and will often rationalize that the symptoms are caused by indigestion or overexertion.

In acute MI, the patient often complains of angina-like chest pain lasting more than 20 minutes but occasionally waxing and waning during that period. Often, dyspnea, diaphoresis, nausea, and dizziness are also reported. Radiation of the pain to the neck, jaw, shoulder, or arm (left more often than right) is usually described. The degree of distress with these symptoms varies greatly, however, from the patient who complains of an "elephant standing on my chest" to the patient who is apologetic for seeking assistance with "just a bit of indigestion that will not clear up." In particular, women, older adults, and persons with diabetes mellitus are likely to have minimal or atypical symptoms with an acute MI.

About 15% of patients suffer a painless MI that may be detected on a future ECG or on autopsy or if the patient presents with other symptoms that prompt the clinician to question the possibility of an MI. This occurs more often in an older patient or a patient with diabetes or HTN. In this instance, the patient may complain of dyspnea, general upper abdominal pain, exacerbation of heart failure, or acute confusion.

Objective

In a patient with angina, the clinician may auscultate a transient third (S_3) or fourth (S_4) heart sound, a transient mitral regurgitant murmur, and/or a carotid arterial bruit. The patient should be asked to describe the pain in terms of its quality, location, radiation, precipitating factors, alleviating factors, and associated signs and symptoms during the attack. In addition, the patient may appear dyspneic and be diaphoretic.

In a patient with an MI, the clinician may observe pallor; cool, diaphoretic skin; crackles on auscultation; a third (S_3) or fourth (S_4) heart sound; murmurs; edema of the extremities; and possibly neck vein distention. In addition, the patient may have a low-grade fever. The presence of diaphoresis with chest pain is particularly worrisome, often indicating a significant drop in cardiac output during the episode of pain and subsequent decreased perfusion of the skin.

The cardiac exam should include inspection, palpation, and auscultation. As with any physical exam, the cardiac exam should begin with the general survey, in which the clinician begins to develop a picture of the overall health status of the patient and continues to gather diagnostic clues.

Diagnostic Reasoning

Diagnostic Tests

The best laboratory tests to rule out MI are cardiac-specific troponin I and T (cTnI and cTnT). Cardiac troponins are cardiac proteins released from dead heart muscle, and they are not detected in the blood of healthy individuals. Troponin levels rise within the first 2 to 4 hours after MI and remain elevated for 7 to 10 days.

Serum cardiac enzymes, which include the specific MB isoenzyme of serum creatine phosphokinase (CPK), are also released from necrotic heart muscle after MI. The CPKmb isoenzyme level rises within 4 to 8 hours after MI and generally returns to normal by 48 to 72 hours. The other cardiac enzymes (rarely used) are serum glutamic oxaloacetic transaminase and lactate dehydrogenase. These become elevated much later in the course of MI and are not indicators of acute MI.

A blood level of the CPKmb fraction remains elevated in the blood more briefly than cardiac troponin. Therefore, episodes of recurrent ischemic discomfort and recurrent MI are more readily diagnosed with a rise in cardiac troponins. The prolonged elevation of cardiac troponins does not allow recognition of repeat episodes of acute MI within the first few days after the initial insult. The rise in CPKmb fraction correlates better with infarct size than does troponin level. If the diagnosis of MI remains uncertain, serum cardiac biomarkers should be measured on admission, at 6 to 9 hours after admission, and again after 12 to 14 hours.

Myoglobin is a muscle protein that rises in the blood within only a few hours after MI. It is one of the earliest serum cardiac markers to rise after MI; however, it is nonspecific for cardiac muscle death and can rise with skeletal muscle injury. Blood levels return to normal within 24 hours of infarction and cannot be relied on for diagnosis of MI.

Other laboratory tests, which include complete blood count (CBC), erythrocyte sedimentation rate (ESR), serum electrolytes, blood urea nitrogen (BUN), and serum creatinine, should be drawn. Leukocytosis is a nonspecific indicator of myocardial injury. White blood cell counts often reach levels of 12,000 to 15,000/mcL.

ESR, a general indicator of inflammation, also rises after MI and remains elevated for several days.

After the patient is stabilized, echocardiography and cardiac catheterization with angiography are procedures that give clinicians significant prognostic information. Echocardiography can be done to detect wall motion abnormalities, right and left ventricular function, valvular or septal defects, and LV ejection fraction. Echocardiography is a noninvasive procedure that is easily performed in most emergency departments; however, it is not recommended as a reliable diagnostic test of MI. When the patient is assessed angiographically, coronary artery occlusion can be estimated along a scale called the Thrombolysis in Myocardial Infarction (TIMI) grading system. The TIMI scale grades coronary artery occlusion from grade 0, indicating complete occlusion, to grade 3, indicating full perfusion of the coronary artery with full normal flow.

In addition, radionuclide imaging can detect reversible ischemic regions or fixed infarcted areas. Radionuclide substances are distributed in proportion to myocardial blood flow. This type of myocardial perfusion imaging reveals a "cold spot" during the first few hours after MI. However, it cannot distinguish acute MI from the scarring of the myocardium from an MI suffered in the past.

12-Lead Electrocardiogram Although chest pain can be caused by a number of conditions, assessing for life-threatening cardiac conditions such as angina and acute MI is critical. In the emergency clinical setting, a 12-lead ECG can reveal myocardial ischemia, STEMI, NSTEMI, or arrhythmias.

An ECG should be performed promptly: The presence of an ST-segment elevation greater than 1 mm in contiguous leads usually indicates acute coronary artery occlusion, usually from thrombosis. In addition, clinically significant ST-segment elevation largely dictates reperfusion therapy. The ECG will further delineate the location of the MI and its corresponding coronary artery.

Ischemic and injured cells have an altered action potential and altered patterns of depolarization and repolarization. Infarcted cells have no action potential and cannot conduct impulses through dead tissue, which leads to changes in the ECG.

Myocardial ischemia is demonstrated by enlargement and inversion of the T wave caused by altered late repolarization. The ischemic area remains depolarized when adjacent areas have returned to the resting state. Myocardial injury is demonstrated by ST-segment changes. With epicardial injury, injured cells depolarize normally but repolarize more rapidly than do normal cells. This causes an elevation in the leads facing the areas of injury. In endocardial injury, the ST segment is more likely to be depressed (usually 1 mm or more) in the leads facing the injury. The decision to proceed with thrombolytic therapy is based in large part on the presence of ST-segment elevation in two or more ECG leads. Because of the absence of depolarization of the cells in the area of an acute MI, Q waves show up about 1 to 3 days after the infarction. Electrical impulses cannot travel through dead tissue and are deflected away, causing an abnormal Q wave. An abnormal Q wave is usually 0.04 seconds wide and 25% or greater in depth than the R wave is tall. Figure 10.1 shows the typical ECG changes seen with cardiac damage.

At times, myocardial perfusion halts temporarily, then is reestablished in a relatively short period of time. This may be the result of vessel spasm or sudden drop

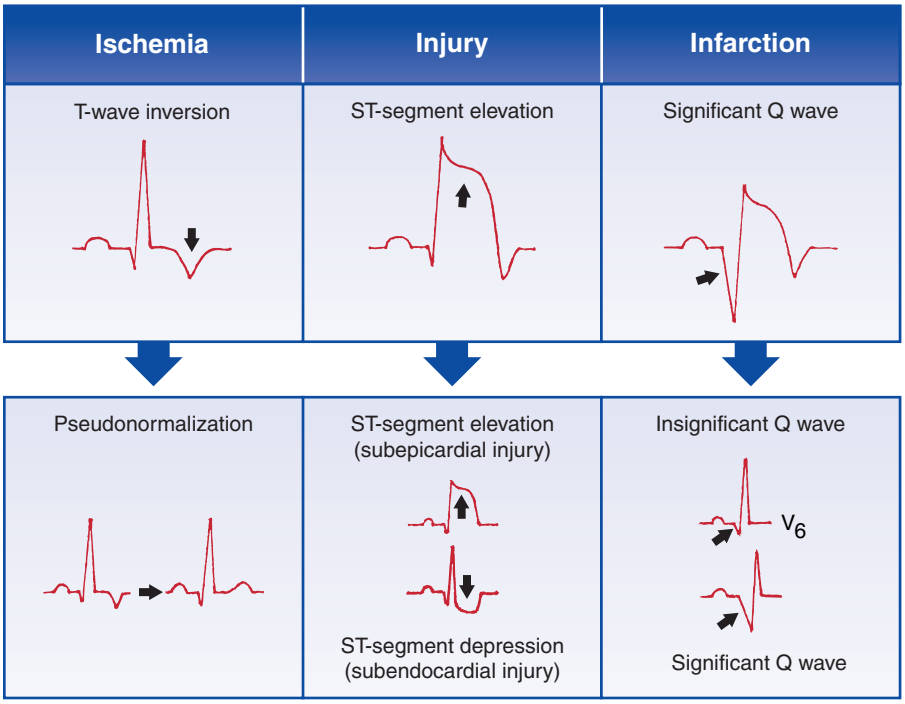


Figure 10.1 Typical ECG changes seen with cardiac damage. *(Source: Lipman, B, and Cascio, T.* ECG assessment and intervention. *FA Davis, Philadelphia, 1994. Reprinted with permission.)*

in BP, such as with severe blood or fluid loss. In this situation, a small portion of subendocardial tissue is damaged, yet adjoining myocardial tissue remains viable. As a result, ECG changes are present but differ significantly from those in a classic transmural MI. Q waves do not form because electrically active tissue backs up the area of infarction. Because tissue injury, ischemia, and infarction are subendocardial rather than oriented toward the epicardium, as in transmural MI, injury pattern is reflected in ST-segment depression. The ECG changes are transient—present only during the acute event and during tissue healing. Thus, if not found during the acute presentation, a non–Q wave MI may never be diagnosed. The terms Q–wave and non–Q wave MI are now referred to as NSTEMI or STEMI (as previously defined). There may be a temptation to think of a non–Q wave MI/non–STEMI as a "small heart attack" with limited long-term sequelae. These patients have well-demonstrated risk for future MI and other cardiac events, particularly during the next 3 to 6 months. The majority of patients with non–Q wave MIs are older adults (aged 70 or older) with a history of prior MI and congestive heart failure (CHF). Figure 10.2 illustrates the difference between NSTEMI and STEMI ECG changes.

The 12-lead ECG presents 12 leads, or "views," of the heart, to detect myocardial damage. Leads I, II, and III are the three standard (bipolar) leads. Leads aV_R, aV_L, and aV_F are augmented or unipolar leads; the chest or precordial leads (V_1 to V_6) view the heart in a horizontal plane. Figure 10.3 shows the normal ECG wave configuration of a normal 12-lead ECG.

By identifying the leads that contain the ECG changes, the location of the myocardial damage and its corresponding coronary artery can be determined (Table 10.7). However, the identification of these abnormal views should be the last step in interpreting a 12-lead ECG. If the clinician is not systematic in an interpretation approach, errors can be made. For instance, if the presence of a left bundle branch block (LBBB) is not observed, these changes may be interpreted as Q-waves in the inferior leads or ST elevation in the precordial leads. An LBBB prevents a true look at the area because the normal path of depolarization is blocked and does not directly travel down the normal conduction pathway. This results in a distorted view, and the typical LBBB ECG changes are observed instead. Therefore, after determining the rate and rhythm of the ECG, observing for LBBB is the second step. However, the clinician needs to keep in mind that an LBBB could result from the acute ischemic process of an MI. If this is a new ECG change, it should be noted and incorporated into the clinical picture.

The 12-lead ECG can also provide information about axis deviation, which is the third step in systematic interpretation. Electrical axis is, for all practical purposes, synonymous with the wave of myocardial depolarization. Healthy myocardial tissue depolarizes in a predictable pattern, thus recording in the ECG a predictable electrical axis. The normal wave of depolarization travels down the heart and to the left. This normal axis shows as a positive QRS complex in lead I and lead aV_F. This is because the net ventricular forces travel toward the pole of lead I and down toward the pole of lead aV_F.

With cardiac disease, the wave of depolarization swings away from areas of damage or necrosis, creating axis deviation, or a change from the norm. When the axis is shifted to the left, the QRS complex is positive in lead I and negative in lead aV_F. Left axis deviation is subdivided into normal left axis deviation (NLAD) and abnormal left axis deviation (ALAD). NLAD is often seen in the presence of LVH. ALAD is seen in a block of the anterosuperior division of the left bundle branch, often referred to as a left anterior fascicular block (LAFB). ALAD is also seen in Q-wave inferior-wall MI and a right apical pacemaker. Right axis deviation (RAD) is seen in a block of the posterior inferior division of the left bundle block, often referred to as a left posterior fascicular block (LPFB). RAD is also caused by an extensive Q-wave lateral-wall MI and may be seen in right ventricular hypertrophy (RVH).

Axis deviation is occasionally present in the absence of cardiac disease. In pregnancy, the heart is shifted in the cavity because of the height of the diaphragm. This may cause a left axis deviation. In addition, adults with

Table 10.7 Location of Myocardial Infarction

Location of MI	Leads	Reciprocal Changes	Coronary Artery Affected
Anterior	V_2–V_4	II, III, aV_F	Left anterior descending (LAD)
Anteroseptal	V_1–V_3	None	LAD
Anterolateral	I, aV_L, V_4–V_6	II, III, aV_F	LAD, left circumflex
Inferior	II, III, aV_F	I, aV_L	Right coronary artery (RCA) in 80%–90%, left coronary artery (LCA) in 10%–20%
Posterior	V_1–V_3	R wave greater than S wave, depressed ST segment, elevated T wave	RCA, left circumflex
Lateral	I, aV_L, V_5–V_6	V_1–V_2	Left circumflex

abdominal obesity may demonstrate left axis deviation. In infants and children and tall, thin adults right axis deviation is normal. Advanced Assessment 10.2 presents a quick quadrant method for determining axis deviation.

The 12-lead ECG may also provide information about heart chamber enlargement. Chamber enlargement, or hypertrophy, is usually a consequence of obstruction of blood flow out of the affected area of the heart. For example, left atrial hypertrophy is a common consequence of mitral valve stenosis because the atrium must generate excessive pressure, thereby becoming enlarged, as a result of forcing open a stiff, diseased valve. The following are the typical ECG findings associated with chamber enlargement:

1. Right atrial hypertrophy (RAH), also known as P pulmonale
   - Peaked P wave in leads II, III, aV_F, V_1
   - P wave more than 2.5 mm in leads II, III, aV_F
2. Left atrial hypertrophy (LAH), also known as P mitrale
   - Notched P wave more than 0.10 seconds in leads II, III, aV_F
   - Prominent negative P terminal in V_1 (more than 1:1)
3. RVH
   - Reversal of R wave progression in the precordial leads
   - Although not routinely seen, RVH may be seen in patients with chronic obstructive pulmonary disease (COPD)
4. Left ventricular hypertrophy (LVH), which uses the Estes Scoring System:
   - 3 points for any or all of the following: voltage of 25 mm or more (S wave in V_1 or V_2); R wave in V_5 or V_6 and/or voltage of 20 mm or more (R or S wave in leads I, II, III, aV_F, aV_L)
   - 1 point for secondary ST-segment T-wave changes if the patient is taking digitalis

Advanced Assessment 10.2 Assessing Axis Deviation

The quadrant method is a rapid, accurate way of assessing electrocardiogram (ECG) electrical axis. Although it does not yield an exact degree measurement, such as obtained when using an ECG ruler, this method can be done without the use of special equipment. When using the quadrant method, do the following:

- Examine leads I and aV_F for the presence of a positive or negative QRS complex.
- Determine the results as follows:

Normal axis: Positive complex (tall R wave) in leads I and aV_F

Left axis deviation: Positive complex (tall R wave) in lead I; negative complex in aV_F

Right axis deviation: Negative complex in lead I, and positive complex (R wave) in aV_F

Extreme right axis deviation: Negative complex in lead I and aV_F

- 3 points for secondary ST-segment T-wave changes if the patient is not taking digitalis
- 3 points for an abnormal P terminal in V_1
- 2 points for left axis deviation
- 1 point for an RS interval of more than 0.09 seconds
- 1 point for ventricular activating time in V_5; 0.05 seconds or more in V_6

If the patient has 4 points, there is the probability of LVH; 5 points is a strong indication of LVH.

The final step in interpretation is identifying the leads that contain ECG changes and assessing for myocardial damage. If the determination of an LBBB has not been made before this last step, the interpretation will be flawed. However, even if the clinician is unable to accurately read the 12-lead ECG due to an LBBB, the clinical context of the situation needs to be noted and appropriate interventions implemented. If an acute STEMI is suspected, additional diagnostics should be obtained and may include left heart catheterization,

Differential Diagnosis

Differential diagnoses for angina may include an acute MI, esophagitis, esophageal spasm, peptic ulcer, gastritis, cholecystitis, costochondritis, pericarditis, aortic dissection, pulmonary embolus (PE), pulmonary HTN, pneumothorax, anxiety, and panic disorders.

Differential diagnoses for MI include pericarditis, myocarditis, acute aortic dissection, pneumothorax, PE, acute cholecystitis, esophageal spasm, unstable angina, biliary tract disease, and panic attack.

Management

In ACS, the goal is to promptly diagnose and treat the underlying condition appropriately. In the primary-care setting, the clinician can attempt to stabilize the patient with ASA and nitroglycerin. However, the patient experiencing ACS needs to be transferred to a hospital emergency medical setting, preferably one with access to a cardiac catheterization lab.

Stable Angina

If a patient presents with ischemic chest pain, and nitroglycerin and rest relieve the chest pain, the result implies stable angina. Chronic anginal pain is typically of short duration, usually 3 to 5 minutes, but it may last up to 30 minutes or longer. For a patient with chronic stable angina who is currently having an attack, rest and nitroglycerin should be ordered. Nitroglycerin may be given as an SL tablet or spray. One tablet or one spray should be used under the tongue every 5 minutes for three doses. If the pain has not been relieved after three doses, the local emergency medical services system should be called and the patient transported immediately to the emergency department.

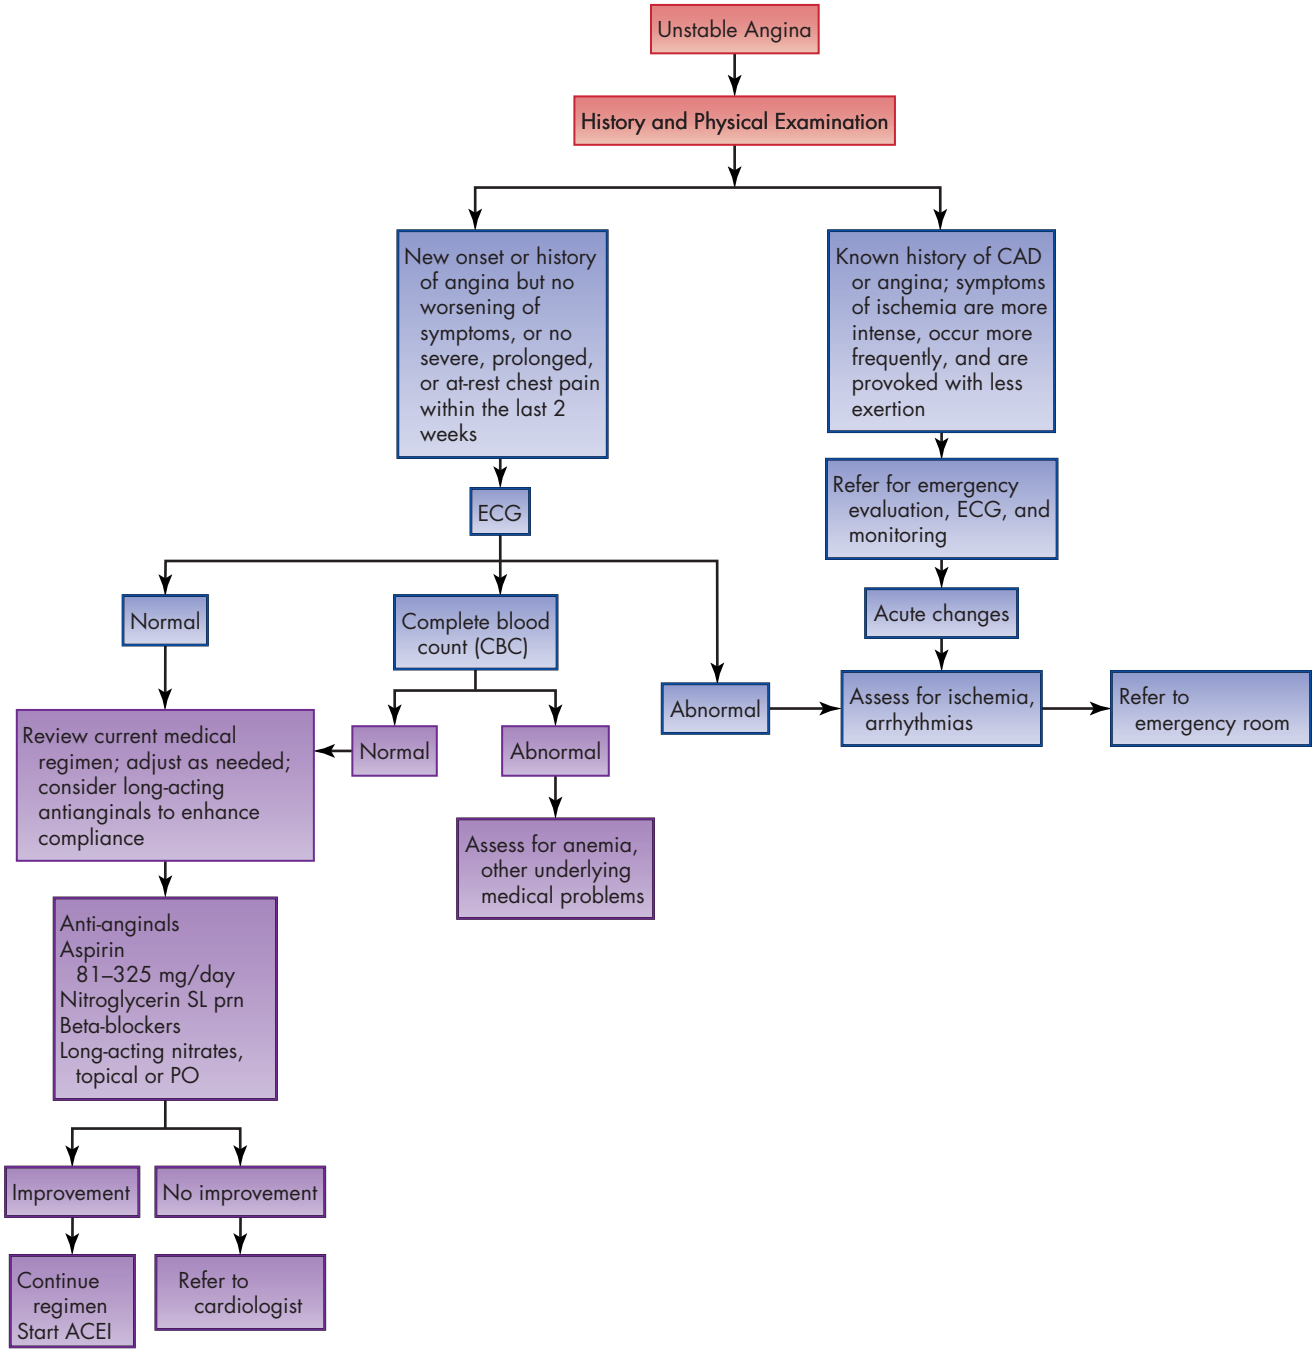
After the patient's chest pain has been relieved, a beta blocker and/or long-acting nitrate may be prescribed. Beta blockers decrease myocardial oxygen demand by interfering with the effects of the sympathetic nervous system on the beta-1 receptors in the heart. Long-acting nitrates, topical or oral, may be added to the beta blocker regimen to decrease myocardial oxygen supply by coronary artery vasodilation. Many beta blockers may be used such as atenolol, metoprolol, nadolol, or propranolol.

Long-acting nitrates, topical or oral, may include the nitroglycerin transdermal patch or paste in varying strengths. The patch should be in place for 12 hours and removed for 12 hours to prevent intolerance. At present the use of hydralazine is being looked at as a way to inhibit nitroglycerin paste intolerance. Isosorbide dinitrate is another good long-acting nitrate that is taken orally. Long-acting nitrates may be taken daily as prophylaxis to prevent recurrent angina.

All patients with diagnosed angina should be placed on daily aspirin therapy to help prevent coronary thrombosis. Aspirin (ASA) 81 to 325 mg daily may be taken (use coated ASA if gastric problems exist). Ticlopidine with food may be ordered for patients who are allergic to aspirin or those with a history of gastrointestinal bleeding.

Unstable Angina

With unstable angina, the goal is to diagnose the underlying condition and treat appropriately. If rest and nitroglycerin do not relieve the chest discomfort, the patient must be immediately transported by ambulance to the emergency department for further evaluation. Treatment Flowchart 10.1 presents the management of unstable angina.



Treatment Flowchart 10.2 Unstable Angina

Variant (Prinzmetal's) Angina

Prinzmetal's angina is an atypical form of angina pectoris that occurs as a result of vasospasm of otherwise normal coronary arteries. Pain is experienced at rest, and an ECG, when taken during the attack, will indicate ST-segment elevation rather than depression. This ECG change will abate when the patient is treated with nitroglycerin (see previous section) and drugs that influence calcium metabolism. A calcium channel blocker such as verapamil HCl may be used in treatment.

Myocardial Infarction

The goal of management is to salvage the ischemic myocardium before it becomes necrotic by reperfusing the area as soon as possible. After that, the goal becomes directed at preventing future attacks.

If an MI is suspected at the time of a clinical visit, a 12-lead ECG should be done promptly. Immediate interventions of rest, aspirin, and nitroglycerin administration should be implemented. Nitroglycerin can be administered sublingually as a tablet or spray. If relief is

not achieved within 2 to 3 minutes after the initial dose of nitroglycerin, a second or third dose can be given at 5-minute intervals for a total of three doses. One or more inches of nitroglycerin gel (Nitropaste) may also be used to vasodilate and lower BP, because this topical form of nitroglycerin may be easily removed by wiping off the skin to stop its effects. Similarly, in an advanced clinical setting, an adjustable IV nitroglycerin drip may be used if appropriate nursing and medical supervision is available. A 162- to 325-mg aspirin tablet can also be administered in the ambulatory clinical setting. Aspirin exerts an antiplatelet effect, and nitroglycerin decreases preload and coronary spasm, thus contributing to the overall beneficial effect in an acute MI. The patient should initially chew and swallow one aspirin. The 325-mg dosage should not be exceeded, because that will negate the platelet effect. This initiation of thrombolytic therapy given at the time of onset (within 70 minutes) of the symptoms, before hospitalization, has lowered the mortality rate of patients.

The patient should then be transferred to an emergency medical setting. The clinician should begin an IV, provide oxygen, and monitor the patient until the emergency medical system can be activated. Once the patient is stabilized, emergency care clinicians can determine if the patient is a candidate for reperfusion treatment with thrombolytic agents or primary percutaneous coronary intervention (PCI). They should be used only for patients with acute MI associated with STEMI or with LBBB with suspected acute MI. Thrombolytic agents, such as alteplase (recombinant tissue plasminogen activator [tPA]), reteplase (rPA), or tenecteplase (TNK), are most effective when administered early in the course of an MI. The first thrombolytic agent, streptokinase, is not commonly used because it is a non–fibrin-specific agent. For the best therapeutic effect, thrombolytics should be administered within the first 3 hours (ideally 30 minutes) of presentation of symptoms of MI. Studies have shown that thrombolytic therapy can be of benefit up to 12 hours after initial presentation of symptoms of MI. Alternatively, thrombolytic therapy can be combined with antiplatelet agents known as glycoprotein IIb/IIIa inhibitors.

Cardiac catheterization with angiography can decipher whether or not the patient is a candidate for reperfusion therapy, percutaneous transluminal coronary angioplasty (PTCA), coronary artery stenting, or coronary artery bypass grafting. Immediate coronary angiography and primary PCI, which includes stenting of the infarct-related artery, have been shown to be more effective than thrombolysis if done within 90 minutes for STEMI. This 90-minute time frame is referred to as "door to balloon" time and is managed only in specialized centers. Stenting may be done in conjunction with administrations of the platelet glycoprotein IIb/IIIa antagonist abciximab in patients with acute MI.

The American Heart Association (AHA) has published guidelines for the management of patients with acute MI. Developed from consensus of nursing and medical experts and evidence-based health care, the AHA recommends the following for a person with suspected MI:

- Community systems, including primary-care providers, should work together to ensure prompt initial care of the patient with suspected MI. Once the patient enters care in the emergency department, initial evaluation should occur within 10 minutes.
- The following care should be provided immediately: Administration of oxygen via nasal prongs; sublingual nitroglycerin unless SBP is less than 90 mm Hg and heart rate is less than 50 or more than 100 beats per minute; adequate analgesia with morphine sulfate or meperidine; and aspirin (ASA) 162 to 325 mg PO (Level II; O'Gara et al, 2013). The ASA should be administered regardless of whether or not thrombolytic therapy is being considered. Chewable ASA has a more rapid effect and is preferred. In addition, some clinicians will give a loading dose of clopidogril (300–600 mg). Nitroglycerin should not be given for the patient who has received phosphodiesterase inhibitor therapy in the prior 24 hours.
- Clinically significant ST-segment elevation largely dictates reperfusion therapy by use of thrombolytic therapy or primary PTCA. When thrombolysis is used, heparin is usually given for 48 hours to ensure continued vessel patency. A viable alternative to unfractionated heparin (if no renal or hepatic impairment is present) is a low molecular weight heparin such as enoxaparin sodium (Lovenox).
- If LBBB is present on ECG and the clinical scenario is consistent with acute MI, the same level of care should be offered. Patients with presentations suggestive of MI but without ST-segment changes should not receive thrombolysis, because it may cause more harm.
- The patient should be hospitalized and placed on continuous ECG monitoring for rhythm disturbances. Serial 12-lead ECGs should be obtained and results correlated with clinical measures of myocardial necrosis such as creatine kinase (CK) or CPK isoenzymes and troponin T or I.
- Aspirin therapy should be continued; the use of heparin should also be considered in the presence of a large anterior MI or LV mural thrombus because of increased risk of embolic stroke. Initially, the dosage for aspirin should be 325 mg/day, with anywhere from 81 to 325 mg given once per day after discharge ad infinitum.
- If no contraindications are present, Core Measures should be implemented. Core Measures as put forth by the Joint Commission include the following: aspirin on arrival and discharge, angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) for left ventricular systolic dysfunction (LVSD) beta blocker therapy as tolerated, and statins

prescribed as indicated on discharge. Beta blocker therapy and ACE inhibitor therapy should be initiated promptly because the use of these products is associated with reduced mortality and morbidity after MI. Beta blocker therapy should be continued indefinitely, with ACE inhibitor use being most appropriate for patients with LV dysfunction characterized by systolic ejection fraction less than 40% or in the presence of heart failure. Beta blockers exert their beneficial effect in patients with an MI by reducing myocardial oxygen demand, reducing myocardial wall stress, and antagonizing the arrhythmogenic effects of catecholamines. ACE inhibitors reduce the progressive ventricular dilation and remodeling after an MI, and in some studies have been shown to reduce myocardial reinfarction (for an unknown reason). ACE inhibitors also reduce the incidence of heart failure, thus reducing mortality in patients with large myocardial infarcts and in patients with left ventricular dysfunction.

- Ongoing care includes a goal of reducing LDL cholesterol to less than 100 mg/dL using diet, exercise, and, if necessary, drug therapy. This is in keeping with an overall plan to reduce or eliminate all cardiac risk factors, including inactivity, tobacco use, and obesity.
- Coronary artery bypass surgery is not usually done during an evolving MI unless the patient has a serious complication such as acute severe mitral regurgitation with or without papillary muscle rupture, acute septal rupture, or a free wall rupture that might be associated with a pseudoaneurysm, refractory cardiogenic shock, or recurrent severe ischemia postinfarction that cannot be managed with drugs and PTCA.

Follow-up and Referral

As previously stated, patients with unstable angina should be referred to the emergency department and a cardiologist for a complete evaluation. Patients with stable angina may be managed by the clinician with either beta blockers and/or long-acting nitrates with nitrolingual tablets or spray as needed for emergency and prophylactic use. Patients should be followed every 3 months to determine their adherence to risk factor modification strategies. From the instant the clinician suspects a patient is experiencing an acute MI, the patient must be immediately transported to the emergency department and be evaluated by a cardiologist. The clinician may follow the patient after hospitalization. When the cardiologist discharges the patient from his or her care, the clinician may become involved in the follow-up care. The cardiologist should have already referred the patient to a cardiac rehabilitation program before discharge. The clinician should take an active role in encouraging the patient to adhere to the prescribed program.

On discharge, a review of the aforementioned Core Measures should be implemented. In addition to a beta blocker (and, if indicated, an ACE inhibitor), the patient should be prescribed nitroglycerin (SL tablet or spray) with instructions on when to take it and how to store it. The patient should also be taking a daily enteric-coated aspirin of at least 81 mg, as well as a statin cholesterol-lowering drug. For patients with residual myocardial ischemia or with significant left ventricular dysfunction, a longer-acting nitrate such as isosorbide (Isordil) should also be considered. Research has shown that with the addition of a diuretic, there has been a decrease in mortality.

Patient Education

Patients should be taught about their medications, usage, adverse effects, and how to take nitroglycerin prophylactically. In addition, the clinician should stress that nitroglycerin tablets should remain in the light-resistant bottle in which they are packaged and not be put in another pill box or remain in areas that are or could become warm and humid. Once opened, the bottle must be dated and discarded after 6 months.

The clinician should assist the patient to reduce CAD risk factors and factors that exacerbate angina. The patient should be placed on a low-fat diet, with minimal calories if weight reduction is necessary. Coexisting conditions such as HTN, anemia, hyperthyroidism, and CHF should be managed aggressively. The clinician should encourage the patient to enter a cardiac rehabilitation program of safe exercise and risk-factor modification. The clinician should also encourage the patient to adhere to activity limitations determined by exercise tolerance testing and to stop smoking and/or using other tobacco products. Patients should be taught to use nitroglycerin prophylactically before any stressful physical activity such as sexual intercourse. Anxiety and fear often accompany anginal attacks because the patient may fear the onset of an MI. Patients and their families should be allowed to express their fears and concerns and should be collaborative partners in necessary lifestyle changes. As with all cardiac conditions, family members should learn cardiopulmonary resuscitation.

Patient teaching after the patient has experienced an acute MI involves aggressive risk factor modification to prevent a recurrence. Lifestyle modifications should be stressed as stated in Table 10.2. Patients should be referred for cardiac rehabilitation to improve exercise tolerance, cardiac symptoms, blood lipid levels, and psychosocial well-being. Exercise training through cardiac rehabilitation increases the arterial oxygen saturation and improves the oxygen uptake by the peripheral tissues, thereby improving the efficiency of oxygen transport and use by the peripheral tissues, resulting in a decrease in the cardiac output required to perform exercises.

There are three phases of cardiac rehabilitation: Phase I begins in the early in-hospital postinfarct phase with range-of-motion exercises progressing to an increase in the activities of daily living. Phase II is a structured outpatient program of exercise training and risk-factor counseling and education. Phase III establishes a lifelong pattern of regular aerobic exercise and further modification of risk

factors; it is usually undertaken in a community wellness center. The Patient's Voice 10.1 shares one person's experience of having an MI.

At every visit to the office, the patient should be educated about risk-factor modification, such as smoking cessation, lipid management, control of coexisting conditions such as diabetes mellitus and HTN, stress reduction, and the use of antioxidants.

HEART FAILURE

Heart failure is a condition in which cardiac output is insufficient to meet the body's demands. Each patient presents differently because there are various causes and stages of heart failure. The patient with left ventricular failure (LVF) presents with symptoms of pulmonary origin due to a backup of hydrostatic pressure into the pulmonary arterial system. Right ventricular failure symptoms occur as a result of hydrostatic pressure buildup in the venous system. Clinical manifestations of systemic edema occur with right ventricular failure. Biventricular heart failure can cause a combination of these clinical manifestations. Clinicians use the term *heart failure* to describe all types of conditions in which cardiac supply is less than metabolic demand. Previously patients with heart failure were generally hospitalized, but many now may be managed at home. Early identification of patients at risk for heart failure and patient education is key, not only for the prevention of the disease but also for the quality of life of these patients.

Epidemiology and Causes

Heart failure, unlike other cardiac disorders, has been increasing in incidence and prevalence, especially in the older adult population. The Centers for Disease Control and Prevention estimates that 5.7 million people in the United States suffer from heart failure, with more than 400,000 new cases each year. The incidence is increasing because of the use of newer medications and technologies that have increased survival at the expense of increased morbidity. Heart failure is the most common discharge diagnosis in patients older than age 65; it is diagnosed in 10% of the population by the time they reach age 75 years. The annual mortality rate is as high as 60%, and the 5-year survival rate for patients with severe heart failure is about 50%. Approximately 280,000 patients each year die of heart failure. The cost for care and evaluation of patients with heart failure exceeds $34.4 billion in resources each year.

Heart failure may occur acutely, or it may occur after a cardiac abnormality has been present for years, when an increased demand is placed on a heart in an already compensated state and there is further deterioration. It is critical for the clinician to identify not only the underlying cause of heart disease but also the precipitating cause of the heart failure. Prompt treatment and elimination of precipitating causes may save the patient's life. Table 10.8 presents causes of heart failure and their effects on the heart. Nursing Research–Based Practice Box 10.2 shares some reasons why elders delay responding to heart failure symptoms.

Ongoing research is being conducted to explore the neurohormonal hypothesis of heart failure. This research began with the discovery that angiotensin-converting enzyme (ACE) inhibitors and possibly beta blockers were better in reducing mortality than potent afterload-reducing drugs. In the neurohormonal model, active molecules that are released in heart failure are toxic to the myocardium. Currently, noradrenaline, angiotensin, vasopressin, endothelin, and tumor necrosis factor–alpha are being studied for their relationship to heart failure. Clearly, heart failure involves a number of complex physiological changes that are progressive. Because of the increasing incidence of heart failure, new theories are being generated to explain the elusiveness of this disease process to intervention and cure.

Pathophysiology

Heart failure is a constellation of clinical manifestations that result from the heart's inability to pump adequate amounts of blood to meet the demands of peripheral body tissues. It can result from a dysfunctional ventricle that is unable to eject an adequate amount of blood *(systolic dysfunction)* or from the inability of the ventricle to fill with a sufficient amount of blood *(diastolic dysfunction).* There are numerous etiologies of heart failure; however, ischemic heart disease and long-standing hypertension (HTN) are common underlying causes. Ischemic heart disease causes diminished coronary perfusion of the myocardium, which weakens strength of contractility of the ventricles. HTN creates excess mechanical stress on the ventricles, resulting

The Patient's Voice 10.1

Myocardial Infarction

It was 4:30 A.M. . . . Damn, what a case of indigestion . . . . Have to get to the golf course. . . . It's the first day of the seniors' tournament, and employees will be there early. Driving to work, the indigestion seemed to be subsiding. Arrived at work and started getting things organized for the day's events. Started pulling kegs of beer to be placed around the course when the pain started coming back and I got nauseated. Pain getting worse now. Now it's starting to feel like someone is sitting on my chest. Someone called the paramedics. I'm in the ambulance now. I'm sweating, feeling clammy, . . . chest pain continues. We get to the hospital. The people there ask if I'm allergic to anything. Pain is getting worse. They're sticking tubes and needles in me. A doctor tells me I'm having a heart attack . . . and not to worry, they have it all under control. Not worry—what does he think! Then he tells me he's going to give me a clot-busting drug. I'm trying to listen, but I really don't understand what's going on. The chest pain is starting to go away. I'm only 40 . . . I can't be having a heart attack! This isn't happening to me!

Table 10.8 Precipitating Causes of Heart Failure

Precipitating Causes	Effect on the Heart
Infection	Increases demand on the heart secondary to fever, tachycardia, hypoxemia, and increased metabolic demands.
Anemia	Increased cardiac rate to meet peripheral oxygen demands leads to increased cardiac demand.
Pulmonary edema	Increased pulmonary arterial pressure leads to increased right ventricular afterload.
Pregnancy, thyrotoxicosis arrhythmias	Adequate tissue perfusion in these conditions requires increased cardiac output. Tachyarrhythmias decrease diastole and lead to cardiac ischemia. Loss of "atrial kick" leads to increased atrial pressures. Abnormal intraventricular conduction can lead to decreased cardiac output, which will lead to further attempts to compensate. Any arrhythmia that alters the formula: cardiac output = heart rate × stroke volume has the potential to increase demands on an already decompensated heart.
Rheumatic heart disease and other forms of myocarditis	Alterations in cardiac output increase cardiac demand secondary to infectious or inflammatory processes.
Infective endocarditis; physical dietary, environmental, and emotional excesses	Valvular damage, fever, and inflammatory processes increase cardiac demand. Electrolyte disturbances, alteration in medication regimen, excessive heat or humidity, overexertion.
Systemic HTN	Sudden elevation of arterial pressure leads to increased systemic vascular resistance and increased cardiac workload.
MI	May lead to impaired ventricular function.

Nursing Research–Based Practice 10.2

Jurgens, CY, et al. Why do elders delay responding to heart failure symptoms? *Nurs Res* 58(4):274–282, 2009.

Elders with heart failure (HF) are at risk for frequent hospitalizations for symptom management. Repeated admissions are partly related to delay in responding to HF symptoms. The purpose of this study was to describe contextual factors such as prior illness experiences and social/emotional factors related to symptom recognition and response among elders hospitalized with decompensated HF. Seventy-seven patients completed several questionnaires. Median duration of early symptoms of HF decompensation was 5 to 7 days, but dyspnea duration ranged from 30 minutes to 90 days before action was taken. Longer dyspnea duration was associated with higher physical symptom distress. Sensing and attributing meaning to early symptoms of HF decompensation were problematic. The physical symptom experience and the cognitive and emotional response to HF symptoms were inadequate for timely care seeking for most of this older age sample.

in the structural change of hypertrophy and eventual left ventricular dilation. Factors that increase risk of heart failure include obesity, valvular disorders, coronary artery disease (CAD), anemia, diabetes mellitus, chronic renal insufficiency, myocarditis, dysrhythmias, thyrotoxicosis, pulmonary embolism (PE), sleep apnea, alcohol abuse, substance abuse, and chemotherapeutics. There are also differences in susceptibility to heart failure associated with gender, race, and genetic background.

Regardless of etiology, heart failure provokes hemodynamic changes, neurohormonal stimulation, vasoactive substance secretion, and cardiac structural alterations (myocardial remodeling)—all of which have systemic consequences. Heart failure may be described as *systolic* versus *diastolic* dysfunction, *right-sided heart failure* versus *left-sided heart failure, right ventricular* versus *left ventricular failure,* or *forward* versus *backward failure.* These contrasting terms are descriptions that illustrate the different pathophysiological mechanisms of heart failure for academic purposes. However, clinically, most patients with heart failure exhibit a combined clinical presentation of the preceding descriptions.

The terms *systolic dysfunction* or *forward failure* describe the same process in heart failure. In *systolic dysfunction* and/or *forward failure,* the diminished ejection of blood from a weakened ventricle sets off a detrimental cascade of events. The weakened ventricle cannot pump sufficient blood volume forward into the arterial system, which results in decreased cardiac output and hypoperfusion of organs. Hypoperfusion of the arteries and kidney stimulate a *neurohormonal response,* which attempts to increase circulation. Blood pressure (BP) drops in the hypoperfused arteries, and this drop is sensed by baroreceptors, pressure

sensors within arterial walls. Baroreceptors stimulate the *sympathetic nervous system* to constrict the arteries in efforts to raise BP. Hypoperfusion of the kidneys stimulates renin, which provokes the *renin-angiotensin-aldosterone cascade.* Renin circulates in the bloodstream, and when it reaches the liver, angiotensinogen is released. Angiotensinogen circulates, and when it reaches the lungs, this proenzyme is converted to angiotensin I. Within the lungs, a key reaction occurs; angiotensin I is converted to angiotensin II by ACE.

Angiotensin II acts in various ways to raise BP further and increase blood volume. Angiotensin II is a potent vasoconstrictor that directly incites peripheral arterial vasoconstriction. It also stimulates the adrenal gland to secrete aldosterone, a hormone that acts at the nephron to increase sodium and water reabsorption into the bloodstream and to excrete potassium. Angiotensin II also directly provokes genetic changes within cardiac myocytes to promote hypertrophic remodeling. Increased BP and blood volume, increased peripheral vascular resistance, and myocardial hypertrophy are the net results of sympathetic stimulation and activation of the renin-angiotensin-aldosterone cascade. These effects, although compensatory mechanisms, raise blood volume and peripheral resistance, which increase workload on the weakened heart pump. As the ventricle endures greater workload, further systolic dysfunction occurs, and the neurohormonal mechanism is cyclically activated. This cycle increases blood volume and leads to fluid overload and further deterioration of systolic function.

Diastolic dysfunction or *backward failure* describes an abnormality of filling, distensibility, or relaxation of the ventricles. There is elevated filling pressure in the left and/or right ventricle, which causes backward buildup of hydrostatic pressure into the atria. In left ventricular diastolic dysfunction or backward failure, there is a backup of hydrostatic pressure into the left atrium and, in turn, the pulmonary venous system, which results in the extravasation of fluid into the pulmonary interstitium. If hydrostatic pressure builds to high levels, pulmonary capillary wedge pressure increases; high amounts of fluid build in the pulmonary interstitial spaces, which is called *pulmonary edema.* Clinical manifestations of fluid in the pulmonary interstitium are dyspnea, cough, orthopnea, paroxysmal nocturnal dyspnea, and crackles heard on auscultation of the lungs. The classic sign of pulmonary edema is *pink, frothy sputum. Orthopnea* is a term that describes the inability of the patient to breathe comfortably while lying supine. As a patient endures diastolic dysfunction or backward failure, the backup of pulmonary fluid in the interstitial spaces creates breathing difficulty. Patients breathe easier with the head of the bed elevated because this position disperses fluid downward into the lung bases. Patients often report needing two or three pillows to breathe comfortably, termed *two-or-three-pillow orthopnea.* Frequently patients report awakening in the middle of the night feeling breathless or awakening due to a "nightmare." This nighttime hypoxia due to fluid accumulation in the pulmonary tissues is *paroxysmal nocturnal dyspnea* (PND).

Left-sided heart failure or *left ventricular failure* (LVF) is the most common type of heart failure. Most often the left ventricle (LV) becomes dysfunctional due to long-standing hypertension. Systemic hypertension increases resistance against the LV, thereby increasing workload. This leads to left ventricular hypertrophy, and eventually the LV decompensates into failure. In addition, the LV is vulnerable to ischemic insults due to coronary artery disease and may endure MI. One of the most common sites of arteriosclerosis is the left anterior descending artery, a branch of the left main coronary artery, a major supplier of the LV. Repeated ischemic episodes can lead to weakening of the LV with eventual failure. LVF can occur as systolic dysfunction (forward failure) and/or diastolic dysfunction (backward failure) as described previously. The classic clinical presentation of LVF involves the pulmonary signs and symptoms of exertional dyspnea, cough, orthopnea, PND, crackles heard on auscultation, and the hemodynamic finding of elevated pulmonary capillary wedge pressure. These symptoms are a result of the buildup of hydrostatic pressure backward into the pulmonary vasculature due to a failing LV. Ejection fraction (EF) is decreased in LV systolic dysfunction to less than 50% of total ventricular volume (normal EF ranging from 55%–70%). In contrast, in diastolic dysfunction, EF may be normal or even increased to greater than 70%, representing the need for the LV to eject a larger proportion of its total blood volume during systole to compensate for reduced diastolic filling.

Right-sided heart failure or *right ventricular failure* most commonly occurs as a result of LVF. The same cardiac muscle comprises both right and left ventricles, which endure biochemical and hemodynamic stresses during heart failure. Therefore, in the clinical setting, often manifestations of right- and left-sided heart failure appear together. The right ventricle (RV) can undergo systolic dysfunction (forward failure) and/or diastolic failure (backward failure) in the same manner as the LV. In right-sided heart failure, the classic signs and symptoms are due to backup of hydrostatic pressure into the venous system. Venous congestion of the superior vena cava is reflected in the classic sign of jugular venous distention. Venous congestion of the inferior vena cava is reflected in the gastrointestinal system as hepatomegaly, splenomegaly, and peritoneal edema *(ascites).* Depending on the position of the patient, peripheral edema is apparent as either sacral edema or ankle edema.

Isolated right ventricular failure can also occur due to pulmonary disease. The term *cor pulmonale* is used to describe right-sided heart failure, which is a result of

a pathological pulmonary process, such as pulmonary fibrosis, recurrent pulmonary emboli, or other phenomena leading to pulmonary hypertension due to arterial vasoconstriction in the pulmonary vascular bed. Chronic hypoxia is a common cause of pulmonary arterial vasoconstriction. The high pulmonary arterial pressure leads to increased resistance against the RV. The RV hypertrophies in response to the increased workload initially. However, eventually the hypertrophic RV decompensates from the excess workload, leading to right ventricular failure. This syndrome is then called *cor pulmonale.*

The most common cause of right-sided heart failure, however, is initial left-sided heart failure. In this case, right-sided heart failure does not occur in isolation, but rather results from a failure of forward cardiac output. This leads to vascular congestion in the pulmonary arterial bed with increased capillary wedge pressure, which is eventually transmitted to the RV, thus compromising its function as it attempts to pump against this increased resistance.

Heart failure evokes the secretion of vasoactive substances and cytokines, which initially help the body adapt to changes from reduced cardiac output. However, in chronic heart failure, these substances cause further myocardial damage and impairment of cardiac function. When cardiac muscle contraction is weakened, *endothelin,* a potent vasoconstrictor, is secreted by the arterial endothelium in response to a drop in BP. Although endothelin helps the body compensate by raising BP, chronic secretion increases afterload and resistance against the heart pump. Another substance, *tumor necrosis factor–alpha* (TNF-α), is found in the circulation and heart muscle during heart failure. TNF-α is an anorexigenic cytokine that also increases wasting of lean body mass. Two important vasodilator peptides are released with dilation of the atria and ventricles in heart failure: *atrial natriuretic peptide* (ANP) and *brain natriuretic peptide* (BNP). These are natural diuretic substances that counteract the excess water reabsorption and fluid overload caused by activation of the renin-angiotensin-aldosterone cascade in response to decreased cardiac output, by stimulating the excretion of sodium and water. Circulating serum BNP level is a useful indicator of the degree of heart failure, compared with a baseline value obtained in the absence of acute cardiac decompensation. Heart failure severity has traditionally been described with the symptom-based New York Heart Association (NYHA) classification system. The newer American College of Cardiology/American Heart Association (ACC/AHA) guidelines supplement this with a staging system describing the progressive phases of heart failure. The two systems are complementary, with the NYHA system describing symptom severity and the ACC/AHA system providing a framework for a stage-based therapeutic approach. Patients who present with a past medical history of HTN, diabetes mellitus, CAD, previous exposure to cardiotoxic drugs, or a strong family history of cardiomyopathy may be screened using the following tools as put forth by the NYHA and ACC/AHA.

NYHA Classification of Heart Failure Severity:

I. Patients with asymptomatic heart failure
II. Patients with heart failure symptoms with significant exertion
III. Patients with heart failure symptoms with minor exertion
IV. Patients with heart failure symptoms at rest

ACC/AHA Staging Criteria of Heart Failure:

A. Patients at risk for developing left ventricular dysfunction
B. Patients with left ventricular dysfunction who have not developed symptoms
C. Patients with left ventricular dysfunction with symptoms
D. Patients with refractory end-stage heart failure

By utilizing a combination of the NYHA heart failure class and the ACC/AHA heart failure stages, a more exacting assessment and subsequent management plan can be afforded. The following are examples of combining the two systems:

- A patient with minimal or no symptoms but a large pressure gradient across the aortic valve or severe obstruction of the left main coronary artery is classified as Function Capacity I, Objective Assessment D.
- A patient with severe anginal syndrome but angiographically normal coronary arteries is classified as Functional Capacity IV, Objective Assessment A.

Clinical Presentation

Subjective

The patient with heart failure will present complaining of symptoms related to the pulmonary system, central nervous system (CNS), and generalized systemic and organ systems.

Complaints related to the pulmonary system are cough, orthopnea, dyspnea, dyspnea on exertion, and paroxysmal nocturnal dyspnea. Orthopnea refers to dyspnea that is positional. The patient feels more dyspneic in a recumbent position but obtains relief by sitting or standing. The number of pillows that the patient sleeps on can grade the severity of orthopnea. Two related symptoms are dry nocturnal cough, seen early in heart failure, and dyspnea in the left lateral decubitus position. As heart failure progresses, the degree of dyspnea increases. If the progression is gradual, the patient may not be aware of the dyspnea. Assessment of the patient during activity may be necessary to elicit this symptom. Paroxysmal nocturnal dyspnea occurs as a result of hypoxia from the accumulation of fluid in the pulmonary interstitium. The patient is usually not aware that he or she is hypoxic and may describe paroxysmal nocturnal dyspnea as awakening during

sleep because of a "nightmare" or extreme shortness of breath. The clinician must have a high level of suspicion because the description of paroxysmal nocturnal dyspnea varies from patient to patient. Slight relief may be noted with sitting, standing, or inspiration of fresh outdoor air. When severe coughing and wheezing are associated with this symptom, the condition is sometimes referred to as *cardiac asthma.* Patient symptoms related to the CNS range from delirium, insomnia, anxiety, and headache all the way to hallucinations and unresponsiveness.

Patient complaints of systemic and organ symptoms are many. Patients may complain of fatigue and generalized weakness, which are associated with low cardiac output and may occur at rest or with increased activity. These symptoms may also be caused by blood volume depletion and electrolyte imbalance secondary to overdiuresis. Patients may also notice a decreased urine output during the day, as well as nocturia that is the result of enhanced renal filtration secondary to recumbency. During the waking hours, renal filtration of sodium and water is decreased in the heart failure patient. Nocturia may not be present if concurrent renal failure is present. The patient may also complain of peripheral and dependent edema. Patients may present with ascites; fullness; nausea; vomiting; constipation; upper abdominal pain; anorexia; or conditions related to liver, spleen, and intestinal congestion. They may also report light-headedness, near-syncope, or syncope. In addition, the patient may be confused or have difficulty concentrating, an impaired memory, headache, insomnia, or anxiety. Some patients may present with chest pain.

Objective

A complete physical exam is necessary to diagnose the condition and determine the etiology of heart failure and provide the clinician with enough information to optimize intervention techniques. On general inspection, the clinician may note breathlessness, dyspnea on exertion, peripheral cyanosis (as a result of low cardiac output), pallor in extremities, and distended peripheral veins. There may be jugular venous distention along with abnormal pulsations. A skeletal deformity (as seen in Marfan's syndrome) may be noted. In addition, the patient may have dependent edema, jaundice (suggesting hepatic congestion), ascites, or anasarca.

Vital signs may show tachycardia; pulsus alternans (a weak pulse alternating with a strong pulse); atrial fibrillation, which may contribute to heart failure; rapid, shallow respirations at rest or with minimal exertion; and possibly Cheyne-Stokes respirations during sleep. Cheyne-Stokes respirations are crescendo-decrescendo patterns of respiratory swings terminating in apnea. Cheyne-Stokes respirations are caused by the prolonged circulation time from the heart to the brain. Verification of this type of sleep disturbance would need to be obtained from either a family member or health-care provider who has observed the patient during sleep.

On cardiac assessment, the clinician may note lateral and downward shift in the point of maximal impulse secondary to cardiac enlargement, the presence of a third heart sound (S_3) in adults older than age 40 (increased likelihood by 11-fold), and the sudden development of the murmurs of mitral or tricuspid regurgitation.

When performing a lung assessment, the clinician may note crackles (rales), generally heard bilaterally in the bases or in the most dependent regions of the lungs on inspiration. Wheezing may also be present, as well as pleural effusion (stony dullness, or shifting of dullness with position changes is characteristic of percussion with pleural effusion). In evaluating these symptoms, the clinician should also consider arterial embolism, which is present in 4% of patients with primary dilated cardiomyopathy.

Diagnostic Reasoning

Diagnostic Tests

The clinician should initially order laboratory tests to assist in the diagnosis. Cardiac myocytes and endothelial tissues manufacture and secrete a family of structurally related peptide hormones termed natriuretic peptides. Atrial natriuretic peptides (ANPs) are secreted in response to the atrial stretch that occurs in heart failure due to increased hydrostatic pressure within the atria. These peptides have diuretic, vasodilating, and kaliuretic (potassium-wasting) effects. B-type natriuretic peptide (BNP) is abundant in the heart and rapidly rises in the bloodstream in the presence of heart failure. A blood test can show elevated BNP within 15 minutes. In patients with the symptom of dyspnea, which can be either cardiac or pulmonary in origin, the BNP blood test can be used to rule out heart failure (Level I; Jessup et al, 2009). BNP is a cardiac marker that can be used in combination with other more definitive tests and is not solely relied on to diagnose heart failure. BNP can be elevated in pulmonary edema, COPD, pulmonary embolism, renal disease, and other conditions. However, a BNP level that is greater than 500 pg/mL is highly indicative of heart failure. In the Breathing Not Properly study, a BNP cutoff of 100 pg/mL alone had a sensitivity of 90% and a specificity of 73% to diagnose heart failure in the emergency department and had a diagnostic accuracy of 81.2% compared with 74% for clinical judgment alone. After instituting treatment for heart failure, the clinician can rely on BNP levels to monitor therapeutic effectiveness. In addition, there is a pharmacological form of BNP, nesiritide, that is used to treat heart failure. However, once nesiritide is initiated, BNP levels would not be of clinical use.

An echocardiogram is the diagnostic test used after demonstrable elevation of BNP. Echocardiography is the

single best test to confirm a diagnosis of heart failure. Abnormalities of systolic and diastolic function are easily visualized, and ejection fraction can be estimated. An echocardiogram can also visualize different etiologies of heart failure and diseases of the pericardium, myocardium, and heart valves.

A CBC may show severe anemia associated with high-output heart failure. A urinalysis that shows proteinuria may indicate nephrotic syndrome, and red blood cells or cellular casts may indicate glomerulonephritis. A serum albumin elevation may indicate volume overload caused by renal failure. An ESR should be ordered because the ESR is typically decreased secondary to impaired fibrinogen synthesis and decreased fibrinogen concentration in patients with heart failure. Electrolytes may show hyponatremia, which may be either genuine (secondary to prolonged sodium restriction and diuretic therapy) or dilutional (secondary to expansion of extracellular volume). Hyponatremia may also signal pronounced activation of the renin-angiotensin system. Hypokalemia may be secondary to diuretic therapy or activation of the renin-angiotensin-aldosterone axis. Hyperkalemia may be secondary to renal failure as a result of the heart failure, especially if ACE inhibitors have been used. The blood urea nitrogen and creatinine may be elevated secondary to decreased renal blood flow. Liver function tests may show abnormalities as a result of hepatic congestion. There is also a decreased hepatic blood flow; therefore, drugs metabolized by the liver should be appropriately dosed. An arterial blood gas study may also be ordered for further acid–base evaluation. Finally, the thyroxine (T_4) and thyroid-stimulating hormone levels may indicate that the heart failure is aggravated by hypothyroidism or hyperthyroidism.

The clinician may also order the following diagnostic procedures to gather information in the diagnosis of heart failure. Although there is no specific ECG pattern for heart failure, an ECG may help diagnose the underlying cause, such as an MI. A chest x-ray film will show an alteration in cardiac silhouette as evidenced by a change in cardiac size and shape, a change in cardiothoracic ratio (cardiothoracic ratio more than 0.50 is considered cardiomegaly), and specific chamber enlargement. A chest x-ray film may also show pulmonary venous congestion as evidenced by distention of the pulmonary veins upward from the hila. Normally in the upright position, larger vessels are seen in the bases; however, with increasing capillary pressures, there is compression of the vessels to the lower lobes and dilation of upper lobe vessels. This might present on x-ray studies as an equalization of upper and lower lobe vessel size; loss of definition of pulmonary vascular markings, which is usually caused by perivascular edema; haziness of hilar shadows; and thickness of interlobular septa (Kerley B lines). Kerley B lines usually result from distended lymphatic vessels. As pulmonary capillary wedge pressure exceeds 25 mm Hg, alveolar edema is indicated by diffuse haziness, usually extending downward toward both lung fields (butterfly pattern). An echocardiogram can be used to identify underlying structural defects such as valvular defects, systolic dysfunction, and abnormal cardiac wall thickness. A radionuclide angiocardiography uses technetium-99m (multigated acquisition scan). This multigated blood pool imaging technique is useful in measuring the EF and wall-motion abnormalities, and right-heart catheterization is useful for determining response to therapy; it can be used in a monitored intensive care unit.

Left-heart catheterization is not usually indicated in heart failure; however, once the condition is stabilized, catheterization can be useful in identifying the underlying causes of the failure. Left-heart catheterization may be performed by the cardiologist if sudden murmurs are auscultated, including severe mitral regurgitation that may be caused by ruptured chordae tendineae, severe aortic regurgitation that may be caused by bacterial endocarditis, or perforation of the interventricular septum or papillary muscle rupture.

Differential Diagnosis

The symptoms of heart failure can be vague and progress slowly, or they can be sudden and overwhelming. In either event, the symptoms and findings of what appears to be heart failure may have other causes such as anxiety neurosis, lung disease, venous insufficiency, nephrotic syndrome, hepatic cirrhosis, superior vena cava syndrome, constrictive pericarditis, or pericardial effusion.

Management

The principles of management include identifying and treating precipitating or aggravating conditions, recognizing and treating underlying cardiac disease, and managing the cardiac failure.

When managing heart failure, the clinician must consider treatments that will decrease the cardiac workload, decrease the clinical volume overload, optimize LV function, reduce mortality, and control atrial fibrillation. To decrease the cardiac workload, the clinician must order rest until the patient's "dry weight" (non–heart failure weight) is achieved, order vasodilators, encourage weight loss if appropriate, and control HTN. Analysis of data acquired from the Systolic Hypertension in the Elderly Program indicates a marked effect in preventing development of heart failure in older patients with isolated systolic hypertension when diuretic therapy was instituted.

To reduce mortality, the health-care provider should order ACE inhibitors, which are indicated for all patients with LV systolic dysfunction unless there are specific contraindications, such as history of intolerance or adverse reactions to these agents, serum potassium greater than 5.5 mEq, or symptomatic hypotension.

ACE inhibitors may be the sole therapy for a patient with fatigue and mild dyspnea on exertion. They are referred to as the "cornerstone of heart failure therapy." ACE inhibitors have been demonstrated to counteract many of the neurohumoral changes in heart failure and, therefore, decrease mortality. For patients who cannot tolerate ACE inhibitors, angiotensin receptor blockers (ARBs) can be used. Vasodilators and nitrates can also be used in those who cannot tolerate ACE inhibitors. Diuretics should be added to this therapy if symptoms persist or volume overload becomes obvious.

To decrease clinical volume overload, diuretics should be initiated at the first signs of volume overload (stage C), e.g., orthopnea, paroxysmal nocturnal dyspnea; however, the clinician should avoid overdiuresis, which will lead to hypotension or renal insufficiency and may interfere with other medications. For mild heart failure, thiazide diuretics are used, and for severe failure, loop diuretics, such as furosemide (Lasix) or bumetanide (Bumex), should be ordered. Doses of these agents can be increased during acute heart failure exacerbations to counteract fluid overload. All patients should be on a sodium-restricted diet.

As a compensatory mechanism in heart failure, the sympathetic nervous system is stimulated. Sympathetic stimulation causes arterial vasoconstriction and increased heart rate, which have detrimental effects on the weakened heart. For this reason, beta-adrenergic blockers, such as carvedilol, have been recommended as part of the drug treatment regimen. Carvedilol is also an alpha-1 antagonist, and along with the beta-adrenergic blockade, slows heart rate, decreasing the work of the heart, and limits peripheral arterial vasoconstriction, decreasing afterload against the ventricles. Bisoprolol and sustained-release metoprolol are the other beta blockers shown to reduce mortality (Level I; Jessup et al, 2009).

Once heart failure has progressed to stage C, spironolactone, an aldosterone antagonist, has been shown to be of benefit in carefully selected patients. Refer to the latest AHA updates for heart failure to review criteria for stage C therapy. In addition, in stage C, the patient should be evaluated for biventricular pacing and an implantable defibrillator (Level I; Jessup et al, 2009). Heart failure often causes ventricular remodeling and arrhythmias such as left bundle branch block (LBBB). These conditions lead to unsynchronized ventricular contractions. Cardiac resynchronization therapy (CRT) has been shown to improve cardiac mechanics by inducing concordant contraction of the two ventricles. CRT involves implantation of a biventricular pacing device, and if necessary, an implantable cardioverter-defibrillator. Implantation of an internal cardiac automated defibrillator may be considered for primary prevention in chronic heart failure patients (NYHA functional class II or III and ACC/AHA stage C) with ischemic or nonischemic cardiomyopathy or with a patient with an EF less than or equal to 35%, given the patient's increased risk of sudden cardiac death due to an increased risk of sustained ventricular tachycardia and ventricular fibrillation. CRT may also be used for patients with NYHA class III or IV heart failure with persistent symptoms who are already receiving optimal medical therapy. Heart transplantation may be considered for patients who have exhausted all other treatment recommendations with poor effect (ACC/AHA stage D). Psychological support is essential; patient support groups have been shown to be very effective in helping patients cope with their conditions and follow the prescribed regimens.

Historically, digoxin has been used to treat heart failure; however, with the establishment of ACE inhibitors and ARBs along with beta blockers and diuretics as the front-line treatment options, use of digoxin has declined. Digoxin may still be used in conjunction with other medications in patients with severe heart failure (ACC/AHA stage C). It may not be necessary in patients who become asymptomatic after treatment with ACE inhibitors and diuretics. Intravenous inotropic agents that may be ordered in a monitored setting for end-stage cardiac failure (stage D) include dopamine (Intropin), dobutamine (Dobutrex), and milrinone (Primacor).

Controlling and, when possible, eliminating atrial fibrillation is essential in treating heart failure. Atrial fibrillation in patients with asymptomatic or symptomatic left ventricular systolic dysfunction is associated with an increased risk of progression of the dysfunction and mortality. Because of this, anticoagulation treatment is instituted in heart failure to decrease the formation of thrombi in the dysfunctional heart chambers, thus preventing embolic cerebral stroke. Long-term oral anticoagulation with warfarin (Coumadin) is usually recommended.

CRT is an option for patients who present with a left ventricular EF less than or equal to 35%, a QRS greater than 120 ms, or who are NYHA class III of IV or who otherwise are not optimized.

Ventricular assist devices (VADs) are becoming more frequently considered in the management of end-stage heart failure than ever before. VADs can be a bridge to transplant or a destination therapy. With the implementation of a VAD program, a designated interprofessional team is implemented to optimize outcomes.

Once drug therapy is initiated, the clinician may manage the patient. Increasingly around the United States, heart failure clinics are becoming popular referral resources.

Other treatments include the following:

- Regular exercise should be encouraged for all patients with stable heart failure, because it improves functional status and decreases symptoms.
- Cardiac rehabilitation programs, although not specifically indicated for patients with heart failure, might benefit patients who are anxious about

exercising on their own or those who have low cardiac output.
- Dietary sodium is restricted to 2 g/day or less.
- Limitation of fluid intake should be advised for each patient based on his or her status.
- Alcohol consumption should be discouraged. A patient should drink no more than one glass of beer or wine or a mixed drink with no more than 1 ounce of alcohol per day.
- The patient should record his or her weight daily and notify the clinician of a weight gain of 3 pounds in 24 hours or 5 pounds or more within 1 week.
- Immunization with influenza and pneumococcal vaccines may reduce the risk of a respiratory infection.
- All barriers to adherence must be removed to assist the patient with management of the disease. Some barriers include the cost of medications, adverse effects, and the complexity of the medical regimen.
- The patient must be counseled concerning the prognosis, so that he or she may have the benefit of understanding the rationale for decisions made about care. This must be done while maintaining hope. The clinician should explain that good quality of life is still possible with cooperation in the treatment regimen. The patient must be given information regarding the prognosis so that plans can be made for the future.
- The patient should be encouraged to complete advance directives.

Follow-up and Referral

Referral to a cardiologist is recommended on onset of symptoms of heart failure; however, initial treatment should begin immediately in the clinician's office, with a phone referral made directly to the cardiologist. Patients in acute failure may be hospitalized. The clinician and the cardiologist will establish a plan of care with the patient and will decide who will manage the patient on an ongoing basis. It must be clear to all involved what the plan of care is to be. The Joint Commission has mandated that specific Core Measures of care be met before discharge. For the patient with heart failure, there must be an assessment of left ventricular function documenting an EF. If the EF is below 40%, the clinician must prescribe an ACE inhibitor or ARB. If the patient has had an allergic reaction to either of these drugs and cannot tolerate the drugs, this must be documented in the medical record. Additional Core Measures are advice/counseling on smoking cessation (other tobacco use should be discouraged) and discharge instructions that include reconciliation of medication regimen. For further information pertaining to Core Measures, the clinician is advised to review the Joint Commission's latest recommendations at www.jointcommission.org.

Patients in chronic cardiac failure may be treated on an outpatient basis. After a complete and detailed baseline history and physical exam, subsequent visits for the patient in chronic failure should assess the patient's cardiac status thoroughly. Questions regarding the patient's health-related quality of life (e.g., sleep, sexual function, mental health or outlook on life, appetite, and social activities) should also be asked. After the patient, family, and caregiver have been educated on the condition, they should be encouraged to communicate all signs, symptoms, fears, and concerns with the clinician. Patients are likely to experience changes in symptoms before there is evidence of deterioration on physical examination.

Frequency of follow-up should depend on the underlying cause of heart failure. Generally, the patient is seen by the clinician at least every 3 months. Intensive home-care surveillance has been shown to decrease the need for hospitalization and improve the functional status of older adult patients with heart failure.

Patient Education

Successful management of patients with heart failure requires an active partnership between the patient and all health-care providers. One of the most critical points in decreasing the possibility of the patient becoming "crippled" by the disease process is a thorough education regarding the condition and encouragement to take responsibility for personal care. The clinician should encourage and assist the patient to do the following:

- Keep a record of daily weights and notify the clinician of a 3-pound weight gain in 24 hours or a 5-pound or more weight gain in 1 week or less.
- Advise the clinician of symptoms or concerns.
- Exercise regularly.
- Rest with elevation of lower extremities.
- Use elastic stockings to reduce the risk of venous thrombosis and PE.
- Ensure emotional rest.
- Maintain an optimum body weight.
- Discuss with the clinician changes made in self-care. The clinician should explain to the patient that some things can be changed, and that by discussing what he or she wants to change with the clinician, before making changes, an "informed" change can be made.

In working closely with the patient and possibly the family to plan the patient's care, the clinician should never lose sight of the high esteem with which his or her opinions and directions are taken. In discussing the plan of care with the patient and family, the clinician should keep in mind that the family, who fears losing their loved one, will attempt to ensure that the plan is followed to the letter; therefore, the clinician should remember to "build in," and teach the patient and family how to "build in," some humane adaptations to the plan of care. For instance, as the clinician stresses that the diuretic must be taken every morning, he or she must realize that if the patient has an important family

function one morning and chooses to take the diuretic later in the day, the mandate may cause needless stress and guilt. The patient may be frightened of getting into distress if he or she does not follow the orders. The family may "harass" the patient for deliberately not following the plan of care, or the patient may feel that participation in events that take place in the morning is forbidden. Any or all of these perceived restrictions compromise the quality of the patient's life and are unnecessary. It is critical that the clinician ensure that the patient understands the rationale for decisions about his or her care.

With the increasing incidence of heart failure, researchers have begun to look at areas of patient involvement in self-care and the impact on outcome. Exercise training is now being recommended for most individuals with moderate-to-severe heart failure. Activity intolerance associated with chronic heart failure has been studied from the perspective of physiological variables; however, very little research has been conducted on the outcomes of exercise training based on subjective data. A research study examined the perception of vigor as a subjective measure of personal health. In this study of person–environment interaction in patients with heart failure, the researcher found that an astute evaluation of the patient's environment, including his or her physical and social milieu, is warranted when assessment of energy level is undertaken. Purposeful activity and exercise should be encouraged and supported. During interviews with patients with heart failure, the researcher noted the hopeful and life-loving attitudes of the participants involved in exercise training in her study, which suggested coping strategies not often attributed to a population experiencing terminal illness. Conclusions were that reinforcement of these attitudes may be a key intervention in reversing the energy-draining sequelae of illness patterns experienced by the individual with a failing heart.

Coaching and encouraging a terminally ill patient in self-care is time consuming and can be draining. The clinician will need to have authentic presence and respond to calls for care that are often not timed with the patient's regularly scheduled appointment; however, the time invested in each patient cannot be charged appropriately on a ledger or justified to other patients who may be late for their visit with the clinician. Nonetheless, to patients with lifelong terminal illness, the importance of life and the significance of the effects of their illness are directly related to their perceptions of the attention and care they perceive being given.

ARRHYTHMIAS

Arrhythmias the clinician may encounter in primary-care practice include the atrial arrhythmias of atrial fibrillation, premature atrial contractions (PACs), atrial tachycardia, atrial flutter, and supraventricular tachycardia (SVT). Ventricular arrhythmias encountered include premature ventricular contractions (PVCs) and ventricular tachycardia (VT). First-, second-, and third-degree heart blocks and arrhythmias associated with digitalis toxicity are other arrhythmias commonly encountered.

Atrial Arrhythmias

Atrial Fibrillation

Atrial fibrillation is one of the most common arrhythmias that clinicians will encounter in clinical practice. In most cases, atrial fibrillation initially will be associated with a rapid ventricular response, and most patients will have some type of underlying heart disease. In these patients, the loss of atrial contribution to left ventricular blood volume (atrial "kick"), along with a rapid ventricular rate, can have serious hemodynamic effects caused by diminished cardiac output. These effects may be seen in the form of hypotension, diaphoresis, dizziness, and syncopal episodes.

The loss of mechanically effective atrial contractions in atrial fibrillation leads to stasis of blood in the left atrium that predisposes an individual to formation of embolic atrial thrombi. Thrombi that form in the left atrium then have a propensity to travel into the left ventricle and into the aorta where they are propelled into the arterial circulation. A common route for the thrombus from the aorta is to the brachiocephalic artery, carotid artery, and then into the cerebral circulation. This pathway makes atrial fibrillation a risk factor for ischemic stroke because an embolus may lodge in a branch of the middle cerebral artery. All persons in atrial fibrillation should be evaluated for the risk of stroke and given recommendations for anticoagulant therapy using the most current version of the CHADS2 scoring tool. The CHADS2 risk score is calculated using 1 point each for **C**HF; **H**TN; **A**ge greater than 75 years; **D**iabetes; and 2 points for **S**troke or TIA (Levine, 2014). The clinician is encouraged to periodically review the latest criteria of this scoring method in the literature for current recommendations. All atrial fibrillation candidates for anticoagulant therapy need to be evaluated with regard to their individual circumstances and using the best available evidence.

Premature Atrial Contractions

PACs are very common, yet in most cases have no clinical significance. PACs are usually a benign arrhythmia that does not require pharmacological intervention unless there are underlying causes that can be corrected. This arrhythmia is commonly seen in young, healthy individuals. Cardiac stimulants such as caffeine, nicotine, alcohol, or over-the-counter medications sometimes induce PACs. They are rarely, if ever, symptomatic and are frequently seen in patients with obstructive lung disease and heart failure.

Supraventricular Tachycardia

Supraventricular tachycardia (SVT) is often described as a "catch-all" term that encompasses rapid arrhythmias

above the ventricles. There continues to be confusion over specific terminology of these SVTs. Some experts feel that the confusion arises from failure to understand the mechanism and inability to differentiate true atrial tachycardias or atrial flutters from paroxysmal supraventricular tachycardias (PSVTs) that use reentry circuits. The use of the term *paroxysmal atrial tachycardia* (PAT) further confounds the terminology issue. This term is often incorrectly used for all SVTs (whether paroxysmal or not) that are not atrial flutter or atrial fibrillation.

Research has shown that the two most common forms of PSVT are atrioventricular node reentry tachycardia (AVNRT) and orthodromic circus movement tachycardia (CMT). For purposes of this discussion, the condition SVT is subdivided into PSVT, which includes AVNRT and CMT, and non-PSVT, which includes atrial tachycardia of nonreentry origin and atrial flutter. Although atrial fibrillation can also be classified as an SVT, this rhythm is discussed separately. Current Advanced Cardiac Life Support (ACLS) treatment standards require that the clinician be able to differentiate the aforementioned atrial tachycardias that are included under the term *SVT.*

The atrial rate differentiates atrial tachycardia from atrial flutter. This rate difference is particularly pertinent when the clinician is attempting to discern if the arrhythmia is an atrial tachycardia with block (seen in digitalis toxicity) or an atrial flutter. Both rhythms can present with more than one observable P wave before the QRS. An atrial tachycardia rate (140–250) is slower than an atrial flutter rate (250–350). Atrial flutter is less common than atrial fibrillation and most commonly occurs in older adults. Atrial flutter must be referred to a cardiologist and managed in an acute-care setting. These patients typically have some form of organic heart disease.

Ventricular Arrhythmias

Premature Ventricular Contractions

PVCs are usually a benign arrhythmia that does not require pharmacological intervention unless the rhythm progresses to VT. VT may be associated with any form of heart disease. It may be sustained or nonsustained. In patients who have had an MI, nonsustained VT is a risk factor for sudden cardiac death.

Heart Blocks

Atrioventricular (AV) blocks are classified as to the degree of severity of the disturbance of the impulse going through the electrical conduction system between the atria and ventricles. Heart blocks may be permanent or transient and are classified as first, second, or third degree. A *first-degree AV block* is observed with a regular rhythm and only a prolonged P-R interval. *Second-degree AV block* may be classified further as type I (Mobitz I or Wenckebach) and type II (Mobitz II). For purposes of this discussion, the terms "type" and "Mobitz" are combined as Mobitz type I and Mobitz type II. Mobitz type I occurs in the AV nodal area with progressive lengthening of the P-R interval until a QRS complex (ventricular contraction) is dropped. Mobitz type II occurs within or below the bundle of His, with a normal or lengthened PR interval and a periodic drop of a QRS complex in a set ratio of atrial to ventricular contractions. A *third-degree AV block* occurs when the atria beat regularly and at a normal rate but no excitation is transmitted from the atria to the ventricles. In turn, the atria and ventricles contract independently at their own intrinsic rates. This complete lack of coordination between the chambers of the heart severely compromises cardiac output and can prove fatal.

Third-degree heart block is classified as third degree at the junctional level or third degree at the ventricular level. A second-degree Mobitz type I block does not progress to Mobitz type II; rather, a Mobitz type I block typically progresses to a third-degree block with an idiojunctional response. In contrast, a second-degree Mobitz type II block progresses to third-degree heart block with an idioventricular response that carries a more ominous prognosis. If a rhythm presents with two P waves with a normal rate to every two R waves (referred to as 2:1 conduction), the origin of nodal or subnodal pathology must be determined. This rhythm is often referred to as second-degree AV block undifferentiated. If the QRS complex is narrow (0.04–0.10), it can be deduced that the location of the block is from the junctional area and Mobitz type I in origin.

Arrhythmias Associated With Digitalis

Historically, one of the most common agents used in the treatment of heart failure and supraventricular tachyarrhythmias has been digitalis. Although digitalis is not seen as often nowadays, it is still prescribed by many clinicians and merits discussion. It is a common cause of various degrees of AV block. There is a narrow therapeutic range for this drug; signs of toxicity can occur before acute symptoms are recognized. Digitalis toxicity can produce virtually any arrhythmia. Those arrhythmias most commonly seen in digitalis toxicity are atrial tachycardia with AV nodal block, accelerated junctional rhythms, atrial fibrillation with a slow or regular ventricular response, second-degree heart block or Mobitz type I (Wenckebach), and ventricular dysrhythmias. The serum digitalis levels may not reflect the amount of digitalis bound to the myocardial membrane, where it cannot be measured. A finding of a normal digitalis level should not be the determining factor in assessing digitalis toxicity. The onset of atrial tachydysrhythmias, noncardiac subjective symptoms (particularly altered visual color perception), and pertinent medication history should make the clinician highly suspicious of digitalis toxicity. ECGs representing these rhythms are shown in Figure 10.4.

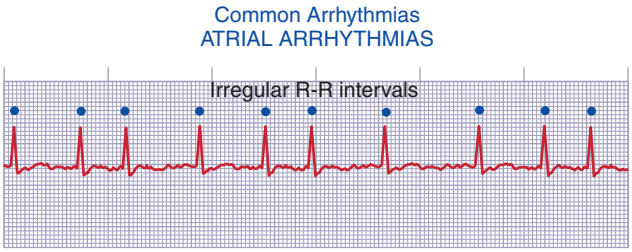


Figure 10.4a Atrial fibrillation. Fibrillatory waves distort the baseline, and the R-R interval is characteristically irregular. The ventricular rate is approximately 100 beats/min.

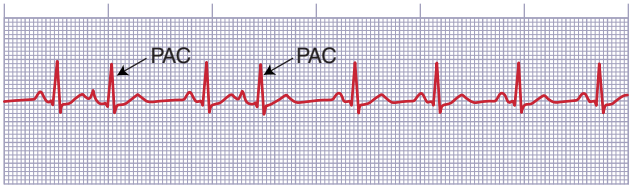

Figure 10.4b Premature atrial contraction (PACs) or atrial premature contractions (APCs). A single complex occurs earlier than the next expected sinus complex. After the PAC, sinus rhythm usually resumes.

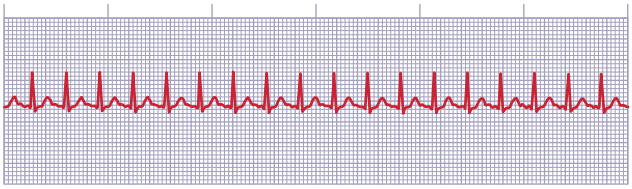

Figure 10.4c Atrial tachycardia with a rate of 180 beats/min.

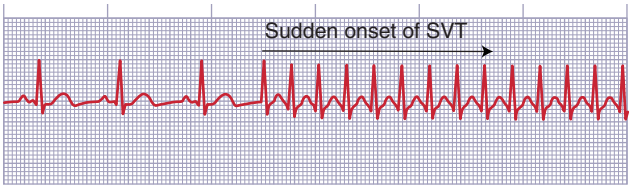

Figure 10.4d Paroxysmal supraventricular tachycardia (PSVT) or paroxysmal atrial tachycardia (PAT). Sinus rhythm which changes into atrial tachycardia at a rate of 230 beats/min.

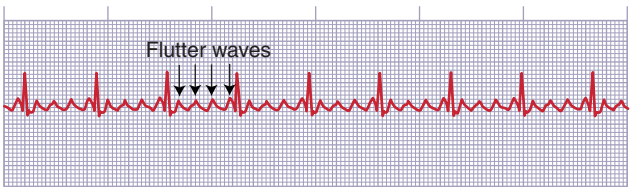

Figure 10.4e Atrial flutter. A characteristic sawtooth pattern at the baseline. Atrial flutter with a 4:1 conduction. The R-R interval is regular.

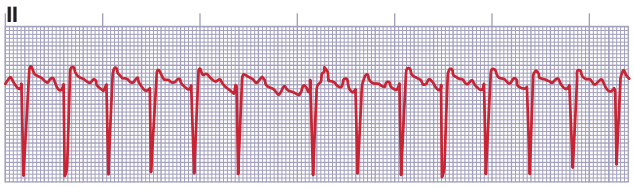

Figure 10.4f Atrial flutter with a 2:1 conduction. Initiation of carotid sinus massage temporarily slows the ventricular rate enough to unmask the flutter waves.

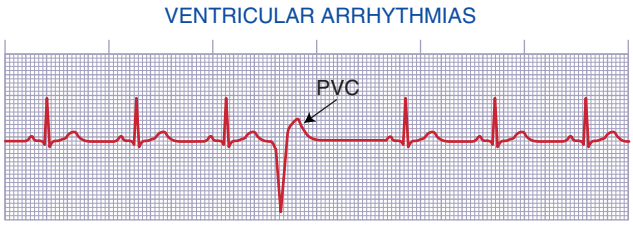

Figure 10.4g Premature ventricular contractions (PVCs). The ectopic QRS complex (the PVC) is wide, abnormally shaped, and appears earlier than expected. The length of the compensatory pause following a PVC indicates that sinus node discharge was undisturbed. A nonconducted sinus P wave distorts the T wave (the P wave appears on time).

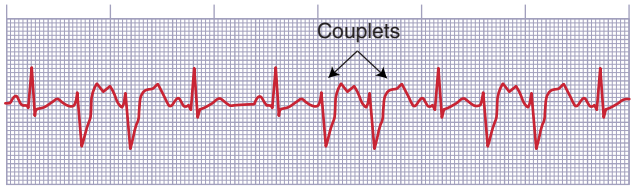

Figure 10.4h PVC couplets. Pairs of uniform PVCs originating from the same ectopic site.

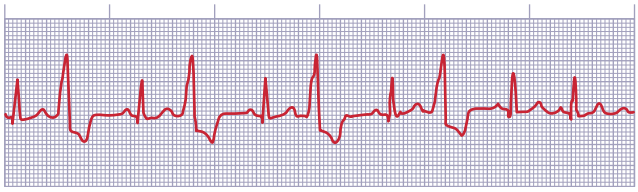

Figure 10.4i PVC bigeminy. A uniform PVC occurring from the same ectopic site; occurs every other beat.

Figure 10.4j Multifocal PVCs. PVCs coming from two ectopic foci.

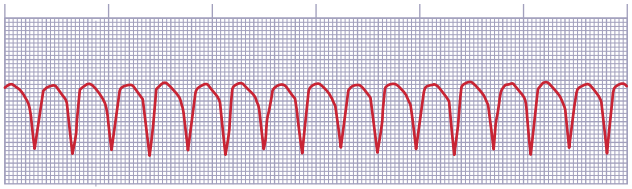

Figure 10.4k Ventricular tachycardia. The ventricular rate is approximately 160 beats/min. The QRS complexes are wide, they look alike, and the R-R interval is regular.

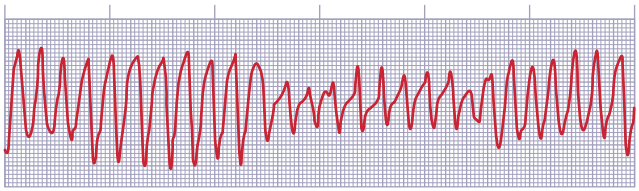

Figure 10.4l Torsade de pointes. Polymorphic ventricular tachycardia, congenital or drug induced.

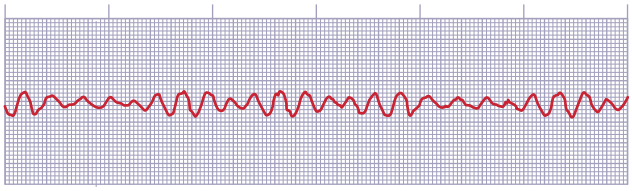

Figure 10.4m Ventricular fibrillation. Chaotic electrical activity with no ventricular contraction.

Figure 10.4n Atrioventricular (AV) blocks: First-degree AV block. The P-R interval is consistently prolonged at 0.20 second or longer. The underlying rhythm is sinus.

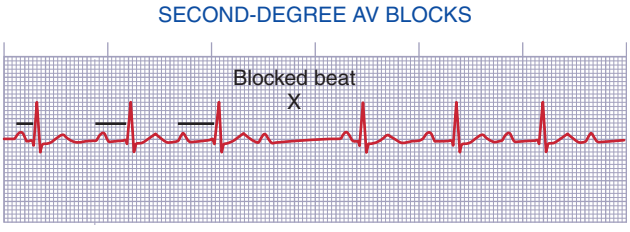

Figure 10.4o Type I (Mobitz I or Wenckeback). The P-R interval lengthens until a beat is dropped. The QRS complexes are narrow. The nonconducted P waves are easily visible.

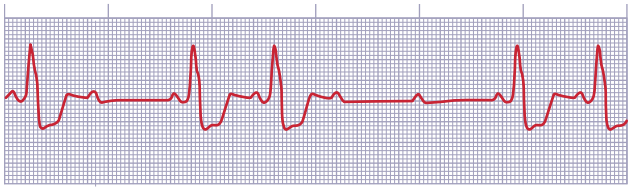

Figure 10.4p Type II (Mobitz II). The P-R interval remains fixed. The QRS complexes are wider than normal. The nonconducted P waves are visible. The conduction ratio (P waves to QRS complexes) is commonly 2:1, 3:1, or 4:1.

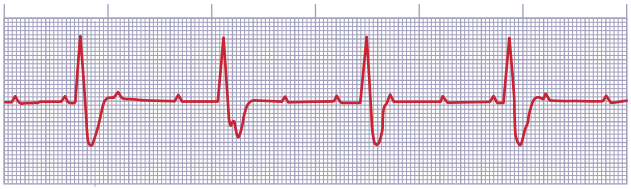

Figure 10.4q Third-degree AV block: There is no relationship between the P wave and the QRS complex. This is a third-degree AV block with a ventricular escape pacemaker.

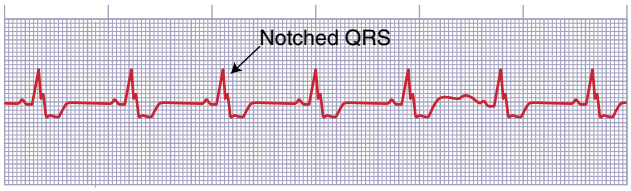

Figure 10.4r Bundle branch block (BBB). Either the left or the right ventricle will depolarize late, creating a "notched" QRS complex.

Epidemiology and Causes

Atrial Arrhythmias

Most patients with atrial fibrillation have some form of heart disease. The most common form is CAD associated with heart failure, followed by hypertension and rheumatic heart disease. Frequently, the precipitating event is an acute illness, electrolyte imbalance, or major cardiac surgery. Atrial fibrillation is seen in 60% of patients after valvular surgery and in 33% to 42% of patients with mitral valve stenosis. Other causes of atrial fibrillation include abrupt discontinuation of beta blockers, alcohol ingestion (sometimes called "holiday heart"), hyperthyroidism, acute MI, and cor pulmonale. A danger of untreated atrial fibrillation, with or without rapid ventricular response, is the significant increased risk of embolic stroke. The risk of stroke is increased in untreated atrial fibrillation after 48 to 72 hours; therefore, it is important to diagnose and treat this arrhythmia in an expeditious manner. A beta blocker or calcium channel blocker should

be given to slow AV conduction and control the ventricular rate of atrial fibrillation.

PACs typically have no clinical significance. In a normal patient, tobacco, caffeine, alcohol, or emotional stress may cause PACs. PACs may also result from stretch of the myocardium as a warning of developing CHF. In patients with organic heart disease, common causes of PACs are mitral valve stenosis and cor pulmonale secondary to atrial enlargement. Occasionally in patients with organic heart disease, PACs may precipitate PSVT, atrial flutter, and atrial fibrillation. Remember that the most common cause of a pause on the ECG is a blocked PAC. To differentiate this from heart block, assess if the P wave is early or on time. If the P wave is early, it is a premature atrial ectopic beat. If the P wave is on time, heart block should be considered.

Ventricular Arrhythmias

Frequent PVCs are seen in patients with cardiomyopathies of differing etiologies and arteriosclerotic heart disease. These patients are rarely symptomatic and in general do not need to be treated. In patients with frequent PVCs, it is worthwhile to rule out acute underlying causes of ventricular ectopy such as hypokalemia, hypomagnesemia, hypoxia, myocardial ischemia, or digitalis toxicity. Other common causes are stress and stimulants such as alcohol and nicotine. Sustained ventricular tachycardia is associated with a prior MI or CAD, electrolyte disturbances, and digitalis toxicity.

Heart Blocks

A first-degree heart block (P-R interval greater that 0.20 milliseconds) may be seen as a result of drugs that slow AV conduction or in persons with CAD and digitalis toxicity. A transient second-degree AV block type I may be associated with an acute inferior MI. It may also be associated with CHF or digitalis toxicity. A Mobitz type II AV block is a less common second-degree heart block; it is marked by an intermittent blocked impulse that can occur at the bundle of His or the right or left bundle branches. This type of block may occur as the result of an anterior wall MI. As this block progresses, complete heart block with an idioventricular response may follow. Insertion of a temporary pacemaker as soon as a Mobitz type II block is discovered is the standard of care. Other causes of AV block at this level are acute infections, valvular heart disease, and digitalis toxicity. This is not commonly a transient arrhythmia and can progress to third-degree AV block at the ventricular level; therefore, it must be monitored and treated appropriately.

Pathophysiology

The mechanism of atrial fibrillation remains controversial. Cardiac disease associated with atrial enlargement is the primary cause of the rapid firing (400–700 beats per minute) of the ectopic foci throughout the atrium. Although electrical atrial activity is very rapid, only a small islet of myocardium is depolarized rather than the entire atrium. Because the atrium does not contract as a whole, there is no P wave. The chaotic atrial activity is seen as a wavy line between the QRS complex and is referred to as fibrillatory waves. These impulses are transmitted in variable fashion from the atria to the ventricles. The ventricular response rate to atrial fibrillation may be fast or slow, depending on the refractory nature of the AV node and the degree of AV nodal heart block or conduction delay within the AV node. In turn, therapy is usually geared toward rate control with AV nodal slowing agents, rather than toward complete resolution of the arrhythmia with antiarrhythmic medications.

Normally, electrical impulses from the sinoatrial node within the atria are conducted down the AV node to the His-Purkinje conduction system, disseminating throughout the two ventricles, thereby leading to subsequent contraction. However, in addition to the AV node, in some individuals a fast conducting accessory pathway exists between the atria and ventricles that bypasses the AV node. The tissue in these pathways depolarizes at a faster rate owing to the presence of faster inward sodium transport channels. One of the most common and well-characterized examples of these bypass tracts is the bundle of Kent accessory tract, which is seen in individuals with Wolff-Parkinson-White (WPW) syndrome. Because conduction down this bypass pathway directly transmits a depolarizing impulse to the ventricles faster than impulses sent down the AV node, this has been termed a "preexcitation" syndrome. ECG patterns in these patients demonstrate QRS fusion beats with a characteristic shape produced by the overlap of QRS complexes transmitted via each pathway in temporal proximity, hence creating a fusion complex. The first portion of the upswing in the R wave in this complex has a characteristic slanted appearance with a less steep angle than the remainder of the upward deflection, termed a *delta wave.* Figure 10.5 shows a delta wave present in WPW syndrome.

The most common mechanisms of PSVT observed in symptomatic patients are CMT (40% of cases) and

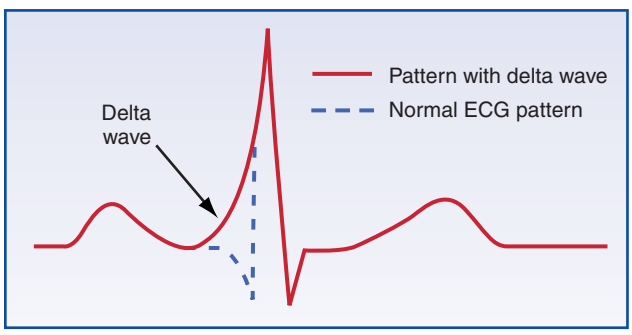

Figure 10.5 Delta wave present in Wolff-Parkinson-White syndrome.

AVNRT (50% of cases). CMT is distinguished by the dependence of the circular, reentrant impulse on an accessory conduction pathway, separate from the AV node itself. Thus, the fast bypass tract found in WPW syndrome is a perfect setup for CMT. Normal physiology dictates that cardiac conducting tissue become refractory (i.e., resistant to depolarization and electrical conduction) for a brief period of time following transmission of an electrical impulse. Bypass pathways such as that seen in WPW syndrome typically have shorter refractory periods than the AV node. Once depolarizing impulses are transmitted down the AV node to the ventricles, the refractory nature of the AV node prevents retrograde conduction back up this pathway. However, the same impulse may be conducted in retrograde fashion from the ventricles back up the accessory bypass tract to the atria. In turn, this impulse may then be conducted back down the AV node, which will have recovered from its refractory state by this time, only to circle back around once again to the atria via the fast accessory pathway. This type of circular, orthodromic conduction accounts for 90% of CMT cases, with a P wave occurring immediately after the QRS complex, rather than before it. The remaining 10% of CMT cases are considered antidromic, with the depolarizing impulse initially conducted down the fast accessory tract, only to circle back up the slower AV nodal pathway to the atria to complete the circular movement.

In AVNRT, PSVT typically results from an interplay of two conducting pathways within the AV node itself—one fast and one slow. The key aspect of this type of PSVT is that reentry of the impulse is dependent on an AV nodal pathway, as opposed to an accessory bypass pathway. In AVNRT, the fast AV nodal conducting pathway has a refractory period that lasts longer than that of the slow AV nodal pathway. Thus, if an electrical impulse enters both pathways of the AV node simultaneously, the fast pathway will remain refractory longer. In turn, if an early PAC then enters the AV node while the fast accessory pathway is still refractory, it can depolarize the ventricles only via transmission down the slower AV nodal pathway. By the time the impulse has traveled down this open slow pathway, the fast pathway is no longer refractory, and the impulse may travel in retrograde fashion back up to the atria via the fast pathway, and then back down again to the ventricles via the slow pathway. This mechanism activates the atria and the ventricles nearly simultaneously, which places the P wave within the QRS complex, distorting its terminal portion.

PVCs and VT may be the results of enhanced normal automaticity from catecholamines within the His-Purkinje system or abnormal automaticity anywhere in the ventricles from ischemia, injury, or electrolyte imbalances. Another mechanism for these arrhythmias is reentry through slowly conducting tissue within the His-Purkinje system or the ventricular myocardium related to catecholamines or digitalis excess.

Digitalis toxicity may cause delayed after-depolarizations that are oscillations in transmembrane potential that follow full repolarization of the membrane. These oscillations are caused by interference of the sodium-potassium pump by digitalis. Digitalis competes with potassium for a binding site on the cellular membrane wall, which disables the sodium-potassium adenosine triphosphatase (ATPase) pump. The less potassium there is to bind to receptors, the greater amount of receptors available for digitalis; thus, hypokalemia potentiates digitalis toxicity. Triggered activity is also another important mechanism in the pathophysiology of digitalis toxicity.

The mechanism of AV block is delayed conduction or nonconduction of an atrial impulse when the AV junction is not physiologically refractory. In first-degree AV block, there is not an actual block but rather a prolongation of conduction. In second-degree block, there is nonconduction of some of the atrial impulses. The pathology is either in the AV node itself or within or below the bundle of His. The QRS complex duration assists the clinician in localizing the level of block. A narrow QRS complex is seen if the ventricular response is initiated at the level of AV node and conducted down both bundle branches simultaneously, as seen in Mobitz type I block. A wider QRS complex indicates that the block is located further down the conduction system at the bundle of His or within the bundle branches. These criteria may not be helpful if the patient has a preexisting right or left bundle branch block, however. Such a patient could present with a prolonged P-R interval with a broad QRS complex, and the pathology could be either in the AV node or within or below the bundle of His. The clinician would then need to assess the P-R interval carefully for varying lengths and Wenckebach conduction patterns. If the patient is in a two P waves for every wide QRS complex (2:1 conduction) pattern, the origin of pathology is difficult to determine from the ECG.

Clinical Presentation

Subjective

A patient presenting with atrial fibrillation may complain of shortness of breath, palpitations, angina, changing level of consciousness, and syncope. If the patient is aware of palpitations, the clinician should have him or her "tap" out the rhythm in the palm of the hand. The irregular tapping at irregular intervals can differentiate this rhythm from the regular patterns of other arrhythmias.

A patient experiencing SVT will complain of dizziness, shortness of breath, and chest pain. As part of taking the patient's history, the clinician should ask about polyuria that is associated with SVT. Polyuria is present

in 20% to 50% of patients with PSVT or atrial fibrillation. It is thought to be related to the cardiac secretion of atrial natriuretic factor released by changes in rhythm and atrial pressure.

A patient presenting with nonsustained VT may complain of palpitations or may present with symptoms similar to those of patients with sustained VT. Usually patients with sustained VT will have complaints compatible with a loss of cardiac output, such as decreased levels of mentation and hypotension.

If the patient is taking digitalis, the clinician should question him or her about anorexia, nausea, and vomiting. In addition, the patient should be asked about changes in the quality of color vision, especially red and green color distortions. These changes may be subtle; patients often do not volunteer them unless asked. Scotomas and flickering halos, although advanced signs, may also be present. Neurological symptoms such as headache, malaise, memory lapses, and insomnia may also be reported.

A patient experiencing first-degree heart block will be asymptomatic. With a third-degree AV block, the patient may exhibit signs of symptomatic bradycardia. The origin of the block may determine the degree of symptomatology. Patients with second-degree AV Mobitz type I that progresses into a third-degree block with an idiojunctional response may or may not exhibit overt signs or report symptoms of a bradycardia. The hemodynamic symptom present will depend on the rate of the junctional response (anywhere from 40–60 beats per minute), the status of the patient's left ventricular ejection fraction, and the loss of atrial kick (up to 20%–30% of the cardiac output). A patient whose Mobitz type II heart block progresses to third degree with a ventricular response of 20 to 40 beats per minute will almost always exhibit signs and symptoms of a severe bradycardia such as profound changes in level of consciousness and hypotension, which will prohibit reports of subjective data.

Objective

Atrial Fibrillation Physical examination of the patient with atrial fibrillation will yield an irregularly irregular heart rhythm. In most cases the rate is rapid (100–180 beats per minute). Some patients with a diseased AV node present with a slow or normal ventricular rate. Patients can be asymptomatic, although most cases present with some symptoms such as palpitations, dizziness, a decrease in BP, or are mildly symptomatic with new-onset activity intolerance. In a few cases, a stroke can be the presenting manifestation of atrial fibrillation as a result of emboli flowing from clot formation in the dysfunctional atrium into the cerebral vasculature. *Cannon waves,* which are unpredictable expansions of the jugular pulse caused when the atria contract against closed AV valves, causing a reflux of blood into the jugular vein, may be seen. When present, Cannon waves signify AV dissociation as a result of the atrial fibrillation. The ECG strip will show fibrillatory waves representing (although unmeasurable) an atrial rate of 350 to 600 beats per minute, with a ventricular rate of 100 to 180 beats per minute. The rhythm is irregular. There are no discernible P waves, and a coarse or fine fibrillatory wave (f wave) is present. It is the hallmark of this arrhythmia and represents chaotic atrial activity. The P-R interval cannot be measured, and the QRS wave is usually normal.

Premature Atrial Contractions PACs may be found on a routine ECG. The rate is usually 60 to 100 beats per minute with a regular rhythm except when the premature beats are present. The premature beats have a different P wave configuration because of origination outside the sinus node. The PAC P-R interval may be different from the sinus P-R interval, and the QRS complex may be normal, aberrant (wide, different QRS complex), or absent.

The most common cause of a pause on an ECG rhythm strip is a blocked or nonconducted PAC. This occurs when the PAC comes so early that it falls in the T wave. If the AV node is still refractory, the early P wave does not conduct, and a pause is seen on the rhythm strip. If the clinician looks closely at the T wave and compares it to the patient's other T waves, the early nonconducted P wave can be seen distorting that specific T wave. If the nonconducted PACs present in a bigeminal pattern, the rhythm may be mistaken for profound sinus bradycardia or sinoatrial (SA) block. The clinician should always assess for nonconducted P waves within preceding T waves in any pauses observed on the ECG.

Observation of the neck veins may help the clinician rapidly distinguish between PSVT and VT. During PSVT, the atria contract against closed AV valves, resulting in a rapid, regular expansion of the neck veins (the same mechanism as Cannon waves). This physical finding has been called the "frog sign" because the rapid, regular expansion of the neck veins resembles the puffing motion of a frog. The patient's family may have noticed the frog sign of PSVT.

Supraventricular Tachycardia The ECG of a patient in SVT will show a regular rhythm with a rate of 150 to 250 beats per minute. The P waves are ectopic and distorted and may be initiated by a PAC. The P-R interval is shortened, and the QRS complex may be normal or distorted. If the patient is in atrial flutter, the atrial rate will be regular at 250 to 350 beats per minute, and the ventricular rate may be regular or slightly irregular. The P waves are discernible and "march out" (can be mapped out with a caliper) consistently throughout the strip. The P-R interval cannot be calculated, and the QRS complex has a variable conduction.

Premature Ventricular Contractions The ECG of a patient with PVCs will usually show a rate of 60 to

100 beats per minute. The rhythm will be irregular secondary to the premature ventricular beat. The PVC usually obscures the P waves; however, P waves may be visible if the PVC is late in diastole. These P waves are not related to the ectopic beat and occur at the same regular rate of the preceding sinus P waves. The P-R interval is not measurable on the PVC. The QRS complex for the PVC is wide and bizarre. It may be observed in patterns of ventricular bigeminy, trigeminy, or couplets. In the setting of an acute ischemic event, PVCs that occur close to the preceding T wave (R on T phenomena) may precipitate ventricular fibrillation.

Ventricular Tachycardia VT can be categorized as monomorphic or polymorphic. The ECG of a patient with monomorphic VT will show a rate greater than 100 beats per minute with a regular rhythm; the P waves will be buried in the QRS complex or discernible after the QRS complex because of retrograde conduction. The P-R interval is not measurable, and the QRS complex is wide and bizarre. The ECG of a patient with polymorphic VT will show a "flipping" of the ventricular axis. For example, torsades de pointe is a form of polymorphic VT whose QT interval demonstrates prolongation before the onset of the dysrhythmia. It is essential to differentiate torsades from non–torsades polymorphic VT to optimize treatment.

Heart Blocks In first-degree AV block, the pulse will usually be 60 to 100 beats per minute. The ECG rhythm is usually regular, with a P wave preceding each QRS complex and a prolonged P-R interval longer than 0.20 milliseconds. QRS complexes follow every P wave and are usually a normal width.

A patient with second-degree AV block Mobitz type I will have a ventricular rate of 50 to 70 beats per minute, although it may vary. The atrial rate is regular, whereas the ventricular rate is irregular. P waves precede each QRS complex, and the P-R interval progressively lengthens. The QRS complex is usually normal in width, unless a preexisting bundle branch block is present. As the P-R interval progresses, eventually the QRS complex disappears for a beat. In contrast, in a Mobitz type II AV block, the P-R interval may be prolonged or normal, but it remains constant, unlike the progressively lengthening P-R of a type I. The blocked P wave may occur in patterns of 2:1, 3:1, or 4:1. The width of the QRS complex indicates where the block is located. The wider the complex, the lower the block is located below the AV node. The P wave is regular and the P-R interval constant, with a wide QRS following every P wave until the QRS complex is not conducted.

With a third-degree block, the AV node (if the block is of a Mobitz I origin) or the ventricles (if the block is a Mobitz II in origin) set up an autonomous rhythm with a ventricular rate of 25 to 60 beats per minute. The atrial rate is 60 to 100 beats per minute. P waves are present and regular, but there is no relationship to the QRS complex. The P-R interval cannot be calculated, and the QRS complex is wider and longer than 0.12 milliseconds if the block is at the ventricles; it is normal if the block is at the nodal/junctional level.

Diagnostic Reasoning

Diagnostic Tests

An ECG is the routine diagnostic test to determine the type of arrhythmia so as to direct treatment appropriately. The most definitive diagnostics are confirmed by electrical physiology studies. Electrophysiological testing using intracardiac electrocardiographic recordings and programmed atrial and/or ventricular stimulation is used in the diagnosis and management of complex dysrhythmias. Electrophysiological testing can evaluate recurrent syncope of possible cardiac origin and differentiate supraventricular from ventricular dysrhythmias.

Tilt-table testing, or autonomic testing, is useful in patients with arrhythmias when syncope may be due to a vasovagal response. The patient is tilted to approximately 70 degrees in conjunction with isoproterenol infusion. Syncope due to bradycardia and/or hypotension will occur in about one-third of patients with recurrent syncope.

Transesophageal echocardiography (TEE) is a diagnostic procedure used to visualize and rule out the presence of thrombi in the left atrium before cardioversion in atrial fibrillation. The presence of clots in the left atrium is a contraindication to cardioversion.

Differential Diagnosis

The differential diagnoses should consider conditions that could mimic the symptoms of dysrhythmia, such as panic attack, anxiety, valvular disorders, and syncopal episodes either neurogenic or cardiac in origin.

Management

Management of these patients by a clinician depends on the expertise of the clinician. If the clinician is at all unsure of the management of an arrhythmia, he or she should consult with the collaborating physician or a cardiovascular specialist.

Atrial Fibrillation

The initial goal of treatment in atrial fibrillation is to control the ventricular response and then convert the patient back to normal sinus rhythm (NSR) by using medications or electrical synchronized cardioversion.

Some patients with afib after cardioversion revert to a NSR. However, many patients with atrial fibrillation after cardioversion return to afib within a short period of time. This is seen particularly in patients with long-standing atrial fibrillation or in patients with advanced heart disease and a very large left atrium. Patients with new-onset atrial fibrillation or chronic atrial fibrillation with a very rapid ventricular response should be admitted to a unit where telemetry is available so that the response

to treatment can be carefully monitored. Drugs that may convert atrial fibrillation to sinus rhythm are amiodarone and disopyramide. Digoxin is effective only for rate control at rest and should be used only as a second-line agent. This drug has been used less frequently with the advent of newer alternatives. Elective synchronized cardioversion is recommended if acute ischemic heart disease is present along with a rapid ventricular rate (120–200 beats per minute) or if the patient is in clinical distress. Always evaluate the patient for risk of atrial emboli before electrical shock.

Before cardioversion, the patient should undergo TEE to assess for the presence of mural thrombi. Successful cardioversion (in the absence of mural thrombi) and prevention of recurrence of atrial fibrillation depends on atrial size and the length of time in atrial fibrillation. In addition, valvular function should be assessed for further therapeutic interventions. Before electrical or pharmacological cardioversion is attempted, anticoagulants should be considered. Anticoagulation therapy should be initiated in all patients who remain in atrial fibrillation longer than 48 hours or who experience atrial fibrillation of unknown duration. Patients may be placed on IV heparin for rapid anticoagulation and started on warfarin (Coumadin), which takes approximately 5 days to achieve its full anticoagulant effect. A prothrombin time (PT) with international normalized ratio (INR) is drawn and the patient started on warfarin at 5 mg/day, with the dose adjusted according to the patient's INR. The target INR is between 2 and 3, and most patients require a maintenance dose of 2 to 7.5 mg/day. The PT should be checked at regular intervals to make sure the INR remains within the appropriate range. If the patient is hospitalized, these levels are usually monitored daily, but typically take 2 to 3 days to equilibrate in response to dosing changes. Once the patient is discharged, levels should be checked every week with the dosage adjusted accordingly, until the clinician has established the patient's individual response and optimal dose. Once a constant appropriate INR range has been established, PTs should be monitored monthly. Alternatives to warfarin may include dabigatran (Pradaxa), rivaroxaban (Xarelto), or apixaban (Eliquis). These agents are for the management of the patient with nonvalvular atrial fibrillation. Commonalities of these agents are shorter half-lives, fewer drug–drug interactions, and earlier peak blood levels compared with warfarin. Additionally, these newer agents do not necessitate dose titration or lab monitoring. Comparative studies suggest that with these agents, there is a 10% reduction in mortality, fewer strokes, and fewer systemic emboli. However, a disadvantage for these drugs is that there is not an established antidote for reversal. The clinician should try to maintain patients in chronic atrial fibrillation who are difficult to convert with a controlled ventricular rate and to keep them on anticoagulant therapy indefinitely. (See Table 10.9 for antithrombotic treatment options for stroke prevention in nonavalvular atrial fibrillation.) For patients refractory to the above therapies, ablation therapy is an option.

Premature Atrial Contractions

Treatment of PACs is not indicated unless patients are symptomatic or there are underlying causes that can be

Table 10.9 Antithrombotic Treatment Options for Stroke Prevention in Nonvalvular Atrial Fibrillation

Agent	Dosing	Implications for Nurse Practitioner Practice
Warfarin* (Coumadin)	Starting dose: 2–5 mg daily in the evening	Goal INR 2.0–3.0. Higher in mechanical valve patients. Antidote: Vitamin K
Dabigatran† (Pradaxa)	150 mg 2 times daily CrCl > 30 mg/mL 75 mg 2 times daily CrCl 15–30 Contraindicated if CrCl <15	Requires no lab monitoring. Do not cut, crush, or open pill. Antidote: None
Rivaroxaban† (Xarelto)	20 mg daily for CRCl > 50 mg/mL 5 mg daily for CrCl 15–49 mg/mL No dosing information if CrCl <15 mL/min	Requires no lab monitoring. If unable to swallow, pill may be crushed. No dosing if patient on dialysis Antidote: None
Apixaban† (Eliquis)	5 mg 2 times daily 2.5 mg 2 times daily with at least two of the following: age >80; body weight less than 60 kg; or creatinine >1.5 Contraindicated if CrCl <25 mL/min	Requires no lab monitoring. Antidote: None

*Pregnant women (with the exception of those who have mechanical heart valves) should not receive warfarin.

†These drugs should not be administered to those patients with prosthetic heart valves, hemodynamically significant valvular heart disease, severe kidney failure, and/or advanced liver disease.

corrected. Simple measures such as stopping tobacco use, reducing caffeine intake, and improving electrolyte imbalance may reduce the incidence of PACs. If symptoms persist, Holter monitoring may be indicated, and the patient should be instructed to maintain a diary of activities. The patient should be monitored for the first 3 months to establish whether this is an acute or a chronic condition. A cardiologist should follow the patient.

Supraventricular Tachycardia

The initial treatment for stable SVT consists of vagal maneuvers, such as carotid sinus pressure. Vagal maneuvers increase parasympathetic tone and slow conduction through the AV node. These techniques include coughing, lying on the floor while elevating legs against the wall, or squatting. If the clinician has the experience and knowledge of carotid sinus massage, this maneuver is usually effective. The vagal maneuver of carotid sinus massage is contraindicated in patients with carotid artery stenosis, bruits, or a history of transient ischemic attacks, or in patients older than age 65 years who may have an exacerbated parasympathetic response to carotid pressure. Facial immersion in cold water (dive reflex) is another method that has been used. The clinician must never use eyeball pressure as a vagal maneuver because it may cause retinal detachment and is unpleasant for the patient.

In the case of PSVT, adenosine is the treatment of choice; 6 mg in a peripheral IV is given rapidly. If treatment is unsuccessful, the dosage is increased to 12 mg and may be repeated once. Adenosine blocks the AV node and has an extremely short half-life of less than 10 seconds. Because of this short half-life, it is critical that this drug be delivered to the heart by a rapid IV push followed by a rapid saline flush. Adenosine does not usually cause a drop in BP and has replaced verapamil in the emergency treatment of PSVT. Verapamil hydrochlorate (verapamil HCl) may be used to treat tachyatrial arrhythmias and is given as a 2.5 to 5 mg IV bolus over 1 to 2 minutes; a second dose of 5 to 10 mg may be given IV 15 to 30 minutes after the first dose.

If the patient is symptomatic with atrial flutter, is hypotensive, has ischemic pain, or has severe CHF, synchronized cardioversion is usually recommended. Pharmacological intervention may involve beta blockers and calcium channel blockers along with digitalis. Patients who have recurrent symptomatic and refractory PSVT will need to see an electrophysiologist for possible radiofrequency ablation of the accessory pathway. Ablation therapy is often chosen over a lifetime course of prophylactic drugs.

Premature Ventricular Contractions

Treatment for PVCs is not usually needed in healthy adults because many adults experience PVCs with no untoward effects. If the patient is having PVCs related to an MI, however, it must be determined whether the PVCs are caused by a problem with oxygenation, hypotension, electrolyte or acid–base imbalance, other medications, or by an increased catecholamine state from unrelieved ischemic pain or anxiety. Typically, therapy in this case involves treating the underlying cause, such as the hypoxia, pain, electrolyte imbalance, or the alteration in hemodynamics with nitroglycerin, oxygen, pain medications, and beta blockers.

Heart Blocks

Treatment for a first-degree AV block is not advised because it is an asymptomatic arrhythmia. However, the clinician should assess and take note of the types of drugs that are being used that prolong AV conduction. For a Mobitz type I AV block, treatment is observational. If symptomatic bradycardia develops, a temporary or transcutaneous pacemaker may be needed, whereas a permanent pacemaker may be required for a Mobitz type II AV block. For third-degree heart block, the underlying pathological sites must be determined to prevent complications. The ability to determine whether this block has an idiojunctional response versus an idioventricular response is necessary for determining appropriate interventions. Third-degree heart block is considered an emergent and potentially life-threatening condition.

PREMATURE VENTRICULAR CONTRACTIONS AND VENTRICULAR TACHYCARDIA

Implantable cardioverter-defibrillator (ICD) devices are multiprogrammable antiarrhythmic devices capable of treating bradydysrhythmias, ventricular fibrillation, and ventricular tachycardia. These devices offer antitachycardia pacing as well as low- and high-energy shocks in multiple ranges of tachycardia rates. These devices are placed under the skin in the left chest. Patients need close follow up with a cardiologist and extensive patient education. Patients should carry a device identification card at all times. The American College of Cardiology/American Heart Association/North American Society of Pacing and Electrophysiology (ACC/AHA/NASPE) guidelines delineate indications for ICD therapy (http://content.onlinejacc.org/article.aspx?articleid=1357576).

Follow-up and Referral

A cardiologist should be consulted to establish the plan of care. The cardiologist may order a Holter monitor to establish if there is a routine pattern to the rhythm. Electrophysiological studies may be indicated to evaluate the patient for ablation therapy for PSVTs, such as WPW syndrome.

Patient Education

The education of a patient for atrial fibrillation should include a list of foods and prescription and OTC drugs

that interfere with warfarin (Table 10.10). The patient on warfarin is at risk for bleeding; therefore, the clinician should provide literature on medical alert identification jewelry and instruct the patient how to assess for signs of bleeding, such as bruising and dark stools and to use electric razors and night lights. Patients should be taught to check their pulse rate. If the pulse rate is decreased (below 60 beats per minute) or the patient notices bursts in the rate, it should be reported to the clinician.

For patients being admitted to hospice care or on a withdrawal protocol, the clinician should consider deactivating the ICD/pacer.

VALVULAR DISORDERS AND MURMURS

Mitral and aortic valve disorders are the most common of the heart valve disorders. These disorders may be congenital or acquired and may be symptomatic or asymptomatic. Many are detected during heart auscultation when alterations in the normal heart rhythm, presence of extrasystoles, murmurs, and abnormal heart sounds are heard.

Heart murmurs are the sound of turbulent blood flow. Blood traveling through the chambers and great vessels is normally a silent event. When turbulence exists in the wall of the heart or a great vessel, a murmur occurs.

Murmurs may be benign, in that the clinician simply hears the blood flowing through the heart, but no cardiac structural abnormality exists. Certain cardiac structural problems, however, such as valvular and myocardial disorders, can contribute to the development of a murmur.

Benign systolic ejection murmurs such as physiological murmurs are found in the absence of cardiac pathology. The term implies that the reason for the murmur is something other than obstruction to flow and is present with a normal gradient across the valve. This murmur may be heard in up to 80% of thin adults or children if the cardiac exam is performed in a soundproof room; it is best heard at the left sternal border. It occurs in early to midsystole, leaving the two heart sounds intact. In addition, the patient with a benign systolic ejection murmur denies cardiac symptomatology and has an otherwise normal cardiac exam, including an appropriately located point of maximal impulse (PMI) and full pulses. No cardiac pathology is present with a

physiological murmur, so no endocarditis prophylaxis is needed.

A *hemic murmur* is heard in hyperkinetic or high-volume states such as anemia, fever, or response to exercise. The murmur is crescendo–decrescendo and harsh, and both heart sounds are preserved. Because there is no cardiac pathology associated with this condition, it resolves when its underlying cause is gone. As with a physiological murmur, no structural cardiac abnormality is present, and no endocarditis prophylaxis is needed.

An *aortic sclerosis murmur* is also called the 50/50 murmur because it is present in about 50% of adults older than age 50 years. Its etiology is likely fibrotic and/or calcific changes in the aortic valve. The valve can open enough to prevent a significant gradient but is restricted enough to cause the murmur. It differs from an aortic stenosis murmur in having an early peak and resolution, as well as lack of hemodynamic significance.

Types of Valvular Disorders

Aortic stenosis is the inability of the aortic valves to open to optimum orifice. The aortic valve normally opens to 3 cm^2; aortic stenosis usually does not cause significant symptoms until the valvular orifice is limited to 0.8 cm^2. The disease is characterized by a long symptom-free period, with rapid clinical deterioration at the onset of symptoms, including dyspnea, syncope, chest pain, and congestive heart failure. The clinician should look for a narrow pulse pressure on BP, a characteristic of severe aortic stenosis.

The murmur of *mitral regurgitation* (also referred to as mitral insufficiency) arises from mitral valve incompetency or the inability of the mitral valve to close properly. This allows a retrograde, "regurgant" flow from a high-pressure area (left ventricle) to an area of lower pressure (left atrium). Mitral regurgitation is most often caused by the degeneration of the mitral valve, most commonly by rheumatic fever, endocarditis, calcific annulus, rheumatic heart disease, ruptured chordae tendonae, or papillary muscle dysfunction. In mitral regurgitation from rheumatic heart disease, there is usually also some stenosis. Once the person is symptomatic, the disease progresses in a downhill course of heart failure over the next 10 years.

Mitral valve prolapse (MVP) is the most common valvular heart problem, with an incidence of 2.4% in the general population based on two-dimensional echocardiographic criteria. In most cases, MVP is a benign condition. However, MVP with mitral regurgitation may predispose the individual to thrombi and endocarditis. In the past, the prevalence of MVP was overestimated owing to lack of the availability of specific diagnostic procedures. Patients given this diagnosis more than 10 years ago may not have the disorder at all and should be reevaluated with two-dimensional echocardiography. (Table 10.11 presents the common valvular disorders.)

Epidemiology and Causes

Bacterial endocarditis, rheumatic heart disease, and aortic calcification are common etiologies of valvular disorders that cause heart murmurs. Bacterial endocarditis is most often due to septicemia caused by *Staphylococcus aureus* or *Streptococcus viridans* (alpha-hemolytic) infection. Valvular deformities are among a spectrum of abnormalities associated with endocarditis. IV drug abusers and patients with indwelling IV catheters are at risk for bacterial septicemia that can lead to endocarditis. Patients with prosthetic heart valves, heart murmurs, or valvular damage require prophylactic antibiotics to prevent endocarditis before any invasive procedures such as dental or surgical interventions.

Rheumatic heart disease is another cause of heart valve injury. Rheumatic heart disease is a result of rheumatic fever, an infection caused by group A beta-hemolytic *Streptococcus* infection. The pathological mechanism involves antibodies developed by the body against the bacteria. Antistreptococcal antibodies are thought to cross-react with the body's own tissues and "mistakenly" attack the heart valves in susceptible individuals. Because of the wide availability of antibiotics, rheumatic fever has become a less common etiology of valvular disease.

Calcification of the aortic valve is a common finding in elderly patients who present with the systolic murmur of aortic stenosis. A calcified aortic valve is often a result of long-standing arteriosclerosis. This calcification causes narrowing of the aortic valve resulting in an audible disturbance in blood flow through the valve.

In children and younger adults, aortic stenosis may also be present; it is usually caused by a congenital bicuspid (rather than tricuspid) valve or by a three-cusp valve with leaflet fusion. This defect is most often found in males and is commonly accompanied by a long-standing history of becoming excessively short of breath with increased activity such as running. The physical exam is usually normal except for the associated cardiac findings.

Mitral valve prolapse occurs in about 2% to 4% of the population and is usually detected in young adulthood. It is more common in women younger than age 20; the incidence is equal in men and women after age 20.

Pathophysiology

Normal heart valves allow one-way, unimpeded forward blood flow through the heart. The entire stroke output is able to pass freely during one phase of the cardiac cycle, and there is no backflow of blood. When a heart valve fails to open to its normal orifice, it is stenotic. When it fails to close appropriately, the valve is incompetent, causing regurgitation of blood to the previous

Table 10.11 Common Valvular Disorders

Disorder	Murmur Characteristics	Physical Exam	Diagnostic Findings
Aortic stenosis	Grade: 1–4/6, harsh systolic usually crescendo-decrescendo pattern. Heard best: Second right intercostal space (RICS), apex. Radiation: To carotids. Other: Softens with standing.	Cardiac: May have diminished S_2, slow-filling carotid pulse, narrow pulse pressure, loud S_4, heaving PMI. Other: Anxiety, difficulty breathing, compromised mental status, cyanosis, peripheral edema, hair loss, shiny skin over shins, cool extremities, decreased SBP, pulmonary edema.	Chest x-ray: Aortic valve calcification, left ventricle (LV) enlargement, prominent ascending aorta. ECG: LVH, sinus tachycardia, atrial fibrillation, AV conduction delay, left or right bundle branch block (LBBB, RBBB). Echocardiogram: Limited aortic valve movement, thickened left ventricular wall. Cardiac catheterization: Increased pressure gradient in systole across aortic valve, decreased size of aortic orifice, increased left ventricular end-diastolic pressure.
Aortic regurgitation	Grade: 1–3/4 high-pitched blowing diastolic murmur. Heard best: Third left intercostal space (LICS). Other: May be enhanced by forced expiration, leaning forward.	Cardiac: Usually with S_3 wide pulse pressure, sustained thrusting apical impulse, palpitations, dyspnea, orthopnea, paroxysmal nocturnal dyspnea (PND), syncope, signs of LV failure, peripheral edema, flushed skin, cardiomegaly. Other: More common in men, usually from rheumatic heart disease; occasionally caused by third-degree syphilis, fatigue, weakness, anxiety, compromised mental state. 16- next column is left ventricular end diastolic pressure	Chest x-ray: Aortic valve calcification, LV enlargement, dilation of ascending aorta. ECG: LVH, sinus tachycardia, PVCs. Echocardiogram: Dilated and hyperdynamic LV, enlargement of aortic root and LA, early closure of mitral valve, diastolic fluttering of aortic valve. Cardiac catheterization: Decreased aortic diastolic pressure, increased LVEDP, decreased regurgitant flow, reflux through aortic valve.
Aortic sclerosis	Grade: 2–3/6 systolic ejection murmur. Heard best: Second RIC. Other: "50 over 50" murmur (found in 50% of those over age 50). Grade: 1–3/4 low-pitched late diastolic murmur. Heard best: Apex. Radiation: Localized. Other: Short crescendo-decrescendo rumble, often with opening snap; enhanced by left lateral decubitus position, squat, cough; also immediately post–Valsalva maneuver.	Cardiac: Full carotid upstroke, no S_4. Cardiac: Accentuated S_1 in mitral area, atrial fibrillation, dyspnea, orthopnea, PND. Other: History of rheumatic fever; protracted latency period, then gradual decrease in exercise tolerance, fatigue, hoarseness, ruddy cheeks, peripheral edema, anorexia, enlarged liver, crackles, bloody productive cough.	Echocardiogram: Benign thickening and/or calcification of aortic valve leaflets. Cardiac catheterization: No change in valve pressure gradient. Chest x-ray: LA and RV enlargement, pulmonary venous congestion ECG: LAH, RVH, P-mitrale, prolonged notched P waves, atrial fibrillation. Echocardiogram: Thickened mitral valve with diminished movement of leaflets, left atrium (LA) and right ventricle (RV) enlargement. Cardiac catheterization: Increased pressure gradient across mitral valve, increased left atrium

Table 10.11 Common Valvular Disorders—cont'd

Disorder	Murmur Characteristics	Physical Exam	Diagnostic Findings
			pressure (LAP) and pulmonary vascular resistance, increased LVEDP, increased PAWP, decreased CO.
Mitral stenosis	Grade: 1–4/6 high-pitched blowing systolic murmur, often extending beyond S_2. Heard best: Right lower sternal border (RLSB). Radiation: Radiates to axilla, often with laterally displaced PMI. Other: Sounds like a loon—"haa," "hoo." Decreased with standing Valsalva maneuver; increased by squat, hand grip.	Cardiac: History of ischemic heart disease, endocarditis, RHD (rheumatic heart disease), other valve abnormalities, dyspnea, orthopnea, PND, diaphoresis, cyanosis, jugular venous distention, peripheral edema. Other: Weakness, fatigue, anxiety, abdominal respirations, enlarged liver, crackles.	ECG: Atrial fibrillation, P mitrale (if patient is in sinus rhythm). Doppler echocardiogram: Detects and quantifies mitral regurgitation.
Mitral regurgitation	Grade: 1–3/6 late systolic crescendo murmur with honking quality. Heard best: Apex. Other: Follows midsystolic click; with Valsalva or standing, click moves forward into earlier systole resulting in a longer sounding murmur; with hand grasp, squat, click moves back further into systole, resulting in a shorter murmur.	Cardiac: Recurrent chest pain in the precordium and substernal areas, dyspnea, syncope. Other: Often seen with minor thoracic deformities (e.g., pectus excavatum, strait back, shallow antero-posterior diameter) or high arched palate, fatigue, light-headedness, migraine headache, exercise intolerance, anxiety, panic attacks; arm span often greater than height.	Chest x-ray: Normal. ECG: Normal. Two-dimensional echocardiogram: Demonstrates MVP.
Mitral valve prolapse	Grade: 1–3/6 ejection murmur. Heard best: Pulmonic area.	Cardiac: Widely split S_2 RV heave. Other: CHF, exertional dyspnea.	Auscultation: A split S_2 may be heard.
Atrial septal defect (uncorrected)	Grade: 1–3/6 ejection murmur. Heard best: Pulmonic area.	Cardiac: Widely split S_2 RV heave. Other: CHF, exertional dyspnea.	Auscultation: A split S_2 may be heard.

chamber or vessel. Both of these events place the patient at significant risk for embolic disease.

Clinical Presentation

Subjective

The patient may be asymptomatic or, depending on the specific problem, may complain of dyspnea, orthopnea, paroxysmal nocturnal dyspnea, fatigue, hoarseness, palpitations, weakness, chest pain, heart failure, vertigo, syncope, and peripheral edema. The patient may or may not know whether or not he or she has a heart murmur. (Table 10.11 lists the signs and symptoms of specific valvular disorders.)

Objective

When evaluating an adult with a cardiac murmur, the clinician should ask about major symptoms of heart disease, including chest pain, heart failure symptoms, palpitations, syncope, and activity intolerance. The bell

of the stethoscope is most helpful for auscultating lower-pitched sounds, whereas the diaphragm is best used for hearing higher-pitched sounds. Systolic murmurs are graded on a 1 to 6 scale, from barely audible to audible with stethoscope off the chest (grades IV to VI must have a palpable thrill). Diastolic murmurs are usually graded on the same scale but are graded from 1 to 4 because these murmurs are not loud enough to reach grades 5 and 6. Advanced Assessment 10.3 gives more information about the cardiac examination, including assessing heart murmurs.

Diagnostic Reasoning

Diagnostic Tests

Initially, the clinician may discover a murmur on physical exam. Depending on the associated symptoms, the clinician may refer the patient for subsequent testing or may refer the patient directly to a cardiologist for more invasive testing. Two-dimensional echocardiography is the definitive procedure to diagnose heart valve disorders.

Various diagnostic tests used to detect valvular lesions or structural heart changes include echocardiography, ECG, chest x-ray film, and cardiac catheterization. The clinician usually should order an echocardiogram, ECG, and chest x-ray to confirm a definitive diagnosis of a murmur and then refer the patient to a cardiologist unless the clinician and patient agree on an initial course of therapy as a trial, such as in MVP. The ECG can reveal left ventricular hypertrophy (LVH). The chest x-ray may show an enlarged cardiac silhouette, left ventricular prominence, calcification of the aortic valve, and dilation and calcification of the ascending aorta. An echocardiogram is useful in demonstrating the underlying pathological process, whether the lesion involves the aortic root, or if valvular disease is present. Cardiac catheterizations can provide an accurate assessment of regurgitation and stenosis, along with left ventricular function and pulmonary artery pressures. Coronary angiography is often indicated to determine the presence of coronary artery disease before valve surgery.

Differential Diagnosis

The differential diagnoses for MVP include hypertrophic cardiomyopathies, papillary dysfunction, coronary artery spasm and/or disease, anxiety disorders, and congenital cardiac anomalies.

The differential diagnoses for mitral stenosis include atrial myxoma or vegetation caused by endocarditis,

Advanced Assessment 10.3 The Cardiac Exam and Assessment of Heart Murmurs

Area of Examination	Assess	Possible Clinical Correlation
Skin temperature	Variations from normal	Cool, moist skin may indicate a decrease in cardiac output Cool, dry skin may reflect environmental temperature or use of vasoconstricting substances such as sympathomimetics (caffeine, nicotine)
Skin color	Central cyanosis Peripheral cyanosis Palmar erythema Pallor	Poor blood oxygenation Excessive removal of oxygen from the blood Suggests liver impairment May be present in severe anemia (hemoglobin [Hgb] <8 g)
Pulse	Rate Rhythm Character and volume	Note presence of bradycardia, tachycardia Regular, irregular, regularly irregular (extrasystoles), irregularly irregular (likely atrial fibrillation) Normally full and rapidly filling
Blood pressure (BP)	Pulse pressure	Narrow pulse pressure may be found in volume depletion, aortic stenosis Wide pulse pressure may be found in aortic regurgitation
Point of maximum impulse (PMI)	Location	Normally located at fifth intercostal space (ICS) at midclavicular line With hypertrophy, PMI shifts laterally and may cover more than one ICS
Apical impulse	Sensation	Normally a gentle tapping sensation Forceful, thrusting seen with ventricular overload Diffuse, weak seen in cardiac hypertrophy Sustained in poorly controlled hypertension, aortic stenosis Double apex impulse in ventricular aneurysm

Advanced Assessment 10.3 The Cardiac Exam and Assessment of Heart Murmurs—cont'd

Area of Examination	Assess	Possible Clinical Correlation
Heart sounds	S_1 (normal heart sound)	Marks onset of systole, heard just before palpation of carotid artery High-pitched, click-like sound
	Variations from normal S_1	Unusually loud: mitral stenosis Unusually soft: In mitral stenosis, S_1 becomes softer as the valve calcifies and becomes more rigid and less mobile (mitral stenosis, mitral regurgitation) Abnormally wide split: delay in closure of tricuspid valve (RBBB)
	S_2 (normal heart sound)	Marks end of systole; vibration of aortic and pulmonic valve after closure
	Physiological split S_2	Occurs at end of systole Widest split at peak inspiration; may disappear with sitting, standing Normal finding in younger adult; usually disappears by middle-age
	Fixed split S_2	Occurs at end of systole No closure of split with position change; does not increase with inspiration Occurs with atrial septal defect, pulmonary stenosis
	Paradoxical split S_2 S_3 (third heart sound, ventricular gallop, protodiastolic gallop)	Occurs with coarctation of the aorta Likely produced by the rapidly filling ventricles at a point where ventricular filling slows or by a recoil of the heart as it is pushed against the chest Occurs in early diastole Heard best by the diaphragm; no change with respiration, although occasionally inspiration or expiration will increase its sound Found in disorders of systolic emptying, CHF, valvular heart disease, ischemic heart disease, hypertrophic cardiomyopathy
	S_4 (fourth heart sound, atrial gallop, presystolic gallop, S_4 gallop)	May be caused by the tug of the chordae and papillary muscles in the state of poor ventricular compliance Found in disorders of diastolic filling; poorly controlled hypertension, angina, ischemic heart disease

anemia, and thyrotoxicosis. For mitral regurgitation, the differential diagnoses include rheumatic or ischemic heart disease, MVP, infective endocarditis, mitral annular dilation or calcification, congenital valve deformities, cardiac trauma, and prosthetic mitral valve malfunction.

Management

The principle of management is to help the patient maintain a normal cardiac output, thus preventing manifestations of heart failure, venous congestion, and inadequate tissue perfusion. For an asymptomatic patient, no treatment is indicated. In recent years the recommendations for use of antibiotic prophylaxis before dental work has undergone revision and is more selective. For current guidelines pertaining to the use of prophylactic antibiotic therapy, the clinician is advised to refer to the ACC/AHA guidelines for the prevention of infective endocarditis (cited at end of Treatment Standards/Guidelines 10.1).

Mitral Valve Disorders

Mitral Valve Prolapse There is no medical treatment to correct MVP. Symptomatic management includes lifestyle changes, such as beginning a mild exercise program to reduce plasma catecholamines, lower the heart rate, decrease stress, and increase the cardiac output and blood volume. Beta blockers may be prescribed for patients with MVP to help control palpitations; however, because fatigue is a problem with this disorder, it may be exacerbated by beta blockers.

The clinician is referred to the most current guidelines available from the ACC/AHA regarding the use of antibiotic prophylaxis. Anticoagulation with aspirin

Treatment Standards/Guidelines 10.1 Infective Endocarditis Prophylaxis

The following are recommendations from the American Heart Association's guidelines regarding infective endocarditis (IE) antibiotic prophylaxis.

Only the people at greatest risk for or negative outcomes from IE should receive preventive antibiotics before routine dental or medical procedures, particularly if involving the gingival tissues or periapical region of a tooth and for those procedures that perforate the oral mucosa.

Antibiotic prophylaxis is recommended for high-risk patients with any of the following:

- Prosthetic heart valves
- Previous history of IE
- Complex cyanotic congenital heart disease (unrepaired or repaired)
- Cardiac valvulopathy in a transplanted heart
- Echocardiographic evidence of substantial leaflet pathology and regurgitation

Antibiotic prophylaxis is no longer indicated for common valvular lesions; however, clinicians should exercise judgment in selecting the dose and duration of antibiotics in individual cases or special circumstances.

Good oral hygiene is considered to be an important factor in preventing IE.

Endocarditis Prophylaxis (30–60 minutes before dental procedure)

If no penicillin allergy: Amoxicillin oral: Adults 2 g; children 50 mg/kg
Unable to take oral: Ampicillin IM or IV: Adults 2 g; children 50 mg/kg
OR
Cefazolin or ceftriaxone IM or IV: Adults 1 g; children 50 mg/kg
If penicillin/ampicillin allergic:
Cephalexin* oral: Adults 2 g; children 50 mg/kg
OR
Clindamycin oral: Adults 600 mg; children 20 mg/kg
OR
Azithromycin or clarithromycin oral: Adults 500 mg; children 15 mg/kg
If penicillin/ampicillin allergic and unable to take oral medication:
Cefazolin or ceftriaxone IM or IV: Adults 1 g; children 50 mg/kg
OR
Clindamycin IM or IV: Adults 600 mg; children 20 mg/kg

*Cephalosporins should not be used in persons with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.

Source: Allen, U. Infective endocarditis: Updated guidelines. *Can J Infect Dis Med Microbiol* 21(2):74–77, 2010.

(81–325 mg/day) is prescribed for some individuals with MVP who also have had a history of TIA, ischemic stroke, or atrial fibrillation.

Persons with MVP and severe mitral regurgitation should be followed with stress echocardiography periodically. Surgical intervention is indicated for MVP with severe mitral valve regurgitation.

Mitral Stenosis For symptomatic mitral stenosis, diuretics and sodium restriction should be initiated to reduce the blood volume and pulmonary and systemic venous pressures, along with anticoagulation therapy with warfarin if there is a history of systemic embolism, atrial fibrillation, or a large left atrium. If the patient is in atrial fibrillation, the antiarrhythmic amiodarone or the calcium channel blocker diltiazem may be prescribed and are replacing the use of digitalis. Surgical intervention may be required for some patients; it may include mitral commissurotomy, balloon valvuloplasty, or mitral valve replacement.

Mitral Regurgitation For a symptomatic patient with mitral regurgitation, vasodilators should be initiated to reduce ventricular filling volume and to decrease systemic vascular resistance. Diltiazem and anticoagulants should be prescribed to control the ventricular rate and decrease the embolic complications if the patient has atrial fibrillation. Sodium restriction and diuretics will relieve symptoms of heart failure if they are present in patients with mitral regurgitation. A mitral valve replacement may be required.

Aortic Valve Disorders

Aortic Stenosis Aortic valve replacement or aortic commissurotomy may be required for aortic stenosis.

Aortic Regurgitation For the patient with symptomatic aortic regurgitation, digitalis and diuretics can be used to treat the symptoms of heart failure; arterial vasodilators will reduce the left ventricular afterload. Aortic valve replacement may be required.

Follow-up and Referral

The clinician should follow the patient at regular intervals for close monitoring, as well as whenever a new drug has been added or a dosage changed. The patient should be referred to the collaborating physician or cardiologist when the diagnosis is unconfirmed or when the symptoms are not well managed with medical therapy.

Patient Education

Valvular heart disorders require lifelong management. Patients may benefit from maintaining a diary to monitor the effectiveness of lifestyle changes and compliance with drug therapy in controlling symptoms of the disorder. Patients with MVP should be instructed to begin a gradual program of exercise and to avoid caffeine, decongestants, and products containing ephedrine, alcohol, chocolate, and cheeses. They should be encouraged to drink at least eight glasses of water a day to prevent dehydration. Patients with aortic stenosis often require activity restrictions. The patient should understand how to pace activity, note an improvement in fatigue, and accept the activity restrictions.

A critical part of the evaluation of a person with a heart murmur is the decision to offer antimicrobial prophylaxis. No prophylaxis is needed with benign murmurs. Treatment Standards/Guidelines 10.1 presents the treatment guidelines for bacterial endocarditis prophylaxis.

PERIPHERAL ARTERY DISEASE

Peripheral artery disease (PAD) is an occlusive disorder of the arteries, which most commonly affects the lower extremities. PAD is most commonly the result of occlusive atherosclerotic plaques that impede blood flow to the peripheral vasculature. The resulting arterial insufficiency most commonly manifests itself in the form of lower extremity *claudication*—cramping pain triggered or exacerbated by exertion and relieved by rest. Although atherosclerosis is the most common etiology of arterial insufficiency, several other disorders may precipitate lower extremity ischemia, including vasculitis, radiation exposure, dissection, and aneurysm.

Epidemiology and Causes

Peripheral artery disease is caused by atherosclerosis, blood clots, trauma, spasms of smooth muscles in the arterial walls, and congenital structural defects in the arteries. Approximately 8 million people have PAD, and its most common symptom is intermittent claudication. In patients older than age 70, 20% suffer from PAD. The 5-year mortality rate for PAD approaches 30% as patients die from comorbid conditions of CAD and cerebrovascular disease. PAD is more common in men than women and nine times more common in smokers. (See Risk Factors Box 10.2.)

Pathophysiology

Atherosclerosis is the most common cause of arterial insufficiency of the lower extremity, also referred to as PAD. Arteriosclerotic plaque obstructs optimal arterial blood flow to the muscles of the lower extremity. With increased muscle activity, there is an increased need for arterial blood flow. For this reason, during ambulation or exercise, limitations of arterial blood flow cause muscle pain due to ischemia. This cramping muscle pain is referred to as *intermittent claudication* because in the initial stages of PAD, ischemia occurs periodically.

Risk Factors 10.2 Risk Factors for Peripheral Vascular Disease (PVD)

Peripheral Vascular Disease	
Arterial Risk Factors (Peripheral Arterial Disease)	Smoking: Vasoconstriction/spasm-decreased circulation Obesity: Increased cardiac workload Inactivity: Decreased circulation Hypertension: Increased fibrous tissue, which decreases stretch of arterial walls, which increases peripheral vascular resistance High cholesterol: Atherosclerotic plaque, which increases hyperlipidemia Diabetes: Increase in atherosclerosis of smaller vessels
Venous Risk Factors	Coagulation abnormalities Abdominal/pelvic surgery: Venous pooling/stasis Estrogen/oral contraceptives Pregnancy: Venous congestion Obesity: Increased cardiac workload, venous pooling Heart disease: Venous stasis Advanced neoplasm: Coagulation abnormalities; interference with venous blood flow

Muscle activity of the lower extremity requires increased circulation and arterial vasodilation. PAD causes lack of arterial vasodilatory ability. Thus, as PAD worsens, arterial circulation diminishes, and less muscle activity causes pain due to worsening ischemia. Eventually pain at rest occurs, which is a sign of severe PAD. In general, the clinical manifestations of PAD are extremity pain (claudication), weak pulse, pallor, paresthesias, and palpable coolness of the lower extremity. Long-standing PAD causes muscle atrophy, diminished hair growth, and discolored, hardened toenails of the extremity. All of these signs and symptoms are due to lack of arterial blood supply to the lower extremities. Early recognition of the signs of PAD and treatment are critical because severe ischemia can lead to the need for amputation.

Arteriosclerotic plaque formation within the lower extremities is accelerated by the presence of diabetes mellitus; therefore, PAD is more common in persons with diabetes. Hyperglycemia in diabetes causes endothelial injury, damaging arterial vessels. Clinical manifestations of arterial insufficiency are apparent in the lower extremities of individuals with diabetes. Many suffer the complications of diminished circulation of the legs, which include poor wound healing and peripheral neuropathy. The smaller caliber arterial vessels of the most distal regions of the lower extremity are initially affected. Therefore, careful periodic physical assessment of the feet and lower extremities is recommended in persons with diabetes, inspecting for poor wound healing and diminished peripheral pulses.

Aneurysms, another manifestation of arterial PVD, result from weakening in arterial walls, which renders them susceptible to rupture. The most common cause of this weakening is arteriosclerosis. Aneurysms appear as bulges in the arterial wall and are classified according to location. The aorta and cerebral arteries are the most common sites of aneurysms. In the aorta, a dissecting aneurysm, which is an incomplete tear in the vascular wall, may occur when elevated blood pressure (BP) leads to separation of the layers of aortic tissue.

Arteritis, a form of vasculitis, involves inflammation of arterial blood vessels. Inflammation decreases the vasodilatory capacity of arteries and may cause spasm of the arteries. This condition is often associated with autoimmune disease. *Raynaud's phenomenon* is a result of cold-induced vasospasm of the small blood vessels in the fingers and toes, causing a characteristic blanching that sometimes extends to the hands or feet. A tricolor change may also be stimulated, which appears first as blanching of the finger tips and toes, followed by cyanosis and rubor (redness).

Clinical Presentation

Subjective

The patient with PAD will usually present with intermittent leg pain (intermittent claudication) that increases in severity with exertion. The location of the lower extremity pain depends on where the occlusion is located. Aortoiliac occlusions typically produce claudication of the thigh and buttock, whereas occlusions of the femoral artery produce pain in the upper calf. The pain is described as severe, "grabbing," and cramplike. The pain lasts minutes (at most) and is relieved by rest and does not reoccur until the patient walks the same distance again. Pain at rest frequently signifies severe PAD. The patient usually denies swelling, pain at night, or color or temperature changes. The patient may also complain of thick toenails with cornlike material under the nails. Eventually, the lower legs and ankles may assume a purple-black color characteristic of cyanosis and gangrene.

Objective

Taking a thorough history distinguishes the cause of leg pain in more than 90% of patients. Assessing the risk factors assists in the diagnosis. The next step should be to determine the rapidity of onset of symptoms. PAD must be differentiated from a limb-threatened state that may need immediate treatment. If the onset of claudication has been gradual, this is more consistent with the progressive obliteration of the lower extremity vessels and the formation of collateral circulation, as seen with PAD, rather than an acute event such as an embolus from the heart or a proximal abdominal aortic aneurysm.

The clinician should evaluate the cervical, radial, ulnar, brachial, femoral, popliteal, dorsalis pedis, and posterior tibial pulses bilaterally. A consistent grading system should be used. Usually 0 refers to an absent pulse, 1+ a diminished pulse, 2+ normal, and 3+ bounding. The clinician should keep in mind that about 10% of the population has absent pedal pulses. Because a bruit indicates turbulence and possible atherosclerotic narrowing, the following pulse sites should be assessed using the diaphragm of a stethoscope: cervical, supraclavicular, abdominal, flank, and inguinal areas.

To differentiate chronic venous insufficiency from PAD, the clinician should raise the patient's legs for several minutes. When the legs are dependent again, the patient with PAD will have pale, dusky red (rubor) extremities and the patient with chronic venous insufficiency will have improved color in the extremities. Circulatory checks should be done to assess for acute arterial ischemia. The six P's of PAD are pain, pulselessness, paresthesia, paralysis, poikilothermia (coolness), and pallor. The clinician should do a sensory examination to rule out peripheral neuropathy associated with ischemia in patients with diabetes.

With PAD, the clinician may observe decreased or absent peripheral extremity pulses. The affected leg may be smaller in size as a result of muscular atrophy. The clinician will note thinning of the skin, loss of hair over the affected area, and possible leg ulcers. The extremity may be cool and pale, and the toenails will be thickened.

The patient will have a history of delayed wound healing. When the extremity is dependent, it will appear reddish blue in color.

Diagnostic Reasoning

Diagnostic Tests

If arterial insufficiency is suspected and the pulses are absent, a Doppler flow study should be performed, which can quantify the degree of the ischemia. Part of the Doppler flow study includes calculating an ankle-brachial index (ABI), which involves a comparison of arm BP to the ankle pressures, using a BP cuff and a Doppler. The normal ratio of ankle to brachial pressure is more than 0.9. An ABI reading of 0.6 to 0.9 indicates moderate level of disease, and levels less than 0.5 indicate severe ischemia. Although an arteriogram is not usually ordered as a diagnostic tool, it should be obtained preoperatively, after the patient has been assessed by a vascular surgeon.

Additional assessment tools and diagnostic procedures for PAD also include a walking impairment questionnaire (WIQ), treadmill exercise testing, lipid profile, and magnetic resonance angiogram. The WIQ is used to assess the ability of patients to walk defined distances at certain speeds and to climb stairs.

Differential Diagnosis

Differential diagnoses for PAD may include chronic venous insufficiency, thrombosis, phlebitis, polycythemia, anemia, Raynaud's disease, vasculitis such as Buerger's disease, aneurysms, and peripheral neuropathy.

Management

Treatment for PAD is aimed at improving blood flow by removing or lessening the cause of impaired circulation. Because the condition is usually chronic and irreversible, treatment involves education and lifestyle changes.

Patients with PAD should be counseled about modification of risk factors, and hypertension and diabetes should be aggressively managed. The clinician should encourage the patient to walk at least 30 minutes three to four times per week. Any ulcers or traumatic lesions to the extremities will need immediate care. The patient should be encouraged to keep the legs dependent (below the level of the heart) to improve blood flow and, therefore, oxygenation in the extremities. Tight bandages and stockings should be avoided.

Although drug therapy is not a substitute for exercise, some medications have been helpful in extending ambulation distances for more than 25% of patients.

Patients with PAD should be started on antiplatelet therapy with aspirin, or if they cannot tolerate aspirin, clopidogrel. These antiplatelet agents do not provide a measurable improvement in symptoms of claudication but are prescribed to reduce the risk of concomitant atherosclerotic disease such myocardial infarction and stroke. Current ACC/AHA guidelines recommend pentoxifylline as a second-line drug to cilostazol for the treatment of claudication. Cilostazol is a phosphodiesterase-3 inhibitor that causes vasodilation and in addition inhibits platelet aggregation. Cilostazol may be ordered specifically to treat leg pain and cramping due to the blockages from atherosclerosis in the leg arteries. Head-to-head trials have demonstrated that cilostazol is more effective at reducing symptoms of claudication compared with pentoxifylline because the former lengthens the pain-free walking distance for patients with claudication. Cilostazol should not be prescribed in the presence of any degree of heart failure because this is a contraindication to its use.

Most patients with moderate PAD can be effectively managed with medical therapy and risk modification alone. Surgical intervention and angioplasty are used selectively in patients with severe PAD. Indications for surgical or percutaneous revascularization include profound functional and occupational limitation due to claudication, disease refractory to pharmacological therapy, and limb-threatening critical ischemia. Patients must be able to demonstrate improvement in their symptoms on revascularization and not be severely disabled by other comorbid conditions (e.g., severe pulmonary disease, heart failure, coronary artery disease) that may render revascularization futile.

Follow-up and Referral

All patients with peripheral artery disease should be followed at least every 3 months to assess the effectiveness of lifestyle changes, skin care, and management of ulcers. If ulcers are present, the patient may need to be seen on a weekly basis. Patients with PAD may be referred to a vascular surgeon for evaluation and potential surgery, including a balloon angioplasty in the distal extremity or an arterial graft using a section of the great saphenous vein or a synthetic graft.

Patient Education

Patients who have been diagnosed with PAD should be counseled about the modification of risk factors. They should totally abstain from nicotine. It is essential to control hypertension and diabetes if present. Dietary control must include limitation of fat and salt intake. Patients must be taught to do meticulous daily foot care that includes inspecting feet daily for sores, ulcers, and abrasions, including the use of a mirror to check the soles of the feet. Patients should not walk barefoot and should wear well-fitting supportive shoes. They should not soak their feet and should be careful trimming their nails. All patients should be taught to watch for the signs and symptoms that might indicate progressive ischemia, such as increased pain, increased pallor or cyanosis, and rest pain.

Patients with PAD should be encouraged to perform Buerger-Allen exercises three to four times per day. The

clinician should teach the patient to raise and lower the extremities, with each of five repetitions taking about 2 minutes. The legs should be raised to a 45-degree angle, and then lowered again to the supine position. The changes in position cause the veins of the legs to refill by gravity.

Additionally, exercise therapy is recommended for peripheral artery disease because it stimulates collateral vessel growth in the lower extremities. Patients should be encouraged to walk distances until moderate pain occurs, stop until pain subsides, and then resume walking. A supervised treadmill walking program three times a week over a 6-month period is part of cardiovascular rehabilitation. Treadmill grade and speed are gradually increased over time as the patient improves.

DEEP VEIN THROMBOSIS/ CHRONIC VENOUS INSUFFICIENCY

Deep vein thrombosis (DVT) is a disorder of the venous system characterized by clot formation in the deep vessels of the venous vasculature. DVT primarily results as a complication associated with Virchow's triad—venous stasis, endothelial injury, and hypercoagulable state. The resulting thrombus formation may lead to a variety of complications including chronic venous insufficiency and, most notably, pulmonary embolism (PE). Pulmonary embolism is a potentially life-threatening complication of DVT in which venous thrombi propagate to the pulmonary vasculature resulting in respiratory compromise. Chronic venous insufficiency is a disorder characterized by valvular incompetence, which manifests as lower extremity edema, skin discoloration, and ulceration as a result of poor antegrade venous flow. Although the condition is commonly a complication of DVT, it may be the result of inflammatory conditions such as phlebitis or anatomical disturbances.

Epidemiology and Causes

Chronic venous insufficiency and varicose veins usually result from venous incompetence secondary to valvular dysfunction. More than 20% of the population is affected with chronic venous insufficiency; the incidence increases with age with no evident ethnic predisposition. Chronic venous insufficiency is more common in women than men. DVT and PE are complications encountered during the treatment of medical and surgical patients. Risk Factors Box 10.3 presents risk factors for DVT. Approximately 300,000 to 600,000 hospitalizations can be associated with DVT and PE each year. Up to 50,000 deaths occur annually because of PE. It is estimated that there are more than 2 million cases per year of DVT. The actual number of cases is often underdiagnosed due to the silent nature of the problem.

Patients undergoing various types of surgical procedures, such as orthopedic, gynecological-obstetric, urological, neurosurgical, and general surgical procedures, are at high risk for developing DVT and PE. Of these groups, orthopedic patients appear to be especially prone to thrombosis, particularly patients with hip fracture. All elective orthopedic surgical patients undergoing lower extremity surgery are at risk for DVT. The risk is greatest for patients undergoing hip surgery and knee reconstruction, for which DVT rates range from 45% to 70%.

Risk Factors 10.3 Risk Factors for Deep Vein Thrombosis (DVT)

Virchow's Triad	Clinical Risk Factors for DVT
Venous Stasis	Immobility
	Venous insufficiency
	Prolonged sedentary position
	Post-stroke
	Post–myocardial infarction
	Heart failure
Vessel Injury	Trauma
	Surgery (especially orthopedic)
	Indwelling IV catheters
Hypercoagulability	High estrogen states (oral contraceptives or hormone replacement therapy)
	Pregnancy/postpartum period
	Cancer
	Inherited coagulation abnormalities

Source: Teri Capriotti, DO, MSN, CRNP.

Patients with various types of medical diseases, usually chronic, are also at a high risk for venous thrombotic events. The risk of DVT in pregnancy has been reported to be five times higher than in nonpregnant patients in the same age-group and may be increased postpartum. A silent DVT may cause a postphlebitic syndrome. The postphlebitic syndrome is characterized by swelling and pain in an extremity that was previously affected by thrombophlebitis. A frequent complication of DVT is PE, which can obstruct blood flow to the lungs and cause significant morbidity. The mortality of PE is estimated to be approximately 30%, although with the availability of newer diagnostic tools such as computed tomography angiogram, which can detect smaller peripheral emboli, it is estimated that the actual mortality rate of PE is about 10%. More than 80% of patients who died from a pulmonary embolism showed DVT on autopsy.

Pathophysiology

Clots can originate anywhere in the venous system, but the majority begin in the deep veins of the pelvis and lower extremities, with a significant number at or above the popliteal vein. Clots that originate in the proximal

veins are potentially more dangerous because they are larger in size and result in more clinically significant thromboembolic events.

The causative factors in the formation of blood clots are referred to as *Virchow's triad* (see Risk Factors Box 10.3). Clots are likely to form when two of the three factors in the triad—stasis, vessel wall damage, and coagulation changes—are altered. Stasis of blood may result from immobility, edema, or anesthesia; blood tends to coagulate in and around the valve cusps of the veins, thus increasing the likelihood of clot formation. Vessel wall damage may result from trauma, surgical incision, laceration, venous wall distention from immobility or anesthesia, or a previous DVT. Coagulation changes leading to activated coagulation factors as a result of damaged endothelium may be the result of surgery, trauma, injury, disease states (such as sepsis, infection, or cancer), pregnancy, or foreign substance invasion via IV lines or catheters. The damaged endothelium causes the local activation of coagulation factors as platelets come in contact with the exposed collagen found in connective tissue, including skin, bone, ligaments, and cartilage. The platelets release substances that cause vasoconstriction and accelerate clotting.

Once formed, a DVT can propagate, embolize, or lyse. When the clot propagates, it extends proximally and becomes larger and thus more dangerous, by obstructing blood flow, which causes the vein to dilate and the vessel wall to be damaged. When a clot embolizes, it travels; it may lodge itself in the arteries of the lungs, resulting in PE. When a clot lyses, it breaks down. Even if a clot lyses, it can still cause irreversible valve damage by allowing blood to reflux in the veins. The damage sets up a cycle of pooling and hypertension known as the postphlebitic syndrome. Patients with this syndrome experience chronic pain, swelling, and venous ulcers.

Deep venous thrombophlebitis/thromboembolism is a critical disorder of the veins of the lower extremity. The presence of a thrombus within a deep vein with an accompanying inflammatory response is termed *deep venous thrombophlebitis or deep venous thrombosis.* If the thrombus breaks away from the wall of the vein and travels upward toward the heart, it is termed a *venous thromboembolism.* Common causes of hypercoagulability are estrogen use, pregnancy, and neoplasms. Venous stasis occurs most often as a result of immobility. Vascular injury can be due to surgery or trauma. Orthopedic surgery is a major risk factor for DVT, and there is a high incidence of concurrent DVT in persons with cancer of the pancreas, lungs, breast, genitourinary tract, and stomach.

The signs of DVT may be subtle. Overt signs of DVT may include tenderness and a palpable cord along the course of a vein, although more often than not the only sign is a unilateral swelling of an extremity with or without signs of inflammation. The most common complaint is calf pain. Although used in the past, a positive *Homans' sign* (pain on dorsiflexion of the foot) is now considered an unreliable diagnostic indicator.

PE is a potential complication of DVT. The venous thrombus may break free from the venous wall and travel from the lower extremity to the inferior vena cava and up to the right atrium, right ventricle, and into the pulmonary arterial circulation. This may cut off blood flow to an entire lung segment, resulting in potentially fatal ventilation/perfusion (VQ) mismatch. In addition, any abnormal communication between the right and left chambers of the heart (e.g., atrial septal defect, patent foramen ovale, ventricular septal defect) creates the potential for cerebral thromboembolism (i.e., cerebrovascular accident or stroke).

It is critical to diagnose DVT early because the complication of PE can be life-threatening. A PE is a thrombus that obstructs circulation within the lungs, causing lack of oxygenation of blood. Signs of pulmonary embolism can be subtle or severe depending on the size of the embolus. Sudden death can result from pulmonary embolism and may not be heralded by clearly observable signs of DVT.

Chronic venous insufficiency is a disorder of the valves within the deep veins of the lower extremities. Valves within veins assist venous blood to flow upward toward the heart, regulating unidirectional flow by preventing retrograde flow of venous blood away from the heart. Weakened venous valves do not form tight closures, failing to prevent retrograde blood flow. The appearance of superficial varicose veins may be associated with chronic venous insufficiency. Superficial varicose veins are benign in most cases and are treatable with conservative measures. However, under more severe circumstances, venous stasis results, as excess pressure builds up in the legs, causing distention of the veins, thinning and scaling of the skin with dusky discoloration (stasis dermatitis), and eventually large venous ulcers. In addition, dependent edema and poor wound healing result.

Clinical Presentation

Subjective

Although many lower extremity thrombi are silent, the patient may present with a complaint of pain in the calf muscle, slight swelling, or muscle tenderness.

The patient with chronic venous insufficiency will complain of dependent edema, venous engorgement (varicose veins), and localized pain. The patient may complain of a darkened color in the lower extremities, along with dryness and scaling of the skin.

Objective

In patients with DVT, the clinician may note slight swelling, muscle tenderness, and pain in the calf muscle. The clinician may assess for warmth or heat of the affected extremity and note distention of the superficial veins. A slight fever and tachycardia may also be present. An acute DVT in the femoral or iliac veins may show

symptoms of tenderness over the veins, swelling, and a slightly bluish skin color.

In patients with chronic venous insufficiency, the clinician may note a brownish hyperpigmentation of the extremities, edema, subcutaneous fibrosis, and possibly leg ulcers. When the clinician elevates the extremity, the sharp, deep muscle pain may be lessened. The peripheral pulses may be normal or diminished. There may be superficial ulcers around the medial malleolus.

Diagnostic Reasoning

Diagnostic Tests

If a diagnosis of DVT is suspected, the clinician should first assess the clinical pretest probability of thrombosis. This may be done using a clinical probability assessment model such as the Well's criteria. Further diagnostic work-up is contingent on the patient's clinical likelihood of DVT. If the patient is determined to have a low clinical probability of DVT, a D-dimer level may be ordered. In patients with an intermediate or high clinical probability of DVT, a Doppler ultrasound of the lower extremity should be obtained in order to confirm the diagnosis.

If the results of the ultrasound are inconclusive and the clinical suspicion for DVT is high, an ascending venogram may confirm the diagnosis. The ascending venogram has long been considered the "gold standard" for diagnosis of venous thromboembolism, although if an ultrasound confirms the diagnosis, usually no further testing is done. An ascending venogram is performed by injecting a contrast material into a vein in the foot. Sequential x-ray films are taken that may show abnormalities such as vein-filling defect, formation of collateral veins, or abrupt termination of the contrast material along the vein. One risk of the ascending venogram, however, is an actual DVT because the invasive nature of the procedure may actually cause the thrombus to release.

Magnetic resonance imaging (MRI) is an alternative to a venogram. MRI is expensive and should be reserved for those who cannot tolerate the IV dye needed for a venogram. Venous ultrasound and venogram are more cost effective. If pulmonary embolus is suspected, a VQ scan or a spiral CT of the pulmonary artery would be indicated.

The D-dimer assay can be helpful in ruling out, but not definitively confirming, the diagnosis of DVT. D-dimer is a breakdown product of fibrin and is positive in venous thrombosis and PE. However, the D-dimer assay has low specificity and cannot be solely relied on for diagnosis. If a D-dimer is present, it does not prove a DVT exists, because many conditions cause a positive result. However, if the D-dimer is negative, it effectively rules out the presence of DVT.

To confirm venous insufficiency if the history and physical exam are inconclusive, a venogram may be performed. This is a radiological test in which the vein is injected with a radiopaque dye. Sequential films will show the engorged and tortuous veins. In addition, plethysmography may be done to determine the changes in the fluid volume of the extremities. The air-cuff plethysmography measures the changes in the circumference of a limb by recording the changes in pressure in an air-filled cuff surrounding the extremity. This test is rarely done because the history, physical exam, and other tests are usually adequate to confirm the diagnosis.

Differential Diagnosis

Patients with chronic venous insufficiency may exhibit some of the symptoms of DVT. Patients who suffer from chronic venous insufficiency have swelling and dilated superficial veins. They may also complain of aching or fatigue in the legs while standing or walking. Other differential diagnoses for DVT include cellulitis, lymphedema, and a strained muscle.

Management

Chronic Venous Insufficiency

For the patient with chronic venous insufficiency, conservative treatment is effective in alleviating symptoms in 85% of patients. The dependent edema can be a guide to the effectiveness of therapy. The clinician should order light exercise, support or compression stockings, and weight loss and should stress the need to elevate the legs several times each day for approximately 30 minutes. Subsequent management involves aggressively treating any ulcers and reducing factors that cause atherosclerosis.

Deep Vein Thrombosis

Pharmaceutical modalities prevent coagulation changes in the blood that result in clot formation or prevent extension of the clot. Low-dose fractionated or unfractionated heparin, administered subcutaneously, is considered the mainstay of therapy for DVT. Some potential complications of low-dose heparin therapy include bleeding, wound hematoma, and thrombocytopenia. Low-dose heparin therapy is contraindicated for neurosurgical procedures, especially intracranial procedures.

Patients with DVT can be treated in an inpatient or outpatient setting (for an otherwise healthy patient with no significant comorbidities). In the hospital, patients are treated aggressively with anticoagulant therapy, IV unfractionated heparin, or low molecular weight heparin (LMWH) and monitored for signs of further thrombosis or iatrogenic bleeding. An initial IV bolus of heparin (5,000–10,000 units IV) should be followed by a continuous infusion at 1,000 units per hour. The dosage of heparin should be adjusted according to the partial thromboplastin time (PTT). The goal is to achieve a PTT of two times the control value. Alternatively, LMWH can be used as inpatient or outpatient management of DVT until warfarin is at a therapeutic level. Candidates for outpatient heparin therapy must have a supportive environment, be hemodynamically stable, be without renal failure, and not be at high risk for bleeding. Enoxaparin (Lovenox), dalteparin (Fragmin), and tinzaparin (Innohep) are examples of types of LMWH. LMWH

can be administered subcutaneously once or twice daily. Lovenox may be used at 1 mg/kg injected subcutaneously every 12 hours. In this case, PTT need not be followed, although factor Xa levels may be measured to assess for therapeutic response to confirm the appropriateness of the dose. The side effect of thrombocytopenia is less likely, and less laboratory testing is required. Simultaneous initiation of warfarin and LMWH has not shown any adverse effects.

Only unfractionated heparin is readily reversible after several hours, once the IV drip is turned off. Subcutaneously injected LMWHs, on the other hand, will exert their effect for at least 12 hours after each dose. Warfarin therapy should be initiated after the patient has been on heparin for 1 to 5 days although the trend now is to start warfarin soon after heparin. Warfarin should be started at 5 to 10 mg orally daily, with the dose adjusted to the PT and INR, as stated previously.

If anticoagulant therapy is contraindicated, filtering devices such as a vena-cava filter may be used to trap emboli before they reach the lungs and cause a PE. Inferior vena caval filters are mechanical barriers that are inserted in the large vena cava under percutaneous radiological guidance. Although they do not prevent clot formation, they prevent clot migration from the legs to the lungs.

High-risk patients should also have nonpharmacological prophylaxis with intermittent pneumatic compression for at least the first 5 days of therapy. External pneumatic compression and gradient compression stockings are effective alternatives for decreasing lower leg thrombosis if lower extremity trauma does not preclude their use. Patients should also elevate the affected limb, apply heat, and limit activity.

Thrombolysis is not indicated for DVT except in cases of massive ileofemoral thrombus. Thrombolytic agents are indicated for patients with massive PE and associated hemodynamic instability. The role of thrombolysis in patients with lesser size PEs is controversial.

Follow-up and Referral

Most patients with acute DVT are hospitalized for about 1 week. Follow-up therapy for these patients includes anticoagulant therapy for 6 months after an initial episode of DVT and for 1 year after each subsequent episode. The clinician will follow the patient after he or she is released from the hospital. The patient on warfarin must be seen daily until the target INR range is achieved (usually in the hospital), then on a monthly basis thereafter.

Patient Education

Patients should be educated about DVT and treated prophylactically, depending on the number of risk factors exhibited and the resulting need for hospitalization or surgery. To prevent DVT, prophylactic modalities should be used for all patients at risk, including pharmacological, physical or mechanical, or a combination of the two.

Physical modalities that prevent DVT by reducing stasis include leg elevation, passive leg exercises, and early ambulation. Although these techniques are somewhat effective, each has some drawbacks and should be combined with other physical measures such as graduated elastic compression or external pneumatic compression devices. Graduated compression stockings provide safe, simple, and inexpensive prophylaxis. Besides preventing stasis, they also prevent venous distention, which potentially initiates vessel wall damage. Pneumatic compression devices are more effective at emptying the veins, sustaining femoral blood flow velocity, and expelling the blood from behind the valve cusps in the femoral vein, thus stimulating fibrinolysis.

Education for patients recovering from DVT includes teaching about the need to avoid trauma to the affected veins. The clinician should be educated regarding potential adverse effects of the anticoagulant medication, including signs and symptoms of bleeding, and when to seek medical care. The patient must avoid food fads and crash diets and should not drink alcohol or take vitamin E, cold medicines, antibiotics, aspirin, cimetidine (Tagamet), thyroid hormones, or NSAIDs without first consulting the clinician. Immobility should be discouraged. Patients must know when to return for a follow-up PT if they are on warfarin.

Chapter 11

Abdominal Problems

Debera J. Thomas, DNS, RN, FNP/ANP •
Dorothy J. Dunn, PhD, RNP, FNP-BC, AHN-BC

COMMON COMPLAINTS

ABDOMINAL PAIN

Abdominal pain is one of the most common complaints for which people seek medical attention. According to the 2010 National Ambulatory Medical Care Survey, abdominal pain is one of the top 20 leading principal reasons for office visits. Colorectal cancer is the fourth most common cancer and the third most common cause of cancer deaths. The *National Vital Statistics Reports* (Centers for Disease Control and Prevention, 2012) revealed that chronic liver disease and cirrhosis continues to rank twelfth in the leading causes of death. The causes of abdominal pain are numerous; a few are serious enough to require surgical intervention. Conditions associated with an acute abdomen can be inflammatory, metabolic, or structural; therefore, any acute abdominal pain must be evaluated quickly and precisely. Abdominal pain that occurs without any other signs or symptoms is rarely a serious problem. In instances when the exact cause of pain is not immediately evident, an empiric trial of therapy or test selection may help suggest the underlying pathophysiology, narrow the differential diagnoses, and guide further assessment and treatment. It is important to keep in mind that extra-abdominal etiologies such as ovarian cancer, ectopic pregnancy (see Chapter 14), or myocardial ischemia (see Chapter 10) may present as abdominal pain.

Half of patients who complain of abdominal pain do not receive an accurate diagnosis. The source of the abdominal pain may be from one of a triad of vascular emergencies: mesenteric ischemia, abdominal aortic aneurysm, or myocardial infarction. Conditions in this triad can cause severe pain and should not be excluded from the differential diagnosis.

Differential Diagnosis

Total patient presentation must be considered when evaluating abdominal pain. A careful history is the key to determining the severity of the condition. The onset, location, duration, characteristics, any associated/aggravating factors, relieving factors, temporal factors, and severity, as well as what the pain means to the patient, are useful in the diagnostic reasoning. The presence or absence of bowel sounds is also an important diagnostic factor. Tachycardia, tachypnea, and hypertension often indicate the intensity of the pain. Many nonsurgical conditions can present with classic acute "surgical" abdomen symptoms such as intense pain, rebound tenderness, and guarding. All patients with abdominal pain should undergo rectal, genital, and pelvic evaluations. Blood found in the stool or intense pain on examination may indicate more serious conditions.

The mechanism responsible for the abdominal pain is what gives certain characteristics to the pain. For example, pain that originates from pain receptors located in the viscera (organs) produces pain that is poorly localized and is described as dull. This is known as *visceral pain* and is caused by distention or spasm of a hollow viscus. Distention of an organ capsule, such as Glisson's capsule around the liver; vascular compromise; and mucosal irritations cause pain that is visceral in nature. Conversely, *parietal pain,* described as sharp and well localized, is caused by irritation of the peritoneum. Appendicitis often causes this type of pain as the peritoneum becomes involved. *Abdominal pain* described as colicky, which simply means that it comes and goes, may result from gallstones or renal stones. *Burning pain,* caused by irritation of the gastric mucosa by gastric contents, is associated with peptic ulcers and esophagitis.

A thorough history and physical examination are essential to narrow the list of differential diagnoses of patients with abdominal pain. First, the nature of the pain should be elicited in order to provide clues to the mechanism of the pain. Location of the pain is valuable information, but it is important to remember that abdominal pain can be referred from areas outside of the abdomen. Timing of the pain (onset, duration, frequency, and relationship to associated symptoms) can help eliminate some causes. The palliative and provocative aspects of the pain can give clues about the cause of the pain. For example, does moving, eating certain foods, assuming different positions, or taking medications make the pain better or worse? Associated symptoms will further narrow the list of diagnostic possibilities. Some causes of abdominal pain will necessitate a surgical referral. Any time the pain is very severe and associated with a rigid abdomen, referral to a physician is essential. Abdominal pain can be the presenting symptom of many different pathophysiological

processes, ranging from very mild gastritis to more serious forms of abdominal pain associated with bowel obstruction or appendicitis.

A complete blood count, serum chemistries, liver function tests, urinalysis, pregnancy test, and abdominal films will help determine the acuity of the problem. Differential Diagnosis Flowchart 11.1 presents selected causes of abdominal pain and their characteristics. Treatment of abdominal pain depends on the cause.

CONSTIPATION

Constipation is a common symptom in Western society and is the most common gastrointestinal (GI) disorder in the United States, particularly in older adults and sedentary individuals. There is no single definition of constipation, although it is often defined as a change in a person's normal bowel pattern, either a decrease in frequency or an increase in difficulty of defecation. The clinician and the patient must have a similar operational definition of constipation and what a normal bowel pattern is for that patient.

The most common cause of constipation in the United States is a lack of dietary fiber; the recommended amount is 30 grams daily for optimal bowel health. The average American consumes only about 10 grams per day. Other common causes of constipation are habitual use of laxatives, irritable bowel syndrome (IBS), decreased physical activity, a change in environment or travel, use of medications with constipating potential, suppression of the urge to defecate, and painful defecation caused by anorectal problems. Other less common but serious causes of constipation include bowel tumors and metabolic disorders such as hypothyroidism, diabetes, hypercalcemia, and depression.

Generally, there are three categories of constipation: simple constipation, disordered motility, and secondary constipation. *Simple constipation* results from a diet that is low in fiber and high in simple carbohydrates and meat. A sedentary lifestyle is also a common contributor to constipation. In addition, some people have difficulty defecating in an environment other than their own home; they frequently suppress the urge to defecate, thereby promoting simple constipation. The next most common category of constipation is *disordered motility,* which is seen most often in older adults and is caused by slowed transit time. Megacolon and megarectum are also common disorders of motility, but they most frequently occur in children with conditions such as Hirschsprung disease. Other conditions that cause disordered motility and constipation include IBS and diverticular disease. *Secondary constipation* often is a result of medications such as codeine, morphine, analgesics, calcium channel blockers, antidepressants, antiparkinsonian drugs, cough medicine, and aluminum antacids. Table 11.1 presents a list of constipating drugs. Other common causes of secondary constipation are chronic laxative use, prolonged immobilization, and organic diseases of the lower GI system, such as colorectal cancer.

Chronic constipation rarely results from a serious condition, and the patient can usually be treated symptomatically by increasing dietary fiber. Those whose constipation developed with a recent disability, a change in diet, recent depressive illness, or the ingestion of a constipating medication can also be treated symptomatically. Patients who develop constipation that cannot be explained, have abdominal pain, report blood or mucus in their stool, or require a substantial increase in their laxative use require more investigation. Constipation occurs in fewer than 30% of patients with colon cancer.

Table 11.1 Medications That Commonly Cause Constipation

- Aluminum-containing antacids
- Anticholinergics
- Anticonvulsants
  - Phenobarbital
  - Phenytoin
  - Carbamazepine
- Antidepressants
  - Amitriptyline
  - Doxepin
  - Imipramine
  - Nortriptyline
  - Protriptyline
- Antihistamines
- Antihypertensives
  - Calcium channel blockers
  - Clonidine
- Antiparkinsonian drugs
- Antipsychotics
- Bismuth-containing products
  - bismuth subsalicylate (Pepto-Bismol)
- Iron preparations
- NSAIDs
- Opiates
  - Codeine
  - Morphine
  - Heroin
  - Fentanyl
  - Methadone
  - Propxyphene
- Sympathomimetics

Differential Diagnosis

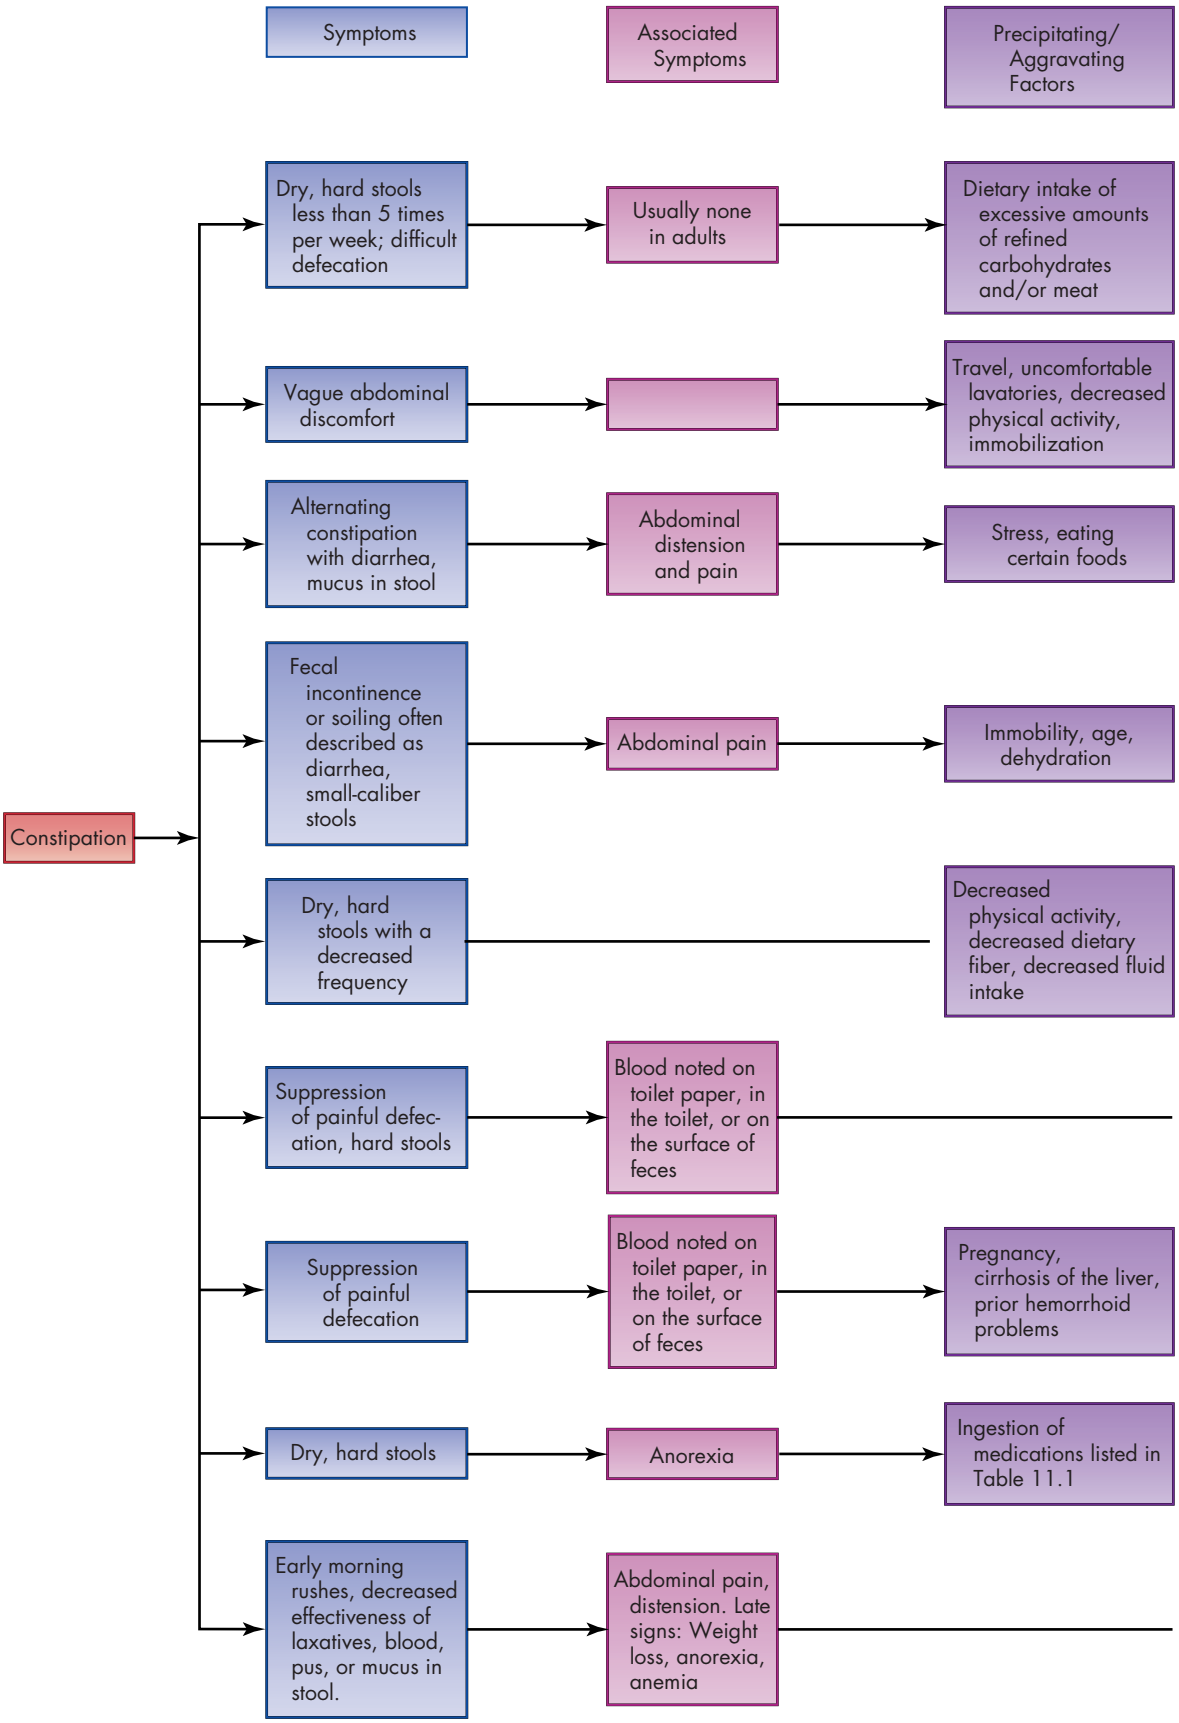
An accurate description of the feces can give clues to the cause of the constipation. For example, ribbon-like stools often indicate a motility disorder but can also be caused by an organic narrowing of the distal or sigmoid colon. If the patient complains of a progressive decrease in the diameter of the stools, this suggests an organic lesion. If steatorrhea and greenish-yellow stools are associated with the constipation, the practitioner should look for a small bowel or pancreatic lesion. Constipation alternating with diarrhea is often a result of IBS.

The cause of constipation is multifactorial, which can make the differential diagnosis difficult. Differential Diagnosis Flowchart 11.2 presents various causes of constipation.

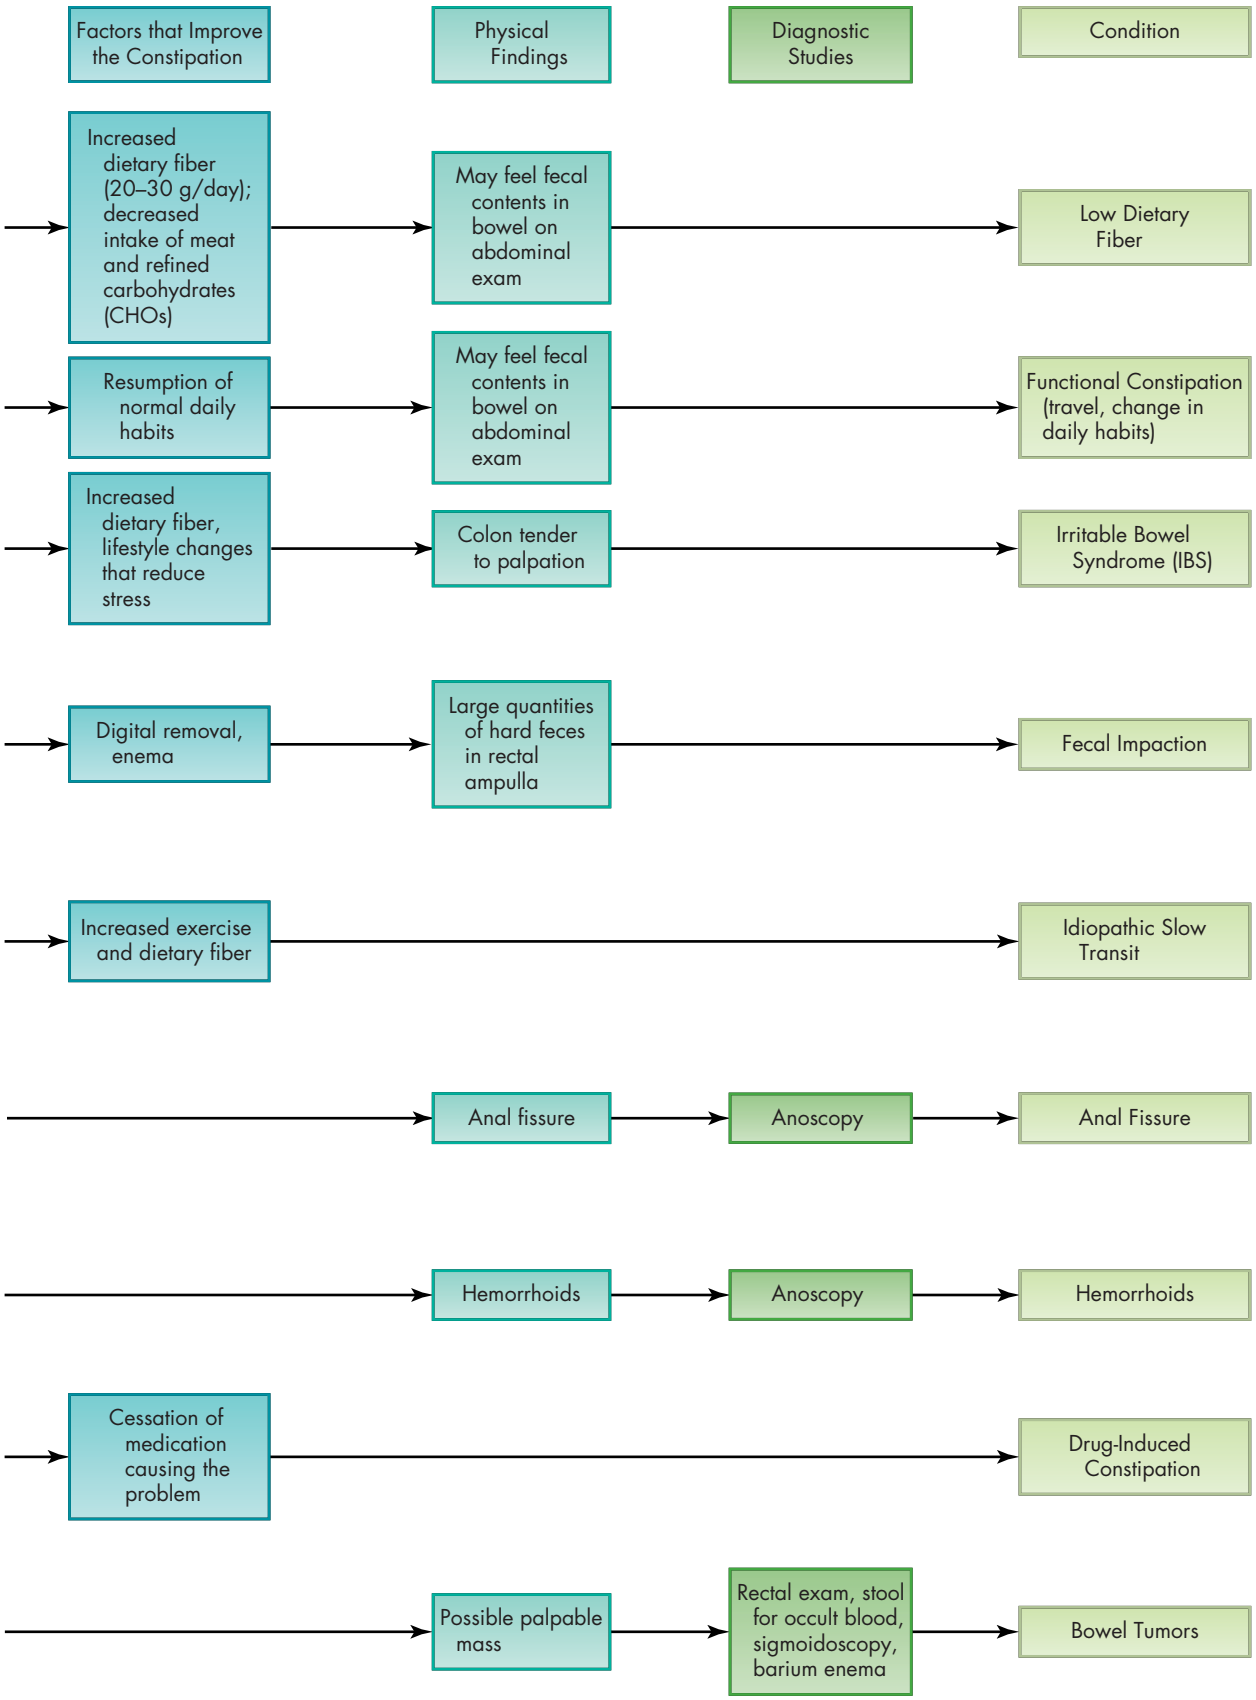
Treatment

The management of simple constipation is straightforward. Most patients respond well to education about bowel habits, activity, and dietary intervention. Some patients may require pharmacological intervention as well. Patients should be instructed to slowly increase the amount of dietary fiber to 25 to 35 grams per day, with at least 12 to 15 grams at breakfast. Mild exercise after the morning meal is often helpful in stimulating peristalsis and promoting defecation. Uninterrupted toilet time in the morning is also helpful. Adequate hydration is essential in the prevention of constipation; patients should be encouraged to drink at least 64 ounces of fluids daily.

Differential Diagnosis Flowchart 11.2



Differential Diagnosis Flowchart 11.2 (continued)



Treatment with a pharmacological agent may be needed for patients who do not respond to increases in fiber, fluids, and exercise. Most drugs should be used for a short time only, and most are available without a prescription. Because these agents are available without a prescription, patients may have self-medicated for some time; and by the time they seek medical attention, they may either have overused laxatives or may have a more serious underlying pathology. The only agents that are appropriate for long-term use are the bulking agents. The different agents used in the treatment of constipation are listed in Drugs Commonly Prescribed 11.1.

DIARRHEA

Just as with constipation, there is no single definition of diarrhea, but it is generally defined as an increase in the frequency, volume, or fluid content of bowel movements over what is normal for the individual. Because dietary intake of fiber in the United States is low, the average daily stool for each individual weighs about 200 grams. For most individuals, if the daily stool is more than 200 grams or the frequency of bowel movements is more than three times a day, the patient's condition can be considered diarrhea. Diarrhea is one of the most common presenting complaints in primary-care practice.

There are several types of diarrhea. The first is *osmotic diarrhea,* which is seen in patients with injury to the small intestine that results in malabsorption or maldigestion of nutrients, as in patients with short bowel syndrome. Lactase deficiency or disaccharidase deficiency can also cause osmotic diarrhea, as can ingestion of poorly absorbed solutes such as magnesium sulfate, laxatives, and sorbitol. Osmotic diarrhea usually responds to fasting. Celiac disease is described as a malabsorption syndrome related to immune reaction to gluten in the diet. It is most common in women, and the peak incidence is in women aged 40 to 50 years. Gluten is found in food products that contain wheat, barley, and rye. The effects on the intestinal mucosa cause the villi to become flat, the crypts to hypertrophy, and an increased number of intraepithelial lymphocytes and plasma cells to appear. Complications such as collagenous sprue and intestinal ulcers, nutritional complications, and malignancy are possible. The patient will have a history of chronic diarrhea, foul-smelling stools, abdominal bloating, weakness, and fatigue. A presumptive diagnosis is based on a combination of clinical presentation and positive serology. Distal duodenal biopsy is needed to confirm the diagnosis. Treatment includes a lifelong gluten-free diet and treatment of nutritional deficiencies such as iron, folate, and vitamin B_{12}.

Another type is *secretory diarrhea,* which produces voluminous watery stools but is unresponsive to fasting. Secretory diarrhea is primarily the result of bacterial enterotoxins (most notably from cholera and strains of *Escherichia coli*). But it can also be caused by laxative abuse; bile salt malabsorption, which stimulates colonic secretion; and endocrine tumors that stimulate pancreatic or intestinal secretion.

Diarrhea is associated with *morphological changes* within the mucosa of the intestinal wall that occur with inflammatory conditions of the intestines, and these changes can result in acute or chronic diarrhea. Both Crohn's disease and ulcerative colitis cause inflammation of the mucosa of the intestinal lumen, resulting in diarrhea.

Diarrhea can also result from *altered intestinal motility* secondary to diabetic neuropathy, dumping syndrome, or irritable bowel syndrome (IBS). Some medications, such as antibiotics, can induce diarrhea by disrupting the normal balance of bacteria. Probiotics have been studied in the treatment of diarrhea. A systematic review

Drugs Commonly Prescribed 11.1 Pharmacological Agents Used to Treat Constipation

Drug	Indication	Adverse Reactions and Prescribing Considerations
Bulking agents Psyllium preparations Methylcellulose preparations	IBS Chronic constipation Diverticulitis	Causes flatulence, bloating and requires adequate fluid intake.
Stool softeners Docusate sodium	Frequently used for prevention of constipation, but not effective.	Hepatotoxic if combined with irritant laxatives.
Saline laxatives Magnesium hydroxide	Intermittent use in chronic constipation and bowel prep.	Can cause dehydration and electrolyte imbalance.
Stimulant/irritant laxatives Bisacodyl Senna Cascara	Acute constipation; should not be used for chronic constipation.	Patient can become dependent. Also causes dehydration and electrolyte imbalance.
Lubricants Mineral oil	Intermittent use in chronic constipation.	Can cause lipid pneumonia if aspirated.

of 63 probiotic studies of adults and children revealed that the duration of antibiotic-associated diarrhea was shortened by a mean of 25 hours with probiotics and hydration therapy. In another systematic review, acute infectious diarrhea of children with rotovirus concluded a decrease of between 17 and 30 hours in diarrhea duration with probiotics (Level II; Piascik & Sanders, 2012). Probiotic use for travelers' diarrhea, *Clostridium difficile,* and inflammatory bowel disease (IBD) has not proved efficacious. Pathogenic bacteria also cause increases in gastrointestinal motility and intestinal secretions. There have been promising results with the use of fecal microbiota transplantation (stool transplant) for the treatment of *C difficile* diarrhea. This procedure involves taking fecal bacteria from a healthy person and infusing this via enema into the person with the *C difficile* infection.

Differential Diagnosis

Differential diagnosis of diarrhea is aided by separating acute diarrhea from chronic diarrhea. *Acute diarrhea* usually has an abrupt onset and lasts for less than 1 week. Nausea, vomiting, or fever may be associated with acute types of diarrhea. On the other hand, *chronic diarrhea* lasts for more than 2 weeks or recurs over months or years. When diarrhea occurs suddenly in an otherwise healthy patient without signs or symptoms of other organ involvement, the most likely cause is an infectious agent, most often viral. The most frequent causes of chronic diarrhea are IBS, medications, dietary factors, IBD, and colon cancer.

A thorough history and comprehensive review of systems can elicit information that the patient may not think is important but that can facilitate diagnosis. For example, recent travel is particularly important because viral, bacterial, and protozoan causes are endemic in many areas. Hikers and campers in the United States who drink unfiltered water are at a high risk for giardiasis. Focus on History 11.1 presents important information to obtain from the patient's history.

Acute viral gastroenteritis is the most common cause of diarrhea. (Gastroenteritis is discussed in detail later in this chapter.) Other common causes of diarrhea the practitioner should consider are IBS, IBD, ingestion of magnesium-containing antacids, lactose intolerance, antibiotic therapy, laxative abuse, and AIDS. Differential Diagnosis Flowchart 11.3 presents the differential diagnosis of diarrhea.

Focus on History 11.1 Diarrhea

Characteristics of Feces

- Frequency
- Amount and fluidity
- Color and characteristics: Bloody, tarry, black, steatorrheaic, mucus

Other History

- Diet history: Intolerance to lactose or certain foods
- Recent travel
- Source of drinking water: Well or city water supply
- Medication use: Magnesium-containing antacids, antibiotics, chemotherapy, immunosuppressive agents
- Medical/surgical history: Diabetes mellitus, hyperthyroid, human immunodeficiency virus (HIV), organ transplant, GI surgery
- Sexual practices: Frequency of anal intercourse, number and sex of partners
- Social history: Living conditions
- Family history: Colon cancer, inflammatory bowel disease

Dimensions of the Problem

- Associated symptoms: Abdominal pain, fever, vomiting, neurological symptoms, headache, malaise, myalgia, muscle weakness
- Exacerbating or alleviating factors

DYSPEPSIA AND HEARTBURN

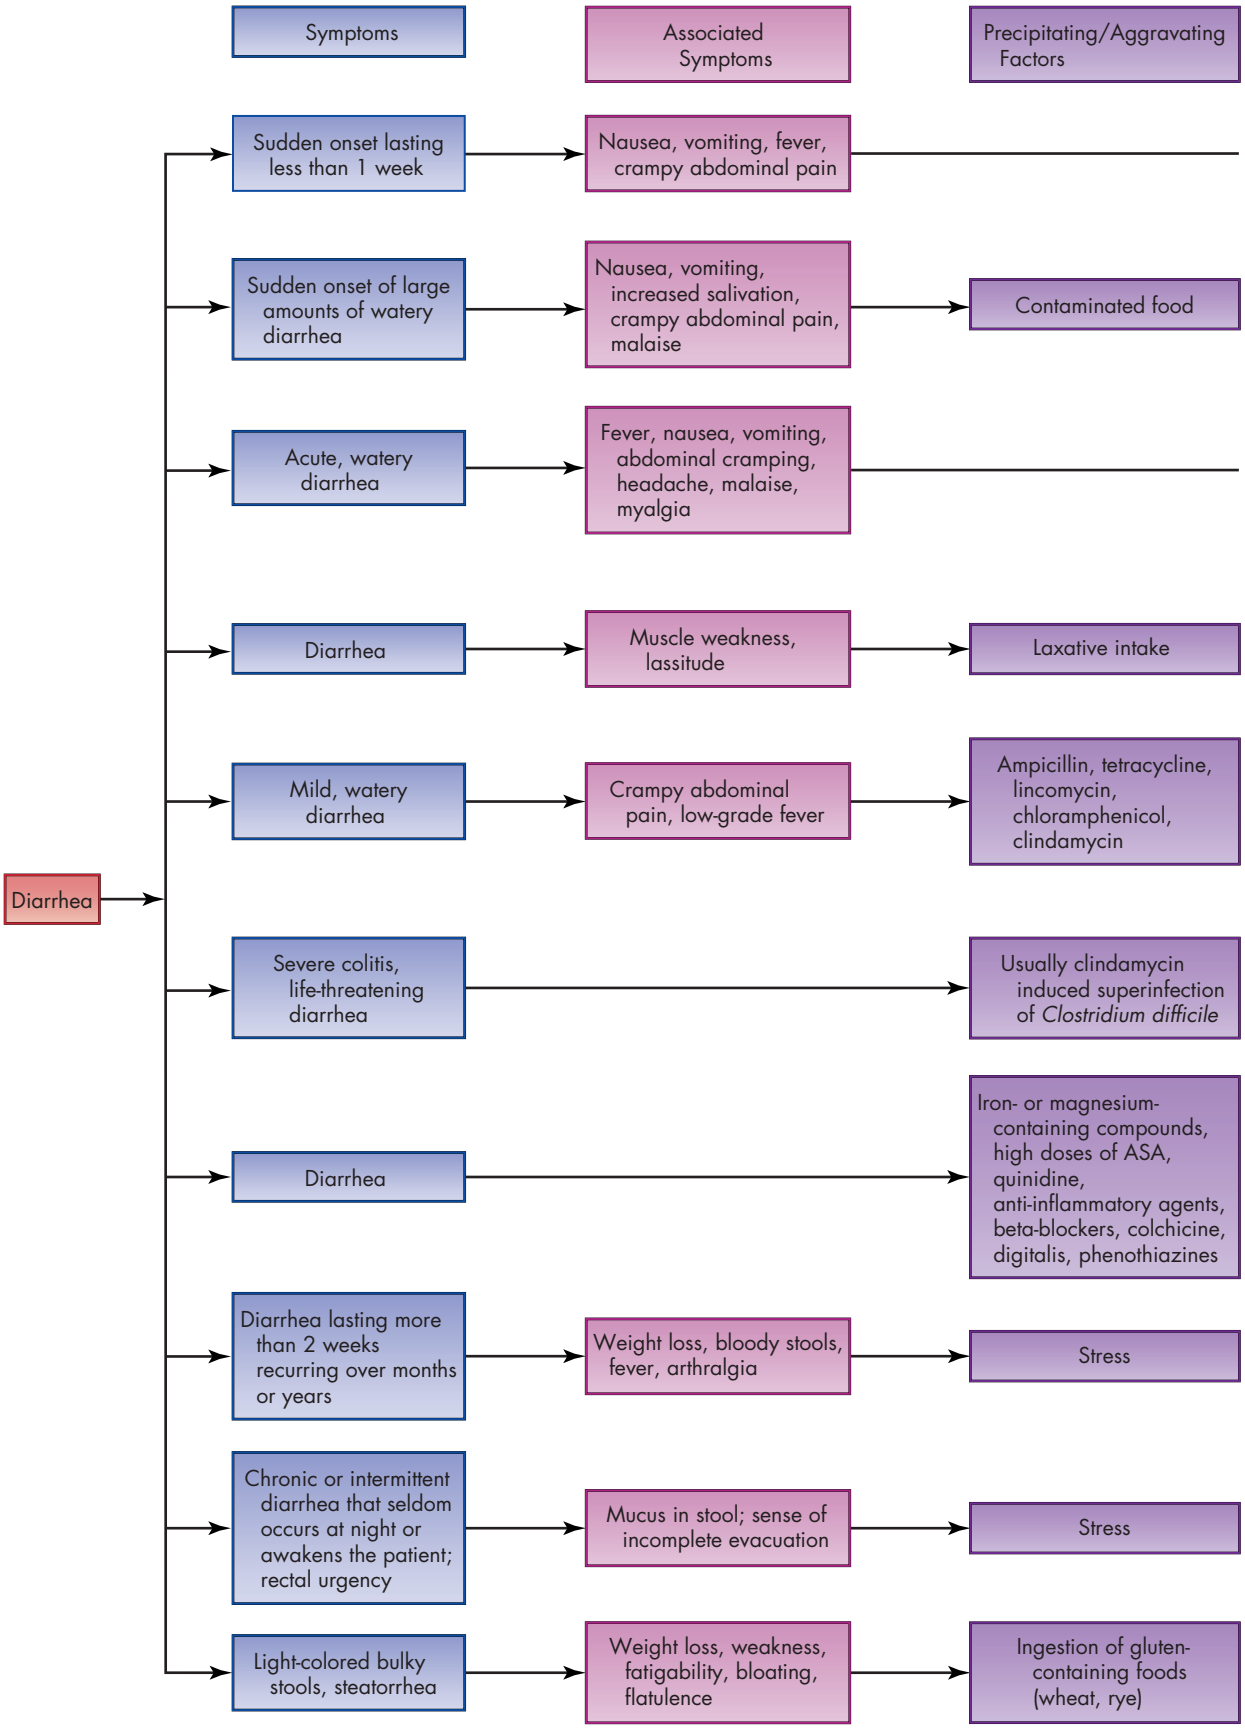
The frequency with which patients present with dyspepsia and heartburn as their chief complaint has been diminishing, probably because of the availability of over-the-counter histamine-2–receptor blockers and proton pump inhibitors. Aggressive advertising of these products by pharmaceutical companies over the last decade has led to the increase in self-medication for what could be a serious illness that the individual mistakes as simple heartburn.

Differential Diagnosis

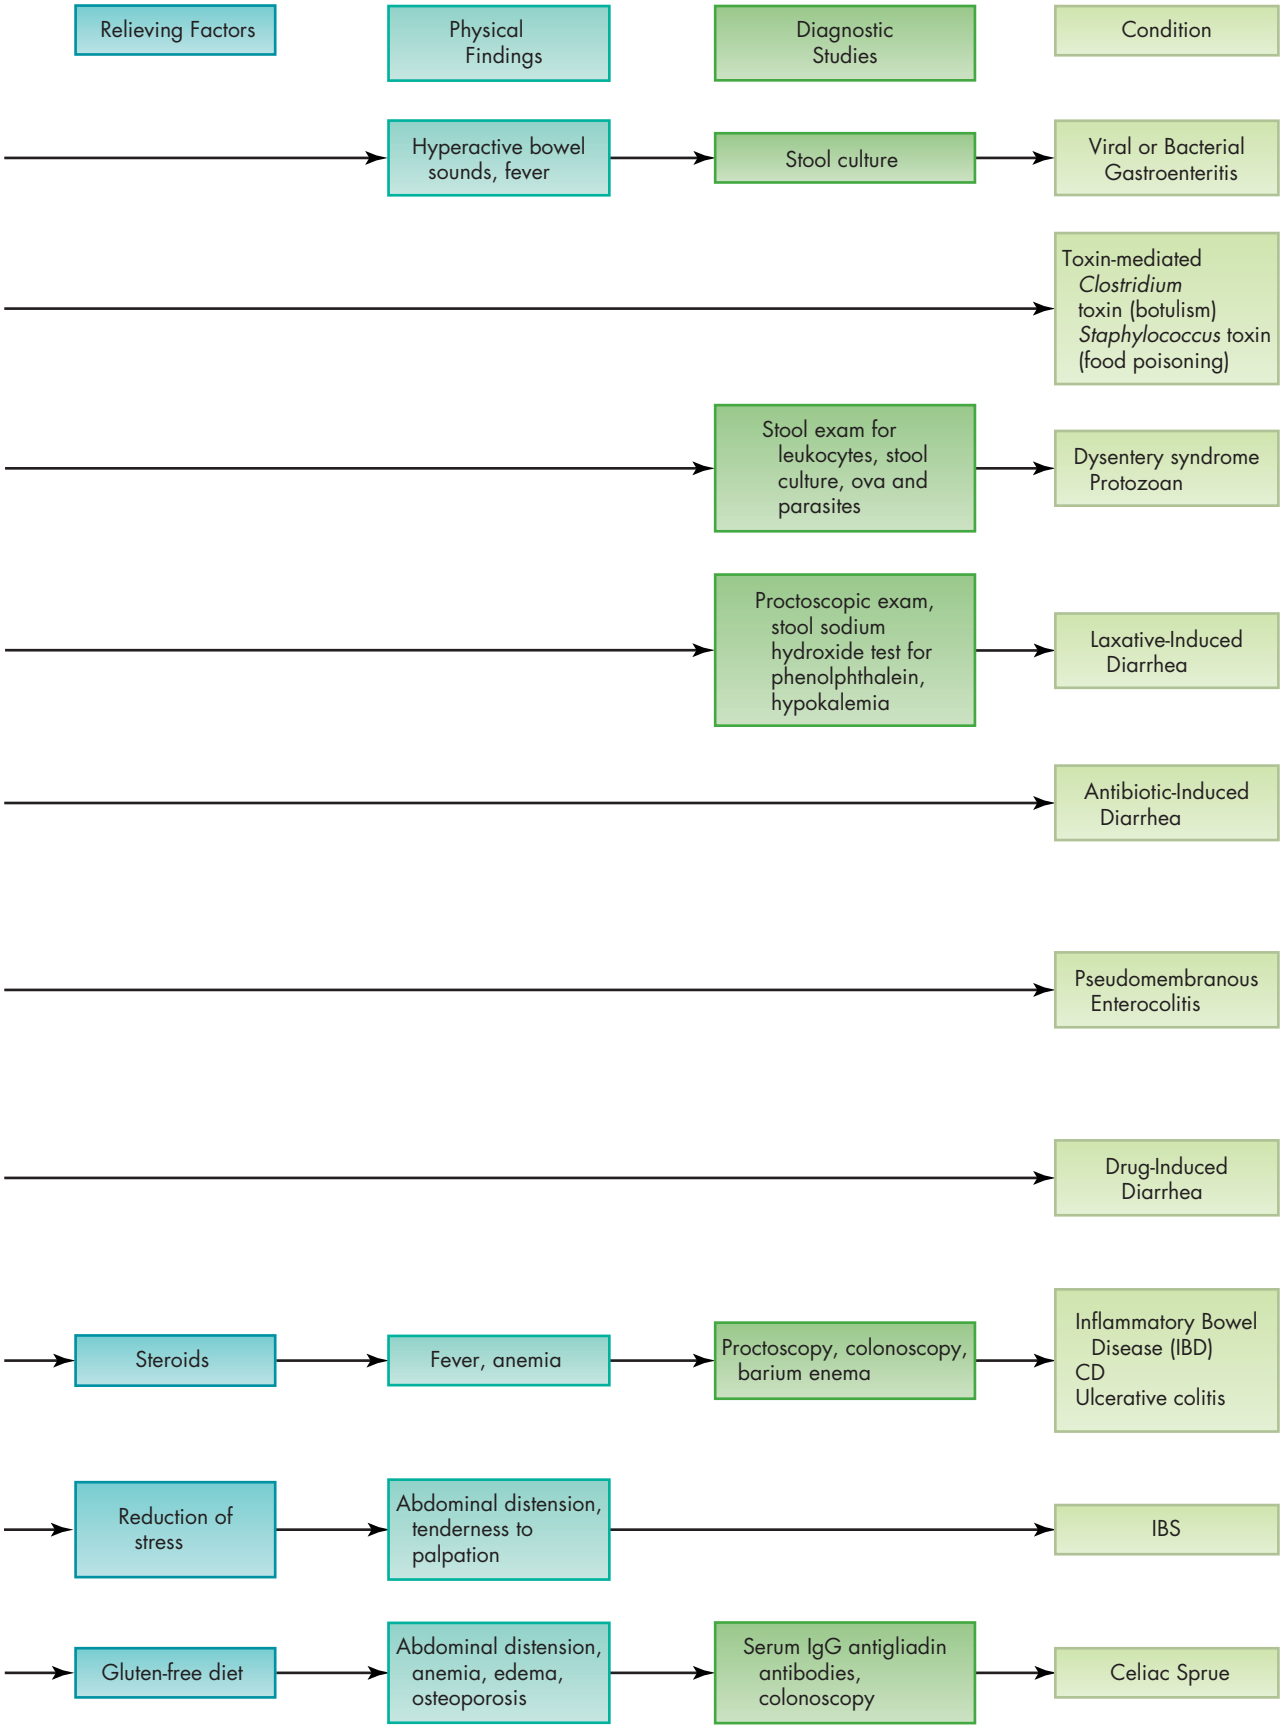
Dyspepsia and heartburn are two different entities. *Heartburn* is occasionally described as extreme pain, and this makes it difficult to distinguish heartburn pain from that of angina pectoris. Patients with heartburn sometimes describe the pain as radiating to the back, arms, or jaw, which further complicates the diagnosis. Symptoms of *dyspepsia* include epigastric discomfort, postprandial fullness, early satiety, anorexia, belching, nausea, heartburn, vomiting, bloating, borborygmi, dysphagia, and abdominal burning. These symptoms most often have functional or organic causes. The possibility of an organic cause for dyspepsia increases as a person ages. Patients who ingest alcohol in significant amounts or take drugs such as salicylates, corticosteroids, NSAIDs, erythromycin (E-Mycin), or theophylline (Theo-Dur, Theo-24) often have dyspepsia as a result of medication-induced gastritis. Giardiasis can cause dyspepsia with only occasional bouts of diarrhea. Nonulcer dyspepsia caused by *Helicobacter pylori* causes vague abdominal pain, a sense of fullness, nausea, and bloating, which are worse after eating. If the symptoms of dyspepsia are continuous and associated with anorexia and weight loss, gastric cancer may be the cause.

Heartburn, a retrosternal burning sensation, is common in the general population, with 7% complaining of daily symptoms, 14% having weekly episodes, and

Differential Diagnosis Flowchart 11.3



Differential Diagnosis Flowchart 11.3 (continued)



36% experiencing heartburn at some time or other in their lives. The most common cause of heartburn is gastroesophageal reflux disease. Pregnant women have a high incidence of esophagitis, most often later in the pregnancy because of increased intra-abdominal pressure. Heartburn is commonly relieved by the ingestion of alkali (antacids) and is precipitated and aggravated by recumbency. Differential Diagnosis Flowchart 11.4 reviews the differential diagnosis of heartburn and dyspepsia.

JAUNDICE

Jaundice is the yellow coloring of the skin, mucous membranes, and sclera resulting from an accumulation of bilirubin in the blood. Patients who develop jaundice usually seek medical attention promptly because it is so dramatic, frightening, and difficult to ignore.

The hyperbilirubinemia that causes the jaundice can be a result of increased production, decreased uptake, decreased conjugation, or decreased excretion of bilirubin. The etiology of hyperbilirubinemia is shown in Table 11.2. Hyperbilirubinemia and jaundice in most patients result from cholestasis, either because of impaired bile formation and/or bile flow, which can be the result of extrahepatic biliary tract obstruction or hepatic parenchymal disease.

Differential Diagnosis

Understanding the laboratory values is essential to determine the type of problem causing the hyperbilirubinemia and establish a differential diagnosis. Icterus is not usually evident until the serum bilirubin level exceeds 2 to 3 mg/dL. The normal serum bilirubin level is 0.3 to 1.0 mg/dL. Most bilirubin is formed from the heme portion of the breakdown of red blood cells. This initial bilirubin is unconjugated and therefore not soluble in water. When measured in the serum, it is reported as indirect bilirubin. This form of bilirubin is reversibly bound to albumin and transported to the liver, where it is taken up by the hepatocyte and conjugated with glucuronic acid. Conjugated bilirubin, which is water soluble, is transported from the hepatocyte into the bile. It is measured in the serum as the direct fraction of bilirubin. Only conjugated bilirubin, by nature of its water solubility, is found in the urine of patients with hyperbilirubinemia. Problems in the metabolism of bilirubin can occur at any point of the cycle.

Serum levels of the transaminases—aspartate aminotransferase (AST) and alanine aminotransferase (ALT)—are good indicators of hepatocyte damage from a variety of causes. Elevated transaminase levels reflect the activity of the disease process, but the actual serum levels do not necessarily correlate with the overall severity of the liver disease, nor with the prognosis. AST is found in hepatocyte mitochondria and cytoplasm and in nonhepatic tissues such as skeletal muscle, the heart, and the brain. ALT is found primarily in hepatocyte cytoplasm, making it a much more specific marker for hepatocyte damage. Levels of AST and ALT that are below 300 U/L are nonspecific; however, some extreme elevations can be quite diagnostic. For example, it is very uncommon for the AST to be elevated 15 times the normal value in biliary obstruction except when it occurs suddenly or is associated with cholangitis. Striking elevations of ALT and AST (greater than 1,000 U/L) occur in patients with acute viral hepatitis, toxin- or drug-induced hepatitis, and ischemic liver injury. If the ratio of AST to ALT is high, it generally indicates severe hepatic necrosis, most often caused by alcoholic hepatitis.

Alkaline phosphatase is found in the biliary canalicular membranes and is useful in assessing cholestasis. Cholestasis is also characteristically accompanied by an increase in the serum gamma-glutamyl transpeptidase (GGT) and 5(-nucleotidase. Extreme elevations in alkaline phosphatase (greater than three times normal) in conjunction with elevation of the GGT indicate a mechanical obstruction of the biliary system by a tumor, stricture, or stone. Because alkaline phosphatase is also found in bone, an isolated elevation of that enzyme without elevation of the GGT is indicative of a bone disorder rather than a cholestatic process.

A patient who presents with jaundice often has complaints of pruritis, anorexia, nausea, vomiting, fever, light-colored stools, weight loss, and fatigue. Examination may reveal right upper quadrant pain and tenderness, dark urine, and abdominal distention. Pruritus, dark urine, and light-colored stools in conjunction with the jaundice are indicative of cholestasis, either intrahepatic or extrahepatic, such as cholelithiasis, cirrhosis, or other biliary obstruction.

MELENA

Melena is defined as black, tarry stools that test positive for occult blood. The most common cause of melena is upper gastrointestinal (GI) bleeding, but bleeding in the small bowel or the right colon can also produce melena. It is the action of gastric acid and intestinal secretions that reduces bright red blood to black, tarry stools. To produce melena, about 100 to 200 mL of blood must be present. Because of GI transit time, it is possible for melena to continue for several days after the acute bleeding has stopped.

Differential Diagnosis

Some patients may present with black, tarry stools that do not test positive for blood. The most common causes for this are iron supplements, bismuth subsalicylate (Pepto-Bismol), and a variety of foods. Table 11.3 lists common causes of GI bleeding. Signs and symptoms associated with GI bleeding depend on the source, rate of bleeding, and coexistent diseases. GI bleeding from a peptic ulcer is common and accounts for roughly half of all episodes of upper GI hemorrhage. A complete blood count can give clues to the severity and duration of the bleeding. Endoscopy is useful in diagnosing the upper GI tract as the source of the bleeding.

Differential Diagnosis Flowchart 11.4

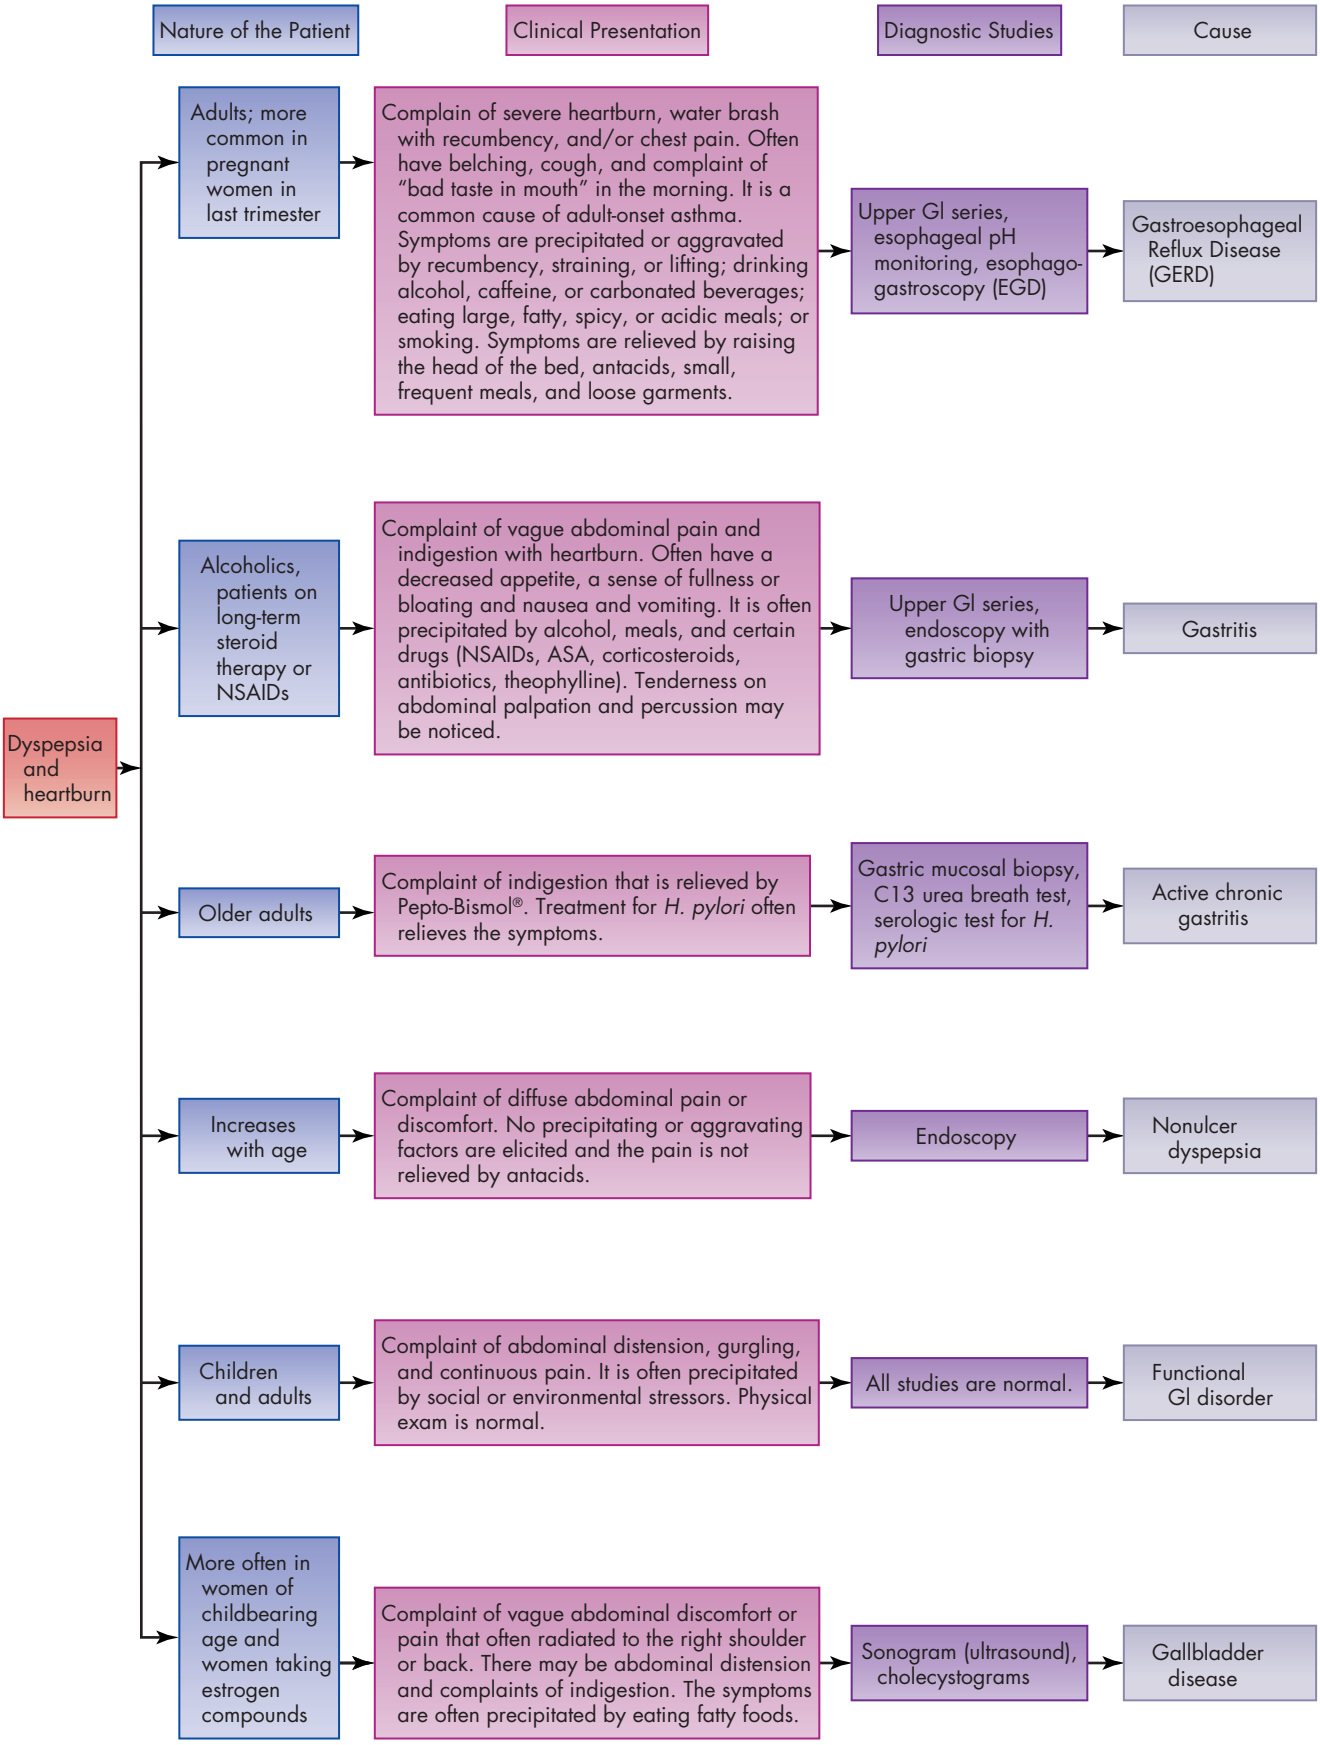


Table 11.2 Etiology: Hyperbilirubinemia

Increased Production

Hemolysis, resorption of hematomas, ineffective erythropoiesis
- Megaloblastic anemia, iron-deficiency anemia, sideroblastic anemia
- Thalassemia minor
- Polycythemia vera
- Lead poisoning

Decreased Clearance

Inherited disorder of bilirubin metabolism
- Gilbert's syndrome, Crigler-Najjar syndrome, Dubin-Johnson syndrome, Rotor's syndrome

Cholestasis
- Hepatocellular disease: Viral, drug-induced, or alcoholic hepatitis
- Biliary tract obstruction: Choledocholithiasis, tumor, sclerosing cholangitis, chronic pancreatitis, pancreatic cancer, primary biliary cirrhosis

Drugs
- Antibiotics (erythromycin, trimethoprim/sulfamethoxazole, amoxicillin/clavulanic acid, nitrofurantoin, griseofulvin)
- Analgesics (propoxyphene, sulindac, diflunisal)
- Allopurinol
- Warfarin
- Steroids (contraceptive and anabolic)
- Phenytoin
- Thiazide diuretics
- Phenothiazines
- Tricyclic antidepressants
- Haloperidol
- Parenteral gold
- Oral hypoglycemics (chlorpropamide, tolbutamide)

Table 11.3 Common Causes of Gastrointestinal Bleeding

Upper Gastrointestinal Tract

Peptic ulcer
- Gastric ulcer
- Duodenal ulcer

Gastric erosions
Erosive esophagitis
Esophageal varices

Lower Gastrointestinal Tract

Diverticular disease
Colon cancer
Intestinal polyps
Inflammatory bowel disease
Ulcerative colitis
Crohn's disease
Infectious colitis
Meckel's diverticulum
Small bowel neoplasm

NAUSEA AND VOMITING

Nausea is an unpleasant sensation in the stomach that is difficult to define because it is a sensory experience. It is often accompanied by diaphoresis, increased salivation, and the vasovagal signs of hypotension and bradycardia. Nausea can occur alone or precede vomiting. Vomiting is the forceful expulsion of gastric contents; it is a reflex response to stimulation of receptor sites in the mucosa of the upper gastrointestinal (GI) tract, the labyrinthine apparatus in the inner ear, higher cortical centers in response to emotional stimuli, or the chemoreceptor trigger zone of the medulla oblongata. Afferent nerve fibers carry these impulses to the vomiting center, where efferent fibers then send impulses to relax the gastric fundus and the gastroesophageal sphincter, to contract the pylorus, and to cause reverse peristalsis in the esophagus. The abdominal muscles and diaphragm contract, increasing the intra-abdominal pressure, which forces the gastric contents out through the mouth.

Differential Diagnosis

Gastroenteritis is the most common cause of nausea and vomiting in adults and children. Contaminated food should be considered in cases of acute nausea and vomiting, especially when more than one person is affected. Gastritis, usually associated with alcohol consumption or drugs (aspirin, NSAIDs, antibiotics, and illicit drugs), is also a very common cause of acute nausea and vomiting in adults. Nausea and vomiting are listed as adverse effects of a large number of medications; they are also common presenting symptoms for many disease entities such as hepatitis, myocardial infarction, and peptic ulcer. Table 11.4 provides common causes of nausea and vomiting.

A bit of detective work is necessary to determine the cause of the nausea and vomiting. The circumstances surrounding the episode or episodes give clues to the cause. Vomiting following a meal can occur with gastritis and in digitalis toxicity. If the vomiting occurs 1 to 2 hours after eating, diseases of the biliary tract or pancreas should be suspected. Projectile vomiting without nausea is classically a sign of a neurological source, such as increased intracranial pressure. If the nausea and vomiting occur in the early morning, the cause may be uremia, pregnancy, or chronic alcohol ingestion. The duration of the nausea and vomiting depends on the cause. Infectious agents in the GI tract usually cause nausea and vomiting only for 24 hours or less. On the other hand, nausea as a result of pregnancy can last for weeks.

The characteristics of the vomitus are important in determining the cause. For example, repeated vomiting without bile staining is indicative of pyloric obstruction, which can be caused by scars from an ulcer or a tumor, whereas vomiting of undigested food could indicate an esophageal obstruction. The odor of the vomitus is important information to elicit from the patient in determining the cause. Odorless vomitus indicates a lack of

gastric acid, possibly from esophageal stricture or achalasia. Fecal odor, on the other hand, indicates a bowel obstruction or gastrocolic fistula.

In the continued search for the cause of nausea and vomiting, associated symptoms can further narrow the field of possibilities. Ménière's disease or middle ear disturbances should be suspected if the patient complains of vertigo, tinnitus, or hearing loss. Nausea and vomiting often accompany migraine headaches, which are usually unilateral. Nausea and vomiting with diarrhea and abdominal pain are often caused by gastroenteritis. Differential Diagnosis Flowchart 11.5 delineates the differential diagnosis of nausea and vomiting.

Treatment

Management of nausea and vomiting is aimed at the underlying cause, which is covered in detail under the specific diagnoses in this chapter and in other chapters of this book. Symptomatic relief, however, is useful for the comfort of the patient and in preventing complications such as dehydration and electrolyte imbalance. Drugs Commonly Prescribed 11.2 presents a list of medications commonly used for the control of nausea and vomiting. Complementary Therapies 11.1 lists the uses of vitamins, minerals, and herbs for GI problems.

DYSPHAGIA

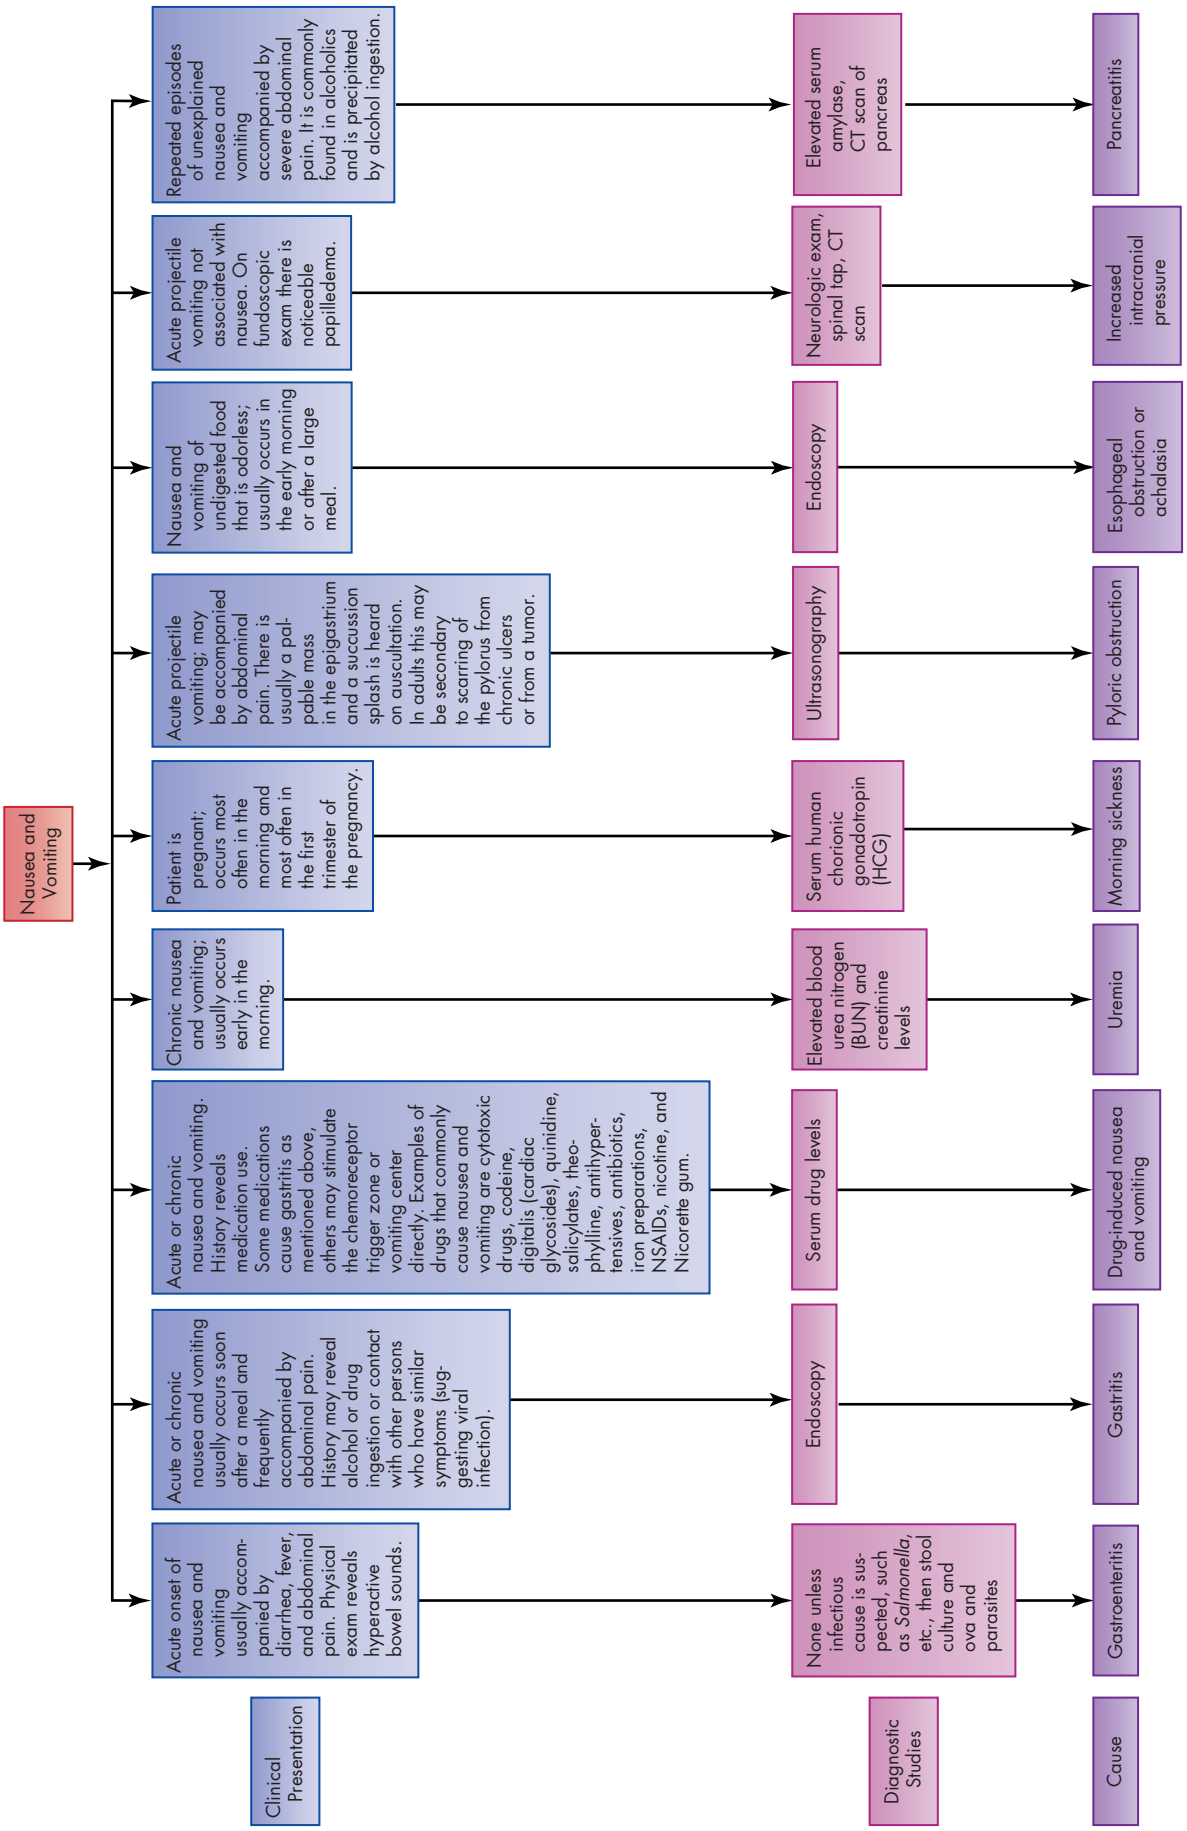
Dysphagia is defined as difficulty swallowing that may or may not have a component of *odynophagia,* or painful swallowing. Although dysphagia may accompany odynophagia, classic dysphagia is not usually painful. The prevalence increases with age and is common in older adults.

The process of swallowing is quite complex and involves 50 pairs of muscles and many nerves. Swallowing has three phases: (1) The *oral phase* involves movement of the tongue and jaw allowing for mastication and preparation of food into a bolus and making it ready for swallowing; (2) the *pharyngeal phase* includes the reflexive passage of the bolus from the oral cavity through the pharynx and into the upper esophagus; and (3) the *esophageal phase* is the reflexive passage of the bolus through the esophagus and into the stomach. There is often a combination of underlying factors that cause dysphagia.

Differential Diagnosis

Dysphagia can be caused by mechanical obstruction or be from a functional problem that impairs motility. Mechanical obstruction can be either intrinsic (strictures, tumors, diverticular outpouchings) or extrinsic (something outside the esophagus that presses inward compressing the esophageal wall with tumor being the most common). Functional dysphagia can have a neurological or muscular cause. Neurological conditions that interfere with voluntary swallowing or peristalsis are cerebrovascular accidents, Parkinson's disease, multiple sclerosis, amyotrophic lateral sclerosis, and achalasia. Eighty percent of oral phase and pharyngeal phase abnormalities have a neurological origin. Dermatomyositis is a muscular disease that causes functional problems in the upper esophagus leading to dysphagia. Dysphagia may be the first sign of such an underlying disorder. Psychological conditions may also cause the symptoms; the term *globus hystericus* refers to a manifestation of acute anxiety disorders and panic attacks. Dysphagia may also be associated with underlying depressive disorder.

Differential Diagnosis Flowchart 11.5



Drugs Commonly Prescribed 11.2 Medications for the Control of Nausea and Vomiting

Drug	Indication	Adverse Reactions and Prescribing Considerations
Antihistamines Dimenhydrinate Promethazine Hydroxyzine Meclizine	Motion sickness Drug-induced nausea Postoperative During labor	Sedation, dry mouth, blurred vision, headache
Antidopaminergics Prochlorperazine	Chemotherapy- and radiation-induced nausea and vomiting Postoperative	Sedation, dry mouth, urinary retention, constipation, extrapyramidal effects
Antidopaminergics and cholinergics Metoclopramide	Postoperative Diabetic gastroparesis	Restlessness, drowsiness, fatigue, extrapyramidal effects
Cholinergic antagonists Scopolamine	Motion sickness	Dry mouth, blurred vision, tachycardia, constipation, sedation
Serotonin receptor antagonists Ondansetron Granisetron	Chemotherapy- and radiation-induced nausea and vomiting	Anxiety, euphoria, depression, headache, insomnia, restlessness, weakness

Complementary Therapies 11.1 Complementary Therapies For Gastrointestinal Problems

Agent	Indication	Adverse Reactions and Prescribing Considerations
Senna *(Cassia senna)*	Constipation	1–2 tsp dried leaves per 8 oz water taken as a tea once daily (not to be taken for longer than a few days)
Milk thistle *(Silybum marianum)*	Hepatitis and liver toxicity	140 mg three times per day (oral)
Acupuncture	Heartburn/GERD IBD IBS	8–12 treatments
Licorice root	Peptic ulcer disease	5–15 mg three times per day Can cause high blood pressure
Ginger	Nausea and motion sickness	250 mg daily

Alterations of the swallowing process may manifest differently depending on the underlying pathology. For example, if there is a problem in the oral phase, dribbling, spillage, pocketing of food in the mouth, or aspiration may be present. The pharyngeal phase is the first reflexive, or involuntary, phase; problems during this phase are characterized by nasal regurgitation, aspiration, and/or altered voice. This is the phase where aspiration most commonly occurs during swallowing. Esophageal phase problems are characterized by neck pain, heartburn, and the sensation of food becoming "stuck" below the sternum.

A videofluoroscopic swallow study is considered the gold standard for evaluating swallowing. This imaging technique videotapes the entire swallowing process and shows an outline of the structures from the oral cavity to the stomach, as well as assessing the velocity and movement of oral and hypopharyngeal structures and their temporal relationship to each other. Through observation of the ingestion of various food consistencies, such as thin liquids, thick liquids, semisolids, and solids, the safest plan for oral intake can be determined.

Treatment

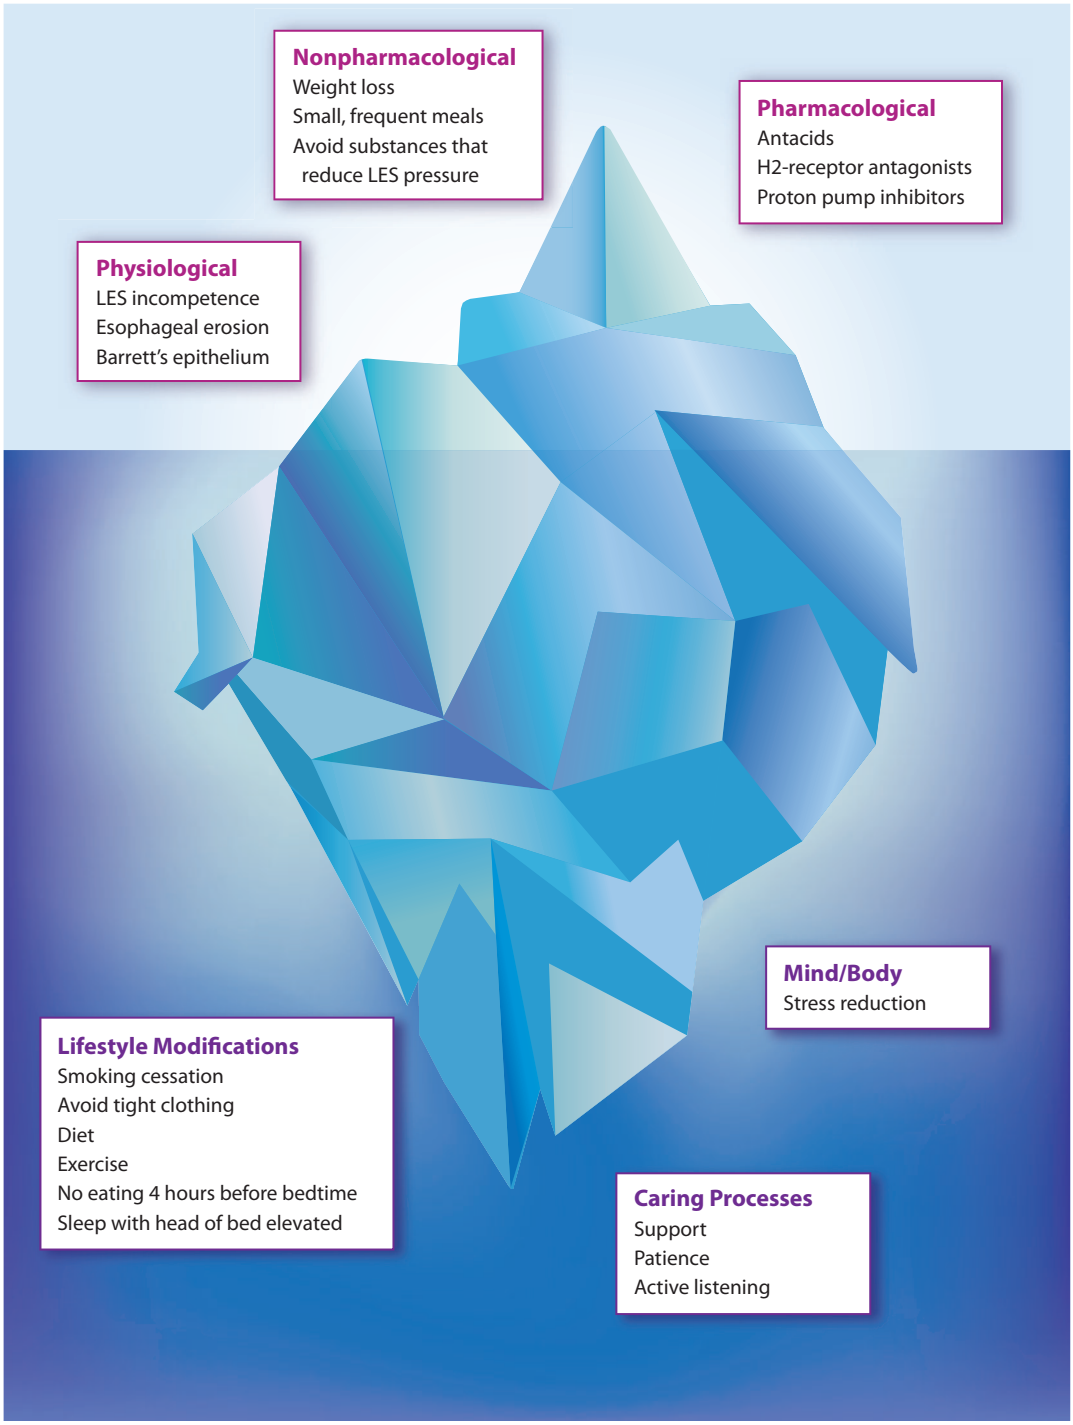
There are a number of approaches to treating dysphagia depending on the cause. One approach involves muscle strengthening exercises of the facial muscles to improve the coordination of swallowing. Most approaches involve instructing the patient and family members in ways to improve safe food intake, including positioning (usually sitting upright, with the head tilted slightly forward and downward) and food-consistency modification (no thin liquids, mechanical soft diet) during food intake. However, if the risk of aspiration is severe, the clinician may have to consider elimination of oral intake. For these patients, enteral feeding is the next choice.

COMMON PROBLEMS

GASTROESOPHAGEAL REFLUX DISEASE

Esophageal reflux is the backward flow of stomach or duodenal contents into the esophagus without associated retching or vomiting. It can occur in otherwise healthy people. If symptoms become severe or frequent or are associated with esophageal mucosal damage, the potential for serious clinical consequences becomes more likely, and the esophageal reflux is considered a disease. Gastroesophageal reflux disease (GERD) is a syndrome that results from esophageal reflux; the characteristic symptoms are caused by repeated exposure of the esophageal mucosa to the deleterious effects of gastrointestinal contents and the gradual breakdown of the mucosal barrier. See the Iceberg of GERD.

The Iceberg of GERD



Epidemiology and Causes

GERD can occur at any age. Some research indicates that it increases with age and then decreases after age 69. The prevalence of GERD is equal across gender, ethnic, and cultural groups in the United States; it is a common condition. There are higher rates of GERD in individuals who are overweight or obese and have a body mass index over 25. The prevalence rate for GERD in the United States is around 20%. The prevalence rate in other countries is less, ranging from 0.1% to 5% in China to 10% to 15% in the United Kingdom. Thirty-five percent to 45% of the adult population complain of heartburn at least once a month, and 10% of the adult population complain of symptoms daily. These figures may be significantly underestimated because many people with mild symptoms use over-the-counter (OTC) H_2-receptor antagonists (H_2-RAs) or antacids. Many individuals also believe that it is normal to have symptoms from time to time and attribute them to stress or dietary indiscretion.

The primary cause of GERD is the inappropriate, spontaneous, transient relaxation of the lower esophageal sphincter (LES) to an unknown stimulus. In most patients, the resting or baseline LES pressure is normal (10–30 mm Hg). In patients who have more severe disease, the LES is incompetent, with a resting pressure of less than 10 mm Hg. The incompetent LES results in free reflux during abdominal straining, lifting, bending, and recumbency. Gastric contents are acidic, and it is this low pH (less than 3.9) that causes injury to the esophageal mucosa in the majority of patients with GERD. Normally, refluxate is neutralized by swallowing salivary bicarbonate and cleared by esophageal peristalsis. Decreased swallowing (by two-thirds) during sleep, coupled with recumbency, significantly increase the duration of exposure of the mucosa to acid at night.

Historically, the presence of a hiatal hernia, which displaces the LES into the thorax, was believed to be the major cause of GERD. This is now disputed because, although most patients with hiatal hernias do experience reflux, not all patients who have reflux have hiatal hernias. The two conditions are related but separate. Delayed gastric emptying, which often worsens as people age, causes increased intra-abdominal pressure and may contribute to reflux. Obesity is also a risk factor for GERD. A number of foods and pharmacological agents are known to lower LES pressure. Table 11.5 lists the common substances that reduce LES pressure or cause direct gastric mucosal irritation.

Table 11.5 Substances That Reduce Lower Esophageal Sphincter Pressure or Irritate the Gastric Mucosa

Food Substances
Alcohol
Caffeinated beverages (cola, tea, coffee)
Chocolate
Citrus fruits
Decaffeinated coffee
Fatty foods, fats (butter, margarine, shortening), and oils
Onions
Peppermint and spearmint
Tomatoes and tomato-based products (ketchup, cocktail sauce, tomato sauce, tomato paste)
Nonfood Substances
Anticholinergic drugs
Beta-adrenergic blocking agents
Calcium channel blockers
Diazepam
Estrogen and progesterone
Nicotine, including secondhand smoke
Theophylline

Pathophysiology

Physiologically, gastric acid is prevented from refluxing into the esophagus by the presence of two areas of high pressure in the distal esophagus. The upper esophageal sphincter is a 3-cm segment at the proximal end of the esophagus. The LES is a 2- to 4-cm segment of the esophagus just proximal to the gastroesophageal junction that prevents the reflux of gastric contents. These areas of the esophagus are under muscular, hormonal, and neural control. The anatomical placement of the LES within the abdomen supports its function, as does the acute angle (angle of His) that is formed as the esophagus enters the stomach.

Esophageal reflux occurs when the gastric volume (e.g., a large meal) or the intra-abdominal pressure is elevated (e.g., in pregnancy). It can also occur when the sphincter tone of the LES is decreased (e.g., by caffeine) or when the LES undergoes inappropriate relaxation. Gravity, saliva, and peristalsis combine to return refluxed contents to the stomach. As the esophagus becomes inflamed with repeated exposure to gastric acid, it cannot eliminate the refluxed material as quickly or efficiently, prolonging the duration of the contact with each subsequent exposure.

Because gastric contents are so irritating to the esophageal mucosa, an inflammatory response is established. With repeated exposure, the inflammation becomes chronic. In response to chronic inflammation, there is increased blood flow to the area, and erosion occurs. Frank bleeding is unusual, but minor capillary bleeding is common. As the erosion heals, the body replaces the normal squamous epithelium with metaplastic columnar epithelium (Barrett's epithelium) containing goblet and columnar cells. This new epithelium is more resistant to acid and, therefore, supports esophageal healing. Barrett's epithelium is a premalignant tissue, however, and presents a 40-fold increased risk for the development of esophageal adenocarcinoma. Fibrosis

and scarring also accompany the healing process, leading to esophageal strictures.

Clinical Presentation

Subjective

The most typical symptom of GERD is heartburn, ranging in degree from mild to severe. It is usually associated with other symptoms, including regurgitation, water brash (reflex salivation), dysphagia, sour taste in the mouth in the morning, odynophagia, belching, coughing, hoarseness, or wheezing, usually at night. Substernal or retrosternal chest pain may also be present, but additional questioning can determine if the pain is activity induced, leading to the conclusion that the pain may be cardiac in origin. Factors that precipitate or make the symptoms worse, such as reclining after eating; eating a large meal; ingesting alcohol, chocolate, caffeine, fatty or spicy foods, or nicotine; wearing constrictive clothing; or working in an occupation in which heavy lifting, straining, or working in a bent-over position is involved also help establish the diagnosis of GERD. It is equally important to ask what the patient does that makes the symptoms better, such as taking antacids, sitting upright after a meal, or eating small meals.

Patients with chronic GERD may present with dysphagia as their chief complaint. The dysphagia is usually present only with the first swallow of every meal and is not progressive. Should the patient complain of progressive or persistent dysphagia, adenocarcinoma or the development of a stricture should be suspected.

Objective

The physical exam of the patient with GERD is usually normal. The only physical sign may be a stool positive for occult blood on rectal exam resulting from microhemorrhages in the irritated esophageal epithelium.

Diagnostic Reasoning

Diagnostic Tests

Diagnosis of GERD is usually made by history alone and has a sensitivity of 80%. The severity of the symptoms does not correlate well with the severity of the disease; some patients with the most severe disease have virtually no symptoms. GERD may also manifest with atypical symptoms such as adult-onset asthma, chronic cough, or sore throat.

When the diagnosis of GERD is unclear or when the patient fails to respond to 4 weeks of empiric therapy, the most accurate method of diagnosing the disease is by ambulatory esophageal pH monitoring, which involves placing pH probes 5 cm above the LES. If the pH is less than 4 above the LES and correlates with the occurrence of symptoms, the test is definitive for GERD. Esophageal manometry is indicated to determine the location of the LES before placement of the pH-monitoring probe. To prevent the overuse of upper endoscopy, the American College of Physicians published best practice advice in 2012 for esophagogastroduodenoscopy (EGD) in adults with GERD symptoms. It recommended EGD for patients with heartburn and dysphagia, bleeding, anemia, weight loss, or recurrent vomiting. Upper endoscopy with a biopsy is the test of choice to document the type and extent of tissue damage (e.g., Barrett's esophagus) in the esophagus. It is also recommended for surveillance evaluation in anyone with Barrett's esophagus every 3 to 5 years and more frequently if there is Barrett's esophagus with dysplasia.

Differential Diagnosis

The symptoms of GERD are similar to those of peptic ulcer disease (PUD), and the two conditions often coexist. Unlike GERD, however, PUD usually produces epigastric pain and tenderness on palpation. One pattern that can help differentiate GERD from PUD is that heartburn from PUD is usually relieved by food. This is not the case in GERD; instead, the symptoms are worse shortly after eating. Another possible differential diagnosis is gallbladder disease, which usually presents with epigastric or right subcostal pain. Nausea and possibly vomiting are usually associated with cholelithiasis and cholecystis; this is not the case in gastric reflux. There may be a strong association between the ingestion of a high-fat meal and the development of the symptoms of cholelithiasis. Occasionally, GERD may present with chest pain. In these patients, the practitioner must differentiate between symptoms of cardiac origin and those of GERD. If the pain is of cardiac origin (e.g., angina), the patient's history usually reveals that the pain is associated with exercise and is relieved by rest and nitrates. Patients with angina are often treated with medications (calcium channel blockers, beta-adrenergic blockers, nitrates) that decrease the LES pressure and produce a coexistent esophageal reflux, which complicates the differential diagnosis further.

Management

The goal of the management of GERD is to rapidly eliminate or reduce symptoms; to prevent meal- or exercise-related symptoms; and to prevent the complications of esophageal stricture, esophageal ulcer, Barrett's esophagus, pulmonary aspiration, and esophageal hemorrhage all in the most cost-effective way. The focus of management is patient education coupled with pharmacological intervention. The guidelines for treatment from the Agency for Healthcare Research and Quality include a "step-up" and a "step-down" approach. For all patients with GERD, lifestyle modifications are the first line of treatment. These include elevating the head of the bed 6 to 8 inches; smoking cessation; and avoiding high-fat meals, large meals, and certain foods such as chocolate, alcohol, peppermint, caffeine, onions, garlic, citrus, and tomatoes. The patient should be instructed to avoid recumbency or sleeping for 3 to 4 hours after a meal and

avoid bedtime snacks. Some medications also should be avoided because they affect the LES pressure; these include calcium channel blockers, beta blockers, alpha-adrenergic agonists, theophylline, nitrates, and some sedatives. Weight loss should be encouraged in those patients who are overweight or obese.

If diet and lifestyle modifications are ineffective in controlling symptoms, the treatment is "stepped up" to medications. For patients with mild to moderate symptoms but nonerosion reflux disease, the first step-up is to H_2-RAs. These include cimetidine (Tagamet), ranitidine (Zantac), famotidine (Pepcid), and nizatidine (Axid). These are available OTC, as well as in prescription dosages. If there is no improvement, proton pump inhibitors (PPIs) are used in a dosage that effectively eliminates symptoms. Another alternative is to begin treatment with PPIs at higher doses and "step down" treatment to the lowest dose that effectively suppresses acid secretion. The most cost-effective approach is the patient-directed or "on demand" approach where the patient takes medication as needed.

Troublesome Symptoms

Initial Therapy Patients who have severe symptoms and have endoscopically documented erosive esophagitis or Barrett's esophagus are treated with PPIs such as omeprazole, rabeprazole, pantoprazole, or lansoprazole once a day 30 minutes before breakfast. An 8-week course of once-a-day treatment usually provides adequate control of heartburn in 80% to 90% of the cases and healing of erosive esophagitis in 80%, whereas twice-a-day dosing heals 95% of cases. If twice-daily dosing provides inadequate symptom relief, the patient should be evaluated with upper endoscopy. Chronic maintenance therapy with PPIs may be necessary for severe erosive esophagitis.

Long-term Therapy Patients with severe erosive esophagitis, Barrett's esophagus, peptic stricture, or who required twice-daily PPI therapy for initial symptom control should be maintained on long-term therapy. Over 80% of patients who achieved good symptom control with initial therapy and discontinue treatment will relapse. These patients may require intermittent 2- to 4-week courses of PPI therapy.

Evidence suggests that PPIs are more effective than H_2-RAs in all cases of GERD. These agents should not be used in combination, especially with older adults. The PPIs should be taken 30 to 60 minutes before breakfast to maximize effectiveness. If the patient requires a twice-a-day dosing, the second dose should be taken 30 to 60 minutes before dinner as well. H_2-RAs are considerably less expensive than PPIs but are ineffective in healing esophagitis in more severe cases. Patients on long-term therapy should have their symptoms reevaluated every 6 months in an effort to avoid potential adverse effects such as PPI-associated pneumonia, *Clostridium difficile,* osteoporosis, and vitamin B_{12} deficiency.

Unresponsive Disease

The 5% to 20% of patients who do not respond to any of the above treatments may require surgical intervention. These patients are referred for laparoscopic Nissen fundoplication. Other minimally invasive procedures are also being used. These include the Endocinch procedure that endoscopically places a stitch at the junction between the esophagus and stomach that narrows the opening, thereby preventing reflux. The Stretta procedure is used to destroy the nerves at the LES, causing scar tissue and some stenosis that prevents reflux. Before referring a patient for surgical intervention, other causes of refractory GERD, such as gastrinoma, proton pump resistance, pill-induced esophagitis, or patient noncompliance, should be investigated.

Treatment Standards/Guidelines 11.1 outlines the step-up and step-down approach to the treatment of GERD and includes medications, dose, and dosing schedule.

Treatment Standards/Guidelines 11.1
Step-up/Step-down Treatment for GERD

Mild, intermittent symptoms	Trial for 4 weeks; if symptoms persist, step-up • Dietary and lifestyle modification • Pharmacological therapy • Antacids—may improve symptoms • OTC H_2-RA
Step-up	• Continue with diet and lifestyle modifications • Pharmacological therapy • H_2-RA at prescription doses (cimetidine 800 mg twice a day or 400 mg four times a day, or ranitidine 150 mg twice a day, nizatidine 150 mg twice a day, famotidine 20 mg twice a day) **OR** • PPI (omerprazole 20 mg, rabeprazole 20 mg, lansoprazole 30 mg, esomeprazole 20 mg, or pantoprazole 40 mg daily)
Troublesome Symptoms	Trial for 8 weeks; if symptoms persist, move to next step. • Dietary and lifestyle modification • Pharmacological therapy • PPI (omerprazole 40 mg, esomeprazole 40 mg daily)
Unresponsive Disease	• Dietary and lifestyle modifications • Surgical intervention (fundoplication)

Follow-up and Referral

GERD is a lifelong condition, and patients must be reevaluated on a regular basis to minimize the development of severe complications. Patients with mild-to-moderate symptoms should be instructed in the appropriate lifestyle modifications and treated with antacids or OTC H_2-RAs for a period of about 4 weeks. If on the 4-week follow-up visit there is no improvement in the symptoms, the patient can be advanced to step 2 treatment for 6 weeks. If this regimen is ineffective, the patient should be referred to a gastroenterologist. Patients who have self-medicated for a length of time may have developed erosive esophagitis or Barrett's esophagus and need aggressive treatment.

Patient Education

Education for patients with GERD includes instructing them on appropriate lifestyle modifications. Patients who are obese should be referred to a dietitian for counseling about weight loss. Dietary modifications are the keystone for lifestyle change; they include reducing the ingestion of foods that are irritating to the gastric mucosa and those that reduce LES pressure. Factors that increase intra-abdominal pressure should be avoided, such as large meals, tight or restrictive clothing, and bending or straining. It is most helpful for patients to eat small, frequent meals, with the main meal at midday. Eating less than 4 hours before bedtime, including snacks, should be avoided because this increases the chance of reflux. Patients should be instructed to sleep with the head of the bed elevated, which can be accomplished by placing blocks or bricks under the legs of the head of the bed. Sleeping with more pillows does not have the same effect as raising the head of the bed. With the head elevated, gravity helps in preventing reflux at night, when the swallowing reflex is reduced. Patients should be given assistance in smoking cessation, but the use of supplemental nicotine should be avoided because it reduces LES pressure. Programs for stress management have not been found to be helpful in reducing the symptoms of GERD.

GASTROENTERITIS

Gastroenteritis, also known as enteritis or gastroenterocolitis, is defined as an inflammation of the stomach and intestine that manifests as anorexia, nausea, vomiting, and diarrhea. Gastroenteritis can be acute or chronic and can be caused by bacteria, viruses, parasites, injury to the bowel mucosa, inorganic poisons (sodium nitrate), organic poisons (mushrooms or shellfish), and drugs. Chronic causes include food allergies and intolerance, stress, and lactase deficiency. Gastroenteritis caused by bacterial toxins in food is often referred to as food poisoning; it should be suspected when groups of individuals present with the same symptoms.

The symptoms and subsequent electrolyte imbalances are usually self-limiting in the healthy adult but can have serious consequences for older adults and immunocompromised or pediatric patients. The severity of the illness is indicated by the presence of dehydration secondary to profuse watery diarrhea, fever greater than 101°F (38.3°C), vomiting, or dysentery (frequent small stools containing blood and mucus). A careful history and physical exam provides clues about the causative agent and the suspected vector of transmission. Travel, dining locations, and antibiotic history should be included as part of the assessment.

Epidemiology and Causes

Acute gastroenteritis results most often from an infectious agent. Although it is one of the most frequent diagnoses in primary-care practice (about 30% of patients seen each year), the exact number of individuals affected is not known because acute gastroenteritis presents with a group of nonspecific symptoms that often go unreported or the etiology cannot be determined. Estimates are that the annual rate for gastroenteritis is approximately one episode per adult per year in the United States and Western Europe. Food- and waterborne outbreaks are of particular importance and gain the attention of the news media in an effort to identify and treat all the individuals who may have been exposed to the potentially harmful pathogen.

The most common mode of transmission for acute infectious gastroenteritis is the fecal–oral route from contaminated food or water. Person-to-person transfer of the disease is more common within the hospital setting and within day-care centers where there are larger groups of people capable of transmitting the disease. Groups considered at high risk for developing gastroenteritis include anyone traveling to a developing country, immunocompromised patients, anyone engaging in anal intercourse, residents of institutions or nursing homes, infants and children attending day-care centers, and individuals consuming raw shellfish and seafood.

Bacterial pathogens account for 30% to 80% of acute gastroenteritis cases and are an important cause of morbidity in tropical areas and in travelers to areas of high risk for the pathogens (traveler's diarrhea). Areas considered high risk for developing traveler's diarrhea include Africa, Southeast Asia, and developing countries in the Middle East or Latin America. Table 11.6 presents the most common bacterial, viral, and parasitic causes of gastroenteritis.

Gastroenteritis can also be caused by dietary factors such as coffee, tea, and sodas containing caffeine, medications (primarily antacids and antibiotics), and metabolic factors, including diabetes mellitus, hyperthyroidism, and adrenal insufficiency.

Pathophysiology

Pathophysiological causes of gastroenteritis are numerous; however, bacterial, viral, and parasitic infections are among the most common. Almost all forms of enteric

(Text continued on page 534)

Table 11.6 Organisms Causing Gastroenteritis

Pathogen	Pathogenesis	Duration/Onset	Clinical Findings	Diagnosis and Treatment
Bacterial Pathogens				
Bacillus cereus	Type of food poisoning from formation of enterotoxins within food or gut; two forms, differing in duration of illness.	Duration is normally less than 24 hours. Onset is within 1–8 hours after exposure.	Illness begins with vomiting and proceeds to diarrhea; no fever. Commonly occurs in rice dishes; the spores are heat resistant and not affected by cooking.	No antibiotic treatment is required; oral hydration and supportive care.
Campylobacter jejuni	Found primarily in eggs and poultry but may be found in domestic animals. Organism invades the intestinal mucosa and produces a cholera-like toxin. Organism grows within ileum and jejunum.	Duration of illness is 2–6 days. Onset of symptoms approximately 48 hours after ingestion of pathogen.	Common cause of traveler's diarrhea from ingestion of contaminated water. Symptoms include fever, bloody diarrhea, and abdominal pain. Stool is positive for polymorphonuclear neutrophils.	Normally self-limiting. Erythromycin ethylsuccinate (EES) can be used in severe cases. Rapid antibiotic resistance is common. Stool culture requires special media. Quinoline antibiotics have been effective in increasing recovery.
Clostridium botulinum	Anaerobic gram-positive bacillus that produces seven distinct toxins. In the food-borne type the toxin is ingested with contaminated food. Once absorbed, the toxin blocks the release of acetylcholine from peripheral nerve endings. Canned foods are the primary source.	Duration of illness depends on diagnosis and treatment. Mortality rate is high. Onset is abrupt, although incubation can be as long as 4–8 days.	GI symptoms often precede neurological findings, which are bilateral, are symmetrical, and occur in a descending fashion. Initial neurological symptoms include dry mouth, diplopia, and loss of pupillary reflex. Dysphagia and dysarthria can lead to aspiration pneumonia. Progression of neurological insult leads to paralysis of the diaphragm and death if mechanical ventilation is not employed.	Diagnosis is made by isolation of organism in suspected food, the serum, or feces. Symptoms are often confused with Guillain-Barré. Treatment is to first eliminate any unabsorbed food (toxin) by inducing vomiting or by gastric lavage, then administration of trivalent antitoxin (A, B, or E) from the Centers for Disease Control and Prevention (CDC). The antitoxin does not reverse the existing neurological symptoms but prevents progression. Little benefit if given after 72 hours. Toxin may cause serum sickness or anaphylaxis. Mechanical ventilation must be considered in an emergency.

Table 11.6 Organisms Causing Gastroenteritis—cont'd

Pathogen	Pathogenesis	Duration/Onset	Clinical Findings	Diagnosis and Treatment
Clostridium difficile	Gram-positive anaerobe maintained in spore form. It colonizes bowel when normal bowel flora are suppressed by antibiotics. It produces two toxins: toxin A, an enterotoxin, and toxin B, a cytotoxin causing pseudomembranous colitis and necrosis.	Duration and intensity of disease vary. Onset normally is in a hospitalized patient who has had recent antibiotic treatment.	Symptoms range from none to acute abdomen secondary to toxic megacolon with perforation; symptoms usually begin after initiation of antibiotics. Profuse, watery, or mucoid diarrhea, which may be blood tinged, accompanied by fever, abdominal cramping and distention, WBCs greater than 20,000, and ascites. Metabolic acidosis indicates severe colitis or toxic megacolon. Common cause of nosocomial infections in hospitals.	Diagnosis is confirmed with isolation of toxin A or B in the stool. Culture alone is no longer diagnostic because of the number of patients who are asymptomatic carriers. Flexible sigmoidoscopy may reveal pseudomembranous colitis. It is associated with recent abdominal surgery. It is treated with oral metronidazole (Flagyl) 250 mg four times daily for 10 days, vancomycin (Vancocin) 125 mg four times daily for 10 days. Relapse (20%) is treated with second course of above. Patients with multiple relapses may require 30 days of antibiotic treatment. Avoid antimotility agents.
Clostridium perfringens	Found in soil, feces, air, water. Outbreaks caused most often by contaminated meat. Type A enterotoxin causes mild to moderate gastroenteritis. Type C enterotoxin can be fatal.	Duration of illness is similar to mild gastritis, lasting 1–4 days without medical intervention. Fatal cases are less common. Onset is usually within 12 hours of ingestion of contaminated food.	Abrupt onset of diarrhea without fever. If fatal, cases have severe diarrhea with abdominal pain and distention.	Diagnosis is made by isolating organism in food or feces. Cultures usually show many clostridia in food or feces. No treatment is necessary for mild forms other than supportive care. Penicillin may be useful in severe cases.
Escherichia coli (E coli)	Five identified strains classified by pathogenesis of diarrhea. All are gram-negative rods.	Dependent on strain; epidemics are due to ingestion of contaminated meat or dairy products.		

	Enterohemorrhagic *E coli* (EHEC). Most serious; produces a hemorrhagic infection; O157:H7 strain produces two toxins, which inhibit protein synthesis in intestinal cells.	Duration typically 1–8 days. Onset is 24 hours after ingestion of contaminated food.	Acute onset of dysentery with 12–24 hours of abdominal cramps, watery diarrhea, and fever is followed by bloody stools. Can cause hemorrhagic infection of colon and can be fatal. Complications include hemolytic-uremic syndrome (HUS) or thrombolytic thrombocytopenic purpura (TTP). WBCs are greater than 20,000; azotemia; dehydration. Infants and older adults are most prone to adverse effects.	Diagnosis is by isolation of *E coli* O157:H7 in stools. Look for the source of undercooked meat. It can be transmitted in feces and dirty diapers. Treatment is supportive. Antibiotics have not proved effective.
	Enterotoxigenic *E coli* (ETEC). Adheres to the mucosa of small bowel releasing toxins, which cause diarrhea.	Duration 2–4 days. Incubation period is 24–36 hours.	Most common cause of traveler's diarrhea from contaminated food or water. Mild fever, abdominal cramps, watery stool, nausea, and vomiting are common.	Usually self-limiting, requiring no treatment other than supportive care. It is common in developing countries.
	Enteropathogenic *E coli* (EPEC).	Duration is 1–3 days; 12- to 36-hour incubation period.	Profuse, watery, foul-smelling diarrhea. It is of special concern to infants and older adults who are prone to dehydration.	Usually self-limiting. Infants and older adults may require hospitalization. It is rare in the United States.
	Enteroinvasive *E coli* (EIEC) causes invasion and proliferation within enterocytes, much like *Shigella* infection.	Duration is 4–10 days; 12- to 72-hour incubation period.	It is an uncommon cause of food-borne dysentery in the United States. Patients have fever, anorexia, cramps, and watery diarrhea. Stools may be mucoid or bloody. Clinical presentation is much like that of *Shigella* infection.	May isolate leukocytes in stool. Diarrhea is self-limiting. Food poisoning of this kind is rare in the United States.
	Enteroadherent *E coli* (EAEC) is rare and adheres to liver cells.		Mild, nonbloody diarrhea; strain is uncommon.	No leukocytes in stool.

Table 11.6 Organisms Causing Gastroenteritis—cont'd

Pathogen	Pathogenesis	Duration/Onset	Clinical Findings	Diagnosis and Treatment
Vibrio cholerae	Commonly found in areas with poor sanitation; food and water contaminated with feces. Enterotoxin causes hypersecretion in small intestine. Rarely found in the United States but may be endemic along the Gulf Coast.	Incubation is 1–3 days. Duration is 1–2 weeks.	Most cases in the United States are hemolytic and are transported here from contaminated foods. Diarrhea can be severe, causing septicemia, especially in immunocompromised patients, children, or older adults. Diarrhea is profuse, "rice water" and can be life-threatening. There is no abdominal cramping or fever. Patients may stool at the rate of 1 L/hr.	To diagnose *V cholerae* a special *Vibrio*-selective medium must be used in the stool culture. Diarrhea requires prompt replacement of fluids and electrolytes. Antibiotic: tetracycline 500 mg PO every 6 hours for 2 days or Bactrim DS every 12 hours for 2 days.
Vibrio parahaemolyticus	Pathogen found in seafood. Produces toxins in the gut or invades intestinal mucosa. Outbreaks frequent in summer; usually associated with improperly cooked seafood.	Incubation period 8–24 hours. Duration is 1–3 days.	Patient presents with abdominal cramping, headache, fever. Usually associated with explosive, noninflammatory, watery diarrhea, which may be bloody depending on the degree of mucosal destruction.	Stool is positive for *Vibrio*. Often diagnosed when a group of people become sick after consuming seafood. Food cultures are positive.
Yersinia enterocolitica	Primarily transmitted via fecal-oral route; food borne. It is rare in the United States; more common in northern Europe and Canada. Organism forms an enterotoxin and invades the intestinal epithelium.	Onset and incubation are unknown. Duration usually resolves in 1–3 weeks.	Symptoms include fever, abdominal pain, and bloody diarrhea. Older children may develop mesenteric adenitis, which presents with fever, right lower quadrant pain, and leukocytosis; similar to symptoms of appendicitis. Adults may present with polyarthritis, Reiter's syndrome, and erythema nodosum. *Yersinia* can cause bacteremia.	Diagnosis is made by isolation of organism in the stool. Stool also tests positive for fecal leukocytes. Treatment for severe cases is tetracycline 250–500 mg every 6 hours for 7–10 days; ciprofloxin 500 mg PO twice daily; tobramycin 3–5 mg/kg per day every 8 hours.
Salmonella	One of the major causes of diarrhea worldwide. Three species: *S typhi, S choleraesuis, and S enteritidis*. Found	Duration is 2–5 days; onset is 8–48 hours after ingestion. Patients may become "chronic carriers," defined as	Peak incidence is in summer and fall. Symptoms begin with nausea and vomiting, followed by colicky abdominal pain and	Diagnosis is made by isolation of organism in stool. No treatment is necessary unless associated with fever

	primarily in chicken, eggs, and livestock, causing 85% of community-acquired *Salmonella* outbreaks. Individuals must ingest 10,000–1 million organisms to become infected.	individuals with positive stool cultures 1 year after initial disease.	bloody or mucoid diarrhea. Enteric fever results from organisms entering the bloodstream via the bowel lymphatics, causing bacteremia, headache, and myalgias. Tissue abscesses may develop. Stools may be foul smelling.	and systemic disease. Treatment includes trimethoprim-sulfamethoxazole (Bactrim DS) or a quinoline, norfloxin 400 mg or ofloxin 400 mg PO twice daily for 7–10 days. Stress proper handling of food, thorough cooking, and good hand washing.
Shigella	One of the most common causes of bacillary dysentery. Several species: *S sonnei* is isolated in 75% of cases in the United States. Because of poor hygiene and overcrowding, it is spread via the fecal–oral route and requires only a small number of organisms to produce disease. Organism causes epithelial invasion of intestinal mucosa.	Duration usually 4–7 days and is self-limiting. Incubation period of 1–2 days after exposure or ingestion of pathogen.	Initially patients present with watery diarrhea and high fever. Later colitis-type symptoms develop: Abdominal cramps, tenesmus, urgency, frequent small stools with blood and mucus. Low-grade fever may persist for 2–20 days. Complications can include hemolytic-uremic syndrome (HUS) and colitis.	Diagnosis is made by isolation of organism in stool or rectal swab. In severe cases sigmoidoscopy shows mucosal hyperemia, friability, and ulceration. Treat with Bactrim DS twice daily for 3 days if infection was acquired in the United States.
Staphylococcus	Common cause of food poisoning. Caused by ingestion of enterotoxin found in improperly handled or stored foods. Enterotoxins produced by *Staphylococcus* act on receptors in the gut, which then transmit impulses to medullary centers.	Abrupt onset 1–8 hours after ingestion of contaminated food. Duration is usually less than 24 hours.	Abrupt onset of nausea, vomiting, colicky abdominal cramps, profuse watery diarrhea.	Definitive diagnosis is made only if contaminated food source is tested; otherwise, diagnosis is made based on short incubation and duration of symptoms.

Table 11.6 Organisms Causing Gastroenteritis—cont'd

Pathogen	Pathogenesis	Duration/Onset	Clinical Findings	Diagnosis and Treatment
Viral Pathogens				
Rotavirus	Very common cause of gastroenteritis in industrialized areas. Organism most often implicated in deaths from diarrhea. Frequently involves small bowel. A disaccharidase deficiency is common after rotavirus infections. Rotavirus is an RNA virus with four antigenic serotypes.	Incubation period 24–36 hours. Duration is 4–6 days.	Common in children younger than age 3. Peak incidence at age 6–24 months. Uncommon in adults because most have developed immunity. Symptoms include low-grade fever and copious watery diarrhea. Outbreaks are more common in winter months.	Diagnosis is made by electron microscopy. Serological enzyme-linked immunosorbent assay (ELISA) tests are available. No leukocytes found in stool.
Norwalk virus	Cube-shaped virus with seven known antigenic variants. It can cause large epidemics spread by contaminated water. It is transmitted by the fecal-oral route. It is a common cause of absenteeism due to "viral gastroenteritis."	Incubation is 18–48 hours. Duration is 48–72 hours.	Illness can be very debilitating to some patients. Symptoms are mild and brief and include vomiting, frequent watery diarrhea, diffuse myalgias, chills, and sometimes fever. Often causes family outbreaks.	No known antiviral therapy is available. Fluid and electrolyte replacement is the treatment of choice. Virus can be isolated with electron microscopy but is costly and the disease is self-limiting.
Protozoal Pathogens				
Giardia lamblia	Approximately 4% of healthy U.S. citizens harbor *G lamblia* in their intestines and are asymptomatic. *G lamblia* is a protozoon that attaches to the mucosa of the small bowel. Patients with hypogamma globulinemia and achlorhydria are predisposed to giardiasis. It is transmitted via oral–anal intercourse and is a common cause of traveler's diarrhea and diarrhea in children who attend day-care centers.	Incubation is 1–4 weeks. Duration usually 1–6 weeks.	Symptoms range from non specific complaints of bloating, flatulence, nausea, and watery, noninflammatory diarrhea to chronic diarrhea with weight loss, anorexia, and malabsorption.	Diagnosis can be made by examination of stool but is most often made by duodenal aspirate or small bowel biopsy. Stool exam is positive for trophozoites in about 50% of confirmed cases. Treatment with quinacrine hydrochloride (Atabrine) 100 mg three times daily after meals for 5–7 days or metronidazole (Flagyl) 250 mg three times daily for 5–7 days.

Entamoeba histolytica (amebiasis)	Transmitted via contaminated food and water, primarily in tropical areas with poor sanitation. Common in Mexican migrant workers and military personnel returning from the Far East. Human host becomes a reservoir after ingesting cysts from source and can transmit disease via fecal–oral route. Venereal transmission is common in the male homosexual population.	Most common clinical variant is the asymptomatic cyst carrier who can be a reservoir for an undetermined length of time. Duration can be weeks to months.	Symptoms include abdominal cramps, abdominal pain, and weight loss. Diarrhea contains blood and mucus. Patients may have hepatomegaly and pain over the cecum and ascending colon. Some patients may have fever, tenesmus, and acute dysentery illness. Complications can include peritonitis, toxic megacolon, and hepatic abscess. The encysted ameba is passed into the environment, where it can survive for up to 10 days.	Diagnosis is important to distinguish amebiasis from ulcerative colitis because treatment with glucocorticoids can accelerate amebic colitis and enhance systemic invasion. Sigmoidoscopy reveals discrete rectosigmoid ulcers with normal intervening mucosa. Indirect hemagglutination test is effective in detecting invasive amebic disease but remains positive long after treatment. Treat with metronidazole (Flagyl) 750 mg three times daily for 7–10 days.
Cryptosporidium	Enteric protozoan parasite that invades the small bowel located just below the basement membrane. Causes two distinct syndromes—one in immunocompetent and one in immunosuppressed individuals. Common cause of water-borne outbreaks from inadequate filtration. Parasite produces an exotoxin.	Incubation is 1–3 weeks. Usually self-limiting but can last 1–2 weeks in immunocompromised patients.	Outbreaks can occur after ingestion of water contaminated with livestock waste. Also common in day-care centers and patients with AIDS. Immunocompromised patients develop severe cholera-like diarrhea, which can last for months and cause daily fluid losses of 5–10 L/day.	Diagnosis by isolation of parasite in stool. Commercially available immunofluorescent antibody test can also assist diagnosis. Leukocytes not present in stool. Intestinal mucosa not inflamed but with ulcerations. Suggested treatment includes paromomycin (Humatin) 500 mg PO four times daily with food for 14–28 days, then 500 mg twice daily indefinitely. If treatment fails: azithromycin (Zithromax) 2.4 g PO on day 1, 1.2 g PO for 27 days, and then 600 mg/day for maintenance indefinitely.

infection manifest with diarrhea. Diarrheal diseases cause an increase in the frequency of stools, less well formed feces, and an increase in the fecal water content. The definition of diarrhea is dependent on each patient's normal bowel habits. Diarrhea is not considered a medical emergency unless it affects children or older adults who are less able to regulate their fluid intake. Diarrhea is a major cause of infant mortality in developing nations.

The gastrointestinal (GI) tract has several defenses against the development of infection. When bacterial or viral pathogens can overcome these barriers, they proliferate, causing varying degrees of gastroenteritis. The acidity of the stomach is normally maintained at a pH of 2, which creates a hostile environment for most microorganisms. This acidic barrier protects the small bowel and colon from ingested pathogens. If the organism is resistant to the acid environment or the patient has taken medications that alter the pH, the organism may thrive and cause illness.

Another host defense mechanism is the constant peristalsis of the small bowel, which prevents the colonization of pathogens within the lumen. Patients who have small bowel stasis as a result of obstruction, diverticuli, or blind loop syndrome frequently develop an overgrowth of bacteria within the stagnant segment, causing gastroenteritis resulting from the increased number of bacteria in the small bowel. In contrast, the colon is relatively stagnant; it typically harbors about 1 billion bacteria per gram of intestinal contents. Normal feces are composed primarily of water and bacteria. These beneficial bacteria protect against potential pathogens by consuming available nutrients and by producing by-products that create a hostile environment to the invading pathogens.

The GI tract also produces specific immunoglobulins that protect against invading organisms. After exposure to certain organisms, immunoglobulins may even protect against future invasions by the same organism, much like an antigen–antibody response. IgA, a secretory immunoglobulin, may help defend against many of the bacteria that cause gastroenteritis by invading the intestinal mucosa.

Ingestion of contaminated food can result in clinical symptoms of gastroenteritis, depending on the number and virulence of the organisms in the food. Almost all bacteria are capable of producing mild diarrhea if ingested in large enough quantities. Other organisms (e.g., *Shigella, Salmonella, Campylobacter, Cryptosporidium*) have such a high virulence that only a small inoculum can produce symptoms.

Often, the incubation time of the pathogen, coupled with the presenting symptoms, will give specific clues for establishing a diagnosis. Infectious processes of the small intestine often result in watery, secretory, or a malabsorptive type of diarrhea; infections of the large intestine tend to produce bloody diarrhea and abdominal pain. Gastroenteritis with an onset of nausea and vomiting within 6 hours after exposure to the pathogen suggests food poisoning resulting from the ingestion of a preformed toxin such as that of *Bacillus cereus.* Incubation periods greater than 14 hours and the initial symptom of vomiting are highly suggestive of viral infections.

Clinical Presentation

Subjective

Patients with gastroenteritis present with varying degrees of nausea, vomiting, diarrhea, fever, and abdominal pain and cramping. Symptoms depend on the underlying cause but can also include fatigue, malaise, anorexia, tenesmus, and borborygmus. Individuals with profuse diarrhea may complain of rectal burning and hematochezia from rectal abrasion and bleeding. Patients may complain of symptoms that suggest dysentery, including passage of numerous small-volume stools containing blood and mucus. Reports of voluminous stools are suggestive of a source in the small bowel or proximal colon; small stools accompanied by a sense of urgency suggest a source in the left colon or rectum. Bloody stools suggest mucosal damage and an inflammatory process secondary to invasive pathogens. Frothy stools and flatus suggest a malabsorption problem.

Objective

The physical exam is usually normal except for the aforementioned GI problems. Depending on the degree of dehydration, the skin turgor may be poor, and mucous membranes may be dry. Vital signs may reflect dehydration, such as a fever with an increase in temperature and heart rate. Older and very young patients with gastroenteritis may show signs of severe dehydration such as orthostatic hypotension and dizziness. Patients who have had prolonged illness and are malnourished may present with edema resulting from hypoalbuminemia.

Diagnostic Reasoning

Diagnostic Tests

Evaluation of the history is of vital importance to the appropriate diagnosis and management of the patient with gastroenteritis. The patient must be questioned thoroughly about the temporal association of symptoms with the suspected pathogen. Patient history should include a thorough drug history, including over-the-counter drugs, antibiotics, antacids, laxatives, alcohol, and sugar substitutes. It is important to know the patient's travel history, surgical history, and sexual orientation and practices. The duration of the illness is important in the differential diagnosis because acute diarrhea is usually caused by infectious agents or toxins, whereas chronic diarrhea usually has a noninfectious etiology.

Laboratory diagnosis of acute gastroenteritis is not always necessary in patients with nonbloody diarrhea and no evidence of systemic toxicity. In the average,

otherwise healthy adult, the disease will normally run its course without incident, and there is no need for costly evaluation. Selection of the most appropriate tests is based on information received from the history and physical exam. In patients with severe diarrhea and dehydration, stools should be examined for consistency, blood, and fecal leukocytes. Numerous fecal leukocytes in patients with acute diarrhea is indicative of diffuse colonic inflammation and is highly suggestive of an invasive pathogen such as *Shigella, Salmonella,* or *Campylobacter.* Other causes of leukocyte-positive stools include *Clostridium difficile, Yersinia, Vibrio parahaemolyticus,* and *Escherichia coli.* In patients with chronic diarrhea, fecal leukocytes suggest inflammatory bowel disease (IBD) or ischemia.

A stool culture should be done on any patient who has severe diarrhea, a fever of 101.3°F (38.5°C) or higher, the presence of bloody stools, or stools that test positive for leukocytes, lactoferrin, or occult blood because these findings are indications of a bacterial pathogen. Routine stool culture will identify the presence of *Shigella, Salmonella, Campylobacter, Aeromonas,* and *Yersinia.* In diarrheal illnesses that are suspected to be caused by eating contaminated hamburger meat, stools can be cultured for *E coli.*

Blood cultures should be obtained from patients who show clinical signs of typhoid or enteric fever or from any hospitalized patient who has an intestinal illness with high fever. It is essential that the blood cultures be obtained before initiation of antibiotic therapy.

Stools should be examined for ova and parasites in cases of persistent diarrhea, especially if the symptoms began after travel to Russia, Nepal, the Rocky Mountains, or other mountainous regions, or after exposure to infants in a day-care center. Parasites should also be considered in homosexual males or any patient with HIV/AIDS who presents with diarrhea, as well as in a patient with diarrhea who lives in a community where a water-borne outbreak has occurred. If a patient has diarrhea that has lasted longer than 2 weeks and the stool is negative for fecal leukocytes, a stool exam for parasites should be considered. Patients with intestinal amebiasis usually have no leukocytes in their stool because of the noninflamed areas of intestinal mucosa between the areas of ulceration, as well as the lytic effects of the exotoxins produced by the parasite. If parasitic infection is highly suspected but the stool culture is negative, a small bowel biopsy is indicated to identify the causative agent. Immunofluorescent antibody tests and diagnostic enzyme-linked immunosorbent assay (ELISA) tests are more sensitive than microscopic studies for identifying *Giardia* and *Cryptosporidium.*

In patients with epidemiological evidence, stool samples should be sent to the laboratory for specific enteropathogen studies that are not normally detected with routine stool culture, such as enterohemorrhagic colitis (*E coli* O157:H7), *Vibrio cholerae,* other noncholera vibrios, and other Shiga toxin–producing *E coli.* Routine stool culture identifies certain strains of *Yersinia* and *E coli* O157:H7; however, some strains can be detected only by research laboratories. Any patient who develops diarrhea after initiation or completion of antibiotic therapy should have tissue culture assay or an ELISA test for *C difficile* toxin.

Viral gastroenteritis should be suspected in patients who present with vomiting as the major symptom and in cases where food- or water-borne contamination is suspected and the incubation period is greater than 12 hours. Although there are commercially available test kits that identify rotaviruses, their application is limited because there is no known treatment for viral causes of illness.

Flexible sigmoidoscopy is usually reserved for patients with colitis that is unresponsive to antibiotic therapy and for patients with persistent diarrhea undiagnosed by laboratory evaluation. Tissue biopsy can help identify the offending pathogen, as well as differentiate infection from chronic inflammatory changes consistent with IBDs or celiac disease.

Differential Diagnosis

The differential diagnosis of gastroenteritis, particularly in patients with persistent or chronic diarrhea and severe abdominal pain, should include inflammatory bowel syndrome, IBD, ischemic bowel disease (especially in patients with peripheral vascular disease), partial bowel obstruction, and pelvic abscess. Other considerations for diagnosis should include ruling out complications from diabetes mellitus, small bowel diverticulosis, Whipple's disease, chronic pancreatitis, and any surgical alteration of the GI tract that might interfere with normal absorption.

Management

All patients who present with diarrhea require fluid and electrolyte management, particularly children, older adults, and immunosuppressed patients. Patients who are dehydrated and able to tolerate oral fluid replacement should be instructed to drink fluids with a sodium content of 45 to 75 mEq/L (Pedialyte or Gatorade) or be provided with oral rehydration salts. In patients who are severely dehydrated or those who have chronic diseases and are hypotensive, hospitalization for IV hydration may be indicated. In otherwise healthy adult patients who are not dehydrated, sports drinks, diluted fruit juices, and broths or soups are usually adequate for fluid and sodium replacement.

Patients with diarrhea require a diet that includes calories that come from boiled starches and cereals (potatoes, pasta, rice, wheat, and oats), which will facilitate enterocyte renewal, with the addition of salt for the duration of illness. Once stools have started to become formed, the diet can be advanced as tolerated. Some authors advise avoiding dairy products; however, this is

not necessary unless there is clinical evidence of lactose intolerance.

Nonspecific symptomatic treatment of acute diarrhea can decrease the occurrence by 50% and is most effective against secretory diarrhea. Antimotility drugs are the most frequently prescribed and most effective drugs for the treatment of symptomatic gastroenteritis. These agents work by slowing intraluminal peristalsis, thereby slowing the passage of fluids through the lumen, which facilitates absorption. Patients with febrile dysentery should not receive antimotility medications because slowing the intraluminal time may prolong the duration of the disease. Drugs Commonly Prescribed 11.3 lists medications commonly recommended for the symptomatic treatment of acute diarrhea.

Empiric antimicrobial therapy is recommended for patients with severe diarrhea, especially those with fever or stool positive for leukocytes. Traveler's diarrhea is treated empirically with trimethoprim-sulfamethoxazole (Bactrim DS), one double-strength tablet twice daily for 3 days. Other antibiotics that are effective for milder forms of illness include a single dose of ciprofloxacin (Cipro) 500 mg, norfloxacin (Noroxin) 400 mg, or ofloxacin (Floxin) 300 mg. Antibiotic prophylaxis, which has a 90% effectiveness rate, for people traveling in high-risk areas includes the antibiotics mentioned above in daily doses continuing for 2 days after returning home. Nonantibiotic preventive therapy includes bismuth subsalicylate (Pepto-Bismol), two tablets before each meal and at bedtime for a total of eight tablets/day for the entire trip. This remedy has an approximately 60% effectiveness rate.

Follow-up and Referral

Follow-up is not usually required except in those patients suffering from the chronic forms of infectious diarrhea such as from *C difficile.* Often, patients with serious infectious diarrhea will require home administration of IV antibiotics. Patients who require sigmoidoscopy for biopsy of intestinal mucosa for identification of the pathogen should be referred to a gastroenterologist.

Patient Education

The aim of patient education is prevention of the spread of disease from patients with infectious diarrhea to other individuals. Teaching includes good hand washing and safe disposal of waste products. Any infant or child with infectious diarrhea should not attend day care until the diarrhea has stopped or the child has completed the prescribed course of antibiotics. Good hand washing technique is imperative to prevent household outbreaks of the disease.

Patients traveling in high-risk areas should be instructed to consume only safe foods and beverages there and on the airplane leaving the area. "Safe" foods include acidic foods such as unpeeled citrus fruits; dry foods such as breads and cereals; steamed foods and beverages such as coffee, tea, and cooked vegetables; foods containing high amounts of sugar such as syrups, jellies, and jams; and bottled carbonated drinks such as soda and beer. It is generally not considered safe to drink bottled water (unless bottled from a safe source) or to eat raw, uncooked vegetables, including salad. Patients with known HIV infection and any other individuals with a known debilitating illness who may not tolerate any degree of gastroenteritis should be encouraged to take antibiotic prophylaxis.

PEPTIC ULCER DISEASE

Peptic ulcer disease (PUD) is a generic name for both gastric ulcers and duodenal ulcers. A peptic ulcer is a break in the surface mucosa of the stomach or duodenum, which results when there is disruption of the normal mucosal defenses and the tissue is exposed to the damaging effects of acid and pepsin. By definition, a peptic ulcer penetrates the muscularis mucosa and is

Drugs Commonly Prescribed 11.3 Symptomatic Treatment of Acute Diarrhea

Drug	Indication	Adverse Reactions and Prescribing Considerations
bismuth subsalicylate (Pepto-Bismol)	Acute diarrhea	Not as effective as loperamide in acute diarrhea. May potentiate the effects of antidiabetic medications. Do not use with antibiotics in patients with HIV infection.
loperamide (Imodium)	Acute diarrhea	Drug of choice for afebrile, nondysenteric cases of acute diarrhea. Minimal central opiate effect.
diphenoxylate with atropine (Lomotil)	Acute diarrhea	Prescription only. For use in afebrile, nondysentery cases of acute diarrhea. Has central opiate effects. Overdose possible. Atropine has adverse effects that may limit use.

usually larger than 5 mm in diameter. Peptic ulcers occur when there is an imbalance between the protective factors of the mucosa and aggressive factors as acid and pepsin. The initial damage to the mucosa is usually a result of infection by *Helicobacter pylori* or medications, particularly NSAIDs.

Epidemiology and Causes

A person's lifetime risk of developing a peptic ulcer is from 5% to 10%. Approximately 500,000 new cases are diagnosed each year in the United States. Men and women are almost equally affected by peptic ulcers, with the incidence in men slightly higher. Most duodenal ulcers occur in patients between age 30 and 55, but gastric ulcers are more prevalent between age 55 and 70.

A variety of conditions are considered to be risk factors for the development of PUD, but the three major causes are infection with *H pylori,* chronic ingestion of aspirin and other NSAIDs, and acid hypersecretion such as in Zollinger-Ellison syndrome. Genetics, blood type, personality type, and cigarette smoking may also play a role in the development of PUD. Patients with chronic obstructive pulmonary disease, cirrhosis, renal failure, and renal transplant have a higher incidence of PUD than the general public, but the mechanism is not known. Dietary factors such as caffeine, alcohol, and spicy foods are no longer considered to be ulcerogenic.

Pathophysiology

The majority of ulcers are located in the duodenum and approximately 90% occur within 3 cm of the pylorus. Almost all patients with gastric ulcers have normal or subnormal amounts of gastric acid secretion. Only about 35% of patients with duodenal ulcers have demonstrated above-average rates of acid secretion but have impaired duodenal bicarbonate secretion that is *H pylori* dependent. The breakdown of the local mucosal defenses appears to play a larger role in the pathogenesis of ulcer formation. Mucosal defense is supported by surface mucus and bicarbonate, which form a thin alkaline gel coating mucosal cells, and by prostaglandin-enhanced mucosal blood flow and cell renewal.

A variety of factors can affect the development of ulcers. Cigarette smoking facilitates ulcer formation, which is proportional to the amount smoked. The mechanism by which cigarette smoking causes ulcer formation is unclear. Aspirin and other NSAIDs decrease the mucosal defense mechanisms by inhibiting prostaglandin synthesis, leaving the area vulnerable to the effects of gastric hydrochloric acid and pepsin. Many infectious agents have been detected in patients with ulcer disease, but *H pylori* is the most important. As many as 75% of patients with duodenal ulcers are infected with *H pylori,* and the bacterium is present in the majority of gastric ulcer patients although the association with gastric ulcers is less. Not everyone with *H pylori* infection, however, develops PUD.

Clinical Presentation

Subjective

The hallmark of PUD is a complaint of a burning or gnawing (hunger) sensation or pain (dyspepsia) in the epigastrium, which is often relieved by food or antacids. These complaints, however, are not specific or sensitive enough to be diagnostic of ulcer disease. Patients with PUD usually describe an episodic pattern of complaints in which the pain tends to cluster and last for minutes, with the episodes separated by periods of no symptoms. It is this alternating pattern that is more predictive of ulcer disease than the nature of the symptoms themselves. Almost half the patients with NSAID-induced ulcers are asymptomatic.

Nocturnal pain is present in two-thirds of patients with duodenal ulcers and one-third of those with gastric ulcers. This corresponds to the circadian stimulation of acid secretion. Nausea and anorexia sometimes occur in patients with gastric ulcer, whereas vomiting and weight loss are indications of more serious complications such as gastric malignancy or pyloric obstruction. Patients with duodenal ulcers may report a reduction in pain after eating; patients with gastric ulcers tend to experience more intense pain after eating, which is a result of secretion of gastric acids.

Objective

The physical exam is not useful in differentiating PUD from other types of upper gastrointestinal (GI) disorders. Patients with duodenal ulcers often demonstrate epigastric tenderness 2.5 cm to the right of the midline, but this may also be present with cholecystitis, pancreatitis, nonulcer dyspepsia, and other GI disorders. Reports of melena or coffee-ground–like emesis usually indicate a bleeding ulcer, and a perforated ulcer may present with abdominal rigidity.

Diagnostic Reasoning

Diagnostic Tests

Most routine laboratory tests are normal in patients with ulcer disease unless there is significant bleeding or vomiting, in which case the results show anemia and fluid and electrolyte disturbances. When a patient is actively bleeding, a complete blood count to evaluate hemoglobin levels is paramount. There is controversy in the literature regarding the hemoglobin level that would require transfusion. Most patients with upper GI bleeding should have *restrictive strategy,* defined as transfusing when hemoglobin levels fall below 7 g/dL. The diagnostic standard for PUD is upper GI endoscopy. It is much more accurate in diagnosing ulcer disease than the previously used upper GI radiographic series. Endoscopy also does not involve exposure to radiation, which is a concern, particularly in pregnant patients.

Research has implicated *H pylori* gastritis in 90% to 95% of both duodenal and gastric ulcers that are not

associated with NSAIDs. *H pylori* infection increases with age, and in the United States more than 50% of asymptomatic persons older than 60 years show evidence of active or past infection. Worldwide, at least 30% to 50% of the population is colonized with this bacterium, but the rate is declining. The mode of transmission is unknown. In response to *H pylori,* the stomach produces more gastrin, which in turn leads to an increase in the amount of acid secreted by the parietal cells. The excess acid and pepsin on the stomach lining can cause the lining to erode and leads to the development of an ulcer. A simple serology test for *H pylori* can be done. *H pylori* can also be diagnosed by direct bacteriological analysis via an esophagogastroduodenoscopy (EGD) biopsy. EGD is an expensive, invasive procedure with possible complications; therefore, it is ordered for examination of individuals who have failed the standard triple-drug therapy for *H pylori* (see Drugs Commonly Prescribed 11.4) or for those who require direct visualization of the gastric mucosa for acute bleeding. There are a number of other ways to diagnose *H pylori.* A serological antibody (enzyme-linked immunosorbent assay) test can be used to detect infection with *H pylori,* but the test does not distinguish between active or past (treated) infection and is expensive. Urease is plentiful in patients with *H pylori* infection. Breath tests for *H pylori* are based on the production of ammonia from the metabolism of urea by urease. These breath tests indicate active infection and are a noninvasive way of diagnosing *H pylori* infection, although negative tests have a poor predictive value because false-negative results are more likely than truly negative findings.

In patients for whom an increase in gastric acid secretion is suspected, a fasting serum gastrin level should be drawn. Levels higher than 200 pg/mL should be confirmed on repeat testing and followed by basal and peak acid-output measurements. Zollinger-Ellison syndrome should be suspected in patients whose fasting serum gastrin level is above 600 pg/mL and who have a basal acid output of more than 15 mmol/hr.

Differential Diagnosis

PUD must be distinguished from other causes of epigastric distress, which can be problematic because a variety of thoracic and upper abdominal disorders can cause similar pain. Diseases to be considered in the differential diagnosis should include nonulcer dyspepsia, cholecystitis, pancreatitis, irritable bowel syndrome, gastroesophageal reflux disease, gastric cancer, myocardial ischemia, gastritis, and gastroenteritis. If the pain does not respond to food or antacids and there is severe pain and rebound tenderness, the cause is not likely to be an uncomplicated peptic ulcer. If the patient presents with weight loss, anemia, or exacerbation of the pain when eating, gastric cancer should be suspected.

Management

The principal aim of management for patients with PUD is to relieve pain, heal the ulcer, and prevent complications

Drugs Commonly Prescribed 11.4 Peptic Ulcer Disease

Drug	Indication	Adverse Reactions and Prescribing Considerations
First-line Therapy Antacids—only for symptom relief Mylanta II 2–4 tsp between meals and at bedtime Sucralfate 1 g four times per day for 4–8 weeks Proton pump inhibitors (PPIs)—all should be administered 30 minutes before breakfast Omeprazole 20 mg Lansoprazole 30 mg Esomeprazole 40 mg Rabeprazole 20 mg Pantoprazole 40 mg	Peptic ulcer disease	These medications should be used only as long as the patient is symptomatic and as needed.
Second-line Therapy PPIs as above PLUS Metronidazole 250 mg 4 times per day or Metronidazole 500 mg 3 times per day PLUS Tetracycline 500 mg 4 times per day PLUS Bismuth subsalicylate 2 tablets 4 times per day	When first-line therapy fails	These medication may inhibit absorption of digoxin, tetracycline antibiotics, and quinolone antibiotics. This regimen should be used for 10–14 days. Long-term use of PPIs is not advised. This drug may potentiate the effects of antidiabetic medications causing hypoglycemia.

or recurrences. Pharmacological therapy is the foundation of management for PUD, but nonpharmacological measures, such as smoking cessation, should be used as well. Cigarette smoking increases the risk for PUD; in patients with documented ulcers, smoking impairs healing, promotes recurrence, and increases the morbidity and mortality. There are no firm dietary measures for patients with PUD other than instructions to avoid foods that precipitate dyspepsia. Pharmacological intervention for PUD consists of H_2-receptor antagonists (H_2-RAs), proton pump inhibitors (PPIs), and agents that enhance the mucosal defenses, such as antacids, sucralfate (Carafate), bismuth subsalicylate (Pepto-Bismol), and prostaglandin analogs (misoprostol), as well as antibiotics.

Proton Pump Inhibitors

The PPIs are now the drugs of choice for treating PUD because they are more effective than H_2-RAs and are easier to use. The duration of action of the PPIs is more than 24 hours, whereas H_2-RAs inhibit only 65% of acid secretion over 24 hours. Another advantage of PPIs over H_2-RAs is that the PPIs are given on a once-a-day dosage schedule whereas H_2-RAs require at least twice-daily dosing. The usual dosage is either omeprazole 20 mg, rabeprazole 20 mg, lansoprazole 30 mg, esomeprazole 40 mg, or pantoprazole 40 mg. All of the PPIs inhibit parietal cell hydrogen-potassium adenosine triphosphatase (ATPase), which mediates hydrogen ion secretion. PPIs heal 90% of duodenal ulcers in 4 weeks of therapy and 90% of gastric ulcers after 8 weeks. Long-term use of these drugs is associated with slightly decreased absorption of vitamin B_{12} and iron.

H_2-Receptor Antagonists

If a patient has mild symptoms and no indicators of complications or a more serious disease, empiric therapy with an H_2-RA should be instituted for 2 weeks. After the initial treatment period, if symptoms persist or worsen, upper endoscopy should be considered for a more definitive diagnosis. When H_2-RAs are used for peptic ulcer treatment, the standard treatment is to administer an H_2-RA once a day at bedtime or half the daily dose twice a day for 8 weeks. More than 80% of ulcers are healed by the completion of this regimen. H_2-RAs effectively reduce basal and food-stimulated secretion of gastric acid and thus facilitate healing; they are generally well tolerated. Cimetidine (Tagamet), however, inhibits the hepatic cytochrome P-450 system and can increase levels of other medications that are metabolized by these enzymes, including warfarin (Coumadin), theophylline (Theo-Dur), and phenytoin (Dilantin). The other H_2-RAs have fewer adverse effects.

Other Pharmacological Agents

Antacids were traditionally the mainstay of ulcer treatment for decades and are still useful today. They neutralize acid rapidly, are generally well tolerated, and are inexpensive. One of the major disadvantages is that they require frequent (1- to 3-hour) dosing, which can contribute to patient nonadherence. They should be used with caution in patients with renal failure because of the risk of aluminum and magnesium toxicity. Antacids that contain calcium should not be used in patients with PUD because calcium causes rebound acid secretion.

Sucralfate is an aluminum hydroxide salt of sucrose that enhances the mucosal defenses and is used in healing duodenal ulcers and in the long-term treatment to prevent recurrence. Sucralfate works by forming a protective barrier to the action of acid and pepsin in the ulcer base. It also stimulates mucus, bicarbonate secretion, and prostaglandin production and binds fibroblast growth factor. Studies have shown that sucralfate 1 g four times daily heals duodenal ulcers as well as H_2-RAs do.

Bismuth preparations promote ulcer healing by stimulating mucosal bicarbonate and prostaglandin production. Bismuth also has antimicrobial action against *H pylori* and has been shown to eradicate the organism in up to 33% of cases. The two types of bismuth preparation available in the United States are bismuth subsalicylate and ranitidine bismuth citrate. Bismuth causes feces to darken or turn black. Patients should be warned of this effect to lessen their anxiety when it occurs. Bismuth subsalicylate also potentiates the effects of antidiabetic medications, so patients should be warned about the possibility of hypoglycemia.

Misoprostol (Cytotec), a prostaglandin analog, stimulates ulcer healing by promoting mucus and bicarbonate secretion. It is indicated for use only as a prophylactic measure to prevent gastric ulcer formation in patients who require treatment with NSAIDs for other conditions. It is ineffective in preventing duodenal ulcers caused by NSAID use. Misoprostol should not be used in pregnancy because it can cause abortion, premature birth, or birth defects.

There are a number of regimens used to eradicate *H pylori,* enhance ulcer healing, and prevent ulcer recurrence. Comparatively speaking, it is more cost effective to employ a regimen to eradicate *H pylori* than it is to maintain a patient on long-term therapy. Despite a number of randomized clinical trials, no optimal regimen has been identified. Most regimens use a combination of several drugs, including bismuth, amoxicillin, tetracycline, clarithromycin, metronidazole, H_2-RAs, and PPIs for a period of 2 weeks. Triple-drug therapy combining two antibiotics (clarithromycin and either amoxicillin or metronidazole) with a PPI has been shown to be very effective in the eradication of *H pylori* (75%–90%) (Level I; Chey and Wong, 2007). Amoxicillin is preferred over metronidazole because there are resistant strains of *H pylori,* and the adverse effects of metronidazole hamper patient adherence. Eradication of *H pylori* has also been demonstrated by combining bismuth subsalicylate and two antibiotics, but the dosing

schedule is four times daily and has a higher incidence of adverse effects. Drugs Commonly Prescribed 11.4 presents the drugs used for PUD.

Follow-up and Referral

In patients empirically treated for ulcers, follow-up is necessary only if symptoms recur. If after 2 weeks the patient has seen no improvement or symptoms have progressed, referral to a gastroenterologist for upper endoscopy is indicated. Any time a gastric ulcer is suspected rather than a duodenal ulcer, the patient should be referred to a gastroenterologist because the incidence of gastric cancer in these patients is increased. In patients treated with an *H pylori* eradication regimen, retesting for *H pylori* is necessary only if symptoms recur. Follow-up is necessary for any patient who does not respond to therapy or who experiences worsening symptoms.

Patient Education

The most important aspect of patient education is to stress the importance of following the treatment regimen prescribed. The patient's anxiety can be eased by informing him or her of possible bothersome side effects of any medications, such as a change in fecal color when taking bismuth preparations. If the patient is taking sucralfate in conjunction with an antacid, PPI, or H_2-RA, it should be stressed that the sucralfate cannot be taken at the same time as the other medications or at the same time as digoxin, ciprofloxacin, or phenytoin because sucralfate binds to all of these medications. Dispelling myths about ulcers is also an important part of patient education.

CHOLECYSTITIS

Cholecystitis is an acute inflammation of the gallbladder wall, which is usually the result of an impacted calculus within the cystic duct, causing inflammation proximal to the obstruction. Cholelithiasis is found in 90% to 95% of patients presenting with cholecystitis. Cholecystitis without gallstones, acalculous cholecystitis, is a very serious disease with high morbidity and mortality rates. It usually occurs in patients who are already critically ill because of trauma, burns, surgery, or sepsis and who have had no oral intake or have been supplemented with hyperalimentation. Patients present with severe pain and tenderness in the epigastrium or right upper quadrant (RUQ) of the abdomen accompanied by nausea, vomiting, fever, and leukocytosis.

Epidemiology and Causes

Cholecystitis/cholelithiasis is prevalent in Western societies. Researchers estimate that the disease affects approximately 20 million Americans, the majority of whom are not aware they have cholelithiasis. About 50% of these asymptomatic patients never require treatment. Gallstones form in people as early as their 30s. In fact, 75% of American Indian women over age 25 have gallstones. The risk of requiring a cholecystectomy increases with age as a consequence of complications secondary to the lithiasis. By age 65, about 20% of women and 10% of men have symptoms related to gallstones that require medical attention. As many as 5,000 to 6,000 deaths each year are attributed to gallstone-related disease.

Cholesterol stones are the most common form and account for 75% of all gallstones. The remaining 25% are pigmented stones, which are categorized as black or brown depending on their chemical composition. Cholesterol stones contain between 50% and 90% cholesterol; the remainder of the stone is made of calcium salts from bilirubin pigment, carbonate, bile acids, phospholipids, fatty acids, and proteins. Risk Factors 11.1 describes the risk factors associated with cholelithiasis.

The well-known mnemonic regarding the typical cholelithiasis patient is the "six Fs": fat, female, forty, flatulent, fertile, and fat intolerant. After age 50, the gender distribution is equal. Pregnancy also predisposes women to cholelithiasis, presumably because of the increased abdominal pressure and increased cholesterol levels during the third trimester. Any condition that increases the development of cholelithiasis increases the chance of developing cholecystitis.

Pathophysiology

From 90% to 95% of cholecystitis cases are associated with cholelithiasis. Cholesterol stones are the most common form of gallstones. Cholesterol is insoluble in water; it is made soluble though interaction with bile salts and phospholipids, allowing it to be carried within the bile. There are two known transport systems for cholesterol within the bile, vesicular and micellar, both of which exist in the bile to maintain equilibrium. When this

Risk Factors 11.1 Risk Factors Associated With Cholelithiasis

Cholesterol Stones	Pigmented Stones
Female gender	Hemolytic diseases
Obesity	Increasing age
Pregnancy	Hyperalimentation
Increased age	Cirrhosis
Drug-induced (oral contraceptives, clofibrates)	Biliary stasis
Cystic fibrosis	Chronic biliary infections
Rapid weight loss	
Spinal cord injury	
Ileal disease with extensive resection	
Diabetes mellitus	
Sickle cell anemia	

equilibrium is disturbed and the bile contains more cholesterol than can be maintained, crystallization of the cholesterol, referred to as nucleation, occurs. Gradual deposition of cholesterol on these crystals leads to the development of a cholesterol gallstone. Although this process seems to contribute to the formation of gallstones, not all people with cholesterol-saturated bile form stones. Thus, there is more to the process of lithogenesis than is known.

The gallbladder is of primary importance in the development of gallstones because it provides an arena for bile stasis and allows time for the slow crystallization of cholesterol, which may also be enhanced by yet unknown proteins or other materials within the bile. Biliary cholesterol is increased by ingestion of estrogen and oral contraceptives, multiparity, and inflammatory terminal ileal disease, which decreases the bile acid pool. Bile stasis, which can contribute to gallstone formation, is increased by strictures within the ductal system, parenteral hyperalimentation, fasting, and mechanical obstruction secondary to tumor or cyst formation.

The pathogenesis of pigmented stones is less well understood but seems to be directly related to elevation in levels of unconjugated bilirubin. Any disease state that increases the amount of bilirubin increases the risk for pigmented lithogenesis. Black pigmented stones are formed within the gallbladder and are commonly associated with hemolytic diseases and in patients with cirrhosis and those who require long-term parenteral hyperalimentation. Black pigmented stones are more fragile and seem to crush more easily than cholesterol stones.

Brown pigmented stones are composed of alternating layers of calcium bilirubinate and calcium fatty acids. Chronic bacterial infections are believed to be partly responsible for the formation of brown pigmented stones because the enzymes the bacteria produce predispose the patient to this type of stone formation. Brown stones are typically found within the intrahepatic ducts and are rarely found within the gallbladder.

The pathophysiological changes occurring within the gallbladder before the diagnosis of acute cholecystitis are directly related to the amount of time the duct has been obstructed and the degree of inflammation that has taken place. The earliest pathological findings are erythema, edema, and a fibrinosuppurative exudate. Tissue examination reveals inflammatory infiltration, hemorrhage, and edema resulting in ulceration of the mucosa within a short period of time. The result is the development of gangrene, with abscess formation. As the acute process resolves, collagen deposits develop, usually within 1 to 2 weeks. The gallbladder eventually contracts and becomes scarred, causing thickening of the wall. Often the gallbladder becomes filled with pus preceding the development of gangrene. Perforation may occur, most often at the fundus, but it can occur anywhere there is erosion of an impacted stone. Perforation of the gallbladder allows bile to spill into the peritoneal cavity, causing bile peritonitis, abscess, and fistula formation.

Clinical Presentation

Subjective

Acute cholecystitis causes various symptoms, ranging from generalized gastrointestinal complaints to intractable pain. Most patients complain of indigestion, nausea, and vomiting, especially after consuming a meal high in fat. Acute cholecystitis usually begins with acute, colicky-type pain. About 80% of patients report that they have experienced this type of pain before. However, the pain associated with acute cholecystitis persists, and as the inflammation progresses, the pain localizes over the RUQ. Patients may complain of referred pain that radiates to the middle of the back, to the infrascapular area, or to the right shoulder. The pain is increased by any movement, including respiration. If the inflammation extends to the peritoneal area, the pain worsens, the abdominal muscles become rigid, and a fever is usually evident.

Objective

Physical findings are dependent on the degree of inflammation present. As the pain over the RUQ becomes severe, there is often involuntary guarding of the abdominal muscles over the right side. A positive Murphy's sign is elicited when the right subcostal region is so tender that there is painful splinting with deep inspiration or when palpation over the RUQ area causes transient inspiratory arrest. The gallbladder is palpable in fewer than 50% of the patients. Fever is usually low grade, 99° to 101°F (38.3°C); high fever suggests sepsis. Patients may develop mild jaundice from edema of the common bile duct. Hyperbilirubinemia should raise the suspicion of choledocholithiasis. Bowel sounds may be diminished.

In most cases, acute cholecystitis subsides spontaneously, with improvement in the first few days and no symptoms after about 4 days. If symptoms persist or become more severe, the potential for perforation, gangrene, empyema, and septic shock increases. Rebound tenderness, shaking chills, or increased fever should raise suspicion that perforation has occurred. Surgical referral is indicated early in the disease process.

Diagnostic Reasoning

Diagnostic Testing

During the acute presentation of cholecystitis, there is usually mild elevation of the white blood cell count, to 15,000/mL. Serum transaminases can be elevated up to four times the normal amount; aspartate aminotransferase and alanine aminotransferase can be elevated to 300 U/L. Alkaline phosphatase is elevated two to four times above normal levels, and bilirubin can be as high as 4 mg/dL. Profound elevation of the alkaline

phosphatase and bilirubin is highly suggestive of choledocholithiasis. An elevation in amylase can be the result of passage of a stone through the common bile duct but may also indicate gallstone pancreatitis.

Abdominal x-ray films may reveal gallstones, enlarged gallbladder, or air within the biliary system or peritoneal cavity. The gold standard for diagnosis of acute cholecystitis is ultrasound; it is a quick, noninvasive, reliable, and cost-effective means of identifying the presence of cholelithiasis. Radionuclide scanning following administration of technetium-99m (99m-Tc) is the most accurate means of confirming the clinical diagnosis of cholecystitis with cystic duct obstruction. If the gallbladder fills with the isotope, the diagnosis of cholecystitis is highly unlikely; however, if the bile duct is visualized and the gallbladder is not, this is highly suggestive of cholecystitis. Oral cholangiograms are of no benefit in the acutely ill patient.

Differential Diagnosis

The differential diagnosis of acute cholecystitis in the presence of RUQ pain, nausea, vomiting, and fever includes pancreatitis, myocardial infarction, appendicitis, peptic ulcer, pneumonia, and hepatitis. Most of these potential diagnoses can be effectively ruled out via standard laboratory tests and ultrasound. Electrocardiogram can rule out myocardial infarction and is necessary as part of preoperative studies.

Management

Treatment of cholelithiasis depends on many variables, including age; presenting symptoms; past medical history; and size, type, and number of gallstones involved. Patients with symptomatic cholelithiasis can often be safely managed on an outpatient basis. Patients must be advised to avoid foods high in fat, which can provoke an attack. Nonsurgical options for the treatment of gallstones include dissolution of the stone by oral ingestion of ursodeoxycholic acid (ursodiol) or direct dissolution by percutaneous instillation of methyl-tertiary-butyl ether. Both types of dissolution therapies are of limited value and can be used only with cholesterol stones. Recurrence rates with these treatments are almost 100%, and the length of treatment may be as long as 2 years.

Patients who are deemed poor surgical risks can also undergo extracorporeal shock wave lithotripsy along with chemical dissolution in an attempt to reduce the size of the stone. Patients who continue to have biliary colic or who have developed other complications should be hospitalized for further treatment, with prompt referral to a gastroenterologist and/or a surgeon.

Initial Management

Initial treatment begins with definitive diagnosis. For many, the diagnosis of gallstones is made as an incidental finding during medical treatment for another problem. These patients are often asymptomatic and require no further treatment except awareness of the signs and symptoms of a "gallbladder attack." Patients who are considered a poor surgical risk can be treated nonsurgically with dissolution therapy or lithotripsy. Those who remain symptomatic despite treatment or have developed other complications should be hospitalized in an attempt to reduce the risk of a life-threatening event such as perforation or septic shock.

Management of acute cholecystitis includes rehydration with IV fluids and replenishing electrolytes as indicated by laboratory results. Patients are not allowed anything by mouth, and if vomiting is persistent, a nasogastric tube is inserted. Pain is managed with intramuscular analgesic agents. A third generation cephalosporin is started once the diagnosis is made. If sepsis is suspected, an aminoglycoside is added to the antibiotic coverage.

The treatment of choice for acute cholecystitis is early surgical intervention. Patients in the acute phase of the disease are usually stabilized before a cholecystectomy is scheduled. Patients who are considered a poor surgical risk may benefit from cholecystotomy, either operatively or percutaneously. Emergency decompression with cholecystotomy may be necessary to remove stones and purulent material before a cholecystectomy, which should be deferred for 6 to 8 weeks.

The mortality rate associated with acute cholecystitis is 5% to 10% and is usually associated with patients older than age 60 with comorbid conditions and those with septic complications. Approximately 50% of patients who do not choose to undergo cholecystectomy have a recurrence within 5 years, and complications are common.

Subsequent Management

The most common complications of acute cholecystitis are empyema and perforation. Perforation into the abdominal cavity can occur early in the disease process and is associated with a 30% mortality rate. Perforation may also occur into another hollow viscus or into the colon, causing draining fistulas, which may relieve the symptoms associated with cholecystitis. Surgical removal of the gallbladder with fistula repair is indicated when the patient is medically stable for surgery.

Follow-up and Referral

Patients with acute cholecystitis require referral to a general surgeon for removal of the gallbladder. Referral should be made after diagnosis of acute cholecystitis. Follow-up includes routine postoperative visits according to the surgeon. Patients who have persistent symptoms after the removal of the gallbladder (postcholecystectomy syndrome) may have a mistaken diagnosis, a functional bowel disorder, retained or recurrent common bile duct stones, or spasm of the sphincter of Oddi. Patients with incidental findings of asymptomatic gallstones should be

referred to a surgeon and given the option for elective surgery, medical dissolution therapy, lithotripsy, or contact solvent dissolution.

Patient Education

Patient education for individuals declining surgical intervention should include the risks and benefits of each therapy. Dietary counseling should include weight loss for those patients who are obese and the avoidance of fatty foods that provoke attacks. Patients taking oral contraceptives should be given information about alternative forms of birth control, and menopausal women taking estrogen should be counseled about alternative sources of phytoestrogens, such as soy products.

ACUTE PANCREATITIS

Acute pancreatitis is defined as an acute inflammation of the pancreas and the surrounding tissues resulting from the release of pancreatic enzymes into these tissues. These enzymes cause a chemical burn in the retroperitoneal spaces, which leads to systemic toxicity. The degree to which the microcirculation within the pancreas is preserved determines the histological classification of pancreatitis. If the microcirculation remains intact, the process is defined as acute interstitial pancreatitis, but if the microcirculation is disrupted, necrotizing pancreatitis results. Acute pancreatitis normally resolves both clinically and histologically.

Epidemiology and Causes

Although there are many causes of acute pancreatitis, approximately 80% of all hospital admissions for acute pancreatitis are the result of biliary tract disease (passing of a gallstone) and alcoholism. The remaining 20% are caused by infection (mumps), hyperlipidemia (particularly types I, IV, and V), metabolic disorders (hyperparathyroidism, hypercalcemia), drugs (furosemide, valproic acid, sulfonamides, thiazides), endoscopic retrograde cholangiopancreatography (ERCP), structural abnormalities of the pancreatic duct (stricture, carcinoma, pancreatic divisum), structural abnormalities of the common bile duct and ampullary region, surgery (particularly of the stomach and biliary tract), vascular disease (atherosclerosis, severe hypotension), or trauma.

Acute pancreatitis is usually the result of some other process, such as passing of a gallstone, excessive alcohol intake, or some other biliary tract disease. Clinical pancreatitis is seen in up to 9.5% of alcoholic patients, and histological evidence is found in 17% to 45% of this group. Cholelithiasis is present in 60% of nonalcoholic patients with pancreatitis.

Pathophysiology

Pathological changes associated with pancreatitis range from acute edema and cellular infiltration to necrosis and hemorrhage. Although the exact pathogenesis is not known, temporary impaction of the sphincter of Oddi by a gallstone before its passage into the duodenum may cause edema or obstruction of the ampulla of Vater, with subsequent reflux of bile into the pancreatic ducts and injury to the acinar cells. This cascade of events causes an autodigestive process within the pancreas that can progress to shock and death without appropriate intervention. Inflammation is confined to the pancreas in edematous pancreatitis, and the mortality rate is less than 5%.

When inflammation and tissue necrosis extends beyond the pancreas, the associated mortality rate is 10% to 50%. Pancreatic exudate containing toxins and activated enzymes permeates the retroperitoneum and causes a chemical burn that increases the permeability of the blood vessels within the peritoneal cavity. As a result, large amounts of protein-rich fluid from the circulation are sequestered in these third spaces, producing hypovolemia and shock. As these toxins and enzymes enter the systemic circulation, they can further reduce vascular tone and, thus, the ability to correct the hypotension and shock.

Acute pancreatitis can be classified as either mild or severe. Mild acute pancreatitis normally improves within 48 to 72 hours and does not involve other organ systems. There is minimal interstitial edema, with only occasional microscopic acinar cell necrosis. Severe, acute pancreatitis is often associated with complications and multisystem organ failure. It can be a life-threatening condition, and the patient may require monitoring in the intensive care unit (ICU).

Complications during the first few days of diagnosis are associated with hemodynamic instability: shock, renal failure, respiratory compromise secondary to adult respiratory distress syndrome (ARDS), and hypoxemia. Pancreatic necrosis with secondary gram-negative sepsis has an associated 100% mortality rate unless there is extensive surgical debridement of the infected tissue. Up to 25% of patients diagnosed with acute pancreatitis develop some degree of fluid collection within a few days of diagnosis that resolves spontaneously half of the time. Those that do not resolve spontaneously form pseudocysts, abscesses, and other necrotic collections.

Pancreatic pseudocysts take at least 4 weeks to form and resolve spontaneously after about 6 weeks in 40% of the cases. If the pseudocyst does not resolve within 12 weeks after acute pancreatitis, the risk of complications in symptomatic patients (infection, bleeding, rupture) are as high as 60%, but there is little associated risk in asymptomatic patients. The decision for invasive intervention will depend on the progression of symptoms and cyst size.

Clinical Presentation

Subjective

The patient with acute pancreatitis usually presents with abrupt onset of deep epigastric pain that persists for

hours to days and may radiate straight through to the back. The pain is intense and often refractory to large doses of parenteral narcotics. It is aggravated by any vigorous activity, such as coughing, and by lying supine; it improves when the patient is seated and leaning forward. The patient appears acutely ill, often with intractable nausea and vomiting. In some cases, depending on the severity, the patient may experience sweating, weakness, and anxiety. The patient may report a history of ingestion of alcohol or a big meal before onset of symptoms or mild biliary colic preceding the episode.

Objective

On physical exam, there is severe abdominal tenderness, particularly over the epigastric area, which may be accompanied by guarding but without rigidity or rebound tenderness, and there may be milder pain in the lower abdomen without guarding or rigidity. Abdominal distention is present in approximately 20% of the patients. Bowel sounds can be hypoactive or absent if associated with paralytic ileus. The rectal exam is normal, and the stool is usually negative for occult blood.

The patient is tachycardic (100–140 beats/min) with rapid, shallow respiration. Inspiratory effort is poor because deep inspiration causes pain. Blood pressure may be high secondary to pain or low if shock is imminent. The patient's temperature may initially be normal or subnormal but increases to 100.4° to 102.2°F (38° to 39°C) within a few hours. Mild jaundice and scleral icterus may be present. The patient's skin may be pale, cool, and clammy if shock is present.

Uncommon findings that can result from the pancreatic inflammatory process include left-sided pleural effusion, bluish discoloration over the flanks (Grey Turner's sign) or around the umbilicus (Cullen's sign), jaundice caused by impingement on the common bile duct, and epigastric mass secondary to pseudocyst development.

Diagnostic Reasoning

Diagnostic Tests

The diagnosis of pancreatitis is strongly suggested through the history and physical exam; however, because many other diseases present with similar symptoms, further testing is necessary. The gold standard for diagnosis is an elevated serum amylase (up to three times the normal level); however, in one-third of patients with alcoholic pancreatitis, the serum amylase level may be normal. The diagnosis of pancreatitis is supported by a concurrent elevation of the serum lipase. Serum amylase and lipase levels are increased on the first day of acute symptoms and return to normal in 3 to 7 days. These levels remain normal if there has been repeated prior damage to the acinar cells, rendering them incapable of further enzyme secretion. The level of elevation of amylase and lipase is not indicative of the severity of the disease.

The white blood cell (WBC) count is usually between 12,000 and 20,000 cells/mL. The hematocrit can be as high as 50% to 55% because of hemoconcentration resulting from sequestered fluids in the third spaces.

A decrease in serum calcium may indicate saponification and is indicative of the severity of the pancreatitis. Calcium levels below 7 mg/dL (with normal serum albumin) can cause tetany and are associated with poor prognosis. Elevated C-reactive protein is correlated with pancreatic necrosis. The risk of infection is positively correlated with pancreatic necrosis and accounts for most of the deaths. Pancreatic necrosis requires surgical intervention; computed tomography (CT)–guided aspiration of the necrotic tissue for Gram stain and culture is indicated.

Patients presenting with biliary pancreatitis have an elevation of the liver enzymes. When alanine aminotransferase is up to three times the normal limit, the positive predictive value is 95% that the pancreatitis is caused by biliary disease (gallstones). Concomitant rises in the aspartate aminotransferase, alkaline phosphatase, and bilirubin suggest gallbladder disease.

Diagnostic imaging, especially CT of the abdomen, can provide fast and accurate information for the definitive diagnosis of acute pancreatitis. Although the CT scan can be normal in 15% to 30% of patients with mild acute pancreatitis, it is the most efficient means of discerning acute pancreatitis from other potentially fatal intra-abdominal processes. CT is also helpful in monitoring the progression or resolution of pancreatic pseudocysts.

Ultrasonography (US) is the gold standard for identification and location of gallstones and is considered mandatory because studies have shown that the morbidity associated with gallstone pancreatitis is dramatically reduced once the stone is removed. US can also detect dilation of the common bile duct, indicating obstruction. ERCP with sphincterotomy and stone extraction can be performed and has been proved to decrease morbidity and mortality.

If there is evidence that the pancreatitis is severe, additional testing with IV contrast is recommended; the necrotic pancreas has damage to its microcirculation and, thus, is not enhanced with IV contrast. If the microcirculation remains intact, there is uniform enhancement of the pancreas. Pancreatic necrosis is associated with much higher morbidity, mortality, and infection rates.

Pancreatic infection is a complication that requires immediate diagnosis and intervention. Infection should be suspected when the patient has persistently elevated WBC counts and fever. The patient normally looks very sick. Positive blood cultures and visualization of gas bubbles within the retroperitoneum on CT support the diagnosis.

Ranson's criteria are the most widely accepted and utilized system for assessing the severity of acute pancreatitis. Identification of early prognostic signs may provide the best indication of a serious outcome and can alert the practitioner that the patient may require transfer to the ICU. Listed within Table 11.7 are the 11 objective signs used to classify the severity of pancreatitis. Mortality rates correlate directly with the number of diagnostic criteria present. Pancreatitis is classified as severe when three or more of Ranson's criteria are met.

Differential Diagnosis

Differential diagnosis of acute pancreatitis is made by history and physical exam and supported by laboratory data and imaging studies. The gold standard for diagnosis is serum amylase; however, in cases in which the level is normal or mildly elevated, diagnosis can be confirmed by CT scan. CT scan is useful in differentiating other intra-abdominal processes from acute pancreatitis. However, it is less helpful in identifying gallstones as a potential cause. Laboratory data are helpful in differentiating other causes of acute abdominal pain with associated hyperamylasemia. Table 11.8 differentiates hyperamylasemia resulting from pancreatic and nonpancreatic causes.

Table 11.7 Ranson's Criteria for Assessing the Severity of Pancreatitis

At admission or at time of diagnosis:

1. Age older than 55 years
2. White blood cell (WBC) count greater than 16,000/mcL
3. Blood glucose greater than 200 mg/dL
4. Base deficit greater than 4 mEq/L
5. Serum lactate dehydrogenase (LDH) greater than 350 IU/L
6. AST greater than 250 U/L

During the initial 48 hours:

1. Hematocrit (Hct) drop of more than 10 percentage points
2. Blood urea nitrogen (BUN) rise of greater than 5 mg/dL
3. Arterial PO_2 of less than 60
4. Serum calcium (Ca) of less than 8 mg/dL
5. Estimated fluid sequestration of greater than 6 L

Number of Diagnostic Criteria	Mortality Rate (%)
0–2	1
3–4	16
5–6	40
7–8	100

Adapted from Ranson, JH, et al. Prognostic signs and the role of operative management in acute pancreatitis. *Surg Gynecol Obstet* 139(1):69–81, 1974.

Table 11.8 Hyperamylasemia: Pancreatic and Nonpancreatic Causes

Pancreatic Hyperamylasemia	Nonpancreatic Hyperamylasemia
Pancreatic pseudocyst	Salivary adenitis (secondary to mumps)
Perforated duodenal ulcer	Ruptured ectopic pregnancy
Small bowel perforation Mesenteric infarction Mesenteric vascular thrombus	Postabdominal surgery Lactic acidosis
Opiate administration Post-ERCP	Leaking aortic aneurysm Renal insufficiency

Management

Treatment of acute pancreatitis is aimed at limiting the severity of pancreatic inflammation, preventing further complications by interrupting the pathological processes, and managing the symptoms as they arise. Mild acute pancreatitis usually resolves spontaneously in a few days, so these patients can be managed conservatively as outpatients. Fasting is necessary until the symptoms of acute inflammation have subsided.

Treatment includes maintaining fluid status with parenteral fluids to prevent hypovolemia and hypotension. Traditionally, pain is controlled with meperidine (Demerol) rather than with other opiates, to prevent increased pressure within the sphincter of Oddi, although research indicates that morphine causes no more spasms in the sphincter of Oddi than meperidine. The patient is allowed nothing by mouth, and nasogastric (NG) tube insertion should be considered when there is persistent nausea, vomiting, or evidence of ileus. The use of empiric antibiotics, H_2-receptor antagonists, and pancreatic enzyme inhibitors have not been proven effective and are not recommended.

Judicious introduction of clear liquids can be instituted once the patient is pain free, the amylase and lipase have returned to normal range, and bowel sounds have returned. The diet may be advanced to regular low fat as the patient tolerates.

Patients with more severe pancreatitis tend to have sequestered larger amounts of fluid as a result of the "chemical burn" sustained by the tissues within the retroperitoneal space. These patients are usually transferred to the ICU under the care of a gastroenterologist or surgeon. Aggressive volume replacement is necessary and may require invasive hemodynamic monitoring to maintain appropriate fluid balance. Fluid resuscitation is an important part of therapy and 6 to 8 L/day may be required. Some patients may require infusion of fresh frozen plasma or serum albumin or blood transfusions,

which can increase the risk of the development of ARDS. Cardiac function and fluid status can be monitored with a central line or pulmonary artery catheter. Measurement of hourly urine output is also necessary. If hemodynamic stability is not achieved through volume replacement, vasopressors may be necessary.

Daily monitoring of serum calcium, magnesium, glucose, electrolytes, total protein, albumin, amylase, lipase, and complete blood count with subsequent correction of abnormalities is required. In febrile patients, cultures of blood, urine, and sputum should be obtained, as well as CT-guided needle aspiration of necrotic areas of the pancreas with initiation of appropriate broad-spectrum antibiotic coverage as necessary to prevent increased morbidity and mortality. Arterial blood gas readings should be obtained daily, and hypoxemia treated accordingly. The patient may require assisted ventilation if hypoxemia persists or ARDS develops.

Correction of serum glucose is done with caution and should not begin until levels are greater than 250 mg/dL. Hypocalcemia is often corrected with the administration of albumin-containing fluids. Neuromuscular irritability, if present, can be corrected with a 10% solution of calcium gluconate. If there is a coexisting hypomagnesemia, correction of the magnesium level will often restore the calcium to its normal level. In patients with renal impairment, magnesium must be replaced cautiously.

Patients with severe pancreatitis must be maintained in a fasting state for prolonged periods of time, often for 2 to 4 weeks. Administration of antacids through an NG tube can help to prevent stress ulceration. The nutritional needs of the patient can be maintained with total parenteral nutrition until the gut becomes functional; enteral feedings can then be started, using the distal jejunum to reduce pancreatic stimulation. Oral feedings should not be started until any and all complications have been treated, the patient is free from nausea and vomiting, and amylase and lipase levels have returned to normal.

Surgical intervention is normally reserved for a pancreatic pseudocyst that has persisted for more than 6 weeks with ongoing symptomatology, necrotizing pancreatitis, pancreatic abscess, or severe hemorrhagic pancreatitis. Despite surgical intervention, the mortality rate for necrotizing pancreatitis remains high.

For pancreatitis caused by cholelithiasis, surgical intervention is determined by the presenting course of events. If biliary decompression is necessary, it can often be accomplished with ERCP. If the pancreatitis is mild, a cholecystectomy can be performed at a later time.

Follow-up and Referral

Patients with severe acute pancreatitis or those who do not respond to conservative treatment should be referred to a gastroenterologist for management. Surgical referral should be made once the diagnosis of pancreatitis is made. The patient who develops a pseudocyst requires long-term follow-up with serial CT scans to observe the resolution or growth of the cyst, which may require surgical intervention. The patient who has gallstone disease should have a cholecystectomy.

The prognosis of the patient with pancreatitis correlates directly with the severity of the inflammatory process. Patients with interstitial, or edematous, pancreatitis even with systemic complications have a mortality rate of 1% to 2%; however, patients with necrotizing pancreatitis have a mortality rate of 10% with sterile necrosis and up to 30% with infected necrosis.

In patients for whom no cause has been found, studies have suggested that half of these patients have occult gallstone disease (biliary sludge) or sphincter of Oddi dysfunction. These patients require repeated abdominal US exams to detect the development of biliary sludge. Patients with hereditary hypercholesterolemia are often missed because serum triglycerides are not obtained until after several days of fasting, at which time the triglyceride level may have fallen to within normal limits.

Patient Education

Patients with biliary disease as the cause of the pancreatitis should be informed of the need for a cholecystectomy, as well as the benefit of reducing their dietary intake of fat. If the etiology of pancreatitis is alcohol abuse, the patient should be encouraged to abstain. Patients with genetic hyperlipidemia require diet instruction and information on avoidance of precipitating factors such as alcohol, estrogens, and certain drugs. These patients may benefit from lipid-lowering medications and must be taught to control their diabetes if present. If a drug is the suspected cause of the pancreatitis, it should not be restarted.

CHRONIC PANCREATITIS

Chronic pancreatitis is defined as a slowly progressive inflammatory process that results in irreversible fibrosis of the pancreas with destruction and atrophy of the exocrine and endocrine glandular tissue. There are varying degrees of ductal dilation and fibrosis. There can be intraductal formation of protein plugs, which calcify and cause further dilation and obstruction. *Chronic relapsing pancreatitis* is defined as acute attacks that occur in the setting of chronic pancreatitis and are usually precipitated by a specific event such as binge drinking or the passage of a stone.

Epidemiology and Causes

There is little reliable information on the prevalence or incidence of chronic pancreatitis. Alcoholism may account for between 70% and 80% of the cases in industrialized countries. Although there is no threshold for alcohol consumption and the development of chronic pancreatitis, there is a statistically significant increase in

individuals who consume 120 grams of ethanol per day (eight 12-ounce beers, 8 ounces of 100-proof whiskey, or 30 ounces of wine). Diets high in protein in combination with either high or low fat can further predispose patients to pancreatic injury from alcohol.

Other causes of chronic pancreatitis include autoimmune disease, genetic mutations, hereditary predisposition, hypertriglyceridemia, severe malnutrition (especially protein-calorie deficiency in developing countries), tropical pancreatitis, and obstruction of the main pancreatic duct caused by stenosis, stones, tumor, or cystic fibrosis. In 10% to 30% of persons with chronic pancreatitis, the cause is unknown, but patients are divided into two groups: (1) those who present with abdominal pain (usually between ages 15 and 30) and (2) older individuals (ages 50–70) who present, often without pain, with pancreatic calcifications, glandular insufficiency, and diabetes.

The tropical, or nutritional, form of chronic pancreatitis is almost exclusively found in tropical countries. In these countries, the disease begins in early childhood and results in death in early adulthood because of complications. This type of pancreatitis also involves large intraductal calculi and a high susceptibility to pancreatic cancer. Malnutrition has a significant role, but it is not the sole cause because many areas with comparable malnutrition do not have equal prevalence of the disease. Key features of tropical pancreatitis include abdominal pain, maldigestion leading to steatorrhea, and diabetes.

Pathophysiology

The pathogenesis of chronic pancreatitis is unclear. Two characteristic findings in chronic pancreatitis are hypersecretion of protein without a subsequent increase in ductal bicarbonate secretion and inflammation. Chronic pancreatitis results in irreversible structural damage with permanent functional impairment of the pancreatic gland. For individuals who have alcohol-related disease, ductal obstruction is thought to be caused by changes in the chemical composition of the pancreatic juice, leading to protein plugging, calcification, and subsequent pancreatic damage. Another theory postulates that continuous injury to the acinar cells causes inflammation, necrosis, and fibrosis. Analysis of pancreatic juice obtained from alcoholic patients revealed protein plugs but not always chronic pancreatitis. Proponents of the theory favoring repeated damage to the pancreatic acinar cells believe that ductal obstruction is a result of changes in the pancreatic juice that cause increased viscosity and damage to the gland itself. These changes in the enzymatic properties result in chronic inflammation and fibrosis of the gland. Biliary disease has not been identified as a causative factor in the development of chronic pancreatitis.

With the progressive inflammatory changes occurring with chronic pancreatitis, it is not uncommon to find a fibrotic common bile duct and jaundice secondary to the obstructed common bile duct. Upper gastrointestinal bleeding can result from the formation of gastric varices or the development of a pseudoaneurysm in an artery within the pancreatic area. Steatorrhea and diabetes mellitus result from destruction of the pancreatic gland with subsequent endocrine and exocrine insufficiency. Steatorrhea develops as lipase and protease secretion drops below 10% of normal. Islet cell destruction reduces insulin secretion, causing glucose intolerance and diabetes.

Clinical Presentation

Subjective

The most frequent presenting symptoms are intractable abdominal pain, weight loss, and diarrhea; but symptoms can be as mild as dyspepsia, nausea, and vomiting. Abdominal pain is usually epigastric or in the left upper quadrant, may radiate to the back or left lumbar region, and is described as dull and constant. Pain may be absent in 5% to 10% of the cases or may represent an exacerbation of acute or relapsing pancreatitis. Pain may precede the development of other symptoms of chronic pancreatitis by years. The pain is often precipitated or aggravated by food or alcohol intake. In some patients, the pain diminishes over time (5–15 years) and is associated with burnout or calcification of the gland. Between 10% and 20% of older adults with idiopathic chronic pancreatitis have no pain with the disease.

Weight loss may result from anorexia caused by pain and nausea, malabsorption secondary to pancreatic exocrine insufficiency, or poorly controlled diabetes mellitus. Diabetes mellitus is present in approximately 50% of patients and is often the presenting sign in individuals who have no pain associated with pancreatitis. Steatorrhea develops after the pancreas loses the ability to secrete digestive enzymes, which results in bulky, foul-smelling, fatty stools. Patients often complain of "oil leakage" from the rectum or an "oil slick" in the toilet bowl, which is indicative of pancreatic insufficiency.

Objective

Abdominal assessment in patients presenting with pain reveals mild to moderate epigastric tenderness with no rebound tenderness or guarding. A palpable abdominal mass is suggestive of a pancreatic pseudocyst. Bowel sounds may be absent in patients with paralytic ileus. Lung sounds may be diminished in the bases, which is indicative of pleural effusion.

Diagnostic Reasoning

Diagnostic Tests

Diagnosis of chronic pancreatitis is normally made through evaluation of pancreatic function and radiographic visualization of structural abnormalities such as pancreatic calcification or abnormalities in the size or consistency of the pancreatic tissue. The patient usually presents with chronic abdominal pain, weight loss,

exocrine insufficiency (malabsorption), and diabetes mellitus.

Tests for pancreatic function include assessment of endocrine and exocrine function. A 2-hour postprandial blood sugar level greater than 200 mg/dL or fasting glucose greater than 120 mg/dL on two occasions is diagnostic for diabetes mellitus. Glucosuria may also be present. The serum amylase level may remain within normal limits because the pancreas has lost the ability to mount a response due to the chronicity of the disease. Malabsorption is documented by a 72-hour stool analysis for fecal fat content. Although helpful for diagnosis of exocrine function, steatorrhea is not diagnostic of chronic pancreatitis because patients do not develop steatorrhea until lipase falls below 10% of normal.

Pancreatic insufficiency can be confirmed by the bentiromide (nitroblue tetrazolium–*para*-aminobenzoic acid [NBT-PABA]) test, which measures urinary excretion of pancreatic chymotrypsin, or a secretin stimulation test, which is more sensitive but is unavailable in many places. The test involves placing a tube within the duodenum and collecting pancreatic secretions after IV stimulation with secretin. Collections that are of normal volume and low in bicarbonate (HCO_3^-) suggest chronic pancreatitis; collections low in volume and with normal HCO_3^- suggest pancreatic cancer. The detection of decreased fecal chymotrypsin or elastase helps to diagnose pancreatic insufficiency, but these tests do not have widespread availability.

Imaging studies include plain films of the abdomen, which may show intraductal stones or a calcified pancreas caused by pancreatolithiasis and mild ileus. Computed tomography (CT) scan and/or ultrasound of the abdomen may show an abnormal size or consistency of the pancreas, a pancreatic pseudocyst, or dilated pancreatic ducts. Endoscopic retrograde cholangiopancreatography (ERCP) may also show abnormality of the main pancreatic duct or its secondary branches. Although not available everywhere, magnetic resonance cholangiopancreatography is an excellent alternative to ERCP.

Differential Diagnosis

Differential diagnosis includes diseases that present with persistent abdominal pain such as peptic ulcer disease or mesenteric ischemia; diseases that result in weight loss and abdominal pain, including abdominal malignancies, especially cancer of the pancreas; and intestinal disorders that may present with steatorrhea. The diagnosis of chronic pancreatitis can be confirmed by visualization of the calcified pancreas on x-ray films, which will also rule out most other disease processes.

Management

The treatment of chronic pancreatitis is aimed at preventing further pancreatic damage, managing pain, and supplementing exocrine and endocrine function. The major cause of chronic pancreatitis is alcohol abuse; therefore, complete abstinence is imperative. Pancreatic enzyme supplementation may relieve pain in some patients. Generally, narcotics are necessary to manage pain. Patients whose pain is not managed by analgesics or pancreatic enzyme therapy should be considered for operative treatment.

Malabsorption is managed with a low-fat diet (less than 50 g/day) and oral pancreatic enzyme supplementation. Oral supplementation should be administered 20 to 30 minutes before meals and snacks. The usual dose is 30,000 units of lipase. Non–enteric-coated pancrelipase formulations (Viokase or Cotazym) should be given with H_2-receptor antagonists to prevent degradation by gastric acids. Enteric-coated preparations of pancrelipase (Pancrease or Creon) or pancreatin (Donnazyme) are stable at an acid pH and should not be given with acid neutralizers because this will promote enzyme release within the stomach. Fat-soluble vitamin (A, D, E, and K) replacement may be required. Favorable outcomes are weight gain, decreased number of stools per day, decrease in oil seepage from the rectum, and subjective improvement in well-being.

Endocrine insufficiency is controlled with insulin supplementation. Extreme caution must be used with insulin supplementation, because there is a deficiency of glucagon secretion, which can lead to prolonged hypoglycemia. Serum glucose levels of 200 to 250 mg/dL are considered acceptable and do not require treatment. The principal step in the management of diabetes associated with chronic pancreatitis is the correction of poor nutritional habits, malabsorption and malnutrition, and the elimination of alcohol. Normal insulin requirements range from 5 to 15 units per day but may fluctuate up to 40 units per day. It is best to maintain these patients at a higher than normal glucose level to avoid hypoglycemia while avoiding significant glucosuria.

Surgical intervention may be required to drain unresolving pseudocysts, for relief of pain, or to treat other complications associated with chronic pancreatitis. The goal of surgical intervention is to alleviate biliary tract disease, establish the free flow of bile into the duodenum, and remove obstruction of the pancreatic duct. Distal pancreatectomy may be necessary if the disease is located at the tail of the pancreas, and the Whipple procedure is performed when the disease is most extensive at the head of the pancreas. These procedures relieve the pain for 60% to 80% of patients.

In patients with alcoholic pancreatitis, ERCP examination often reveals alternating stricture and dilation ("chain of lakes") of the pancreatic duct. Treatment for this is a modified Puestow procedure (lateral pancreaticojejunostomy), which is 70% to 80% effective for pain relief.

Follow-up and Referral

Follow-up of the patient with chronic pancreatitis will depend on the complications resulting from the disease

and the medical and surgical interventions employed to remedy the disease. Patients who have developed pseudocysts that have not resolved spontaneously will require periodic CT scans to monitor resolution or evolution of the cysts. Cysts that are consistently larger than 6 cm and are expanding should be referred for invasive treatment.

A nutritionist may be helpful in managing any protein-calorie malnutrition. The pancreas is very nutrition sensitive, and an improper diet can lead to atrophy and fibrosis. Follow-up with the nutritionist is often necessary for control of diabetes mellitus as well.

Patient Education

Patients should be taught about the natural history of this chronic disease, the common complications, and what to expect in the long term. Patients with chronic pancreatitis can expect that after 5 to 10 years, the episodes of pancreatic pain diminish in frequency and may in fact disappear. Patients should fully understand their medicine regimen, including appropriate time of medication and adverse effects. Patients have a tendency to be more compliant when they understand that the goal of treatment is to control diarrhea and gain body weight. Patients can be provided with written instructions to assist with adherence.

Patients should be cautioned against long-term narcotic analgesic use because it can result in drug dependence. If long-term narcotic use is necessary, patients may benefit from referral to a pain control clinic to learn how to relieve pain using nonpharmacotherapeutic measures.

HEPATITIS

Hepatitis is a common problem throughout the world and has many causes, including infectious, drug, vascular, and metabolic etiologies. Many cases of hepatitis are subclinical. Symptoms may be "flu-like" and go unreported so that the true incidence of the disease may be underestimated. Table 11.9 lists some of the causes of acute hepatitis.

Acute viral hepatitis is a systemic infection that predominantly affects the liver and can lead to liver inflammation and necrosis. There are many viral agents that cause hepatitis, but the most common, and the ones that have public health concerns, are hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (HDV), and hepatitis E virus (HEV). All are endemic to the United States except HEV, which is common in Southeast Asia, India, parts of Africa, and Mexico. The prevalence of acute hepatitis has been slowly rising for the past few years.

Table 11.9 Causes of Acute Hepatitis

Viral	Cytomegalovirus; Epstein-Barr virus; hepatitis A, B, C, D, and E viruses; herpes virus; rubella; varicella-zoster virus; yellow-fever virus
Nonviral	Amebic abscess, bacterial abscess, Lyme disease, syphilis
Metabolic disorders	Alpha-1-antitrypsin deficiency, Wilson's disease
Vascular	Budd-Chiari syndrome, congestive heart disorders failure, ischemia (hypotension, shock)
Drugs	Acetaminophen, allopurinol, ASA (high doses), captopril, carbamazepine, isoniazid, ketoconazole, methyldopa, NSAIDs, procainamide, sulfonamides
Toxins	Alcohol (ethanol), carbon tetrachloride, herbs, mushrooms

Epidemiology and Causes

Hepatitis A

HAV is a small, single-stranded RNA virus of the picornavirus family. There was a 92% decline in the incidence of hepatitis A infections in the United States between 1995 and 2007. In 1995, there were 12 cases per 100,000; in 2007 that number dropped to 1 case in 100,000. A total of 1,670 HAV cases were reported in 2010. HAV is endemic in the United States, with periodic outbreaks occurring in certain populations: Native Americans, Alaskan natives, and some Hispanic populations. Because the symptoms of HAV are often mild and nonspecific, many cases are undetected. Many other cases are asymptomatic, making it almost impossible to quantify the number of infections annually. Risk factors include crowded conditions, such as prisons, nursing homes, and day-care centers, and poor sanitation. Contaminated food or water is a common source of HAV. HAV can cause fulminant liver failure on rare occasions, usually in combination with an underlying liver disease.

Transmission is by the fecal–oral route, but HAV has been detected in blood. People contract HAV by consuming contaminated water or ice; raw shellfish harvested from sewage-contaminated water; and fruits, vegetables, or other foods eaten uncooked that may have become contaminated in handling. But HAV is also contracted through transfusion of infected blood. The virus is killed by heating at 185°F for 1 minute. Adequate chlorination of water also kills the virus. According to the Centers for Disease Control and Prevention (CDC) Viral Hepatitis Surveillance Program, household or sexual contact with a person who has HAV is the most frequently reported source of infection, accounting for 24% of the cases. The incubation period is 30 days but can be as long as 6 weeks. Excretion of HAV in feces occurs up to 2 weeks before

clinical illness. It is rarely found in feces after the first week of illness. Blood and stools are infectious throughout the incubation period and early illness until the aminotransferase levels peak. A person is most infectious about 2 weeks before and during the first week that symptoms appear.

Chronic HAV does not occur. There is no carrier state, and HAV usually causes no long-term damage. HAV may persist for up to 1 year with relapses before full recovery. The mortality rate is less than 0.2%.

Hepatitis B

HBV is a DNA hepadnavirus with eight different genotypes and replicates in the liver. The incidence of HBV has decreased 81% in the United States since 1990, with 1.5 cases per 100,000 in 2007. There were 2,168 confirmed cases of chronic HBV in 2010. However, the risk of chronic HBV is as high as 90% for infected infants. The frequency of infection and the mode of transmission vary in different parts of the world. According to the CDC, in the United States, Canada, Western Europe, Australia, and New Zealand, the infection is of low endemicity and occurs primarily in adolescents and adults; 5% to 8% of the total population have been infected, and 0.1% to 2.0% are HBV carriers. More than 1 million people in the United States have chronic HBV infection; and although the overall prevalence of HBV in the United States is only 2% to 3%, the prevalence in the native Alaskan population is 6.4% and 14% among African Americans. Between 2000 and 2010, the reported number of HBV cases in the United States declined.

High-risk groups include male homosexuals, IV drug abusers, first generation immigrants from endemic regions (Southeast Asia, China, and the Middle East), and people with multiple sex partners. Other high-risk groups include nurses, physicians, dentists, and personnel working in clinical and pathology labs and blood banks where direct needle-stick contamination may occur. The risk of infection from a contaminated needle is 10% to 30%. Patients and staff at hemodialysis centers are also at high risk. The risk of contracting HBV from a blood transfusion is now 1 in 600,000 units transfused in the United States.

Transmission is usually by direct contact with infected blood or blood products or by sexual contact. The highest concentrations of HBV are found in the blood; however, other body fluids such as semen, cervical secretions, saliva, and wound exudates contain lower concentrations of hepatitis B surface antigen (HBsAg). Parenteral exposure is the most efficient route of transmission, most often occurring in IV drug abusers sharing or using nonsterilized, contaminated needles and in health-care workers by accidental needle sticks. HBV can be transmitted from contact with contaminated inanimate objects because the virus is capable of living in the open environment for approximately 1 week. HBV is not transmitted via the fecal–oral route. The vast majority (90%) of acute HBV infections occur in young adults, especially men. HBsAg-positive mothers may transmit HBV to their babies during childbirth. HBV is not spread through food, water, or casual contact. The average incubation period for HBV is 12 to 14 weeks but can be anywhere from 6 weeks to 6 months.

The mortality rate for acute HBV infection is 0.4% to 1% but is higher when hepatitis D is superimposed. About 10% of patients infected with HBV develop chronic hepatitis. The risk of chronic infection with HBV is inversely proportional to the age at which infection occurred. Patients with chronic hepatitis are at an increased risk for cirrhosis and hepatocellular cancer. Infection with HBV is also associated with arthritis, glomerulonephritis, and polyarteritis nodosa.

Hepatitis C

HCV was first identified in 1989 and was previously known as hepatitis non-A non-B. It is a single-stranded RNA virus with 6 genotypes and more than 50 subtypes. Genotype 1 is the most common type in the United States and Europe (60%–70%). The clinical significance of the genotype is unclear, but different genotypes and subtypes have different responses to interferon treatment. The incubation period of HCV is 6 to 7 weeks. Transmission is similar to the routes for HBV, and before 1990, HCV was responsible for 90% of cases of post-transfusion hepatitis, but now very few cases of HCV infection are attributable to blood transfusion. IV drug use accounts for about 50% of HCV cases today. In 2011 there were 1,229 reported cases of acute HCV, but the estimated number of actual new cases of HCV is 16,500. This was a 44% increase over the previous year. The estimated number of chronic cases of HCV is between 2.7 and 3.9 million.

There are about 3.2 million Americans who have chronic hepatitis C infection. The prevalence of this infection is greatest in those individuals born between 1945 and 1965. They were most likely infected in the 1970s and 1980s. Injection drug use is the strongest risk factor. Having sex with an injection drug user is also a risk factor, although less robust. There is a 5% risk of maternal–neonate transmission at the time of birth, which tends to be greatest in patients with high circulating levels of HCV RNA. Anti-HCV antibodies are more common in non-Hispanic black and Mexican American people. Low family income and a lifetime history of more than 20 sexual partners are also risk factors. Rates of HCV infection are higher for men than for women, possibly due to more risky behavior. Other possible transmission can be through body piercing and tattooing, although there is little evidence to date. For many patients infected with HCV, the source is never determined.

Fewer than 25% of people with HCV infection are symptomatic, making diagnosis and treatment difficult in the 75% who are HCV RNA positive. Most acute

cases go undetected until they present with symptoms of chronic liver disease. Seventy percent to 90% of patients with HCV develop chronic hepatitis. Of this group, 20% progress to chronic liver disease, liver failure, or hepatocellular carcinoma. Alcohol consumption appears to increase the chances of chronic disease and serious complications.

Hepatitis D

HDV is a defective RNA virus that requires HBsAg for its replication. Only individuals with HBV are at risk for HDV. The major risk factor for HDV is IV drug use. Transmission is by the parenteral route and should be suspected in any HBsAg-positive person with acute or chronic hepatitis. New cases of HDV are uncommon in the United States today, probably because of widespread vaccination for HBV. Incubation is 1 to 6 months, and the mortality rate is 3%.

Hepatitis E

HEV, formerly called enterically transmitted or water-borne non-A non-B hepatitis, is a single-stranded RNA virus. It is similar to HAV but not as easily transmitted. It is transmitted through fecally contaminated water and is responsible for water-borne hepatitis outbreaks; it is endemic in Southeast Asia, India, North Africa, and Mexico. Large outbreaks have occurred in refugee camps in Sudan and Chad. There have been relatively few cases in the United States, and most have been associated with global travel. There have documented cases in Germany and Japan of HEV infection with consumption of meat from animals that are infected with the virus. Interestingly, the seroprevalence of HEV in the United States is 21%. The illness is self-limiting, and there is no carrier state. The incubation period is from 2 weeks to 2 months. The mortality rate is low except in pregnant women, in whom the mortality rate is 10% to 20%. Table 11.10 lists the features of hepatitis A, B, C, D, and E.

Hepatitis G

Hepatitis G virus, also known as HGV/GB virus-C (HGV/GBV-C), is a single-stranded RNA flavivirus that is transmitted percutaneously. The clinical significance is yet to be determined. Most patients (75%) who are positive for HGV have normal liver function tests. Co-infection with HCV, HBV, and HIV is common. In patients with HIV infection, co-infection with HGV improves the survival rate (Jacobson, 2002). There is no evidence at this point that HGV causes liver damage.

Chronic Hepatitis

Chronic hepatitis, characterized by elevated aminotransferase (aspartate aminotransferase [AST] and alanine aminotransferase [ALT]) levels for more than 6 months, occurs in 1% to 2% of immunocompromised adults with HBV and in as many as 90% of neonates and infants with HBV. Chronic hepatitis occurs in up to 90% of the people infected with HCV. Cirrhosis develops in 40% of patients with chronic HBV, and 20% of those with chronic HCV are at high risk for developing hepatocellular carcinoma as well.

Pathophysiology

Hepatitis is an inflammation of the liver. It can result from a variety of causes. Viral hepatitis usually presents in one of three clinical manifestations: anicteric, icteric, or cholestatic. Despite the presentation, the progression of the disease follows the same pattern, differing only in severity, enzymatic abnormality, and possible outcomes. The pathological lesions of hepatitis are similar to those caused by other viral infections. Regardless of the type of hepatitis causing the infection, all the liver acini cells are affected by patchy cell dropout, acidophilic hepatocellular necrosis, scarring, Kupffer cell hyperplasia, and mononuclear inflammatory infiltrate. The degree of cellular change is proportionate to the severity of infection. Hepatocellular injury is mediated by cell-mediated immune response. Cytotoxic T cells and natural killer cells play an important part by killing the infected cells and releasing inflammatory cytokines. An intense immune response can decrease the chance of chronic infection; however, it does foster development of hepatocellular necrosis. Histological examination of tissue from livers infected with hepatitis demonstrates that even early in the disease process liver regeneration has already started.

Normally, in patients infected with hepatitis, the underlying reticulin network is preserved, allowing for complete histological recovery. If extensive necrosis of the bridging acini occurs, however, the inflammatory process can damage and obstruct the bile canaliculi, causing cholestasis and obstructive jaundice. In most mild cases of hepatitis, the liver parenchyma is not damaged; HBV and HCV tend to be the more severe forms of hepatitis, with histological evidence of parenchymal inflammation and necrosis. Although the histological changes in the liver tissue are the same for each type of hepatitis, occasionally HBV can be diagnosed from the presence of "ground glass" hepatocytes caused by HBsAg-infiltrated cytoplasm and by using special staining techniques that detect certain viral components. These findings are most often associated with chronic HBV infection. The long-term, asymptomatic chronic-carrier state is thought to result from an immunological tolerance to the hepatitis virus. The virus is not totally cleared by the immune system, and the hepatocellular injury is minimal, leading to a lifelong asymptomatic carrier state. This carrier state is most common in infants, whose immune system is immature and may be unable to overcome the virus. This chronic-carrier state is associated with a 10- to 100-fold risk of hepatocellular carcinoma.

HCV causes hepatocellular injury through direct cytopathic invasion by the virus. The viral load is directly

Table 11.10 Key Features of Hepatitis A, B, C, D, and E

Features	Hepatitis A Virus (HAV)	Hepatitis B Virus (HBV)	Hepatitis C Virus (HCV)	Hepatitis D Virus (HDV)	Hepatitis E Virus (HEV)
Transmission	Fecal–oral, sewage, contaminated water, and shellfish and possibly blood	Percutaneous, permucosal through infected blood and body fluids, sexual	Percutaneous, community, a large percentage have no known risk factors	Percutaneous, but must have co-infection with HBV	Fecal–oral
Incubation period (days)	15–50 (average 20–37)	25–160 (average 60–110)	42–49	Same as for HBV	10–56
Laboratory tests	Anti-HAV IgM (acute); anti-HAV IgG (resolving)	HBsAg (confirms), IgM anti-HBs (acute phase), IgG anti-HBs (resolving/immunity), HBeAg, anti-HBe, anti-HBc (persists in carriers)	Anti-HCV appears in 6–37 weeks	Anti-HDV appears late	Anti-HEV IgM detected within 26 days of jaundice; IgG antibody persists
Immunity/immunization	45% of United States population has antibodies against HAV; HAV vaccine available	5%–15% of U.S. population has anti-HBs; HBV vaccine available	Unknown; no vaccine available	People immune to HBV are also protected against HDV	Unknown
Prevalence	Increasing in adults	Decreasing in the United States	4% of post-transfusion hepatitis; 50% IV drug users	Common in IV drug abusers	Rare in United States; endemic in Southeast Asia, India, North Africa, Mexico
Course/mortality	Does not progress to chronic state; mortality is 0–0.2% with fulminant hepatitis	Chronic liver disease occurs in 1%–5% of adults and 80%–90% in children; mortality rate is 0.3%–1.5%	Chronic active hepatitis develops in 70%–90% of cases; 20% develop chronic liver disease; mortality rate is the same as for HBV	Chronic liver disease develops if present in chronic HBV; mortality rate is 2%–20% for acute icteric hepatitis	Does not progress to chronic liver disease; mortality rate is 1%–2% but as high as 10%–15% in pregnant women

proportionate to the histological inflammation seen on liver biopsy. HCV is capable of rapid mutation, which allows it to elude immunity by development of resistant strains to the existing antibodies. Autoimmune hepatitis is most commonly associated with HCV, lending itself to the multiple extrahepatic manifestations of the disease. These patients develop autoimmune responses leading to membranous glomerulonephritis, vasculitis, dermatitis, pulmonary fibrosis, and rheumatoid arthritis. Chronic HCV occurs in approximately 50% of cases, with inflammatory changes leading to cirrhosis within 20 years.

Different drugs can cause different histopathological abnormalities in the liver. For example, acetaminophen damages hepatocytes by producing toxic metabolites that damage the cellular and subcellular structures of the liver. Hepatic injury resulting from sepsis is caused by direct bacterial invasion of the parenchyma, circulating endotoxins, and hypoxia. Cytotoxic lymphocytes attack hepatocyte membrane antigens in autoimmune chronic active hepatitis. All of these agents result in varying degrees of hepatocyte injury.

Clinical Presentation

Subjective

The clinical presentation of viral hepatitis is extremely variable; it can range from asymptomatic infection without jaundice to a sudden severe infection and death in a few days. Table 11.11 displays the clinical findings and corresponding laboratory values for the different phases of viral hepatitis.

Prodromal Phase During the prodromal phase, the onset may be abrupt or insidious with anorexia, nausea, vomiting, malaise, upper respiratory infection, or flu-like symptoms. The patient may also complain of myalgia, arthralgia, and easy fatigability. Many patients report an aversion for smoking if they are smokers. Nausea and vomiting occur frequently. Diarrhea or constipation may be reported. In the early stage of acute HBV, skin rashes and arthritis may be seen.

Fever is usually present but rarely exceeds 103°F (39.4°C), except in HAV, in which it may go higher. Chills may mark an acute onset. A decrease in fever often coincides with the onset of jaundice.

Abdominal pain is usually mild and constant in the right upper quadrant or epigastrium. The pain can be aggravated by jarring or exertion. It is occasionally severe enough to simulate cholecystitis or cholelithiasis.

Icteric Phase During the icteric phase, jaundice and dark urine appear, usually 5 to 10 days after the initial symptoms, although some patients do not experience jaundice. With the onset of jaundice, the prodromal symptoms worsen and are followed by progressive clinical improvement.

Convalescent Phase The convalescent phase is marked by an increased sense of well-being. The jaundice, abdominal pain and tenderness, and fatigability disappear and the appetite returns. Chronic HBV begins at this point in the case of chronic disease.

Table 11.11 Clinical Findings: Viral Hepatitis

Stage	Subjective and Objective Complaints	Laboratory Tests
Incubation	None	HBsAg late in the stage HBeAg
Prodromal	Onset abrupt or insidious Anorexia, nausea, vomiting, malaise, upper respiratory infection (nasal discharge, pharyngitis), myalgia, arthralgia, easy fatigability, fever (HAV), abdominal pain	HBsAg in HBV
Icteric	Jaundice, dark urine, light-colored stools Continued prodromal complaints with gradual improvement	Anti-HBc Anti-HAV (IgG and IgM) Anti-HCV HBsAg becomes negative High urine bilirubin Markedly elevated ALT and AST Elevated LDH, bilirubin, alkaline phosphatase Markedly increased PT indicates increased mortality
Convalescent	Increased sense of well-being Appetite returns Jaundice, abdominal pain, and fatigability abate	Anti-HAV IgG Anti-HBs Decreased liver enzymes

The acute illness usually subsides over 2 to 3 weeks. Complete clinical and laboratory recovery occurs by the ninth week in HAV and after 16 weeks in HBV. Five percent to 10% of the cases may last longer, and fewer than 1% have an acute fulminant course. Hepatitis B and C may become chronic.

Hepatomegaly is present in 50% of patients with viral hepatitis, and splenomegaly is seen in 15% of cases. Lymphadenopathy, especially in the cervical and epitrochlear areas, is commonly present. Signs of general toxemia may vary from minimal to severe. The clinical features of all the types of viral hepatitis are similar, with the exception of onset. Hepatitis A and E usually have an abrupt onset, whereas hepatitis B, C, and D have a more insidious onset, and the liver enzyme levels are higher. HVC is often asymptomatic.

Diagnostic Reasoning

Diagnostic Tests

Laboratory tests are used to diagnose, identify the serological type, and determine the current status of the disease.

Hepatitis A Two types of antibodies to HAV can be detected by radioimmunoassay and enzyme-linked immunosorbent assay. The first type of antibody to HAV is the immunoglobulin M (IgM) antibody (IgM anti-HAV), which appears about 4 weeks after exposure, or just before hepatocellular enzyme elevation occurs, and disappears in 3 to 6 months. Detection of IgM is the diagnostic gold standard for acute hepatitis A. The second type of antibody, immunoglobulin G (IgG) anti-HAV, appears about 2 weeks after the IgM anti-HAV begins to increase and peaks after about 1 month of disease. The IgG antibody persists for more than 10 years and provides immunity. If the IgM is elevated in the absence of IgG, acute hepatitis is suspected. If IgG is elevated in the absence of IgM, this indicates previous exposure to HAV, noninfectivity, and immunity to recurring HAV infection.

Hepatitis B Acute and chronic HBV can be differentiated from other forms of viral hepatitis by serological markers representing the body's immunological response. The HBV is made up of an inner core surrounded by an outer capsule. The outer capsule contains HBsAg (hepatitis B *surface* antigen). The inner core contains the HBV *core* antigen (HBcAg). HBeAg (the *extracellular* form of HBcAg) is also found within the core. Antibodies to these antigens are called anti-HBs, anti-HBc, and anti-HBe.

Detection of HBsAg is diagnostic for HBV and is the first test to order when HBV is suspected. It will appear 1 to 10 weeks after exposure to the hepatitis B virus and will remain positive throughout the acute phase of the illness. If HBsAg persists longer, this may indicate chronic hepatitis. HBsAg rises before the onset of clinical symptoms, peaks during the first week of symptoms, and returns to normal by the time the jaundice subsides. HBsAg indicates acute infection and infectivity. Anti-HBs appears about 4 weeks after the disappearance of the surface antigen and signifies recovery from the infection and noninfectivity, as well as immunity.

There are no tests available to detect the HBV core antigen (HBcAg), but the IgM anti-HBc appears shortly after HBsAg is detected and can persist for 3 to 6 months. The anti-HBc level is elevated during the time lag between the disappearance of HBsAg and the appearance of anti-HBs; this interval is called the *core window*. During this window, anti-HBc is the only detectable marker of a recent hepatitis infection. Anti-HBs is composed of IgG and IgM antibodies. The IgM titer is diagnostic for acute hepatitis, whereas the IgG antibody is usually positive for life after infection.

HBeAg is generally not used for diagnostic purposes but rather as an index of viral replication and infectivity. The presence of HBeAg correlates with early and active disease and with high infectivity in patients with acute HBV infection. HBeAg appears during the incubation period shortly after the detection of HBsAg. The continued presence of HBeAg predicts the development of chronic HBV infection. Table 11.12 displays the serology testing and results for HBV infection.

Hepatitis C The diagnosis of HCV is based on enzyme immunoassays (EIA) that detect antibodies to HCV (anti-HCV). Limitations of the enzyme immunoassay include moderate sensitivity for the diagnosis of acute HCV (false-negative result) and low specificity (50%) in healthy blood donors and some people with elevated gamma-globulin levels (false-positive result). In these

Table 11.12 Serologic Testing for Hepatitis B

Interpretation	HBsAg	Anti-HBs	HBeAg	Anti-HBe	Anti-HBc
Acute hepatitis (confirms diagnosis)	+	–	+	–	IgM
Acute hepatitis	–	–	+ or –	–	IgM
Recovery from hepatitis (immunity)	–	+	–	+ or –	IgG
Vaccination (immunity)	–	+	–	–	–
Chronic HBV with active viral replication	+	–	+	–	IgG
Chronic HBV with low viral replication	–	–	–	+	IgG

particular cases, a diagnosis of HCV may be confirmed by use of a polymerase chain reaction to detect HCV RNA. The risk of transfusion-associated HCV has decreased from 10% in the early 1990s to less than 0.1% today as a result of the testing of donated blood for HCV.

Hepatitis D Diagnosis of HDV is via detection of anti-HDV or HDV RNA in the presence of hepatitis B markers. Rising titers of anti-HDV indicate acute infection and are detectable early in the disease.

Hepatitis E HEV is diagnosed via history and exclusion of other causes. There are no commercially available tests in the United States at this time, although certain research laboratories can detect anti-HEV in serum and HEV genomes in blood and stool.

Additional Testing In any patient in whom hepatitis is suspected, liver enzyme levels should be checked for signs of injury. Elevated aminotransferase levels are the hallmark of all forms of acute hepatitis. AST is usually markedly elevated early in hepatitis. ALT is often very elevated early in hepatitis, as is lactate dehydrogenase. All of these hepatocellular enzymes are elevated during the acute and chronic active phases of hepatitis. AST and ALT levels fluctuate during the course of the disease for unknown reasons. Bilirubin and alkaline phosphatase are usually elevated and may remain elevated after the AST and ALT have normalized.

The white blood cell count is normal or low, especially in the preicteric phase. Large atypical lymphocytes may occasionally be seen and are similar to those found in infectious mononucleosis. Mild proteinuria is common, and there is bilirubinuria just preceding and during the icteric phase. The prothrombin time may be prolonged in severe hepatitis and signifies increased mortality risk. Liver biopsy is rarely indicated unless there is evidence of liver damage from a chronic state of hepatitis.

Differential Diagnosis

Differential diagnosis for hepatitis includes other viral diseases that affect the liver, such as infectious mononucleosis, cytomegalovirus infection, and herpes simplex virus. Drug- or toxin-induced liver damage should also be included in the differential diagnosis list, as well as conditions that cause jaundice.

Management

The principle of the management of hepatitis includes prevention of transmission and symptomatic relief. Vaccinations are available to prevent HAV and HBV. Vaccination against HAV is recommended for people living in or traveling to endemic areas and prevents infection for at least 20 years. Immune globulin is recommended for close contacts of people with HAV within 2 weeks of exposure because it may prevent or lessen the severity of the disease.

HBV vaccine is recommended for people with high-risk factors, such as health-care workers, day-care workers, IV drug users, male homosexuals, household contacts of HBsAg carriers, heterosexual contacts of HBsAg carriers, people with anticipated multiple transfusions, and patients undergoing dialysis.

Treatment for hepatitis, no matter what the cause, is largely supportive. Patients rarely require hospitalization. Balanced nutrition with adequate calories and fluids is recommended, and avoidance of alcohol is stressed. Activity is generally restricted during the acute phase and during a relapse with gradual resumption of activity.

Treatment of chronic HBV is currently intramuscular pegylated interferon alfa-2a. Treatment with interferon alone is not sufficient to eradicate HBV in most patients, so it is used in combination with an antiviral agent such as lamivudine. Candidates include patients with compensated liver disease, persistent elevated ALT, detectable HBsAg and HBeAg, low concentrations of HBV DNA, and fibrosis seen on liver biopsy. The response rate after this expensive therapy, however, is only about 40%.

HCV causes chronic hepatitis and liver damage. The goal of treatment is to eradicate HCV RNA. Treatment with pegylated interferon and ribavirin in the acute phase decreases the risk of chronic hepatitis. This treatment has a high sustained viral response rate (SVR) for those infected with genotype 2 or 3, and a liver biopsy is not necessary. However, SVR is not as good in persons with genotypes 1a, 1b, and 4. Pegylated interferon is a slow-release, long-acting drug that, when given once a week in a dose of 180 mg for 48 weeks, has shown an SVR in 38% of patients who already have chronic hepatitis C. SVR in patients who have genotype 2 or 3 is about 80%. Ribavirin in combination with pegylated interferon has been shown to be more efficacious in clearing the viremia. Ribavirin is given in divided doses of 1,000 mg per day for those weighing less than 75 kg (165 lb) and 1,200 mg for those over 75 kg.

Response to therapy is judged by an ALT returning to normal by 12 weeks and negative viral markers (HCV RNA). After the ALT has returned to normal, treatment is slowly discontinued. Consuming alcohol increases the risk of these patients progressing to cirrhosis and liver failure, so abstinence from all forms of alcohol (including in medications) is especially important.

Hepatic transplantation is indicated for patients with advanced liver disease as a result of chronic HCV, and in fact it is the most common reason for liver transplantation in the United States.

Follow-up and Referral

Any patient diagnosed with HCV should be referred to a hepatologist for follow-up because the chance of developing chronicity is great with this type of hepatitis. Patients with HAV usually do not require follow-up. Patients with HBV should be seen in 1 month and should have blood drawn for HBsAg after 6 months. Persistent

elevation of HBsAg indicates a chronic state, and these patients should be referred to a hepatologist.

Patient Education

Patients and their intimate contacts should be given careful instructions about the cause of hepatitis, the mode of transmission, and measures to prevent the transmission. It is recommended that household contacts and sexual contacts be given passive immunity (immunoglobulin) for HAV and HBV, as well as active immunization. Hand washing and personal hygiene can help prevent the spread of the disease. Patients should also be taught not to share personal items such as toothbrushes, razors, and eating utensils during the period of infectivity. Patients with chronic hepatitis or a carrier state should be instructed to practice safe sex.

Patients who develop chronic liver disease as a result of hepatitis can contact the American Liver Foundation at www.liverfoundation.org.

CIRRHOSIS AND LIVER FAILURE

Cirrhosis is the end result of hepatocellular injury involving the entire liver, resulting in fibrosis, nodular regeneration, and distorted hepatic architecture. Cirrhosis is considered permanent and irreversible. Fibrous bands are formed during nodular regeneration in an attempt by the liver to repair itself, and these bands give the liver a hobnailed appearance. The fibrotic changes that occur within the liver parenchyma cause disruption and compression of the vascular, biliary, and lymphatic vessels and result in many of the characteristic findings common to liver failure. *Cirrhosis* and *fibrosis* are not synonymous terms; fibrotic changes are characteristic findings of cirrhosis.

Epidemiology and Causes

In the Western Hemisphere, cirrhosis is a leading cause of death in individuals older than age 40. Although there are many causes of cirrhosis (Table 11.13), chronic alcohol abuse remains the leading pathological insult in the United States.

Table 11.13 Causes of Cirrhosis

- Alcohol
- Direct hepatotoxins
  - Carbon tetrachloride
  - Phosphorus
- Indirect hepatotoxins
  - Tetracycline
  - Methotrexate
  - Acetaminophen
  - Mushroom toxin—*Amanita phalloides*
  - Alkylated anabolic steroids
  - 6-Mercaptopurine
- HBV and HCV
- Autoimmune chronic active hepatitis
- Diabetes mellitus and insipidus
- Thyroiditis
- Ulcerative colitis
- Glomerulonephritis
- Biliary cirrhosis
- Primary biliary cirrhosis
- Primary sclerosing cholangitis
- Chronic pancreatitis
- Sclerosing cholangitis
- Vasculitis
- Cholelithiasis
- Cystic fibrosis
- Genetic diseases
  - Wilson's disease
  - Hemochromatosis
  - Galactosemia
- Vascular/congestive disorders of the liver
  - Budd-Chiari syndrome
  - Ischemic hepatitis/shock liver
  - Right-sided heart failure (chronic)

Alcoholic cirrhosis—also known as Laennec's, portal, fatty, or micronodular cirrhosis—is the most common type of cirrhosis in the United States. An estimated 18 million people in the United States abuse alcohol, but only 25% of alcoholics develop cirrhosis. It is estimated that more than 30,000 people in the United States alone die from liver disease caused by alcohol abuse each year. Men are affected three times more often than women.

Alcoholic cirrhosis is often associated with nutritional and vitamin deficiencies but occurs in well-nourished individuals as well as in alcoholics. Studies have found no safe amount of alcohol that can be ingested daily without causing cirrhosis, which supports the theory that there are additional factors (genetic, environmental, nutritional) that may influence the development of alcoholic liver disease. Women tend to develop cirrhosis more quickly with less alcohol intake than men, which suggests that a smaller, leaner body mass and enhanced absorption are both factors in the development of alcoholic cirrhosis.

There are three consequences of alcohol abuse: fatty liver, alcoholic hepatitis, and alcoholic cirrhosis. Fatty liver is a reversible condition where large vacuoles of triglycerides accumulate in the hepatocytes. The accumulation of fat in the liver causes an inflammatory reaction in the liver called steatohepatitis. Alcoholic hepatitis results from moderate to severe alcohol abuse for years and can lead to alcoholic cirrhosis quickly even with abstinence, but it is not an obligatory phase in the development of cirrhosis.

Primary biliary cirrhosis (PBC) is a disease that almost exclusively affects women aged 40 to 60. It is an autoimmune disease that causes destruction of the intrahepatic bile ducts, resulting in cholestasis. Autoimmune disorders such as scleroderma, Raynaud's syndrome, autoimmune

thyroid disease, celiac disease, and Sjögren's syndrome have been linked to the development of PBC.

Primary sclerosing cholangitis (PSC) is most common in men aged 20 to 40 and is associated with inflammatory bowel disease, as well as with the histocompatibility antigens HLA-B8, HLA-DR3, and HLA-DR4, suggesting a genetic link. It is characterized by diffuse inflammation and fibrosis throughout the biliary tree. Factors contributing to the development of PSC are anything that obstructs or inhibits the flow of bile through both the extrahepatic and intrahepatic bile ducts. Smoking is associated with a *decreased* risk of PSC.

Budd-Chiari syndrome (BCS) is a disorder resulting from hepatic vein thrombosis and outflow obstruction, which can occur anywhere from the hepatic veins to the inferior vena cava (IVC) or the right atrium. Other disease processes associated with this form of cirrhosis are coagulopathies, lymphoreticular malignancies, ischemic hepatitis resulting from profound hypotension associated with shock, and liver arteriovenous malformations characteristic of hemorrhagic telangiectasia. There are numerous causes for BCS, and definitive diagnosis is found in only approximately 65% to 75% of cases. In the Western Hemisphere, thrombosis of the hepatic veins is most often associated with myeloproliferative and coagulation disorders, as well as oral contraceptive use. Venous thrombosis is also an associated risk factor in the third trimester of pregnancy. Malignant tumors arising from within the liver or metastatic renal carcinoma can result in mechanical obstruction of the IVC, causing thrombosis within the hepatic veins and resulting in cirrhosis.

Wilson's disease and *hemochromatosis* are both autosomal recessive metabolic disorders that often present with hepatocellular dysfunction and can lead to cirrhosis if left untreated. The liver is the primary organ involved in the metabolism of both iron (hemochromatosis) and copper (Wilson's disease); overload of either metal can cause cirrhosis. Hemochromatosis is diagnosed primarily in middle-aged whites, whereas Wilson's disease is a disease of adolescents and young adults of all ethnicities.

Pathophysiology

Cirrhosis is the irreversible, end stage of liver injury caused by a variety of insults. Fibrotic scarring and hepatocellular changes result from chronic inflammation; obstruction; and toxic, metabolic, and congestive injuries. The morphological changes resulting from the injury are often classified according to the size of the regenerative nodules: Patients may have micronodular, macronodular, and mixed forms of cirrhosis. The liver can develop cirrhosis as a result of severe acute injury, as is seen with hepatitis; or subsequent to moderate damage sustained over months, as seen with obstructive biliary diseases; or from chronic continuous abuse, as seen in alcoholic cirrhosis.

With cirrhosis, the normal lobular liver architecture is replaced by diffuse disorganization, resulting in proliferation of bands of fibrous tissue and nodular regeneration of the surviving hepatocytes. The extent to which this occurs depends on the degree of injury, the length of exposure to the injury, and the liver's reaction to the insult. The end result is a decrease in the total liver cell mass because of the collagen formation or fibrosis. During the repair process, there is distortion of the microcirculation, resulting in an increased resistance to blood flow, thereby causing portal venous hypertension. As the liver attempts to repair itself, it develops a series of collateral vessels from the newly regenerated nodules to the existing portal vein and hepatic artery. These vessels, which are much less efficient than those of the normal circulation, cause portal hypertension.

Histological classification of cirrhosis is useful for describing the major anatomical changes that result from the various insults. This type of classification gives no etiological information other than narrowing the scope to the injurious agents resulting in this specific histological category of injury. Moreover, it is important to remember that at any point in the disease process, a patient may exhibit varying degrees of histological change.

Micronodular (Laennec's) cirrhosis is characterized by regenerative nodules that are 1 cm in diameter or less, no bigger than normal liver lobules. Histological examination fails to identify portal tracts and hepatic venules. Alcohol abuse often results in this type of cirrhosis; the theory is that continuous damage is being done to the liver, preventing it from regenerating. Initially the liver becomes enlarged and fatty as changes in lipid metabolism lead to fatty infiltrates. As the disease progresses, the liver atrophies and hardens. Fibrous tissue forms in thin, regularly spaced bands throughout the liver, which in time result in a decreased liver mass.

Macronodular cirrhosis is characterized by larger nodules (diameters of 5 cm), which may be multinodular with varying size nodules and may contain central veins. These nodules are surrounded by broad fibrous bands of varying thickness, which correspond to postnecrotic types of cirrhosis as seen following hepatitis. As the normal liver architecture collapses, the portal tracts converge between the fibrous scars, which is a key histological finding. *Mixed cirrhosis* has characteristics of both micronodular and macronodular cirrhosis.

Drug-induced liver disease can be the result of the drug's metabolism itself or a combination of several drugs together. The resultant liver toxicity may be caused by metabolism that is enhanced, altered, or the result of idiosyncratic processes such as hypersensitivity or certain genetics. Intrinsic hepatic injury is drug-dose dependent, whereas idiosyncratic drug reactions are more frequent and are not dose dependent. Patients who have hypersensitivity reactions to a drug develop hepatotoxicity secondary to the formation of drug metabolites, which are harmful to the liver.

PBC and PSC are both chronic cholestatic liver diseases that affect adults. There is an immunological component to both diseases that causes inflammation and fibrosis, which ultimately results in bile duct destruction. Liver biopsy in patients with PBC is of limited value because the disease varies from portal tract to portal tract; biopsy is, however, helpful to validate cirrhotic changes. The beginning stages of PSC are characterized by portal infiltration of lymphocytes, plasma cells, macrophages, and eosinophils. These inflammatory changes are followed by "ductular proliferation," which is characterized by the replacement of mature bile ducts with small, ineffective ones. The inflammatory changes lead to fibrosis, and as fibrotic changes ensue, increased signs of cholestasis appear. The end result of these changes is cirrhosis.

Primary sclerosing cholangitis can involve any part of the biliary tract from the ampulla of Vater to the small bile ducts within the liver. The lumens of these ductal systems can be narrowed or completely obstructed by fibrous scar tissue, resulting in the key functional abnormality, which is cholestasis. The biopsy results show fibrosis with inflammatory changes as described for PSC. Bacterial infections that often occur in the area above the strictures and in the presence of long-standing disease lead to biliary cirrhosis.

The pathophysiology of liver disease caused by hereditary factors is essentially the same for both Wilson's disease and hereditary hemochromatosis. Wilson's disease results from decreased hepatic excretion of copper and excessive absorption of copper from the small intestine. There is a gradual accumulation of copper within the tissues, resulting in hepatotoxicity. Initial presentation of Wilson's disease may vary from acute hepatitis or chronic hepatitis, neuropsychiatric disease, cirrhosis, or fulminant hepatic failure in young adults. Histological examination of the initial lesions reveals hepatic steatosis, with increased glycogen deposits. These lesions eventually progress to fibrosis and finally cirrhosis.

Hereditary hemochromatosis is characterized by increased intestinal absorption of iron. Liver biopsy reveals increased iron deposition, predominantly within the hepatocytes. When levels of iron exceed 20,000 mcg/g of liver tissue, fibrosis and cirrhosis usually ensue.

Vascular causes of liver disease, which include BCS and congestive hepatopathology, cause cirrhosis as the end result of necrosis. Liver biopsies show centrilobular congestion, hemorrhage, necrosis, and dilation. The resultant disruption of the hepatic circulation causes portal hypertension, fibrosis of the surrounding tissues, and ultimately cirrhosis.

Clinical Presentation

Cirrhosis is often an incidental finding on an annual exam, revealed either by an asymptomatically enlarged liver or an elevation of the liver enzymes. The clinical manifestations of cirrhosis are the result of hepatocellular damage and portal hypertension. The cumulative effect of these signs and symptoms is often referred to as "the stigmata of liver disease." The onset of symptoms is usually gradual, and patients with cirrhosis may appear well and remain asymptomatic for years.

Subjective

Initial complaints generally include weakness, anorexia, weight loss, and fatigue. Malnutrition is usually evident and can be the result of anorexia or the effect of reduced bile salt excretion, resulting in fat malabsorption and deficiency of fat-soluble vitamins.

As cirrhosis advances, patients may present with upper gastrointestinal (GI) bleeding from esophageal varices, which develop secondary to portal hypertension. As the liver continues to fail, patients may present with ascites and/or encephalopathy. Patients with cirrhosis may complain of abdominal pain that is caused by the enlargement of the liver and stretching of Glisson's capsule or by the ascites itself.

Menstrual abnormalities, loss of libido, impotence, sterility, and gynecomastia are manifestations of increased levels of estrogen that result from the liver's inability to inactivate hormones. These symptoms may prompt individuals to seek medical attention. Previously undiagnosed cirrhosis is often the underlying cause of symptoms in patients presenting with one of the aforementioned complaints.

Objective

The physical exam findings depend on the stage and severity of the disease process. Initial exam findings may reveal an enlarged, firm liver edge (which is the left lobe) palpable below the right costal margin; however, in patients with advanced disease, the liver may be small and difficult to palpate. Often, a firm smooth mass is palpable over the epigastric area, which is the right lobe of the liver (Riedel's lobe). Occasionally, nodular deformities may be palpable along the liver's edge. These areas of liver enlargement are dull to percussion and can aid in measuring the expanse of the liver.

Manifestations of cirrhosis that are nonspecific but suggestive of chronic liver disease include spider nevi, which are normally found over the anterior chest; pectoral alopecia; generalized muscle wasting; Dupuytren's (palmar) contractions; parotid gland enlargement; palmar erythema; hair loss; and testicular atrophy. Patients may have dilated cutaneous veins called *caput medusae* (Medusa's head) radiating out from around the umbilical area. These varicose veins are a result of the shunting of blood to the paraumbilical veins and are a manifestation of portal hypertension. Signs of vitamin and mineral disturbances are glossitis, cheilosis, and peripheral neuropathies. Fever may indicate complications such as peritonitis, cholangitis, or hepatitis.

Jaundiced sclera, skin, and mucous membranes usually develop in the later stages of cirrhosis. The hyperbilirubinemia is a consequence of the liver's inability to

conjugate and excrete bilirubin. Patients with hereditary hemochromatosis may have slate-colored skin from increased levels of iron stored in the tissue. Pruritus, although nonspecific, is often the presenting symptom in several forms of cirrhosis and can develop as a result of bile salts accumulating in the skin. Disruption in the liver's ability to synthesize clotting factors may manifest with bruising and complaints of a tendency to bleed. Peripheral edema results because of the decreased plasma osmotic pressure caused by hypoalbuminemia.

Ascites is a direct result of portal hypertension, which is a consequence of increased portal vein pressure. As liver function fails and healthy hepatic cells are replaced with fibrous nodules, the blood flow through the liver is impaired, causing increased resistance and back pressure that result in the accumulation of serous fluid within the abdomen. An abdominal exam reveals a positive fluid wave and shifting dullness on percussion. Splenomegaly results from splenic vein congestion. Esophageal varices, another consequence of portal hypertension, may be discovered after bleeding causes hematemesis, hematochezia, and/or melena. Hemorrhoids, which result from portal hypertension, are also present and cause bright red bleeding from the rectum.

Hepatic encephalopathy can range from mild confusion to coma and is the result of increasing blood ammonia, which is toxic to the brain. Characteristics of encephalopathy include asterixis (liver flap), reversal of sleep–wake patterns, tremors, hyperactive deep-tendon reflexes, dysarthria, delirium, and drowsiness.

Patients who present with Wilson's disease may have golden brown rings of color—called Kayser-Fleischer rings—located within Descemet's membrane of the cornea. These rings are usually found in patients with central nervous system (CNS) involvement and are seen with a slit lamp.

Diagnostic Reasoning

Diagnostic Tests

Results of initial laboratory testing vary depending on the stage of the disease process. If cirrhosis is in the early stages, laboratory results may be normal; however, in other patients, elevation of liver enzymes may be the only indicator of liver disease. Laboratory testing may reveal abnormalities, but these are nonspecific unless correlated with the history and physical exam.

Alcoholic cirrhosis may manifest in different ways depending on other coexisting processes such as malnutrition or hepatitis. The complete blood count commonly shows a macrocytic anemia and, depending on the severity of the disease, pancytopenia from the overall suppression of the bone marrow. The mean corpuscular volume does not correct quickly with abstinence from alcohol and may be the only key to occult alcohol use. Anemia can represent suppression of erythropoiesis from folic acid deficiency, occult losses from the GI tract, or a combination of the two. The white blood cell and platelet counts can vary depending on whether there is infection or splenic sequestration. As the liver continues to fail and liver cell mass decreases, the prothrombin time (PT) increases as the liver loses the ability to synthesize the proteins necessary to produce clotting factors.

The blood chemistry may show mild to moderate increases in alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels; if, however, the patient has a superimposed alcoholic hepatitis, the classic enzyme elevation of ALT/AST may be reversed, with an AST/ALT ratio ranging from 2:1 to 3:1. The levels of AST/ALT do not reflect the severity of the disease process. The gamma-glutamyl transpeptidase level is a good measurement of recent alcohol ingestion and declines rapidly with abstinence. Alkaline phosphatase levels may be markedly elevated when there is biliary obstruction. Serum bilirubin levels can be as high as 30 mg/dL. Hypoalbuminemia is common and contributes to the development of edema.

The diagnosis of alcoholic cirrhosis may be difficult to differentiate from alcoholic hepatitis, which is a reversible process, unless a liver biopsy is obtained. Histological examination reveals hepatocellular necrosis and evidence of Mallory bodies within the damaged cells. Depending on the stage of the disease, there is fatty infiltration and fibrosis. In early disease, there are micronodular changes, which over time develop into macronodular cirrhosis.

Abdominal ultrasound (US) is helpful in determining the size of the liver and any ascites or nodule formation. Doppler studies, in combination with US, are used to evaluate patency of the venous system that, if disrupted, can lead to portal hypertension. Any nodular findings that are suspicious for malignancy should be biopsied. If a patient presents with melena or hematemesis, an esophagogastroscopy should be performed to assess for esophageal varices or ulcerative processes.

Diagnosis of cholestatic liver disease, specifically PBC and PSC, may be made in conjunction with various autoimmune disease processes. The initial hepatic blood work-up usually shows an alkaline phosphatase level that is three to four times normal, with mild to moderate increases in the transaminases. The cholecystitic nature of both processes leads to prolonged PT.

Patients with PBC may also present with mild elevation of serum bilirubin and more often hypercholesterolemia. Serum IgM levels are elevated in 50% of cases. Antimitochondrial antibodies (AMAs) are found in 95% of the patients with PBC; titers can exceed 1:500. Definitive diagnosis is made via liver biopsy, which reveals granulomatous bile duct destruction and accumulation of inflammatory cells within the portal tracts with resultant segmental necrosis of the interlobular and septal bile ducts (chronic nonsuppurative destructive cholangitis). Ultrasound evaluation of the biliary tree is negative for biliary obstruction.

Laboratory studies of patients with PSC show the typical cholestatic profile; however, unlike with patients with PBC, the AMA is negative. Total cholesterol levels increase as the disease progresses. Endoscopic or transhepatic cholangiography reveals characteristic beading and stricturing of the intrahepatic and extrahepatic bile ducts. Liver biopsy is diagnostic for fibrous obliterative cholangitis, with the hepatic ductal system being replaced with fibrous cords of connective tissue. The end result for both PBC and PSC is biliary cirrhosis.

Diagnosis of cirrhosis caused by vascular disorders such as BCS and other veno-occlusive diseases is normally made through imaging studies because laboratory findings are nonspecific. Serum bilirubin, transaminases, and alkaline phosphatase can be elevated as much as four times normal. A computed tomography scan demonstrates failure of the hepatic veins to opacify, indicating an occlusive process. Pulsed Doppler studies illustrate absent hepatic flow; a normal pulsed Doppler effectively rules out BCS. Venographic studies also demonstrate narrowing and obstruction of the hepatic venous system. Histological exam reveals centrilobular congestion with associated hemorrhage and necrosis.

Wilson's disease and hemochromatosis are inherited metabolic liver diseases that result in cirrhosis if diagnosis and treatment are not made early. Diagnosis of Wilson's disease is suggested by elevated serum copper levels in conjunction with low serum ceruloplasmin levels. Once an abnormal ceruloplasmin level has been documented, a 24-hour urine check for copper should be completed. Definitive diagnosis is made through quantitative copper levels in the liver on biopsy. The majority of patients with Wilson's disease have histological findings consistent with hepatic steatosis, which in time progresses to fibrosis and cirrhosis.

Iron metabolism studies are used to diagnose hereditary hemochromatosis and should be collected with the patient in the fasting state. The presence of an elevated transferrin saturation level in combination with an elevated ferritin level is suggestive of hereditary hemochromatosis. Liver biopsy is necessary for definitive diagnosis. Histological studies with quantitative iron levels greater than 20,000 mcg/g are consistent with advanced disease and cirrhosis.

Differential Diagnosis

The patient who presents with cirrhosis can be a diagnostic challenge. The differential diagnosis of cirrhosis varies little between the different etiologies, so the challenge is determining the cause in an attempt to prevent further liver damage. The differential diagnosis of alcohol-induced liver disease includes biliary tract disease, idiopathic hemochromatosis, nonalcoholic fatty liver disease, drug toxicity, and/or viral hepatitis. US exam of the liver can often rule out an obstructive process. Alcoholics with chronic pancreatitis frequently develop jaundice secondary to stricturing of the common bile duct, which is differentiated through endoscopic retrograde cholangiopancreatography. A liver biopsy is often the only definitive test for differentiating many of the hepatobiliary diseases from each other. Thorough history and physical exam can suggest a diagnosis, but histological study is necessary to distinguish one process from another.

Alcoholic patients also have a high incidence of coinfection with hepatitis, the cause of which is often unclear; this can alter the typical serological findings. A hepatitis panel will reveal active or prior infection. Drug toxicity, specifically with acetaminophen, even in low doses, can alter transaminase levels and necessitates obtaining a careful drug history from each patient. Because of the preexisting liver injury, alcoholics who present with acetaminophen toxicity have significantly higher morbidity and mortality with relatively low doses of acetaminophen.

The differential diagnosis of cholestatic liver disease must include all other causes of chronic cholestasis, such as tumors, strictures, or obstructions resulting from stone formation. Autoimmune chronic active hepatitis can mimic the signs and symptoms of PBC; however, laboratory studies will show a low or negative titer for AMA. US exam may reveal biliary duct dilation, a process consistent with both PBC and PSC, thus making cholangiography the diagnostic test of choice.

Management

Treatment of cirrhosis is aimed at identifying and removing the causative agent and treating the symptoms.

Alcohol-Induced Liver Disease

In a patient with alcohol-induced liver disease, the most effective treatment remains abstinence. Patients who continue to ingest alcohol and present with ascites can increase their 2-year survival rate to 95% if they can completely abstain from alcohol. Those who continue to drink have a 2-year survival rate of less than 25%. The liver has a remarkable regenerative potential; and despite slow progress, the patient can become functional if he or she is motivated to remain abstinent. Nutritional assessment with dietary supplementation to ensure adequate caloric intake (25–35 kcal/kg body weight per day) is imperative because many patients with alcohol-induced liver disease are also malnourished. Protein intake should be increased to 1 to 1.5 grams per kilogram of body weight per day unless there is evidence of hepatic encephalopathy, which necessitates a reduction in protein intake. Daily vitamin and mineral supplementation is also indicated: Specifically, patients should receive a multivitamin, additional vitamin B_{12}, folate, thiamine, magnesium, and zinc supplementation if 100% of the daily requirement of these minerals is not contained in the multivitamin. Patients who continue to show clinical deterioration despite abstinence can be considered for liver transplantation, provided they have remained alcohol free for more than 6 months.

Treatment of Complications

Many of the complications of alcohol-induced liver disease are the direct result of the development of portal hypertension and include ascites, hepatic encephalopathy, anemia, hemorrhage, spontaneous bacterial peritonitis, hepatorenal syndrome, hepatopulmonary syndrome, and hepatocellular carcinoma. Table 11.14 presents the treatment of these complications. Portal hypertension is the result of disruption of the hepatocellular circulation causing an increase in portal venous pressure. As the liver becomes progressively more cirrhotic, collateral venous circulation develops to overcome the increased resistance to blood flow. The collateral circulation that develops between the portal and systemic circulation, specifically the azygos vein, is a much weaker system and results in dilated, tortuous vessels commonly known as varices. Development of varices within the esophagus and submucosa of the gastric fundus predisposes patients to

Table 11.14 Complications of Alcohol-Induced Liver Disease

Portal Hypertension and Variceal Hemorrhage

Portal hypertension is the result of disruption of the hepatocellular circulation, causing an increase in portal venous pressure. As the liver becomes progressively more cirrhotic, there is development of collateral venous circulation to overcome the increased resistance to blood flow. The collateral circulation that develops between the portal and systemic circulation, specifically the azygos vein, is a much weaker system and results in dilated, tortuous vessels commonly known as varices. Development of varices within the esophagus and submucosa of the gastric fundus predisposes patients to hemorrhage when the portal pressure gradient is greater than 12 mm Hg.

The most common site of variceal hemorrhage is from within the esophagus and can be life-threatening, with a mortality rate of approximately 50%. Patients with a massive acute hemorrhage require immediate attention to prevent hemodynamic instability and shock. Endoscopic exam can help identify the site of the bleeding and allows for banding or sclerotherapy, the treatments of choice for acute variceal bleeding. Pharmacological intervention includes IV infusion of vasoconstricting agents that assist in decreasing portal pressures.

Octreotide causes reduced splanchnic and hepatic blood flow and is effective in reducing portal pressures. Octreotide (Sandostatin) can be infused at 50–250 mcg/hr. A combination of band ligation or sclerotherapy and octreotide is the most effective treatment for bleeding varices. Patients who have failed both endoscopic and pharmacological intervention require emergent insertion of a Sengstaken-Blakemore tube for balloon tamponade of the bleeding variceal site. The risk for aspiration, esophageal rupture, or rebleed is great, and patients normally require intensive care monitoring.

Some patients may benefit from surgical placement of a portacaval shunt or more recently placement of a transjugular intrahepatic portosystemic shunt (TIPS). Both procedures are performed to decrease portal hypertension but are associated with a high operative mortality rate especially if performed on an urgent basis. Portacaval shunts are effective in reducing esophageal bleeding but carry an associated risk of developing postshunt encephalopathy and hepatic failure of about 50% and eliminate the possibility for future hepatic transplantation.

The risk of rebleeding from esophageal varices is about 70%, so patients should be placed on preventive therapy. The most well-known pharmacological intervention is the initiation of a nonselective beta blocker such as propranolol (Inderal) or nadolol (Corgard) to reduce portal pressure. Dosages of propranolol can range from a starting dose of 40 mg twice daily up to a total daily dose of 200 mg. The goal of treatment is to reduce the resting heart rate by 25% but not below 60 beats/min. The usual contraindications to beta blocker therapy must be considered before initiation of therapy. Also, any patient with known alcohol-induced cirrhosis should have beta blocker therapy as tolerated to decrease the risk of initial variceal bleed.

Prevention of recurrent bleeding can also be accomplished using sclerotherapy or variceal banding. Although both procedures are equally effective, endoscopic banding is associated with lower complications from ulcers or strictures than sclerotherapy. Surgical decompression of the portal system by shunt insertion or TIPS procedure can also be performed to reduce the risk of future variceal bleeding. Complications resulting from these procedures include hepatic encephalopathy, infection, shunt stenosis, and shunt occlusion.

Ascites

Ascites, the excess accumulation of serous fluid within the peritoneal cavity, is associated with unfavorable outcomes. Abdominal paracentesis should be performed and the ascitic fluid analyzed for cell count, culture, and albumin level. The serum albumin level minus the ascitic albumin level equals the serum-ascites albumin gradient (SAAG). An SAAG level greater than 1.1 g/dL is highly suggestive of portal hypertension but offers no information regarding the cause of the ascites. Ascites results from a combination of increased hydrostatic pressure (portal hypertension), decreased oncotic pressure (hypoalbuminemia), peripheral vasodilation probably mediated by nitric oxide released from the splanchnic vasculature, volume expansion resulting from a disturbance in the renin-angiotensin system with subsequent sodium and water retention, and impaired activation of aldosterone by the liver.

Continued

Table 11.14 Complications of Alcohol-Induced Liver Disease—cont'd

Ascites can be clinically observed on physical exam when 1,000 mL or more of fluid has accumulated within the abdominal/peritoneal cavities; smaller amounts are detectable with the use of ultrasound. Shifting dullness to percussion and a positive fluid wave are two findings consistent with the diagnosis of ascites.

Treatment of ascites begins with sodium restriction of 400–800 mg/day. The goal of treatment for the patient with ascites and peripheral edema is a daily weight loss of approximately 1 pound; if fluid is mobilized too quickly, it can further impair renal function by causing a prerenal azotemia. Treatment of ascites includes daily monitoring of weight, serum electrolytes, and renal function. Patients who present with ascites and have hyponatremia (serum levels less than 125 mEq/L) need fluids restricted to 800–1,000 mL/day. Although some patients respond with sodium and water restriction, diuretic therapy is usually required. Spironolactone (Aldactone), a potassium-sparing, aldosterone antagonist, is started at 100 mg/day and increased by 100 mg/week until diuresis is achieved or a maximum dose of 400 mg/day is reached. Adverse effects include painful gynecomastia and hyperkalemia. If effective diuresis has not been achieved, a loop diuretic is added. Furosemide (Lasix) is started at 40 mg/day and is titrated up to 240 mg/day as necessary.

Approximately 10% of patients with cirrhosis are resistant to diuretic therapy despite spironolactone 400 mg/day and furosemide 160 mg/day. These patients have persistent tense ascites and may also develop azotemia with creatinine levels greater than 2.0 mL/dL as a result of the intense diuretic regimen. The treatment for this "intractable" ascites is a large-volume paracentesis, but the practitioner must first determine whether the patient is adhering to the medical regimen, especially sodium restriction. If a large-volume paracentesis is necessary, up to 4–6 L of fluid can be removed per procedure. Intravascular volume expanders can be infused simultaneously to prevent hemodynamic instability secondary to removal of large volumes of ascitic fluid. Large-volume paracentesis is often the treatment of choice because it requires a shorter hospital stay and has fewer complications in comparison to diuretic therapy with regard to electrolyte imbalance and renal insufficiency.

The procedure can be performed daily until ascites is resolved, and then the patient can be maintained on diuretic therapy. The two major complications of paracentesis are spontaneous bacterial peritonitis (SBP) and hepatorenal syndrome.

Spontaneous Bacterial Peritonitis

SBP is a common complication of cirrhosis that can be fatal. Patients may present with abdominal pain, increasing ascites, fever, and progressive encephalopathy. Definitive diagnosis is made by paracentesis. The gold standard for the diagnosis of SBP is a total white cell count of greater than 300 cell/mcL with a polymorphonuclear neutrophil cell count of greater than 250/mcL. The protein concentration is usually less than 1 g/dL. Gram-negative bacilli are the causative pathogen in 70% of SBP, with *Escherichia coli* being isolated in 50% of the cases. Gram-positive organisms are isolated in approximately 25% of the cases, and infection with anaerobic organisms is rare due to the high oxygen content of the ascitic fluid. Because the mortality rate for untreated SBP is 50%, initiation of treatment is suggested before culture results are obtained. Cefotaxime (Claforan) is a broad-spectrum, third generation cephalosporin and is considered the treatment of choice for SBP. The usual dose is 2 g IV every 8 hours for 5 days. Post-SBP prophylaxis can be accomplished with norfloxacin 400 mg/day.

Hepatorenal Syndrome

Hepatorenal syndrome is a terminal complication frequently associated with advanced liver damage and is almost always found in patients with advanced ascites. The syndrome is characterized by oliguria, hyponatremia, azotemia, low urine sodium (less than 10 mEq/L), and hypotension. The hallmark to diagnosis is a disproportionate rise in creatinine with respect to the blood urea nitrogen. Histologically, the kidneys are normal, and diagnosis is often one of exclusion. Individuals with decompensated cirrhosis and ascites can precipitate hepatorenal syndrome after large-volume paracentesis, aggressive diuresis aimed at decreasing ascites, or sepsis. Patients are often misdiagnosed with prerenal failure, and the only way to differentiate between the two is through insertion of a central venous catheter and assessment of venous pressures. Treatment includes restoring the intravascular volume and avoiding any procedures that will dramatically disturb the patient's volume status, such as large-volume paracentesis and aggressive diuresis. The definitive treatment of patients with hepatorenal syndrome is liver transplantation.

Hepatic Encephalopathy

Hepatic encephalopathy, also known as portosystemic encephalopathy, is a complex process involving a change in mental status resulting from the failure of the liver to detoxify elements of gut origin and shunting of this blood from the portal to the systemic circulation and then to the brain. Nitrogenous agents such as ammonia are believed to enter into the CNS by way of shunted blood resulting in disturbances in neurological function. Although ammonia is thought to be the sole toxin responsible for hepatic encephalopathy, the serum levels do not correlate with the degree or presence of encephalopathy.

Table 11.14 Complications of Alcohol-Induced Liver Disease—cont'd

The diagnosis of hepatic encephalopathy is made clinically and often follows an event such as increased dietary protein, GI bleeding, constipation, infection, deterioration in hepatic function, hypokalemia, azotemia, alkalosis, and hypovolemia. Physical exam findings include an altered mental status such as personality (mood) changes, decreased reaction time, and intellectual deterioration, as well as neuromuscular dysfunctions such as asterixis or metabolic flap, absence of fixed sensory or motor deficits, and hyperreflexia. Other findings include fetor hepaticus (garlic odor of the breath caused by exhalation of sulfur-containing mercaptans), hyperthermia, and hyperventilation. Obtaining a fasting arterial blood ammonia level or a spinal fluid glutamine level can be helpful in confirming the diagnosis of hepatic encephalopathy although they are not necessary.

Treatment of hepatic encephalopathy begins with identification and treatment of factors that precipitate encephalopathy in patients with liver disease.

- *GI Bleeding.* Increases production of ammonia and other nitrogenous toxins.
- *Increasing Dietary Intake of Protein.* Provides building substrate for formation of nitrogenous toxins in the intestine.
- *Diuretic-Induced Problems.* Overdiuresis causes increased circulation of urea and ammonia production. Hypovolemia resulting in hypokalemia and alkalosis enhances the transfer of ammonia across the blood–brain barrier.
- *Constipation.* Decreases transit time within the intestine, which enhances contact time with ammonia-forming bacteria in the colon.
- *Drugs Causing CNS Depression.* Impaired liver function causes alteration in degradation and may accumulate, causing further depressant effects.
- *Infection.* Increases catabolism and production of nitrogenous toxins.

For instance, GI bleeding and diets high in protein provide the basic elements for formation of ammonia and other nitrogenous compounds from the action of bacteria in the gut, which can induce or aggravate the symptoms of encephalopathy. Colonic bacteria responsible for the formation of ammonia and other nitrogenous compounds can be reduced by administering oral neomycin (Mycifradin Sulfate Oral, Neo-Tabs Oral) 0.5–1.0 g every 4–6 hours for 5–7 days. Lactulose (Cephulac, Heptalac) is a nonabsorbable synthetic disaccharide, that, when digested by intestinal bacteria, is fermented and causes acidification of the colon contents. The lower stool pH binds the ammonia in the colon, rendering it nonabsorbable. Lactulose also changes the bowel flora so that there are fewer ammonia-forming bacteria. The initial dose of lactulose is 30 mL three to four times daily and is titrated until the patient has two or three softly formed stools daily.

Iron-Deficiency Anemia

Iron-deficiency anemia is a common finding in alcoholics. It can be treated with ferrous sulfate taken three times daily after meals. To avoid the constipating effect of iron, a stool softener can be given as well. If there is evidence of a macrocytic anemia, the patient may benefit from 1 mg of folic acid daily.

Hepatopulmonary Syndrome

Hepatopulmonary syndrome is a recently recognized pulmonary complication of cirrhosis and portal hypertension, which manifests through abnormal arterial oxygenation. The diagnosis is made when there is intrapulmonary dilation in the absence of other morphological pathology. The results are reversible with liver transplantation.

hemorrhage when the portal pressure gradient is greater than 12 mm Hg.

Irreversible, Chronic Liver Disease

Liver transplantation is the treatment of choice for irreversible chronic liver disease. Cirrhosis, hepatitis C, primary biliary cirrhosis, primary sclerosing cholangitis, alcoholic liver disease, autoimmune hepatitis, and genetic disorders of the liver are diseases for which transplantation has been successful. Five-year survival rates are documented as high as 80% with advancements in surgical techniques and immunosuppressive agents such as cyclosporine and tacrolimus (FK506). Contraindications to transplantation include malignant hepatobiliary processes, sepsis, and advanced cardiopulmonary disease. In cases of hepatitis B and C, the virus can infect the new liver.

Primary Biliary Cirrhosis

Treatment of PBC is symptomatic. Pruritus is often the most aggravating manifestation of PBC. Cholestyramine (Questran) or colestipol relieves itching in patients with cholestasis by lowering serum bile acids and increasing the intestinal secretion of bile by preventing its resorption. The usual dose is 4 g or 5 g, respectively, in water or juice three times daily until the pruritus has been controlled, and then the dosage is decreased to that which maintains control of the symptom. Rifampin (Rifadin) 150 to 300 mg twice daily has been beneficial in relieving pruritus in some cases; ondansetron, a

5-HT_3 serotonin receptor antagonist, shows promise as well.

Fat-soluble vitamin deficiency occurs with the onset of steatorrhea and can be made worse with the administration of cholestyramine (a bile acid sequestrant). Vitamins A, D, E, and K can be replaced orally. Laboratory studies will reveal vitamin K deficiency as a prolonged PT. The deficiency can be treated with 5 to 10 mg daily of vitamin K by mouth; subsequent monitoring of the PT will indicate whether therapy is adequate. Overdosage of vitamin A can cause hepatotoxicity, so the dosage must be individualized based on serum levels and response to treatment.

Patients with PBC often have associated osteoporosis, which has no known treatment. If patients have been diagnosed with PBC and have osteomalacia, calcium supplementation with 500 mg three times daily and vitamin D 400 to 800 IU/day is indicated. Patients should be instructed to eat foods rich in calcium and phosphorus and to increase their exposure to sunlight.

Several immunosuppressive agents including corticosteroids, methotrexate, and azathioprine and the antifibrinogenic colchicine have been effective in reducing elevated serum alkaline phosphatase and bilirubin levels. Ursodeoxycholic acid (ursodiol), a choleretic, acts by stimulating excretion of bile by the liver, is much less toxic than the other drugs mentioned above, and has been effective in reducing symptoms and improving long-term survival.

Surgical reconstruction of the biliary tract, choledochoduodenostomy, and choledochojejunostomy are palliative treatments that alleviate the symptoms of PBC. If there is notable stricturing within the biliary tree, patients often do well with stenting. Liver transplantation for advanced PBC is the treatment of choice.

Hemochromatosis and Wilson's Disease

Two important but treatable inherited metabolic causes of cirrhosis are hemochromatosis and Wilson's disease. Early diagnosis and treatment are key to the management of hereditary hemochromatosis (HHC) and begin with liver biopsy for definitive diagnosis. If treatment is initiated in the precirrhotic phase, the disease can be controlled with weekly phlebotomies of 1 unit (500 mL) of blood, which contains approximately 250 mg of iron. This process is continued until there is depletion of the iron stores (which can be 2 years or more). Every 2 to 3 months, iron metabolism studies monitor the patient's progress. Once the iron stores are depleted—when serum ferritin levels fall below 50 ng/mL and transferrin saturation is less than 50%— patients can be maintained with periodic phlebotomies. Patients who are exhibiting cardiac symptoms may require the use of iron-chelating agents such as deferoxamine. Administered intramuscularly, it increases the urinary excretion of iron up to 5 to 18 g annually. Phlebotomy decreases the cardiac conduction defects and lowers insulin requirements. Patients should be instructed to consume a low-iron diet that eliminates foods such as red meat, and they should avoid alcohol, vitamin C, raw shellfish, and any supplement containing iron. Patients may require specific treatment of diabetes mellitus, heart disease, arthropathy, hypopituitarism, and portal hypertension, all complications due to HHC. Patients whose disease has progressed to cirrhosis must be monitored for hepatocellular carcinoma either by liver US or measurement of alpha-fetoprotein levels. Because the disease is inherited, screening of all first-degree relatives is necessary.

Wilson's disease is also an inherited disease the early diagnosis and treatment of which can prevent the development of neurological or hepatic damage. Treatment includes both dietary and medicinal components. Limiting dietary intake of copper (legumes, animal organs, and shellfish) should become a lifelong habit. The administration of oral penicillamine (Depen) 0.75 to 2 g/day in divided doses induces the urinary excretion of chelated copper. If GI upset or hypersensitivity prohibits the use of penicillamine, trientine (Syprine) 250 to 500 mg three times daily can be substituted. Oral administration of zinc 50 mg three times daily as maintenance therapy also promotes excretion of copper in the feces. Patients who are receiving penicillamine, an antimetabolite of vitamin B_6, should receive pyridoxine (supplemental vitamin B_6) 50 mg/week. Liver transplant is the treatment of choice for patients with cirrhosis or fulminant hepatitis. Siblings and family members should be screened for the disease.

Vascular or Congestive Liver Disorders

Management of patients who present with vascular or congestive liver disorders, such as those with BCS and other hepatic occlusive diseases, is essential. Because of the many causes of BCS, initial treatment must begin with finding and treating the cause of the hepatic congestion. Hepatic vein thrombus is difficult to manage and requires a multidisciplinary approach including a hematologist, surgeon, hepatologist, and gastroenterologist. Ascites is initially managed with sodium restriction and diuretics; however, over time this is usually ineffective, and most patients will require large-volume paracentesis or shunting for symptomatic relief.

If diagnosis of acute thrombus is made early, thrombolytic therapy can be instituted and long-term anticoagulation with warfarin (Coumadin) can help prevent further thrombus formation. Surgical decompression shunting for refractive ascites can delay development of hepatic failure or cirrhosis but often results in graft thrombus. Patients with associated myeloproliferative diseases and hypercoagulopathies may benefit from low-dose aspirin therapy and chemotherapy as directed by a hematologist.

Follow-up and Referral

Any patient with advanced liver disease should be referred to a hepatologist or gastroenterologist trained to

treat the disease and its subsequent complications. All patients require referral for liver biopsy to establish a definitive diagnosis. It is the responsibility of the clinician to recognize the onset of the disease process and obtain all the necessary testing in order to provide the most complete information to the accepting consultant. Patients with end-stage liver disease should be referred to a liver transplant facility. Patient follow-up can be shared between the primary-care practitioner and the consulting physician. Patients with chronic or advanced liver disease will require indefinite monitoring of their liver function tests, as well as their fluid and electrolyte status. Maintaining good nutrition is an important component of treatment of any disease process. Patients with advanced liver disease may benefit from consultation with a registered dietitian, who can review dietary restrictions and help patients understand how to achieve a balanced diet.

Patient Education

Patients with hepatic failure should be taught to check their weight daily as a way to monitor increasing fluid retention and ascites, which may indicate a developing complication. Patients with cirrhosis have a life-threatening terminal disease; therefore, attention must be given to promoting psychological well-being. Patients should be provided with education regarding medications to avoid to prevent further hepatotoxicity, such as acetaminophen (Tylenol), vitamin A, cocaine, tetracycline (Sumycin), phenytoin (Dilantin), and ethyl alcohol. Patients with liver failure should always ask their health-care provider about the potential liver toxicity of each of their medications. Patients with hepatic encephalopathy should avoid CNS depressants, which might intensify their lethargy or fatigue. These patients may also require education about the need for self-administering enemas if they become constipated, in order to decrease the time for bowel absorption of nitrogen-based compounds. All patients with ascites must be informed of the signs and symptoms of infection, which may indicate developing spontaneous bacterial peritonitis.

ABDOMINAL HERNIAS

An abdominal hernia is the protrusion of a peritoneally lined sac through some defect or weakened area in the abdominal wall. A history of heavy physical labor or heavy lifting can elicit a hernia. There are several different types of hernias, which are usually classified by the anatomical location of the protrusion.

Epidemiology and Causes

It is estimated that up to 10% of the population has some form of hernia. *Groin hernias* are the most common type and are classified as *indirect inguinal hernias,* which are responsible for 50% of hernias treated; *direct inguinal hernias,* which represent 25% of hernias seen; and *femoral hernias,* which represent 10% of hernias. Hernias occurring through the anterior abdominal wall are called *ventral hernias;* these account for only 15% of all hernias. Ventral hernias are further broken down into epigastric hernias (5%), incisional hernias (5%), and umbilical hernias (3%).

Groin hernias are by far the most common type of hernia and occur in both men and women. Indirect inguinal hernias are the most common and occur in both genders, although they are frequently seen in young men. Direct inguinal hernias are more common in men older than age 40 and are caused by a congenital abnormality. Femoral hernias occur more often in women than in men and are rare in children.

The recurrence rate of hernias in general is about 10%, with direct and indirect hernias having a recurrence rate that is approximately equal. The subsequent recurrence rate of recurrent hernias is much higher, at 35%.

Ventral hernias include all other hernias of the anterior abdominal wall. Epigastric hernias are much more common in men than in women and are multiple in 25% of the cases. The peak age of incidence is age 20 to 50. Umbilical hernias are considered a normal occurrence in newborn infants, with about 20% of infants being affected. These hernias are more common in males of all ages and in African Americans of either gender. The presence of an umbilical hernia is considered normal until the child reaches age 2. Incisional hernias are considered the only iatrogenic type of herniation. Approximately 2% to 11% of all patients undergoing abdominal surgery develop incisional hernias. Women are affected twice as often as men.

Hernias occur because there is sufficient pressure to force tissue out through a defect in the abdominal wall, as well as a potential space for that protrusion. The etiology of hernias is multifactorial, with biological, congenital, and environmental influences contributing to their development.

Pathophysiology

In general, for any type of groin hernia to occur, two of the body's protective mechanisms must be overcome. The first is called the *shutter mechanism,* whereby the internal oblique muscle and the transversus abdominis muscles contract to overlap, strengthening the posterior wall of the inguinal canal. Second, a *closure* or *sphincter-type mechanism* causes contraction of the musculature, displacing the transversalis fascia, which in effect decreases the diameter of the deep inguinal ring.

Indirect Inguinal Hernias

Indirect inguinal hernias result when tissue herniates through the internal inguinal ring, which in men extends the length of the spermatic cord. With continued pressure, the sac can actually reach the scrotum, where it is then palpable just proximal to Hesselbach's triangle. The pathophysiology of indirect inguinal hernias in most cases begins with the herniation of tissue through

a still-patent vaginal process that remains after the descent of the testes. In women, the vaginal process exists within the canal of Nuck. Indirect inguinal herniation is caused by a combination of this congenital defect and a disruption in the functioning of the sphincter mechanism as a result of a variety of environmental conditions, including increased abdominal pressure and trauma to the area.

Direct Inguinal Hernias

Direct inguinal hernias occur when the transversus abdominis and internal oblique muscles are attached, forming a high arch on the inferior border that results in a faulty shutter mechanism. Any environmental factors that increase abdominal pressure enhance the chance of herniation. As with indirect inguinal hernias, the presence of this congenital defect does not explain why herniation is more common later in life.

Femoral Hernias

Femoral herniation occurs at the fossa ovalis where the femoral artery exits from the abdomen. It is presumed to be caused because women have a larger femoral canal and smaller iliopsoas muscles. Other factors that contribute to femoral herniation are femoral engorgement during pregnancy and the size of the female pelvis.

Epigastric Hernias

Epigastric hernias occur along the midline between the xiphoid process and the umbilicus. The fibers along the linea alba are brought together in a patchwork-type closure; the defect exists within this decussation. As these fibers weaken, the contents can herniate through the abdomen. Epigastric hernias are three times more likely to occur in men than in women. Peritoneal fat, bowel, and omentum are the most common abdominal contents to protrude through the wall.

Umbilical Hernias

Umbilical hernias that develop in adulthood occur through a weakening in the abdominal wall around the umbilical ring. The herniation of abdominal contents through this defect is also dependent on environmental factors that increase intra-abdominal pressure. Of particular importance when diagnosing an umbilical hernia is to look for underlying ascites secondary to liver disease.

Incisional Hernias

Incisional hernias can occur anywhere along a surgical incision into the abdomen. They are classified into those that cannot be controlled by surgical technique and those that can be controlled by surgical technique. Controllable factors include the type of incision chosen and choice of suture and surgical techniques. Factors that are considered uncontrollable include the prior medical history of the patient, age, steroid use, nutritional status, obesity, and complications of the surgery, especially wound sepsis.

Clinical Presentation

Subjective

In any patient presenting with an abdominal hernia, the provider must determine whether there is an abnormal increase in intra-abdominal pressure that has contributed to the herniation. A thorough history and physical exam, with special attention to the genitourinary, respiratory, and gastrointestinal systems, will provide clues. All male patients who present with an abdominal hernia, regardless of age, require a prostate exam to determine if there is any obstructive process inhibiting urinary output, which in effect increases intra-abdominal pressure. Patients should be evaluated for ascites, which also increases intra-abdominal pressure.

Patients who have respiratory difficulty, such as obstructive pulmonary disease processes, have an increased risk of hernia because of the increased abdominal pressure associated with coughing and the downward expansion of the diaphragm found with hyperinflated lungs.

Objective

The presentation of inguinal hernias is not always obvious and is quite often an incidental finding on routine exam. Patients may present with complaints of pain while straining or lifting heavy objects or a swelling in the groin area. In general, the physical exam for all groin hernias begins with visual inspection of both groins and the genitalia. With the male patient standing, the spermatic cord is located on both sides and is palpated for any swelling into the scrotum. Once the inguinal canal has been palpated, three additional areas must be examined. After invaginating the scrotal sac, the examining finger follows the spermatic cord up to the external inguinal ring and the fascia of the external oblique muscle. The posterior wall is inspected for weakness or bulging, and the inguinal ring is also palpated for structural soundness. Once these areas have been examined, the provider then withdraws the finger slightly and the patient is asked to cough, which increases the intra-abdominal pressure. If the provider feels the presence of a tissue-like sac tapping against the finger, hernia is present. Other findings indicative of herniation are feeling a rush of fluid (peritoneal) under the examining finger or a patient's report of pain. In a female patient, the femoral areas are palpated while the patient increases intra-abdominal pressure by performing the Valsalva maneuver. Any bulging in the area is considered a positive finding.

Once a groin hernia has been diagnosed, the practitioner must determine whether the hernia is incarcerated or strangulated, both of which require immediate surgical attention, or whether a more chronic situation is

present, which can be cared for electively. Most often this can be determined by patient history, as well as the physical ability to reduce the hernia on examination. A strangulated hernia is a nonreducible herniation in which the blood supply to the herniated tissue is compromised. An incarcerated hernia is a hernia that has caused a bowel obstruction as a result of the protrusion.

An indirect inguinal hernia presents as a soft swelling within the internal ring, when either provoked or unprovoked, and often descends into the scrotum. A direct inguinal hernia presents as a bulge in the area of Hesselbach's triangle (Fig. 11.1). Direct inguinal hernias are usually painless and easily reducible. The hernia bulges anteriorly, pushing against the side of the examining finger. Femoral hernias are more common on the right side and may be accompanied by severe pain. There is a palpable bulge through the femoral ring, and the inguinal canal is empty. Normally, it is the intestine that has herniated through the abdominal wall.

Epigastric hernias are normally asymptomatic and present as a small bump or bulge along the midline above the umbilicus. There may be variation in size with increasing intra-abdominal pressure. Peritoneal fat, omentum, and bowel are usually the tissues that herniate through the abdomen. The smaller hernias tend to be more painful because they involve the herniation of the preperitoneal fat, which is irritating. Larger hernias must be examined for incarceration and obstruction.

Incisional hernias manifest along the incision line of a previous abdominal operation and can be painful. Patients with incisional hernias may also have signs and symptoms of bowel obstruction, which are discussed under Bowel Obstruction later in this chapter.

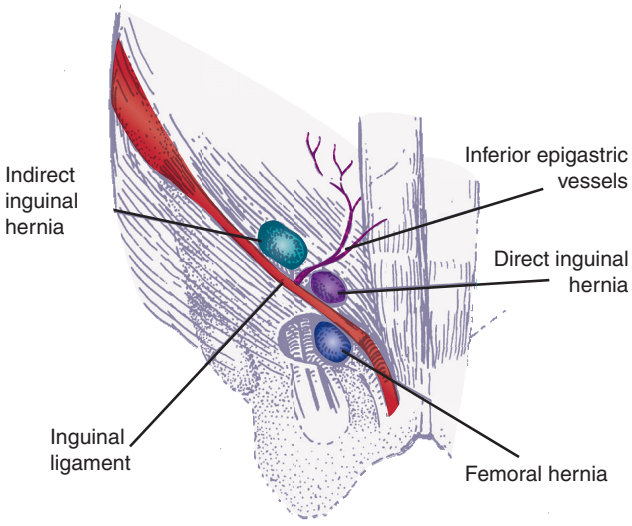

Figure 11.1 Locations of indirect and direct inguinal and femoral hernias. Anterior view of the groin, showing locations of indirect inguinal hernia, direct inguinal hernia, and femoral hernia, based on anatomical landmarks. *(Source: Kozol, AK, et al.* When to call the surgeon: Decision making for primary care providers. *FA Davis, Philadelphia, p 170. Reprinted with permission.)*

Diagnostic Reasoning

Diagnostic Tests

Hernias are diagnosed almost exclusively by physical exam findings, as described in the preceding text. On occasion, a radiographic study is necessary to determine if an obstructive process is taking place. Other studies, such as pulmonary function testing or evaluation of a mass or lesion within the abdomen, may be indicated to assess the cause and/or extent of increased intra-abdominal pressure.

Differential Diagnosis

The differential diagnosis list for hernia is limited. It includes hydrocele, psoas abscess, femoral adenopathy or inguinal adenopathy, and ectopic testis.

Management

When a hernia is detected, the patient should be referred to a surgeon. Despite the evolution of hernia repair over the last century, the underlying principles remain the same: reinforce the two natural defense mechanisms discussed previously; decrease the size of the inguinal ring; and strengthen the posterior wall of the canal. Repair of femoral hernias is accomplished by reducing the size of the canal, whereas repair of indirect hernia is accomplished by dissecting the hernial sac and reduction of the repaired tissue. Frequently, there is not sufficient tissue to reconstruct and strengthen the posterior wall of the canal and synthetic mesh materials are used. Laparoscopic surgery has decreased the recovery time and allowed for a single intervention for bilateral hernia repair. All ventral hernias should be repaired to decrease the possibility for incarceration.

Postoperatively, the patient may experience incisional pain, which is relieved by oral analgesics. Pain that persists for more than a few days suggests impending wound infection. Normally, there is slight postoperative swelling, ecchymosis, and erythema of the skin, up to the scrotal area in male patients. Hernia repair with significant scrotal involvement may result in increased scrotal edema, which can be relieved with ice packs, elevation, and wearing a scrotal support. In female patients, swelling is usually limited to the surgical site but may extend to the labia and vulva.

Follow-up and Referral

All patients with abdominal hernias require surgical consultation, whether emergently or electively, and appropriate referral should be made. The patient is usually seen in the surgeon's office 3 to 7 days after surgery.

Patient Education

After typical groin surgery, the patient is allowed to return to normal activities, including work, after about

1 week but is instructed to avoid heavy lifting or contact sports for at least 4 to 6 weeks. Patients who have undergone laparoscopic repair of groin hernias are allowed to resume regular activities, including heavy lifting, as soon as 2 days postprocedure. Patients who have had a ventral hernia repair should follow routine postoperative instruction as directed by the surgeon.

APPENDICITIS

The appendix is a fingerlike projection located at the apex of the cecum just below the ileocecal valve. It has no known function in humans; however, it is thought to have some immunological function, based on the amount of lymphoid tissue it contains. The appendix fills with food, just as the cecum does, but because the lumen of the appendix is smaller, it has a tendency to become obstructed. Appendicitis is the inflammation of the vermiform appendix caused by an obstruction and/or infection. It is the most common cause of acute right lower quadrant (RLQ) abdominal pain requiring surgical intervention. Acute appendicitis results in more than 250,000 appendectomies annually in the United States and represents 1 million hospital day stays.

Epidemiology and Causes

Appendicitis can occur at any age; however, it is most common between ages 10 and 30 years. It is rare in infants and in older adults and is often associated with higher morbidity within these age-groups because of delayed diagnosis and intervention. During the peak incidence years, men are twice as likely to be diagnosed with appendicitis as are women, but the occurrence in both genders tends to equalize over the life span. It is estimated that appendicitis will affect 10 in 100,000 people in the United States, with an incidence of 1.1 cases per 1,000 people per year.

Appendicitis is more common in Western countries, where people have diets that are low in fiber, high in fat, and high in refined sugars and other carbohydrates. Obstruction of the appendix by a variety of pathological processes is the cause of the majority of appendicitis. Other contributing factors include intra-abdominal tumors and positive family history. Recent roundworm infestation or viral infection of the gastrointestinal (GI) tract have also been implicated.

Pathophysiology

Appendicitis typically begins with dilation of the appendix, followed by obstruction and subsequent bacterial infection. When the lumen of the appendix is obstructed by hardened feces (fecalith), inflammatory processes (including parasites, viruses, or bacteria), strictures, neoplasms, or foreign bodies (including vegetable or fruit seeds or barium), the mucosa of the appendix continues to secrete fluid, which further distends the lumen, impairing the venous blood flow and leading to tissue necrosis. Left untreated, this increased distention impedes arterial inflow. Bacteria continue to proliferate and, in the absence of treatment, perforation of the appendix occurs. The incidence of perforation in patients with appendicitis is between 17% and 40%, with rates as high as 60% to 70% in older adults because of the nonspecific presenting symptoms. Gynecological disorders and gastroenteritis are the most common causes of misdiagnosis.

Clinical Presentation

Subjective

The diagnosis of acute appendicitis is made clinically and is based primarily on the patient's history and physical exam. The historical presentations of signs and symptoms are important keys to prompt diagnosis and treatment; therefore, it is important to obtain a thorough and accurate account of the events. The classic presentation of appendicitis begins with the acute onset of mild to severe colicky, epigastric, or periumbilical pain. The pain is often vague at first, but within 24 hours usually it shifts and localizes over the RLQ and is exacerbated by walking or coughing. In male patients, the pain may radiate into the testicles; pain (rigidity) also may be associated with abdominal muscle spasm in male or female patients. Most patients complain of nausea and anorexia after the onset of pain, which may or may not be associated with vomiting. If vomiting is present, the patient usually reports that abdominal pain was present before vomiting began. The sensation of constipation is typical, although diarrhea is present in some patients.

A mildly elevated temperature of 99° to 100°F is common. If the patient with RLQ pain presents with shaking chills (rigors), perforation of the appendix should be suspected. An important point to remember is that the very young and older adults may have an atypical presentation, which can mimic other less acute disease processes. For example, older adults with appendicitis may present with weakness, anorexia, abdominal distention, and mild complaints of pain. A delay in the diagnosis in this age-group has led to an associated increase in morbidity and mortality.

Objective

On physical examination, the patient may or may not look sick depending on the degree of pain and other symptoms. The patient may have hypertension and tachycardia proportionate to the degree of fever and pain. When the patient is lying recumbent, he or she may flex up the right knee to relieve the tension on the iliopsoas muscle, which overlies the appendix. Palpation of the abdomen early in the process may reveal diffuse tenderness over the umbilicus and midepigastric areas. As the process progresses, the tenderness localizes over the RLQ and may be accompanied by guarding. *Guarding* is defined as "the voluntary contraction of the abdominal muscles in anticipation of examination," as opposed to *rigidity,* which is caused by "the involuntary

reflexive spasm of the muscles of the abdominal wall." Rebound tenderness is tested by placing the palmar aspect of the hand on the abdomen and pressing hard enough to depress the peritoneum. This may cause the patient pain, but the clinician should keep the abdomen depressed with constant pressure until the patient becomes accustomed to the pressure, and the pain decreases. Then, without warning, the clinician should remove the hand suddenly, preferably when the patient's attention is directed elsewhere. If positive for rebound tenderness, the patient will grimace in pain, which is a more reliable sign than a subjective complaint of pain. Asking the patient to cough helps to localize exactly the site from which the pain is coming. Advanced Assessment 11.1 outlines exam maneuvers that aid in the diagnosis of appendicitis.

A rectal exam can be performed, but it is open to greater subjective interpretation. Patients with appendicitis will normally perceive greater tenderness and fullness on the right than on the left during the rectal exam. The provider must keep in mind that both the bowel and the appendix are mobile organs; they can shift posteriorly or suprapubically, causing altered exam findings. Bowel sounds are a nonspecific finding—they may be present, absent, or decreased in patients with appendicitis.

Other physical exam findings can include alterations in vital signs consistent with increased pain, such as tachycardia or elevated blood pressure. Patients may be reluctant to take a deep breath for fear they will cause themselves pain.

If there is perforation of the appendix, there may be a sudden cessation of the pain, which is considered an emergency. Findings consistent with peritonitis include diffuse abdominal tenderness with rigidity. The patient may exhibit signs of septic shock, with marked leukocytosis, fever, and hemodynamic instability.

Diagnostic Reasoning

Diagnostic Tests

Laboratory findings are not diagnostic and are nonspecific, so they must be used in combination with data from the history and physical exam. The complete blood count usually reveals a mild to moderate leukocytosis (white blood cell count 10–20,000 mcg/L) with a left shift. Urinalysis shows microscopic hematuria or pyuria in 25% of patients. Women should have a urine human chorionic gonadotrophin test completed to rule out (ectopic) pregnancy. The lack of laboratory findings should not preclude the diagnosis of appendicitis.

No radiologic exam is of diagnostic importance early in appendicitis, but x-ray studies become more important as appendicitis progresses. A chest x-ray film rules out pneumonia as a source of abdominal pain and is necessary as part of the preoperative procedure in most hospitals. Plain x-ray films of the abdomen may show evidence of a fecalith, a gas-filled appendix, small bowel ileus, a deviation in the bowel gas pattern, or a loss of the right iliopsoas shadow. Any of these findings is suggestive of appendicitis when combined with a suspect history and physical exam.

A computed tomography scan of the abdomen is helpful in ruling out other diagnostic possibilities, as well as determining if there has been perforation of the appendix or development of a periappendiceal abscess. An abdominal ultrasound helps to visualize the inflamed appendix and is also useful in ruling out other potential diagnoses. Diagnostic laparoscopy may be considered in female patients to rule out ectopic pregnancy, tuboovarian processes, or pelvic inflammatory disease (PID).

Differential Diagnosis

The differential diagnoses of appendicitis include a host of problems, which include, but are not limited to,

Advanced Assessment 11.1 Physical Exam Maneuvers for Diagnosing Appendicitis

Maneuver	Examination	Comments
Rovsing's sign	Deep palpation over the LLQ with sudden, unexpected release of pressure.	This causes tenderness over the RLQ and is considered a positive finding.
Psoas sign	The patient is instructed to try to lift the right leg against gentle pressure applied by the examiner or by placing the patient in the left lateral decubitus position and extending the patient's right leg at the hip.	An increase in pain is considered positive and is an indication of the inflamed appendix irritating the psoas muscle.
Obturator sign	With the right hip and knee flexed, the examiner slowly rotates the right leg internally, which stretches the obturator muscle.	Pain over the RLQ is considered a positive sign and indicates irritation of the muscle by the inflamed appendix.
McBurney's sign	Pressure is applied to McBurney's point, which is located halfway between the umbilicus and the anterior spine of the ilium.	Pain when pressure is applied to this area is considered a positive response.

urinary tract infection, ectopic pregnancy, ovarian cyst, pneumonia, gastroenteritis, Crohn's disease, diverticulitis, mesenteric adenitis, pancreatitis, PID, and cholelithiasis. If the diagnosis of appendicitis remains questionable after the history and physical exam have been completed and initial lab work has been obtained, radiographic studies are helpful in ruling out many of the processes found within the differential diagnoses. For women of childbearing age, the clinician should always obtain a pregnancy test before ordering any radiographic studies. In some cases, laparotomy or laparoscopy may be required to assist in definitive diagnosis.

Careful attention must be given to the sexual and menstrual history of all female patients because of the myriad of potential gynecological problems that present with the same signs and symptoms as appendicitis. A pelvic exam and a diagnostic laparotomy are often necessary for differential diagnosis.

Many GI disorders have symptoms that mimic those of appendicitis, and watchful waiting may be indicated in some cases. If appendicitis is at all a suspicion, however, the prudent practitioner will follow these patients closely until a diagnosis has been reached.

Management

The treatment of appendicitis is surgical; therefore, once a definitive diagnosis is made, prompt referral to a surgeon should follow. From 9% to 15% of appendectomies between 1998 and 2007 were considered unnecessary, or negative. This number is considered acceptable because of the morbidity and mortality associated with perforation. The incidence of appendiceal perforation ranges from 17% to 40% in patients with appendicitis; it is as high as 60% to 70% in older adults. With effective and timely treatment, the mortality rate is less than 1%; however, in the older adult population, mortality remains at 5% to 15%.

Preoperative management includes correction of fluid and electrolyte imbalances; bedrest; nothing by mouth, with placement of a nasogastric tube if indicated; and IV antibiotics. Narcotics should be avoided if possible because they mask any developing symptoms that might indicate a complication such as perforation. Laxatives are contraindicated in patients with appendicitis because they may cause the appendix to rupture. Stool softeners may be given if the patient is complaining about constipation and diarrhea is not present.

Third generation cephalosporins are the antibiotics of choice. If there has been perforation and peritonitis is suspected, antibiotic coverage for both gram-negative aerobic and anaerobic organisms is recommended. Some of the choices include ampicillin, gentamicin, clindamycin, metronidazole (Flagyl), ampicillin-sulbactam (Unasyn), and ticarcillin/clavulanate (Timentin).

Patients are normally discharged the same day as surgery unless there are complications. Early ambulation is encouraged, with progression to full activity as soon as possible. Diet is advanced when bowel sounds return. The patient is given standard postoperative guidelines for individuals who have had abdominal surgery.

Follow-up and Referral

The patient is normally followed by the surgeon, who will see the patient 5 to 7 days postoperatively to remove the sutures. If there was perforation of the appendix and the patient must remain hospitalized, the surgeon will follow the patient until discharge.

Patient Education

The patient will be given standard postoperative instructions from the surgeon, which should include advice to return to the hospital if anorexia, nausea, vomiting, abdominal pain, fever, or chills develop. Patients should understand that they are not to do any heavy lifting for at least 2 weeks.

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) is the term used to describe a chronic immunological disease that manifests in intestinal inflammation. The two most common IBDs are ulcerative colitis (UC) and Crohn's disease (CD). The disease is characterized by exacerbations and remissions that are experienced throughout an individual's lifetime and therefore result in significant disruption in the quality of life. The Patient's Voice 11.1 describes the impact of Crohn's disease on a 39-year-old woman with a 20-year history of the disease.

The Patient's Voice 11.1

Crohn's Disease

As a 39-year-old woman with a 20-year history of severe Crohn's disease (CD), I remain undecided as to which has been most difficult to deal with: the symptoms of the disease—uncontrolled diarrhea, bowel incontinence, malnutrition, pain, bloating, and flatulence, to name a few; the results of the symptoms—fatigue, malaise, anemia, anorexia, anxiety, embarrassment, guilt, fear, and shame; or the constant discipline necessary to incorporate lifestyle changes instrumental to the adaptation and management of this debilitating disorder—diet, stress elimination, exercise, rest, vitamin supplementation, and prescription compliance. Experience with CD has taught me that health and wellness is a personal choice and that whatever intestinal ailments or conditions one struggles with, incorporating the dietary changes necessary to promote wellness through nutrition, particularly raw, fresh fruit and vegetable juices, should be part of a comprehensive approach to achieving optimal health.

UC and CD are both IBDs that share similar characteristics and causes but are considered two separate diseases. UC involves only the mucosal surface of the colon, which ultimately results in friability, erosions,

and bleeding. It occurs most often in the rectosigmoid area but can involve the entire colon. CD is also known as regional enteritis because of the characteristic segmental presentation of the diseased bowel, which is clearly separated by areas of normal mucosa, often referred to as "skipped lesions." CD can involve all or any layer of the bowel wall and any portion of the gastrointestinal (GI) tract from the mouth to the anus. Disease of the terminal ileus is present in about 80% of patients with CD, and in 20% of the cases only the colon is involved.

The peak age of onset is 15 to 30 years old, although it may occur at any age. UC is more common in males, and CD is more common in females. It is estimated that as many as 1.4 million people in the United States suffer from these diseases.

Epidemiology and Causes

The incidence and prevalence of these diseases vary widely, which supports a multifactorial theory in the development of the disease. Research supports a genetic predisposition for IBD, even though less than 15% of cases are familial. A gene on chromosome 16 that encodes the protein nucleotide-binding oligomerization domain 2 *(NOD2)* has variants that are found in about 62% of patients with CD. Genes associated with IBD have also been found on chromosomes 10 and 7 that encode for proteins that mediate epithelial cell–cell interactions and the transport of molecules into and out of cells. Another factor is the ability of bacteria in the gut to cause inflammation. Researchers believe that there is an exaggerated cell-mediated immune response to the bacteria. The intestinal epithelium plays an important role in the immune response, interacting with microbes and antigens and communicating with immune cells triggering the production and secretion of cytokines and chemokines.

The incidence of IBD is about equal in men and women. The highest prevalence for the disease is in Scandinavian and Northern European countries. The overall incidence and prevalence for both of these diseases is about equal worldwide, with incidence rates between 3 and 10 per 100,000 and a prevalence rate between 30 and 50 per 100,000. The age at onset is frequently in early adulthood but can be anywhere from age 10 to 40. Table 11.15 compares UC and CD.

Pathophysiology

Ulcerative Colitis

The inflammatory process of UC is confined to the mucosa of the colon and rectum and begins with neutrophil infiltration at the base of the crypt of Lieberkühn. The

Table 11.15 Comparison of Ulcerative Colitis and Crohn's Disease

Feature	Ulcerative Colitis	Crohn's Disease
History		
Age at onset	Age 10–40	Age 15–25; age 50–80
Etiology	Unknown	Unknown
Genetic tendency	Familial tendency	Familial tendency
Nicotine use	Nonsmoker	Smoker
Assessment Findings		
Serological	+ (positive) for antineutrophil cytoplasmic antibodies (pANCA)	– pANCA
Fever/malaise	With severe disease	Common
Weight loss	Uncommon	Common
Rectal bleeding	Common	Dependent on location of lesion; occurs in about 50% of cases
Abdominal pain	Usually mild	Can be moderate to severe
Abdominal mass	Negative	May be present
Perianal lesions	Absent	May develop fissures, abscesses
Fistulas	Absent	Common
Strictures	Uncommon	Common
Common		
Rectal involvement	Always	50% of the cases
Distribution	Confined to colon; continuous	Any portion of GI tract; discontinuous, skipped lesions
Mucosa	Friable, granular	Cobblestone appearance
Ulceration	Crypt abscess development	Aphthous or linear ulcers
Inflammation	Surface involvement	Transmural involvement

disease most often occurs in the rectum and sigmoid colon. The mucosa in this area is thinner and has a dark red and velvety appearance in susceptible individuals. The cytokines released from the macrophages and neutrophils during the inflammatory response are responsible for tissue damage. Ulcers form in the eroded tissue, and abscesses form in the crypts. These abscesses become necrotic and ulcerate. The muscularis mucosa becomes edematous and thickened, narrowing the lumen of the colon. Bleeding, cramping pain, and the urge to defecate result from the mucosal destruction. The characteristic stool is diarrhea that contains blood and purulent mucus. There is also a loss of the absorptive surface leading to large volumes of watery diarrhea. Fecal leukocytes are always present with active colitis. Absence of these inflammatory changes within the deeper layers of the intestinal mucosa helps to differentiate UC from other inflammatory processes. Patients diagnosed with severe UC are at risk for a perforated colon. They require close observation and should have consultation with a surgeon.

Crohn's Disease

CD is an inflammatory process that begins in the submucosa of the intestine and gradually spreads to involve the mucosa and serosa. Any portion of the GI tract can be affected, but 80% of patients have small bowel involvement. There are abnormalities in the intestinal immune response where proinflammatory cytokines, interleukins, and tissue necrosis factor produce areas of tissue damage. Typically, some haustral segments are affected while others are not, creating a pattern called skip lesions. The ulcerations form longitudinal and transverse fissures, extending inflammation into Peyer's patches and the lymphoid tissue. The typical lesion is granulomatous with projections of inflamed tissue that is surrounded by scar tissue. It is described as a "cobblestone" appearance. With progression of the disease, fibrosis thickens the bowel wall, narrowing the lumen. Serosal inflammation causes bowel loops to adhere to one another, contributing to transmural inflammation, ulceration, and fibrosis, which can lead to obstruction, fistulas, and shortening of the bowel.

Individuals with IBD are at greater risk for developing colorectal cancer than the general population. Clinical findings suggest that carcinoma is less common in patients with CD than with UC and is attributed to the treatment of CD with colectomy.

Clinical Presentation

Subjective

Individuals with mild forms of UC commonly report four or fewer loose bowel movements per day associated with abdominal cramps that are relieved with defecation, small amounts of blood and mucus in the stool, and sometimes tenesmus. Usually there are no associated systemic symptoms. With moderate disease, patients have four to six loose stools a day containing more blood and mucus. They also have systemic symptoms such as tachycardia, mild fever, and weight loss and may have mild edema depending on the serum albumin level. Severe disease manifests with more frequent bloody bowel movements (6–10) per day; abdominal pain and tenderness; and symptoms of anemia, hypovolemia, and impaired nutrition.

The most common presenting symptoms of CD are abdominal cramping and tenderness, fever, anorexia, weight loss, spasm, flatulence, and right lower quadrant (RLQ) pain or mass. Individuals may report an increase in symptomatology during periods of stress or emotional upset or after meals consisting of poorly tolerated foods such as fatty or spicy foods or milk. Stools are soft or semiliquid. Observable blood is found in the stool intermittently; when present, it occurs in a larger amount than with UC. Because of the loss of healthy bowel mucosa, there may be insufficient resorption of bile salts, causing steatorrhea (foul-smelling, fatty stools). CD can involve the entire thickness of the bowel wall, causing microperforations and symptoms of acute localized peritonitis, which can mimic appendicitis or diverticulitis. If there is fistula formation, these symptoms may dominate the clinical picture.

Several patterns of symptom onset have been manifested—gradual, with vague abdominal discomfort, malaise, cramping, and bloody, mucopurulent stools; abrupt, with frequent periods of bloody diarrhea, anorexia, fever, and weight loss; and abrupt and fulminating, with sudden, violent diarrhea occurring nocturnally, high fever, intense abdominal cramping, signs of peritonitis, weight loss, and anorexia. Stools may contain blood, mucus, and/or pus. Typically, CD has a more insidious and gradual onset. Individuals often experience intermittent symptoms long before presenting for medical attention. The disease is characterized by periods of acute exacerbation alternating with complete remission.

If the UC is confined to the rectal or sigmoid area, the stools can be normal or hard and dry; however, the rectum will continue to dispel mucus containing both red and white blood cells. As the disease process moves proximally, the stools become looser. Patients may report eating less to decrease the frequency of bowel movements, which leads to more pronounced nutritional deficiencies.

Objective

On physical exam, there may be tenderness in the left lower quadrant or across the entire abdomen, often accompanied by guarding and abdominal distention. A digital rectal exam should be performed to assess for anal and perianal inflammation, rectal tenderness, and blood in the stool. Depending on the severity of the

disease and the extent of potential complications, signs and symptoms of ileus and peritonitis may be found. Perirectal abscesses and fistulas are not associated with UC.

The physical exam may reveal abdominal tenderness with a tubular, tender mass in the RLQ. Fifty percent of individuals with CD have perianal involvement, including anal fissures, perianal fissures, and edematous, pale skin tags, which are often misdiagnosed as prolapsed hemorrhoids. Extraintestinal findings include episcleritis, erythema nodosum, nondeforming peripheral arthritis, and axial arthropathy, which may be more apparent than bowel symptoms and should prompt the practitioner to look for a diagnosis of CD.

CD tends to present in one of four patterns: (1) inflammation, RLQ abdominal pain, and tenderness, often presenting as appendicitis; (2) obstruction, fibrosis, and stenotic changes within the bowel, causing recurrent obstruction associated with severe colic, abdominal distention, constipation, and vomiting; (3) diffuse jejunoileitis involving the jejunum and ileum and characterized by both inflammation and obstruction, which can result in malnutrition and chronic debility; and (4) abdominal fistulas and abscesses, normally occurring late in the disease process and causing fever, generalized wasting, and abdominal masses. Although CD is uncommon among children, those with CD often present with extraintestinal symptoms, especially growth retardation, fever of unknown origin, and anemia.

Diagnostic Reasoning

Diagnostic Tests

Definitive diagnosis is made by correlating the symptoms with the history and physical exam. The results of diagnostic testing help to differentiate UC from CD. Stool analysis and cultures are obtained to rule out bacterial, fungal, or parasitic infection as the cause for diarrhea. The stool is also examined for mucus and blood, which are normally present with UC.

Patients with CD who have small intestine involvement may also require evaluation for malabsorption, which manifests as anemia secondary to bleeding and iron deficiency; for macrocytic anemia from inflammation of the terminal ileum and poor absorption of folate; and for hypocalcemia and vitamin D deficiency, hypoalbuminemia, and steatorrhea resulting from bile salt deficiency. Liver function tests may be helpful in screening for primary sclerosing cholangitis and other liver problems associated with IBD. Fluid and electrolyte disturbances are common in both diseases because of the extracellular fluid loss. CD may also present with an elevated white blood cell count and sedimentation rate, as well as a prolonged prothrombin time.

Imaging studies are necessary to confirm the diagnosis of IBD. Contrast radiography and endoscopy are the primary diagnostic tools. The diagnosis of UC should be supported with sigmoidoscopy, which defines the actual extent of the mucosal inflammation. Early in the disease, the mucous membrane is granular, friable, and edematous, with loss of the normal vascular pattern. In many patients, there may be scattered areas of hemorrhage that bleed with minor trauma. The resulting ulcerations develop after the mucosa breaks down, leaving the mucous membranes dotted with numerous bleeding and pus-oozing ulcers. Severe disease is characterized by copious amounts of purulent exudate. Colonoscopy should be avoided in individuals with severe colitis or deep ulcerations because of the risk of perforation or the development of toxic megacolon. Although there are periods of remission, sigmoidoscopy always shows some degree of friability and granulation in patients with UC. Biopsy results reveal chronic inflammation.

Plain films of the abdomen can help estimate the severity and proximal extent of the disease by demonstrating loss of haustration and the absence of formed stool within the diseased sections of bowel.

Every patient with UC requires a colonoscopy to determine the extent of the disease, but in order to avoid perforation, this is normally reserved for patients who have already begun treatment. Colonoscopy is preferred over barium enema (BE) because the former allows direct assessment of the colon and permits histological examination through biopsy. Ulcers suggestive of UC are shallow and confluent; they are erythematous, edematous, and friable, causing them to bleed easily. Individuals with UC usually have disease that begins in the rectum and extends proximally, without "skipped areas." Although BE is informative, it is contraindicated in individuals with moderate or severe disease because it can precipitate toxic megacolon.

Definitive diagnosis of CD is normally made via x-ray studies. The earliest manifestations of CD are aphthous and linear ulcers, which are best visualized with air contrast BE or small bowel follow-through, depending on the location of the lesions. BE may show reflux of barium into the terminal ileum. The ileum is stiff and nodular, and the lumen shows signs of thickening and narrowing. In advanced disease, the upper GI tract with small bowel follow-through may show the characteristic "string sign"—ileal strictures and evidence of bowel loop separation resulting from marked circumferential inflammation and fibrosis.

Colonoscopy reveals ulcers that are either minor erosions or deep longitudinal fissures. Segmental transverse fissuring creates the characteristic cobblestone appearance and is usually found above the rectum and rectosigmoid areas. Biopsies may be obtained to rule out pseudopolyposis, adenomatosis, or cancer. Computed tomography (CT) is often used in the evaluation of CD to identify bowel wall thickening or abscess formation.

If an abscess is found, CT may be useful for guided drainage of the abscess.

Differential Diagnosis

Differential diagnosis of UC must begin with the exclusion of an infectious cause for the colitis before treatment is initiated. Enteric infection is ruled out through fresh stool culture for ova and parasites. Infectious colitis caused by *Entamoeba histolytica, Campylobacter enteritidis,* and *Shigella* species and *Chlamydia* species can cause acute colitis, which is difficult to differentiate from UC both clinically and endoscopically. The distinction must be made because treatment with corticosteroids can be catastrophic. Obtaining a thorough travel, sexual, and antibiotic history is imperative. If the individual has had antibiotic exposure within the last 30 days, a stool sample to test for *Clostridium difficile* should be obtained. Homosexual men practicing anal intercourse should be screened for infectious proctitis as a cause of colitis. Individuals with HIV are susceptible to many opportunistic infections, which must also be considered as part of the differential diagnosis and treatment.

Older adults, patients with a history of coagulation disorders, and young women using oral contraceptives should be examined for ischemic colitis. Radiographic findings of "thumbprinting" and segmental distribution of lesions are typical of ischemic colitis. Although colon cancer rarely presents with fever and purulent diarrhea, it should be ruled out as a cause for bloody diarrhea.

As with UC, evaluation of CD must begin with ruling out infectious enteritis as the source of colitis. Enteric tuberculosis and fungal disease must also be considered in the differential diagnosis of CD. *Yersinia enterocolitica* enteritis, although a self-limiting infection, may require a 3-month follow-up examination because the initial clinical presentation is so similar to that of CD.

Although only 20% of patients with CD have disease that is limited to the colon, differentiation from UC must be made. CD is the more likely diagnosis when there is evidence of perianal disease and rectal bleeding. RLQ pain without a history of chronic bowel symptomatology may mimic appendicitis, pelvic inflammatory disease, ectopic pregnancy, ovarian cysts, or tumors; all of these must be ruled out in the differential diagnosis of CD. Both diverticular disease and ischemic colitis can present with the segmental involvement and luminal stricturing characteristic of CD.

Many drugs have been implicated in drug-induced colitis, the most common being NSAIDs and antibiotics. Many individuals who routinely take NSAIDs suffer damage to the GI tract characterized by bloody diarrhea and weight loss. Some antibiotics alter the bowel flora, allowing overgrowth of pathogens such as *C difficile,* which produces a toxin that is damaging to the bowel mucosa and can cause bloody diarrhea, abdominal pain, and weight loss. Although initial radiographic studies may be similar to those for CD, endoscopic examination reveals a more segmental distribution of lesions, and biopsy results are not supportive of inflammatory disease.

Colon cancers can cause bloody diarrhea; however, they usually do not have the associated fevers, leukocytosis, and purulent discharge. Diverticulitis can cause abdominal pain, fever, leukocytosis, obstruction, and diarrhea; however, endoscopic evaluation reveals the characteristic mucosal herniations in the bowel wall.

Management

There is no cure or definitive treatment for IBD. The initial therapy should depend on the severity of the presenting symptoms and must be individualized. Medical therapy is directed at reducing inflammation, correcting or maintaining fluid and electrolyte balance, and relieving the signs and symptoms of the disease.

Ulcerative Colitis

Initial treatment of UC includes nutrition counseling. Patients should avoid caffeine, raw fruits, vegetables, and other foods high in fiber, which can cause trauma to the already inflamed mucosal surface. Some patients may benefit from a lactose-free diet, but that is not recommended unless a trial produces symptomatic relief. A bland diet that is high in calories and protein yet low in fat can help to control diarrhea and flatulence and maintain nutrition and weight. Parenteral nutrition may be necessary in individuals with severe anorexia or uncontrollable diarrhea.

Antidiarrheal medications should be avoided in the acute phase but can be helpful for patients with mild symptoms. Patients with mild to moderate diarrhea may benefit from diphenoxylate with atropine (Lomotil) 2.5 to 5.0 mg by mouth twice daily up to four times per day, loperamide (Imodium) 2 mg after each bowel movement, or codeine 15 to 30 mg by mouth every 4 to 6 hours.

Disease that is limited to the rectosigmoid area can often be successfully treated with topical steroids or mesalamine (Drugs Commonly Prescribed 11.5). Steroid enemas and foams (e.g., hydrocortisone [Cortifoam] 100 mg) should be administered nightly for 2 weeks. If effective, this treatment will bring about remission in 70% of initial episodes of idiopathic UC. Patients may then taper the dose over the next week to prevent the side effects associated with rapid steroid withdrawal. Mesalamine (Rowasa), a form of 5-aminosalicylate (5-ASA), is more expensive; it is sometimes more effective than hydrocortisone for patients with refractory or left-sided colitis and is available in enema and suppository forms. Oral preparations of 5-ASA medications (e.g., Asacol) help to maintain remission after the enemas have been discontinued. 5-ASA preparations lack the sulfapyridine moiety (a by-product of the metabolism of sulfasalazine and responsible for most of the drug's toxicity), have

Drugs Commonly Prescribed 11.5 Inflammatory Bowel Disease

Drug	Indication	Adverse Reactions and Prescribing Considerations
5-Aminosalicylic acid agents mesalamine (Asacol)	None	Research indicated that these drugs are of little value in Crohn's disease. Continue to be used for ulcerative colitis.
Antidiarrheals loperamide (Imodium) diphenoxlate with atropine (Lomotil)	Diarrhea	Do not use in acute ulcerative colitis. Constipation may occur. Do not use if toxic megacolon occurs.
Corticosteroids prednisone budesonide (Entocort)	Moderate to severe disease	Drastically suppresses clinical symptoms. This preparation is ileal released and induces remission in 50%–70% of cases of Crohn's disease. Treatment is for 8–16 weeks followed by a 2–4 week taper in 3-mg increments.
Immunomodulating Drugs azathioprine mercaptopurine methotrexate	Moderate to severe disease that does not respond to corticosteroid therapy	This class of drugs can cause bone marrow suppression, and patients are at risk for life-threatening infections.
Anti-TNF therapies infliximab adalmumab certolizumub	Moderate to severe disease	This class of drugs causes bone marrow suppression and increase the risk for life-threatening infections.

fewer adverse effects, and are better tolerated for prolonged courses of treatment. Subsequent exacerbations of UC tend to show increasing resistance to therapy, requiring longer treatment regimens.

More advanced disease usually requires the addition of a systemic glucocorticoid in combination with sulfasalazine or 5-ASA therapy. Glucocorticoids are especially helpful in controlling the extracolonic manifestations of UC, which include peripheral arthritis, ankylosing spondylitis, erythema nodosum, anterior uveitis, and pyoderma gangrenosum. Peripheral arthritis and the skin lesions often parallel the course of the disease. Oral prednisone (Prelone), up to 40 to 60 mg in single or divided doses, must be tapered and not discontinued abruptly.

Severe or fulminant UC is manifested by 10 or more bloody stools per day, abdominal tenderness, fever, colon dilation, and tachycardia. Patients often require hospitalization for these symptoms. Patients with severe disease must be monitored closely for the development of toxic megacolon and colonic perforation. Any patient who does not show improvement after 7 to 10 days of maximized therapy should be considered for surgical intervention. Subtotal or total colectomy is often required to prevent perforation of the bowel and its complications. Some individuals may require restoration of their fluid volume and electrolytes, as well as blood transfusions, depending on the severity of the diarrhea and bleeding.

Immunosuppressive agents—azathioprine (Imuran), cyclosporine, and metabolite 6-mercaptopurine (6MP)—are used in cases of UC that are unresponsive to other medical treatment and in patients who are not surgical candidates. The long-term use of immunosuppressive agents for relapse prevention must be balanced with the increased risk of developing a malignancy. Most commonly, these agents are used to allow patients to reduce the maintenance dosage of glucocorticoids. For disease that is unresponsive to other therapies, anti–tumor necrosis factor (anti-TNF) agents can be used. These include infliximab (Remicade) 5 mg/kg and adalimumab (Humira) administered subcutaneously 160 mg at week 1, 80 mg at week 2, and then maintenance of 40 mg every other week beginning at week 4.

Individuals who progress to fulminant disease are at risk for developing toxic megacolon—an atonic and distended, thin-walled colon. Approximately 1% to 2% of patients with UC develop this complication, which is characterized by fever, sepsis, electrolyte imbalances, hypoalbuminemia, and dehydration. Definitive diagnosis is made when radiographic measurement of the midtransverse colon shows it to be dilated to greater than 6 cm. The patient is at risk for perforation until the dilation is reduced. If medical reversal is not accomplished within 48 hours, surgical intervention is indicated and consultation should be made early.

Patients with toxic megacolon should receive nothing by mouth, a nasogastric tube should be placed for intermittent suction, and all antidiarrheal medications should be discontinued. Fluid and electrolyte disturbances, particularly hypokalemia, should be corrected, and total parenteral nutrition may be required until the patient is

able to tolerate oral food and fluids. Broad-spectrum antibiotics for peritonitis prophylaxis and parenteral administration of glucocorticoids are indicated. Patients must be monitored closely for signs and symptoms of perforation, which may be blunted because of the large doses of glucocorticoids. Loss of hepatic dullness on percussion may be the first sign of perforation. Daily abdominal x-ray films are necessary to assess colon distention and the presence of free air within the abdomen.

Over the long term, 25% of those with UC will require surgery. Emergent total colectomy is indicated for patients who do not respond to intensive medical therapy within 48 hours or who have massive hemorrhage or perforation. Surgical intervention is sometimes done in stages for patients who are severely ill. The most common procedure is the proctocolectomy with a Brooke ileostomy; it is a curative and functional procedure. Surgical intervention is also considered in patients who require large maintenance doses of glucocorticoids, are experiencing quality of life issues caused by severe diarrhea, or in children who are manifesting signs of growth retardation.

Crohn's Disease

Treatment of CD parallels that of UC including sulfasalazine (Azulfidine); however, 5-ASA medications have not been shown through research to be of any benefit. Glucocorticoids are used when initial treatment fails and for patients with moderate to severe disease. There is no curative therapy for CD; therefore, treatment is aimed at suppressing the inflammatory process and symptomatic relief of complications. The patient with CD has a much greater incidence of relapse once medications are discontinued; 70% of patients started on steroid therapy must remain on the therapy to prevent relapse. Oral prednisone 40 to 60 mg/day is used as initial outpatient treatment. Once maximal response has been achieved, the dose can be tapered over 2 to 4 months. Some patients may require a daily maintenance dose of 5 to 10 mg/day. As with UC, steroids are often helpful in managing the extraintestinal manifestations of the disease. Patients with disease within the rectum may benefit from enema preparations as well.

Sulfasalazine (Azulfidine) remains a common treatment for CD; however, new research is showing that it may have little value. There is a high incidence of intolerance, including nausea, anorexia, rash, and headache. When it is used, the initial dose of sulfasalazine for treatment of mild to moderate disease of the colon or ileocolon is 500 mg twice daily; the dose can be increased to 3 to 4 g/day. Clinical improvement is usually noted in 3 to 4 weeks, at which time the medication can be tapered to 2 to 3 g/day for 3 to 6 months. Sulfasalazine interferes with folic acid absorption, so patients should receive folic acid 1 mg/day while taking this medication.

The use of metronidazole has been effective in patients who are intolerant of sulfasalazine, although metronidazole's use is also limited by adverse effects, including nausea, anorexia, metallic taste, furry tongue, and paresthesias. Although the mechanism of action is not clear, metronidazole has been effective in the treatment of perianal disease and in controlling Crohn's colitis. There is a high rate of relapse, however, once the drug has been discontinued. Other antibiotics such as ciprofloxacin, ampicillin, and tetracycline have been effective in controlling Crohn's ileitis and ileocolitis.

The use of immunosuppressive medications has been shown to be effective in patients with CD that is unresponsive to other treatments, in individuals dependent on high-dose steroids, or in those with nonhealing fistulas. The clinical benefit of 6MP (the active metabolite of azathioprine [Imuran]) can take up to 3 months before being realized. These drugs can cause bone marrow suppression and pancreatitis; therefore, patients must be monitored frequently for leukopenia. The risk for developing malignancy is low but still must be considered. Patients remain on treatment for up to 2 years; in extremely refractory cases, treatment is continued indefinitely. Cyclosporine (Neoral, Sandimmune), an immunosuppressant drug typically used to prevent organ transplant rejection, is helpful in patients with steroid-resistant CD. Its use remains experimental, and it should be administered by practitioners who are experienced in caring for patients with complicated CD.

Other immunomodulating agents called TNF-α blockers such as infliximab (Remicade), adalimumab (Humira), and certolizumab are proving helpful in patients with moderate to severe CD. Rapid improvement is seen when infliximab is used initially. The regimen includes an initial dose of infliximab 5 mg/kg followed by repeat doses again at 2 weeks and 6 weeks, with maximal response seen in the first 2 weeks. Adalimumab (Humira) by subcutaneous injection is prescribed at 160 mg at week 1, 80 mg at week 2, and then maintenance of 40 mg every other week beginning at week 4. The side effects include infusion-related reactions and hypersensitivity reactions as a result of the development of antinuclear antibodies. This can be reduced by concomitant administration of other immunosuppressive medications. Serious infections may develop while patients are being treated with this medication.

Surgical intervention for CD is normally not indicated except for complications including intestinal obstruction, fistulas and abscess drainage, or perforation. Over the long term, up to 75% of patients with CD will require surgery. Patients with fistula formation (which may be enterocutaneous, enterovaginal, or enterovesicular) should be managed with bowel rest, parenteral nutrition, and antibiotic therapy before surgery is considered. Surgery is not curative and must be reserved for complications that are resistant to medical therapy. Intestinal obstruction caused by stricture formation is often successfully treated with strictureplasty, thus avoiding multiple colon resections and the

risk of short bowel syndrome. Patients with symptoms of obstruction should avoid foods that contain nuts or seeds.

As with UC, the use of anticholinergic and antidiarrheal medications should be avoided in patients with severe disease because the drugs may precipitate toxic megacolon or ileus. Loperamide (Imodium), diphenoxylate (Lomotil), and codeine may be helpful in controlling chronic diarrhea in patients with mild Crohn's colitis.

Follow-up and Referral

UC and CD are both complex illnesses with periods of exacerbation and remission requiring lifelong intervention and follow-up. Adjustment of therapy is based on symptom analysis and examination. Confirmation of the diagnosis and uncontrolled exacerbations should be referred to the physician. Referral to a gastroenterologist is often necessary for endoscopic evaluation and tissue biopsy. Long-term use of steroids and immunosuppressive drugs dictates ongoing patient follow-up. Repeat evaluation may be indicated if symptoms of a major complication have developed. Routine colonoscopy for colon cancer surveillance is necessary in any patient with long-standing disease. Stool analysis for occult blood is not an effective means of surveillance. Individuals whose disease is not controlled with established medical therapy of low-dose prednisone should be referred to a gastroenterologist who is knowledgeable in the treatment of these chronic disease processes.

Patient Education

All patients need to be informed about the disease process, the treatment options, and the expected outcome of the treatment regimens. Patients must be a part of the treatment plan and must have the knowledge necessary to make informed decisions. Education about the disease, diagnostic and laboratory tests, and diet and lifestyle changes should be included in the education. Open, honest information is important in helping patients to develop realistic expectations with regard to treatment and outcomes.

The importance of adequate rest and stress reduction in an attempt to decrease bowel motility and promote healing is essential. Stress management techniques, such as guided imagery, should be taught, and patients can be referred for counseling if necessary. Patients should be provided with the information and addresses for national organizations such as the Crohn's and Colitis Foundation of America that have up-to-date information and local support groups.

Dietary concerns for patients with CD include a low-residue diet when obstructive symptoms are present. Patients on a low-residue diet should avoid all foods high in fiber, including whole grain breads and cereals, all fresh fruits and vegetables, and seeds and nuts. Patients are allowed to have canned fruits and vegetables and should have only white breads. If the patient is unresponsive to medical treatment or is exhibiting signs of growth retardation, oral elemental or parenteral nutrition may be necessary. Patients who are intolerant of lactose should be taught to avoid dairy foods. When patients are not in the middle of an acute attack, they can eat whatever they can tolerate.

Dietary instruction for patients with UC is the same as that for CD. If they are not having symptoms of an acute attack, patients may eat whatever they can tolerate. During an acute exacerbation, parenteral nutrition or oral supplementation for malnutrition may be necessary. Some patients will ask questions about the use of diet as a treatment. Studies to date show that diet is ineffective as a treatment or therapy for UC. Foods that can cause diarrhea and gas-producing foods should be avoided during acute attacks.

Female patients with IBD require special guidance and counseling before they attempt pregnancy. If pregnancy does occur, the patient must be followed closely by a gastroenterologist throughout her pregnancy.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is a functional gastrointestinal (GI) disorder that is characterized by abdominal pain or discomfort. To be considered IBS, two of these features must be present: abdominal pain or discomfort that is relieved by defecation; change in frequency in stool; and a change in the appearance of the stool. Patients usually have other symptoms such as frequent stools (more than three per day) or fewer stools (less than three per week), passing mucus, feelings of straining, urgency or incomplete evacuation, flatulence, and abdominal distention. IBS is a common GI problem encountered in primary care. When patients present for medical attention, they have usually had the complex of symptoms for several weeks to several months.

Epidemiology

Traditionally, women have been affected more often than were men, at a rate of 3:1. Recent epidemiological studies, however, suggest that men and women are affected equally, but that men are underdiagnosed based on the current IBS diagnostic criteria. It is estimated that 9% to 20% of the general population is affected by symptoms that can be classified within the diagnosis of IBS, but fewer than one-third of those individuals seek medical attention. Typically, the symptoms first present in late adolescence and early adulthood but rarely in patients older than age 50.

Pathophysiology

The exact cause of IBS is unknown. IBS was once considered to have no organic cause, but several mechanisms have been identified. Normal bowel function is regulated by segmental contractions that limit the movement of bowel contents through the colon. An increase in these

contractions causes constipation, and a decrease in the contractions results in frequent stooling or diarrhea. Myoelectric studies of colonic movement in individuals with IBS were inconclusive for diagnostic criteria, but the studies did demonstrate patterns of hypermotility, including high-amplitude pressure waves in patients, with pain as the predominant symptom during an acute IBS attack. Likewise, patients with diarrhea-predominant IBS had decreased and lower-amplitude pressure waves. Studies have confirmed alterations in colonic activity during periods of emotional stress, in which motility is decreased or inhibited with depression and increased with feelings of hostility and anger.

Another major investigative focus of IBS has centered on visceral hypersensitivity. Approximately 50% of the patients with IBS have perceptual abnormalities including heightened gut sensitivity, leading to a lower tolerance for abdominal pain and distention of the colon with gas and feces. Studies in which the rectums of IBS patients were distended by balloon dilation resulted in spastic contractions, leading to the characteristic symptoms seen with IBS. Patients with IBS are acutely aware of the intraluminal activities occurring with the digestive process. Sensations range from mild discomfort and tugging to frank pain. In summary, IBS patients do show evidence of abnormal colonic smooth muscle activity; however, the level at which the lesion originates is yet unknown.

Up to one-third of patients with IBS develop the disorder after bacterial gastroenteritis. It appears that patients with increased life stressors are more prone to developing IBS postinfection. Although the importance is unknown at this time, increased inflammatory cells have been found in all layers of the bowel in some patients with IBS.

The correlation between the symptoms of IBS and food intolerance is high. Careful diet history is necessary to distinguish between the two. The most common dietary triggers are lactose, fructose, sorbitol, and glutens. There is also a correlation between depression, anxiety, and somatization in patients who seek medical attention for their IBS symptoms.

Clinical Presentation

Subjective

Individuals with IBS typically present with symptoms that fall into two broad categories—those with abdominal pain and altered bowel habits, consisting of both diarrhea and constipation, and those with painless diarrhea.

Most patients with abdominal pain describe their pain as originating over some area of the colon, with the left lower quadrant (LLQ) being most often affected. The pain can be sharp and burning with cramping or a diffuse, dull ache. The description of the pain usually remains constant for the individual but can vary greatly among the patient population. Pain is often precipitated by eating or stress and can be relieved with a bowel movement or passing of flatus. The pain associated with IBS is usually not significant enough to interfere with sleeping, nor is it great enough to wake the patient from sleep.

More than 50% of patients with IBS describe an overly acute sensory ability with regard to the GI tract and the digestive process. This visceral hypersensitivity is manifested by frequent complaints of abdominal distention, gas, and belching. Many of these symptoms occur 2 hours after having a meal and are often thought to be food intolerances. Patients typically complain of urgency to defecate, abdominal pain, bloating, and gas. Some patients with IBS have upper GI complaints, including dyspepsia, pyrosis, nausea, and vomiting.

Patients who present with painless diarrhea usually report an urgent need to defecate immediately on awakening or after eating. Although diarrhea rarely occurs nocturnally, urgency is so great that it may cause incontinence.

Alteration in bowel habits is the most consistently reported symptom. The typical presentation is diarrhea alternating with constipation. Patients report that constipation that was once responsive to laxatives has become continuous and that the stool has become harder and is decreased in caliber. Many patients complain of a sense of incomplete evacuation and thus repeated attempts at defecation are necessary within a short period of time. Periods of predominant constipation can last for months, interrupted by periods of diarrhea and then back to constipation. Patients who have diarrhea as their predominant symptom complain of frequent, low-volume (less than 200 mL), loose stools. Diarrhea does not normally occur at night; however, it can be exacerbated by eating or stress. Many patients report the passage of large volumes of mucus within the stool. This differs from the mucus occurring with colitis because there is no associated inflammatory process nor is there any blood in the stool, other than if there is an incidental finding of hemorrhoids.

Patients diagnosed with IBS frequently have an associated psychiatric diagnosis, which presents in the form of anxiety, depression, and somatoform disorders. IBS symptoms are often precipitated by a recent stressful life event such as marital discord, death, or abuse.

Objective

As with any illness, a thorough and detailed patient history is the key to definitive diagnosis. The physical exam is usually normal except for tenderness in some area of the colon, most often the LLQ and over the umbilicus or epigastric area in those with small bowel involvement. Digital rectal exam is normal but may reveal tenderness and exacerbate symptoms in some individuals.

There is usually no associated weight loss or deterioration in health. History of psychosocial stressors can

often be correlated with the onset of symptoms. Key to diagnosis is the lack of other systemic symptoms such as fever, leukocytosis, or bloody stools, which might suggest an organic cause for symptoms.

Diagnostic Reasoning

Diagnostic Tests

IBS is diagnosed based on a careful history and physical that reveals the characteristic increase in bowel symptoms with the onset of pain, relief of pain with defecation, heightened sensation of bowel activity, or sense of incomplete defecation. The criteria used for diagnosing IBS are provided in Advanced Assessment 11.2.

Initial laboratory testing should include complete blood count, erythrocyte sedimentation rate (ESR), chemistry panel including electrolytes and serum amylase, urinalysis, and stools for occult blood, ova and parasites, and cultures. Any abnormal lab value should prompt further investigation in the direction of the abnormal finding because most laboratory studies in the patient with IBS are normal and any diagnostic clue as to the cause is helpful. If white blood cells (WBCs) are found in the stool, it suggests an infectious or inflammatory process and not IBS.

Flexible proctosigmoidoscopy enables the provider to see up to 60 cm of the colon. No abnormalities are seen with IBS with the possible exception of an increased volume of mucus; however, increased tenderness and spasm may inhibit passage of the scope beyond 15 cm. Patients who present for initial treatment at age 40 or older should also be given an air contrast barium enema or colonoscopy.

Food intolerances should be ruled out, especially in patients who present with diarrhea and gas as predominant symptoms. Lactase deficiency can be identified with a hydrogen breath test or lactose tolerance test. Other intolerances are identified by removing the most common causative agents from the diet for 3 weeks and then slowly reintroducing them to the diet one at a time.

IBS is no longer a diagnosis of exclusion; thus, the practitioner must direct diagnostic testing as information is received and lends itself toward an organic cause of the symptoms. Patients should not be subjected to endless batteries of expensive and uncomfortable tests in search of an organic disease. Laboratory findings that support a cause other than IBS include elevated ESR, anemia, leukocytosis, blood or WBCs in the stool, or stool volumes greater than 300 mL.

Advanced Assessment 11.2 Criteria for Diagnosing Irritable Bowel Syndrome

Abdominal pain or discomfort that is consistently relieved by defecation or has been associated with a change in the frequency or a change in the consistency of the stool for a period of 3 months either continuously or recurrently within that time frame
AND
Defecation with varying patterns of constipation and diarrhea 25% of the time
AND
Two or more of the following:

Altered stool frequency
Altered stool form including hard, loose, watery, mucoid
Altered sensory act of defecation including straining, urgency, tenesmus
Passage of mucus
Varied degrees of bloating and abdominal distention

Differential Diagnosis

The differential diagnosis of IBS can include any of the processes in Table 11.16, with emphasis on the organic GI disorders. Most of the disease processes can be ruled out with careful history and physical exam. Patients presenting with diarrhea as the dominant symptom should have thyroid function tests, 24-hour stool check for fecal fat, and stool weight and stool testing for laxative content. Patients who present with constipation as their predominant symptom may require referral to a specialist who can measure colonic transit time. A careful medication history is necessary for either presentation.

Patients with epigastric pain must have the pain differentiated from that produced by biliary tract pain, ulcerative disease, or malignancies of the stomach and pancreas.

Management

The initial step to successful management of IBS is making the diagnosis and then identifying the symptom pattern for each individual patient. Based on the symptom pattern of each patient, therapy may include diet, education, and pharmacological and supportive interventions. The patient with IBS requires reassurance and guidance throughout the course of the disease. There is evidence that a therapeutic relationship between the provider and the patient can reduce symptomatology (Level II; Kaptchuk et al, 2008). Patients must understand that there is no proven treatment and the therapy is often symptomatic. Much of the recent literature suggests that there is a high degree of placebo effect with varying treatments.

A careful diet history is important in identifying foods that may precipitate symptoms. IBS is often confused with lactose intolerance and can be evaluated by removing lactose from the diet for 2 weeks and monitoring the symptoms. Other foods that are frequently identified in producing IBS syndromes include caffeine, legumes (and other fermentable carbohydrates), and artificial sweeteners. If any foods are identified that provoke symptoms, they should be eliminated from the diet. Patients who

Table 11.16 Differential Diagnosis of Irritable Bowel Syndrome

Food intolerance

seem to suffer from postprandial discomfort may alleviate symptoms by eating a lower-fat diet that contains more protein. Dietary consultation can be helpful in assisting patients in developing a diet program that is palatable to them.

Diets high in fiber are beneficial regardless of predominant bowel habit. Patients are encouraged to increase their fiber intake to 20 to 30 grams per day. The hydrophilic properties of fiber or bulk-producing agents help to prevent excessive hydration or dehydration of stool; thus, fiber is indicated for both diarrhea and constipation symptom presentations. Foods high in fiber include whole grains, cereals, fruits, and vegetables; however, they must be introduced slowly for IBS patients in order to avoid the sensation of bloating. Bulk-producing agents can be substituted for individuals who choose not to change their diet. Commercially prepared bulk-producing agents are started once a day and increased gradually to three to four times daily. Patients are encouraged to continue treatment for at least 2 months before termination in order to allow the bowel to adjust to the bulking agents. All patients should try to drink at least eight 8-ounce glasses of water per day. Individuals with constipation as their predominant symptom should be aware that fiber-bulking agents are not overnight laxatives, and they should not abandon this therapy because they did not get overnight results.

Pharmacological treatment is reserved for patients with moderate to severe symptoms and is directed at specific symptoms. Antidiarrheal medications are used only as a temporary measure. When the diarrhea is severe, episodic use of loperamide (Imodium) 2 mg or diphenoxylate (Lomotil) 2.5 to 5.0 mg every 6 hours can be used as needed. The use of codeine, tincture of opium, and paregoric should be avoided because of their addictive nature. Patients who anticipate stressful situations can use antidiarrheals prophylactically.

Patients with constipation who have not responded to a high-fiber diet, hydration, exercise, and bulking agents may benefit from intermittent use of stimulant laxatives such as lactulose or magnesium hydroxide. Long-term use of laxatives is discouraged.

Antispasmodic agents have been used successfully in controlling abdominal pain caused by intestinal spasm. Patients who suffer with postprandial pain not responsive to diet therapy can benefit from dicyclomine 10 to 20 mg three to four times a day by mouth or hyoscyamine 0.125 to 0.75 mg twice a day. Anticholinergics should be avoided in patients with glaucoma and benign prostatic hypertrophy because of the adverse effects and used with caution in the elderly.

Tricyclic antidepressants and selective serotonin reuptake inhibitors have been shown to relieve symptoms in some individuals. Individuals with IBS need reassurance and understanding that their disease is chronic. They often benefit from support groups and counseling. Psychiatric interventions that teach behavior modification and biofeedback or that can provide psychotherapy or hypnosis are helpful alternative measures for patients with refractory IBS.

Follow-up and Referral

The emotional support provided by regular follow-up appointments is important in the management of patients with IBS. A strong, honest relationship with the patient is necessary to allay fears and prevent unrealistic expectations of the patient regarding his or her disease. Follow-up is important to encourage preventive behaviors including high-fiber diet, regular exercise, and avoidance of foods that precipitate symptoms. Patients who are not responding to treatment should be referred to a gastroenterologist.

Patients who have IBS are often dissatisfied with treatment because no organic cause of their symptoms can be found. A second opinion is helpful in the management of these individuals; however, they must also be discouraged from continuing to search for organic causes for their symptoms. Referral for psychological intervention tends to be more helpful in patients with intermittent symptoms; those with chronic pain or intractable symptoms usually respond poorly.

Patient Education

Care of patients with IBS requires a positive and honest practitioner–patient relationship. Education is important in reducing the number of return visits for symptoms common to patients with IBS. The patients should understand that they have a real intestinal disorder, which is characterized by hypersensitivity to certain foods, hormonal changes, and stressors. Patients should be taught how to recognize these triggers and how to avoid or diminish their effects. Patients should understand that they have a chronic disease but that they do not have a shorter life expectancy because of it. A thorough understanding of the treatment regimen and setting realistic goals regarding treatment is the key to building a positive relationship with the patient. Patients must understand that the goal of treatment is to improve their symptoms, not cure the disease, and that improvement in symptoms can be a time-consuming process.

Dietary education is paramount to relief of the symptoms. Increasing fiber and water intake is an important component of the treatment. Teaching patients how to read nutrition labels will help them to quantify the amount of fiber they are consuming daily. Patients must be encouraged to take an active role in their treatment program and to understand that elimination of foods that trigger symptoms can be time consuming and requires their careful attention.

Establishing good bowel habits is also important in the treatment of IBS. A high-fiber diet and increasing water intake to eight 8-ounce glasses per day can help in maintaining a regular bowel program. Patients who suffer with constipation should avoid laxatives and instead practice bowel training. Allowing adequate time after breakfast to sit on the toilet without straining can help establish a daily schedule.

Helping patients recognize and understand environmental stressors that trigger symptoms should be included in patient education. Involving the patient's family is important in establishing a support system. A resource available to patients for both education and support is the International Foundation for Bowel Dysfunction.

BOWEL OBSTRUCTION

Bowel obstruction is the consequence of any condition that inhibits the normal flow of chyme through the intestinal lumen. It can be complete or partial and can involve any segment of the large or small bowel. Bowel obstruction is considered simple when it results from a mechanical blockage or functional (paralytic ileus) when there is a disruption in motility.

Epidemiology and Causes

Intestinal obstruction can be classified according to the onset. Acute obstruction is sudden and can be caused by torsion, herniation, or intussusception (the slipping of a proximal piece of intestine into the part below it). Chronic obstruction usually indicates a slow, gradual process often from tumor growth or strictures. Obstructions are also classed according to the degree of obstruction, either complete or partial, and the location of the obstructing lesion. Obstructions can develop within the lumen, as in the case of foreign bodies, tumors, or intraluminal fibrosis. This type of obstruction is considered intrinsic. Conversely, they can be extrinsic or from obstruction that arises outside the intestine. For example, intussusception, torsion (volvulus), fibrosis, and hernia can all cause intestinal obstructions from outside the bowel. Another aspect in the classification of intestinal obstruction is the effect it has on the intestinal wall. A simple obstruction indicates that there is no impairment of the blood supply to that portion of the intestine. A strangulated obstruction means that the lumen is obstructed and the blood supply is compromised. Bowel obstruction can be a complication of adhesions, which are fibrous bands of tissue that develop after a surgical procedure.

Pathophysiology

There are numerous physiological alterations resulting from an intestinal obstruction related to the onset, location of the obstruction, and the amount of intestine proximal to the obstruction. Immediately after the obstruction begins, there is distention of the intestine with sequestration of fluid and gas proximal to the obstruction. The gas is a result of bacterial fermentation and swallowed air. When the intestine begins to distend, its ability to absorb water and electrolytes decreases and more is left in the lumen adding to the distention. Sources of water and electrolytes include saliva, gastric juice, bile, and pancreatic juice, as well as intestinal secretions. Within 24 hours, as much as 8 liters can accumulate in the intestinal lumen, leading to vomiting. Because of the vomiting and sequestration of fluid and electrolytes in the intestinal lumen, profound fluid and electrolyte imbalances result, leading to dehydration, hemoconcentration, and ultimately hypovolemic shock. The increasing distention causes pressure on the diaphragm, thereby reducing the respiratory volume leading to atelectasis and pneumonia.

Depending on the location and stage of the intestinal obstruction, alkalosis or acidosis is possible. Alkalosis occurs early in intestinal obstruction or if the obstruction is in the proximal portion of the small bowel. This occurs

because gastric juice, which is high in hydrogen ions, does not get absorbed through the intestinal lumen, resulting in loss of the ion. However, later in the course of obstruction, or if the obstruction is more distal, acidosis occurs because alkaline pancreatic secretions and bile cannot be reabsorbed. Potassium is sequestered in the intraluminal fluid, causing hypokalemia, which promotes acidosis and atony of the intestinal wall.

As pressure within the intestinal lumen increases, arterial blood flow may be compromised leading to ischemia, necrosis, perforation, and peritonitis. Metabolic acidosis is compounded by the buildup of lactic acid that results from the decreased arterial blood flow. Venous return is reduced leading to edema within the bowel wall. As the edema progresses, there is an increase in capillary permeability causing fluid to be lost into the peritoneum, contributing to the hypovolemia already present.

Clinical Presentation

Subjective

In general, patients with obstruction generally complain of a sudden onset of colicky abdominal pain accompanied by nausea and vomiting. The pain is usually intermittent and corresponds to peristaltic waves. Patients with obstruction at the jejunum or below may have emesis that has changed to a brownish, feculent type material. They may complain of initial bouts of diarrhea, but this is soon followed by constipation.

In the later stages of obstruction, patients may have constipation and lack of flatulence. It is important to obtain information regarding previous abdominal operations, which may help in the diagnosis of intestinal obstruction. The abdominal pain of small bowel obstruction is usually centered about the umbilicus or in the epigastric area, and vomiting usually occurs early in the disease process. If the arterial circulation to the bowel is compromised, the pain becomes more constant and severe. Perforation produces severe generalized abdominal pain, as well as the classic signs of peritonitis.

Objective

The physical exam should include careful inspection for abdominal scars and the presence of hernias. The patient may show signs of dehydration including poor skin turgor, dry mucous membranes, sunken eyeballs, and tachycardia. Blood pressure may be elevated depending on the degree of pain and if there is evidence of strangulation and subsequent ischemia. The degree of abdominal distention depends on the level of obstruction. The more distal the obstruction, the greater the length of proximal intestine producing greater distention. Also, if the obstruction is in the distal portion of the intestine, vomiting may occur only late in the course of the disease. The abdomen may be tender to palpation if strangulation is present. Bowel sounds are high pitched and hyperactive; they may be accompanied by rushes, which coincide with the colicky abdominal pain. Patients with strangulation tend to have increased distention, abdominal tenderness, tympany to percussion, and hypoactive or absent bowel sounds. Sometimes a mass is palpable. If perforation has occurred, there may be a short period of pain relief, which is soon followed by increased pain, rebound tenderness, and fever, all suggestive of peritonitis.

Patients presenting with large bowel obstruction usually have a more gradual onset of symptoms, beginning with increasing constipation and abdominal distention. Large bowel obstruction is rare in patients younger than age 50. Lower abdominal cramps are unproductive of feces and are painful. Patients report a several-day history of no stools or flatus production. Vomiting occurs if there is an incompetent ileocecal valve or if there is a resultant superimposed, small bowel obstruction. The most common cause of large bowel obstruction is carcinoma of the sigmoid colon or diverticulosis.

Physical exam findings include a distended abdomen, particularly over the transverse and descending colon, with the presence of borborygmi. Patients are normally afebrile unless diverticulitis is suspected. There is usually no abdominal tenderness or guarding unless there are areas of ischemic bowel or associated small bowel obstruction with impending cecal perforation. A mass may be palpable over the area of obstruction. Rectal exam reveals an empty vault without tenderness unless there are obstructing rectal carcinomas. The systemic manifestations of large bowel obstructions are much less serious than those caused by small bowel obstruction.

Diagnostic Reasoning

Diagnostic Tests

Before diagnostic testing, patients must be thoroughly examined for any type of hernia that may be precipitating the obstruction. Diagnosis of small bowel obstruction is usually confirmed by supine and upright abdominal x-ray films that reveal a ladder-like distention of the small bowel. Upright films show multiple air-fluid levels within the loops of small bowel, which are the hallmark of small bowel obstruction. Findings indicative of other causes of small bowel obstruction are evidence of a foreign body or an actual mass suggestive of infarcted bowel. Oral contrast with small bowel follow-through can identify areas of partial obstruction. Oral barium studies are contraindicated and must be avoided unless large bowel obstruction has definitely been ruled out.

Laboratory studies include complete blood count and chemistry profile but are rarely useful for the diagnosis. Leukocytosis can indicate impending ischemia or strangulation of the bowel but is not diagnostic of such. Chemistry evaluation can help with proper fluid and electrolyte replacement. Serum amylase may be elevated

and can lead to the erroneous diagnosis of pancreatitis. A finding of metabolic acidosis or an elevated lactic acid is highly suggestive of intestinal infarction.

Abdominal x-ray films of patients with large bowel obstruction usually show distention of the intestine down to the level of the obstruction. It is important to note the size of the cecum because as the diameter approaches 14 cm, the danger of perforation is imminent. If air is noted under the diaphragm, it is likely that perforation of the cecum or sigmoid colon has occurred.

Differential Diagnosis

Volvulus, a twisting of the bowel on itself, can happen suddenly, with loss of blood supply to the area and subsequent ischemia. Cecal volvulus presents as a large gas bubble within the midabdomen or left upper quadrant on abdominal x-ray film. A volvulus of the sigmoid colon usually occurs only in older adults. It typically appears as a "coffee bean" dilation arising from the pelvis. For both cecal and sigmoidal volvulus, a barium enema is done to reveal the precise location of the obstruction.

Colonoscopy and endoscopy are contraindicated in patients suspected of mechanical bowel obstruction because to visualize the intestine, air must be introduced into the colon and can increase the chance of perforation. The differential diagnosis of small and large bowel obstruction is presented in Table 11.17.

Management

All patients with suspected intestinal obstruction should be hospitalized and immediately referred to a surgeon. Therapy must be administered as definitive diagnosis is being obtained. Most patients with a bowel obstruction will require placement of a nasogastric tube to decrease passage of secretions, aid in decompression, and ameliorate vomiting if present. Rehydration with IV fluids and replacement of electrolytes should be done as indicated by laboratory studies. Placement of an indwelling urinary catheter is necessary to monitor urine output accurately, which is recorded on a daily intake and output sheet.

Treatment of small bowel obstruction proceeds after the aforementioned therapies have been instituted and the patient is medically stabilized. Patients with upper small bowel obstruction are prone to alkalosis and hypokalemia caused by emesis; they must be monitored carefully and given IV fluid and electrolyte replacement as necessary. All medications that can decrease intestinal motility, including anticholinergics, narcotics, and calcium channel blockers, should be discontinued. If strangulation is suspected, the patient should be started on broad-spectrum antibiotic therapy, which provides coverage for anaerobic and gram-negative organisms. Laparotomy is indicated for all patients with complete bowel obstruction.

Patients with a large bowel obstruction are rehydrated and stabilized as previously described. If the patient has evidence suggestive of sigmoidal volvulus, an initial attempt to reduce the volvulus can be made with sigmoidoscopy, but surgery is required if that attempt is unsuccessful. Patients with Crohn's disease, intestinal lymphoma, or diverticulitis with subsequent concentric narrowing of the intestinal lumen may be given a trial of medical therapy specific to the disease process in an attempt to relieve the obstruction before surgical intervention.

Obstructing carcinomas can be treated with surgical resection and anastomosis. (Colon cancer is discussed later in this chapter.) If fecal impaction has been identified as the cause, it can often be removed digitally. If the impaction is barium and is located within the sigmoid colon, open laparotomy is required for removal. Adhesions can be relieved by surgical intervention; however, the chances are great that they will recur. Hernia reduction is indicated if this is the determined cause of obstruction. All patients who have undergone surgical intervention as definitive therapy must be monitored for paralytic ileus postoperatively.

Table 11.17 Differential Diagnosis of Bowel Obstruction

- Pseudo-obstruction
- Toxic megacolon
- Twisting of a loop of bowel
  - Cecal volvulus
  - Sigmoid volvulus
- Incarcerated or strangulated hernias
  - Abdominal
  - Femoral
  - Inguinal
- Kinking of a loop of bowel
  - Adhesions secondary to previous abdominal surgery
- Concentric narrowing of the lumen of the intestine
  - Neoplasms
  - Diverticulitis
  - Crohn's disease
- Foreign body
  - Gallstones
  - Ingested objects
- Intussusception
- Paralytic ileus

Follow-up and Referral

All patients with suspected bowel obstruction must be referred to a surgeon, who will manage the patient's hospitalization and postoperative care. The prognosis of appropriately treated simple intestinal obstruction is good, with a mortality rate of less than 2%. If strangulation is suspected and intervention is delayed, the mortality rate can be as high as 25%.

Because patients are usually acutely ill, postoperative teaching should be delayed until the patient is more receptive to instruction. Initial follow-up visits should

be with the consulting surgeon, who will direct the patient's care until the patient is released to his or her primary-care provider.

Patient Education

Follow-up of patients with bowel obstruction will be guided by the surgeon. Instructions on care of the incision, including dressing changes and signs and symptoms of infection, are provided before discharge from the hospital. Once the patient has been cleared by the collaborating surgeon, he or she will return to the primary-care setting. Patients should be instructed to report any recurrent abdominal pain with or without vomiting, fever, or problems regarding bowel function. Laxatives should not be taken without consulting the primary-care provider first. Stool softeners are prescribed as needed, and patients are encouraged to avoid foods that cause constipation. Patients should refrain from strenuous activity for at least 6 to 8 weeks.

DIVERTICULAR DISEASE

Diverticular disease is the term used to describe the inflammatory changes that occur within the diverticular mucosa of the intestine (diverticulitis), as well as the asymptomatic, uninflamed outpouchings called diverticulosis. Diverticula are pouchlike protrusions of the intestinal mucosa that occur most often within the descending and sigmoid segments of the colon. They decrease in frequency in the cecum and rarely are found in the rectum. Diverticula occur infrequently in the small bowel. There are two types, congenital and acquired. Congenital diverticula are situated on the antimesenteric margin of the bowel and consist of the intestinal wall layers. The acquired diverticula occur on the mesenteric margin of the bowel, where the blood vessels enter the bowel wall. A diverticulosis of the small bowel may cause malabsorption and steatorrhea. Diverticula tend to form at weakened areas of the intestinal wall, usually where arterial vessels perforate the colon. The inner layer of these pouchlike protrusions forms a narrow neck, which is continuous with the inner layer of the colon, and the sac herniates through the muscle wall. Most diverticula are asymptomatic and pose a problem only when they become inflamed or bleed. Most diverticula are found incidentally with endoscopy or barium enema (BE). Diverticula vary in size from 3 mm to 3 cm in diameter.

Epidemiology and Causes

Diverticula are uncommon in individuals younger than age 40, with the prevalence increasing steadily after that. More than one-third of the U.S. population is affected by age 60. Diverticular disease is more common in developed nations than in less-developed countries, with estimates as high as 40% to 50% in Western populations. The incidence is 2,200 to 3,000 per 100,000 people, occurring equally among men and woman. Diverticula are a rare finding in pediatric patients. Although they are common in older adults, it may be difficult to diagnose diverticular disease in these patients because of their blunted immune response.

Although there is no known cause for diverticular disease, a low-fiber diet has been implicated because it causes increased intraluminal pressures within the colon, which lead to mucosal herniation through the weaker areas in the bowel wall. Other factors believed to contribute to the formation of diverticula include hypertrophy of the segments of the circular muscle of the colon, chronic constipation and straining, irregular and uncoordinated bowel contractions, obesity, and weakness of the bowel muscle brought on by aging. Risk factors are directly related to the suspected causes of the disease: older than age 40, low-fiber diet, previous diverticulitis, and the number of diverticula present within the colon. Diverticula occur most often in the left lower quadrant (LLQ); a right lower quadrant presentation is a rare condition, with a higher incidence in Asian populations.

Pathophysiology

The exact cause of diverticulosis is unknown; therefore, the pathophysiology is based on the speculative findings already mentioned. As a consequence of increased ingestion of refined foods and decreased fiber intake, the stool bulk is decreased and the colon transit time is increased, leading to the development of diverticula. Diverticula are thought to result from the increased pressure produced with the segmental contraction of the muscular portion of the wall of the colon. This increased pressure causes the herniation of the bowel wall through the weaker points in the muscle layer of the colon, normally occurring along the teniae at the penetration site of colonic vasculature. Inflammation occurring around the diverticular sac is often caused by the retention of undigested food and bacteria, which when formed into a hardened mass is called a *fecalith.* This mass in turn can disrupt the blood flow and lead to abscess formation. When the opening of this saclike projection becomes occluded and inflammation ensues, it can progress to the point of rupture. Acute diverticulitis is the result of this localized inflammation within the wall of the colon or peritoneum, causing the characteristic LLQ abdominal pain and tenderness. If the perforation is not localized, the patient can develop acute peritonitis and septic shock.

Fistula formation following acute diverticulitis is the result of a tract forming between the colon and other structures within the abdomen. These fistulas include colovesicular fistulas (urinary bladder), colovaginal fistulas (vagina), enteroenteric fistulas (loop of bowel), and colocutaneous fistulas (peritoneal tissue). Pericolitis is inflammation around the colon, which can result in fibrous strictures and obstruction.

Bleeding is a common complication of diverticulosis and is the most common cause of substantial lower gastrointestinal (GI) bleeding. Postbleeding examinations

have discovered that most bleeding occurs from uninflamed rather than inflamed diverticuli.

Clinical Presentation

Subjective

Approximately 25% of patients with diverticular disease develop symptoms. Patients with diverticulosis characteristically present with pain in the LLQ of the abdomen. Some patients report that the pain is worse after eating, which may be a result of colonic distention, and that the pain is sometimes relieved with a bowel movement or passing flatus. Elimination patterns may alternate between diarrhea and constipation, and there may be associated abdominal distention and tenderness. Diverticulitis may present with bleeding, which can be massive and is not associated with pain or discomfort.

When the diverticula have become inflamed, there are the usual signs and symptoms of infection—fever, chills, and tachycardia. Patients typically present with localized pain and tenderness in the LLQ of the abdomen with associated anorexia, nausea, and vomiting. If there is fistula formation, there are symptoms associated with the particular organ involved. Patients may complain of dysuria, pneumaturia (passage of air in the urine), and/or fecaluria (passage of fecal matter in the urine) if there is fistula formation involving the bladder. Patients may be concerned about the development of hematochezia or frank bleeding from the rectum.

Objective

A physical exam reveals tenderness in the LLQ of the abdomen, and—if the patient can tolerate more vigorous examination—a firm, fixed mass may be identified in the area of the diverticuli. Patients may have rebound tenderness with involuntary guarding and rigidity. Bowel sounds may initially be hypoactive or can be hyperactive if an obstructive process has developed. Examination of the rectum may reveal tenderness, and the stool is usually positive for occult blood.

Diagnostic Reasoning

Diagnostic Tests

Initial laboratory testing can show mild to moderate leukocytosis, depending on whether the patient presents with diverticulitis or with a more advanced inflammatory process such as peritoneal abscess. The white blood cell (WBC) count is usually normal in patients with diverticulosis. Hemoglobin and hematocrit may be low if there is associated rectal bleeding. If there is fistula formation between the diverticula and the bladder, urinalysis may show elevated levels of both WBCs and red blood cells, and urine culture may be positive. Patients with signs suggestive of peritonitis should have a blood culture to assess for bacteremia.

Abdominal x-ray films should be obtained on all patients with suspected diverticulitis, especially if there are signs of perforation or peritonitis. Plain films of the abdomen can reveal free air (indicating perforation), ileus, or obstruction (small or large bowel). A BE outlines the lumen of the bowel clearly defining diverticula and is thus most helpful in the diagnosis of the disease process. If perforation is suspected, the study can be performed with Gastrographin, a water-soluble contrast medium. Barium studies help to identify sinus tracts, fistula formation, or obstructive processes. Diverticula are often an incidental finding on colonoscopy; however, colonoscopy is much less sensitive for the diagnosis of diverticular disease than BE. Colonoscopy may be helpful in ruling out cancer as the source of the symptomatology, as is cystoscopy in evaluation of colovesicular fistula.

Although diverticulitis can often be diagnosed clinically, a computed tomography (CT) scan with oral contrast is a much more sensitive and accurate test for cases in which confirmatory testing is necessary. CT scan can also determine if there is clinical deterioration by measuring the thickness of the bowel wall and assessing for the development of phlegmon over time using serial exams.

Patients who present with lower GI bleeding may require radioisotope scanning to locate the site of bleeding. Angiography is often nondiagnostic because the rate of bleeding is too slow or because bleeding has stopped.

Differential Diagnosis

The differential diagnosis of diverticular disease includes irritable bowel syndrome, carcinoma of the colon, inflammatory bowel disease, lactose intolerance, pelvic inflammatory disease, ovarian cyst, colitis (infectious or ischemic), appendicitis, and pyelonephritis. Most often the diagnosis can be made using the clinical findings and initial noninvasive ultrasonography. BE and colonoscopy are most helpful for definitive diagnosis of diverticulitis and colon surveillance for other colonic disease processes.

Management

With early detection and treatment of diverticulitis and the associated complications, the prognosis is good. An incidental finding of uncomplicated diverticulosis requires no further intervention and can be managed with a high-fiber diet or daily fiber supplementation with psyllium. Treatment of a patient presenting with mild symptoms can often be managed on an outpatient basis with rest, oral antibiotics, and a clear liquid diet. Initial antibiotic therapy varies with the extent of the inflammatory process and can include metronidazole (Flagyl) 500 mg by mouth three times daily with ciprofloxacin (Cipro) 500 mg by mouth twice daily, or trimethoprim/sulfamethoxazole (Bactrim DS) 160/800 mg by mouth twice daily for 7 to 10 days. The symptoms usually

subside quickly; then the diet can be advanced to soft, low roughage and next to high fiber as tolerated. Pain due to spasms can be managed with antispasmodics such as hyoscyamine (Levsin) 0.125 mg every 4 hours, dicyclomine (Bentyl) 20 to 40 mg four times daily, buspirone (BuSpar) 15 to 30 mg/day, and/or meperidine (Demerol) 100 to 150 mg/day in divided doses.

Patients with more acute illness require hospitalization for intravenous antibiotics and hydration, analgesia, bowel rest, and possible nasogastric (NG) tube placement. If the patient requires analgesia, morphine sulfate should be avoided because it increases intraluminal pressures within the colon and causes or exacerbates the presenting symptoms or perforation. An NG tube should be placed if there is evidence of ileus or if there is intractable nausea and vomiting.

The choice of antibiotics will depend on the severity of the disease process and should cover both gram-negative bacteria and anaerobic organisms. If cultures are obtained from the diverticular abscess, antibiotic coverage can be altered according to the results of the culture. Use and dosage of aminoglycosides should depend on renal function as indicated by the creatine clearance. Patients who are immunocompromised will require broader antibiotic coverage, including an anti-*Pseudomonas* agent. IV antibiotic therapy is normally continued for 7 to 10 days and may be continued orally for an additional 7 to 10 days after discharge, depending on the severity of the illness.

Patients will usually experience relief in symptoms after 3 to 5 days of antibiotic therapy and may resume oral intake as tolerated. Once patients are able to maintain adequate nutrition and hydration, they can be discharged. A BE should be scheduled for 2 weeks after discharge to evaluate treatment.

Patients whose cases are complicated by bleeding that does not subside will require angiography to locate the site of bleeding; they may also require infusion of vasopressin (Pitressin) 0.2 to 0.3 units/min via an intra-arterial catheter placed during the radiographic procedure. If the patient shows signs and symptoms of acute blood loss, transfusion may be indicated. Twenty percent of patients who have experienced diverticular bleeding bleed again within a year.

If there is no improvement or if there is clinical deterioration after 72 hours of medical treatment, surgical intervention may be indicated. Approximately 20% to 30% of patients with the diagnosis of diverticulitis require surgical management. Surgery is usually required for patients who have had several episodes of diverticulitis within 2 years or for those who have had a single episode of diverticulitis with complications. Findings such as free peritonitis and large abscesses that do not respond to medical treatment are indications for emergent surgical intervention. The surgical procedure of choice is colon resection with a temporary colostomy. Once the inflammation and infection have resolved, the patient can undergo elective reanastomosis of the colon. Patients who have undergone the surgical procedure will require routine postoperative care, with emphasis on pain management, pulmonary hygiene, hydration, nutrition, and wound assessment.

Localized abscesses can be drained percutaneously with the assistance of the interventional radiologist. Once the inflammation and infection have resolved, the patient may require an elective single-stage colon anastomosis in which the affected portion of the colon is removed. Despite medical treatment, it is estimated that up to 40% of patients with diverticulitis continue to experience symptoms, and approximately half of these patients will need surgical intervention.

Follow-up and Referral

To evaluate or diagnose diverticular disease, all patients will require colonoscopy at some point during their disease process; therefore, referral to a gastroenterologist is indicated for symptoms that do not respond to treatment after 6 months. Early in the disease process, patients with diverticulitis should consult with a surgeon who can follow them and determine the necessity for emergent surgical intervention if complications should develop. If patients respond well to antibiotic therapy but suffer subsequent attacks of diverticulitis, they should be referred to a surgeon for elective removal of the affected portion of the bowel. Any patient who has had an acute attack of diverticulitis before age 40 will usually require surgical intervention and should be referred accordingly. Follow-up BEs can be repeated every 3 years if symptoms persist or after corrective surgery has been completed.

Patient Education

Patients diagnosed with diverticular disease will need to make modifications in their diets with an emphasis on increasing the amount of dietary fiber. Diet changes should be made slowly to avoid bloating, gas, and other GI problems that may discourage compliance. Fiber can be increased by eating bran, fresh fruits, vegetables, and whole grains. The goal of diet therapy is to avoid constipation and straining during bowel movements, which can further increase intraluminal pressures and cause complications.

Patients should also be instructed to drink at least ten 8-ounce glasses of water a day to have regular, soft bowel movements. If patients continue to have constipation despite increasing their fiber and fluid intake, a bulk-forming laxative such as psyllium (FiberCon, Metamucil) can be added.

Patients who have had a colostomy will need instruction regarding follow-up care, including how to assess the stoma and the skin (for skin breakdown); how to clean the stoma; and how to empty, reclose, and change the colostomy pouch. Diet instruction as previously discussed is important for patients with a

colostomy to prevent constipation and promote bowel regularity.

Symptoms will recur in approximately one-third of all patients with diverticulitis who were initially treated with medical management. All patients with diverticular disease, therefore, should be instructed to return for follow-up if they develop signs and symptoms of infection or other associated complications of diverticulitis. Patients who present with another episode of diverticulitis warrant elective surgical resection. Patients should understand that despite adherence to diet and medication, they may have another attack.

COLORECTAL CANCER

Colorectal tumors are both curable and preventable; however, the systematic screening of such cancers is in its infancy. Colorectal tumor presentation can be either symptomatic or asymptomatic and is dependent on the location of the tumor. Polyps, the most benign form of tumors, are classified as hyperplastic (nonneoplastic), adenomatous (neoplastic), or submucosal (lipomas). Adenomatous polyps are believed to be the precursors to the malignant adenocarcinomas, which comprise more than 95% of all malignant tumors of the colon. Over the past 20 years, there has been a decline in the mortality rate associated with colorectal carcinoma, which has been attributed to improvement in screening, diagnosis, and treatment. Cure rates of colorectal carcinoma are estimated to be as high as 50%.

Epidemiology and Causes

Of cancers affecting both men and women, colorectal cancer is the second leading cancer killer in the United States. In 2009, 136,717 people were diagnosed with colorectal cancer and 51,848 people died from it; the incidence rate is 49.2 per 100,000 people, making colorectal cancer the third ranked incidence of top 10 cancer sites. Over a lifetime, colorectal cancer will affect 1 in 17 Americans. Approximately 148,810 individuals are diagnosed with colorectal cancer every year in the United States; the vast majority (108,070) have colon cancer, and the rest have rectal cancer.

Age is the most important risk factor for developing colorectal cancer in the United States. The risk increases steadily with age, especially after age 45, and is rare in individuals younger than age 35 unless they are predisposed to rare genetic diseases. The older adult population is at the greatest risk of developing colorectal carcinoma, with the median age at the time of diagnosis being 71 years. Colon cancer affects men and women equally; however, rectal cancers are more common in men. The overall survival rate of patients with colorectal cancer is approximately 50% to 55% and is attributed to early detection and treatment. African American males and members of low-income minority groups have, for unknown reasons, lower survival rates in comparison to national data for other groups. It is presumed—though not proved—that the lower survival rates among minorities are in part a result of decreased accessibility to or underutilization of health care.

Seventh-Day Adventists are a religious group that subscribes to a vegetarian diet, and they also have a lower incidence of colorectal cancer. In the past, studies have shown that the Japanese have had a lower incidence of colorectal cancer; however, Japanese Americans who have adopted a diet high in fat and refined carbohydrates have a higher incidence of this type of cancer. In general, groups that migrate from areas of low to high incidence of colorectal cancer experience a change in cancer incidence that parallels that of the new region.

Other risk factors for colorectal cancer include a family history and a personal history of adenomatous polyps (multiple polyps or individual polyps greater than 1 cm in size) or colon cancer. Twenty-five percent of patients diagnosed with colon cancer have a family history of colon cancer. The risk of developing colon cancer is directly proportional to the number of first-degree relatives affected: For patients who have one first-degree relative with colon cancer, the risk increases twofold to threefold. Disorders involving increased colon mucosal cell turnover (such as inflammatory bowel disease and ulcerative colitis) have been implicated in greater risk for colon cancer. Familial adenomatous polyposis is an autosomal dominant condition that results in the development of thousands of adenomas within the colon but accounts for less than 1% of colon cancers. Other hereditary conditions that increase the chance of developing colorectal cancer include Peutz-Jeghers syndrome, Gardner's syndrome, and Turcot syndrome. Patients with a family history or personal history of gynecological (breast, ovarian, endometrial) cancers and individuals diagnosed with Barrett's esophagus also have an increased risk of developing colon carcinoma.

Although the etiology of colorectal cancer (adenomas) is unknown, both environmental and genetic factors have been implicated. Geographical variances and a positive correlation in the incidence of disease among migrant workers both suggest that environmental factors play a role. Diets high in fat, red meat, and refined carbohydrates and low in plant fiber have been correlated with the areas of highest incidence of colorectal cancer, whereas areas with the lowest incidence of colorectal cancer have diets high in fiber and rich in vegetables and fruits. It has been theorized that the excess fat interacts with colonic bacteria to form deconjugated bile acids, which have been associated with tumor-producing activity, increased deposition of fatty acids within the cell membranes, and increased synthesis of prostaglandins, which further stimulates cell proliferation. Ketosteroids are thought to be metabolic by-products of cholesterol that induce genetic damage and have been found in higher concentrations among high-risk populations. Products of pyrolysis—decomposition of organic matter secondary to increases in temperature

such as those resulting from char-broiling and frying—have also been implicated in carcinoma of the colon. Geographical areas with low levels of selenium also have higher incidence of colorectal cancer.

Conversely, diets high in fiber tend to reduce the transit time within the colon, thus decreasing exposure to potentially carcinogenic substances and altering the gut flora and decreasing fecal pH. (Populations with the highest incidence of colorectal cancer have an associated higher fecal pH.) When fecal contents take longer to transit the bowel, the deionized bile acids and free fatty acids stay in contact with the intestinal mucosa, which has been associated with development of colorectal cancer.

Pathophysiology

Adenocarcinomas account for more than 95% of colorectal malignancies. The evolution from adenoma to invasive carcinoma can take up to 10 years. *Adenomas* are benign neoplasms composed of granular epithelium that are not capable of metastasis or invasion of the muscularis mucosa. They are either sessile (attached by a broad base) or pedunculated (attached by a stalk). Most smaller adenomas (less than 1 cm in diameter) are of the tubular type, and less than 1% contain carcinoma. As the polyps increase in size (greater than 2 cm in diameter), they begin to show villous changes with increasing dysplasia; the chance of one of these polyps containing cancer is about 50%.

Most adenocarcinomas of the colon form hard, nodular areas that grow irregularly. Colon cancers are staged or classified according to histological changes in the infiltrative character of the tumor. The most common classifications used today are the Joint Committee Classification, Duke's staging system, and the tumor-node-metastasis system (Table 11.18). Histologically, colon cancers vary from well-differentiated cells that appear normal (grade 1) to highly anaplastic, poorly differentiated cells (grade 4). The accuracy of specimen collection is crucial. The most accurate method of evaluating a polyp is by removing the entire lesion for cytological examination. If the polyp is less than 7 mm in diameter, tissue for biopsy can be obtained while the polyp is destroyed through "hot" (fulguration) biopsy.

Metastatic progression of colon cancer usually involves spread by local invasion, lymphatic extension with

Table 11.18 Staging Classifications of Colorectal Cancer

Tumor-Node-Metastasis (TNM) Class*	Description	Staging Groups
Tis	Carcinoma in situ	Stage 0
T1	Tumor invades submucosa. • Greater than 80% 5-year survival	• Tis N0M0 Stage I
T2	Tumor invades muscularis.	• T1N0M0 (Duke's classification Stage A) • T2N0M0 (Duke's classification Stage B1) Stage IIA
T3	Tumor penetrates through bowel wall. • 60%–80% 5-year survival	• T3N0M0 (Duke's classification Stage B2) Stage IIB • T4N0M0 (Duke's classification Stage B3)
T4	Tumor invades adjacent organ.	Stage IIIA
Any T	Any bowel wall perforation with lymph node involvement. • 20%–50% 5-year survival	• T1–2N1M0 (Duke's classification Stage C3) Stage IIIB
N0	No regional lymph node involvement.	• T3–4N1M0 (Duke's classification Stage C2–3)
N1	One to three pericolic or perirectal lymph nodes.	Stage IIIC
N2	Four or more pericolic or perirectal lymph nodes.	• Any T, N2M0 (Duke's classification Stage C1–3)
N3	Metastasis to lymph nodes along a vascular trunk.	Stage IV
M0	No metastasis.	• Any T, Any N, M1 (Duke's classification Stage D)
M1	Distant metastasis. • Less than 25% 5-year survival	

*American Joint Committee on Cancer.

spread to the mesenteric lymph nodes first, and then hematogenous spread through the portal system to the liver. In some patients, the cancer metastasizes throughout the peritoneal cavity and to the lungs. Rectal carcinoma spreads by direct extension through the perirectal fat to the lymph nodes and less often to the lungs and distant organs through hemorrhoidal circulation. Prognosis of colorectal carcinoma is a function of several factors, including poorly differentiated tissue histology, mucin production, aneuploidy (DNA abnormalities), tumor invasion to other organs, perforation, and venous involvement. The prognosis is not influenced by tumor size.

Colon cancers can develop as polyps within the lumen of the intestine or as a mass on the wall of the colon. Bulky polypoid tumors are more common within the right colon, whereas tumors that encircle the bowel, causing obstruction, are more common on the left side of the colon. Tumor growth is normally slow and, in most cases, is asymptomatic until the tumor becomes large. Diagnosis is usually made late in the course of the disease, often after metastasis, thereby making a surgical cure difficult. Colon cancers that produce intracellular mucin are called "signet ring"–type carcinomas; these tumors have a tendency to be more aggressive in their spread.

Several types of colon cancers have been linked to specific genetic defects. Hereditary nonpolyposis colorectal cancers include two autosomal dominant conditions that have been associated with a markedly increased risk for developing colon cancer. Although these patients have few or no adenomatous polyps, individuals diagnosed with Lynch syndrome I are at increased risk of developing colon cancer at an early age. This cancer has a propensity for the right side of the colon. Lynch syndrome II includes the features of Lynch syndrome I as well as an increased risk of developing tumors within the ovary, uterus, urinary tract, and stomach.

Clinical Presentation

Subjective

Signs and symptoms in patients with colorectal cancer will vary, depending on the tumor size, anatomical location, and associated complications, if any. There are very few early warning signs of colorectal carcinoma; in fact, most individuals are totally asymptomatic. Frequently, the cancer is found incidentally during abdominal surgery or during screening sigmoidoscopy.

Patients may present with melena or bright red bleeding from the rectum, depending on the location of the tumor. A change in bowel habits, including constipation alternating with diarrhea or a change in stool caliber (described as narrowed or ribbonlike), can be signs of colon cancer. Stools streaked with blood may be mistakenly dismissed as a sign of hemorrhoidal irritation. Abdominal pain is a rare presenting symptom but may indicate obstruction resulting from tumors on the left side of the colon, which has a smaller diameter lumen, or from invasion of the bowel wall by a tumor. Patients rarely report colicky pain as a result of a right-sided colon cancer because of the larger diameter of the colon and the liquid consistency of the stool. Patients with rectal cancer may complain of tenesmus (spasm of the anal sphincter), urgency, and/or hematochezia. Patients with chronic occult blood loss from an undiagnosed tumor may experience weakness and fatigue caused by iron-deficiency anemia. Weight loss and anorexia are common with any malignant process but are usually manifested late in the disease process.

Objective

Physical exam may reveal a mass within the abdomen or an enlarged liver, which may be suggestive of metastasis. A digital rectal exam should be done even though most tumors are not palpable. The stool should be tested for occult blood, which, if positive, is pathognomonic for right-sided colon cancer. Approximately 50% of patients with a positive fecal occult blood test have either an adenoma (38%) or a neoplasm (12%). Conversely, fecal occult blood testing is positive in only 60% to 70% of patients with known large intestinal cancers; however, annual screening can reduce colorectal mortality rates by 33%.

Diagnostic Reasoning

Diagnostic Tests

Although there are no definitive laboratory tests for diagnosis of colorectal cancer, a complete blood count should be obtained to assess for iron-deficiency anemia or anemia of chronic blood loss, either of which can be a common finding in patients with colorectal cancer. Liver function tests may reveal an elevation of the liver enzymes, especially of alkaline phosphatase if there has been metastasis to the liver and/or bone. Usually, when there is liver metastasis, the bilirubin level tends to remain normal until late in the disease process.

The serum immune assay for carcinoembryonic antigen (CEA) was developed with the intent of providing an early means of detection for colon cancer; however, the test is too insensitive and nonspecific for screening. CEA levels have been poorly correlated with the stage of cancer; however, this test is useful for monitoring a patient's response to therapy, whether surgical or chemotherapeutic. CEA levels usually normalize after colon resection, and levels that remain elevated are associated with poor prognosis. A secondary spike in the CEA level after surgery is highly suggestive of recurrence and must be evaluated.

Colonoscopy with a biopsy and barium enema (BE) are used to establish definitive diagnosis of colorectal cancer. Air contrast BE enables the radiologist to detect small defects or lesions within the intestinal mucosa.

Colonoscopy is a more specific and sensitive test that can be used as follow-up to the findings of the BE; colonoscopy can also be used by itself to provide more definitive data through the biopsy of the suspect lesions. Colonoscopy establishes the diagnosis of colon cancer with almost 100% accuracy and is thus the diagnostic procedure of choice. Flexible sigmoidoscopy can be used for confirming lesions within the rectosigmoid area; however, full colon examination with colonoscopy is preferred. Computed tomography (CT) scan is used for evaluation of distant metastasis. Endoscopic ultrasound has been used to stage regional rectal cancers and is more accurate than CT scan in this particular area.

Patients with colonic polyps will require histological examination of the polyp. Polyps larger than 7 mm should be totally removed by snare cautery. Polyps that are less than 7 mm in size are usually not malignant and can be removed by "hot" biopsy, which destroys the polyp while obtaining the necessary tissue for cytological exam.

Differential Diagnosis

The symptoms of colorectal cancer are nonspecific; therefore, many disease processes can mimic the presenting symptoms of colon carcinoma and must be differentiated from it. Most of the inflammatory and irritable bowel disease processes can be confused with colon carcinoma. Ischemic colitis, diverticular disease, irritable bowel syndrome, inflammatory bowel disease, or infectious colitis can form strictures within the bowel that are indistinguishable from colon carcinoma. Colonoscopy with biopsy of the lesion is the diagnostic procedure of choice. Any patient older than age 50 who presents with iron-deficiency anemia, stool positive for occult blood, change in bowel habits, or hematochezia should have a thorough evaluation to rule out the possibility of neoplasm.

Management

The first step in the treatment of colon cancer is the staging of the disease. The staging of the cancer is of critical importance not only for the determination of the patient's long-term survival but also for determining which patients should receive adjuvant therapy. Staging of a neoplasm first involves understanding the characteristics used to describe the histological findings: tissue of origin (adenocarcinoma, sarcoma), origin of specimen (colon, breast), and the degree of tissue differentiation. Staging of the carcinoma includes both the primary site and the metastatic sites and allows for the development of the most optimal treatment plan based on those findings. More than half of all cancers are not curable using approved treatments available today. Many of the treatment regimens involve some form of experimental drugs or procedures; therefore, accurate staging is necessary to determine the efficacy of the treatment.

The only known cure for colon cancer is surgical resection. This is the treatment of choice for all patients who can tolerate the surgery. Even patients who have known metastasis can benefit from surgical intervention to reduce the chance of developing an intestinal obstruction or rectal hemorrhage later in the disease process. Most patients with colorectal cancer present with penetration of the mass through the bowel wall and with associated lymph node involvement. The surgeon will decide, based on the staging, what type of surgical resection is appropriate. The anatomical location of the tumor—left or right side of the colon—will dictate whether left or right hemicolectomy is performed. A wide margin of intestine (with careful ligation of the total arterial blood supply) will be resected to ensure that mesenteric and associated lymph node drainage is removed.

Lesions located within the rectosigmoid area are usually treated with anterior resection, which protects the rectal sphincter. (The rectum is the distal 8–11 cm of large bowel.) If the rectal lesions are small and are discovered early, they can sometimes be treated by local incision, laser photoablation, or cryosurgery. Larger lesions located within this lower portion of the large bowel usually require a combination of abdominal-perineal resection with a colostomy. Unresectable rectal cancers can be palliated with a diverting colostomy, or, if the patient is a poor surgical candidate, laser fulguration of the tumor mass can minimize the bleeding and maintain the patency of the rectum.

Adjuvant chemotherapy for colon cancer is based on the stage of the disease (see Table 11.18). From 6 months to 1 year of chemotherapy with 5-fluorouracil (5-FU) and levamisole continues to be the treatment of choice for carcinomas classified as stage III (node-positive) and, although it is not curative, it enhances the survival rate. Evaluation of the treatment is based on the initial response of the tumor to the therapy (e.g., shrinkage), as well as improvement in the 5-year survival rate.

Rectal carcinomas are typically treated with chemotherapy and radiation therapy. Radiation therapy for rectal cancer may involve both preoperative and postoperative radiation therapy. Depending on the size of the tumor, preoperative radiation therapy can help shrink the tumor, making it more amenable to resection. Postoperative combination therapy with 5-FU and radiation therapy has been effective in reducing both local and metastatic node occurrences.

Twenty percent of patients with colorectal cancer have known metastases at the time of diagnosis. Patients with known metastases to the liver may have improved survival rates with resection. Some patients with liver metastases have opted for infusions of 5-FU into the hepatic artery or portal vein, which has proved superior in the treatment of hepatic disease; however, this treatment has little effect on the overall survival rate for colorectal cancer and can be extremely toxic to the patient. Radiation therapy is often employed as a palliative measure

for patients whose pain has been unresponsive to chemotherapy or other treatment modalities.

Although the oncologist will manage the patient's chemotherapy, the primary-care practitioner will continue to work closely with the patient to treat any of the numerous adverse effects caused by the chemotherapy and/or the radiation therapy. The potential toxic effects of adjuvant therapy for colorectal cancer are numerous and can range from nausea, vomiting, and weight loss to cystitis and radiation proctitis. Radiation therapy to the pelvic area can cause severe gastrointestinal disorders, including intractable diarrhea and even malabsorption syndromes.

Follow-up and Referral

Initial assessment and screening for colorectal carcinoma is the responsibility of every primary-care provider. Patients who are known to be at higher risk for the development of colorectal cancer, such as those who have a first-degree relative with the disease, a family history of adenomas, a personal history of adenomas or colorectal cancer, or a long-standing history of inflammatory bowel disease, will require a more in-depth screening by a practitioner who is well trained in this area. Screening for high-risk patients should include colonoscopy, which is best done by an experienced gastroenterologist. The recommended screening for average- and high-risk individuals is provided in Screening Recommendations/Guidelines 11.1.

Follow-up is vitally important in the treatment of colorectal cancer. In an effort to prevent recurrence, scheduled colon surveillance is required. Early detection and removal of adenomas can improve survival rates. Close surveillance is necessary for patients who have undergone "curative resection" surgery. Recommendations include office visits every 3 months, which should include a CEA level, an annual CT of the abdomen and pelvis, and a chest x-ray film for the first 3 years postoperatively. A colonoscopy should be completed postoperatively; but, if the exam was not completed at that time, a colonoscopy should be scheduled for 3 months postoperatively and then again at 1 year, with special attention to anastomotic recurrences. If the results of the exam are within normal limits, patients may continue with follow-up exams every 3 years. Patients whose CEA levels normalize or stabilize after surgery and then spike suddenly require a thorough examination.

Patients who have undergone surgical resection for colon cancer and have a temporary or permanent colostomy may benefit from assistance from an enterostomal therapist. Consultation with a urologist for urological or sexual dysfunction resulting from surgical or radiation therapy may provide medical and social support. Patients suffering from metastatic disease can be referred to hospice service personnel, who are trained in providing comfort and support to both the family and the patient. They can give guidance regarding home and hospital care and are specially trained in providing appropriate analgesia for patients. Criteria for admission to the hospice program differ from one area to another; most require a physician statement that the patient has less than 6 months to live and is receiving only palliative or supportive treatments. Some hospice services require patients to have a "do not resuscitate" (DNR) order in place as a condition for admission.

Screening Recommendations/Guidelines 11.1 Colon Cancer Screening Recommended by the American Cancer Society

Risk	Screening Recommendations
Average risk	Annual fecal occult blood (FOB) test Flexible sigmoidoscopy every 5 years beginning at age 50 or colonoscopy every 10 years
High risk (general)	Annual FOB testing Double-contrast barium enema OR Colonoscopy every 3–5 years starting at age 40
Specific High-Risk Groups	
Prior colorectal cancer	Colonoscopy 1 year postfinding, then every 3 years
Hereditary nonpolyposis colorectal cancers	Colonoscopy screening must begin 10 years before the age at onset of the earliest affected family member OR Colonoscopy every 1–2 years beginning at age 20–25 and continuing until age 35 and then yearly
Inflammatory bowel disease	Annual colonoscopy beginning 8 years after onset of disease
First-degree family history	Colonoscopy every 3–5 years beginning 5 years before the age at onset of the youngest affected relative

Patient Education

Patient education should focus first on the prevention of colon cancer, stressing a diet that is low in fat and refined carbohydrates and high in fiber, fruits, vegetables, and complex carbohydrates. Some studies have shown favorable statistics when individuals supplement their diets with vitamins E and C and beta carotene and pursue a lifestyle that includes exercise. The risk/benefit/cost ratio makes these preventive measures worth suggesting.

HEMORRHOIDS

Hemorrhoids are defined as a mass of dilated and tortuous veins that represent prolapsed submucosal tissue. Hemorrhoids are classified as either internal or external, depending on their location. The primary cause of hemorrhoids is believed to be straining during defecation, which is further complicated by constipation, prolonged sitting, pregnancy, and anal infection. Some hemorrhoids are asymptomatic and require no treatment and typically resolve on their own within 3 weeks; others can result in profuse bleeding, requiring emergency ligation.

Epidemiology and Causes

Every year approximately 1 million people, or 5% of the American population, visit their medical provider for symptoms of hemorrhoids. Although hemorrhoids can occur at any age, their incidence increases with age.

Although the cause of hemorrhoids is not completely known or understood, they are common in countries where there is a known deficiency of dietary fiber. Thus, increased straining during defecation has been recognized as an important predisposing factor in the development of hemorrhoids. Heredity may also be a factor because 10% of the patients with hemorrhoids have a family history of the disease. Patients suffering from illnesses characterized by chronic diarrhea, such as inflammatory bowel disease, are also more likely to develop hemorrhoids.

Pathophysiology

External hemorrhoids are dilated varicose veins originating from the inferior hemorrhoidal plexus and are located below the anal-rectal line. Internal hemorrhoids are a dilation of the veins within the superior hemorrhoidal plexus and are located within the distal rectum and the anal canal.

The inferior hemorrhoidal plexus is prone to increased distention during defecation, which can result in rupture of a vessel and subsequent development of a perianal hematoma or thrombus within one of the vessels of the plexus. Patients who have a thrombosed hemorrhoid may present with a painful perianal lump.

Internal hemorrhoids are further classified by the degree of prolapse present. Table 11.19 describes the difference between each degree of prolapse.

Table 11.19 Classification of Internal Hemorrhoids

Severity	Description of the Process
First degree	Protrude into the lumen of the anal canal, usually without the sensation of protrusion.
Second degree	Protrude beyond the anal canal during defecation but spontaneously reduce when defecation is completed.
Third degree	Protrude beyond the anal canal during defecation but must be manually reduced after the completion of the bowel movement.
Fourth degree	Protrude beyond the anal canal and are permanently prolapsed despite attempts at manual reduction.

Clinical Presentation

Subjective

External hemorrhoids may present with an abrupt onset of pain that is associated with the development of a perianal lump. Many patients complain of more intense pain after defecation or other straining maneuvers, which result in further inflammation and engorgement. Mucus discharge from the anus can lead to poor hygiene and complaints of pruritus. The natural history of a resolved hemorrhoid is the formation of external skin tags, which are asymptomatic but may be irritating and interfere with daily hygiene.

Objective

On physical examination, external hemorrhoids may not be visible at rest but usually protrude on standing or with the Valsalva maneuver. Thrombosed hemorrhoids may appear as shiny, blue masses located at the anus. Evidence of hemorrhoidal skin tags may appear at the site of resolved hemorrhoids; these skin tags are fibrotic and painless.

Internal hemorrhoids most often present with rectal bleeding described as bright red streaks on the toilet paper. Patients may report that blood actually drips into the toilet after a bowel movement. Occasionally the bleeding is sufficient enough to cause anemia, which in any case merits further investigation.

Diagnostic Reasoning

Diagnostic Tests

Initial diagnosis is made by visual inspection of the anal area. Digital rectal examination is not considered an accurate means of diagnosis because most internal hemorrhoids are soft swellings that usually are not palpable,

nor are they painful unless they have thrombosed or become infected, or unless a fissure has developed. External hemorrhoids can usually be diagnosed at physical exam, whereas internal hemorrhoids are visible on physical examination only if they have prolapsed.

Definitive diagnosis of internal hemorrhoids requires anoscopy for a proper inspection of the anal canal. With the anoscope in place, the patient is asked to strain as he or she would while having a bowel movement so that the degree of prolapse can be assessed. Patients may undergo proctosigmoidoscopy to effectively rule out any precipitating or coexisting diseases of the colon or rectum.

Differential Diagnosis

The differential diagnosis of hemorrhoids includes polyps, carcinoma of the anus, anorectal fistula, cryptitis, papillitis, or rectal prolapse. Proctosigmoidoscopy is an effective means of establishing the appropriate diagnosis.

Management

Initial treatment for symptomatic external hemorrhoids is focused on adequate pain relief with oral analgesia and sitz baths. If the hemorrhoids do not spontaneously regress, care is directed at decreasing straining with defecation and modification of toilet habits. Patients are encouraged to avoid sitting on the toilet for long periods of time, to use some form of bulk-forming laxative, and to increase their daily fiber intake slowly to 25 to 35 grams to establish regular, formed stools. Patients who suffer from diarrhea should be treated accordingly to control frequent loose stools. Individuals who suffer from pruritus should be instructed to maintain anal hygiene. Sitz baths, witch hazel, and application of topical hydrocortisone creams are all effective in controlling pruritus. If the external hemorrhoids continue to be painful or bothersome despite treatment, referral for surgical excision should be made.

Medical treatment of internal hemorrhoids follows the same principles previously outlined, with attention toward avoiding straining during defecation, modification of diet with the addition of fiber, increasing fluids, and the addition of bulking agents. If medical treatment is not effective, there are a number of nonsurgical treatments that may be employed. First-degree hemorrhoids can be treated by injection sclerotherapy or infrared coagulation. Infrared coagulation, much like electrocoagulation, uses high-intensity light to shrink the swelling. Second- and third-degree hemorrhoids are normally treated with rubber-band ligation, in which a rubber-banded ring is placed around the base of the hemorrhoid. This band acts a tourniquet, strangulating the tissue while fixing the mucosa proximal to the ligation into the muscularis. All of the nonsurgical techniques used to treat internal hemorrhoids are associated with some degree of pain and bleeding.

Large, advanced-degree hemorrhoids will most often require referral to a surgeon for a formal hemorrhoidectomy. Again, proper anal hygiene and correction of chronic constipation and diarrhea are essential to prevent the recurrence of hemorrhoids.

Follow-up and Referral

Excision of a single external hemorrhoid, evacuation of a thrombosed external hemorrhoid, and injection sclerotherapy of simple internal hemorrhoids can all be performed in the office by a trained provider. Band ligation and other specialized treatment of hemorrhoids will require referral to a gastroenterologist more familiar with these procedures. Follow-up will be based on the patient's postprocedure course. Most patients will require no further care except for instruction on proper anal hygiene and diet. The addition of a nonirritating laxative after the procedure will usually prevent the development of constipation and the associated fear of defecation.

Patient Education

Patient education for hemorrhoids is aimed at preventing the problem through increasing fiber in the diet. Fiber should be increased to 25 to 35 g/day, but this should be done slowly to prevent bloating and gas formation. Teaching patients to read the labels of their food can help them gain control over their nutrition. Often, patients associate salad and cereal with very high levels of fiber. This is not accurate information in many cases; for example, most breakfast cereals have only 1 to 3 g of fiber per serving, and iceberg lettuce has very little fiber as well. Over-the-counter bulking agents, such as psyllium (Metamucil), can be suggested to help eliminate constipation. It is important to teach patients the necessity of drinking no less than 64 ounces of water a day.

Chapter 12

Renal Problems

Debbie J. Nogueras, PhD, MSN, ANP/FNP-BC • Debera J. Thomas, DNS, RN, FNP/ANP • Brian Oscar Porter, MD, PhD, MPH

COMMON COMPLAINTS

DYSURIA

Dysuria is the subjective experience of pain or a burning sensation on urination and can include frequency, hesitancy, urgency, and strangury (slow, painful urination). Symptoms of dysuria can be secondary to several different medical conditions or certain medications; for example, a light burning sensation or discomfort can be normal when associated with concentrated acidic urine. Dysuria is most commonly associated with lower urinary system infection.

Differential Diagnosis

Dysuria is most often associated with a bladder problem and rarely with renal disease. Inflammatory lesions of the prostate, bladder, and urethra—including prostatitis in men, urethrotrigonitis in women, and bladder and urethral infections in men and women—are the most common causes of dysuria. When caused by bladder problems, frequency of urination usually occurs secondary to diminished bladder capacity or with pain when the bladder becomes distended. Urinary frequency may be a manifestation of urinary incontinence and can occur with prostatic hypertrophy or neurogenic bladder disorders.

Other conditions associated with dysuria are bladder tumors, chronic renal failure, nephrolithiasis, and occasionally diseases of the upper urinary system. Dysuria may also be associated with diseases outside the renal system such as sexually transmitted diseases, vaginitis, or prostatitis. For example, female patients may present with symptoms of dysuria or external irritation from the urine passing over the irritated labia. The dysuria may or may not be accompanied by vaginal discharge. Any woman who presents with dysuria should be questioned about an associated vaginal discharge or irritation. The symptoms of dysuria may lead to other diagnoses, including urethral strictures, prolapsed uterus, pelvic peritonitis, cancer of the cervix or prostate, dysmenorrhea, and conditions of the prostate. Prescribed medications such as opiates and those used to prevent motion sickness can also cause dysuria.

Urinalysis is the easiest, least invasive, and most economical way to identify urinary tract infections and other renal problems (Advanced Assessment 12.1). Once the underlying problem has been identified, appropriate treatment can be instituted.

Conditions associated with dysuria, such as bladder tumors, chronic renal failure, nephrolithiasis, and infections of the upper and lower urinary system, are discussed in the Common Problems section of this chapter. Problems associated with conditions of the prostate are discussed in Chapter 13 and those associated with dysmenorrhea in Chapter 14.

HEMATURIA

Hematuria is defined as blood in the urine and can be visible (gross) or occult (microscopic). It is characterized by more than three red blood cells (RBCs) per high-power microscopic field (hpf). Normal urinary excretion of RBCs is 2,000,000 per day, which corresponds to two or three RBCs per hpf. It actually takes very little blood to make the urine look very red. Urine will appear pink between 20 and 30 RBCs per hpf and becomes red at about 100 RBCs per hpf. There is a direct relationship between the quantity of blood found in the urine and the likelihood of pathology.

Transient hematuria occurs on one occasion whereas *persistent hematuria* occurs on two or more consecutive occasions. Both transient and persistent hematuria can be a sign of serious underlying disease. Urine color can vary widely from light pink to dark red and is sometimes characterized as "smoky." The color of urine is dependent on the amount of blood present, as well as on dietary intake, use of medications, and the dilution and pH of the urine. For example, the ingestion of beets can color the urine red to pink, and medications such as rifampin and phenazopyridine (Pyridium) can give urine a reddish-orange color. The presence of porphyrins, hemoglobin, or myoglobin can color the urine reddish-brown. Pus in the urine is indicative of bacterial infection, such as cystitis, urethritis, or prostatitis.

Rates of hematuria can be as high as 15% in the general population but are usually less than 1%. The age, gender, and activity level of the patient with hematuria should be considered on assessment. For example, long-distance runners and other athletes can have rates of hematuria as high as 18%. However, even transient hematuria in men older than age 50 may be an

Advanced Assessment 12.1 Urinalysis

Name	Abnormal Value	Common Differential Diagnosis
Appearance	Colorless	Diabetes insipidus, diuretic agents, fluid overload
	Dark	Hematuria, malignancy, stones, acidic urine
	Cloudy	UTI, hematuria, bilirubin, mucus
	Pink/red	Hematuria, hemoglobin, myoglobin, beets, food coloring
	Orange/yellow	Phenazopyridin, rifampin, bile pigments
	Brown/black	Myoglobin, bile pigments, melanin, cascara, iron preparation
	Green	Bile pigments, methylene blue, indigo carmine
	Foamy	Proteinuria, bile salts
Specific gravity	Increased	Dehydration, congestive heart failure, adrenal insufficiency, diabetes mellitus, nephrosis, antidiuretic hormone
	Decreased	Diabetes insipidus, pyelonephritis, glomerulonephritis, excess fluid intake
pH	Acidic	Diet, medications, acidosis, ketoacidosis, chronic obstructive pulmonary disease
	Alkaline	Diet, sodium bicarbonate, vomiting, metabolic alkalosis, UTI
Bilirubin	Positive	Jaundice, hepatitis
Blood	Positive	Kidney stones, tumors, kidney disease, trauma, infection, injury from instrumentation, coagulation problems, menses
Glucose	Positive	Diabetes mellitus, pancreatitis, Cushing's disease, shock, burns, steroids, renal disease, hyperthyroidism, cancer
Ketones	Positive	Starvation, diet, ketoacidosis, vomiting, diarrhea, pregnancy
Nitrate	Positive	Infection
Protein	Positive	Kidney disease, pregnancy, congestive heart failure, diabetes mellitus, cancer, benign cause
Leukocyte esterase	Positive	Infection
Reducing substance	Positive	Medications, glucose, fructose, galactose Liver disease, hyperthyroidism

indication of serious disease, with up to 2.4% of this population having urinary tract malignancies, typically a transitional cell carcinoma. In men older than age 60, this incidence of urinary tract malignancy increases to 9%. In older men with gross hematuria, the rate of associated malignancy is as high as 20%. In general, there is a higher correlation between underlying malignancy and gross hematuria as opposed to microscopic hematuria, especially in patients with a history of cigarette smoking.

Differential Diagnosis

A drug history is important because many drugs can cause hematuria. In addition, dietary substances such as caffeine, spices, tomatoes, chocolate, alcohol, citrus fruits, and soy sauce may act as bladder irritants. The patient's drug and food intake history should be assessed to rule out these substances as the causative agent. The drugs involved may be prescribed, over the counter, herbal, supplemental vitamins, or recreational in nature.

Some medications—beta-lactam antibiotics, sulfonamides, NSAIDs, rifampin, ciprofloxacin (Cipro), allopurinol (Zyloprim), cimetidine (Tagamet), and phenytoin (Dilantin)—can cause *nephritis,* which can result in destruction of nephrons and subsequently lead to impaired renal function and hematuria. Other conditions such as anticoagulation and papillary necrosis can result from the use of anticoagulants such as warfarin (Coumadin), heparin, aspirin, and NSAIDs. Glomerulonephritis can be caused by the use of hydralazine, hydrocarbons (including glue and paint sniffing), gold, penicillamine, amphetamines, NSAIDs, allopurinol, and Paraquat. Urolithiasis (discussed later in this chapter) can occur from the use of carbonic anhydrase inhibitors, triamterene, sulfonamides, and vitamin D metabolites and often presents with hematuria.

Menstrual history is always important in a female patient, as well as history of recent strenuous exercise, streptococcal infection (especially poststreptococcal glomerulonephritis), or nephrolithiasis; family history

(e.g., of polycystic kidney disease); and recent travel (potential exposure to parasitic infections). Gross painless hematuria is a cardinal symptom of certain malignancies such as bladder cancer.

The physical exam may reveal costovertebral angle tenderness, which could indicate pyelonephritis, tumor, or glomerulonephritis. An abdominal mass may indicate a neoplasm (renal cell cancer) or polycystic kidney disease. Suprapubic tenderness is indicative of a bladder etiology, whereas urethral discharge indicates a urethritis. An enlarged prostate could indicate benign prostatic hypertrophy, whereas a tender prostate would more likely be suggestive of prostatitis; a prostate nodule may indicate a neoplasm. Skin lesions (e.g., ecchymosis) may indicate an underlying coagulopathy or vasculitis.

The most important diagnostic test in cases of hematuria is urinalysis. One major drawback of doing a urine dipstick test is that it detects the presence of heme (an iron-containing nonprotein portion of the hemoglobin molecule) in the urine but not RBCs. If the dipstick is positive for heme, but the number of RBCs on the microscopic exam is within normal limits, myoglobinuria and hemoglobinuria should be suspected. When hematuria of renal origin is suspected, laboratory tests should include antinuclear antibodies (ANAs); immunoglobulins; cryoglobulins; antiglomerular basement membrane antibodies; a full chemistry panel, including creatinine clearance and blood urea nitrogen; complete blood count and platelets; antistreptolysin O (ASO) titer; serum protein electrophoresis; and a Venereal Disease Research Laboratory (VDRL) test (to rule out syphilis). If these studies indicate a renal problem, the patient should be referred to a nephrologist. A urine culture and sensitivity should be done on all patients with hematuria, and if bacterial infection is found, treatment with appropriate antibiotics should be instituted with reevaluation for a persistent hematuria 2 weeks after completion of treatment.

Isolated asymptomatic hematuria is often found on a routine screening urinalysis with no apparent source determined by history and physical exam. The possibility of occult malignancy or other potentially serious etiology increases with age, and if the patient is older than age 40, he or she should be evaluated for urological tumor. Patients younger than age 40 should be monitored at least monthly for 3 months, and if the hematuria persists a more aggressive work-up is indicated.

Examination of the morphology of RBCs present in the urine using phase-contrast microscopy can provide clues as to the etiology of hematuria. Dysmorphic RBCs may indicate glomerular disease. A fresh urine sample is essential, because changes in morphology occur if the urine is allowed to sit. If the hematuria persists without evidence of infection, an intravenous pyelogram or renal ultrasound should be done to assess kidney structure. A computed tomography (CT) scan is the preferred imaging method for follow-up if a possible solid renal mass is found. Other tests that should be done include a prothrombin time and partial thromboplastin time, a purified protein derivative test, erythrocyte sedimentation rate, an ANA test and complement level, antistreptococcal enzyme titers (ASO, anti-DNase B), cryoglobulin screen, and a urinalysis for cytology.

Cystoscopy is done to evaluate the upper urinary tract, and cytology can be done to evaluate the lower urinary tract. If the findings of these studies are negative and the patient continues to have gross hematuria, further investigation should include a CT scan, arteriogram, and/or ureteroscopy. The outcome of these studies will determine whether a referral for urologist or nephrologist follow-up is necessary.

The causes of hematuria are grouped according to anatomical site of the blood source. For example, *isolated hematuria* (no other abnormal urine components) may be from bleeding anywhere from the renal pelvis to the urethra, but is rarely caused by systemic disease. RBC casts usually indicate injury to the nephron and are diagnostic of hematuria of a renal origin. However, intact uniform RBCs with no casts suggests hematuria originating in the lower urinary tract. The presence of bacteria in the urine is diagnostic of a bacterial origin, as is fever. Acute cystitis and urethritis produce gross hematuria and are more common in women. The presence of both proteinuria and hematuria is suggestive of glomerular or interstitial nephritis. Hematuria accompanied by colicky flank pain suggests a ureteral stone. When bleeding occurs only at the beginning or end of urination, a prostatic or urethral source is likely. Hematuria accompanied by hypertension, edema, and a sore throat or a skin infection may be indicative of glomerulonephritis. Thirty percent of patients with gross hematuria are diagnosed with a malignancy of the prostate, urethra, bladder, kidney, or ureter. Differential Diagnosis 12.1 lists possible differential diagnoses of hematuria.

PROTEINURIA

The primary proteins found in urine are globulin and albumin. *Proteinuria* is usually indicative of a renal pathology, most often of glomerular origin. Proteinuria can be functional as a result of acute illness, emotional stress, or excessive exercise and is a benign process. It can also develop from overproduction of filterable plasma proteins, especially Bence Jones proteins associated with multiple myeloma. Abnormalities in the glomerular basement membrane produce glomerular proteinuria. Damage to the proximal tubule where filterable proteins are reabsorbed can result in tubular proteinuria.

Intermittent proteinuria is most often asymptomatic and discovered incidentally through urine dipstick testing and is associated with functional disorders. Continuous proteinuria is associated with renal pathology. The dipstick test does not detect Bence Jones proteins or light chain immunoglobulins and is most sensitive to albumin. A false-negative reading can occur because of a diluted urine

Differential Diagnosis 12.1 Hematuria

Problem	Differential Diagnoses
Urethra	Urethritis (gonococcal, nongonococcal)
	Stricture
	Calculus
	Trauma
Prostate/male genitourinary tract	Infection (prostatitis, epididymitis)
	Benign prostatic hypertrophy
	Tumor
Kidney	Infection (pyelonephritis)
	Nephrolithiasis
	Cancer (renal cell)
	Trauma
	Glomerular disease (vasculitis, idiopathic)
	Ischemia (embolism, thrombosis, papillary necrosis)
	Allergic interstitial nephritis (drug induced)
Ureters	Nephrolithiasis
	Tumor
	Endometriosis
Bladder	Infection (bacterial, parasitic)
	Calculus
	Tumor
	Endometriosis
	Drugs (hemorrhagic cystitis)
Pseudohematuria	Menstrual contamination
	Phenothiazines
	Red food dye
	Quinine
	Rifampin
	Hemoglobinuria
Systemic illness	Intense exercise
	Coagulopathies (thrombocytopenia, hemoglobinopathy, sickle cell)

sample, alkaline pH (normal 4.5–8 [usually 5.5–6.5]), or Bence Jones proteinuria. The most accurate way to quantify the amount of protein in the urine is a 24-hour urine collection; however, a spot urine albumin to urine creatinine ratio can be measured and is a close approximation of the 24-hour urine measurement. A 24-hour urine with more than 165 mg of protein is considered abnormal and a specimen with more than 3.5 g is indicative of a nephrotic problem. A urine albumin to urine creatinine ratio of less than 0.2 is normal and corresponds to an excretion of less than 200 mg/dL of protein.

Differential Diagnosis

Proteinuria may occur from "benign" causes. Causes of benign, or functional, proteinuria include orthostatic proteinuria, exercise, environmental conditions, fever, and acute illnesses. Orthostatic proteinuria occurs when the protein level is elevated only when the patient has been standing but not while he or she has been reclining. Exercise-induced proteinuria may occur in athletes such as runners or boxers; it may be accompanied by elevated catecholamines, hemoglobinuria, or hematuria. Proteinuria caused by environmental conditions such as emotional stress, exposure to cold, prolonged lordotic posture, and excess in the body's norepinephrine level will resolve spontaneously when the precipitating element is eliminated or removed. A mild, transient proteinuria may result from an albumin infusion or acute illnesses such as fever, congestive heart failure, acute pulmonary edema, head injury, or cerebrovascular accident; this type of proteinuria typically resolves as the medical condition improves.

When proteinuria is identified in a low-risk (nondiabetic or nonpregnant) patient, the urine should be tested for Bence Jones protein, the presence of which suggests multiple myeloma. In addition, a full chemistry panel should be done, including a fasting blood sugar, a lipid profile, urine culture and sensitivity, and a complete blood count with differential. If the patient's urine is positive for Bence Jones proteins, a serum protein electrophoresis should be done. Proteinuria associated with multiple myeloma, lymphosarcoma, Hodgkin's disease, and leukemia is called Bence Jones proteinuria. Bence Jones proteinuria is characterized as a free monoclonal light chain of protein.

Any persistent proteinuria that is not classified as functional proteinuria requires further work-up, beginning with a 24-hour measurement of urine protein and creatinine levels. If the excretion rate is above 3.0 to 3.5 g/day, the patient, by definition, has nephrotic syndrome and must be referred to a nephrologist. Nephrotic syndrome can lead to acute renal failure, hypertension, and end-stage renal failure.

If the excretion rate of protein is more than 2 g in 24 hours, a glomerular cause is most likely and further evaluation is warranted. If renal function is normal in a patient with an elevated urine protein, the patient should then be evaluated for orthostatic proteinuria. This involves having the patient collect a urine specimen on awakening but before assuming an upright position for longer than 1 minute. After the patient has been standing or walking for 2 hours, a second specimen is collected. If the patient has orthostatic proteinuria, the first specimen will be free of protein and the second will be positive for protein, and referral to a nephrologist is necessary. Although this condition is largely benign and self-limiting, orthostatic proteinuria is not well understood. Patients with nonorthostatic proteinuria and normal renal function in whom no Bence Jones proteins have been detected should also be referred to a renal specialist for renal biopsy. Proteinuria associated with a specific disease process involving the renal system is presented in Table 12.1.

Table 12.1 Proteinuria

Type of Proteinuria	Major Mechanism	Disease Process
Bence Jones proteinuria	Elevated plasma concentration	Multiple myeloma (lymphosarcoma, leukemia, Hodgkin's disease)
Tamm-Horsfall proteinuria	Increased tubular cell secretion	Normal mucoprotein in urine
Tubulointerstitial area involvement	Decreased tubular reabsorption of normal filtered protein	Pyelonephritis
Altered glomerular capillary permeability	Increase of filtered proteins	Glomerulonephritis, nephrotic syndrome
pH > 8.0	High-alkaline urines	False positive

Management of proteinuria depends on the underlying cause. Angiotensin-converting enzyme agents have been found to reduce proteinuria by decreasing interglomerular pressure. If hyperlipidemia and/or hypertension are present, they should be aggressively treated. Patients found to have chronic renal failure should also be aggressively managed to prevent or delay the onset of end-stage renal disease.

COMMON PROBLEMS

URINARY INCONTINENCE

Urinary incontinence (UI) is the involuntary loss of urine from the bladder. Incontinence is so frequent in women that many consider it normal. Incontinence is also common in older men as a result of an enlarging prostate. Incontinence can affect a person's quality of life and may be psychologically devastating. Ignoring the incontinence, or inadequate treatment of this condition, can lead to social isolation, body image problems, anxiety, or depression; therefore, prompt treatment is essential (see the Iceberg of Incontinence).

Epidemiology and Causes

The direct cost of treating and managing UI is reported to be more than $26 billion per year and affects more than 25 million Americans. Costs include diagnostic testing, medication, and adult incontinence products such as disposable pads and undergarments. One study estimates that more than 40% of American women are affected, and there seems to be a strong association between urinary incontinence and major depression. The prevalence of UI in the community population varies from 5% to 15% depending on age and gender, and more than 50% of the patients in long-term care facilities have incontinence. Women are more likely than men to have incontinence, and the incidence increases with age; in fact, the risk of UI increases 14% with each decade of life.

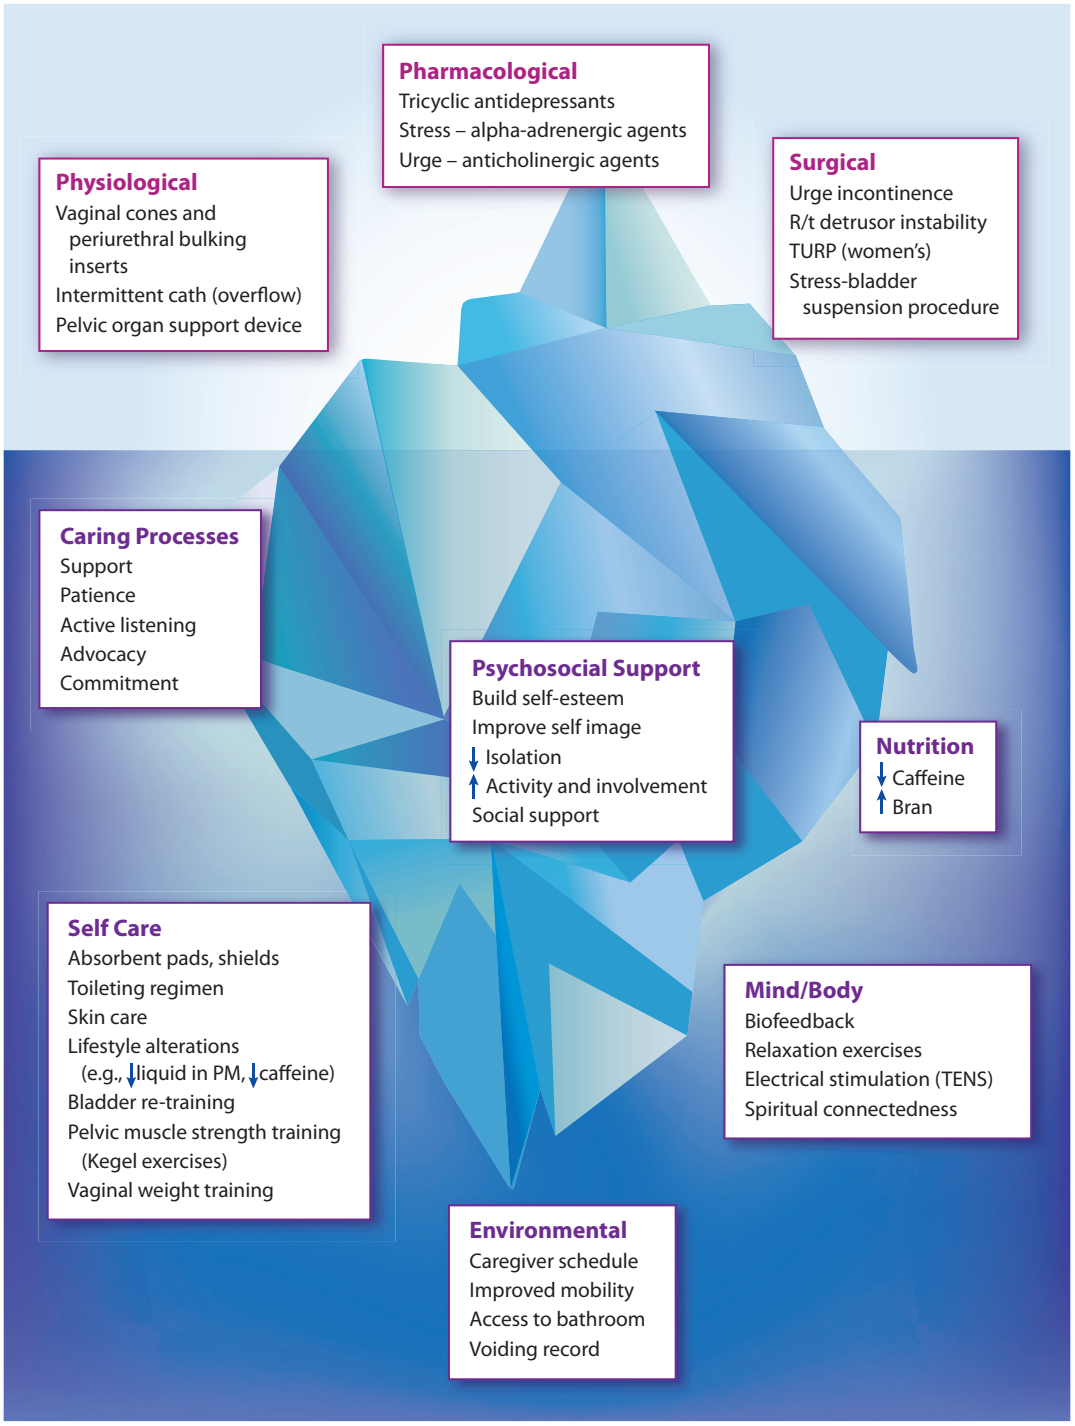
Transient UI is characterized by a sudden onset and can have several causes including delirium, infection, pharmacological agents, or underlying systemic illnesses such as diabetes, fecal impaction, and restricted mobility. Most new-onset incontinence that occurs in the hospital resolves with appropriate treatment, but this acute transient phase can become a chronic problem if left untreated. The basic types of persistent UI are categorized as stress, urge, overflow, and functional UI. A patient may present with mixed symptoms of urge and stress incontinence. Table 12.2 provides an overview of the types of urinary incontinence.

Pathophysiology

An understanding of incontinence requires knowledge of the physiology of micturition. Three major components are involved in urine storage and release: the central nervous system (CNS), the bladder, and the bladder outlet (urethral sphincters). Within the CNS, micturition is controlled by both the cortical (central) and brainstem (pontine) micturition centers. The cortical micturition center coordinates inhibitory stimuli from the frontal lobes and basal ganglia, permitting bladder relaxation and filling, as well as urethral sphincter closure to prevent urinary leakage, as the bladder increases in size. These efferent signals emanate from spinal levels T11 to L2 and are mediated by alpha-adrenergic receptors and cholinergic somatic stimulation. This maintains urethral pressure along the bladder outlet by both internal and external sphincters. Alpha-adrenergic stimulation causes muscle contraction of the internal sphincter, whereas the external sphincter is under voluntary control of striated muscle tissue (allowing patients to "hold their urine" for purposes of social appropriateness).

In contrast, bladder emptying is mediated by the parietal lobes and thalamus, which modulate afferent proprioceptive stimuli from the distended bladder wall detrusor muscle, sensing an increase in bladder pressure that is interpreted as bladder fullness. Once the patient has the urge to void, the inhibition by the cortical micturition center ceases. In turn, the brainstem micturition center sends impulses from the pons down the spinal cord to the sacral micturition center at S2 to S4,

The Iceberg of Incontinence



subsequently triggering the bladder detrusor muscle to contract via cholinergic stimulation of parasympathetic M2 and M3 type muscarinic receptors found within the smooth muscle of the bladder walls. This latter action is simulated by the pharmacological agent bethanechol (Urecholine), which is used to treat urinary retention from an atonic or poorly responsive bladder. In addition, preganglionic sympathetic inhibition relaxes the urethral sphincter, allowing for the egress of urine.

Age-related changes that may affect urological functioning are decreased bladder capacity, increased postvoid residual urine volume (greater than 50 mL), increased disinhibition of bladder contractions (i.e., overactive bladder), increased nocturnal sodium and

Table 12.2 Types of Urinary Incontinence

Type	Cause	Assessment	Management
Stress	Failure to store due to hypermobility of bladder neck, intrinsic sphincter deficiency, neurogenic sphincter deficiency Medications: Sedatives, hypnotics, antispasmodics	History of vaginal deliveries, urine leakage with cough or sneeze Evidence of urine loss Pelvic exam, pad test, stress test, urinalysis culture and sensitivity, video-urodynamics, cystometrogram	Pelvic floor reeducation with biofeedback (Kegel exercises) Weight loss, if obese Electrical stimulation Hormone replacement therapy (estrogen) Alpha-adrenergic agonist Surgical correction of hypermobile bladder neck Periurethral bulking injections
Urge	Failure to store due to urinary tract infection; vaginitis; bladder stones and tumors; cortical, subcortical, and suprasacral lesions; cerebrovascular accident; dementia; multiple sclerosis; Parkinson's disease; spinal cord transection Medications: Diuretics, narcotics	History of dysuria, frequency, urgency, hematuria, nocturia Evidence of a large amount of urine loss, evidence of unstable detrusor with decreased capacity Assess perineal hygiene Pelvic exam, smear, neurological exam, urinalysis, culture and sensitivity, cystometrogram, video-urodynamics	Antimicrobial agents, antiseptics, topical estrogen, anticholinergics, smooth muscle relaxers, tricyclic antidepressants, imipramine Pelvic floor reeducation with biofeedback (Kegel exercises) Prompted voiding and scheduled voiding Fluid intake management Removal of bladder stones, resection and/or tumor treatment
Overflow	Failure to empty due to underactive detrusor, outlet obstruction, diabetes mellitus Medications: Anticholinergics, disopyramide, antihistamines, calcium channel blockers	History of hesitancy, dribbling, decreased stream, feeling of not emptying, constipation Neurological exam, prostate exam (for males), prostate-specific antigen (for males), urinalysis, culture and sensitivity, serum creatinine, voiding cystometrogram, video-urodynamics	Scheduled toileting (Credé's maneuver) Treatment of underlying conditions Collection devices (intermittent or suprapubic) Alpha blockers Resection of prostate, balloon dilation
Functional	Delirium, fecal impaction, manual dexterity and immobility Medications: diuretics, hypnotics, alcohol, narcotics, decongestants	Fecal impaction Assess sleep patterns, mental state, hearing, vision, functional ability, intake and output, accessibility, infection, neurological function	Remove barriers Provide barrier-free environment Bowel and bladder program Collection devices Physical therapy Habit training

fluid excretion (nocturia), urinary overflow phenomena resulting from increased urethral resistance in men related to benign prostatic hypertrophy (BPH), and weakness of the pelvic muscle walls in women. Postmenopausal estrogen deficiency can result in decreased competence of the internal and external sphincters via atrophy of the urethral mucosal epithelium resulting in atrophic urethritis, loss of compliance, and a diminished urethral mucosal seal. It is important to note, however, that normal aging in and of itself does not cause urinary incontinence.

Clinical Presentation

Subjective

All assessments of the urinary system should begin with a detailed medical and surgical history, including the patient's voiding history. A voiding history includes the date of incontinence onset; number of times per day or night the patient voids; amount of urine voided each time; fluid-intake history, with types of fluids consumed; and the characteristics of the urinary incontinence, such as "occurs when sneezing," nocturia, frequency, urgency,

or dysuria. Information regarding underlying medical conditions such as diabetes, cancer, acute illness, and neurological disease should be elicited.

Objective

The aim of the physical exam is to identify the underlying pathophysiological causes of incontinence, which can be multiple. The neurological assessment is important in differentiating diagnoses such as cerebrovascular accident (CVA) and Parkinson's disease and should include an assessment of the functional and cognitive ability. This provides information about limitations in mobility, self-care ability, mental status, and communication barriers, such as aphasia or language.

An abdominal exam should be done to rule out constipation, fecal impaction, masses, distended bladder, or cystitis, which can lead to incontinence. A pelvic exam will reveal the pelvic muscle strength, conditions such as uterine prolapse, and any problems associated with perineal structures. Inspection of the skin around the pelvic area is important. For example, in women, there may be atrophic vaginitis; in men, there may be abnormalities of the foreskin, penis, or perineum. A rectal exam should be done to determine the sphincter tone and the presence or absence of feces, to support causative complications such as fecal impaction. In men, a prostate exam is crucial in evaluating urinary tract complaints. The skin condition should be evaluated for breakdown or pressure areas during the pelvic exam because incontinence can lead to skin breakdown in the perineal area and buttocks which then can lead to decubitus ulcers. In female patients, particularly postmenopausal women, the perineum should be assessed for dryness and atrophy from decreased estrogenization of the vaginal mucosa.

During the physical exam, signs of congestive heart failure should be assessed; a cough stress test (which will allow direct observation of urine loss with a full bladder), bladder scan, or, if necessary, catheterization to determine postvoid residual volume should be done as well. The patient or caretaker should be instructed to keep a voiding record for 3 to 7 days. The voiding record includes the time of the incontinence episode, the amount of urine, whether there was an urge to void, and the patient's activity at the time of the voiding. This record also includes an hourly record of fluid intake. For patients with a questionable history of UI, a "pad test" can be done. This involves having the patient take oral phenazopyridine (Pyridium), which will color the urine orange, and then wear a sanitary pad that can be checked at intervals for staining.

Diagnostic Reasoning

Diagnostic Tests

A urinalysis and urine culture and sensitivity should be done, as well as measurements of serum electrolytes, blood urea nitrogen, creatinine, calcium (for polyuria in the absence of diuretics), and glucose. Catheterization to assess postvoiding residual volume is important even on initial evaluation of the patient. Further testing will also depend on whether the onset of incontinence is acute, in which case testing related to other concurrent conditions may be warranted. The urinalysis is often normal but may show glycosuria (in patients with diabetes), proteinuria (in patients with glomerular disease), white blood cells (in patients with a bacterial infection), red blood cells (which may indicate the presence of a tumor), or bacteria (another sign of infection). A urine culture that is positive for bacteria also indicates infection; specific findings can be used to guide antibiotic therapy.

Other diagnostic options include urodynamic testing and cystometry, cystometrogram, video-urodynamics, and a postvoid residual catheterization to indicate the amount of retained urine. Reviewing the patient's use of medications for possible drug interaction, obtaining an accurate record of intake and output, and evaluating for other risk factors contributing to UI are also important. Patients who have indwelling catheters should be urodynamically evaluated for possible bladder retraining. Renal ultrasound may show renal pathology; a transrectal ultrasound can provide evidence of prostate disease; and a pelvic ultrasound may demonstrate pelvic pathology. A cystogram may show abnormal sphincter pressure or bladder pathology.

Differential Diagnosis

Many older patients may normally compensate for their incontinence, but any alteration—either physiologically or psychologically—such as a hospitalization can precipitate an acute onset of incontinence. The administration of IV hydration in an acutely ill or older adult may be sufficient to precipitate incontinence. Although the endpoint is the same for all types of incontinence (involuntary bladder emptying), the context in which this occurs may vary markedly. Thus, the primary goal of differential diagnosis is for the clinician to correctly identify the type and etiology of incontinence, which in turn drives management and treatment decisions.

In persistent UI, a number of factors must be evaluated. Normal micturition requires the coordination of both the central and peripheral nervous systems. The cerebral cortex exerts an overall inhibitory influence on the sacral spinal cord reflex. Delirium, dementia, parkinsonism, and stroke may all lead to urge incontinence without awareness. The brainstem, on the other hand, and the suprasacral spinal cord exert a predominantly facilitating and coordinating influence that may be overcome in disorders such as stroke and multiple sclerosis, leading to overflow incontinence without awareness. This is referred to as neurogenic or detrusor-sphincter dyssynergy. Local irritation and bladder or outflow obstructions may also lead to urge incontinence without awareness. Injuries to the sacral cord, which controls

reflex bladder filling and emptying, persistent outlet obstruction, and diabetes mellitus may all lead to an acontractile bladder and overflow incontinence without awareness. Likewise, the bladder and lower genitourinary tract must perform their storage and emptying functions properly for normal micturition. Failure to store urine may be a result of a hyperactive or poorly compliant bladder (e.g., secondary to cystitis, stones, tumor, or diverticuli), leading to urge incontinence. Laxity of pelvic floor muscles, bladder outlet, or sphincter weakness all may cause diminished outflow tract resistance, leading to stress incontinence. The bladder may fail to empty completely if it is poorly contractile as a result of diabetes mellitus, thus resulting in overflow incontinence. Increased outflow obstruction may be caused by anatomical obstruction by the prostate, stricture, or cystocele, resulting in chronic urinary retention and overflow incontinence.

Mixed types of incontinence are the norm rather than the exception; many patients have an overlap of pathologies. Just as multiple etiological factors must be considered, a broad variety of interventions must be made available and are best approached through the *Circle of Caring.*

Management

Stress Incontinence

Stress incontinence is the involuntary loss of urine resulting from increased intra-abdominal pressure such as coughing, sneezing, and laughing. In this condition, the bladder is unable to retain urine because of hypermobility of the bladder neck, intrinsic sphincter deficiency, neurogenic sphincter deficiency, or use of medications such as sedatives, hypnotics, alpha blockers, and/or antispasmodics. Patients who present with stress incontinence report urine leakage with coughing or sneezing and typically have a history of vaginal deliveries and/or hysterectomy, as well as evidence of urine loss. A detailed history guides the diagnostic work-up, which will then include a pelvic exam, pad test to determine the amount and frequency of leakage, cough stress test, urinalysis with culture and sensitivity, video-urodynamics, and/or cystometrogram.

Once the diagnosis of stress incontinence has been made, treatment should be individualized and instituted to meet the patient's needs. Noninvasive treatments include pelvic floor reeducation (Kegel exercises) with biofeedback, weight loss (if the patient is obese), electrical stimulation, and medications such as alpha-adrenergic agonists, which improve the muscle tone of the urinary tract. Eliminating diuretics will also improve symptoms. Surgical options include correction of hypermobile bladder neck and periurethral bulking injections. See Drugs Commonly Prescribed 12.1 for a list of medications used for UI.

Urge Incontinence

Urge incontinence, also known as detrusor instability, is the involuntary leakage of urine resulting from inability to delay voiding. The patient has the sensation of a full

Drugs Commonly Prescribed 12.1 Urinary Incontinence

Drug	Indication	Adverse Reactions and Prescribing Considerations
Anticholinergic/Antispasmodic Agents		
tolterodine (Detrol LA) oxybutynin (Ditropan XL) solfenacin (Vesicare) darifenacin (Enablex) trospium chloride (Sanctura XR) transdermal oxybutynin (Gelnique) fesoterodine (Toviaz)	Urge incontinence Overactive bladder (OAB) Stress incontinence	**Contraindications:** Closed-angle glaucoma Myasthenia gravis Partial or complete gastric obstruction Severe colitis Urinary retention Gastric retention **Side effects:** Dry mouth Drowsiness Blurred vision Urinary hesitance Urinary retention Decreased GI motility Headache Constipation Vertigo/dizziness Abdominal pain

Drugs Commonly Prescribed 12.1 Urinary Incontinence—cont'd

Drug	Indication	Adverse Reactions and Prescribing Considerations
Topical Estrogen		
Premarin cream (conjugates estrogen) Estrace cream Estring	Stress incontinence Urge incontinence associated with atrophic vaginitis	**Contraindications:** Hypersensitivity Breast cancer Thromboembolic disorders Estrogen-dependent neoplasia Abnormal genital bleeding Pregnancy **Side effects:** Premenstrual syndrome–like syndrome Amenorrhea Nausea/vomiting Headache Dizziness Depression Changes in libido Dysmenorrhea Breakthrough bleeding Breast tenderness Photosensitivity Endometrial cystic hyperplasia
Alpha-1-Adrenergic Blocking Agents (Men)		
tamsulosin hydrochloride (Flomax) terazosin hydrochloride (Hytrin) doxazosin mesylate (Cardura)	BPH and related urinary symptoms	**Contraindications:** Hypersensitivity to tamsulosin terazosin, or doxazosin **Side effects:** Orthostatic hypotension Palpitations Dizziness Impotence GI upset Headache
Tricyclic Antidepressants		
imipramine (Tofranil) amitriptyline (Elavil)	OAB Urge incontinence	**Contraindications:** Hypersensitivity to tricyclic antidepressants Use of monoamine oxidase inhibitors **Side effects:** Dry mouth Urinary retention Blurred vision Orthostatic hypotension Sedation Confusion in the elderly Tachycardia Anxiety and nervousness Sexual dysfunction Constipation

bladder but is not able to store the urine long enough to reach the toilet. This failure can be caused by urinary tract infection; vaginitis; bladder stones; bladder tumors; cortical, subcortical, and suprasacral lesions; CVA; dementia; multiple sclerosis; Parkinson's disease; prostate problems; spinal cord transection; and medications such as diuretics and narcotics. The patient's history and physical exam may reveal evidence of dysuria, increased frequency or urgency, hematuria, large amounts of urine loss, and unstable detrusor muscle with decreased capacity, or nocturia. Assessment should include perineal hygiene, pelvic exam and a vaginal discharge smear, and a neurological exam including an assessment of mental status; a urinalysis with a culture and sensitivity should also be ordered. Invasive procedures that may be needed include cystometrogram and video-urodynamics.

Treatment begins conservatively, with pelvic floor reeducation and biofeedback, if the patient is capable. A prompted and/or scheduled voiding by a caregiver, with management of the patient's fluid intake, may be useful for patients who have cognitive impairments or are forgetful. Medications such as antimicrobial agents may be necessary to treat underlying conditions. Other medications may include topical estrogen, anticholinergics, smooth muscle relaxants, and tricyclic antidepressants to improve the neuromuscular function of the bladder and sphincter (see Drugs Commonly Prescribed 12.1). Surgical treatment may be indicated for the removal of bladder stones or tumors.

Overactive Bladder

The term *overactive bladder* (OAB) is often used interchangeably with the term *urge incontinence;* however, they are different conditions. OAB is a syndrome of symptoms that include urgency, frequency, and nocturia, all of which are associated with involuntary contractions of the detrusor muscle. Urge incontinence may or may not be a feature of this syndrome; about one-third have urge incontinence. OAB may occur as a component of other types of UI, such as with stress incontinence. The cause of OAB is multifactorial in that it can include disorders of the lower urinary tract, ingestion of alcohol and caffeine, use of a variety of prescribed drugs, or neurological conditions. This condition is most common in women and often results in anxiety and depression because of the restricted daily functioning. Sexual dysfunction can occur because of the fear of urine loss during sexual intercourse.

Treatment for OAB first begins with identifying women with the problem. It is estimated that only about 6% to 27% of women with this condition seek treatment. Nonpharmacological methods mentioned earlier are used to manage OAB as well, but pharmacotherapy plays an important role. Antimuscarinic agents are the most commonly used drugs and are effective because they block the parasympathetic stimulation of the detrusor muscle by blocking acetylcholine. See Drugs Commonly Prescribed 12.1 for a complete list of medications used for OAB.

Overflow Incontinence

Overflow incontinence is the involuntary leakage of small amounts of urine. This is caused by an overdistended bladder in a patient who does not feel the need to void because of an atonic detrusor muscle, outlet obstruction, BPH, diabetes mellitus, or use of medications such as anticholinergics, disopyramide (Norpace), antihistamines, diuretics, or calcium channel blockers. The history and physical exam may indicate hesitancy, dribbling, nocturia, decreased stream, feeling of not emptying the bladder, and/or constipation. A neurological exam, prostate exam, urinalysis with culture and sensitivity, serum creatinine, voiding cystometrogram, and/or video-urodynamics should be done.

Management of incontinence consists of treating the underlying condition; teaching scheduled toileting and Credé's maneuver; and the prescribing of medications such as alpha blockers (see Drugs Commonly Prescribed 12.1). It may be necessary to discontinue certain medications or to alter dosages to reduce the adverse effects causing overflow incontinence. Teaching scheduled toileting and Credé's maneuver to force the urine from the bladder may be helpful. Credé's maneuver involves applying pressure over the symphysis pubis and slowly pressing down. This is particularly helpful in patients who have a spinal cord injury or other neurological problems. Alternative collection devices may be indicated, including the use of external catheters; pads; and indwelling, intermittent, or suprapubic catheterization. In the case of outlet obstruction, a resection of the prostate may be necessary.

Functional Urinary Incontinence

Functional UI is incontinence that occurs in a normal functioning urinary system. The leakage of urine is caused by factors outside the lower urinary tract and can be transient in nature. The causes of functional incontinence may vary from delirium or fecal impaction to lack of manual dexterity and immobility problems. Medications such as diuretics, hypnotics, narcotics, and decongestants, as well as alcohol, may also play a role. Assessment for fecal impaction, sleep pattern disturbances, mental status, hearing and vision, functional ability, fluid intake, infection, and neurological function is essential.

Treatment for functional incontinence consists of removing barriers, providing education regarding a scheduled bowel and bladder program and the use of collection devices, referring patients for physical or occupational therapy, and habit training. Barriers to elimination may be identified when the patient cannot remove clothing or reach the toilet in sufficient time to avoid leakage. By identifying the barrier(s), interventions to resolve the problem can be developed. Some solutions

include the use of hook-and-loop (Velcro) closures (which are easily managed by arthritic hands and fingers) instead of buttons and zippers, bedside commodes for nighttime use to eliminate the amount of time needed to get to the bathroom, or monitors for obtaining immediate assistance in getting out of bed and to the toilet.

A caregiver may be necessary to assist the patient in toileting; therefore, it is imperative to assess the caregiver's ability to provide care and determine his or her level of competency. Nursing research shows that caregivers want to give "good" care; however, the caregiver must be physically capable of providing the care through manual dexterity, strength, and cognition. Further, the caregiver must be able to comprehend and follow through with instructions that may be complex and require problem-solving ability.

Identifying patients who need physical or occupational therapy to improve their functional skills may be required. Initiation of a bowel and bladder program can decrease the incidence of constipation and fecal impaction; patients should also be encouraged to retrain the bladder to empty completely on a regular basis. For patients who cannot avoid UI, alternatives are available to keep them clean and dry. Condom catheters are effective in keeping male patients dry, and pads of various types are available for both males and females. Indwelling catheters, suprapubic catheters, and intermittent catheterization are options for urine collection in patients who cannot maintain bladder function or who have frequent or regular UI.

Medications used to treat incontinence are effective for patients who suffer from the inability to store urine. Pharmacological agents should be used in conjunction with other treatment modalities such as toileting and behavioral modification. Scheduled toileting along with regulation of fluid intake can have a positive effect on bladder control. Behavioral modification treatment such as pelvic floor reeducation is designed to increase pelvic floor muscular strength and endurance. Reeducation is accomplished through Kegel exercises of the targeted muscle group using biofeedback for a period of 4 to 6 weeks. Kegel exercises are the tightening and releasing of the pubococcygeal and levator ani muscles, accomplished by tightening the muscle group used to avoid defecation or urination. The patient may experience results within 2 weeks to several months of initiating the program. This treatment is noninvasive and, when appropriate, should be attempted before surgical intervention (Table 12.3).

Vaginal cones or rings may be used to retain the uterus in a more normal position. Cones can reduce the pressure on the bladder of the prolapsed uterine musculature.

Surgical intervention may be appropriate if all other measures have failed or in conjunction with the previous conservative approaches. Surgery may be indicated to correct anatomical abnormalities such as prolapsed uterus, hypermobile bladder neck, or obstructions such as enlarged prostate or tumors. Surgery should be used as the last treatment option unless the causative agent is diagnosed as a tumor or severe obstruction.

Table 12.3 Kegel Exercises

Instructions for the patient:

- Locate the correct muscle. To do so, try stopping your urine flow by contracting the muscle. When the urine slows or stops, you are using the pubococcygeus (PC) muscle.
- Squeeze the muscle for 2 seconds. (Do not hold your breath or contract your abdomen, buttocks, or thighs.) Then relax for 10 seconds. This is one repetition. Do 10 repetitions twice a day.
- After you have mastered the technique, begin to lengthen the time you contract the muscle. Increase the time by 1 second every few days until you are able to contract the muscle for 10 seconds at a time (and relax for 10 seconds). Continue to do 10 repetitions twice a day.

Follow-up and Referral

Close follow-up is essential for patients with incontinence. This may be biweekly at first, while the patient is being taught the exercises and the medication dosage is being adjusted. Quarterly follow-up visits may be sufficient once incontinence is under control and medication dose has been stabilized. The patient should be monitored for adverse effects of medication and orthostatic hypotension. Periodic urinalysis should be done to detect any urinary tract infections early. Women should have regular pelvic exams to detect pelvic abnormalities early, and men should have regular rectal exams to pick up prostatic abnormalities.

Patient Education

Patient and family education is crucial in the treatment of UI. Environmental assessment should include recommendations about proximity of toilet facilities. An individualized toileting schedule should be geared to each patient's pattern of incontinence. Bladder training in the form of timed voiding, working up to 3-hour intervals, is an important intervention. Good general nutritional and exercise practices are important to the upkeep of overall health. Support and encouragement are essential. Interventions geared toward preventing social isolation, setting up necessary support services, and optimism in dealing with the problem are important interventions in the primary-care setting.

LOWER URINARY TRACT INFECTIONS

A lower urinary tract infection (UTI) occurs when the normally sterile environment of the urinary tract system is invaded by pathogenic bacteria. Infections of the lower

urinary tract can occur in the urethra, bladder, and prostate. Infection of the urethra *(urethritis)* and infection of the urinary bladder *(cystitis)* usually occur together. Women may be diagnosed with chronic inflammation of the bladder wall *(interstitial cystitis [IC]). Prostatitis* is infection of the prostate gland.

Infections can be acute, chronic, recurrent, complicated, or uncomplicated. *Acute infections* are characterized by the onset of UTI in a previously symptom-free individual. Infections can become *chronic* when unresolved after the usual treatment is rendered. UTIs become chronic because of obstructions, antibiotic-resistant bacteria, or the presence of multiple strains of bacteria that are not susceptible to the antibiotic therapy prescribed. A UTI is considered *recurrent* when it recurs within 2 weeks of the original infection. A *complicated* UTI is either an acute or chronic infection that is accompanied by factors that complicate the infection, such as catheters (e.g., indwelling, suprapubic, or intermittent), underlying chronic disease, or pregnancy. An *uncomplicated* UTI is one that can be resolved without addressing such complicating factors.

Epidemiology and Causes

Lower UTI is a common problem that affects approximately 20% of women and 1% of men each year and accounts for more than 6 million visits to primary-care providers each year. UTI rarely occurs in men younger than age 50 and is usually caused by urinary catheters, anatomical abnormalities of the urinary tract, unprotected anal intercourse, or vaginal intercourse with a woman who has a bacterial infection. UTI may occur at all ages but is more prevalent in sexually active adults, very young children, or frail older adults. Other populations at risk include individuals with predisposing conditions such as a suppressed immune system, pregnancy, urinary obstruction, catheter dependency, neurogenic bladder, or diabetes mellitus.

Lower UTI may be the result of other conditions within the renal system. A urethral obstruction can create stasis of urine, providing a medium for bacterial growth. Other conditions that can contribute to UTI are a descending infection from the kidney, an anatomically short urethra (in female patients), and acute infections elsewhere in the body. UTI may also occur as a result of poor or nonsterile catheterization technique or reuse of disposable catheters, poor hygiene, unprotected anal intercourse, or simply from an indwelling catheter, which, as a foreign body, serves as a nidus of infection.

Interstitial cystitis (IC) is found primarily in women. Statistically, 3 to 8 million women and 1 to 4 million men seeking treatment for bladder pain are diagnosed with IC, also known as painful bladder disease. The cause of this condition is unknown at this time, but some researchers theorize that there is an abnormality in the bladder surface that allows potassium and urea to leak and absorb into the bladder interstitium. Other factors being investigated are lymphatic, infectious, neurological, psychological, autoimmune, and vasculitic. IC does not respond to antibiotics.

Pathophysiology

Lower UTIs usually occur as a result of contamination from the patient's own gastrointestinal tract. Bacteria may be introduced into the urinary tract from fecal contamination secondary to poor perineal hygiene, unprotected sexual intercourse, and/or an anatomically shortened urethra in women. The use of a spermicide during intercourse (especially with diaphragm forms of contraception) alters the vaginal microenvironment, predisposing to bacterial colonization. Immunosuppressed or medically compromised patients may have difficulty in suppressing bacterial growth as bacteria ascend the urethra. Patients who are dependent on catheters are at risk for introduction of bacteria into the urinary tract through contamination of the catheter. Alkaline urine is a common complication of diabetes mellitus. The elevated pH of the urine creates a medium in which bacteria can grow and proliferate. Renal stones can also create an environment that promotes bacterial growth, as the blockage causes stasis of urine or reflux. In turn, contamination can occur in the kidney when urine "backs up" in the kidney due to vesicoureteral reflux, in which the urine back-flows freely into one or both ureters, leading to urinary stasis.

In women, approximately 80% to 90% of cases of uncomplicated UTI are a result of the gram-negative rod bacterium *Escherichia coli.* The second most common cause (5%–20% of cases) of uncomplicated bacterial infection is the gram-positive coccus *Staphylococcus saprophyticus,* although this agent is rare in complicated UTI. Other gram-negative rods identified as causative pathogens in a smaller number of cases, but particularly in complicated UTI, are *Proteus mirabilis, Klebsiella, Enterobacter, Serratia,* and *Pseudomonas.* In addition, the gram-positive coccus *Enterococcus* has been identified. *Staphylococcus aureus* is a gram-positive coccus that can be introduced into the urinary tract system through instrumentation or as a complication of renal stones. Fungi, particularly *Candida* species, may also be causative agents in complicated UTI that fails to respond to antibiotic therapy, especially in the presence of an indwelling catheter. Candiduria may be asymptomatic, and fungal structures should be sought on urine microscopy, because fungal colonies may be more difficult to elaborate on standard urine culture, in turn leading to delays in treatment.

In up to 50% of all bacterial species associated with cystitis, genetic virulence determinants may be identified that contribute to the uropathogenicity of these organisms, such as adherence factors that allow for greater binding to the uroepithelium. Another is the urease gene, expressed by certain gram-negative bacteria such as *Proteus, Klebsiella, Ureaplasma, Providencia,* and

Pseudomonas species. This enzyme splits urea molecules within the urinary tract, creating ammonium and hydroxyl ions that produce an alkaline microenvironment. This higher pH facilitates survival of these bacteria, particularly when housed within triple phosphate (magnesium ammonium phosphate) stones, also known as struvite stones.

Cystitis is rare in men because the increased length and drier environment around the urethra contribute to less frequent bacterial colonization. In addition, prostatic fluid has inherent antibacterial properties, but when UTI does occur, it is often associated with abnormal urethral anatomy or inadequate treatment of prostatitis. Most antibiotic agents do not penetrate the prostatic tissue and, therefore, do not eliminate the infection. As a result, the bladder is reinfected from contaminated prostatic fluid.

Two well-documented phenomena related to classic UTI are asymptomatic bacteriuria and the dysuria–pyuria syndrome. As the name implies, in asymptomatic bacteriuria patients experience no obvious clinical symptoms or signs of UTI (including altered mental status in the elderly), yet urinalysis and culture yield findings consistent with bacteriuria. In contrast, the dysuria–pyuria syndrome (also called "acute urethral syndrome") is characterized by painful urination with white blood cells (WBCs) on microscopic urinalysis in the absence of a positive bacterial culture. Such a condition may be due to organisms such as *Chlamydia* that do not grow well on standard urinary culture. This condition may, however, be difficult to distinguish clinically from vaginitis due to sexually transmitted infection.

Clinical Presentation

Subjective

The presenting signs and symptoms of UTIs vary widely in intensity and occurrence. Women may present with urethritis and cystitis simultaneously. The most frequently reported symptoms in both males and females are dysuria, urinary frequency or urgency, nocturia, hematuria, low back or suprapubic pain, urinary incontinence, or cloudy, foul-smelling urine. These symptoms can occur in any combination. In elderly patients, altered mental status may be the sole manifestation of UTI and should create a high level of suspicion.

Urethritis in men is rare; if left untreated or treated inadequately, it can lead to complications such as urethral strictures, periurethral abscess, urethral diverticuli, and fissures. Vaginal discharge in women and urethral discharge in men may suggest sexually transmitted diseases (STDs). Purulent urethral discharge *(Neisseria gonorrhoeae)* or whitish-mucoid discharge *(Chlamydia trachomatis)* should be treated aggressively with the appropriate antibiotic therapy.

Objective

The physical exam should include a clean-catch, midstream urine sample for urinalysis. The urinalysis will reveal an infectious process in the urinary tract system and may exhibit any of the following: cloudy appearance, alkaline pH, hematuria, elevated levels of nitrites, leukocyte esterase (detecting pyuria of greater than 10 leukocytes per hpf), and urine sediments of red blood cells (RBCs), WBCs, mucus, and bacterial overgrowth. Of note, the *Enterobacteriaceae* convert urinary nitrates to nitrites, producing positive results on urine dipstick analysis if present in adequate numbers (greater than 100,000 organisms/mL). In contrast, however, staphylococci do not convert this substrate and are not detectable by this test. Moreover, false-positive urinary nitrite tests may result in the presence of the urinary tract analgesic phenazopyridine. A urine culture and sensitivity may be ordered to speciate and determine the sensitivity of the causative organism to specific antibiotic therapy.

Patients with IC may present with the need to urinate frequently because of reduced bladder capacity. This may occur up to 60 times per day in extreme cases. Other symptoms include pain or discomfort in the abdominal area that holds the bladder.

Diagnostic Reasoning

Diagnostic Tests

Diagnosis of lower UTI is made based on the subjective complaints of the patient and a clean-catch midstream urine sample showing the presence of bacteria, especially if more than 100,000 organisms/mL of the same morphology are present in a sample from a female patient. Traditionally, this concentration of bacteria (i.e., 100,000 cfu/mL on urine culture) has been used to define UTI, but UTI may result from far lower bacterial loads, UTI is currently defined as a urine sample with greater than 100 organisms/mL in the presence of characteristic clinical symptoms. The method of urine collection also influences interpretation of the urine culture, because the sterility of commonly performed "clean-catch" techniques is heavily dependent on the patient's ability to clean around the urethra before voiding. Sterile wipes containing iodine, chlorhexidine, or other acceptable cleaning agent must be used to wipe the urethral opening at least two to three times consecutively in a direction away from the perineum to minimize contamination by anorectal flora. Alcohol swabs are unacceptable cleaning agents. Straight catheterization samples obtained with sterile technique are the most reliable, whereas samples obtained from receptacles connected to indwelling catheters may prove unreliable owing to repeated manipulation of the collecting bag.

Although urine culture is considered the gold standard with the greatest sensitivity for laboratory confirmation of UTI, urinalysis with microscopy is also helpful and

provides rapid results. Urinalysis also typically indicates pyuria (greater than 10 neutrophils per hpf on microscopic exam) and often the presence of RBCs. Hematuria is common in UTI but not with urethritis or vaginitis; however, blood in the urine is not a marker of complicated infection. UTIs may be treated with empiric antibiotic therapy based on knowledge of the most common bacterial etiologies. However, a urine culture and sensitivity testing will definitively identify the infecting microorganism and the appropriate antibiotic therapy. Although the diagnosis of UTI is made both clinically and by urinalysis, generally urine culture and sensitivities are indicated if complicated infection is suspected, if atypical symptoms are present, or if symptoms persist or recur within 1 month of the patient's receiving an empiric course of antibiotic therapy and a new regimen is desired.

Interstitial cystitis is mostly a diagnosis of exclusion. Although somewhat controversial, a useful diagnostic tool for this condition is the potassium sensitivity test. This test involves slow instillation of 40 mL of sterile water into the bladder and the patient is asked to grade the discomfort on a 0 to 5 scale, with 5 being the most severe. This establishes a baseline. Then the water is emptied and potassium chloride solution is instilled into the bladder and the discomfort graded as in the instillation of water. IC is suggested when there is a 2-point increase in the pain or urgency, indicating abnormal epithelial dysfunction.

Differential Diagnosis

The differential diagnosis of tumors, upper UTI (pyelonephritis), vaginitis, and STDs must be explored. Tumors of the renal system and upper UTI are discussed in this chapter. Vaginitis and STDs are discussed in Chapters 13 and 14. Patients with lower UTI differ from those with upper UTI in that they do not exhibit signs of sepsis such as fever and chills, have WBC casts in the urine (reflecting the passage of neutrophils through the renal tubules), or experience flank and costovertebral angle tenderness on exam.

Management

Pharmacological antimicrobial management is the mainstay of treatment. Drugs Commonly Prescribed 12.2 presents the oral agents typically used for the treatment

Drugs Commonly Prescribed 12.2 Urinary Tract Infections

Drug	Indication and Dosage	Adverse Reactions and Prescribing Considerations
Sulfonamides		
trimethoprim and sulfamethoxazole (TMP-SMX) Bactrim, Septra (80 mg TMP/400 mg SMZ) Bactrim DS (160 mg TMP/800 mg SMZ) [double strength]	Precoital or postcoital prophylaxis 100 mg trimethoprim after sexual intercourse Acute uncomplicated UTI 1 DS tablet 2 times daily × 3 days for uncomplicated UTI Complicated UTI 8–10 mg/kg/day IV in 2–4 equally divided doses every 6, 8, or 12 hours for up to 14 days For pyelonephritis 1 DS tablet every 12 hours for 7–14 days	**Contraindications:** Hypersensitivity to trimethoprim or sulfonamides Allergy to sulfa Folate deficiency megaloblastic anemia Pregnancy at term and lactation **Side effects:** Abdominal distress Nausea Rash Neutropenia **Special instructions:** Take with a full glass of water. Complete full course of therapy.
Fluoroquinolones		
ciprofloxacin (Cipro) (Cipro XR) [extended release] levofloxacin (Levaquin) ofloxacin (Floxin) norfloxacin (Noroxin)	Ciprofloxacin Uncomplicated UTI 250 mg 2 times daily × 3 days Complicated UTI 500 mg PO 2 times daily × 7–14 days Levofloxacin Uncomplicated 250 mg daily × 3 days Complicated 250 mg daily × 10 days or 750 mg daily × 5 days	**Contraindications:** Hypersensitivity to fluoroquinolones **Side effects:** Nausea Abdominal discomfort Diarrhea Photosensitivity Dizziness Superinfections

Drugs Commonly Prescribed 12.2 Urinary Tract Infections—cont'd

Drug	Indication and Dosage	Adverse Reactions and Prescribing Considerations
	Ofloxacin Uncomplicated 200 mg 2 times daily × 3 days Complicated 200 mg 2 times daily × 10 days Norfloxacin Uncomplicated 400 mg 2 times daily × 3 days Complicated 400 mg 2 times daily × 10–21 days	**Caution:** QTc prolongation, hyper- and hypoglycemia, tendinitis, and tendon rupture have all been associated with fluoroquinolones. Concomitant use with NSAIDs may increase risk of CNS stimulation and seizures. **Special instructions:** Complete the full course of therapy. Do not take at the same time as antacids, calcium, iron, or zinc preparations. Norfloxacin, ofloxacin should not be taken with food or milk.
Aminopenicillins		
amoxicillin (Amoxil) amoxicillin and potassium clavulanate (Augmentin)	Amoxicillin Mild/moderate infections: 500 mg 2 times daily or 250 mg 3 times daily × 10 days Severe infections: 875 mg 2 times daily or 500 mg 3 times daily × 10 days Amoxicillin and potassium clavulanate Mild/moderate infections: 500 mg/125 mg 2 times daily or 250 mg/125 mg 3 times daily × 10 days Severe infections: 875 mg/125 mg 2 times daily or 500 mg/125 mg 3 times daily × 10 days	**Contraindications:** Penicillin allergy **Side effects:** Hypersensitivity reactions Urticarial rash Nausea Diarrhea Superinfections **Special instructions:** Complete full course of therapy. May decrease effectiveness of oral contraceptives. Augumentin should be given with food to decrease nausea.
Cephalosporins—Second Generation		
cefaclor (Ceclor) cefuroxime (Ceftin)	Cefaclor 250–500 mg 3 times daily Cefuroxime (uncomplicated) 250 mg 2 times daily × 7–10 days	**Contraindications:** Allergy to cephalosporins **Side effects:** Pruritis Uticaria Erythema multiforme Rashes Arthritis/arthralgia (with or without fever) Diarrhea Nausea **Special instructions:** Renal dysfunction prolongs half-life. May be taken without regard to meals. Complete full course of therapy.
Cephalosporins—Third Generation		
cefixime (Suprax) cefpodoxime (Vantin)	Cefixime 400 mg daily × 3–7 days Cefpodoxime 100 mg 2 times daily × 7 days	**Contraindications:** Allergy to cephalosporins **Side effects:** Diarrhea Abdominal pain Nausea

Continued

Drugs Commonly Prescribed 12.2 Urinary Tract Infections—cont'd

Drug	Indication and Dosage	Adverse Reactions and Prescribing Considerations
		Dyspepsia Flatulence **Special instructions:** Reduce dose of cefixime by 25% if renal dysfunction present. Cefpodoxime: avoid antacids 2 hours before and after dose. Complete full course of therapy.
Anti-infectives		
nitrofurantoin (Macrodantin, Furadantin)	UTI 100 mg 2 times daily × 7 days	**Contraindications:** Hypersensitivity to nitrofurantoin Renal function impairment Anuria or oliguria Pregnancy in third trimester, labor, or delivery **Side effects:** Nausea Vomiting Anorexia Abdominal discomfort **Special instructions:** Take with food. May cause urine to darken.
Urinary Analgesic		
phenazopyridine (Pyridium)	Relief of pain, burning, urgency, and frequency from UTI 200 mg 3 times daily after meals; maximum 2 days	**Contraindications:** Hypersensitivity to phenazopyridine **Side effects:** Headache Rash Itching **Special instructions:** Take after meals. May turn urine reddish-orange color and stain fabric.
Antispasmodic		
flavoxate (Urispas)	Relief of dysuria, urgency, frequency, and incontinence 100–200 mg 3–4 times a day	**Contraindications:** Use with caution in patients with glaucoma and older adults. **Side effects:** Nausea Vomiting Dry mouth Headache Drowsiness Blurred vision Vertigo

of lower UTI. Epidemiological surveillance has revealed increasing rates of resistance in *E coli* isolates to ampicillin and sulfonamides, including trimethoprim-sulfamethoxazole (TMP-SMX), but only a small percentage of these isolates were resistant to nitrofurantoin (Macrodantin, Macrobid), which is known to concentrate in the urine. Nitrofurantoin is also effective against many gram-positive cocci such as *Enterococcus faecalis,* whereas other key uropathogens such as *Proteus, Enterobacter,* and *Klebsiella* may be highly resistant. Thus, both TMP-SMX and nitrofurantoin may be used as empiric therapy for uncomplicated UTI only and, in fact, may prove to be inadequate. Indeed, one of the strongest risk factors predicting microbial resistance to TMP-SMX is the previous use of this or any other antimicrobial agent for any type of infection within the past 3 months.

The fluoroquinolones (e.g., ofloxacin, ciprofloxacin, gatifloxacin, levofloxacin), on the other hand, have widespread efficacy against most uropathogens, although their increasing use as first-line empiric therapy has clearly been associated with steadily rising rates of resistance, as well. Thus, for uncomplicated UTI, a 3-day regimen of TMP-SMX should be used empirically in patients with no history of sulfa drug allergy, previous hospitalization, or antibiotic use for any reason within the past 3 months (Level I; American College of Obstetricians and Gynecologists, 2008) in geographical areas where *E coli* resistance to this agent is known to be less than 20% (e.g., the Northeastern United States, as opposed to the Western United States). A 7-day course of nitrofurantoin should be used as an alternative in patients with documented sulfa allergies or in those with previous antibiotic use within the last 3 months.

The cost-effective 3-day treatment regimen for uncomplicated lower UTI reduces the risk of nonadherence and the development of *Candida* vaginitis due to clearance of normal urogenital flora. It is recommended for TMP-SMX or the fluoroquinolones, but not nitrofurantoin, which requires a longer course of therapy for maximum efficacy. Complicated UTI, on the other hand, requires at least 10 to 14 days of antibiotic therapy. The antimicrobial effects of these medications persist for several days after the final dose is administered. In particularly severe cases of UTI (especially in high-risk groups such as elderly or bed-bound patients) or in cases involving urinary tract instrumentation, hospitalization and broad-spectrum IV antibiotic coverage (e.g., ceftriaxone, piperacillin-tazobactam, or ampicillin plus gentamicin) may be required until symptoms wane and urine culture and antibiotic sensitivities confirm the most appropriate antibiotic choice. The same approach may be required for upper UTI (i.e., pyelonephritis).

Empiric treatment of UTI in men (by definition, a complicated UTI) should be extended to at least 7 days. Nitrofurantoin and beta-lactams should be avoided; fluoroquinolones are generally the antibiotics of choice, given their effectiveness in treating occult prostatic infection.

Treatment of UTI during pregnancy is especially important, because an established link exists between premature delivery and UTI (especially pyelonephritis). Empiric therapy may include ampicillin 500 mg PO four times daily, nitrofurantoin (Macrobid, Macrodantin) 100 mg PO two times daily, cephalexin (Keflex) 500 mg PO four times daily, or sulfisoxazole 1 g PO four times daily. Broader-spectrum regimens may include amoxicillin-clavulanate (Augmentin) 500 mg/125 mg PO two times daily or cefpodoxime (Vantin) 100 mg PO two times daily. Most clinicians will choose to treat UTI during pregnancy for 1 full week. Fluoroquinolones should be avoided, given concern for their effects on bone and cartilage formation in the developing fetus, and TMP-SMX should be avoided in the first and third trimesters of pregnancy. In women with a prior history of recurrent UTI, postcoital prophylaxis with a single oral dose of nitrofurantoin 50 mg or cephalexin 250 mg has been shown to be highly effective.

Fungal UTI due to *Candida* infection is typically associated with an indwelling urinary catheter, and nearly half of all cases resolve simply with removal of the catheter. However, reinsertion of a new catheter is associated with a high rate of relapse. Antifungal treatment is typically not required for asymptomatic colonization, but if indicated in the presence of dysuria, an appropriate regimen would be fluconazole (Diflucan) 200 mg PO (or IV for hospitalized patients) daily for 7 to 14 days.

The management of asymptomatic bacteriuria deserves special mention. This condition should be treated with antibiotics in pregnant women (Level II; Scottish Intercollegiate Guidelines Network, 2006), because it increases the risk of premature delivery. Although some studies suggest treatment in girls beyond preschool age is not warranted owing to the high rate of recurrent asymptomatic infection without obvious sequelae, general practice also calls for treating asymptomatic bacteriuria in young children. Treatment is also indicated in patients before they undergo a urological procedure to avoid operating on a contaminated field, after removal of a bladder catheter in place for less than 1 week, and in any patient with an underlying structural abnormality of the urinary tract, vesicoureteral reflux, or struvite stones. In contrast, treatment of this condition in adult men, nonpregnant women, the elderly, diabetic persons, and spinal cord patients with indwelling urinary catheters is not warranted. Although asymptomatic bacteriuria may be a harbinger of future UTI, antibiotic therapy has not been shown to persistently eradicate bacteriuria or urinary tract colonization in these populations.

After completion of antibiotic treatment, follow-up cultures may be obtained to ensure complete eradication of the pathogen in patients with a history of recurrent infection, during pregnancy, or in those prone to complicated UTI. Chronic or recurrent UTI may be

prevented through prophylactic treatment either on a daily basis or after sexual intercourse, but this should be done only after all options to eliminate the causative factors of UTI have been explored. Strategies should be emphasized to decrease the incidence of infection through the guidelines outlined under Patient Education.

Although appropriate antibiotic treatment is often adequate to relieve dysuria, certain medications may also be prescribed for the first few days to decrease the pain and discomfort of UTI. Use of these agents should not be prolonged, however, given their significant side-effect profile. Effective treatment may involve anticholinergics, which produce an antispasmodic effect, including atropine (Donnatal), hyoscyamine (Levsin, Cystospaz), propantheline (Pro-Banthine), or oxybutynin (Ditropan). However, anticholinergics may also contribute to urinary retention (especially in the elderly), which is a clear risk factor for UTI, and should thus be used with caution. Analgesics may be prescribed such as phenazopyridine (Pyridium), but this alters the color of urine to orange and may cause urinary leakage secondary to anesthetization of the urethra and sphincter.

IC does not respond to antibiotics. However, this condition may be treated with pentosan polysulfate sodium (Elmiron), which tends to reduce the bladder wall inflammation. This drug has been shown to improve symptoms in 38% of patients with IC. IC is not curable, but it is controllable. If IC is left untreated, it becomes more difficult to treat and in severe cases can progress to the development of a fibrotic contracted bladder. Complementary therapies used for lower UTI are presented in Complementary Therapies 12.1.

Follow-up and Referral

Patients should follow up with a midstream, clean-catch urine sample for urinalysis to evaluate for the presence of WBCs or a culture and sensitivity for all recurrent infections. UTI that is secondary to other pathological conditions will not resolve until the primary causative factor is addressed. Indwelling urinary catheters should be changed every 4 to 6 weeks with new equipment using sterile technique. It is important to maintain adequate hydration and to monitor the urine output for signs of obstruction or renal failure. Urinary tract obstructions must be identified and removed to reduce the chances of chronic infection and renal damage leading to renal insufficiency and failure. It may be necessary to prescribe analgesics for the patient to reduce the pain associated with the UTI. Pain-relieving medications such as phenazopyridine (Pyridium) can be effective but should be prescribed for no more than 3 days.

Self-medication is usually adequate for female patients who have relatively few recurrences of UTI. If a diagnosis of recurrent bacterial UTI is confirmed, the patient should be given a supply of an antibiotic (preferably TMP-SMX or nitrofurantoin) and instructed to take it for 3 to 7 days whenever the symptoms recur. The patient should keep a diary of her infections and response to treatment and review it annually with a health professional so as to track medication-associated problems. The patient should also be advised to notify the clinician if symptoms such as flank pain, fever, hematuria, or lack of response to treatment occur.

If UTI recurs frequently (e.g., monthly), prophylactic therapy should be prescribed. After a course of 10 to 14 days of a suitable antibiotic (e.g., a fluoroquinolone), the patient should begin low-dose antimicrobial prophylaxis every other day at bedtime over a 4- to 6-month period. This regimen has proved as effective as daily dosing. Nighttime therapy is recommended because the patient generally does not void for a prolonged period, thus giving the bacteria the opportunity to adhere to the bladder wall. If this period of prophylaxis has been effective, the patient may switch to self-medication. If the frequency of recurrence increases at this point, however, prophylaxis should be extended to every other night indefinitely. However, all lifestyle issues should be investigated first. There is evidence that the use of cranberry products can reduce the frequency of UTI recurrence (Level I; Scottish Intercollegiate Guidelines Network, 2006).

Patient Education

Patient education should focus on teaching the patient to prevent recurrence of UTI. This is accomplished by advising the patient to follow these guidelines:

- Complete the full course of antibiotic therapy even if all symptoms subside (treatment may be anywhere from 3–14 days in duration).
- Increase fluid intake to eight 8-ounce glasses of water per day; this is most important to continue flushing out bacteria.

Complementary Therapies 12.1 Lower Urinary Tract Infections

Therapy	Dosage	Comments
Herbs		
Cranberry	300–400 mg PO 2 times daily standardized cranberry extract capsules	Prevents the adherence of bacteria to the bladder wall (proanthocyanidins, active ingredient, inhibits adhesion of *Escherichia coli* to uroepithelial cells)

- Take cranberry supplement and drink cranberry juice to decrease the bacteria's ability to adhere to the epithelial cells that line the bladder.
- Self-medicate if symptomatic.
- Wear cotton underclothes rather than nylon to avoid moisture buildup and avoid wearing "thong" underpants.
- Avoid the use of harsh soaps or feminine hygiene products that can irritate the urethra.
- Use condoms to provide a barrier to infection from intercourse.
- Use proper techniques for self-catheterization to reduce the incidence of introducing bacteria.
- Empty the bladder frequently to avoid stasis of urine.
- Take showers instead of tub baths or bubble baths to avoid chemical irritation of the urethra.
- Keep a diary of urinary symptoms and review it annually if recurrent infections are a problem.
- Empty the bladder completely, possibly by double-voiding (i.e., completely emptying the bladder two times in 5 minutes), especially if recurrent infections are a problem.

The patient should also be educated regarding any potential adverse effects of medication, including urinary leakage associated with phenazopyridine (Pyridium) treatment or the subsequent development of vaginal yeast infections.

UPPER URINARY TRACT INFECTION: PYELONEPHRITIS

Pyelonephritis is an infection of the kidney that is characterized by infection within the renal pelvis, tubules, or interstitial tissue that may be unilateral or bilateral. The condition may be classified as either acute or chronic. The chronic condition leads to changes in the kidney that create atrophy and scarring of the kidney and calyceal deformity that may eventually lead to renal failure.

Epidemiology and Causes

Pyelonephritis occurs in both men and women, but it is more common in women. The occurrence is higher in older adults (especially if institutionalized or hospitalized), children, and immunocompromised patients. Community-acquired pyelonephritis is estimated to occur in approximately 15.7 persons per 100,000 per year. However, hospital-acquired pyelonephritis occurs in approximately 7.3 persons per 10,000 hospitalized persons. The incidence and risk of developing this disease is increased in patients with predisposing factors including anatomical abnormalities such as ureterovesical reflux, urinary obstruction, stress incontinence, multiple or recurrent urinary tract infections (UTIs), renal disease, kidney trauma, pregnancy, and metabolic disorders such as diabetes mellitus. Having an indwelling urinary catheter is always a prominent risk factor for pyelonephritis, especially in hospitalized elderly women. An episode of acute pyelonephritis within the prior year also puts the patient at increased risk. Most of these risk factors alter the vaginal microenvironment and predispose individuals to lower UTI, as well.

In acute pyelonephritis, the actual insult to the kidney may be hematogenous seeding or urinary tract reflux, but most commonly it is an ascending infection from the bladder. It can often be attributed to untreated lower UTI that spreads to the upper urinary system or is introduced through instrumentation. Chronic pyelonephritis usually has no specific pathological explanation if anatomical abnormalities have been ruled out.

Pathophysiology

Pyelonephritis is typically caused by fecal flora that colonize the vaginal introitus and subsequently ascend along the urinary tract to the kidneys. It is unclear whether lower UTI always precedes pyelonephritis, because many patients present without clinical evidence of prior cystitis. However, bacteria are believed to enter through the urethral meatus and ascend upward from the lower urinary tract (urethra and bladder) to one or both kidneys via the ureters, the bloodstream (i.e., hematogenous spread), or the lymphatic system.

Escherichia coli (75%–95% of cases), *Proteus mirabilis, Klebsiella,* and *Pseudomonas* are the most common gram-negative causative agents. From 5% to 10% of cases are caused by gram-positive organisms, including *Enterococcus, Staphylococcus saprophyticus,* and *Staphylococcus aureus* (particularly in severe infection). *Ureaplasma urealyticum* and *Mycoplasma hominis* are rarer causative agents. In patients with normal urogenital systems, nearly all bacterial agents of pyelonephritis express virulence factors that contribute to their uropathogenicity (e.g., the *pap* and *sfa* operons and pathogenicity islands found in virulent *E coli* strains).

In acute pyelonephritis, swelling of the renal parenchyma occurs as a result of the patchy distribution of the acute infectious process throughout the kidney. In rare instances, scarring of the renal parenchyma leading to kidney atrophy, renal hypertension, and renal failure may occur if left untreated. When the infection is severe, abscesses may develop in the renal medulla leading to necrosis of the renal papillae. This infection can be potentially life-threatening in the elderly, in children, or in immunocompromised patients. In addition, diagnosis and treatment in pregnant women is particularly critical, because upper UTI has a clear association with premature delivery.

Chronic pyelonephritis is usually caused by a recurrent or chronic bacterial infection of the kidney, often related to the presence of instrumentation such as an indwelling catheter that serves as a nidus of infection. Patients often have other urological problems such as vesicoureteral reflux, neurogenic bladder, or urinary obstruction caused by renal tumors, stones, or prostatic

hypertrophy. The persistent unresolved infection and inflammation cause fibrosis (scarring) of the tubulointerstitium, which may lead to hypertension as the body senses decreased renal blood flow or eventually chronic renal insufficiency.

Clinical Presentation

Subjective

The patient with acute pyelonephritis may present with a sudden onset of fever, persisting over a few hours or days and ranging up to 103°F (39.5°C). The patient may present with shaking, chills, nausea, and vomiting, as well as unilateral flank or localized back pain over the affected kidney (i.e., costovertebral angle tenderness), fatigue, diarrhea, or other symptoms resembling those of a gram-negative sepsis. Signs of urinary urgency or frequency and suprapubic discomfort may be present. In some cases, the presentation may mimic pelvic inflammatory disease. Otherwise, the patient may be largely asymptomatic and then progress to full-blown sepsis (i.e., urosepsis). In the elderly patient, altered mental status may be the initial manifestation of pyelonephritis.

Chronic pyelonephritis may present with the patient complaining of fatigue, nausea, decreased appetite with weight loss, nocturia, and/or polyuria. Patients may present with symptoms of renal failure resulting from asymptomatic chronic pyelonephritis that has persisted for several years. Symptoms of renal failure are discussed in detail later in this chapter.

Objective

The physical exam will elicit marked tenderness on deep abdominal palpation and/or percussion of the affected flank and back overlying the affected kidney (i.e., costovertebral angle tenderness). Patients may be hypertensive, and with severe pyelonephritis may remain symptomatic for several days, even if appropriate antibiotic therapy is administered.

Patients with chronic pyelonephritis may show minimal symptoms or symptoms similar to those of acute pyelonephritis. The early signs and symptoms may be vague; chronic pyelonephritis usually is first diagnosed when the patient presents with impaired renal function caused by damage to the kidneys.

Diagnostic Reasoning

Diagnostic Tests

The diagnosis of pyelonephritis is confirmed through urinalysis, which is positive for bacteria, proteinuria, leukocyte esterase, urinary nitrites, hematuria, pyuria, and specifically white blood cell (WBC) casts (reflecting the passage of neutrophils through the renal tubules), as well as urine culture, which typically demonstrates greater than 100,000 cfu/mL, allowing for identification of the causative organism. Any of these findings may be altered, however, if the patient is already on antibiotic therapy, and colony counts may be as low as 10,000 cfu/mL in some cases. Blood cultures may also be positive in 10% to 20% of mild to moderate pyelonephritis, reflecting urosepsis.

Cystoscopy with ureteral catheterization, renal ultrasound (to reveal hydroureter and/or hydronephrosis), or intravenous pyelogram (IVP) may be indicated. However, the nuclear medicine–based dimercaptosuccinic acid (DMSA) scan is most sensitive for detecting pyelonephritis and renal scarring. Although rarely used, renal biopsy in acute pyelonephritis may reveal abscess formation with neutrophilic invasion. The area of the infection is wedge shaped, pointing toward the medulla, and the glomeruli are spared. Findings in chronic pyelonephritis will include fibrosis, scarring, and reduction of renal tissue, with calyceal clubbing, dilation, and distortion. A voiding cystourethrogram may reveal vesicoureteral reflux, which predisposes to both lower and upper UTI.

Differential Diagnosis

It can be difficult to differentiate pyelonephritis from cystitis; however, the presence of WBC casts is diagnostic for pyelonephritis. Hematuria is also often present in lower and upper UTI, but not in vaginitis or urethritis. Chronic pyelonephritis can sometimes be diagnosed through IVP, DMSA scan, and ultrasound, which may identify atrophied kidneys with "clubbing" of the affected calyces. A definitive diagnosis of chronic disease is made by identifying persistent pyuria and by positive urine cultures. Sometimes, chronic pyelonephritis is diagnosed only via kidney biopsy.

Management

Aggressive therapy is necessary to prevent permanent damage to the kidneys, a potential complication of upper versus lower UTI. Tissue penetration of antibiotics into the renal medulla appears more important than serum or urine levels. Oral antibiotics may be prescribed in mild cases of acute pyelonephritis, characterized by the absence of nausea and vomiting or signs of sepsis. First-line therapy includes ciprofloxacin (Cipro) 500 mg two times daily for 7 days, or ciprofloxacin extended-release (Cipro XR) 1,000 mg daily for 7 days, or levofloxacin (Levaquin) 750 mg daily for 5 days. In second-line therapy, trimethoprim-sulfamethoxazole (TMP-SMX) (Bactrim DS, Septra DS) taken orally for 14 days may be as effective as amoxicillin-clavulanate for 14 days in young women with their first pyelonephritis and without anatomical abnormalities. However, given the prevalence of sulfonamide and ampicillin resistance among common uropathogens, TMP-SMX and amoxicillin are likely to be ineffective in cases of recurrent or moderate to severe pyelonephritis (except in cases of *Enterococcus* infection, which calls for the addition of amoxicillin [Amoxil] 500 mg PO three times daily).

Nitrofurantoin should be avoided because it does not achieve adequate tissue levels. Other effective choices are third generation cephalosporins (e.g., cefixime, cefpodoxime, ceftriaxone), aminoglycosides (e.g., gentamicin, tobramycin), or aztreonam, with fluoroquinolones reserved for antibiotic-resistant organisms, hence the critical need for early urine culture to guide pharmacotherapy. Drugs Commonly Prescribed 11.2 presents the oral agents commonly prescribed for lower UTI and mild to moderate pyelonephritis (not requiring hospitalization or IV therapy).

Hospitalization may be indicated, depending on the patient's ability to maintain adequate fluid intake and to tolerate oral antibiotics, along with the severity of the symptoms and evidence of bacteremia. Hospitalization of patients who are pregnant, vomiting, or dehydrated should be strongly considered. Likewise, the patient's degree of systemic illness (bacteremia or urosepsis), age, history of chronic disease, or nonadherence to therapy may lead to the assessment that hospitalization is necessary. Ninety-five percent of patients demonstrate a good response within 48 hours to IV antibiotic treatment and may be discharged on appropriate oral medication, once urine culture and antibiotic sensitivity results are available and subsequent antimicrobial therapy may be narrowed in spectrum. Treatment courses should typically last for 7 to 10 days for mild to moderate cases, 14 days for severe cases, or 21 days in particularly slow responders. Ample evidence has demonstrated that once common 6-week regimens lead to increased adverse effects without improved treatment effectiveness. Selection of a regimen should be based on local resistance and susceptibility results.

Common choices for non-*Enterococcus* infection include ciprofloxacin (Cipro) 400 mg IV every 12 hours, or levofloxacin (Levaquin) 250 mg IV daily for 10 days or 750 mg IV daily for 5 days, except in pregnant patients, in whom fluoroquinolones are contraindicated, given the potential for adverse effects on bone and cartilage development in the developing fetus. Second-line therapy includes ceftriaxone 1 to 2 g IV daily, as well as other extended-spectrum cephalosporins or penicillins, carbapenems, monobactam (in penicillin allergy), and aminoglycosides (except in pregnant patients), such as gentamicin 3 to 5 mg/kg IV daily or tobramycin 3 to 5 mg/kg IV daily in three divided dosages. Fluoroquinolones are also appropriate choices, except in pregnant women, given concerns over their effects on bone and cartilage formation in the developing fetus. This class of antibiotics has virtually equivalent absorption when administered orally or intravenously at the same dose (see Drugs Commonly Prescribed 11.2). Thus, IV fluoroquinolone preparations should be used only for patients with active nausea and vomiting. When enterococcal infection is suspected, ampicillin 1 to 2 g IV every 6 hours should be combined with either gentamicin or tobramycin at 1 mg/kg IV every 8 hours added for synergy. Another option for empiric therapy is the broad-spectrum antibiotic piperacillin-tazobactam (Zosyn) 3.375 g IV every 6 hours given over 30 minutes. If the creatinine clearance is between 20 and 40 mL/min, the dose should be 2.25 g every 6 hours. If the creatinine clearance is less than 20 mL/min, the dose should be 2.25 g every 8 hours.

If the patient does not respond adequately within 48 hours, he or she should be reevaluated, the cultures reviewed, and an ultrasound, IVP, or DMSA scan performed. IV antibiotics may need to be administered for up to 7 to 10 days in severe cases. During treatment the patient must increase fluid intake, and an accurate intake and output record must be maintained for appropriate fluid management. Surgery may be indicated to remove or correct secondary causes of UTI such as urinary obstruction or anatomical abnormalities and neuropathic genitourinary tract lesions. Diagnostic studies requiring insertion of instruments should be delayed until the urine is sterile or free of bacteria and/or pus, to avoid the complications of bacteremia or septic shock. A urological anatomical evaluation should be performed for all men with pyelonephritis and women with recurrent pyelonephritis to elicit structural abnormalities that may be contributing to or causing the condition.

Follow-up and Referral

If undergoing outpatient treatment, the patient should be seen 48 hours later to assess responsiveness to therapy. Similarly, patients in the hospital should be evaluated in 48 hours for response to therapy and consideration of discharge. Follow-up urine cultures are not routinely recommended in asymptomatic patients. However, for those with recurrent pyelonephritis, reculturing at 2, 6, and 12 weeks after antibiotic therapy is initiated may be done to ensure complete and lasting eradication of infection. Further treatment decisions are based on clinical findings such as fever, pain, and culture of bacteria. When a diagnosis of chronic pyelonephritis is determined, the patient should be referred to a nephrologist because of the severe damage that can occur to the kidney. As discussed previously, a renal ultrasound, renal colic CT scan, or voiding cystourethrogram may detect structural abnormalities, renal stones, or vesicoureteral reflux—all of which predispose the patient to infection. Patients should also be monitored and treated for other conditions secondary to the pyelonephritis such as hypertension, chronic infection, renal insufficiency, or renal failure.

Patient Education

The focus should be on teaching the patient to prevent recurrence of lower UTI and pyelonephritis by following these instructions:

- Complete the antibiotic therapy even if symptoms subside.
- Prevent or reduce the incidence of lower UTIs by following the guidelines under Patient Education in the previous section.

- Increase fluid intake to eight 8-ounce glasses of water per day.
- Report any recurrence of UTI symptoms immediately.
- Take a cranberry supplement and drink cranberry juice to decrease the bacteria's ability to adhere to the epithelial cells that line the bladder.
- Control hypertension with medications, dietary regimen, and lifestyle changes as detailed in Chapter 10.

NEPHROLITHIASIS

Nephrolithiasis is a condition in which stones (renal calculi) originate in the kidney. The stones form from calcium salts (approximately 75%–85%), struvite (approximately 10%–15%), uric acid (approximately 7%), and cystine (1%–2%). These stone formations often cause acute episodes of urinary tract obstruction, infection, and severe pain in adults.

Epidemiology and Causes

The incidence of renal calculi occurs in people aged 20 to 60 years but peaks in those aged 20 to 30 years. It affects approximately 2% to 5% of individuals at some time during their lifetime, or about 70 to 210 per 100,000 of the population. Calcium oxalate stones occur more often in men, whereas struvite stones are more common in women. Formation of renal calculi is more prevalent in the Southeast, West, and Midwest. The patient may report a sedentary lifestyle or occupation that exposes him or her to high environmental temperatures. Renal stones can occur because of obstruction, urinary stasis, infection, dehydration and urine concentration, increased consumption of calcium or vitamin D, excessive excretion of uric acid, or vitamin A deficiency. Hereditary factors can also predispose the patient to kidney stone formation.

Calcium oxalate and calcium phosphate stones account for 65% to 85% of all cases of renal calculi. These types of stones are found predominantly in men and in individuals whose diet is high in salt, animal fat, animal protein, and oxalate from green leafy vegetables. Interestingly, a low-calcium diet is also a risk factor, as it leads to increased oxaluria because less oxalate is bound to calcium in the gastrointestinal tract. Vasectomy is a risk factor as well, and hypertension doubles the risk of stone formation for reasons that are as yet unclear. Patients with calcium oxalate or calcium phosphate stones typically do not have hypercalcemia except with certain disorders such as hyperparathyroidism, sarcoidosis, and hyperuricemia, which may lead to hypercalciuria or hyperuricosuria. Loop diuretics such as furosemide (Lasix) also promote calciuria, and hypocitraturia and hyperoxaluria similarly predispose to calcium stone formation, because an increased amount of calcium is available for complexing with oxalate or phosphate within the urinary tract. Inflammatory bowel disease is associated with marked hyperoxaluria. Medullary sponge kidney disease is found in 10% to 30% of persons with calcium stones.

Struvite stones are found predominantly in women; these stones are associated with urinary tract infections (UTIs). They occur when the urine is alkaline (pH greater than 7.0) and a urea-splitting organism such as *Proteus* or *Klebsiella* is present. Uric acid stones are formed from an increase in uric acid production or ineffective elimination of uric acid, as found in gout. This may result from dietary intake of foods high in uric acid, acidic urinary pH (e.g., type I renal tubular acidosis, significant bicarbonate loss associated with severe diarrhea), regional enteritis, hereditary factors (including a predisposition to gout), or ulcerative colitis. Uric acid stones account for approximately 15% to 20% of all cases of nephrolithiasis. Cystine stones are created because of a rare autosomal recessive disorder called cystinuria. These stones are formed when there is a metabolic error that causes a decrease in tubular reabsorption in the kidney, leading to urinary cystine concentrations greater than 250 mg/L. Cystine stones account for approximately 1% to 3% of all cases of renal stones.

Pathophysiology

Renal stone formation occurs when normally soluble mineral substances supersaturate the urine and deposit out of solution as crystals, which serve as nuclei for stone-forming substances such as calcium oxalate, calcium phosphate, triple-phosphate struvite (magnesium ammonium phosphate), uric acid, or cystine. Stone formation may also be facilitated by extremes in the urinary pH (alkaline or acid). This crystal combination becomes trapped within the renal system, where it continues to attract other crystals, causing the stone to increase in size. Stones are typically anchored at the ends of collecting ducts at sites of epithelial injury. The calculi vary in size and composition and typically grow within the renal tubules, calyces, renal pelvis, ureters, or bladder. Large stones are called staghorn calculi if they span more than one of the renal calyces. Although over the span of years their presence in the kidneys may lead to chronic renal failure, unless they fragment and pass through the urinary system, they are generally asymptomatic.

The four major types of stones and their characteristics, causes, etiology, diagnosis, and treatment are listed in Table 12.4. These forms are not mutually exclusive and share certain risk factors, and many patients have renal stones of a mixed etiology. Calcium stones are light in color; their crystals characteristically resemble red blood cells (RBCs) in shape and size or may be a larger "dumbbell" form. Formation of these stones may be secondary to hypercalcemia or they may be idiopathic. Hyperoxaluria and hyperuricosuria are more associated with calcium oxalate stones, whereas calcium phosphate stones are more associated with primary hyperparathyroidism. Struvite stones are flat and consist of hexagon-shaped crystals that are radiopaque. They often form secondary to UTI caused by *Proteus mirabilis.* Staghorn calculi are more likely to be struvite stones. Uric acid

Table 12.4 Renal Calculi

Type of Stone (percentage of all stones)	Characteristics	Causes	Management
Calcium (75%–80%)	Resembles RBCs in shape and size or large dumbbell form Light color	Idiopathic, hypercalcemia, or increased levels of uric acid	Thiazide diuretics Diet Cholestyramine or oral calcium Surgery
Struvite (15%)	Flat, hexagon shape Radiopaque	Alkaline urine, infection with urea-splitting organisms such as *Pseudomonas*	Antibiotic therapy Surgery
Uric acid (7%)	Teardrop-shaped or flat square plates Red-orange color	Increased uric acid production, high intake of uric acid, acidic urine, regional enteritis, ulcerative colitis, or idiopathic	Allopurinol Fluid replacement Diet Surgery
Cystine (<1%)	Lemon yellow and sparkle	Hereditary	Force fluids D-Penicillamine Tiopronin

stones are radiolucent and red-orange, with a teardrop or flat square shape. Formation of these stones may be associated with a hereditary etiology of gout or with idiopathic causes. Uric acid crystals may also serve as a nidus for calcium stone formation. Cystine stone crystals are lemon yellow, hexagonal, and sparkle under light microscopy. Finally, certain medications promote crystalluria and predispose the patient to renal stones; these medications include topiramate, triamterene, and sulfadiazine. The protease inhibitor indinavir (Crixivan) used to treat HIV-positive patients may actually precipitate within the renal collecting system, causing direct stone formation.

The incidence of recurrence of certain stones is approximately 40% to 50% within 5 years, with an estimated one-third of patients eventually losing a kidney if the condition is untreated or inadequately treated. Complications can occur when the stone obstructs the flow of urine. This can lead to urinary retention, accumulation of uremic wastes, end-stage renal failure, and/or electrolyte imbalances. Stones can predispose the patient to UTI and hematuria.

Clinical Presentation

Subjective

The patient with an acute episode of nephrolithiasis may present with a variety of signs and symptoms, depending on the location, size, and type of stone. Onset is usually sudden, with renal colic, which is a type of flank pain that is not relieved by changes in position or other measures. The pain may present with a referral pattern that originates in the flank or kidney area and radiates across the abdomen down into the groin, perineal area, and inner thigh. This colicky pain occasionally progresses to constant pain at a level that can be excruciating and intractable. Other symptoms of renal calculi may include nausea, urinary frequency, vomiting, diaphoresis, dysuria, hematuria, and weakness. The patient may report a history of a recent or chronic UTI, previous diagnosis with nephrolithiasis, a dietary history consistent with stone formation, or alterations in voiding patterns.

Objective

The patient may present with abdominal distention and guarding on palpation, flank tenderness on percussion, and decreased or absent bowel sounds on auscultation. Fever may be present if there is acute infection related to obstruction. Blood pressure (as well as pulse rate and respiratory rate) may be elevated because of pain.

Diagnostic Reasoning

Diagnostic Tests

The diagnostic work-up should begin with a routine urinalysis, complete blood count, and blood chemistry profile. The urinalysis may be normal or it may show RBCs, WBCs, crystals, cast minerals, bacteria, pus, and an alkaline or acidic pH. Table 12.5 identifies the tests and the expected results that would lead to the suspicion of renal calculi. Either gross or microscopic hematuria is observed in the majority of cases but may be absent in up to 30% of cases, depending on the time of presentation. Identification of the type of stone formation is important for the appropriate treatment to be instituted. The results of these tests should lead the clinician to

Table 12.5 Tests for Renal Calculi

Test	Rationale
Urinalysis	Shows RBCs, WBCs, crystals, casts, minerals, bacteria, pus, abnormal pH.
24-hour urine	May show increased levels of creatinine, uric acid, calcium, phosphorus, oxylate or cystine.
Serum chemistry	May show increased levels of magnesium, calcium, uric acid, phosphorus, protein, and electrolytes.
Serum BUN and creatinine	Shows BUN elevated secondary to urinary tract obstruction; creatinine elevated secondary to damage to the kidney.
Complete blood count	May show infection or septicemia.
Kidney and upper bladder	Shows calculi and/or anatomical changes.
Intravenous pyelogram	Shows calculi and any abnormality in anatomic structures.
Cystoureteroscopy	May show calculi and/or abnormal structural defects.
CT scan	Identifies calculi and other masses in the renal system.

continue the diagnostic work-up with noninvasive tests to identify obstructions, masses, or anatomical abnormalities. Further diagnostic tests include the kidney, ureters, and bladder x-ray studies, abdominal or transvaginal ultrasonography (used for pregnant women and those of childbearing age in whom radiation must be avoided), or noncontrast helical computed tomography scan (contrast is avoided due to potential renal toxicity). Invasive procedures may be necessary to visualize or assist in removing the stone through IVP, cystourethroscopy, or other surgical procedures.

Differential Diagnosis

The differential diagnosis for renal calculi may include a variety of diseases, including appendicitis, diverticulitis, mesenteric adenitis, pancreatitis, ileus, peptic ulcer disease, abnormalities of the fallopian tubes and ovaries including ovarian cysts, ectopic pregnancy, gallbladder disease, and abdominal aneurysms. A tentative diagnosis of renal calculi is made from the history and the findings of the physical exam showing increased intensity of renal colic with flank pain or a pattern of referred pain, coupled with flank tenderness. Because hematuria may be the only presenting sign of stone formation, malignancy (renal cell carcinoma), which is typically painless, must also be considered. Diagnosis of renal stones is confirmed by urinalysis that is positive for blood and renal visualization by radiography or ultrasound.

Management

Treatment goals are to decrease the symptoms and complications arising from existing stones and prevent subsequent recurrence. It is important, therefore, to decrease the concentration of stone-forming substances in the urine. An intake of six to eight 8-ounce glasses of water a day is essential; this high fluid intake must continue indefinitely. Most stones smaller than 5 mm pass spontaneously; rates of spontaneous passage steadily decrease for stones larger than this and is highly unlikely for stones larger than 10 mm.

Initially, pain management is the priority. Oral NSAIDs in doses of 600 to 800 mg 3 times daily or oral narcotics such as hydrocodone-acetaminophen (Vicodin, Lortab), acetaminophen-codeine (Tylenol #3), or oxycodone-acetaminophen (Percocet) are often necessary. In some cases, intramuscular or IV narcotic analgesics may be necessary, but most studies have demonstrated that NSAIDs are as effective as oral opiates, albeit slower acting. In addition, they have also been shown to relax ureteral smooth muscle, which may facilitate stone passage. Antispasmodics such as flavoxate or oxybutynin may also provide temporary relief, but the anticholinergic effects of these medications must be taken into account, because they may lead to urinary retention. Warm compresses to the lower back, focused breathing, imagery, and diversional activities may provide minimal relief.

Certain drugs help to reduce urinary excretion of stone-forming substances. Most notably, thiazide diuretics (e.g., hydrochlorothiazide) reduce calcium excretion; allopurinol reduces uric acid production by inhibiting xanthine oxidase; and D-penicillamine affects the excretion of cystine. Importantly, loop diuretics such as furosemide (Lasix) and triamterene increase calciuria and typically worsen renal stone formation.

Noninvasive or invasive surgical interventions may be necessary if the stone does not pass spontaneously; these are presented in Table 12.6. Noninvasive procedures to treat renal calculi are aggressive and have many of the same risks that occur with surgery. Extracorporeal shock wave lithotripsy (ESWL) sends shock waves throughout the outside of the body to disrupt proximal and midureteral calculi and is preferred for stones smaller than 10 mm. NSAIDs should be avoided at least 3 days before this therapy to minimize the risk of bleeding. The percutaneous ultrasonic lithotriptor (PUL) applies

Table 12.6 Surgical and Other Procedures for Renal Calculi Management

Procedure	Type of Procedure	Location of Calculi	Description
Lithotripsy	Invasive	Bladder or urethra	Crushing of the calculi under direct visualization using a lithotriptoscope
Lithotony	Invasive	Renal system	Arthroscopic removal of the calculi
Lithonephrotomy	Invasive	Kidney	Incision of the kidney to remove the calculi
Lithotomy	Invasive	Bladder or urethra	Incision of the bladder or ureter to remove the calculi
Ureteral stent	Invasive	Kidney or ureter	Stent is placed in front of the calculi to facilitate elimination
Lithotrophic	Noninvasive	Renal system	Agent used to dissolve calculi
Percutaneous ultrasonic lithotriptor	Noninvasive	Renal system	Ultrasound waves are applied to the outside of the body to crush the calculi
Extracorporeal shock wave lithotripsy	Noninvasive	Renal system	Shock waves are applied to the outside of the body to crush the calculi

therapeutic ultrasound waves to the outside of the body to achieve the same results. A lithotriptic agent may also be used to dissolve the calculi stones.

Invasive procedures may be necessary to remove the stone because of the location of the stone or the failure of noninvasive procedures to destroy the stone. The procedure chosen is dependent on the location, size, and type of stone (e.g., struvite stones typically require ESWL or surgical intervention). First and second generation lithotriptors originally visualized stones via fluoroscopy or ultrasonography. However, advances in urethroscopy with flexible fiber-optic systems now allow for the direct visualization of stones virtually anywhere along the urinary tract from the urethra to the renal pelvis. Stones may be crushed via electrohydraulic or laser lithotripsy in conjunction with these visualization techniques. Flexible ureteroscopy combined with laser lithotripsy is now the preferred treatment for proximal ureteral stones larger than 10 mm. The patient is then able to eliminate the stones naturally after they are crushed into smaller pieces. *Lithotomy* is an incision into the bladder or ureter to remove calculi or place a ureteral stent, whereas *lithotony* specifically denotes arthroscopic extraction of a renal stone from the bladder. Ureteral stents may be placed within the ureters to facilitate the passage of stones through natural elimination. *Lithonephrotomy* is an incision into the kidney to remove a stone.

Preventive measures should be taken to reduce the incidence of recurrence. The incidence of calcium-based stones may be reduced by increasing fluid intake (greater than 2 L/day) and taking thiazide diuretics or allopurinol. In addition, an acidic diet higher in meat content actually promotes calcium excretion. Hypocitraturia and hyperuricosuria may both be treated with potassium citrate supplementation. However, this may alkalinize the urine, creating another risk factor for stone formation, and care must be taken to stop this drug if urine pH is greater than 6.0. In similar fashion, appropriate treatment of UTI must be initiated to avoid recurrence of struvite stones, and the urease inhibitor acetohydroxamic acid (Lithostat) 250 mg PO three to four times daily may be given as adjunctive therapy to prevent urinary alkalinization, if infection with urease-producing organisms is confirmed.

Oxalate-containing stones should be prevented with a low-oxalate diet (see Patient Education). Struvite stone production may be decreased by preventing UTIs through patient education and self-care as previously discussed, maintenance of antibiotic therapy, or acidifying the urine with methenamine mandelate. Uric acid stones may be decreased through diet modification (see Patient Education) or medications that facilitate uric acid excretion, such as allopurinol. Recurrence of cystine stones may be reduced through maintenance doses of D-penicillamine, tiopronin, or captopril, which binds cystine via sulfhydryl moieties.

Follow-up and Referral

Most patients with renal calculi are treated and followed on an outpatient basis. The patient may need hospitalization for secondary complications that can occur, such as severe nausea and vomiting leading to dehydration, urinary obstruction, decreased renal function, severe bleeding, intractable pain, and significant infection. The patient should be referred to a urologist and/or nephrologist for stone removal under these circumstances or if stone formation is thought to be secondary to a metabolic abnormality.

Patient Education

The patient should be instructed to increase fluid intake to six to eight 8-ounce glasses per day unless prevented

by cardiac complications, such as congestive heart failure. Increasing fluids will assist in the elimination of the stones. The patient should monitor intake and output and strain the urine for passed stones. Over-the-counter drugs that contain phosphorus or calcium, such as many antacids (e.g., Tums), and most vitamin supplements, especially vitamin D_3, should be avoided. The role of vitamin C supplementation is controversial. Although some promote high-dose vitamin C supplementation to acidify the urine and facilitate stone dissolution (especially the calcium phosphate type), excess vitamin C (1 g/day) is known to undergo chemical conversion to oxalate, which may promote oxaluria and calcium oxalate stone formation. In contrast, vitamin B_6 and magnesium are both known to decrease oxaluria by facilitating oxalate metabolism. Magnesium further competes with calcium, reducing calcium-containing stone formation. In turn, supplementation of vitamin B_6 and magnesium has been shown to reduce the incidence of oxalate stones, although the ideal doses have not been established.

The patient should be encouraged to increase his or her activity level as tolerated, because inactivity contributes to stone formation secondary to calcium shifts and urinary stasis. Dietary modification is also important. In general, caffeine, beer, and wine should be avoided. A low-oxalate diet is appropriate for calcium oxalate stones, which avoids oxalate-rich foods including beets, black tea, chocolate and cocoa, lamb, nuts, rhubarb, and spinach. A low-phosphorus diet for calcium phosphate or struvite stones would eliminate milk products and cola drinks. A low-purine diet is often effective in reducing stones formed from excess uric acid. This diet limits the intake of purine-rich foods, such as organ meats, red meats, seafood (especially sardines, anchovies, and scallops), poultry, legumes, whole grains, and alcohol (which decreases uric acid clearance).

RENAL TUMORS

Renal tumors (neoplasms) are characterized by abnormal tissue formations on or around the kidney that may cause or contribute to renal disease. They may be primary or secondary (resulting from malignant spread), although the latter are rarely clinically relevant and are typically found during postmortem examination. *Renal adenomas* (benign tumors) and adenocarcinomas are rare; these tumors usually create complications requiring surgical removal.

Epidemiology and Causes

Renal cell carcinomas originating in the renal cortex are the most common (85%) malignant renal tumors. These tumors occur most often in the parenchyma of the kidney, with ureteral and urethral tumors occurring rarely. Histologically, they are classified as clear cell (75%–85%), chromophilic or papillary (15%), chromophobic (5%), and the uncommon forms of oncocytic and collecting duct tumors. Transitional cell carcinomas are the next most common, comprising 5% to 8% of all tumors; these typically affect the bladder and are discussed extensively in the next section.

Renal tumors are responsible for approximately 3% of all adult malignancies. The incidence is higher in men (although the difference in incidence has been decreasing over time), with onset between ages 55 and 70 years and rarely occurring in people younger than 35 years of age. These cancers are curable in more than 90% of patients if they are superficial and/or localized in the renal pelvis or ureter. Tumors that are invasive have a 10% to 15% chance of being cured. In children, nephroblastoma (Wilms' tumor) is common, comprising 5% of primary tumors, whereas sickle cell disease has a known, albeit rare, association with carcinoma of the renal medulla.

Obesity; exposure to asbestos, cadmium, and/or gasoline; the use of phenacetin- and aspirin-containing analgesics; and chronic hemodialysis for acquired polycystic kidney disease are all risk factors for renal cell carcinoma. Cigarette smoking has a 25% to 30% correlation with the development of renal cell carcinoma.

Pathophysiology

The urinary system is lined with transitional cell epithelium where tumors may form. The tumors often are asymptomatic and grow undetected until complications from the tumor present. The tumors are usually encapsulated and located near the cortex unilaterally. Renal neoplasms may be diagnosed as benign or malignant; they may be identified as either primary (originating in the kidney) or secondary (originating or spread from another source). Primary malignancies usually spread through the lymph nodes and blood vessels to the lungs, liver, and bone. Metastatic disease that spreads to the kidney, usually from the lung, is more common than primary renal neoplasms. Metastatic lesions to the ureter typically originate via hematogenous spread from breast or colorectal primary lesions. Direct extension into the ureter may also occur from cervical or colonic neoplasms, as well as pelvic retroperitoneal lymphoma. Benign renal neoplasms are rare but should be removed because of complications that may occur such as pain, bleeding, and obstruction.

Carcinogen exposure has been associated with specific gene mutations that appear to underlie the development of various forms of hereditary renal cell carcinoma, for example, the von Hippel–Lindau tumor suppressor gene on chromosome 3p25 to 26 (associated with both sporadic and hereditary clear cell carcinoma, i.e., von Hippel–Lindau disease), the fumarate hydratase gene, the Birt-Hogg-Dubé tumor suppressor gene on chromosome 17p, the c-*met* oncogene on chromosome 7 that codes the hepatocyte growth factor receptor (associated with hereditary papillary renal cell carcinoma), the *ras* gene family, and *p53* overexpression (implicated in cellular division). However, definitive causal relationships

between these various mutational hot spots and renal cancer have not been proven.

Clear cell carcinomas consistently display mutations spanning the 3p14 to 3p26 chromosomal region. In contrast, chromophilic carcinomas lack these mutations but have been associated with various trisomies, including chromosomes 12, 16, and 20. Chromophobic carcinomas, which arise from the intercalated cells of the collecting duct system, typically display hypodiploidy with a wide variety of whole chromosomal deletions. The much less common oncocytic carcinomas have been associated with deletions in chromosome 11q13, but as with collecting duct tumors, no consistent chromosomal abnormalities have been identified.

Clinical Presentation

Subjective

Signs and symptoms vary depending on the size of the tumor. Early signs of tumor growth are silent: Approximately 60% of the time, patients present with gross hematuria as the only symptom. The patient complains of a dull, achy flank pain or abdominal mass in approximately 30% of cases. In 10% to 15% of patients, the triad of flank pain, hematuria, and abdominal mass is found, which is often a sign of advanced disease.

Objective

Examination of the patient may reveal other symptoms that may present alone or in combination with hematuria. General signs of advanced disease include weight loss and fatigue; more specific signs and symptoms of renal tumors include intermittent fever (not associated with infection), palpable abdominal mass, and nephralgia. Metastasis of renal cancer indicates a poor prognosis; it typically involves the lungs, lymph nodes, liver, bones, and contralateral kidney.

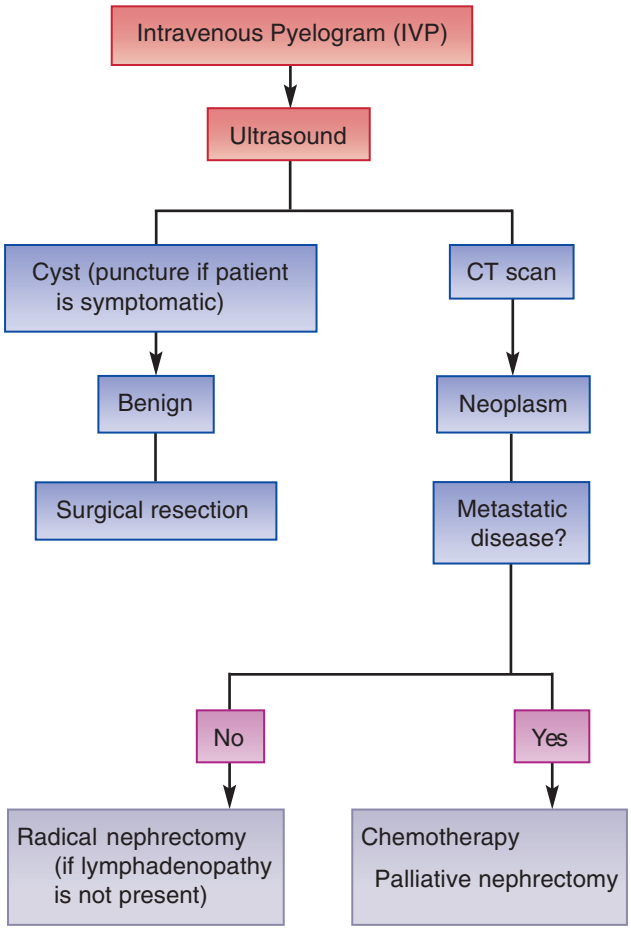
Diagnostic Reasoning

Diagnostic Tests

The diagnosis of a renal mass is initially confirmed by intravenous pyelogram (IVP) with nephrotomography; however, it is often impossible to determine if the mass is solid or cystic with this test. Generally speaking, a cancerous tumor splays, distorts, or occludes the visualization of the collecting system and prevents normal filling and draining of the renal system. Although hematuria is common, urine cytology is not consistently reliable for diagnosing these tumors. Ureteroscopy or ultrasonography with IVP can be used to differentiate a potentially neoplastic tissue from a cyst formation by direct or indirect visualization of the entire renal system. Once tissue biopsy samples are obtained, flow cytometric analysis is used to determine the ploidy (DNA content) of the tumor, and histological analysis determines morphology and tumor grade (degree of cellular differentiation). Urine cytology samples often provide inadequate tissue for such analyses, however, and the mass must be biopsied directly. Treatment Flowchart 12.1 presents evaluation of treatment of a renal mass.

Magnetic resonance imaging and CT scan are useful in preoperative work-up and staging of the metastatic lesion. It is necessary to stage the advancement of the tumor to initiate appropriate treatment. Staging of the neoplasm is confirmed through surgical intervention. Staging identifies the tumor advancement and potential for survival.

- Stage I is defined as a tumor confined within the kidney capsule; it is treated by nephrectomy. The 5-year survival rate is 60% to 75%.
- Stage II is defined as the invasion of the renal capsule that is confined within the Gerota's fascia; it is treated by nephrectomy. The 5-year survival rate is 47% to 65%.
- Stage III is defined as involvement of the regional lymph nodes ipsilateral, renal vein, or vena cava. The 5-year survival rate is 5% to 15%.
- Stage IV is defined as distant metastasis, with a 5-year survival rate of less than 5%.



Treatment Flowchart 12.1 Evaluation of Treatment of a Renal Mass

Approximately 30% of patients with renal tumors have metastatic disease when diagnosis is made. The most common sites of metastasis are the lung (50%–60%), bone (30%–40%), regional nodes (15%–30%), brain (10%), and adjacent organs.

Differential Diagnosis

A renal cyst is differentiated from a renal tumor by biopsy. Renal calculi and renal infarction must be ruled out, as well as (rarely) renal tuberculosis. In addition, polycystic kidney disease and hydronephrosis must be considered and may be ruled out on biopsy.

Management

As with any cancer, treatment of renal tumors requires immediate specialist referral to a urologist or surgical oncologist, often with additional consultation by a medical oncologist or nephrologist, depending on the patient's renal function. Treatment for a renal neoplasm is primarily surgical with a partial or total nephrectomy, with or without regional lymphadenectomy if no metastatic disease is present. Less radical surgical interventions have been suggested by a minority of urologists, who stress the poor prognosis of advanced renal tumors, regardless of surgical intervention, as well as increased morbidity and mortality associated with radical surgery.

No universal standards have been accepted for the treatment after nephrectomy. Chemotherapy is not effective with this type of cancer; however, immunotherapy using lymphokine-activated killer cells with or without interleukin-2 may be helpful for selected patients. Radiation therapy is controversial but may be used in combination with nephrectomy or for palliative effects in patients with bone metastasis.

Follow-up and Referral

For follow-up of patients with a total nephrectomy, a CT scan of the abdomen and renal fossa should be done in 3 to 6 months; then the patient may be followed with renal ultrasound every 6 months for 3 years, then annually, unless symptoms occur. Chest x-ray studies are done quarterly for a year to monitor for pulmonary metastasis.

At the time of the neoplasm diagnosis, the patient should be referred to a urologist for a surgical evaluation and to an oncologist for cancer treatment. The patient should be seen by the primary-care provider as needed for problems not related to the cancer and to assist the patient with counseling regarding grief, death and dying, body image changes, and quality of life.

Patient Education

The patient needs preparation for the surgical intervention. Postoperatively, the focus is on pain management and promoting comfort through the use of moist heat, analgesic/narcotics, or positioning on the side with pillows and back support. Additional interventions include preventing pneumonia and atelectasis by encouraging the patient to do coughing and deep breathing exercises, incision care, and monitoring bowel and bladder function.

BLADDER TUMORS

Bladder tumors are abnormal tissue masses that occur in the bladder wall lining, which is composed of transitional cell epithelium, or "urothelium." These tumors commonly recur despite aggressive treatment.

Epidemiology and Causes

Bladder tumors are the most common cancer of the urinary system; they represent approximately 2% of all malignant tumors and result in 3% of cancer deaths per year. Bladder cancer is the fifth most common neoplasm in the United States; it occurs in men three times more often than in women, and most often in adults aged 60 to 70. It is also more common among non-Hispanic white men than in other ethnic or racial groups.

There is a significant correlation between bladder tumors and risk factors including cigarette smoking, presence of renal tumors, exposure to aromatic amine dyes known as arylamines (e.g., beta-naphthylamines, xenylamine, 4-nitrobiphenyl, and benzidine), arsenic, chronic use of phenacetin-containing analgesics, saccharin (in rodent studies), chronic lower urinary tract infection (UTI), schistosomiasis, and recurrent nephrolithiasis. Other predisposing factors include previous radiation treatment for cervical, ovarian, or prostate cancer and prior cyclophosphamide chemotherapy.

Pathophysiology

The second most common form of renal carcinomas arise from the transitional cell uroepithelium (urothelium), which lines the mucosal surfaces of the collecting tubules, renal calyces, renal pelvis, ureters, bladder, and urethra. Transitional cell carcinomas account for 90% of all tumors of renal pelvic or ureteral origin. Bladder tumors are primarily transitional cell carcinoma, which have the most favorable prognosis, but may also include squamous cell carcinoma and adenocarcinoma. Bladder tumors are described as papillary (90%) or nonpapillary (10%). Papillary bladder lesions form as a small protuberance attached to a stalk. Nonpapillary lesions are more invasive and have a poorer prognosis. Primary bladder cancer tends to metastasize to the lymph nodes, liver, bones, and lungs. Bladder cancer may be secondary to local extension and/or metastatic disease from adjacent organs such as the cervix in women and the prostate in men.

Genetic analyses of transitional cell carcinomas demonstrate a loss of heterozygosity at any one of multiple chromosomal locations, including 9q (most common), 5p, 8p, 10q, 11p, and 17p—all of which may represent sites of tumor suppressor genes. Genetic predispositions also appear to exist, based on allelic variants of the p450 cytochrome enzyme complex. For instance,

smokers afflicted with bladder cancer express p450 enzyme variants that lead to increased activation of arylamine metabolites, a required step for their role in bladder carcinogenesis. Along this same line, allelic variants exist for the *N*-acetyltransferase gene *NAT2,* which (along with *NAT1*) serves as the primary pathway for the metabolism and detoxification of arylamines via *N*-acetylation. Individuals with *NAT2* variants conferring a "slow-acetylation" phenotype are up to 17 times more likely to develop bladder cancer than those with a "fast-acetylation" phenotype. A similar phenomenon exists regarding the glutathione-*S*-transferase M1 gene *(GSTM1),* which contributes to detoxification of carcinogenic compounds via conjugation to glutathione and the facilitation of excretion. In the United States, nearly 50% of white men display deletions in both alleles of this gene, effectively eliminating any enzymatic activity from the *GSTM1* gene product.

Transitional cell carcinomas often present multifocally along the urinary tract, spreading via intraluminal seeding or intraepithelial migration in a process known as "field cancerization." However, these multifocal tumors still display monoclonality along their entire distribution. Squamous cell carcinoma, a less common form of bladder cancer that also accounts for 7% of renal pelvis tumors, is typically associated with inflammatory processes, including chronic UTI and renal calculi. These tumors tend to be deeply invasive and carry a poor prognosis.

Clinical Presentation

Subjective

The patient with a bladder tumor frequently is asymptomatic until he or she has an episode of hematuria that varies in severity from microscopic to gross amounts and may be intermittent or continuous. Other presenting symptoms may include dysuria, frequency, chills, low-grade fever, weight loss, and urinary urgency. Patients with advanced disease may complain of pelvic pain and symptoms associated with urethral obstruction.

Objective

The physical exam may be positive for a palpable mass and/or metastatic manifestations. The urinalysis shows trace to gross hematuria, possibly with abnormalities in protein level, RBCs, or WBCs. The serum complete blood count may indicate that anemia is present.

Diagnostic Reasoning

Diagnostic Tests

The diagnosis of bladder tumor is confirmed by visualization of the lesion through cystoscopy and biopsy. A urine cytology positive for transitional cell cancer can confirm the diagnosis; however, negative results do not rule out the possibility of bladder cancer. Cystoscopic evaluation can be used to confirm the suspected diagnosis, to determine the location of the tumor, and to aid in the staging of the tumor. The cystoscopy should include a bladder washing for cytology and a mucosal biopsy. An abdominal or pelvic CT scan, with or without IVP, may be useful for determining the metastatic progress of the disease.

In general, transitional cell carcinomas are staged from A to D, according to level of invasion: stage 0 tumors are confined to the mucosa; stage A tumors invade the lamina propria; stage B tumors invade the muscular layer; stage C tumors extend to the peripelvic fat or renal parenchyma; and stage D indicates metastatic disease. The tumor-node-metastasis (TNM) system of the American Joint Committee on Cancer may also be used, with nodal metastases reflecting stage IV cancer. When transitional cell carcinomas are looked at as a whole, in situ disease has a 5-year survival rate of 95%, localized disease nearly 90%, regional disease just over 60%, and distant disease only 17%.

Urine tumor marker tests can detect recurrent tumors. The *N*-benzoyl-L-tyrosyl-*p*-aminobenzoic acid (BTA) and nucleoside 5′-monophosphate (NMP22) tests are more sensitive for recurrent tumors than urine cytology.

Differential Diagnosis

Because this disease most often presents as painless hematuria, differential diagnoses such as stones, infections, trauma, other tumors such as renal cell carcinoma, arteriovenous malformations, and glomerulonephropathies should be ruled out. Differential diagnosis for bladder irritability includes inflammation, stones, neurological dysfunction, and foreign bodies. Biopsy is necessary for definitive diagnosis.

Management

Treatment is dependent on the type, size, and degree of invasion of the bladder tumor, which is classified as superficial, invasive, or metastatic. *Superficial tumors* involve the bladder mucosa and submucosa; they are treated by endoscopic resection or laser resection. These tumors tend to recur, and the patient must be reexamined every 6 months. *Invasive tumors* involve the muscle and/or perivesical fat around the bladder. These tumors are treated with radical cystectomy or with radiation and chemotherapy. The 5-year survival rate is 65% to 75% with treatment. Research indicates that neoadjuvant chemotherapy can improve the survival rate in cases of advanced urothelial cancer (Level I; Siefker-Radtke et al, 2013; International Collaboration of Trialists, 2011). *Metastatic tumors* involve the lymph nodes, bone, or viscera and are treated with radiation and/or chemotherapy. This stage of the disease has a 5-year survival rate of 10% to 15%.

For the majority of bladder tumors, surgical resection is the treatment of choice. Immediate referral to a urologist or surgical oncologist is critical, as well as follow-up

with a medical oncologist and/or nephrologist, depending on functional renal status. Intravesical chemotherapy may prevent recurrence, but radiation therapy for bladder tumors is less effective than the other interventions. See Treatment Standards/Guidelines 12.1.

Follow-up and Referral

All patients diagnosed with bladder cancer should be referred to a urologist for evaluation and treatment. Obtain a urinalysis and cystoscopy every 3 to 6 months because of the increased risk of recurrence of bladder tumors. Patients who have been diagnosed with advanced metastatic disease should be referred to an oncologist. Home health or hospice care may be appropriate for patients who need skilled care and ongoing patient teaching; an ostomy nurse may be necessary for patients who have undergone an ileostomy or urostomy.

Patient Education

Teach the importance of ongoing follow-up care. For terminal patients, many issues must be addressed and discussed to give patients and their caretakers an improved quality of life. Some of these are fear and anxiety, grieving, anticipation, self-image issues (including loss of hair), nausea and vomiting, weight loss, anorexia, impotence, sterility, pain, fatigue, loss of job, loss of family member, and potential for infection. Ileostomy/urostomy teaching is indicated for patients whose bladders have been surgically removed. Preventive measures include not smoking and avoidance of other chemical carcinogens.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI), also known as *acute renal failure,* is the sudden and rapid deterioration of renal function resulting in an inability to maintain acid-base, fluid, and electrolyte balance and an accumulation of nitrogenous wastes. AKI now has a universal definition and staging system to allow for earlier detection and management of disease. AKI is defined when one of the following criteria is met: serum creatinine rises 26 μmol/L or greater within 48 hours or 1.5-fold or greater from the reference value, which is known or presumed to have occurred within 1 week, or urine output is less than 0.5 mL/kg/hr for more

Treatment Standards/Guidelines 12.1 Bladder Tumors

Stage	Description	Treatment Options	Characteristics
Stage 0	Noninvasive papillary carcinoma (Ta). Has grown toward hollow center of bladder but not into connective tissue or muscle of bladder wall. Has not spread to lymph nodes or distant sites.	Endoscopic or laser resection intravesical immunotherapy OR intravesical chemotherapy	Recurrence is common; follow up every 6 months Relative 5-year survival rate 98%
Stage I	Cancer has grown into the layer of connective tissue under the lining layer but has not reached the muscle layer in the bladder wall. Has not spread to lymph nodes or distant sites.	Simple or radical cystectomy, radiation, chemotherapy	Relative 5-year survival rate 88%
Stage II	Cancer has grown into thick muscle layer of bladder wall, but has not passed through the muscle to reach the fatty tissue surrounding the bladder. Has not spread to lymph nodes or distant sites.		Relative 5-year survival rate 63%
Stage III	Cancer has grown into the fatty tissue surrounding bladder. May have spread to prostate, uterus, or vagina, but not growing into pelvic or abdominal wall. Has not spread to lymph nodes or distant sites.		Relative 5-year survival rate 46%
Stage IV	Cancer has grown through the bladder wall and into pelvic or abdominal wall, may have spread to nearby or distant lymph nodes or to sites such as the bones, liver, or lungs.	Treatment is palliative only Systemic chemotherapy and/or radical cystectomy or external beam radiation therapy	Relative 5-year survival rate 15%

than 6 consecutive hours. The reference serum creatinine should be the lowest creatinine value recorded within 3 months of the event.

The most common causes of AKI are associated with intrarenal injury caused by renal hypoperfusion or nephrotoxins. The signs and symptoms vary with each patient and are most often due to uremia or its underlying cause. Persons with AKI usually do not experience the profound neurological and musculoskeletal disorders seen in patients with chronic renal failure (CRF). Although recovery from AKI may be rapid and complete, this disorder nonetheless has a high mortality rate, estimated at anywhere between 5% and 80%, depending on the patient's age, the cause of AKI, and the extent of multiorgan involvement.

Epidemiology and Causes

It is estimated that 5% of all hospitalized patients develop AKI; for patients in intensive care units, the rate is as high as 15%. Two percent to 7% of all post–open-heart surgery patients are estimated to develop AKI. Fifty percent of AKI that develops in hospitalized patients is considered iatrogenic. AKI affects all ages and both sexes equally.

Risk factors for AKI include surgery, especially for older patients or patients of any age with elevated creatinine levels. Community-based AKI occurs more frequently among vulnerable populations such as individuals with underlying renal disease, multiple myeloma, or diabetes. AKI is also one of the potential risks related to open-heart surgery and other cardiac procedures (e.g., cardiac catheterization) and use of IV contrast dyes. Any problem that causes decreased blood flow to the kidneys can lead to AKI: anaphylactic shock caused by drug or transfusion reactions, ingestion of nephrotoxic substances (aminoglycosides, angiotensin-converting enzyme [ACE] inhibitors in renal artery stenosis), malignancy, sepsis, cardiac problems, aneurysm, liver cirrhosis, trauma, dehydration, or shock.

AKI is classified into three major groups based on the anatomical nature of the lesion: prerenal azotemia, intrarenal azotemia, or postrenal azotemia. *Prerenal azotemia* is the name given to any condition that leads to an overall decrease in renal perfusion; etiologies in this group include hypovolemia, renovascular disease, decreased cardiac output, systemic vasodilation, renal vasoconstriction, and impairment of renal autoregulation of blood flow, which is often associated with drugs such as ACE inhibitors or NSAIDs. *Intrarenal* refers to disorders that affect the renal parenchyma itself, such as glomerulonephritis, acute tubular necrosis (often caused by ischemic insult or nephrotoxic drugs such as aminoglycosides), interstitial nephritis (often an allergic type of reaction to various drugs or transfusion reactions), and tubular obstruction. Immune-mediated phenomena may lead to AKI following acute bacterial infection, for example, thrombotic thrombocytopenic purpura (TTP) or hemolytic uremic syndrome (HUS) following *Escherichia coli* gastroenteritis. *Postrenal* azotemia refers to any etiology that might lead to an obstruction of flow of urine from the kidneys, including ureteral obstruction, bladder neck obstruction, or urethral obstruction. Major causes include benign prostatic hyperplasia/hypertrophy (BPH), prostate or bladder cancer, and metastatic disease affecting the urinary tract. An important consideration in the male patient with preexisting BPH is the use of over-the-counter sympathomimetic decongestants and other cold remedies, the alpha-agonist properties of which may lead to acute worsening of prostatic hypertrophy with resultant anuria.

Table 12.7 presents the major causes of AKI. Complications commonly seen as a result of AKI include intravascular volume overload, metabolic acidosis, anemia, hyperkalemia, and uremic syndrome, which is characterized by nausea, vomiting, anorexia, pericarditis, and both central and peripheral nervous system abnormalities including altered mental status, seizures, or coma. *Prerenal, intrarenal,* and *postrenal* mechanisms of AKI are not mutually exclusive, however, and many patients present with a combination of these pathologies.

Table 12.7 Major Causes of Acute Kidney Injury

Prerenal Acute Kidney Injury
- Fluid and electrolyte depletion
- Hemorrhage
- Septicemia
- Cardiac failure
- Liver failure
- Heat stroke
- Burns

Intrarenal Acute Kidney Injury
- Ischemia
- Toxins
- Radiocontrast agents
- Hemoglobinuria
- Myoglobinuria
- Acute glomerulonephritis
- Arterial or venous obstruction
- Tubulointerstitial nephritis
- Pyelonephritis
- Papillary necrosis
- Precipitation from hypercalcemia
- Urates
- Myeloma protein

Postrenal Acute Kidney Injury
- Prostatism
- Bladder tumor
- Pelvic tumor
- Retroperitoneal tumor
- Renal calculi

Pathophysiology

Prerenal Azotemia

Prerenal azotemia is caused by decreased blood flow to the kidneys, usually associated with poor systemic perfusion. Etiologies includes hypovolemia, altered peripheral vascular resistance, diminished cardiac output, congestive heart failure, renal artery disorders such as vasculitis, and to a lesser extent thromboembolic disease, as well as chronic liver diseases such as cirrhosis and the hepatorenal syndrome.

The kidney's compensatory mechanisms to hypoperfusion are autoregulation and activation of the renin-angiotensin-aldosterone axis via the release of renin. In the face of damage to select renal tissue, these mechanisms attempt to shunt blood to undamaged nephrons in a process called adaptive hyperfiltration. Autoregulation depends on the body's ability to control afferent arteriole dilation and efferent arteriole constriction in order to maintain normal glomerular filtration rate (GFR) and creatinine clearance. The release of renin activates the proenzyme angiotensinogen to the biologically inactive angiotensin I. In turn, ACE converts angiotensin I into angiotensin II, one of the most potent vasoconstricting agents in the body. Its production results in peripheral vasoconstriction and increased sodium reabsorption via increased aldosterone production. Antidiuretic hormone (ADH) is released in response to the increased plasma sodium concentration. ADH further enhances vasoconstriction and increases water reabsorption, thereby decreasing urinary output and increasing blood volume.

These mechanisms attempt to maintain systemic and renal perfusion. However, if the adaptive mechanisms of the kidneys fail, AKI develops because of hypoperfusion. As a result, glomerular filtration and the excretion of urea decrease, along with increased sodium and water reabsorption, resulting in an overall increase in blood urea nitrogen (BUN). Thus, although adaptive hyperfiltration is initially beneficial, allowing normal serum creatinine to be maintained in the face of mild renal insufficiency, prolonged activation of this compensatory mechanism leads to progressive renal failure.

Intrarenal (Parenchymal) Azotemia

Intrarenal azotemia results from injury to renal tissue; it is usually associated with intrarenal ischemia, toxins, or both. Accounting for up to 50% of all cases, intrinsic dysfunction is considered after prerenal and postrenal causes have been excluded. The sites of injury are the glomeruli, vasculature, interstitium, and tubules.

Acute tubular necrosis (ATN) is the most common cause of intrarenal azotemia and AKI in general. In ischemic ATN, the ischemic event refers to prolonged hypoperfusion and ischemia of the kidneys, with a sustained mean arterial pressure (MAP) in adults of less than 75 mm Hg. When renal autoregulation fails, the sympathetic nervous system (SNS) responds by initiating the renin-angiotensin system as the kidney attempts to redirect blood flow to the remaining healthy nephrons in a process called adaptive hyperfiltration, as explained in the preceding text. Again, however, this initial compensatory mechanism can eventually lead to progressive renal failure, because the SNS response and possibly endothelin production may lead to severe afferent renal arteriole constriction. As a result, overall glomerular hydrostatic pressure, glomerular blood flow, and GFR are decreased.

The length of the ischemic episode determines the amount and degree of renal cellular damage, which may continue after MAP and renal reperfusion are restored. Studies in animal models have demonstrated that a number of immunological mechanisms contribute to renal tubular injury, most notably early complement activation; intracellular adhesion molecule–1 (ICAM-1) expression, which may promote neutrophilic damage to the endothelium; T-cell–mediated cytotoxicity; macrophage activation; and pro-inflammatory cytokine expression (e.g., tumor necrosis factor–α, interleukin [IL]–6, IL-7, various chemokines).

Renal blood flow can be reduced by 50% after an ischemic episode; this is termed *no-reflow phenomenon.* The kidneys are unable to synthesize vasodilating prostaglandins, which usually exacerbates the ischemic injury. Blood flow is redistributed from the cortex to the medulla as a result of SNS stimulation and angiotensin II production. This further decreases glomerular capillary flow and worsens tubular ischemia because these structures are located primarily in the cortex.

With renal ischemia, the availability of nutrients and oxygen for basic cellular metabolism and the tubular transport system is diminished. There is a significant decrease in the production of adenosine triphosphate (ATP) by the mitochondria; and, with insufficient oxygen and ATP, metabolism shifts from aerobic to anaerobic. This shift corresponds with extracellular and intracellular acidosis that alters kidney function. Ischemia also causes a decrease in renal cellular potassium, magnesium, and inorganic phosphates and an increase in intracellular sodium, chloride, calcium, and reactive oxygen species. Sodium and calcium exchange is abnormal because of low ATP, altered Ca-ATPase activity, and increased intracellular sodium. This results in an increase in cellular calcium, which seems to increase cell injury. The formation of oxygen-free radicals further exacerbates cellular damage and apoptosis (programmed cell death) during reperfusion after a prolonged renal ischemic event, an event termed *reperfusion injury.*

The basement membrane is altered by tubular cellular edema and becomes necrotic because of prolonged tubular ischemia. Tubular obstruction occurs from sloughed necrotic cells and cast formation, which seems to be facilitated by a translocation of basement membrane cellular adhesion proteins called integrins to the

luminal membrane. Tubular hydrostatic pressure and Bowman's capsule hydrostatic pressure, which opposes the glomerular hydrostatic pressure, increase as a result of tubular obstruction. This decreases GFR. Injury to the basement membrane increases tubular permeability, allowing tubular filtrate to leak back into the interstitium and peritubular capillaries, further decreasing tubular filtration.

Ischemic ATN is usually associated with oliguria (less than 500 mL/day in adults) because of extensive nephronal injury. Other clinical indications of ATN include decreased urea excretion and elevated BUN, decreased creatinine clearance and elevated serum creatinine, abnormal renal handling of sodium, and an inability to concentrate urine. Urinary osmolality may approximate plasma osmolality of 300 to 350 mOsm/L, a condition called *isosthenuria.*

Toxic ATN involves exposure to toxic by-products of microorganisms or to nephrotoxic agents. Renal toxic drugs often cause allergic interstitial nephritis, characterized by eosinophilic damage. Toxic ATN begins with an event that causes injury to tubular cells. Subsequent pathophysiology is similar to that of ischemic ATN because there is tubular cell necrosis, cast formation, tubular obstruction, and altered GFR. Unlike in ischemic ATN, the basement membrane is usually intact, however, and the injured necrotic areas are more localized. Other differences are nonoliguria, which occurs more often with toxic ATN than with ischemic ATN, as well as the extent of injury with toxic ATN, which may be less than with ischemic ATN. The healing process, therefore, can be more rapid in patients with toxic ATN.

There are several reasons why the kidney is so susceptible to toxic damage. Blood continuously circulates through the kidney, repeatedly exposing the kidney to all components in the blood. Also, the kidney is the major excretory organ for toxic substances, and, as these substances await transport within renal cells, they disrupt cellular function. If liver disease is present, substances that are usually detoxified by the liver can overload the kidney. The kidney also transforms many substances into metabolites that can be toxic to the kidney, and the countercurrent mechanism concentrates bodily substances and other substances that, in increased concentrations, can be toxic to the kidney.

Postrenal Azotemia

Bilateral (ureteral) or distal (bladder outlet or urethral) postrenal obstruction impedes urine flow and results in oliguria or frank anuria. Urine congestion increases pressure retrograde through the collecting system and nephron and slows the tubular fluid flow rate and GFR. There is increased reabsorption of sodium, water, and urea, which results in decreased urine sodium, increased urine osmolality, and increased BUN. The decreased GFR results in a decreased creatinine clearance and, therefore, in an increased serum creatinine level. If the postrenal obstruction is prolonged, the collecting system dilates and compresses parenchymal tissue. The nephron is injured, which results in dysfunction of the concentrating and diluting mechanism, causing the urine osmolality and sodium level to be similar to those of plasma. If the postrenal obstruction is temporary, there is little dilation of the collecting system and loss of renal tissue.

Clinical Presentation

Subjective

Symptoms of AKI are not usually present until the GFR falls to approximately 10% to 15% of normal. The most common symptoms, which are secondary to the accumulation of toxic metabolites such as urea, are fatigue, malaise, nausea, vomiting, pruritus, and mental status changes. Of note, the development of uremic syndrome symptoms bears no direct correlation to increases in BUN or serum creatinine, despite the critical role of hemodialysis in clearing the body of as yet unidentified uremic toxins. Oliguria or even anuria may also be a presenting symptom of AKI but is not present in every case; urine output depends largely on the stage of AKI, as well as the precipitating cause. In some cases, fluid overload may be present, resulting in dyspnea and orthopnea.

A detailed history can give clues to the etiology of AKI. The patient should be questioned about history of drug use, surgery, trauma, or infection as possible sources of renal insult. However, the actual diagnosis of AKI is often made by routine laboratory assessment.

There are multiple signs and symptoms of AKI and four identified stages: initiating, oliguric, diuretic, and recovery. The *initiating stage* begins when the kidney is injured; this stage is variable in length, from minutes to several days (e.g., damage caused by contrast dye occurs within 2 minutes). Decreased urine volume and other signs and symptoms of renal impairment may then become evident. These may include anorexia, lethargy, nausea, headache, muscle cramps, and fatigue. The cause of AKI must be determined, and the plan of treatment should be established in consultation with a nephrologist.

The *oliguric stage* usually lasts from 5 to 15 days but can persist for weeks, depending on the nature of renal damage. Renal repair begins as tubular cells regenerate. Destroyed basement membrane is replaced with fibrous scar tissue, and nephrons become obstructed with inflammatory products. Decreases in glomerular filtration, tubular transport of substances, urine formation, and renal clearance occur. When AKI persists for weeks or longer, renal endocrine functions such as the secretion of erythropoietin are altered. The longer this stage persists, the poorer the prognosis.

The next phase is the *diuretic stage,* defined as beginning when urine output is greater than 400 mL per day and when the BUN begins to fall. This stage is

considered to last until the BUN is stabilized or is in the normal stage.

The fourth and final stage, referred to as the *recovery phase,* extends from the time the BUN is stable and the urine output normal to the day the patient returns to normal activity. The entire process may take 10 months, and some patients never recover but instead progress to CRF.

Objective

The objective manifestations of AKI depend on the stage of the disorder and may be extremely variable; however, these signs can provide an assessment of the degree of renal failure and provide clues as to the underlying etiology. Orthostatic vital signs, skin turgor, and distention of jugular veins should be assessed to obtain information on the patient's fluid balance. Signs of fluid depletion can point to a prerenal etiology, whereas signs of fluid overload suggest a greater degree of renal impairment. Severe proteinuria may lead to generalized edema (anasarca) due to the lack of intravascular oncotic pressure from hypoalbuminemia. Abdominal bruits can suggest renovascular disease. In cases of polycystic kidney disease or hydronephrosis, the kidneys may be palpable. A pelvic or renal exam may reveal causes of outflow obstruction such as an enlarged prostate or pelvic mass.

Diagnostic Reasoning

Diagnostic Tests

Elevated BUN and serum creatinine levels assist in establishing the diagnosis of AKI. GFR is difficult to measure directly and is most commonly estimated using a simplified formula for creatinine clearance (see Diagnostic Tests section under Chronic Renal Failure for complete discussion). However, because acute trends are most important in the diagnosis and follow-up of AKI, direct serum creatinine levels are often used as an estimate of renal function. However, it is critical to remember that these absolute values are heavily influenced by a patient's muscle mass, age, and gender, as well as the presence of any underlying renal disease. As such, serum creatinine levels may overestimate or underestimate renal function in certain populations (e.g., elderly or obese patients).

Serum electrolyte levels (sodium, potassium, chloride, bicarbonate, calcium, phosphate) should also be monitored for potentially life-threatening abnormalities that may develop secondary to impaired renal function. The presence of RBCs, either alone or as casts, may suggest a vascular or glomerular lesion, whereas WBCs and white blood cell casts are seen in interstitial nephritis and cases associated with infection. Eosinophiluria, in particular, is characteristic of allergic interstitial nephritis due to renal toxic drugs. "Muddy-brown" granular casts and epithelial cell casts are strongly associated with ATN but are not considered very specific. Moreover, their absence does not exclude intrinsic renal disease.

Urinary sodium tends to be less than 20 mEq/L in prerenal disease, whereas the kidneys "leak" or "spill" sodium by failing to reabsorb this electrolyte in ATN, resulting in urinary sodium values typically greater than 40 mEq/L. However, variations in water reabsorption also affect urinary sodium concentration. Thus, the fractional excretion of sodium (FENa) is easily remembered as the urinary clearance of sodium divided by the glomerular filtration rate:

$$\text{FENa} = 100 \times \frac{\text{sodium (urinary)} \times \text{creatinine (plasma)}}{\text{sodium (plasma)} \times \text{creatinine (urinary)}}$$

The FENa is more helpful in distinguishing prerenal azotemia from ATN. The FENa is generally less than 1% in prerenal disease related to hypoperfusion because the kidneys try to preserve intravascular volume by maximally conserving sodium. A FENa of greater than 2% reflects acute tubular necrosis, but values between 1% and 2% are considered inconclusive. Of note, FENa has little or no predictive value in the presence of diuretic therapy, because natriuresis is a mechanistic outcome of both thiazide and loop diuretics. Thus, increased urinary sodium may not exclude a prerenal etiology or implicate ATN. In addition, FENa is less helpful when ATN is superimposed on a chronic intravascularly depleted state, such as in hypoalbuminemic cirrhotic liver disease.

ATN is also characterized by an inability to concentrate urine; thus, urine osmolality is typically lower than 450 mOsm/L and in many cases lower than 350 mOsm/L. In contrast, the urine is highly concentrated in prerenal azotemia due to the secretion of ADH and intensified water reabsorption, producing urine osmolalities greater than 500 mOsm/L. As renal tubular function worsens under prerenal conditions, however, this distinction tends to blur, and concentrating ability may wane as ischemic damage sets in.

If a glomerular process is suspected, measurement of antinuclear antibody, antineutrophil cytoplasmic antibody (ANCA—seen in Wegener's granulomatosis), antiglomerular basement membrane (anti-GBM) antibodies, complement levels, and cryoglobulins can help the clinician determine whether immune-mediated disease is present (Level II; Lewington & Kanagasundaram, 2011).

A 24-hour urine test is the best way to measure proteinuria. A protein loss of more than 3.0 to 3.5 g every 24 hours indicates a glomerular lesion, whereas lesser amounts in the urine are more indicative of an interstitial disorder.

Renal ultrasound is commonly used to assess kidney size and rule out hydronephrosis. Ultrasound is used instead of intravenous pyelogram to avoid the risk of radiocontrast nephrotoxicity. If hydronephrosis indicative of obstruction is detected, the patient should be referred to a urologist. Computed tomography (CT) scan, retrograde pyelogram, and cystoscopy may all be useful in determining the exact location of the obstruction. Renal

scan may be helpful in detecting unilateral renal artery stenosis but is less sensitive in detecting bilateral renal artery disease. Renal artery stenosis is better diagnosed via CT scan or magnetic resonance imaging/magnetic resonance angiography (MRI/MRA), although direct renal angiography is still considered the (albeit invasive) gold standard for diagnosis.

If the noninvasive work-up proves inconclusive, renal biopsy may be indicated in some cases. Most notably, biopsy is performed in cases of isolated glomerular hematuria with proteinuria to confirm acute nephritic syndrome, to better characterize nephrotic syndrome or suspected vasculitis, and to aid in the diagnosis of acute or subacute renal failure of unknown etiology. Percutaneous versus open biopsy techniques are chosen based on the propensity for bleeding diatheses and the difficulty in reaching the affected kidney as determined by renal imaging.

Differential Diagnosis

The main diagnostic challenge in AKI is to determine the underlying cause. This is often complicated by fluid and electrolyte alterations. Assessment of the patient involves taking a thorough history, physically assessing the patient, and ordering appropriate laboratory studies. When determining whether or not prerenal azotemia exists, the patient's history can provide information indicating poor renal and/or systemic perfusion. This information may include surgery, high fever, alterations in diet or fluid status (such as a patient receiving nothing by mouth and given bowel preparation repeatedly for diagnostic tests), a low-sodium diet with fluid restriction, use of diuretics and antihypertensives, anaphylactic drug or transfusion reaction, penetrating or nonpenetrating abdominal trauma, hemorrhage, burns, shock, excessive sweating and dehydration, peritonitis, malignancies, sepsis, neurogenic shock, drug overdose, acute myocardial infarction, congestive heart failure, cardiac tamponade, cardiac dysrhythmias, cardiac arrest survival, renal artery emboli, thrombi, stenosis, aneurysm, occlusion, trauma, and liver cirrhosis.

Physical assessment findings may vary depending on the etiology of AKI and need to be correlated with the patient's history and laboratory findings, such as fluid volume depletion or oliguria. Findings on physical exam consistent with a prerenal etiology may include dry mucous membranes, poor skin turgor, reduced jugular venous pressure, hypotension, oliguria, or weight loss. Significant laboratory findings are increased urine osmolality and specific gravity, decreased urine sodium and urea, increased BUN, increased BUN to plasma creatinine ratio (a ratio greater than 20:1 because plasma creatinine is usually normal), normal urinary sediment (in most cases), and oliguria.

Prolonged azotemia caused by a prerenal condition often leads to intrarenal failure. Nephrotoxic agents that may cause damage to the kidneys are drugs such as antineoplastics, anesthetics, antimicrobials, and anti-inflammatory agents; x-ray contrast media; biological substances (e.g., toxins, tumor products, and heme pigments from hemoglobin or myoglobin); environmental agents (e.g., pesticides and organic solvents); heavy metals (e.g., lead, mercury, and gold); and plant and animal substances (e.g., toxic mushrooms and snake venoms).

Other factors that may injure renal (parenchymal) tissue include inflammatory processes related to bacterial or viral infection and toxemia of pregnancy; immune processes, such as autoimmunity, hypersensitivity, and tissue or organ transplant rejection; trauma or radiation to the kidney; and obstruction (e.g., neoplasm, stones, and scar tissue). Intravascular hemolysis related to transfusion reaction and microangiopathic hemolytic anemia as seen in TTP and HUS also causes damage to renal tissue. In addition, systemic and vascular disorders, such as renal vein thrombosis, nephrotic syndrome, Wilson's disease, malaria, multiple myeloma (direct proteinaceous deposition of immunoglobulin light chains into the renal parenchyma), sickle cell disease, malignant hypertension, diabetes mellitus, and systemic lupus erythematosus all cause intrarenal injury. Pregnancy-related disorders, such as septic abortion, preeclampsia, abruptio placentae, intrauterine fetal death, and idiopathic postpartum renal failure, can also cause damage to the kidneys.

Data that identify an event, a series of events, an agent, or agents that may have caused renal injury, especially those related to ischemia or exposure to toxins, should be collected during the history. These may include nephrotoxins; radiological tests that require administration of a dye; hypersensitivity reaction to a drug or dye; recent infections, trauma, or sepsis; antineoplastics, with or without radiation therapy; multiple myeloma or pregnancy; and a history of cardiac, renal, or liver disease.

There is no one specific finding that pinpoints intrarenal azotemia during physical assessment. Findings on exam must be correlated with history and laboratory findings. Differentiating prerenal problems and actual ATN is a challenge. Because prerenal problems often correspond with the onset phase of ATN and because this is a reversible phase, it is essential for diagnosis and aggressive management to begin early. Laboratory plasma values, urinalysis, and microscopic examination of the urine provide important data that can help to differentiate prerenal azotemia from ATN.

Prerenal problems are indicated by high urinary specific gravity and osmolality, low urinary sodium caused by decreased renal blood flow, avid tubular sodium reabsorption, and decreased GFR. The kidneys interpret this as a state of dehydration and respond with aldosterone and ADH to maximize sodium and water reabsorption from the distal tubule and collecting duct into the peritubular capillary plasma. This results in a small amount of very concentrated urine with high specific

gravity and high osmolality. Despite maximal sodium reabsorption, urine is concentrated because of urea or other solutes. Urinary and plasma creatinine levels often show wide variation in prerenal problems, with a slower rate of rise than in ATN and periodic decreases in serum creatinine.

ATN is characterized by altered renal ability to conserve sodium; clinically, ATN is seen as a urinary sodium level greater than 20 mEq/L. Depending on the state of hydration, the serum sodium levels vary in ATN. Oliguria is usually associated with postischemic ATN, whereas either oliguria or nonoliguria may be associated with nephrotoxic ATN. Creatinine clearance is severely decreased, and plasma creatinine rises about 0.5 to 1 mg/dL per day in ATN. BUN to serum creatinine ratio does not typically exceed 10:1 to 15:1 in ATN.

Response to therapy is another factor that distinguishes ATN from prerenal problems. The kidneys typically respond very quickly to therapy aimed at correcting an underlying prerenal problem in which no actual nephron damage has occurred; however, in ATN, response to treatment of the underlying cause may be minimal depending on the degree of *nephron damage.* Additional therapy for ATN should be aimed at correcting alterations related to inability of the kidneys to maintain their functions.

Postrenal azotemia results from interference with the flow of urine from the kidneys and is associated with obstruction or disruption of the urinary tract. Ureteral, bladder, bladder neck, or urethral obstruction may be the result of calculi, urinary tract or bladder neoplasms, or sloughed papillary tissue; strictures, trauma, or blood clots; congenital or developmental abnormalities; foreign objects or surgical ligation; prostatic hypertrophy; retroperitoneal fibrosis; abdominal and pelvic neoplasms; pregnancy; neurogenic bladder; bladder rupture; or use of drugs such as antihistamines and ganglionic blocking agents. The history should focus on collecting data that indicate obstruction or disruption of the urinary tract. Significant findings include change in urine volume, history of prostatic disease or abdominal neoplasms, history of urinary tract stones or nephralgia, pregnancy, recent abdominal surgery, and paralysis (e.g., quadriplegia).

Postrenal azotemia physical assessment findings also vary with etiology and need to be correlated with laboratory and history findings (e.g., nephralgia associated with moving urinary tract stones or rapidly developing hydronephrosis; or bladder distention associated with prostate, bladder neck, or urethral disorders). Laboratory findings include urine volume variations such as oliguria, polyuria, or abrupt anuria; urine osmolality variations (may be increased or similar to plasma osmolality); urine specific gravity variations; a decrease in urine sodium and urine urea; and a BUN to serum creatinine ratio that is normal to slightly increased. Microscopy of the urinary sediment is usually normal unless urinary tract infection (UTI) is present.

Management

Approximately 50% of patients with AKI are nonoliguric and have less severe signs and symptoms than oliguric patients. Because frequent causes of death are cardiac arrest resulting from hyperkalemia, gastrointestinal bleeding, and infection, the patient should be monitored very closely and treated appropriately on a day-to-day basis. The main goal is to keep the patient alive and to determine the underlying cause of the renal failure. The etiology of AKI will determine long-term management strategies.

In many cases of ATN, which is often caused by nephrotoxic agents, the removal of the offending agent will allow renal function to return gradually to normal. In the meantime, supportive measures should be provided, often in the form of peritoneal or hemodialysis. Prerenal azotemia secondary to absolute hypovolemia necessitates the restoration of intravascular volume. Replacement of fluids depends on the mechanism of loss. Gastrointestinal fluid loss is generally hypotonic and should be replaced accordingly; fluid loss as a result of hemorrhage usually indicates the need for administration of both saline and RBCs. In addition, fluid and electrolytes must be managed. Hyperkalemia in AKI can be life-threatening; emergent management is required in patients with extreme elevation of potassium levels (more than 6.5 mmol/L) or in any patient with electrocardiogram (ECG) abnormalities.

Certain diseases, such as glomerulonephritis or Wegener's granulomatosis, require immunosuppressive treatment with prednisone and cyclophosphamide to prevent irreversible renal damage. Postrenal azotemia involves identification of the level of obstruction followed by treatment to relieve the obstruction. If the obstruction is high, at the vesicoureteral junction or in the ureter or renal pelvis, percutaneous nephrotomy or ureteral stent placement by a urologist is necessary. For urethral obstruction, bladder catheterization or placement of a suprapubic tube may be sufficient to relieve the obstruction. Intermittent bladder catheterization four to five times a day poses less risk of UTI than an indwelling urinary catheter and is the preferred method for urinary outflow in cases of bladder atony and neuromuscular compromise such as with spinal cord injury. However, the presence of a bladder outlet or urethral obstruction, which is more likely to cause AKI, may necessitate placement of a long-term catheterization device until surgical intervention is possible.

In cases of intrarenal (intrinsic) failure, supportive methods are necessary while waiting for the kidneys to respond to reversal of the underlying problem. Several indications exist for temporary hemodialysis including, but not limited to, fluid overload unresponsive to diuretic therapy; hyperkalemia with symptoms or

ECG changes; uremic encephalopathy; severe metabolic acidosis; cardiorespiratory failure; and pleuritis, pericarditis, and other forms of inflammatory serositis. Forms of dialysis include traditional intermittent hemodialysis via large-bore venous and arterial catheters; peritoneal dialysis, which operates by osmotic diffusion via an indwelling dialysate within the peritoneal cavity; and continuous renal replacement therapy, which is a prolonged form of low-flow arteriovenous or venovenous hemofiltration appropriate for hemodynamically unstable patients.

Follow-up and Referral

After hospitalization, patient follow-up is necessary in about 1 week, then 1 month, 3 months, 6 months, and annually thereafter, providing there are no further complications. Blood chemistries, such as a basic metabolic profile and a complete blood count, should be checked at each follow-up visit. The patient should be assessed for signs and symptoms of fluid overload, such as crackles on lung auscultation, elevated blood pressure, shortness of breath, weight gain, jugular vein distention, and/or edema.

Patient Education

During the recovery stage there is no special form of treatment other than general healthy living. Lack of knowledge is a major problem with regard to acute episodes of renal failure. Patients require continual education throughout their clinical pathway and their treatment of AKI. Follow-up care, support, and prevention of another episode should be the teaching focus.

CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD) is characterized by a progressive loss of functioning nephrons, eventually leading to end-stage renal disease (ESRD). As the functional reserve of the kidneys is lost, signs and symptoms of renal failure appear. These signs may arise as sequelae of acute kidney injury (AKI), but most often CKD arises as a complication of chronic systemic disease, such as diabetes or hypertension. The time frame for the development of CKD is typically thought of as ranging from months to years, whereas AKI typically sets in over days to weeks (see previous section).

Epidemiology and Causes

According to the National Health and Nutrition Examination Survey (NHANES) (a large population-based representative health survey of the entire country done every 2 years), approximately 13% of the U.S. population suffers from CKD. The number of people with a chronic elevation of creatinine greater than 2.0 mg/dL is estimated to be 2.8 per 100,000. There are approximately 485,000 patients with ESRD, of whom 341,000 are on chronic dialysis. Older adults represent 33.8% of new patients, and diabetes mellitus and hypertension cause about 70% of ESRD cases. Compared with the general population, African Americans are 3.9 times more likely to have ESRD and 6.7 times more likely to have hypertensive ESRD. It is estimated that HIV-associated nephropathy may soon be the third leading cause of ESRD (after diabetes mellitus and hypertension) in African Americans aged 20 to 64 years. Men are 1.3 to 1.4 times more likely than women to have ESRD. The peak age for onset of ESRD is between 65 and 75 years. Geriatric patients have the highest incidence and morbidity and mortality rates, because renal disease can result from many age-related illnesses. Some older patients tolerate dialysis quite well, however.

The major underlying conditions leading to ESRD are diabetes mellitus and primary hypertension (approximately 70%); glomerulonephritis, cystic diseases, and other urological diseases (approximately 15%); and assorted other causes (approximately 15%). Renal artery stenosis and chronic ischemic renovascular disease may cause up to 20% of CKD cases in persons older than 50 years. Analgesic overuse (e.g., NSAIDs), cigarette smoking, collagen vascular disease, AIDS-related nephropathies, cirrhosis, and multiple myeloma are examples of other risk factors for the development of CKD. Several hereditary renal diseases (e.g., polycystic kidney disease and Alport syndrome, which also causes congenital deafness) can lead to CKD in children and some adults.

Hypertension is present in at least 85% of patients with CKD. Hypertensive- and diabetic-related CKD is a form of microvascular end-organ damage caused by these cardiovascular risk factors. Thus, these patients must also be evaluated for other forms of end-organ damage related to atherosclerotic disease, because a significant correlation exists between microvascular CKD, peripheral vascular disease, coronary artery disease, and cerebrovascular disease.

Pathophysiology

The pathophysiology of renal failure is manifested somewhat differently depending on the underlying cause, although the end result is the same—a nonfunctional kidney. Diabetic nephropathy is the most common cause of ESRD and involves several mechanisms, including hyperglycemia, hormonal imbalances, and renal hemodynamic changes. Hyperglycemia leads to alterations in tubuloglomerular feedback, abnormalities in polyol (e.g., sorbitol) metabolism, and the formation of advanced glycosylation end products (AGEs) in tissues. Increases in circulating AGE peptides parallel the severity of renal dysfunction in diabetic nephropathy. Ultimately, defects in glomerular cellular metabolism lead to hemodynamic changes in the kidney.

Hormonal imbalances associated with diabetes and ESRD include decreased insulin, increased growth hormone and glucagon, and altered concentrations of or responsiveness to vasoactive hormones (angiotensin II, catecholamines, and prostaglandins). Growth hormones and glucagon (both elevated in poorly controlled

diabetes) have been shown to produce glomerular hyperfiltration in the laboratory in recent studies.

Renal hemodynamic changes implicated in diabetes and ESRD involve glomerular hypertension and glomerular hyperfiltration. Changes in circulating levels of vasoactive hormones, or altered responsiveness to them, can result in hyperfiltration. Regardless of the inciting event, factors such as hyperglycemia-induced increases in extracellular fluid volume, renal hypertrophy, and/or altered glycoregulatory or vasoregulatory hormone action contribute to increased pressure and flow across the glomerular membrane, resulting in glomerular hypertension. This, in turn, along with associated renal vasodilation and hyperfiltration, increases transglomerular protein filtration. This leads to proteinuria and mesangial deposition of circulating proteins. As a result, mesangial expansion and glomerulosclerosis cause destruction of nephrons, and the glomerulus becomes a fibrinous scar that can no longer function. In addition, a positive feedback stimulus for compensatory hyperfiltration is initiated, with further increase in GFR and progressive renal injury. Ultimately, it is glomerular hypertension that mediates the progressive nephron destruction. Based on this glomerular hypertension–hyperfiltration hypothesis, therapies directed at lowering glomerular hypertension would protect the kidney from further progression of nephropathy.

Hypertensive nephropathy is the second most common cause of renal failure. The kidney is one of the major organs injured by hypertension. The resultant disease is termed *nephrosclerosis.* Benign nephrosclerosis is associated with chronic, mild, or moderate hypertension in which renal insufficiency develops slowly. The renal arterial vessels become thickened while the lumens become narrowed, resulting in decreased renal flow and autoregulation. Renal tubular changes correlate with the degree of reduction in renal blood flow. Signs and symptoms vary with the severity of renal injury; they include proteinuria, nocturia, casts, and azotemia. Patients with benign nephrosclerosis are very susceptible to AKI when a situation occurs that decreases blood flow to the kidney. Treatment is focused on control of hypertension.

Malignant nephrosclerosis is associated with marked hypertension, headache, congestive heart failure, and blurred vision. Unlike the progression of benign nephrosclerosis, renal failure develops rapidly. Renal arterioles and glomerular capillaries become thickened and necrotic, and tubules atrophy. Signs and symptoms are hematuria with red cell casts, proteinuria, and azotemia. Treatment includes immediate reduction of blood pressure (BP), which is necessary to prevent permanent renal loss and damage to other organs.

Renal artery stenosis occurs when the renal artery and the branches become thickened, stiff, and narrow because of atheromatous plaques (two-thirds of cases) or fibromuscular dysplasia (one-third of cases). As the body perceives the decreased blood flow (i.e., hypoperfusion) via the stenotic renal arteries as hypovolemia, the renin-angiotensin-aldosterone axis is activated, and mild to severe hypertension results from the retention of sodium and water. This condition becomes critical if both renal arteries are affected or if blood flow is compromised in patients with only a single kidney, either congenitally or after live organ donation of the other kidney. Other signs include a bruit auscultated in the flank or midabdominal region over the affected renal artery and an elevated blood renin level from the ipsilateral renal vein. The incidence of fibromuscular dysplasia is higher in women than in men, especially from 20 to 40 years of age. The treatment required is angioplasty or surgical repair to stent or reconstruct the stenotic vessels, along with medical therapy consisting of antihypertensives and diuretics.

Glomerulonephritis (GN) is the third most common cause of renal failure. GN is an inflammatory process that primarily affects the glomerular capillaries. It is also a major cause of ESRD. Approximately 25% of GN cases result from nonimmune mechanisms, whereas 60% to 75% stem from autoimmune mechanisms. Glomerular injury can be divided into two major categories based on pathology: *nephritis,* which is characterized by glomerular inflammation and/or necrosis; and *nephrosis,* which is characterized by abnormal permeability of the glomerular membrane. This allows macromolecules such as albumin to pass. These two forms of injury are not mutually exclusive. A single etiology can produce both forms of injury.

The immunological injury that characterizes glomerulonephritis functions in several different ways. Antiglomerular basement membrane (anti-GBM) disease is a result of direct glomerular injury occurring as a result of inflammation triggered by antibodies directed against components of the glomerular basement membrane. Linear deposits of immunoglobulin are seen via immunofluorescence (IF) microscopy of renal tissue. IF also reveals granular immunoglobulin deposits. Part of the inflammatory response that occurs is secondary to the glomerular deposition of immune complexes, composed of antibodies bound to a variety of circulating antigens. This is referred to as *immune complex disease.* Finally, pauci-immune ANCA disease is characterized by the presence of serum antibodies against the neutrophil cytoplasm that are associated with the multisystem disease. Minimal or no immunoglobulin is seen by IF, hence the name "pauci-immune." Nonetheless, the glomerular injury is still believed to be immune in nature.

The hallmark of nephrosis is increased permeability of the glomerular capillary wall to macromolecules, including serum proteins. Inflammatory changes are generally not seen but may be present. In classic forms of glomerulonephrosis, nephrotic syndrome develops, and various degrees of proteinuria may be present. In addition to hypertension, other characteristic findings include hypercholesterolemia with lipiduria and central edema from hypoalbuminemia due to albuminuria. In more than two-thirds of cases of glomerulonephrosis in adults, the cause

is idiopathic; in the remainder, nephrosis is secondary to systemic disease such as diabetes, lupus, or amyloidosis.

Clinical Presentation

Subjective

Because of the significant functional reserve of the kidneys, symptoms do not generally appear until renal function (as measured by the GFR) declines to 10% to 15% of normal. At about 30% to 40% of normal GFR, biochemical evidence of renal failure may be apparent, but patients typically remain asymptomatic. Early prominent symptoms in renal failure include anorexia, lassitude, fatigability, and weakness.

The inability of the kidneys to perform their normal excretory, metabolic, and endocrine functions results in *uremia,* a complex syndrome that includes a variety of physiological and clinical abnormalities. Dermatological abnormalities may result in the patient complaining of pruritus and dry skin; gastrointestinal alterations may manifest themselves as complaints of anorexia, nausea, vomiting, and hiccupping. Neurological complaints may include emotional lability or depression, insomnia, fatigue (especially on exertion), confusion, headache, seizures, and coma. There may be a urine odor to the breath and perspiration, complaints of shortness of breath, a metallic taste in the mouth, impotence, nocturia, and muscle cramps. The patient may present with foot drop, infection, bleeding, or gout. Often the patient is being treated for a major systemic disease such as diabetes. It is, therefore, important to be alert to the potential for the onset of CKD.

Objective

The patient may appear pale, with a characteristic uremic frost appearance to the skin, or, conversely, hyperpigmentation may be apparent. There may be bruising and asterixis (i.e., hand-flapping on hyperextension of the wrists with complete forward extension of the upper extremities). Peripheral neuropathy and altered mental status may be present, along with peripheral edema and ascites from severe proteinuria and the resulting hypoalbuminemia, as well as auscultatory crackles and a pericardial rub. There may be an elevated BP and a hard, rapid pulse. Some abnormalities are the result of the accumulation of toxic metabolites; others are caused by underproduction (e.g., of vitamin D and erythropoietin) or overproduction (e.g., renin) of biochemically active substances produced by the kidney.

Diagnostic Reasoning

Diagnostic Tests

If a patient has a condition known to predispose the individual to the development of CKD, especially if that patient is in a high-risk population, biochemical monitoring (BUN, creatinine, and creatinine clearance) should be done to detect renal failure before it becomes clinically apparent. Serum creatinine can track the progression of CKD; however, the GFR (normally about 140–180 L/day) can fall to 40% to 50% of normal with only small changes in serum creatinine levels. Accurate measurement of the GFR itself is based on experimental calculations of renal inulin clearance. Inulin is a polymer of fructose secreted from the blood exclusively via the renal glomeruli and displaying no tubular reabsorption. Measurement of inulin clearance, however, requires a complex assay too cumbersome for daily clinical use and tends to be reserved solely for research purposes.

Alternatively, GFR can be estimated using the Cockcroft-Gault formula for creatinine clearance: (140 minus age × lean body weight in kilograms) divided by (72 stable serum creatinine in mg/dL). This value is multiplied by 0.85 (i.e., reduced by 15%) for women. It is important to realize that trends in GFR (as estimated by creatinine clearance or serum creatinine levels) are far more important in assessing renal function and stability of CKD than are the absolute values of these indices. A meta-analysis of 13 studies found that a lower GFR and a higher albuminuria independently predict mortality and ESRD in patients with CKD (Level I; Astor et al, 2011). This is especially true of direct serum creatinine measurements, whose interpretation must take into account a patient's muscle mass, age, and gender. Thus, creatinine clearance is a far more informative diagnostic tool as a measure of renal function.

Although no universally agreed on definition of chronic kidney disease exists, GFR and proteinuria are often used to stratify CKD patients by disease severity. The Third National Health and Nutrition Examination Survey defined **Stage 1** disease as persistent albuminuria with a normal GFR greater than 90 mL/min per 1.73 m^2 of body surface area (BSA); **Stage 2** disease has persistent albuminuria with a GFR between 60 and 89 mL/min per 1.73 m^2 of BSA; **Stage 3** disease is defined as a GFR between 30 and 59 mL/min per 1.73 m^2 of BSA; **Stage 4** disease is defined as a GFR between 15 and 29 mL/min/1.73 m^2 of BSA; and **Stage 5** disease is ESRD, defined as a GFR less than 15 mL/min/1.73 m^2 of BSA. Routine monitoring of the complete blood count (CBC) can detect anemia secondary to erythropoietin deficiency. Monitoring of urinalysis can detect increasing proteinuria. When renal function declines further, closer monitoring of routine laboratory tests to detect dangerous electrolyte imbalances (e.g., hyperkalemia) and acidosis is required.

Numerous laboratory alterations occur in patients who have developed ESRD. A CBC will usually reveal a normochromic, normocytic anemia; decreased hematocrit; increased bleeding time; capillary fragility; thrombocytopenia; and a decreased immune responsiveness. Blood chemistries typically reveal some of the following abnormalities: decreased active vitamin D; elevated ammonia, BUN and serum creatinine, uric acid, sulfate, potassium, phosphate, parathyroid hormone, and glucose levels, along with insulin resistance and a type IV hyperlipidemia. Urinalysis may reveal proteinuria (the greater

the proteinuria, the quicker the progression of CKD) and coarse granular casts. Ketosis may artificially raise creatinine levels, and certain drugs (cimetidine, trimethoprim, cefazolin) may also alter diagnostic test results.

Twenty-four–hour urine studies (protein, creatinine clearance) may be done although samples often are difficult to obtain in ambulatory patients and have been largely replaced by spot urine checks. Complement levels, antinuclear antibody, and serum and urine protein electrophoresis may all provide data as to the underlying pathophysiology of CKD.

Renal ultrasound performed at least at baseline is indicated in all cases of CKD. Among other pathologies, sonography may reveal decreased kidney size (less than 11 cm), polycystic kidney disease, or an obstructed ureter or bladder outlet with hydroureter and/or hydronephrosis. Renal CT scan/CT angiography or MRI/MRA may detect and localize harder to visualize structural abnormalities, renal parenchymal disease, or renal artery stenosis. Duplex Doppler ultrasonography to assess renal vascular flow has a high sensitivity and specificity for arterial stenosis if conducted by an experienced ultrasonographer, but renal angiography remains the diagnostic gold standard for this condition. However, unilaterally decreased kidney size on renal imaging is highly suggestive of vascular occlusive disease and may be quite helpful as a screening method. Renal biopsy is not utilized for CKD as much as for AKI, unless noninvasive modes of testing are unable to suggest a likely etiology.

Differential Diagnosis

The differential diagnosis of CKD is aimed at identifying the underlying etiology of renal failure, as discussed earlier. Although the terms *chronic kidney disease* and *chronic renal insufficiency* (CRI) are often used interchangeably, some authorities reserve the use of CKD to imply a dialysis-dependent state, whereas CRI denotes an earlier form of the condition not yet requiring dialysis or kidney transplantation, but that may clearly progress to CKD. The signs and symptoms and diagnostic test results commonly seen in the three stages of CKD (decreased renal reserve, renal insufficiency, and ESRD) are presented in Table 12.8.

Management

General principles of CKD management include (1) the determination and control of underlying etiology,

Table 12.8 Differentiating the Stages of Chronic Kidney Disease

Stage	Glomerular Filtration Rate	Signs and Symptoms	Management
D1. Decreased renal reserve	Greater than 90 Normal kidney function	Asymptomatic Hypertension (mild)	Control blood pressure and observation
K2. Kidney Damage	60–89 Mildly reduced kidney function	Hypertension (mild) ↑ PTH Early bone disease ↑ BUN and serum creatinine	Observation Control blood pressure
3. Renal insufficiency 3a. 3b.	Moderately reduced kidney function 45–59 30–44	Hypertension Anemia due to ↓ erythropoietin ↑ BUN and serum creatinine Risk of cardiovascular events	Refer to specialist Evaluate serum creatinine, potassium, hemoglobin, urinary protein every 6 months Control blood pressure
4. Severe renal insufficiency	15–29 Severely reduced kidney function	Moderate hypertension Anemia Hyperphosphatemia ↑ Triglycerides Metabolic acidosis Hyperkalemia Water/salt retention ↑ BUN and serum creatinine	Refer to specialist Control hypertension Oral phosphate binders Cholesterol-lowering therapy Administration of erythropoietin drug (epoetins)
E5. End-stage kidney disease—kidney failure	<15 or on dialysis	Severe hypertension Anemia Hypophosphatemia Uremia	Refer to specialist Dialysis Transplant Same management as for Stage 4

Adapted from www.renal.org/whatwedo/InformationResources/CKDeGUIDE/CKDstages.aspx and www.kidney.org/PROFESSIONALS/kdoqi/guidelines_ckd/toc.htm

(2) monitoring changes in renal function, (3) conservative treatment of the physiological effects of CKD, and (4) instituting more aggressive treatment (dialysis and/or renal transplantation) when appropriate in later stages of treatment-refractory disease. Glucose levels and hypertension must be strictly controlled in diabetic patients, with a target hemoglobin A1C (HbA1c) less than 7%. For any patient with proteinuria of more than 1 g/day, the target BP is 125/75 mm Hg; for a patient with proteinuria of less than 1 g/day, the goal is a BP of 130/80 mm Hg. Given the importance of maintaining renal perfusion, systolic blood pressures lower than 110 mm Hg should be avoided. Angiotensin-converting enzyme (ACE) inhibitors or the newer class of angiotensin II receptor blockers (ARBs) should be used for BP control in patients with diabetes mellitus given their renoprotective effects. If monotherapy with one of these agents is insufficient to control BP, a diuretic should be added, followed by a calcium channel blocker (diltiazem or verapamil) or a beta blocker, as needed. If combination therapy using agents from these additional classes proves ineffective, an ACE inhibitor or ARB should be added (whichever class was not used initially).

Pharmacological BP management is equally as important for the medical treatment of renal artery stenosis. However, ACE inhibitors and ARBs are usually avoided in patients with bilateral renal artery stenosis, because their vasodilatory effects on the efferent renal arterioles effectively decrease GFR in the presence of reduced afferent blood flow from stenotic renal arteries. In turn, this may precipitate potentially devastating acute or chronic renal failure. Percutaneous angioplasty or surgical revascularization with arterial stenting should be considered for patients with severe hypertension refractory to pharmacotherapy, recurrent episodes of flash pulmonary edema due to CKD-related fluid overload, and progressive renal insufficiency that fails to improve despite effective BP control. Individuals with particularly severe CKD (serum creatinine greater than 4 mg/dL) or chronically atrophied kidneys (less than 7 cm) are unlikely to respond to such interventions, however. Revascularization is more likely to be effective in patients whose renal function rapidly declines, particularly after beginning ACE inhibitor or ARB therapy.

Dietary therapy is a cornerstone of conservative management of CKD. Restriction of fluid (limited to maintain a serum sodium concentration of 135–145 mEq/L) and sodium (especially if volume expanded) may decrease secondary hypertension or congestive heart failure, although volume depletion must be avoided given the potential for acute worsening due to renal hypoperfusion. Restricted protein intake is recommended (0.58 g/kg per day), although an adequate caloric intake (40–50 cal/kg per day) should be maintained, because malnutrition is a common complication of CKD. Consultation by a skilled nutritionist is recommended at the time of diagnosis and periodically as the disease progresses and the patient's nutritional needs change. Foods rich in essential amino acids are the most effectively utilized source of nitrogen. Restriction of dietary phosphate (800 mg/day) and potassium may be necessary because of reduced excretion and the potential for hyperphosphatemia and hyperkalemia. Strict dietary restrictions may be unnecessary in older patients because they often have low protein and sodium intake, but treatment regimens must be individualized.

Low-dose sodium polystyrene sulfonate (Kayexalate) 5 mg PO daily to three times daily with meals may be used as a potassium binder for hyperkalemia. Oral phosphate binders such as calcium carbonate (2.5–20 g/day), calcium acetate (Phos-Lo; 1334 mg three times daily), or sevelamer (Renagel; 800 mg three times daily) are typically taken with meals when GFR falls below 30 mL/min. Sevelamer is used when CKD is complicated by iatrogenic hypercalcemia. Aluminum- and magnesium-containing salts should be avoided, owing to cumulative toxicity.

Given the kidneys' reduced ability to synthesize activated vitamin D in CKD and the propensity for subsequent hypocalcemia and renal osteodystrophy, oral 1,25-dihydroxyvitamin D (calcitriol 0.25 mg daily) and calcium carbonate (600 mg two times daily) supplements should be given, along with a renal-specific multivitamin (Nephrocaps). Importantly, however, this chronic treatment may result in hypercalcemia and worsen coronary artery calcification. Thus, close monitoring of serum calcium levels is critical. Vitamin E may also be helpful in treating muscle cramps.

Anemia should be treated with erythropoietin (80–120 units/kg subcutaneously per week), taking care not to induce polycythemia (goal Hgb = 11–12 g/dL) with its attendant risk of stroke. Dosing usually begins around 10,000 units per week but may be adjusted upward in frequency or dose, as needed. Darbepoetin alfa is an alternative erythropoietic agent with a longer half-life, allowing for less frequent dosing (0.45 mcg/kg subcutaneously per week). Patients with iron-deficiency anemia should take ferrous sulfate 325 mg PO daily to three times daily with meals, with lower doses in elderly patients being less likely to induce constipation. Gentle transfusion with packed red blood cells may be required in cases of extreme or acutely worsened anemia, but care must be taken not to induce high-output heart failure or fluid overload, because the heart typically adapts to the chronic anemia of CKD. In relation to this, bleeding diatheses due to uremic platelet dysfunction are not uncommon in both AKI and CKD. Active bleeding in these patients should be treated with desmopressin (DDAVP), cryoprecipitate, estrogen, or dialysis to remove uremic toxins believed to be qualitatively inhibiting platelet function.

Hypercholesterolemia should be treated with a statin drug with the low-density lipoprotein goal of less

than 100, because CKD is considered a coronary artery disease equivalent. Recent evidence suggests this goal should be even lower to minimize the rate of disease progression due to atherosclerotic renovascular disease. Dietary modification to restrict cholesterol and saturated fats is also critical to adequately address hyperlipidemia, especially hypertriglyceridemia.

Both hypovolemia (renal hypoperfusion) and renal toxic drugs may exacerbate CKD and must always be considered when acute or chronic renal failure is observed. A judicious trial of isotonic fluid repletion may be appropriate in patients displaying the physical stigmata of dehydration, and careful attention must be paid to the dosing of all chronic and newly started medications. All nephrotoxic agents (e.g., NSAIDs, radiocontrast dye) should be avoided.

Other measures to relieve symptoms include skin moisturizers for dry skin, and menthol or phenol lotion, a trial of capsaicin cream, or diphenhydramine (Benadryl) may all be useful in treating pruritus. It may be necessary to give diuretics for edema, but dehydration must be avoided. Thiazide diuretics may be tried first, but they are far less effective at a GFR less than 20 to 30 mL/min (approximated by serum creatinine levels of greater than 2.5 mg/dL); however, they do provide an additive effect when used with a loop diuretic initiated for refractory edema. Potassium-sparing diuretics should be avoided, owing to the kidneys' reduced ability to excrete potassium.

As CKD progresses, the patient will have increased difficulties with fluid balance and may experience episodes of hyperkalemia, hypertension, acidosis, and severe uremia with altered mental status and qualitative platelet dysfunction with a tendency for bleeding diatheses. Metabolic acidosis should be treated with sodium bicarbonate 600 mg two times daily initially to titrate serum bicarbonate to the 16 to 20 mEq/L range. However, patients must display adequate respiratory function to avoid the accumulation of metabolized carbon dioxide and respiratory acidosis. The potassium and calcium levels should be monitored during treatment of acidosis, because both might fall. Hospitalization may be required for control of fluid overload, hypertension, hyperkalemia, or infection.

A GFR less than 10 mL/min per 1.73 m^2 of BSA, a serum creatinine level approaching 12 mg/dL, or BUN greater than 100 mg/dL all typically require more aggressive therapies to avoid life-threatening sequelae, including peritoneal or hemodialysis. Continuous venovenous or arteriovenous hemofiltration may be used in hemodynamically unstable patients, as an alternative to classic hemodialysis. Such therapies must be done only under the supervision of a nephrologist, however. Life-threatening indications for dialysis include pericarditis, diuretic-refractory fluid overload (e.g., pulmonary edema), medication-resistant or rapidly worsening hypertension, uremic syndrome with an attendant bleeding diathesis or neurological symptomatology, and persistent nausea and vomiting. In addition, protein malnutrition in the face of a creatinine clearance of less than 20 mL/min is considered an indication for early dialysis.

Follow-up and Referral

Patients with CKD should be referred to a nephrologist. The course of CKD is typically punctuated by periods of rapid deterioration, often precipitated by dehydration or infection. The rate of progression to kidney failure will depend in part on the underlying renal disease: It is usually more rapid in patients with diabetic nephropathy or severe hypertension and slower in patients with polycystic kidneys. In patients with advanced renal failure (creatinine levels greater than 10 mg/dL), however, mean survival time without intervention (e.g., dialysis or transplantation) is 100 to 150 days. Vascular access for hemodialysis (arteriovenous grafts or fistulae) must be obtained 2 to 3 months in advance to permit maturation of the fistulae and allow for potential revisions. Decisions regarding dialysis and transplantation require a team approach with the primary-care provider, nephrologist, patient, and family. Comprehensive evaluation of the patient's medical, psychological, and social situation is necessary for successful planning.

The patient may need to be hospitalized to control fluid overload, hypertension, hyperkalemia, or infection. In general, the multiplicity of metabolic demands on the patient with CKD will require careful and close follow-up and constant adjustments in treatment. The most important cornerstone of care is the monitoring and treatment of all underlying disorders known to lead to chronic renal failure. Successful therapy depends in good part on the maintenance of a strong relationship between the health-care provider and the patient and family. Nowhere is a *Circle of Caring* approach more important than in a chronic, progressive disorder such as CKD. Interventions should be geared toward minimizing the patient's dependence and social isolation. See Case Study 12.1.

CASE STUDY 12.1 Giving Up Hope

Hope began her life as a juvenile diabetic. She became sick early in life, but did not let that stop her from having a rewarding career as a teacher. Her favorite hobby was painting—a talent that proved to strengthen her throughout her illnesses.

When I met Hope, she was 47 years old, her kidneys were no longer functioning, and she had lost one leg below the knee. She also had recently been diagnosed with breast cancer and had chosen to undergo chemotherapy. No longer able to work, she began to paint and continued to fight her illness. Each complication drained her body more. She endured peritoneal dialysis and then hemodialysis after a bout with peritonitis. Finally, her breast cancer metastasized to the peritoneal cavity.

Hope returned from hemodialysis early one day. It would be for the last time. Her sixth dialysis shunt was no longer patent. I then realized why I had been drawn to Hope. She no longer needed medicine or therapy; she needed someone to help her die.

I'll never forget that day. Hope looked at me through her tears and said, "I don't want to die." Not knowing exactly what to say, I looked in her eyes and told her it was time. Her life was in someone else's hands now, not hers. She didn't have any more decisions to make, and she could try to find peace. Although her soul was strong, her body was not. By letting go, she wasn't giving up; she was saving herself.

I feel that we, as clinicians, touch life in the most profound way by giving certain patients permission to die. The true challenge lies in knowing when medicine is no longer what the patient needs.

Patient Education

For care to be effective, the patient and family must have a good understanding of the chronic and progressive nature of CKD, of the importance of treating all underlying systemic diseases such as diabetes and hypertension, and of the specifics of the treatment plan. Avoidance of infection is important, as is maintaining a healthy diet as recommended. Patients should know when and how to report bleeding, fever, decreases in urine output, or episodes of nausea and vomiting.

Chapter 13

Men's Health Problems

Debbie J. Nogueras, PhD, MSN, ANP/FNP-BC • Debera J. Thomas, DNS, RN, FNP/ANP • Brian Oscar Porter, MD, PhD, MPH

COMMON COMPLAINTS

NOCTURIA AND INCONTINENCE

Nocturia is currently defined by the International Continence Society as having to wake at night one or more times to void, each time being preceded and followed by sleep (Level I; Cornu et al, 2012). Recording the number of times a patient urinates at night and making a reasonable estimate of the amount voided is extremely important. The frequency of urination may vary from large volumes of urine (polyuria) voided infrequently to small quantities passed at frequent intervals. Adult men normally void five to six times during the day and once or not at all during the night. As men age, nocturia is usually a sign of a prostate problem, most often benign prostatic hyperplasia (BPH). Typically, 50% of men older than age 50 years have BPH, and the rate increases by 10% for every 10 years of age (i.e., to 60% of men older than age 60 years, to 70% of men older than age 70 years, and so on). BPH is discussed in more detail later in this chapter.

The occurrence of nocturia without discomfort may be due to diminished bladder capacity, overflow incontinence, or habit. In men with a normal bladder, the absence of nocturia while suffering from increased frequency of urination during the day suggests psychogenic origin. A rare finding might be a polyp or irritative lesion in the posterior urethra that is relieved by recumbence, so nocturia is not present.

Detrusor muscle instability may cause urinary incontinence as well as nocturia. Fifty percent of male patients in nursing homes are incontinent, whereas 15% to 30% of elderly men in the community have urinary incontinence, which may be caused by decreased bladder capacity, increased residual urine (from inability to empty the bladder), or involuntary bladder contractions. Moderate dribbling of urine may indicate overflow from a partially incompetent outlet and can be congenital or an acquired anomaly. Less common causes of incontinence are spinal cord disease, multiple sclerosis, tumors, trauma, syphilis, and diabetic neuropathy. Microorganisms that can cause nocturia and incontinence include *Klebsiella pneumoniae, Proteus mirabilis, Enterobacter, Staphylococcus,* enterococci (*Streptococcus* bacteria associated with the intestines), or *Pseudomonas.*

Medications, such as methyldopa, phenothiazines, diazepam, excessive vitamin D, and diuretics, may also cause nocturia, as well as precipitate or aggravate incontinence. Drugs that cause urinary retention include alpha-adrenergic agents, androgens, and sympathomimetic agents such as ephedrine and pseudoephedrine. Urinary retention can cause nocturia and incontinence.

Differential Diagnosis

Increased frequency may occur as a result of primary disease of the urinary tract or may result from metabolic disease such as diabetes mellitus or diabetes insipidus; it may also be associated with emotional tension. Documentation of the pattern of urination during a 24-hour period is vital to a diagnosis of nocturia. Although a patient may complain if he awakens frequently to urinate, the precipitating events and activities of the day may also give a hint to the cause. For example, alcohol intake before sleep may increase the number of times the patient urinates at night and may also increase urine volume.

Urgency, a desire to urinate, can be constant or intermittent. Urgency and frequency of urination often occur together. Urgency is frequently the result of prostatic disease or bladder infection. Hesitancy refers to difficulty in initiating a urine stream. *Oliguria* is a decrease in urinary output and can be caused by a decrease in the production of urine secondary to acute glomerulonephritis or other renal disease, as well as conditions that drastically decrease cardiac output. Dribbling can be symptomatic of disease; it may occur at night and during the day and usually indicates the presence of a urethral stricture or prostatic obstruction, but it may be caused by a neurological disorder.

Treatment

Treatment of nocturia depends on identifying the cause. A simple urinalysis is performed to rule out urinary tract infection. A prostate-specific antigen blood test and a digital rectal exam are done to rule out a prostate problem. The results may indicate a need for further testing.

Specific patient education is discussed under the particular disease causing the nocturia.

TESTICULAR PAIN

Testicular pain is probably the most urgent of patient complaints. Testicular pain as a single symptom is a fullness or heaviness of the scrotum, ranging from a dull ache to a sticking pain, and may occur in a wide variety of patients with no differentiation based on culture, race, or socioeconomic status.

The tunica vaginalis is a remnant of the processus vaginalis; a painful hernia can occur when an evagination of the peritoneal cavity is occluded by the adult spermatic cord. A patent processus vaginalis predisposes the patient to indirect or congenital hernias. Partial occlusion of the processus vaginalis can result in fluid accumulation, or hydrocele, that cannot be distinguished from a hernia or an incompletely descended testicle until surgery is performed. Anterior and lateral to the testes, the processus vaginalis remains patent, forming the tunica vaginalis, which represents the detached portion of the peritoneal cavity within the scrotum.

Differential Diagnoses

A cause of testicular pain may be swelling of the testis, the epididymis, or the spermatic cord or torsion of the testicle (the testicle may become twisted around the spermatic cord, causing acute pain; this condition is a urological emergency). Differential diagnoses for testicular pain include hydrocele, varicocele, epididymitis, and prostatitis. Pain from prostatitis usually occurs in the lower back and radiates to the testicles and is typically accompanied by fever. Cultures usually show *Escherichia coli,* with or without fistula formation. Hernias, hydroceles, and hematomas all must be excluded. A detailed history and physical exam will direct the assessment to exclude other diagnoses. A spermatocele may also cause testicular pain, although most spermatoceles are painless. A syphilitic gumma is a possibility, as is a varicocele; however, these conditions are usually not painful.

Because of the multiple possible diagnoses, specialized tests are performed. A scrotal ultrasound can identify any mass originating in the testicles and is noninvasive. An echo-texture pattern reveals the presence of a hypoechoic mass that is distinct from surrounding normal testicular tissue, spermatoceles, hydroceles, or varicoceles.

Treatment

Treatment of testicular pain is dependent on finding the underlying cause for the pain and treating it appropriately.

TESTOSTERONE DEFICIENCY (LOW T)

Testosterone levels peak during adolescence and early adulthood, and then gradually decline about 1% per year after age 30 years. As men age, there is a rise in follicle-stimulating hormone, which controls sperm production, and luteinizing hormone, which controls testosterone production; there is a simultaneous decline in testosterone. Normal testosterone levels are less than 300 ng/dL and are best assessed in the morning between 7:00 a.m. and 10:00 a.m. Testosterone decline may be a function of normal aging or may be due to hypogonadism. Other factors suppressing testosterone levels include stress, obesity, tobacco and alcohol use, obstructive sleep apnea, diabetes mellitus, and illness. Medications such as suramin (Germanin), ketoconazole (Nizoral), glucocorticoids, alkylating agents, and opiates used chronically may cause a decrease in serum testosterone.

Low testosterone (low T) affects multiple body systems. Cardiovascular effects include dyslipidemia and hypertension. Metabolic syndrome consists of these disorders, in addition to obesity and diabetes mellitus, which collectively increase the risk of cardiovascular disease. Low T is associated with type 2 diabetes mellitus, and men with the lowest levels of free testosterone are four times as likely to have diabetes. Osteopenia, osteoporosis, and fracture prevalence rates are greater in hypogonadal men, with 30% of fractures occurring in men with low T. Erectile dysfunction and decreased libido correspond with a decline in testosterone, which regulates nerve structure and function in areas of the spinal cord that are involved in erections. In addition, a decline in mental functioning has also been associated with low T.

First-line treatment for symptomatic men with low testosterone levels is testosterone replacement therapy. Testosterone gels and patches are the most prevalent hormone replacement formulations and can be found in the Drugs Commonly Prescribed 13.1. Testosterone therapy is contraindicated in men with breast or prostate cancer, palpable prostate nodules or induration, untreated obstructive sleep apnea, severe lower urinary tract symptoms with an International Prostate Symptom Score of greater than 19, and New York Heart Association Class III or IV heart failure.

COMMON PROBLEMS

BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (also called benign prostatic hypertrophy) (BPH) is the common name for nodular hyperplasia of the prostate and is one of the most common conditions affecting men older than age 40 years. The prostate gland is a walnut-size gland positioned at the base of the bladder and in front of the rectum. The prostate gland, which starts enlarging in puberty and stops growing at around age 20 years, begins to enlarge again after age 50 years. The prostate has three distinct zones: the central zone, the peripheral zone, and the transition zone, which lies adjacent to the urethra (see Prostate Cancer later in this chapter for a more detailed description of prostatic anatomy). BPH develops primarily in the transition zone,

Drugs Commonly Prescribed 13.1 Erectile Dysfunction

Drug	Adverse Reactions	Prescribing Considerations
Hormone Replacement		
Parenteral agents: testosterone cypionate (Depo-Testosterone) testosterone enanthate (Delatestryl)	Sodium retention with dependent edema, increased risk of bleeding, pain at injection site, mild gynecomastia, mood swings, lipid abnormalities	Do not use in patients with serious liver, kidney, or cardiac disease, prostate or breast cancer, or in those with mercury allergy. The peak and trough effects that may lead to aggression, feelings of well-being, energy, and increased libido within 72 hours of injection. As the peak level falls, the patient may experience depressed mood and loss of libido.
Oral agents: fluoxymesterone (Halotestin) methyltestosterone (Android, Methitest, Testred, Virilon)	Same as for parenteral agents Not used much as transdermal or parenteral agents because of the difficulty in achieving adequate blood levels due to high first-pass loss in the liver.	Oral agents are not generally recommended because of the hepatotoxicity and unreliable androgenic effects.
Transdermal testosterone patch: Androderm Testoderm	Local irritation; burn-like blistering or irritation of skin where transdermal patch is worn.	NOT to be applied to the scrotum. Should be applied to the arm, back, abdomen, or thigh. May cause local irritation.
Transdermal testosterone topical gel or solution: AndroGel 1% (2.5- to 5-g packets) Testim 1% Gel (5- to 10-g packets) Axiron solution (60–120 mg)	Burn-like blistering or irritation of skin where gel is applied. Problems with urination.	Apply to the axilla, upper arm or shoulder, NOT the scrotum. May transfer to partner during close contact.
Testosterone implantable pellets: Testopel (150–450 mg)		Produces steady blood levels; must be implanted in subcutaneous tissue every 3–4 months.
Testosterone buccal system: Striant (30 mg)	Mouth or gum irritation Allergic reactions. Swelling of ankles or legs. Breathing disturbances, including those associated with sleep. Liver damage	Insertion twice a day, in the morning and in the evening, provides continuous systemic delivery of testosterone.
Vasoactive Therapy		
Oral agents: sildenafil (Viagra) vardenafil (Levitra) tadalafil (Cialis) avanafil (Stendra)	Headache, flushing, dyspepsia, nasal congestion, visual color changes, back, lower limb pain for all phosphodiesterase-5 inhibitors.	None of these agents should be used in patients taking nitrates or alpha blockers. Must wait 24 hours before giving a nitrate after sildenafil or vardenafil. The duration of action for tadalafil is 36 hours. Must wait 48 hours before giving a nitrate.
Injectables: alprostadil (Caverject)	Penile pain, prolonged erection, penile fibrosis, injection site hematoma, numbness, yeast infection, priapism. May also cause upper respiratory infection, headache, dizziness, hypotension.	Should not be used in patients with sickle cell anemia, penile fibrosis, coagulopathy, severe cardiovascular disease, myeloma, leukemia, penis deformity, morbid obesity, or penile implants. Can be used only once every 24 hours and a maximum of 3 times a week. Patient should be instructed to choose injection site along side of proximal third of the penis, alternate injection sites, and avoid visible veins.

Drugs Commonly Prescribed 13.1 Erectile Dysfunction—cont'd

Drug	Adverse Reactions	Prescribing Considerations
Vasoactive Therapy		
Transurethral suppositories: alprostadil (Muse)	May cause urethral irritation.	As above. Should not be used if partner is pregnant unless a condom is used. The suppository is inserted in the penis about 1 inch after the patient urinates. The button on the top of the applicator is pushed to release the suppository. A gentle rocking motion will separate the suppository from the applicator. After the applicator is removed, the patient should massage the penis firmly for about 10 seconds while standing. An erection begins in about 5–10 minutes.

whereas carcinoma of the prostate usually develops in the peripheral zone.

Epidemiology and Causes

The cause of BPH is not fully understood, but androgens play a key role. Aging is a primary risk factor, and BPH occurs in more than 50% of men older than age 50 years and 90% of men older than 80 years. Of these, 20% of men older than age 60 years have obstructive and irritative symptoms that are severe enough to require treatment. Genetic susceptibility to the disorder is also underscored by twin concordance and family history studies, with inherited forms predominating in men younger than 60 years of age.

Epidemiological studies of BPH have been hampered by inconsistencies in the definition and clinical criteria of this disorder. Most authorities consider not only prostate size (greater than 30 mL) but also decreased urinary flow rates (less than 15 mL/sec) and significant postvoid residual bladder volumes (greater than 50 mL).

BPH arises from a systemic hormonal alteration, which may or may not act in combination with growth factors that stimulate stromal or glandular hyperplasia. One risk factor for BPH is intact testes—more specifically, functioning Leydig cells. Castrated men or those with untreated hypogonadism before age 40 years rarely develop BPH. There has been no concrete evidence that dietary, environmental, or sexual practices are implicated in BPH, although obesity substantially increases the risk of BPH.

Pathophysiology

The prostate consists of two main sections. The inner section of the gland produces secretions needed to keep the lining of the urethra moist. The outer section contributes to seminal secretions. Prostatic secretions form part of the seminal fluid during ejaculation. The ejaculatory ducts from the seminal vesicles pass through the prostate gland and enter the urethra.

The importance of dihydrotestosterone (DHT) as a key androgenic hormone in the pathogenesis of BPH is well supported. Although concentrations of this pro-hormone (which is subsequently converted into testosterone) do not differ in men with or without BPH, prostatic receptors for this hormone have a much more heterogeneous distribution in men with BPH, whereas in normal controls, these receptors predominate within the epithelia. Thus, although necessary to the pathogenesis of BPH, androgen exposure alone is not sufficient to cause the disorder. Similarly, estrogen has been implicated as a necessary factor to maintain BPH in older men, but it is not sufficient to cause its pathogenesis alone. The data are conflicting, however. For instance, the concentration of estrogen receptors is actually lower in hyperplastic prostatic tissue, whereas the concentration of progesterone receptors does not differ in BPH versus the normal prostate.

The earliest histological signs of BPH usually appear in men in their 30s and 40s. The development of pathological BPH is similar in most cases. BPH usually presents as a predominance of stromal nodules (up to a fourfold increase), consisting primarily of smooth muscle and connective tissue, in the periurethral area of the transition zone. This may be followed by glandular hyperplasia (up to a twofold increase) with an increase in epithelial cells. Key growth factors include fibroblast growth factor, insulin-like growth factor–2, and transforming growth factor–b. In vitro data demonstrate a wider array of growth factors that stimulate prostatic epithelial cell growth. Anti-apoptotic factors such as bcl-2 are also upregulated in BPH tissue, and animal studies have implicated higher numbers of stem cells in hyperplastic prostatic tissue.

There are two documented mechanisms of obstruction—static and dynamic. *Static constriction* is caused by the buildup of prostatic tissue, with direct obstruction of the bladder neck. *Dynamic constriction* is an increase in prostatic muscle tone through adrenergic stimulation, leading to constriction of the bladder neck. A predominance of alpha-adrenergic receptors in the sympathetic nervous system controls stromal hyperplasia. If middle-lobe enlargement of the prostate predominates, the symptoms produced are similar to those of a ball-valve obstruction at the bladder neck.

Obstruction of the bladder outlet forces the bladder to generate higher pressures than normal to achieve micturition. Increased muscle mass in the bladder leads to reduced bladder elasticity and compliance, which manifests as a reduction in bladder capacity. If the bladder neck obstruction is not relieved, the bladder's smooth muscle begins to be replaced by connective tissue, leading to bladder failure.

Clinical Presentation

Subjective

Use of a standardized questionnaire such as the American Urological Association Symptom Index (AUASI) (shown in Focus on History 13.1), also known as the International Prostatic Symptom Score, is important in assessing the impact of BPH on the patient. This questionnaire is designed to uncover the degree of symptomatology in each patient. There are 7 items on the questionnaire that determine the severity of obstructive or irritative symptoms. Total symptom scores may range from 0 to 35. Obstructive voiding symptoms can be mild, with a score of 0 to 7. A score of 8 to 19 is considered moderate; 20 or higher indicates severe symptoms. Symptom scores are helpful to quantify the patient's symptoms. A score of 7 or higher on the AUASI, for example, can reinforce the need for further investigation of the cause of the symptoms. Although the scores alone are not diagnostic, they help to support the

Focus on History 13.1 AUA Symptom Score Index—cont'd

Directions: Circle one number on each line.

Question to be answered	Not at all	Less than 1 time in 5	Less than half the time	About half the time	More than half the time	Almost always
7. Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	0	1 time	2 times	3 times	4 times	5 times

Total sum of the 7 circled answers (AUA Symptom Score): _____

AUA Symptom Score Index

Score	*Severity*
0–7	Mild
8–19	Moderate
20–35	Severe

Source: Barry, MJ, et al. The American Urological Association symptom index for benign prostatic hyperplasia. *J Urol* 148(2): 1549–1557, 1992. Retrieved from www.ncbi.nlm.nih.gov/pubmed/1279218

diagnosis, as well as being useful in following a patient after initiating therapy to track the decrease in symptoms.

The symptoms of BPH vary and are dependent on the type of obstruction, but usually include a combination of obstructive and irritative voiding symptoms. Because the symptoms are not specific to BPH and may have other causes, a complete work-up is necessary. BPH is non–life-threatening, but it is a lifestyle-changing diagnosis.

Symptoms of obstructive BPH include decreased force of stream, hesitancy, postvoid dribbling, sensation of incomplete bladder emptying, overflow incontinence, inability to voluntarily stop the urinary stream, urinary retention, double-voiding (voiding a second time within 2 hours), and straining. Irritative symptoms of BPH include nocturia, urinary frequency, urgency, dysuria, and urge incontinence.

Objective

A digital rectal exam (DRE) is done to determine enlargement of the prostate gland. The prostate in BPH is usually diffusely smooth and enlarged. If the prostate is nodular and unusually firm, prostate cancer may be present. The size of the prostate does not correlate with the severity of the symptoms in men with BPH. Many men with palpably enlarged prostates are asymptomatic, whereas some patients with small prostates have irritative or obstructive symptoms.

Objective findings can include gross hematuria (in men older than 60 years of age), observation of a weak stream, distended bladder (to greater than 150 mL detected by percussion), increased postvoid residual volume (more than 100 mL), and prostate enlargement (to more than the normal "walnut" size, weighing 20 g or less).

Diagnostic Reasoning

Diagnostic Tests

Laboratory tests include a urinalysis, prostate-specific antigen (PSA), and the Prostate Health Index (phi). Urinalysis is done to exclude infection or hematuria. The American Urological Association (AUA) no longer recommends serum creatinine on the initial evaluation. PSA is done to assess for prostate cancer. There may be an elevation of the PSA in either prostate cancer or BPH; therefore, the PSA value alone is not diagnostic of cancer or BPH. Acute lower urinary retention or prostatitis will also elevate the PSA. The PSA in BPH is usually less than 10 ng/mL. PSA is a glycoprotein that aids in the liquefaction of the seminal coagulum. The phi blood test detects the [-2] proPSA isoform of prostate-specific antigen. This test may reduce the number of unneeded prostate biopsies, using a threshold of 27 when the total PSA is 4 to 10 ng/mL. An elevated pH results from the chronic residual urine. If an obstructive uropathy is present, the serum creatinine level will be elevated. Urine cultures are sometimes positive for bacteria because of the chronic residual urine. Urine cytology should be done to rule out carcinoma, particularly when hematuria is present. An intravenous pyelogram can identify an increased postvoid residual (PVR) volume of urine, a large prostatic impression on the bladder, trabeculated

bladder, bladder diverticula, upper tract dilation, and/or bladder stones.

Subsequent testing should be done by a urologist if initial treatment does not relieve symptoms or if prostate cancer is suspected. Uroflow, for example, measures the amount of urine voided per unit of time. Flow of less than 10 mL/sec is indicative of obstruction. This test is accurate when the voided volume is greater than 200 mL. A cystometrogram measures bladder compliance and is usually reserved for patients with suspected neurological disease or whose prostate surgery was unsuccessful in relieving symptoms. A cystoscopy is usually done only to determine the best surgical approach for BPH.

Differential Diagnosis

The differential diagnoses that must be considered when evaluating a patient with suspected BPH are numerous and fall into three distinct categories: bladder outlet obstruction, nonobstructive etiologies, and irritative symptoms. Differential Diagnosis 13.1 presents the differential diagnosis for BPH.

When BPH is the presumptive diagnosis, other obstructive etiologies of the lower urinary tract (bladder calculi, bladder neck contracture, urethral stricture, and prostate cancer) should be explored. Careful history may reveal previous urethral instrumentation, urethritis, or trauma as the source of the obstruction. Bladder calculi may present with pain and hematuria. Irritative etiologies (bladder cancer, lower urinary tract infection, prostatitis, or urethritis) may present with hematuria, urgency, and frequency. A history of diabetes mellitus, stroke, neurological diseases, or spinal cord injury can contribute to a neurogenic bladder, which has many of the same symptoms as BPH. Cancer of the prostate and BPH have many of the same symptoms. A PSA and DRE can help differentiate between these two disorders.

Differential Diagnosis 13.1 Benign Prostatic Hyperplasia

Bladder Outlet Obstruction
- Prostate cancer
- Urethral stricture due to trauma or sexually transmitted disease
- Bladder neck contracture (acquired or congenital)
- Anterior or posterior urethral valve failure
- Müllerian duct cysts
- Inability of bladder neck or external sphincter to relax during voiding

Nonobstructive Etiologies
- Neurogenic bladder (detrusor denervation)
- Myogenic cause (detrusor muscle failure)
- Diabetes mellitus
- Parkinson's disease
- Cerebrovascular accident
- Medications (parasympatholytics, sympathomimetics)
- Psychogenic stress–induced performance anxiety

Irritative Symptoms
- Neurogenic bladder (detrusor denervation)
- Neoplasm
- Bladder cancer
- Bladder calculi
- Prostatitis
- UTI
- Urethritis

Management

Medical Management

Most patients with BPH can be treated as outpatients; the goal is to relieve the symptoms, specifically nocturia. The Patient's Voice 13.1 illustrates the patient's need for symptom relief. Inpatient treatment is required to manage fluid and electrolyte abnormalities of obstructive uropathy.

The Patient's Voice 13.1

Nocturia

I had been getting up three or four times a night to urinate. It was getting to be a nuisance. At my annual exam, I was told I had mild BPH and that my PSA was normal. I told my primary-care provider that I was tired of getting up so often at night and that it made me tired the next day. The primary-care provider told me that if getting up several times a night was bothering me, that there were some medications I could try. I decided to give it a try. What relief! A simple pill and now I can sleep all night and wake up refreshed. I feel great. I am grateful that my primary-care provider took the time to listen to me.

Most urologists and primary-care providers have adopted a "watchful waiting" technique for BPH that has only mild symptoms. A patient with mild to moderate symptoms, minimal PVR, and no objective changes in the urinary tract may only require monitoring. The "watchful waiting" medical treatment is usually considered the most conservative and the most effective treatment for BPH, as long as more serious conditions have been ruled out. Watchful waiting is also the recommended treatment when BPH has little or no impact on the quality of life. As lifestyle changes do occur, however, or as the AUA score increases, several options may be offered to the patient. Avoidance of caffeine and alcohol, both known to be bladder irritants, is recommended. A patient with a high AUA symptom score, urinary retention, or complications of BPH, including a high PVR, renal insufficiency, hematuria, bladder stones, or anatomical urinary tract abnormalities, should not be treated with only watchful waiting, because these conditions require more vigorous treatment.

Once prostatic cancer has been ruled out, medications may be tried initially to treat the BPH symptoms. Medical

management is used when no strong indication for surgery exists or when a patient refuses surgery or is a poor surgical candidate. Because the prostate and bladder contain alpha$_1$-adrenergic receptors that cause the prostate and bladder neck to contract when bound, alpha blockade decreases this effect and results in objective and subjective improvement in the manifestations of BPH. Most of the alpha blockers used in the treatment of BPH are selective alpha$_1$-adrenergic agonists. These include silodosin (Rapaflo) 4 or 8 mg daily or the longer-acting terazosin (Hytrin) 1 to 10 mg daily and doxazosin (Cardura) 1 to 8 mg daily. The subtype alpha$_{1a}$-adrenergic receptors have been identified in the bladder neck and prostate, with the subsequent development of medications that target these receptors, which include tamsulosin (Flomax) 0.4 or 0.8 mg daily and alfuzosin (UroXatral) 10 to 15 mg daily (immediately after the same meal each day).

The long-acting alpha$_1$-adrenergic blockers have the advantage of once-a-day dosing but still require a gradual dose titration. For example, doxazosin is usually started at 1 mg daily for 7 days and then increased by 1 mg per week until the dose is 4 mg daily. Terazosin is started at 1 mg daily for 3 days, then 2 mg daily for 11 days, then increased to 5 mg daily. The alpha$_{1a}$-adrenergic blockers (tamsulosin and alfuzosin) do not need to be titrated, but should be started at the lowest dose and increased if necessary. The dosage of silodosin is once daily with a meal. No dosage adjustment is required with mild renal impairment or mild or moderate hepatic impairment. In moderate renal impairment, the dose would be reduced to 4 mg daily. For those with severe hepatic or renal impairment, silodosin is contraindicated.

Another class of medications used to treat BPH are the 5-alpha-reductase inhibitors, which include finasteride (Proscar) and dutasteride (Avodart). These medications block the conversion of testosterone to DHT by inhibiting the enzyme 5-alpha-reductase. DHT is primarily responsible for the enlargement of the prostate gland. The maximum reduction in prostate size (20% reduction) may take 6 months of therapy. However, improvement in symptoms is seen only in men with very enlarged prostates (greater than 40 g). Finasteride is well tolerated in most patients, but adverse effects include decreased ejaculate volume, reduced libido, and erectile dysfunction in 3% to 5% of all patients. The adverse effects may decrease with time, however, and are reversible with the cessation of treatment. Finasteride also decreases the PSA concentration by almost 50%, which can complicate prostate cancer detection. Dutasteride (a second generation 5-alpha-reductase inhibitor) produces a more rapid reduction in DHT. For example, dutasteride 0.5 mg daily for 2 weeks reduced serum DHT concentrations by 90% and resulted in significant improvement in symptoms after 3 to 13 months of treatment. The side effects of dutasteride were similar to those of finasteride, but decreased over time and were only slightly higher than in men receiving placebo.

There is some evidence that combination therapy of terazosin and finasteride is superior to single-medication therapy (either alpha blockers or 5-alpha-reductase inhibitors) in long-term but not in short-term treatment. If a patient has reached the maximum dose of the alpha blockers and symptoms continue to progress, finasteride can be added at that point to improve prostate size and symptoms.

Complementary therapies may also be used to treat BPH. Complementary Therapies 13.1 presents herbal therapies, along with vitamin and mineral therapies, that may be used in the treatment of the symptoms of BPH and other men's health problems.

Invasive and Surgical Management

Urological surgery is another treatment option for BPH and in fact is the second most common surgery in men (cataract surgery is the first). Prostate surgery is indicated when there is urinary retention or when other symptoms are intractable because of the prostatic obstruction, as gauged by the AUA index (that is, in patients with a score of greater than 8). Obstructive uropathy, recurrent and persistent urinary tract infections (UTIs) resulting from the prostatic obstruction, or recurrent gross hematuria caused by the enlarged prostate also are indications for surgical resection.

Transurethral resection of the prostate (TURP) is the surgical treatment of choice for a patient with BPH. Candidates for surgical intervention include patients with severe symptoms, high PVRs, complications, upper urinary tract changes, and those who fail medical therapy. TURP is performed through a cystoscope, using a diathermy loop for resection of prostatic tissue. It usually is performed under spinal or general anesthesia, with a urethral catheter maintained in place for 36 to 48 hours postoperatively. Some patients may also need to be discharged from the hospital with a urinary catheter in place

Complementary Therapies 13.1 Benign Prostatic Hyperplasia

Problem	Therapy	Dosage	Comments
BPH	Saw palmetto *(Serenoa serrulata sabal)*	60 mg 2 times daily	Saw palmetto inhibits 5-α-reductase activity and mimics the effects of finasteride (Proscar).
Urinary infection (cystitis, urethritis)	Cranberry	500 mg 2 times daily	(Level II; Vidlar et al, 2010)

for up to 2 weeks after surgery. Symptomatic improvement following a TURP occurs in 90% of the patients. Flow-stream rates are increased as much as 15 mL/sec. Unfortunately, a complication of TURP can be retrograde ejaculation, occurring in 65% of patients; another potential complication is erectile dysfunction, which occurs in up to 15% of patients. Less frequent problems include bleeding, UTI, and urethral stricture.

A transurethral incision of the prostate (TUIP) is limited to patients with moderate to severe symptoms and a small prostate who have an elevated bladder neck or posterior commissure hyperplasia. In this procedure, an instrument is passed through the urethra to make one or two cuts in the prostate and the prostate capsule, reducing urethral stricture. This procedure can be performed on an outpatient basis or during a 24-hour stay; TUIP has a lower complication rate than TURP.

Open prostatectomy is a surgical option reserved for prostate glands weighing more than 40 to 100 g. An open prostatectomy is the surgical removal of the inner portion of the prostate via a suprapubic or retropubic incision in the abdominal area. This procedure requires longer hospitalizations than the other two options and has far more complications. Nonetheless, this may be the only alternative for a patient who has failed medical treatment or when a carcinoma of the prostate is suspected.

Robotic simple prostatectomy is now being used with increasing frequency for the treatment of BPH. It is used for patients with very large prostates. During the procedure, the inner part of the prostate that is causing the obstruction is removed. This is a substitute for open prostatectomy and has drastically reduced blood loss, postoperative pain, and hospital length of stay. Although robotic prostatectomy has better outcomes with regard to sexual and urinary functioning than the open prostatectomy, most patients will experience some sexual dysfunction and urinary incontinence.

There are several minimally invasive procedures for BPH. Transurethral laser–induced prostatectomy (TULIP) is a type of coagulation necrosis and is done under transrectal ultrasound guidance. Other types of laser surgery (coagulation necrosis) are performed under direct visualization. In laser procedures, the ablated tissue sloughed in 3 weeks to 3 months. The main advantage of laser surgery is that it is minimally invasive and can be done in the outpatient setting. There is also minimal blood loss, and the occurrence of retrograde ejaculation and erectile dysfunction is reduced. Also, this procedure can be performed in patients who are taking anticoagulants.

Another procedure is transurethral electrovaporization of the prostate. This seems to provide results equivalent to those of laser ablation. In transurethral electrovaporization of the prostate, a grooved roller-blade electrode administers diathermic energy to the prostate, vaporizing the prostatic tissue. The procedure provides a patient with improved urinary flow through the urethra. Because this is a recent innovation, long-term studies are not yet available.

Transurethral microwave thermotherapy (TUMT) is another procedure that results in the ablation of prostatic tissue. In TUMT, microwave energy is applied to the prostate through a microwave antenna in a urethral catheter; temperature monitoring of the rectum and urethra is essential. Prostate tissue is heated to 55°C, resulting in necrosis of the tissue, causing obstruction. Urethral cooling prevents urethral necrosis and limits postoperative irritative symptoms. One of the adverse effects of TUMT postoperatively is urinary retention, requiring catheterization. Although symptom score and urine flow rates are improved, long-term studies are needed to assess the efficacy.

In transurethral needle ablation (TUNA), two radiofrequency energy waves are administered to prostatic tissue via needle electrodes applied through a cystoscope. Temperatures up to 120°F (48.9°C) destroy the prostatic tissue that had caused the urinary retention or obstruction while preserving prostatic urethral mucosa.

Another means of thermal tissue ablation is the high-intensity focused ultrasound. A rectal probe delivers a short burst of high-intensity focused ultrasound energy that heats the prostate tissue, resulting in coagulative necrosis. Clinical trials are ongoing and demonstrate symptom improvement, but long-term efficacy is not known yet.

Stents have been placed cystoscopically and may be effective in relieving severe urinary obstruction or retention without further surgical intervention. Within 4 to 6 weeks after placement, the stents become covered in urothelium. Stent placement is reserved for patients who are poor surgical risks or who have a limited life expectancy. Stent placement is being used less since the development of minimally invasive procedures such as the TUNA and TULIP.

Transurethral (balloon) dilation of the prostate involves the insertion of a catheter with a balloon at the end through the urethra and into the prostatic urethra. The balloon is then inflated to stretch the urethra at the stricture where it has been narrowed. Although this treatment has been associated with fewer complications, dilation is less effective than other methods. It may provide only a temporary solution, with symptoms recurring within 2 years, and is rarely used today.

Follow-up and Referral

Patient monitoring includes the use of the AUA symptom index, which should be monitored every 1 to 6 months; urodynamic testing, which should be done every 3 to 6 months; and DRE and PSA, which should be done yearly. In addition to the yearly PSA, urodynamic studies should be done every 3 to 6 months to evaluate flow rates and voiding pressures. Any patient with BPH who is suspected to have prostatic carcinoma should be referred to a urologist.

Patient Education

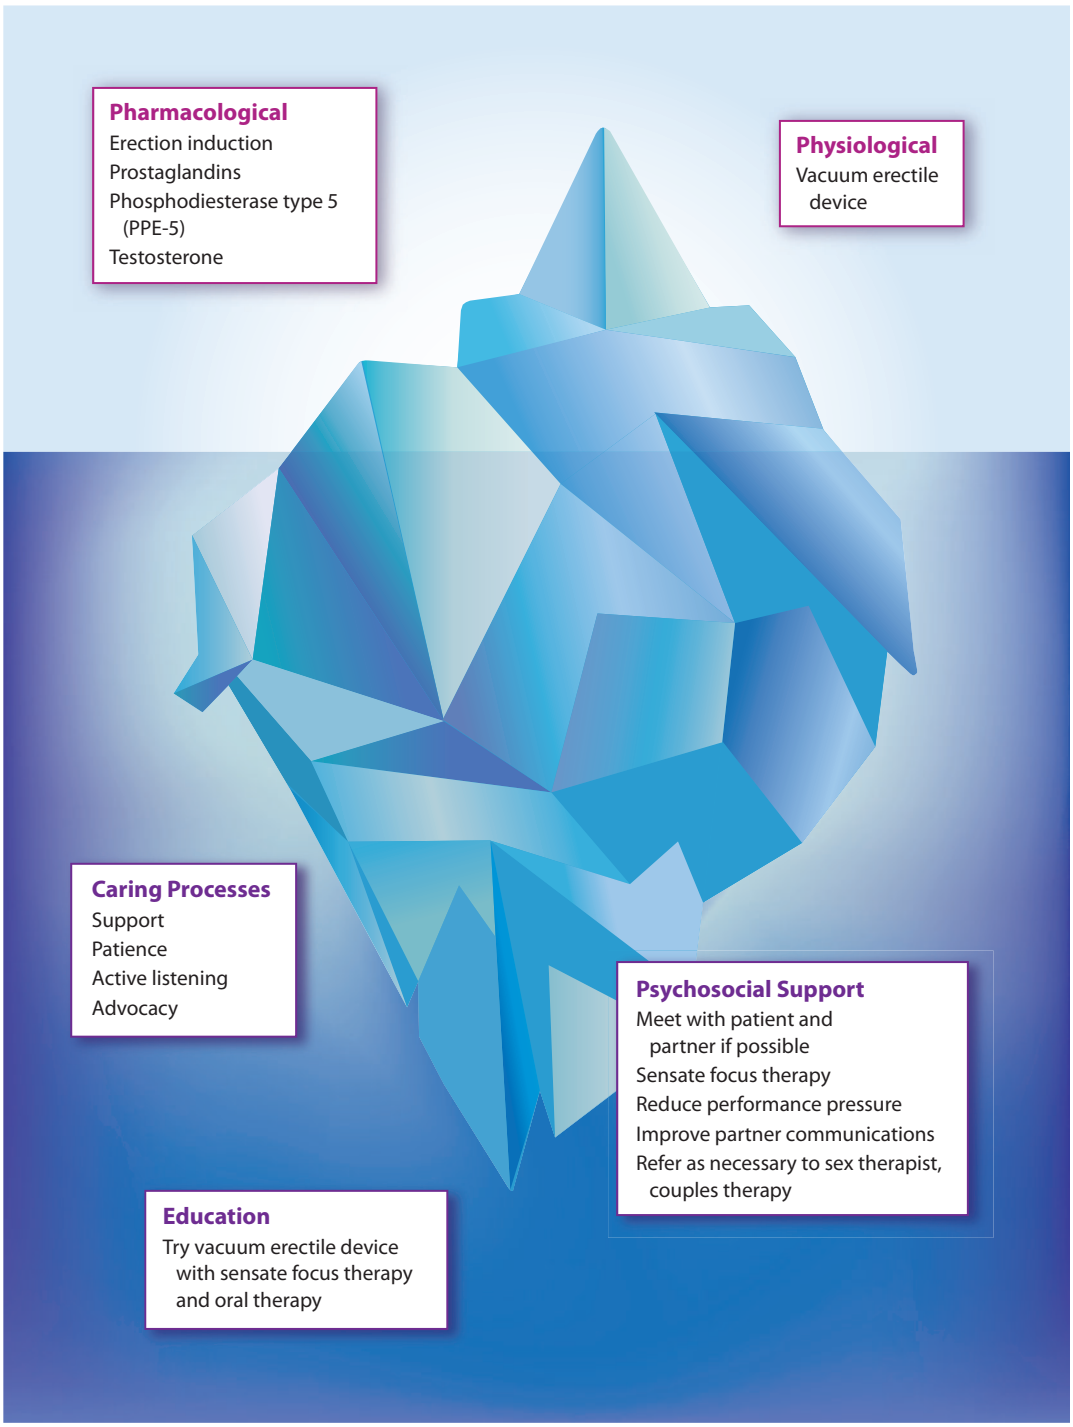
It is extremely important to stress to the patient with BPH that taking over-the-counter medications containing alpha agonists or anticholinergic agents can cause

acute urinary retention that can result in acute renal failure. These patients may require an indwelling urinary catheter until the acute urinary retention is resolved. The most common offending medications are various cold and flu preparations. Patients should also be advised to avoid bladder irritants such as coffee, spicy foods, and alcohol. Patients should be instructed to void at least every 2 hours to help reduce the possibility of UTI.

ERECTILE DYSFUNCTION

Erectile dysfunction (ED), sometimes referred to as impotence, is the failure to consistently maintain a sufficiently rigid erect penis to allow for sexual intercourse and is considered a facet of male sexual dysfunction. ED can also manifest as a lack of sexual desire or inability to ejaculate. ED can result from many causes, including physiological, psychological, endocrine, vascular, and neurological.

The Iceberg of Erectile Dysfunction



Epidemiology and Causes

ED is classified as mild if the patient fails to achieve a satisfactory erection in 2 out of 10 attempts. If all attempts at satisfactory erection fail, the ED is classed as severe. Moderate ED is somewhere in between mild and severe. It is difficult to estimate the number of men with ED because the definition is broad and some men may be reluctant to seek medical attention for the problem. Transient and limited episodes of impotence occur in about half of all adult men at one time or another in their lives and are not pathological. In the United States, between 15 and 30 million men are believed to suffer from ED at some time in their lives. Aging affects sexual functioning, and more than 25% of men older than 65 years of age have ED. Most cases of ED have an identifiable organic as opposed to a psychogenic cause.

Although the focus of this section is on the physiological causes of ED, it is critical for the primary-care clinician to assess both physical and mental health aspects in the patient with ED and make appropriate specialist referrals if needed. In some cases, ED may result from a combination of both physical (organic) and psychological/emotional (psychogenic) causes, because such etiologies are not mutually exclusive. In turn, it is critical to determine whether the patient with ED still experiences sexual arousal, despite the inability to achieve or maintain an erection.

Several categories of ED should be considered when determining the cause of the problem. First, there may be a failure to generate the nerve impulse that is required to initiate an erection. This can be caused by a number of endocrinological or neurological conditions or can be psychogenic in origin. ED can also be the result of a failure to adequately fill penile blood vessels, most often arteriogenic in origin. Another category is the failure to retain blood in the penis, which is usually veno-occlusive in origin.

A loss of libido may indicate androgen deficiency arising from either pituitary or testicular disease, resulting in a failure to initiate the nerve impulse needed to initiate an erection. Plasma levels of testosterone and gonadotropins are measured to rule out this possibility. Endocrine factors are unlikely if the patient has normal semen volume. Some of the organic causes of ED are listed in Table 13.1.

Medications are a common cause of ED, either directly or by adverse effects. Loss of erection can be caused by central sympatholytics such as methyldopa, clonidine, and reserpine, whereas alpha blockers cause few problems with erection. However, beta-adrenergic blocking agents and spironolactone can cause a loss of libido. Certain drugs, such as calcium channel blockers, can increase prolactin secretion and thereby cause ED. Some of the drugs of addiction can lower testosterone levels and lead to ED. In addition, zinc deficiency seen in malabsorption or malnourishment syndromes may also cause ED.

Table 13.1 Organic Causes of Erectile Dysfunction

Neurological Diseases
• Anterior temporal lobe lesions
• Disease of the spinal cord
• Loss of sensory input (secondary to diabetes mellitus, polyneuropathies), tabes dorsales (disease of dorsal root ganglia)
• Disease of nervi erigentes (secondary to complete prostatectomy, retrosigmoid operations, aortic bypass)
Vascular Disease
• Leriche syndrome
Endocrine Disorders
• Testicular failure (primary or secondary)
• Hyperprolactinemia
Penile Disorders
• Failure of detumescence
• Priapism
• Penile trauma
• Peyronie's disease
Medications
• Phenothiazines
• Thioridazine
• Imipramine
• Methyldopa
• Guanethidine
• Reserpine
• Spironolactone
• Alcohol
• Heroin
• Methadone
• Estrogen
• Beta blockers
• Antihypertensives
• Thiazide diuretics

Pathophysiology

To understand ED, a knowledge of normal erectile physiology is necessary. Normal sexual function in men has five phases: libido, erection, ejaculation, orgasm, and detumescence. For an erection to occur, there must be an intact autonomic and somatic nerve supply to the penis and the pudendal arteries. Erection begins with neurological and vascular stimulation and is maintained by increased arterial blood flow, increased venous resistance, and relaxation of the smooth muscle of the sinusoids in the corporal bodies of the penis. Additional rigidity of the penis is accomplished by contraction of the bulbocavernosus and ischiocavernosus muscles. The process is initiated by neurotransmitters, possibly nitric oxide, vasoactive intestinal peptide, acetylcholine, and

prostaglandins, although the exact mechanism is unknown at this time.

In addition to the increase in arterial flow, the efflux of blood is reduced. As the erectile tissue expands, the peripheral veins are compressed against the enveloping tunica albuginea, which effectively impedes drainage of blood from the cavernous sinuses. The less turgid corpus spongiosum allows the urethra to dilate during ejaculation.

With continued sexual stimulation, the urethral meatus dilates and sperm move to the ejaculatory duct. Seminal fluid is added to the sperm cells by the seminal vesicles and prostate gland. At the time of vaginal penetration, the male secretions produced by the bulbourethral glands and the glands of the penile urethra combine with the female cervical secretions. The sperm cells move by emission into the prostatic urethra, where they become activated by seminal fluid and are motile. In the male, orgasm is concomitant with ejaculation, which is brought about by sympathetic activity transmitted along the hypogastric nerve and lateral pelvic plexus, and then through the prostatic and cavernous plexuses. Ejaculation is the strong rhythmic contraction of the vas deferens, seminal vesicles, epididymis, prostate, urethra, and penis. Retrograde ejaculation is prevented by partial bladder neck closure, mediated by sympathetic nerves. Orgasm is a sensory phenomenon in which the rhythmic contractions of the muscle are perceived as pleasurable.

Postcoital resolution, or detumescence, results from the sympathetic outflow to the genital areas; the periarterial muscle increases its tone, thereby reducing the flow to the erectile tissues of the penis. A refractory period of variable duration follows.

An understanding of vascular disease as a cause of ED is essential because continual high blood flow into the vascular system of the penis is necessary to maintain an erect state. Atherosclerosis can cause failure to fill; therefore, risk factors for this type of ED are heart disease, cigarette smoking, diabetes mellitus, aging, dyslipidemia, and hypertension. Trauma can also damage the pudendal and cavernous arteries, for example, from prolonged bicycling, and cause failure to fill. Leriche's syndrome, with impedance of the blood flow into the penis, occurs as the result of obstruction of the distal aorta at the bifurcation of the common iliac arteries. Presenting symptoms of this syndrome are claudication and ED, either separately or in combination.

Because resistance to the efflux of blood from the penis is necessary to maintain an erection, anything that impairs this ability is considered as a failure-to-store defect. It can result from insufficient relaxation or fibrosis of the corporeal smooth muscle. Adrenergic agonists and/or psychological stress can cause insufficient relaxation of the corporeal smooth muscle, whereas atherosclerosis and penile trauma can result in fibrosis. *Priapism,* persistent painful erection, is usually idiopathic but can be associated with sickle cell anemia, chronic granulocytic leukemia, or spinal cord injury. The persistent erection disrupts this vascular network and can lead to fibrosis and subsequent failure to store.

In addition to the inability to achieve or maintain an erection, ED may also involve abnormal functioning of several other sexual processes. Premature ejaculation seldom has an organic cause. It is usually related to anxiety about the sexual situation, performance-related fears, or an emotional disorder. Psychological disorders such as depression, bipolar disorder, anxiety disorders, and relationship dysfunction may all cause ED.

The absence of emission may be caused by three organic disorders: retrograde ejaculation, sympathetic denervation, or androgen deficiency. Retrograde ejaculation may occur after surgery on the bladder neck, or it may develop spontaneously in a male patient with diabetes. A postcoital urine sample can be analyzed to confirm the diagnosis. Smooth muscle contractions may not occur at the time of ejaculation as a result of the loss of the autonomic innervation of the prostate and seminal vesicles after sympathectomy. An androgen deficiency may lead to absence of secretions from the prostate and seminal vesicles. If libido and erectile function are normal, the absence of orgasm is almost always due to a psychiatric disorder.

Various penile diseases and anatomical abnormalities may also cause ED. Structural causes of ED include microphallus, Peyronie's disease, scarring of the corpora cavernosa, phimosis, hypospadias, and postsurgical sequelae. Peyronie's disease results from localized fibrotic thickening of the tissue around the corpora cavernosa. Plaque may be palpated along the penile shaft, usually on the dorsum, but plaque is sometimes present on any part of the corpora cavernosa. Inelasticity produces a curvature of the penile shaft on erection that may be very painful. There is a high correlation between Peyronie's disease and Dupuytren's contracture of the palmar fascia.

Clinical Presentation

Subjective

Because male sexual dysfunction can manifest in many ways and because the causes are numerous, a careful history is essential for the correct diagnosis and subsequent treatment. Impotence is a very personal complaint, and discussion requires a trusting relationship between patient and clinician and sufficient time during the visit for the patient to voice his concerns. He may complain of a loss of desire, an inability to obtain or maintain erection, premature ejaculation, or an absence of emission or inability to achieve orgasm. Frequently, the patient has a combination of these symptoms. It is essential to determine whether or not the patient has normal erections, most likely during sleep or early in the morning. If an erection does occur, an organic cause is most likely not the cause of the ED. In 25% of cases, medication use may be the cause of ED. The use of alcohol, tobacco, and recreational drugs increases the risk of sexual dysfunction.

Objective

A physical exam, including a thorough genital exam to rule out any abnormalities of the penis itself, is done. The testes should be palpated for size or abnormal masses. If the length is less than 4 cm, hypogonadism should be considered. Evidence of feminization such as gynecomastia and abnormal body hair distribution should be assessed. All pulses should be palpated, including the penile pulse, which can be felt by pressing both corpora between the thumb and forefinger and palpating to either side of the midline. If there is an indication of a vascular etiology from either the patient's history or physical exam, an aortogram may be indicated.

A neurological exam to evaluate the erectile reflex, including anal sphincter tone, perineal sensation, and the bulbocavernosus reflex, should be part of the physical exam. The reflex can be evaluated by squeezing the glans penis and noting the degree of anal sphincter constriction. An examination for signs of peripheral neuropathy, including distal muscle weakness and loss of tendon reflexes in the legs, is important, along with tests that will reveal any impairment of vibratory, position, tactile, and pain sensation.

Diagnostic Reasoning

Diagnostic Tests

Initially, laboratory tests that rule out causes of ED should be done. These tests include a fasting blood sugar to rule out diabetes mellitus, lipid profile to rule out dyslipidemia, thyroid-stimulating hormone (TSH), and a testosterone level. If the testosterone level is below 300 ng/dL, a serum prolactin level is warranted. Laboratory tests for patients with established ED should include a complete blood count, a blood chemistry profile (including fasting glucose or glycosylated hemoglobin levels), a TSH level, and a PSA in men as young as 40 years if they have a family history of prostate cancer. Most men older than age 55 years will have some abnormal laboratory findings or risk factors, but these may not necessarily be the cause of the ED. Several specialized tests can be done but usually only if the cause of the ED is not apparent from the more standard tests. The most useful of these tests is the nocturnal penile tumescence and rigidity (NPTR) test and color Doppler sonography of the penis.

NPTR testing is useful to assess the patient's physical ability to achieve an erection. Sensors are placed at the base and tip of the penis and record the circumference and rigidity of the penis during sleep. Typically, the test is done from one to three nights. Men usually have erections during rapid eye movement (REM) sleep. A physiological cause of ED is indicated if there is an absence or impairment of erections during sleep. This test is self-administered in the patient's home; however, it can be used in the clinical setting to determine erectile response to sexual stimuli.

There are, however, two medical conditions that cause ED in sexual situations yet still allow normal erectile activity during NPTR. The first is disruption of the afferent nerves that amplify the erectile response to external sexual stimuli but are bypassed in the nocturnal erectile activity. The second is called *pelvic steal syndrome,* which may occur in physiological states when the patient is awake, but not when he is asleep. This condition involves partial blockage of the iliac vessels and causes all erections to occur when the patient is at rest. Loss of erection ensues, however, with gluteal muscle activity during thrusting.

Color Doppler sonography is being used to assess vascular causes of ED. It measures the integrity of arterial influx in the cavernous artery during erection by measuring the peak systolic velocity in this artery.

Differential Diagnosis

Differential diagnosis of ED requires consideration of fibrosis secondary to trauma, severe urethritis, late-stage syphilitic lesions, penile infiltration with lymphogranuloma venereum, benign and malignant tumors, and congenital curvature. Urethral strictures produce an indurated area that may be identified by careful palpation along the penile urethra. A stricture can be identified more easily by the passage of a small urethral probe or catheter (urethral sound). Occasionally, strictures may be recognized by the presence of an indolent, firm, tender mass that may even involve the skin over the penile shaft. Restricted erections may cause ventral curvature of the penis, periurethral inflammations, and, at times, a purulent urethrocutaneous fistula.

Management

A number of options are available for the treatment of ED. If an organic cause cannot be found, these men will most likely benefit from behaviorally based sex therapy. Pharmacological treatments including hormone replacement are presented in Drugs Commonly Prescribed 13.1. Nonpharmacological interventions including vacuum constriction devices, vasoactive therapy, penile prostheses, and penile revascularization are discussed in the sections that follow.

Hormone Replacement

For men with documented testosterone deficiency who do not have prostate cancer, testosterone replacement is the treatment of choice. Testosterone replacement can be accomplished by several delivery methods that include injections, oral medication, topical patches, or topical gels.

Vacuum Constriction Devices

Most vacuum devices work in similar ways, using a process that takes about 2 minutes. The patient inserts his penis into the cylinder, then uses the pump to create a partial vacuum. This causes venous blood to enter the corpora cavernosa, initiating tumescence and rigidity. Once a sufficient erection is achieved, a latex constriction ring is placed around the base of the penis to help

maintain the erection. This is a noninvasive procedure and complications are rare. Vacuum constriction devices are now available over the counter and cost between $300 and $500.

Vasoactive Therapy

The development of drugs that decrease the breakdown of 5-cyclic guanosine monophosphate (cGMP) has revolutionized ED treatment. cGMP is the intracellular second messenger of nitric oxide, which is the primary vasodilator and neurotransmitter involved in the erectile response. The first of these drugs was sildenafil citrate (Viagra). Sildenafil is an orally active cGMP-specific phosphodiesterase inhibitor. It results in an increased blood flow necessary for successful penile erection. The standard dose is sildenafil 50 mg taken orally at least 1 hour before sexual activity. Contraindications that can cause severe hypotensive effects are listed in Drugs Commonly Prescribed 13.1. Other medications in this class are vardenafil (Levitra), avanafil (Stendra), and tadalafil (Cialis). Phosphodiesterase-5 inhibitors do not affect libido and do not initiate an erection without sexual stimulation.

Vasoactive prostaglandins have been shown to be an effective treatment for ED. Alprostadil (Caverject) 5 to 40 mcg is injected directly into the base and lateral aspect of the penis using a tuberculin syringe. Erection occurs within 20 minutes and lasts for approximately 30 to 60 minutes. Prolonged erection (priapism) occurs rarely, but the patient should be instructed to seek medical attention if this does occur. Alprostadil is also available in a transurethral suppository in dosages of 125, 250, 500, or 1,000 mcg. Results have been good, with the suppositories producing an erection in about 5 to 10 minutes (see Drugs Commonly Prescribed 13.1 for instructions for use).

Penile Prostheses

Several prosthetic devices that can be surgically implanted into the penis are available in a variety of sizes and diameters. They are placed directly in the corporal bodies. Penile prostheses may be rigid, semifirm, hinged, or inflatable. The inflatable devices are more natural appearing; however, there is more opportunity for mechanical failure. Implantation of a prosthesis, which is a highly reliable but invasive form of therapy, may help men who have failed therapy with other methods; it is very expensive, however, ranging in cost from $9,000 to $20,000. Implantation may be covered by some insurance plans. Most patients desiring implants prefer spontaneity and therefore choose this invasive treatment. Significant problems associated with implants are infection, erosion, and occasional mechanical failure (in fewer than 5% of patients). The most common types of implants are nonhydraulic (using semirigid rods) and hydraulic (using inflatables). Both types of implants involve surgical placement of two cylinders inside the corpus cavernosum. Healing takes 4 to 6 weeks, after which the patient may have intercourse.

Penile Revascularization

The experience with penile revascularization is limited, and some patients fail to have a sufficient erection even after the procedure. Patients with arterial disorders may be candidates for the various procedures, which include endarterectomy and balloon dilation, or arterial bypass. For patients with venous disorders, ligation of the deep dorsal vein or emissary vein or ligation of the crura of the corpora cavernosus may be somewhat effective.

In younger men, several conditions may warrant penile revascularization surgery. Men younger than age 45 whose impotence is caused by severe pelvic trauma are the best candidates for this surgery. In patients with impotence of sudden onset, the possibility that trauma to the peritoneum or pelvis may have led to vascular injury should be considered. A congenital shunt should be ruled out in any patient who reports that he has never had a full erection.

Follow-up and Referral

Hormonal replacement therapies should be guided by a clinician experienced in the evaluation and monitoring of patients on hormonal replacement. For example, patients on testosterone replacement therapy should undergo monitoring prostate examinations and PSA screening tests, given the theoretical risks of BPH and prostate cancer associated with testosterone exposure. Blood levels of the hormone being supplemented (e.g., serum testosterone) and other regulatory hormones along the hypothalamic-pituitary-gonadal axis (e.g., luteinizing hormone, which stimulates testosterone secretion) should also be followed to prevent the risks of medication overexposure. However, interpretation of these levels requires expert knowledge of reproductive endocrinology and is influenced by both the timing of the hormonal treatments and the monitoring of blood draws.

Common psychogenic causes of ED include performance anxiety and relationship problems. Thus, referrals to sex therapy and/or marriage and couples counseling may be particularly helpful for some patients, especially in combination with other therapies. In addition, all of the invasive surgical interventions described above require appropriate referrals to a qualified urologist or pelvic surgeon.

Patient Education

The primary role of the provider in educating the patient with ED is to stress the importance of management of chronic conditions such as hypertension, diabetes mellitus, and stress. Guided imagery, regular exercise, and yoga may be recommended as a modality to reduce stress. Tight control of blood pressure and blood sugar should be encouraged as a way to limit further deterioration of erectile function. In addition, counseling for the psychogenic causes of ED is essential. Instructions regarding topical hormone replacement formulations should include warnings regarding the possibility of transfer to sexual partners during intimate contact, as well as the general

risk to women and children from unintended exposure to medications affecting the hormonal axis.

PROSTATITIS

Prostatitis is one of several inflammatory and/or painful conditions affecting the prostate gland. Prostatitis accounts for about 25% of all office visits by men. Fifty percent of men will experience prostatitis in their lifetime. The classification of the type of prostatitis is important for both diagnostic and treatment purposes. Patients may present with acute bacterial prostatitis, chronic bacterial prostatitis, nonbacterial prostatitis, or prostatodynia (see Chronic Pelvic Pain Syndrome later in this chapter). Chronic nonbacterial prostatitis is the most common type; it is eight times more frequent than bacterial prostatitis.

In an effort to standardize this classification schema, the National Institutes of Health suggested that nonbacterial prostatitis and prostatodynia be grouped together as chronic prostatitis/chronic pelvic pain syndrome, which may be inflammatory or noninflammatory in nature. In addition, a final category of asymptomatic inflammatory prostatitis is used to denote persons with a significant inflammatory infiltrate in prostatic secretions but without overt pain or difficulty with urination.

Epidemiology and Causes

Acute bacterial prostatitis is always associated with a urinary tract infection (UTI) and has a characteristically abrupt onset. Chronic bacterial prostatitis is a major cause of recurrent bacteriuria. Nonbacterial prostatitis has findings similar to those associated with chronic bacterial prostatitis, but no evidence of bacterial infection will be present in a urine culture. Prostatodynia presents with signs and symptoms of prostatitis but without evidence of inflammation. Prostatitis occurs predominantly in sexually active men aged 30 to 50 years. Chronic bacterial prostatitis is more common in patients older than 50 years old. Athletes who run long distances—including cross-country runners and athletes who have vigorous exercise regimens—may be predisposed to prostatitis, although the etiology is not well documented at present.

Acute and chronic bacterial prostatitis are both caused by an infection that originates from the ascending urethral flexion or from the reflux of urine into the prostatic ducts. Infection may also spread directly to the prostatic ducts from the rectum. Infection may spread via the lymphatic system or bloodstream, with prostatic calculi serving as a nidus for infection. The most common aerobic gram-negative bacteria involved in prostatitis include *Klebsiella, Pseudomonas, Enterobacter, Escherichia coli, Proteus mirabilis,* and *Neisseria gonorrhoeae.* The causative gram-positive bacteria are *Streptococcus faecalis* and *Staphylococcus aureus.* Some organisms suspected but as yet unproven are *Staphylococcus epidermidis, Micrococcus,* non–group D *Streptococcus,* and diphtheroids. Rarely, fungi and *Mycobacteria tuberculosis* have been implicated in chronic prostatitis. The cause of nonbacterial prostatitis is currently under scrutiny; however, *Ureaplasma, Trichomonas vaginalis,* and *Chlamydia trachomatis* may be involved. Risk factors for prostatitis are age (older than age 50 years), history of prostatic calculi, and history of a previously diagnosed UTI. Chronic prostatitis, in particular, is associated with a history of recurrent UTI, presumably due to repeated seeding of the urinary tract by the infected prostate.

Pathophysiology

The infectious processes resulting in acute or chronic bacterial prostatitis are a result of the organisms mentioned previously. Purulent prostatic discharge may or may not be evident in the absence of prostatic massage. Among patients who fall into the chronic prostatitis/chronic pelvic pain category, prostatic massage will effectively double the number of cases that are considered inflammatory, due to the presence of white blood cells (WBCs) in postmassage urine or seminal fluid.

The pathophysiology of nonbacterial prostatitis is less clear, but it may be related to a voiding dysfunction such as spasm of the bladder neck or urethra. The cause of prostatodynia is unclear, although it may be related to internal urethral sphincter problems or to abnormal tension of the pelvic floor musculature. Prostatodynia is also related to stress, anxiety, and depression.

Clinical Presentation

Subjective

The patient may present complaining of *tenesmus* (a spasmodic contraction of the anal sphincter), with pain and a persistent desire to empty the bowel or bladder accompanied by involuntary, ineffective straining efforts. Focus on History 13.2 presents common signs and symptoms of the different types of prostatitis. Obstructive symptoms, including weak urine stream, incomplete bladder emptying, and terminal dribbling, are common in both acute bacterial prostatitis and prostatodynia. Irritative symptoms are present in all of the classifications but are more common in chronic bacterial prostatitis and prostatodynia. In addition, the patient with prostatodynia typically does not have a history of recurrent UTIs.

Objective

The practitioner should assess the patient for the signs and symptoms listed in Focus on History 13.2. The rectal exam should be performed with care, because vigorous manipulation of the prostate can result in septicemia. In chronic prostatitis, the rectal exam may reveal a tender prostate, but it is usually not swollen or boggy.

Diagnostic Reasoning

Diagnostic Tests

A complete blood count will show leukocytosis and a shift to the left if the patient has acute bacterial prostatitis. A urinalysis is done to check for bacteriuria, which if found indicates the need for a fractional urine examination. In

Focus on History 13.2 Signs and Symptoms of Prostatitis

Type of Prostatitis	Common Signs and Symptoms
Acute bacterial prostatitis	General complaints: Fever, chills, low back pain; malaise, arthralgia, myalgia Urinary complaints: Frequency, urgency, dysuria, nocturia, bladder-outlet obstruction Physical exam: Warm, tense, boggy, very tender prostate
Chronic bacterial prostatitis	General complaints: Symptoms often absent, perineal pain, low back pain, lower abdominal pain, scrotal pain, penile pain, pain on ejaculation Urinary complaints: Dysuria, irritative voiding Physical exam: Normal, boggy, or focally indurated prostate
Nonbacterial prostatitis	Similar to chronic bacterial prostatitis Physical exam: Prostate tender on palpation
Prostatodynia	General complaints: Pelvic pain Urinary complaints: Irritative voiding, abnormal flow

this test, the first 10 mL of urine in a void (VB_1), 10 mL from midstream (VB_2), expressed prostatic secretions (EPS) obtained by prostate massage, and 10 mL of urine following massage (VB_3) are obtained, cultured, and microscopically examined. If VB_1 shows the highest number of WBCs and colonies on culture, urethritis is diagnosed. If VB_2 is highest, cystitis is probable. If EPS and/or VB_3 is highest, chronic bacterial prostatitis is confirmed. Some clinicians feel that vigorous prostatic massage can lead to bacteremia; therefore, the use of this test is left up to the individual clinician's discretion. Because this test is cumbersome to perform and studies have shown that prescribing patterns do not differ substantially between clinicians who do or do not perform this test, it is not necessarily done. A urine sample from a patient with nonbacterial prostatitis will show the presence of WBCs, but the urine culture will be negative. There are no abnormal laboratory findings associated with prostatodynia.

If a malignancy or abscess is suspected, computed tomography scanning or transrectal ultrasonography is indicated. A needle biopsy of the mass or aspiration of the abscess for culture may be done by the urologist.

Differential Diagnosis

The differential diagnosis for prostatitis includes cystitis, urethritis, pyelonephritis, epididymitis, prostatic abscess, malignancy, obstructive calculi, foreign bodies, and acute urinary retention. Abscess is more common in men who are HIV positive. The manifestations of acute prostatitis can mimic those of acute diverticulitis, but history and laboratory tests usually differentiate between the two conditions. In the case of nonbacterial chronic prostatitis or chronic pelvic pain syndrome, the diagnosis is one of exclusion; other sources of perineal pain (hernias, testicular masses, and hemorrhoids) should be ruled out first. Asymptomatic inflammatory prostatitis is not yet fully understood, and guidelines as to its natural history and need for treatment are not yet established.

Management

The main principle of management for prostatitis is to treat the patient on an outpatient basis if he does not have a fever. Hospitalization may be necessary if the patient is toxic, is immunocompromised, has a proven or suspected abscess, or has signs of urosepsis.

An extremely ill patient with bacterial prostatitis should be treated in the hospital with ciprofloxacin (Cipro) 200 to 400 mg IV every 12 hours until he has been afebrile for 24 to 48 hours, then oral ciprofloxacin 500 mg PO every 12 hours or levofloxacin (Levaquin) 500 mg PO daily is used to complete 6 total weeks of treatment.

Men with bacterial prostatitis may be treated on an outpatient basis for 4 to 6 weeks with antibiotics such as ofloxacin (Floxin) 400 mg PO every 12 hours, ciprofloxacin 500 mg PO every 12 hours, or norfloxacin 400 mg PO every 12 hours. Alternatives to the quinolones are trimethoprim and sulfamethoxazole (TMP-SMX [160 mg/800 mg]: Bactrim, Septra, Cotrim) one double-strength (DS) tablet every 12 hours, or doxycycline (AK-Ramycin, AK-Ratabs, Doryx, Doxy-Caps, Doxychel Hyclate, Doxy-Lemmon, Vibramycin, Vibra-Tabs) 100 mg every 12 hours.

It is extremely important that the patient with acute bacterial prostatitis be kept well hydrated. IV fluids must be given if the patient is hospitalized and is unable to consume liquids orally. Urethral catheterization is contraindicated in patients with acute bacterial prostatitis, and percutaneous suprapubic catheterization is required if urinary retention develops.

The best cure rates in chronic bacterial prostatitis are associated with treatment with TMP-SMX, although other antibiotics such as carbenicillin, erythromycin, cephalexin, and the quinolones are effective as well. The patient with chronic infection is usually treated for 6 to 12 weeks.

The etiology of nonbacterial prostatitis is uncertain, but the patient may benefit from erythromycin 250 mg four times daily, TMP-SMX DS one tablet daily, or in combination with a fluoroquinolone. Other patients with nonbacterial prostatitis have responded to treatment with nitrofurantoin (Furadantin, Furalan, Furanite, Macrodantin, Nitrofan, Nitrofurantoin), 100 mg daily.

The irritative voiding symptoms associated with nonbacterial prostatitis may be treated with NSAIDs, muscle relaxants, anticholinergics, warm sitz baths, normal

sexual activity, and regular mild exercise. Avoidance of spicy foods, caffeine, and alcohol may help some patients alleviate the irritative voiding symptoms. For patients with severe urinary retention, insertion of a suprapubic catheter may be necessary. Surgical resection for intractable chronic disease or to drain an abscess may also be performed.

Follow-up and Referral

Depending on the acute nature of the illness and the patient's response to treatment, referral to a urologist may be warranted. The patient with hematuria or significantly elevated prostate-specific antigen should prompt immediate urological referral. Patient monitoring for acute bacterial prostatitis should include a follow-up urinalysis and culture 30 days after beginning treatment. Chronic bacterial prostatitis requires urinalysis and culture every 30 days. Monitoring should continue until the patient no longer shows signs of infection. Suppression therapy with prophylactic antibiotics has also been tried if recurrent symptomatic infections occur.

Patient Education

The patient should be told that the prognosis for recovery from prostatitis is good, with a 55% to 97% cure rate. The cure rate depends on the population and the medications used. Prostatitis can, however, be difficult to cure and can last for a prolonged time. The National Kidney and Urologic Diseases Information Clearinghouse has printed information available for patient education.

CHRONIC PELVIC PAIN SYNDROME

As discussed in the section on prostatitis, the term *prostatodynia* is often used as a designation for unexplained chronic pelvic pain in men, which may be mistaken for inflammatory prostatitis. However, the nomenclature and conceptualization of prostatodynia has been expanded in modern clinical practice into a broader disorder called chronic pelvic pain syndrome (CPPS). This is considered predominantly a noninflammatory disorder that has many causes, including voiding dysfunction and pelvic floor dysfunction, but the prostate is normal.

Epidemiology and Causes

The term *prostatodynia* is not considered accurate nomenclature for CPPS, because it suggests that the condition stems from the prostate itself, despite the term being used historically to describe nonspecific groin pain of unclear etiology. No unifying cause of CPPS is known. CPPS affects mostly young and middle-aged men and is characterized by pain in the groin that may extend to the genitalia and perineum.

Pathophysiology

CPPS is considered by some clinicians to be equivalent to chronic nonbacterial prostatitis, although several lines of evidence point to nonprostatic causes. It may be considered an umbrella disorder of male patients with an array of chronic pelvic symptoms, consisting predominantly of groin pain that relates largely to anatomical structures in proximity to the prostate gland. Importantly, the symptoms of CPPS have no adequate treatment, cure, or objective explanation, although the disorder appears to relate to a combination of dysfunctional immune, endocrine, neurological, and psychological factors.

Clinical Presentation

Subjective

CPPS is often mistaken for chronic prostatitis because many of the symptoms and signs of these disorders are the same. The patient with prostatodynia may present with low back and perineal pain, urinary hesitancy, and interruption of urine flow. Unlike in chronic prostatitis, there is no history of urinary tract infections with CPPS.

Objective

On physical exam (including digital rectal exam), the prostate is normal, but there may be increased anal sphincter tone and periprostatic tenderness. The primary value of physical assessment is in ruling out identifiable diagnoses, such as prostatitis, urethritis, and prostate cancer.

Diagnostic Reasoning

Diagnostic Tests

There are no tests that specifically diagnose CPPS. Elevated prostate-specific antigen is not typically associated with classic prostatodynia and is more consistent with prostatitis. Urinalysis is normal without bacteriuria or pyuria, as are expressed prostatic secretions in most patients. Of note, some patients with CPPS have evidence of white blood cells (WBCs) in prostatic secretions, suggesting an inflammatory component, although this finding is not classically associated with prostatodynia. Moreover, significantly elevated WBCs in prostatic secretions should trigger the suspicion of acute or chronic infectious prostatitis.

There may be detrusor contraction without urethral relaxation, high urethral pressures, and spasms of the urinary sphincter on urodynamic testing. However, these tests are not performed unless the patient has no response after a trial of alpha blockers or anticholinergic medication, as described under Management.

Differential Diagnosis

The differential diagnoses for prostatodynia include acute and chronic prostatitis and nonbacterial prostatitis. Because the urinalysis is normal, acute infection can be ruled out. The normal expressed prostatic secretions distinguish prostatodynia from nonbacterial prostatitis. Of note, however, some clinicians may diagnose CPPS in patients, despite evidence of an inflammatory component to their condition, as reflected by WBCs in expressed prostatic secretions, suggesting heterogeneity of the diagnosis.

Management

The patient with CPPS is usually treated with alpha blockers to reduce bladder neck and urethral spasms. The most commonly used drugs are terazosin (Hytrin) 1 to 10 mg PO daily, doxazosin (Cardura) 1 to 8 mg PO daily, and tamsulosin (Flomax) 0.4 to 0.8 mg PO daily. Some patients benefit from myofascial release therapy and warm sitz baths, whereas others may experience relief using the muscle relaxant diazepam and biofeedback to relieve tension myalgia associated with pelvic floor muscle dysfunction. Psychotherapy is appropriate if sexual dysfunction accompanies CPPS. Antibiotics have no established role, given that CPPS is not infectious in origin, yet patients may be inappropriately prescribed antibiotics for prolonged periods of time, given the lack of a clear etiology.

Follow-up and Referral

Given that CPPS should only be diagnosed after thorough evaluation that rules out chronic prostatitis and other identifiable causes for persistent symptoms, referral to a urological specialist may be required for patients with intransigent symptoms.

Patient Education

Several patient education resources are available for patients with CPPS, including the Chronic Prostatitis/Chronic Pelvic Pain Syndrome Network, the Prostatitis Foundation, and the International Association for the Study of Pain interest group on Pain of Urogenital Origin.

EPIDIDYMITIS

Epididymitis is an inflammation of the epididymis, the coiled structure connecting the sperm-producing rete testis to the vas deferens, allowing for maturation and immunosurveillance of the sperm. This inflammation results in scrotal pain, swelling, and induration of the posterior-lying epididymis, with eventual scrotal wall edema and involvement of the adjacent testicle, possibly with reactive hydrocele formation. The inflammation of the testicle results in a unilateral painful testicle known as *epididymo-orchitis.*

Epidemiology and Causes

There is a predisposition to epididymitis when the patient has a history of unprotected intercourse, a new sexual partner, a history of urinary tract infection (UTI) with dysuria, or urethral discharge. Symptoms may also occur following heavy lifting or straining. Younger sexually active men or older men with UTI are the patients who most commonly present with epididymitis. It may also (but rarely) occur in prepubertal boys, which likely heralds a structural abnormality in the genitourinary tract.

The causes of epididymitis in males younger than 35 years are usually sexually transmitted diseases (STDs) such as *Chlamydia* or *Neisseria gonorrhoeae* infections. There is usually a difference in the type of discharge. *Chlamydia* infection produces a serous urethral discharge, whereas gonorrhea produces a purulent discharge.

Causes of epididymitis in men 35 years of age and older include coliform bacteria (such as *Escherichia coli,* which is most common) and sometimes *Pseudomonas aeruginosa* or *Staphylococcus aureus.* Epididymitis is often associated with a distal urinary tract obstruction in men older than 35 years or with coliform infections in men engaging in insertive anal intercourse. Tuberculous epididymitis will present with sterile pyuria and nodularity of the vas deferens, as well as pain. Another cause of epididymitis is sterile urinary reflux following transurethral prostatectomy. A granulomatous reaction following bacille Calmette-Guérin intravesical therapy for superficial bladder cancer may also cause epididymitis.

Rare causes of epididymitis include syphilis, brucellosis, blastomycosis, coccidioidomycosis, and cryptococcosis. When nonbacterial epididymitis and epididymo-orchitis occur, the cause is not clear, but may be secondary to retrograde extravasation of urine.

Pathophysiology

UTIs, particularly prostatitis, predispose a patient to the development of epididymitis. Other risk factors include transmission of pathogens via indwelling urethral catheters or urinary instrumentation, or as a consequence of transurethral prostate surgery. A urethral stricture of any type may also be a risk factor. Epididymitis caused by STDs is transmitted through the urethra and may be accompanied by symptomatic or asymptomatic urethritis.

Other causes include immunosuppression, trauma, or reflux of urine from the urethra through the vas deferens, causing chemical inflammation and edema within the epididymis that leads to ductal obstruction. Predisposing factors for subacute presentations of epididymitis in otherwise healthy postpubertal male patients include heavy physical activity, prolonged bicycle or motorcycle riding, and sexual activity. These patients may have negative urinalyses and often do not experience dysuria.

Clinical Presentation

Subjective

The major complaint of patients with epididymitis is scrotal pain that often radiates along the spermatic cord or to the flank. The pain may appear relatively acute over several hours. Many experience pain at the tip of the penis and complain of urethral discharge or other symptoms of UTI, such as frequency of urination, dysuria, cloudy urine, or hematuria. Initially, only the lowermost tail section of the posterior-lying epididymis will be painful, tender, and indurated. Elevation of the testes and the epididymis will relieve the discomfort. Fever and chills occur with a severe infection and an abscess formation.

Objective

Physical exam reveals scrotal swelling, and the testis may be indistinguishable from the epididymis. The scrotum

wall will be thick and indurated, and a reactive hydrocele may occur. In addition to nodularity of the vas deferens and tenderness of the epididymis, patients with the nonsexually transmitted variety of epididymitis will have pyuria. Rectal exam reveals a tender prostate.

Diagnostic Reasoning

Diagnostic Tests

Initially, a urinalysis will show pyuria and leukocytosis. A Gram stain of the urethral discharge may reveal gram-negative intracellular diplococci that are diagnostic of *N gonorrhoeae.* Culture of the penile discharge may be consistent with *Chlamydia* or gonorrhea infection. If no organisms are visible on the urethral smear, but white blood cells (WBCs) are evident, the diagnosis is usually nongonococcal urethritis and *Chlamydia* is the most likely pathogen. A complete blood count shows increased WBCs with a left shift. Interstitial congestion and fibrotic scarring may be present. An ultrasound of the scrotum can confirm the diagnosis of epididymitis.

Differential Diagnosis

The differential diagnoses for epididymitis include epididymal congestion following a vasectomy, testicular torsion, torsion of the appendix testis, mumps, orchitis, testicular tumor, and testicular trauma. An epididymal cyst, spermatocele, hydrocele, or varicocele should also be ruled out as part of the differential diagnosis. In epididymitis, the pain often improves when the scrotum is elevated above the level of the pubic symphysis (Prehn's sign).

Management

Initial treatment includes bedrest with scrotal elevation and ice packs, along with appropriate antibiotics; in severe cases, a spermatic cord block with local anesthetics may be necessary to relieve the pain. In men younger than age 35 with sexually transmitted epididymitis, treatment is a one-time dose of ceftriaxone 250 mg IM in addition to doxycycline (Vibramycin), 100 mg PO two times daily for 10 days. If the patient is allergic to cephalosporins or tetracyclines, a fluoroquinolone such as ofloxacin 300 mg PO two times daily or levofloxacin 500 mg PO daily can be given for 10 days. It is important to treat the sexual partner as well. Patients with nonsexually transmitted forms of epididymitis may be treated with ciprofloxacin 750 mg PO two times daily, ofloxacin 200 to 300 mg PO two times daily, or TMP-SMX (Bactrim, Septra) one DS tablet PO two times daily for 2 to 3 weeks. For patients with noninfectious epididymitis, treatment is with NSAIDs, rest, and scrotal support. Antibiotic therapy is for patients who are refractory to conservative treatment. Tylenol with codeine may be used for moderate to severe pain. For the septic or toxic hospitalized patient, ceftriaxone (Rocephin), 1 to 2 g given IV or IM every 24 hours, is the preferred treatment. An aminoglycoside (gentamicin) 1 mg/kg IV or IM every 8 hours (adjusted to the patient's renal function after a loading dose of 2 mg/kg) may also be administered.

Surgical procedures may be needed, depending on the severity of the case. An aspiration of the hydrocele may assist in examination of the scrotal contents and relieve discomfort. A vasostomy to drain the infected material may be done as well. Scrotal exploration should be done if there is uncertainty in differentiating epididymitis from testicular torsion. Drainage of abscesses, epididymectomy, or orchiectomy may be considered in severe cases that do not respond to antibiotics. The activity of the patient after these procedures is limited to bedrest for a minimum of 1 to 2 days.

Follow-up and Referral

Patient monitoring with office visits should continue until there are no signs of infection. Early treatment of prostatitis may prevent the development of epididymitis. Vigorous rectal examination of patients experiencing acute prostatitis should be avoided because this can lead to epididymitis. The prognosis is good if epididymitis is treated promptly. Pain improves in 1 to 3 days, but induration may last several weeks and take several months to resolve completely.

Complications of epididymitis include infertility or decreased fertility, recurrent epididymitis, abscess formation, or Fournier's gangrene (necrotizing synergistic infection), all possible when treatment is delayed or inadequate. Patients with sensory neuropathy as a result of diabetes may have little pain despite severe infections or abscesses; older adult patients may also present without significant pain.

Patient Education

The patient is instructed to limit activity and immobilize the scrotal contents, which will relieve the pain and aid in treating the infection. The patient will need to wear an athletic supporter and avoid sexual contact and physical activity as long as pain persists. Patient education includes stressing the need to complete the full course of all antibiotics, even after the patient becomes asymptomatic.

TESTICULAR TORSION

Testicular torsion is the twisting or rotation of the testes, resulting in acute ischemia. It is a urological emergency. The torsion may vary from 90 degrees to 360 degrees about the spermatic cord. An even more common phenomenon is torsion of the testicular appendix or appendiceal torsion, in which a small vestigial remnant of the Müllerian duct located on the anterosuperior portion of the testis twists about its base.

The testis is approximately 4.5 cm × 3 cm × 2.7 cm. Within the scrotum, each testis is surrounded by the tunica albuginea, a tough layer of connective tissue, as well as the tunica vaginalis, which is a potential space formed by a membranous sac covering the anterior two-thirds

of the testicle. A cryptorchid testis that fails to descend into the scrotal sac is most prone to undergoing torsion.

Epidemiology and Causes

Testicular torsion can occur at any age, from the newborn to age 80 years; however, two-thirds of the cases occur between 10 and 20 years, with the peak at age 14 years. Testicular torsion is possible but rare in older men. Torsion of the appendix testis is more common in children aged 7 to 14 years.

The contributing factors of testicular torsion are usually idiopathic and spontaneous. There is a history of trauma in 20% of the cases, with one-third of the patients having had prior episodic testicular pain. One initiating factor of torsion appears to be the contraction of the cremaster muscle, which may occur during sleep in approximately 50% of patients. The contraction of the cremaster muscle may also be stimulated by trauma, exercise (most frequently in runners), extreme cold (torsion is more common in winter months), and sexual stimulation. Paraplegics are also at high risk for developing testicular torsion, probably as a result of constant pressure while sitting. Other factors contributing to testicular torsion are possible alterations in testosterone levels and cremasteric contractions during the nocturnal sex response cycle or a congenital abnormality of the tunica vaginalis or the spermatic cord.

Pathophysiology

If the base of the testis is inadequately fixed to the tunica vaginalis via the gubernaculum, the testis may twist around the spermatic cord under several of the conditions listed above. Arterial inflow becomes compromised and venous outflow is obstructed, resulting in ischemia of the testis. This is exquisitely painful and may lead to necrosis if it is not treated on an emergency basis. Irreversible cellular damage may result in as little as 6 to 12 hours. Even if the testis is salvaged, fertility may be permanently compromised owing to a disruption of the blood–testis immunological barrier. This exposes germ cell antigens to the systemic circulation, resulting in sperm-specific antibodies that lead to permanent destruction of spermatozoa.

Clinical Presentation

Subjective

The most common symptom of testicular torsion is acute onset of pain accompanied by swelling. Torsion of the appendices of the testis also presents with pain, but it may be more gradual in onset. The patient may have pain for several days before seeking medical attention.

Objective

The most common clinical sign of testicular torsion is the absence of the cremasteric reflex. The testicle may also be high in the scrotum, with a transverse, rather than longitudinal, lie known as a "bell-clapper" deformity. Elevation of the testis does not relieve testicular pain, as is sometimes observed in epididymitis (Prehn's sign). However, this physical finding is insufficiently specific to distinguish between these two disorders. Occasionally with torsion of the appendices of the testis there may be a small lump that is palpable on the superior pole of the testis. If the skin is pulled tautly over it, the lump may appear blue ("blue dot sign"). This "blue dot" results from infarction and necrosis of the appendix testis and is present in about one-fifth of cases.

Diagnostic Reasoning

Diagnostic Tests

Testicular torsion is diagnosed by the history and presenting manifestations. The only initial assessment required is a physical exam. Color Doppler ultrasonography or radionuclide scanning can be used to diagnose both testicular torsion and appendiceal torsion. Doppler ultrasound can detect an absent or reduced pulse with torsion and an increased flow with an inflammatory process (Doppler ultrasound is reliable only in the first 12 hours following torsion). A radionuclide testicular scintigraphy with technetium 99-m (99m-Tc) pertechnetate will show absent or decreased vascularity in patients with torsion; increased vascularity will be evident in patients with inflammatory processes, including torsion of appendix testes.

Differential Diagnosis

Differential diagnoses for testicular torsion include epididymo-orchitis, an incarcerated or strangulated inguinal hernia, an acute hydrocele, a traumatic hematoma, an idiopathic scrotal edema, a torsion appendix testis, an acute varicocele, a testicular tumor, or Henoch-Schönlein purpura. Scrotal abscesses and leukemic infiltrates are also important considerations in the differential diagnosis and must be ruled out.

Some pathological findings associated with testicular torsion include venous thrombosis, tissue edema, necrosis, and arterial thrombosis.

Management

Compression of the testicular vessels leads to ischemic necrosis of the testes within 6 hours. Failure to recognize the torsion and intervene immediately results in the loss of the testicle in 80% of the cases, with subsequent atrophy of the testis in 10% or more. Fertile resolution occurs in only 10% of patients.

On diagnosis, immediate referral of the patient to the emergency department is indicated. Testicular torsion is a urological emergency. In the emergency department, manual reduction may be successful. Manual reduction of the testis is classically done with gentle external rotation of the testis toward the thigh, because most cases of torsion occur with medial rotation away from the thigh. However, retrospective studies have demonstrated lateral testicular torsion in up to one-third of cases. Relief of pain, resolution of the "bell-clapper" deformity, and a restoration of arterial blood flow are used as the primary

indications of effective reduction of testicular torsion. Reduction is followed by surgical exploration. Any testis that is not clearly viable (and obvious) is removed. Surgical exploration via scrotal approach—with detorsion, evaluation of testicular viability, orchidopexy of the viable testicle, and orchidodectomy of the nonviable testicle—is the preferred surgical intervention.

For a patient with torsion of the appendix, testis surgery may also be performed, but recovery is quicker, just several days. Conservative medical treatment may be initiated with rest, ice, and NSAIDs, but recovery is much slower and pain may persist from weeks to months. The dead appendiceal tissue is usually reabsorbed, though, and fertility is preserved.

Follow-up and Referral

Testicular salvage is directly related to the duration of torsion; the salvage rate is 85% to 90% if torsion has persisted for less than 6 hours. The salvage rate becomes less than 10% if the duration of the torsion is greater than 24 hours. Depressed spermatogenesis occurs in 80% to 94% of individuals and may be related to the duration of ischemic injury.

Patient Education

As many as two-thirds of testes salvaged may atrophy in the first 2 to 3 years post-torsion. The possibility of testicular atrophy in a salvaged testis, with depressed sperm counts, necessitates patient education and understanding. Patients should be taught to seek immediate care when experiencing testicular pain, to prevent permanent sequelae.

HYDROCELE

A *hydrocele* is a collection of peritoneal fluid within the scrotum around the testes, between the parietal and visceral (adjacent to the testis) layers of the tunica vaginalis—the two-layered sac that surrounds the testis and spermatic cord. A hydrocele forms when secretion of fluid into this potential space outweighs its reabsorption. These collections may range from only a few milliliters of fluid to enormous volumes measured in liters.

Epidemiology and Causes

The incidence rate of hydrocele is about 1% in adult men. Most hydroceles occur in men older than age 40 years. Causes of an acute hydrocele include nonspecific acute epididymitis, tuberculous epididymitis, trauma to the testes, tumor of the testes, or sequelae as complications of radiation therapy. Exstrophy of the bladder may increase the risk for hydrocele formation. Patients with Ehlers-Danlos syndrome have an increased risk for hydrocele, as do patients with a ventricular peritoneal shunt for dialysis or peritoneal dialysis.

Pathophysiology

A basic knowledge of scrotal anatomy is required to understand the pathogenesis of a hydrocele. The processus vaginalis originates as a diverticulum of the peritoneal sac that lines the abdomen, just inferior to the testis. During development, as the testis descends into the scrotum, it brings this diverticulum down with it, eventually becoming engulfed by it. The sac surrounding the testis (now called the tunica vaginalis) remains connected to the peritoneal sac via the processus vaginalis. Typically, throughout infancy and childhood, the connecting portion of the sac between the tunica vaginalis and the processus vaginalis gradually closes, breaking communication with the peritoneal sac.

Hydroceles in infants typically result from a patent processus vaginalis that fails to close during in utero development, allowing for the free flow of fluid between the peritoneal sac and the tunica vaginalis. These hydroceles have been directly correlated with the risk of indirect inguinal herniation in which gut contents bulge through the patent processus vaginalis. A noncommunicating hydrocele results from complete closure of the processus vaginalis, trapping peritoneal fluid within the tunica vaginalis. This type of hydrocele may be self-limited in adults. A hydrocele of the spermatic cord forms when the distal processus vaginalis closes but the midportion surrounding the cord remains patent and filled with fluid. The proximal portion may be opened or closed.

Rapidly forming hydroceles may result from reactive inflammatory processes within the scrotum such as testicular or appendiceal torsion, epididymitis, and even testicular cancer. A chronic hydrocele may result from gradual fluid accumulation within the tunica vaginalis in young boys or men, caused by an imbalance in fluid secretion, conduction, and reabsorption.

Clinical Presentation

Subjective

Patients with hydrocele typically present with swelling in the scrotum or inguinal canal. If the size of the scrotum fluctuates, a communicating hydrocele could exist. Hydroceles are usually painless, although patients report a sense of heaviness in the scrotum. If pain is present, it may radiate to the lower back.

Objective

The scrotum is transilluminated with a penlight in a darkened room during the physical exam. The trapped fluid appears light pink, yellow, or red. The hydrocele can be illuminated to show the full size and shape, which assists in the diagnosis. The testes themselves do not transilluminate, nor do hematomas. Swelling may be noted in the groin or in the upper scrotum.

Diagnostic Reasoning

Diagnostic Tests

A detailed description of the events that precipitated finding the hydrocele should be obtained. Details of any trauma incurred will assist in the evaluation. If a hydrocele

cannot be confirmed, the patient should be referred for an inguino-scrotal ultrasound, which can distinguish the presence or absence of bowel within the inguinal ring. A testicular nuclear scan is used to distinguish testicular torsion. Abdominal x-ray studies may be useful in distinguishing an incarcerated hernia from a hydrocele but are rarely needed.

Differential Diagnosis

The differential diagnoses for hydrocele include indirect inguinal hernias (because of the location of the hydrocele), orchitis (inflammation or infection of the testes) or epididymitis (an inflammatory process that can produce symptoms that mimic those of a hydrocele), or varicocele. Pain is more likely to be present with epididymitis. Traumatic injury to the testes must be ruled out by history and physical exam. Torsion of the testicle or torsion of the appendix of the testes must also be ruled out. Exploratory surgery is indicated for definitive diagnosis of a patent processus vaginalis in a communicating hydrocele. A mass of any type requires further evaluation for testicular or scrotal cancer.

Management

For adults, no treatment of a hydrocele is required unless complications are present or the clinician suspects a significant underlying cause, such as a tumor. If the hydrocele is painful, large, unsightly, or uncomfortable, however, several treatments are available. For example, a variety of outpatient surgical procedures are used to treat hydrocele. The Jaboulay-Winkelmann surgical procedure is for thick hydrocele sacs that form when the hydrocele has wrapped itself posteriorly around the cord structures. The Lord procedure is used for a thin hydrocele sac; the radial suture is used to gather the hydrocele sac posterior to the testis and the epididymis. The hydrocele can be surgically drained and the tunica vaginalis resected. Sclerotherapy (injection of a sclerotic irritant into the tunica vaginalis to induce scarring and adhesions between the adjacent layer of the tunica) and endoscopic procedures can also be performed to alleviate hydroceles. Aspiration of hydroceles is usually not done because the fluid rapidly reaccumulates; however, it may be done for a postoperative hydrocele.

Follow-up and Referral

Patient monitoring for a hydrocele should be at 3-month intervals until the decision is made for or against surgery. Postoperatively, patient monitoring should be in 2- to 3-week intervals, followed by 2- to 3-month intervals until there is resolution.

Postoperative traumatic hydroceles are common and usually resolve spontaneously. Other possible complications may be injury to the vas deferens spermatic vessels, suture granuloma, hematoma secondary to the surgery, or a wound infection.

Patient Education

For patients with a hydrocele, education regarding an explanation of the disease process and management plan is appropriate, along with reassurance of the overall benign nature of the condition (depending on the underlying cause).

VARICOCELE

A *varicocele* is an abnormal degree of venous dilation of the pampiniform plexus above the testes, which usually results in pain and engorgement of the testis.

Epidemiology and Causes

There is no ethnic predisposition or age differentiation among patients with varicoceles. The overall rate of incidence is 8% to 20%. In men evaluated for infertility, however, the rate of varicocele increases to 25% to 40%. A weak wall in the spermatic vein or excessive pressure are the leading causes of varicoceles.

Pathophysiology

The pathophysiology of a varicocele results from vascular engorgement of the internal spermatic vein. A varicocele almost always appears on the left or bilaterally, because the left spermatic (gonadal) vein empties into the left renal vein, whereas the right spermatic vein empties into the inferior vena cava. One of the longest veins in the body, the left spermatic vein, empties into the renal vein at a perpendicular angle. Compared with the right renal vein, the left renal vein has a higher intravascular pressure owing to its anatomical positioning between the aorta inferiorly and the superior mesenteric artery. In turn, if the valves of the left renal vein become incompetent because of this increased pressure, retrograde blood flow causes back-pressure to be transmitted to the pampiniform venous plexus, which overlies the testis. In contrast, a unilateral right-sided varicocele may result from serious pathology, causing increased pressure within the inferior vena cava, such as a tumor or thrombus.

Clinical Presentation

Subjective

The patient may present with pain and engorgement of the testes. The recognition of a varicocele is usually secondary to a problem with fertility, however. A patient with a varicocele often describes the sensation as feeling like a "bag of worms."

Objective

On physical exam, with the patient in an upright position, tortuous veins located posterior to and above the testis can be assessed. The engorged veins may extend up into the external inguinal ring, depending on development. Venous dilation can be increased by having the patient perform the Valsalva maneuver in a recumbent position. The reverse is also true: In the recumbent position, the

venous distention will abate. Testicular atrophy with impaired circulation may be present.

Diagnostic Reasoning

Diagnostic Tests

A system of grading has been established to better define varicocele. A *grade 1* varicocele is one that is palpable only when the patient performs the Valsalva maneuver. A *grade 2* varicocele is palpable when the patient is standing. A *grade 3* varicocele may be assessed with light palpation and visual inspection.

Sperm counts and motility of the sperm are significantly decreased in patients with a varicocele approximately 65% to 75% of the time. There is evidence of a progressive decline in fertility in men with varicocele. Scrotal ultrasound, venography (shows testicular venous reflux from a varicocele), and thermography (shows increase in temperature at the varicocele) all help to confirm the diagnosis.

Differential Diagnosis

A differential diagnosis for varicocele must include a hydrocele, a spermatocele, testicular tumor, epididymal cyst, and a renal tumor. A diagnostic priority is questioning the patient. It is essential to note whether the onset of the varicocele has been rapid or has resulted from a gradual increase in the varices of the testicles. In an elderly patient, the development of a varicocele may be a late sign of a renal tumor.

Management

After a varicocele has been diagnosed, referral to a surgeon is indicated although most patients do not require surgery because most varicoceles are minor. Surgical treatment of a varicocele involves ligation of the internal spermatic vein, which usually results in decompression of the varicocele and improvement of the quality of semen, as well as decrease in the pain. The surgery can be laparoscopic, anteriorly via an inguinal or subinguinal approach; posteriorly, via a lumbar approach; or even microsurgical. Embolization with coils is a second-line approach, but appears to have a higher complication rate owing to migration of the coils. Testicular atrophy is a definite indication for treatment. Conservative treatment in older men with only minor pain or for whom fertility is no longer an issue or for men with normal fertility may consist of NSAIDs and scrotal support. Treatment has not consistently improved sperm count or fertility in controlled trials.

Follow-up and Referral

Complications of a varicocele (if not corrected) include infertility and testicular atrophy. A referral to a urologist is indicated and recommended for affirmation of the diagnosis and further explanation of treatment options. Any patient with a recent onset of varicocele, infertility, pain, or testicular atrophy should have a urology consultation.

Patient Education

Education for the patient should include an explanation of the disease process, signs, symptoms, and implications. The patient should be taught how to monitor growth and symptoms of the varicocele, especially if it is right sided. To relieve pain, the patient should be encouraged to wear a scrotal support; for some patients, wearing jockey shorts (briefs) rather than loose boxer shorts is sufficient to relieve discomfort.

PROSTATE CANCER

To properly understand the pathophysiology, diagnosis, and treatment of carcinoma of the prostate, a brief review of prostatic anatomy is warranted. The prostate is composed of acinar glands and their ducts, which are arranged in a radial fashion with the stroma containing blood vessels, lymph vessels, and nerves. Ninety-five percent of all prostate cancers are acinar adenocarcinomas. The prostate gland secretes 0.5 to 2 mL of fluid a day, and this constitutes 10% to 20% of the seminal fluid of the ejaculate. The prostatic fluid contains citric acid, prostaglandins, and fibrinogen. The epithelial cells of the prostate gland are the only source of the glycoprotein prostate-specific antigen (PSA).

The prostate lies between the base of the urinary bladder and the upper surface of the levator ani and deep transverse peritoneal muscles. The anterior surface is adjacent to the retropubic space; the posterior surface lies adjacent to the seminal vesicles and recto-vesicular (rectum–bladder) septum.

The prostate is palpable per rectum. The prostate gland is 2 to 3 cm across; at its midpoint, it is twice the breadth of the examining finger. A 20 g size is normal. A slightly enlarged gland is documented as +1 and is considered three finger-breadths across, with +2 being twice the normal breadth (or four finger-breadths across). Occasionally a +3 or +4 classification will present, which involves the anterior pelvic outlet with marked encroachment of the posterior lobe on the rectal wall, reducing the caliber of the rectal passage. A normal prostate posterior area can be palpated without moving the hand, but the clinician may need to move the hand side to side in order to palpate an enlarged prostate or nodular area.

The prostate gland is subdivided into five lobes, which include the left and right lateral lobes (which are extensive and make up what was formerly termed the anterior lobe), the left and right posterior lobes (which also include the apex of the gland), and the median lobe. Prostatic cancer is known to have a propensity for the gland's posterior and apical peripheral zone (thus palpable through the rectal wall), whereas benign prostatic hyperplasia (BPH) tends to affect the transition zone that surrounds the urethra.

Epidemiology and Causes

Prostate cancer is the most common cancer found in American men and ranks second in the number of

cancer deaths (lung cancer is number one). In fact, more than 40% of men older than 50 years of age have been found to have prostate cancer on autopsy, and the prevalence increases with age. Clinical incidence of prostatic carcinoma is highest in North America and Europe and lowest in the Far East, suggesting that there may be environmental or dietary factors that increase prostate growth. In American men, those at highest risk for prostate cancer are African Americans; men with a family history of prostate cancer; and men with a diet high in fat, particularly animal fat.

Recently a major susceptibility focus for prostate cancer was found on chromosome 1 and is still under investigation. A man with a first-degree relative (a father or a brother) with prostate cancer is twice as likely to develop the disease and to do so at an earlier age. Occupational and environmental risks for development of prostate cancer include exposure to cadmium nitrates and heavy metals. As an occupational group, farmers are at the highest risk for development of prostate cancer. Further investigation continues on the subject of occupations as a risk factor.

Smoking has also been identified as a risk factor for prostate cancer; the risk appears to be proportional to the amount of smoking the patient does and may be related to the cadmium content of cigarettes. A patient's endogenous hormonal influences, characterized by increased levels of testosterone, have been shown to contribute to increased risk.

Pathophysiology

Prostate cancer is believed to result from a sequential accumulation of genetic abnormalities affecting the androgen receptors on prostatic tissue. These defects have been characterized as either genetic predispositions to disease that are seen to run in families (e.g., deletions in chromosome 1q); somatic mutations that activate prostatic oncogenes such as c-*myc, MKP-1, bcl-2,* and telomerase (e.g., mutations in the 7p and 8q regions); and somatic mutations that inactivate tumor suppressor genes such as *PTEN/MMAC-1, Mxi1, GSTP1, TGF-1,* and *Rb* (e.g., mutations in the 8p, 10q, 12q, 13q, and 17p regions). Such mutations accumulate over time, thus accounting for the strong correlation between age and disease prevalence.

The degree of malignancy may be graded according to several different scales. One method (Jewett system) utilizes the following stages:

A1–A2 and B1–B2 neoplasms are confined within the capsule.
C1 has extension of the carcinoma beyond the capsule.
C2 has malignancy that involves the seminal vesicles.
D1 involves metastatic disease in the regional lymph nodes.
D2 involves metastatic disease in bone or other organs.

The left and right posterior lobes of the prostate are most predisposed to malignant transformation. Extensive carcinoma may involve the capsule and the periprostatic tissues. Carcinomas of the prostate usually extend to the base of the bladder and the region of the seminal vesicles to form a shelf or a plateau. Usually, the periprostatic spread is limited by Denonvilliers' fascia, but once this area has been invaded, circumferential extension about the rectum occurs.

The lethality of malignant prostate cancers is a direct function of the heterogeneity in their cellular composition, which consists of both androgen-sensitive and androgen-insensitive cells. Anti-testosterone therapies work by suppressing androgen, which itself represses pro-apoptotic genes in cancer cells that would otherwise lead to cellular death. However, the apoptosis (non-necrotic or programmed cell death) of androgen-insensitive cancer cells is not induced by anti-androgen therapies. Through progressive genetic mutations, the androgen receptors on cancerous prostatic tissue are increased in number, level of androgen-independent activity, and resistance to apoptotic death signals from tumor suppressor genes. This accounts for the progressive and inevitably increased androgen insensitivity of malignant prostatic tissue and, in turn, the persistent spread of disease.

Clinical Presentation

Subjective

Men with prostate cancer are usually asymptomatic early in the disease and may also be asymptomatic late in the disease. Latent symptoms include bone pain, weight loss, anemia, shortness of breath, lymphedema, and lymphadenopathy. Neurological symptoms (inability to perceive touch, pain, and temperature in the perineal or scrotal areas and a lack of sensation of bladder distention) occur with epidural metastasis and cord compression. Patient complaints also include bladder-outlet symptoms or acute urinary retention with very large or locally extensive tumors, but are most often due to BPH.

Objective

Rectal exam reveals a palpable hard prostate that may be localized or diffused; several hard areas may be present or the nodules may be limited to one hardened area. An induration of the prostate may also be noted. Hematuria and hemospermia are signs that appear late in the course of the disease; they are very rarely detected in early prostate cancer. Evaluation of the rectal sphincter, and the anal and bulbocavernosus reflex, directs attention to the possible lesion at the level of the conis.

Diagnostic Reasoning

Diagnostic Tests

PSA is prostate specific but not cancer specific (found only in the cytoplasm of benign and malignant prostate cells). The effectiveness of using PSA in screening programs for prostate cancer has been questioned because

of the lack of evidence that routine screening for PSA can improve the quality and quantity of life for the overall population. The American Cancer Society (ACS) recommends that men with no symptoms of prostate cancer, who are in relatively good health and can expect to live at least 10 more years, should start screening at age 50 years. ACS recommends that African American men and men who have a father, brother, or son diagnosed with prostate cancer before age 65 years begin conversations about initiating screening at age 45 years. Men at higher risk should be screened beginning at age 40 years. The American Urological Association (AUA) recommends the use of PSA-based screening programs in conjunction with digital rectal exam (DRE) to detect prostate cancer in men aged 55 to 69 years who are at average risk and asymptomatic. The AUA guidelines state that PSA screening is not recommended for men younger than 40 years, for men 40 to 54 years who are at average risk, for men 70 years and older, or for men with a life expectancy of less than 10 to 15 years. The predominant age range for onset of prostate cancer is 50 to 60 years, which influences the recommendations for screening. Although approximately 67% of men 80 years of age have prostate cancer, only about 3% are expected to die from it.

Research continues on PSA levels as a viable means of identifying true prostate cancer, and the goal is to increase the specificity of the test. The strongest evidence of benefit for PSA screening is in the age-group of 55 to 69 years. In younger higher-risk men, screening should be individualized based on the uncertainty of benefit and associated harms of screening (false positives, unnecessary biopsies, etc.). Recent guidelines recommend 2-year PSA intervals, and for men over 60 years with PSA levels below 1.0 ng/mL, even longer PSA screening intervals (e.g., up to 4 years). There is no PSA level below which prostate cancer can be definitively ruled out; rather, the risk of prostate cancer increases as PSA level increases. Traditionally, a PSA level greater than 4.0 ng/mL is considered positive, and a level of 4.1 ng/mL has been considered a threshold for performing prostate biopsy. Serial PSAs are thought to be more accurate than a single test. Age-specific PSA norms have also been suggested as a method to increase the accuracy of the PSA test for the diagnosis of prostate cancer. However, the use of age-specific norms as biopsy decision points is controversial, given that they may potentially delay detection of prostate cancer in some patients.

Considering the current guidelines for PSA screening and the possible risks of biopsy (e.g., bleeding, infection, nerve damage), individualized informed decision making with the patient's active involvement is the best practice with regard to PSA testing and subsequent interventional diagnostic procedures. The ACS, the AUA, and the American College of Physicians all recommend that health-care providers have an open discussion with patients about the pros and cons of prostate cancer screening, as discussed in this section, and decide on a mutually agreeable course of action based on the patient's individual risk of developing prostate cancer and the implications of such a diagnosis (morbidity and mortality of both prostate cancer and its treatment). If screening is agreed to, it should begin at age 55 to 69 years for most men and at age 40 years for African American men or those with a family history of prostate cancer, especially in a father or brother. Screening may stop by age 75 years or in those with severe health problems, because prostate cancer is unlikely to be the cause of death for the large majority of these patients.

If prostate cancer is suspected (PSA greater than 10 ng/mL or laboratory-specific threshold), the patient should be referred to a urologist for a transrectal ultrasound (TRUS) and a transrectal biopsy of the prostate. The identification of any malignancies using TRUS-guided biopsy is not only a conclusive finding; this diagnostic procedure also provides information that is helpful in staging the disease and planning subsequent treatment, which may include radiation therapy and chemotherapy. Prostate screening using a combination of DRE, TRUS, and PSA with age-related values provides the most positive, predictive value of diagnosing prostate cancer. The potential complications of the TRUS-guided biopsy are hematospermia, hematuria, fever, hematochezia, or rectal bleeding. Biopsy may be repeated if initial results are negative and cancer is highly suspected. Free PSA levels in the bloodstream have also been tested as a screening tool and criteria for patients to have a follow-up TRUS. Free PSA occurs in greater concentrations in men without prostate cancer. Alternatively, the ratio of complex PSA to a total PSA is greater in individuals with prostate cancer. Complex PSA is PSA bound to the protease inhibitor alpha-1-antichymotrypsin, which is the form that is most elevated in prostate cancer. The predicted value is 24%, based on patients who underwent biopsies after having had the free PSA test.

Another group of researchers has been using the prostate-specific antigen density (PSAD) to screen for prostate cancer. PSAD can help differentiate BPH from prostate cancer because it is calculated by dividing the PSA by the volume of the prostate that is estimated via TRUS. Alkaline phosphatase is typically elevated in patients with metastases, but this finding is not specific for cancer of the prostate. Further studies that are done in patients with prostate cancer include a bone scan, which may show the presence of metastases. Computed tomography of the pelvic lymph nodes, ultrasound of the prostate, lymphoscintigraphy, and magnetic resonance imaging are alternate techniques that show metastases. On the horizon are molecular diagnostic tests on the urine postprostatic massage that detect highly specific genetic markers of prostate cancer, such as DNA hypermethylation (i.e., inactivation) of the genetic promoter for the tumor suppressor gene glutathione *S*-transferase *(GSTP1).*

Differential Diagnosis

BPH is the number one differential diagnosis in someone with suspected prostate cancer because the urinary outlet symptoms of nocturia, frequency, hesitancy, and weak urinary stream can be seen with both conditions but are far more commonly due to BPH. New-onset erectile dysfunction (ED), hematuria, or hematospermia are less common presentations of prostate cancer. Other differential diagnoses for prostate cancer include a benign nodule, prostate stones, nodular whorls, and seminal vesicle enlargement.

Management

Unfortunately, neither chemotherapy nor immunotherapy can cure prostate cancer once it has spread beyond the gland. If the findings are positive on both DRE and PSA, the patient should be referred to a urologist for a definitive diagnosis (biopsy) and staging.

Staging

Prostate tumors are classified according to the Gleason system in which first a "grade" is applied to the architectural pattern of the cancer in the largest segment of the specimen and then a second "grade" is given to the next largest area. The pathologist adds the two scores together to produce the Gleason score, which is on a scale of 1 to 10. Accurate staging provides an indication of the best treatment options.

Gleason score 1 to 4: Indicates a well-differentiated cancer that is likely to be slow growing.
Gleason score 5 to 7: Indicates a moderately differentiated cancer.
Gleason score 8 to 10: Indicates poorly differentiated cancer cells that are likely to be aggressive and rapid growing.

Prostate cancer is further staged according to the extent of the tumor, based on additional diagnostic studies or findings at the time of surgery. The most commonly used staging system is the American Joint Committee on Cancer tumor-node-metastasis (TNM) system, which grades tumors numerically within more detailed subcategories: "T" describes *tumors* according to their degree of differentiation; "N" describes the extent of *node* involvement; and "M" describes the degree of *metastasis.* For example, T1 tumors are microscopic, nonpalpable, and not visible by TRUS. Tumors classified as T2 are palpable but not beyond the prostate itself, and T3 tumors go beyond the capsule or into the seminal vesicles. T4 tumors are fixed and extend far beyond the prostate. Prostate cancer extending beyond the prostate itself is often fatal, and treatment is typically only palliative; however, localized disease is often curable by surgery, radiation therapy, and/or chemotherapy.

Patients Older Than Age 70 Years

Patients older than age 70 years are usually offered conservative treatment as an alternative to surgery. Radiation external beam therapy or brachytherapy with implants and total androgen ablation are the general measures that are used to treat prostate cancer in older men.

Patients Younger Than Age 70 Years

If the patient is younger than 70 years of age, surgery is often recommended for a prostate cancer cure. Surgical interventions may be used for Jewett stages A and B and selected C stages. If the patient is in agreement, an orchiectomy may be warranted to ablate endogenous hormonal effects.

The standard treatment options for prostate cancer include radical prostatectomy, radiation therapy, and watchful waiting. Treatment decisions are based more often on the adverse effects, long-term risks, and financial and emotional costs of different therapies, depending on the individual patient. Younger healthy patients are often encouraged to undergo the most radical treatment, whereas older patients are often directed to watchful waiting (observation) or radiotherapy. A relatively new surgical approach uses the da Vinci robotic system. For this surgery, a few small incisions are made rather than the typical large abdominal incision. The da Vinci system uses a magnified, three-dimensional, high-definition vision apparatus and mechanical wristed instruments that allow the physician to operate with enhanced vision, precision, dexterity, and control. The benefits of this surgical approach are a more precise removal of the prostate that causes less nerve injury, thereby improving sexual function and decreasing the chance of urinary incontinence. In addition, there is less blood loss during surgery and fewer postoperative complications.

Other treatments for prostate cancer include hormonal therapy to inhibit cancer growth by testosterone deprivation or administration of endogenous estrogen to block the release of luteinizing hormone (LH) from the hypothalamus. Unfortunately, estrogen therapy is associated with hypercoagulopathy, cardiomegaly, and gynecomastia. Newer hormonal preparations include leuprolide (Lupron), goserelin acetate (Zoladex), triptorelin (Trelstar), and histrelin (Vantas), which block the release of follicle-stimulating hormone (FSH) and LH. Luteinizing hormone–releasing hormone (LHRH) antagonists such as degarelix (Firmagon) reduce testosterone levels more quickly and are used to treat advanced prostate cancer. These agents are typically administered monthly. Adverse effects include loss of libido and hot flashes. Oral antiandrogens are also available, including asflutamide (Casodex), flutamide (Eulexin), and nilutamine (Nilandron), which inhibit the binding of testosterone to cancer cells. Finasteride (Proscar) is used to block the enzyme 5-alpha-reductase, which converts testosterone into DHT. A newer antiandrogen treatment is enzalutamide (Xtandi), which blocks signaling from the androgen receptor to the prostate cancer cell; abiraterone (Zytiga) blocks the CYP17A1 enzyme in the testosterone synthetic pathway and, in turn, reduces androgen production.

Cryosurgical ablation of the prostate is used to destroy cancer cells in patients who have had negative bone scans for metastatic prostate cancer. Cryosurgery destroys the prostate cancer cells through freezing. Unfortunately, the major adverse effects of this ablation technique include possible destruction of nerves and/or circulation, which can cause incontinence and ED.

Some research indicates that lifestyle modification in conjunction with "watchful waiting" improves the attitudes of men with early-stage prostate cancer. (See Nursing Research–Based Practice Box 13.1.)

Follow-up and Referral

Patient follow-up is determined by the radiation oncologist and urologist. Without fail, the patient should have a clinical examination every 3 months for a year. Chest x-ray studies and bone scans should be done every 6 months for a year and yearly thereafter. Potential complications of treatment may include cardiac failure, phlebitis, and pathological fractures secondary to the hormonal changes (testosterone suppression), as well as those mentioned in the previous section. With early diagnosis and treatment, the expected prognosis is good, and lesions should be curable, especially in young, healthy males.

Once prostate cancer has been diagnosed and treatment regimens have been chosen and implemented, the patient should be followed by the specialist and also seen by the primary-care clinician regularly for health maintenance, reassurance, positive outlook, and laboratory test follow-up.

Patient Education

Support groups and other advocacy organizations for prostate cancer patients are available, along with books on the subject, including reports from prostate cancer survivors. Churches are also being used as a forum for patient education, particularly those with older congregations. Given the widespread impact of prostate cancer, it is important for the clinician to be knowledgeable regarding the latest diagnostic and treatment options, as well as to remain attuned to patients' desires and fears regarding this diagnosis.

TESTICULAR CANCER

Primary testicular neoplasms may arise from any testicular or adnexal cell component. Each testis is covered externally by two layers of fascia: the outer layer, the tunica vaginalis; and the deeper albuginea layer, which extends internally and divides the testis into 250 to 300 lobules. Each lobule contains seminiferous tubules (the site of spermatogenesis) and the interstitial cells that produce androgens including testosterone. The epididymis lies along the external surface of each testis and is the site of sperm maturation and storage. Tumors of the germ cells

Nursing Research–Based Practice 13.1

Osei, DK, et al. Effects of an online support group for prostate cancer survivors: A randomized trial. *Urol Nurs* 33(3):123–133, 2013.

Prostate cancer is the most frequently diagnosed cancer in men. The American Cancer Society estimates for new diagnoses of prostate cancer in 2012 were at least 241,740 new cases and 28,170 deaths. The 5-year survival rate is close to 100%, and the 15-year survival rate is 91%. Thus, the number of prostate cancer survivors is significant, and although treatment options are highly successful, quality of life may be affected significantly.

The purpose of this study was to evaluate the effects of an online support intervention for patients with prostate cancer. This method of support is convenient, inexpensive, and anonymous. The sample consisted of 40 men between the ages of 53 and 87 years, with a diagnosis of prostate cancer within the previous 5 years, who were divided into two groups: those who participated in the online support group (treatment group) for 6 weeks and the control group who were given prostate cancer resource kits. Most participants were Caucasian (95% treatment, 75% control) with an education level of some college, college graduate, or graduate school (90%). This was a longitudinal, randomized, experimental study that collected data on quality of life and symptom manifestations using an online survey platform. Data were collected at 3 time points; baseline, 6 weeks, and 8 weeks. Quality of life was measured using 4 different tools, and the treatment group also completed a scale to measure their satisfaction with the online support group.

Multivariate analysis of variance was used to analyze differences across time and within groups, with outcomes on quality of life scales considered collectively. The results indicated the prostate cancer patients in the treatment group reported a statistically significant improvement in urinary irritation, sexual health, and hormonal health. Conversely, in the control group, quality of life declined with regard to perceived physical health, urinary irritation, sexual health, hormonal health, life satisfaction, and spouse negative characteristics at the 6-week time point. However, quality of life measures returned to baseline levels at the 8-week time point.

The researchers concluded that those patients who participated in the online support group had a positive improvement in their perception of quality of life. However, generalization of these findings is limited by the study's extremely low return rate using the online survey data collection platform. The researchers sent out 1,000 letters inviting potential subjects to participate, but received back only 51 responses (5%), with only 40 of those meeting the inclusion criteria.

and the seminiferous tubules are the most common testicular carcinomas.

Epidemiology and Causes

Although testicular malignancies comprise only 1% to 2% of all neoplasms in males, the psychologically and physically debilitating effects of testicular cancer affecting young men aged 15 to 35 years deserve mention, because testicular cancer is the most common solid malignancy in the age-group. Fortunately, it is also one of the most curable of solid cancers.

In the United States, there are five to six new cases of testicular cancer per year per 100,000 males. It is less common in African Americans, at 0.9 cases per 100,000 males. In adults, germ-cell types comprise 90% to 95% of testicular cancers, and in boys they represent 60% to 75%. The peak age at onset is between age 20 and 40 years. Smaller peaks occur between birth and 10 years of age and in men older than age 60 years.

No clear cause-and-effect relationships are identified for testicular cancer. Risk factors for testicular cancer include HIV infection and Caucasian race (especially Scandinavian background), with a much lower incidence among African Americans. Men who have experienced undescended or partially descended testes (cryptorchidism) are at a much higher risk for testicular cancer. Prior cryptorchidism is the only undisputed risk factor for this type of cancer, with 10% of testicular tumors associated with this condition. Importantly, a fourth of these tumors occur in the contralateral, descended testis.

Other possible risk factors that have been identified for testicular cancer include higher social status, being unmarried, or living in a rural area. Weak associations demonstrate that hormonal imbalances associated with in utero exposure to estrogen may increase the risk for testicular cancer later in life. One study of mothers who used diethylstilbestrol (DES) during the first trimester found a 2.5- to 5-fold increase of testicular cancer in the sons of exposed mothers.

Pathophysiology

Primary testicular neoplasm may arise from any testicular adnexal cell component. These are divided into germinal (90%–95%) and nongerminal (sex cord–stromal) tumors. For treatment purposes, the germinal tumors are further divided equally based on histology into seminomas and nonseminomas (i.e., embryonal carcinomas, teratomas, choriocarcinomas, and yolk sac tumors), which are epithelial in nature. In contrast, far rarer are the sex cord–stromal tumors, which consist primarily of Leydig cell variants that produce estrogen due to increased aromatase activity and Sertoli cell tumors, which may also present with estrogenic overload.

Only a small number of molecular markers have been consistently associated with testicular cancers, for example, an isochromosome of chromosome 12p, activating mutations in c-*kit,* increased p53 and telomerase expression. Abnormal DNA ploidy is also common in germ cell tumors. Although certain genetic alterations differ in germ cell tumors found in prepubertal males, all germ cell tumors are believed to arise from pluripotential primordial germ cells. One exception to this is the relatively rare spermatocytic seminoma, the pathogenesis of which appears to be fundamentally different based on unique molecular markers.

Except for spermatocytic seminomas, all germ cell tumors may be preceded by a premalignant condition known as intratubular germ cell neoplasia of unclassified type (ITGCNU) or testicular carcinoma in situ. It is found adjacent to 90% of germ cell tumors, implying that genetic mutations lead to gonadal dysfunction and subsequent malignancy over a large area of tissue—a phenomenon known as a field defect. At least half the cases of untreated ITGCNU will progress to invasive malignant disease within 5 years, predictably spreading to the retroperitoneal draining lymph nodes. Men with a history of cryptorchidism are recommended to have empiric testicular biopsy between ages 18 and 20 years to evaluate for ITGCNU.

Clinical Presentation

Subjective

Typically, the patient with testicular cancer presents with a hard lump or nodule on his testis that he felt while performing a testicular self-exam. He may also note scrotal swelling, heaviness in the scrotum that may be interpreted as pain, a sensation of fullness, or a previously small testis that has enlarged to the size of a normal testis or the contralateral testis. Generally, testicular cancer presents as a painless enlargement of the testis.

Objective

During routine physical exams (e.g., a sports physical), a scrotal nodule or swelling is most commonly detected in men with testicular cancer. A firm, nontender mass within the confines of the tunica albuginea is usual, palpable, and distinct from the spermatic cord structures. Acute or chronic epididymitis or epididymo-orchitis may result in delay of diagnosis of testicular cancer in about 10% of the cases. Gynecomastia may be present in 5% of patients with testicular malignancies. Hydroceles (seen in 5%–10% of patients) may be secondary to testicular cancer.

As many as 10% of patients with testicular cancer will be asymptomatic, and another 10% will present with manifestations of metastasis. Symptoms of metastases include respiratory symptoms (cough) due to lung metastases, low back pain and nerve root or psoas muscle irritation due to retroperitoneal metastasis, or lower extremity swelling from vena cava obstruction.

Diagnostic Reasoning

Diagnostic Tests

Several biochemical markers can aid in the diagnosis of testicular carcinoma, but their main use is in following disease progression or remission after treatment (looking at trends). These tests include human chorionic

gonadotropin (hCG), alpha-fetoprotein (AFP), and lactate dehydrogenase (LDH). AFP levels are elevated by the pure embryonal carcinoma, teratocarcinoma, yolk sac tumor, or combinations of these three malignancies, but not by pure choriocarcinoma or seminoma. However, AFP may be elevated in benign liver disease; telangiectasis; tyrosinemia; and malignancies of the liver, pancreas, stomach, and lung. Heavy marijuana smoking can also elevate levels of AFP. hCG levels are elevated by all choriocarcinomas and occasionally in seminomas; however, they are also elevated in liver, lung, pancreatic, and stomach malignancies, as well as by kidney, breast, and bladder tumors. Forty percent to 60% of patients with an embryonal carcinoma and 5% to 10% of patients with seminomas have detectable levels of hCG (usually under 500 ng/mL). Testing for LDH has fallen into disfavor because of the ubiquitous nature of the test. An elevated LDH level may be the sole biochemical abnormality in 10% of patients who have persistent or recurrent seminomatous tumors, and other liver function tests are elevated in the presence of hepatic metastases. In general, elevated AFP, hCG, or LDH is a poor prognostic sign, and prognosis worsens with the level of elevation. Elevated placental alkaline phosphatase (PLAP) may be the marker of choice for seminomas in 70% to 90% of patients. Patients with recurrent or disseminated seminomas have elevated PLAP levels. PLAP may also be elevated by heavy tobacco smoking.

Scrotal ultrasound is also a useful diagnostic tool for testicular cancer. The mass can be seen clearly originating within the testis. Using an echo-texture (hypoechoic) pattern, the mass will appear distinct from the surrounding normal testicular tissue on ultrasound. Uniformly cystic or fluid-filled masses are not likely to be testicular cancer, which is a solid tumor. However, ultrasound is not accurate for staging and should not replace orchiectomy as the procedure of choice. Magnetic resonance imaging is not usually more informative than scrotal ultrasound and pelvic/abdominal computed tomography (CT) for staging and identifying enlarged retroperitoneal lymph nodes, implying the need for lymph node dissection. Positron emission tomography scanning is usually used only to identify residual masses after treatment.

Chest x-ray studies, with both posterior-anterior and lateral views, are important for identification of metastasis and to rule out spread of malignancy above the diaphragm. A CT scan is able to define pelvic retroperitoneal and mediastinal lymphadenopathy, as well as to detect metastases to the abdominal viscera.

Differential Diagnosis

Definitive diagnosis of testicular cancer may be made with a transinguinal scrotal exploration and biopsy and/or radical orchiectomy (excision of the testicle and spermatic cord). Transscrotal open or cutaneous biopsy and transscrotal orchiectomy are contraindicated because of the potential for anatomical trespassing into the various lymphatic drainage systems. Testicular cancer is typically a painless mass in the testis, but the differential diagnosis should include epididymitis, hernia, hydrocele, hematoma, spermatocele, syphilitic gumma, and varicocele.

Management

The main principle of management for testicular cancer is a radical orchiectomy, which is also the major diagnostic tool, because the whole testis is removed for biopsy. Testicular cancer is very treatable, with fewer than 400 deaths per year in the United States at the present time. Treatment does, however, leave the patient with a high possibility of being infertile. Sperm-banking (semen cryopreservation) should be done before radiographic diagnostic studies, if desired. Many of these men have gonadal dysgenesis with baseline sperm count and morphology problems, but banking in general works well and future children do not have higher rates of congenital defects fathered by this banked sperm.

Staging

Testicular carcinoma is divided into two main categories when considering treatment. The first category, nonseminomas, includes embryonal cell carcinomas (20%), teratomas (5%), choriocarcinomas (less than 1%), and mixed cell types (40%). The second category is seminomas (35%). Staging depends on the type of tumor. See Table 13.2 for staging criteria.

The TNM classification of the American Joint Cancer Committee is also used for testicular cancer. The primary tumor (T) is classed from T0 (no evidence of primary tumor) to T4 (invades scrotum). Lymph node assessment (N) is from N0 (no regional lymph node metastasis) to N3 (metastasis in lymph node greater than 5 cm). Distant metastasis (M) is classified from M0 (no distant metastasis) to M1b (distant metastasis to sites other than nonregional lymph nodes or lungs).

Seventy-five percent of nonseminomas can be cured with orchiectomy alone, usually with modified retroperitoneal lymph node dissection. This is done to preserve

Table 13.2 Staging and Classification for Testicular Carcinoma

Nonseminoma Germ Cell Tumor Staging	
Stage A	Lesion confined to testis
Stage B	Regional lymph node involvement in retroperitoneum
Stage C	Distant metastasis
MD Anderson System for Seminomas	
Stage I	Lesion confined to testis
Stage II	Spread to retroperitoneal lymph nodes
Stage III	Supradiaphragmatic nodal or visceral involvement

the sympathetic innervation so the patient will still have ejaculatory function. The serum markers are monitored postorchiectomy, and those that return to normal have an excellent prognosis. For patients with nonseminomas that have metastasized or who have significant lymph node involvement (greater than 3 cm), combination chemotherapy is used following orchiectomy. Commonly used chemotherapeutic agents include cisplatin (Platinol) and etoposide (VePesid) and bleomycin (Blenoxane), or paclitaxel (Taxol). If the serum tumor markers do not normalize after chemotherapy, salvage chemotherapy is needed. Salvage chemotherapy includes cyclophosphamide (Cytoxan)– or ifosfamide (Ifex)–based protocols with mesna (Mesnex) to protect against hemorrhagic cystitis.

The 5-year survival rate for those with stage A nonseminomas is 96% to 100% after treatment. Patients with stage B nonseminomas have almost a 90% 5-year survival rate after treatment. For patients with stage C nonseminomas, the 5-year survival rate is between 55% and 80%.

Seminomas are chemosensitive and have good chemotherapeutic response and are also extremely sensitive to radiation therapy. All patients with seminomas will have radical orchiectomy surgery; and then, depending on the stage, irradiation and chemotherapy will be used. For patients with stage I and stage IIa (retroperitoneal disease less than 10 cm), surgery and radiation are the treatments of choice and are associated with a 5-year survival of 98% and 92% to 94%, respectively. More advanced stage II (retroperitoneal disease greater than 10 cm) and stage III seminomas received primary chemotherapy either with etoposide and cisplatin or a combination of cisplatin, etoposide, and bleomycin. If enlarged lymph nodes (more than 3 cm in diameter) persist after chemotherapy, a retroperitoneal lymph-node resection is done. In 40% of cases, there is residual carcinoma in these lymph nodes. Ninety-five percent of patients with stage III seminoma have a complete response to orchiectomy and chemotherapy. A viable tumor is present in more than 40% of cases. Primary chemotherapy is a last resort.

As with all chemotherapeutic agents, the precautions are specific for each. Cisplatin causes ototoxicity, nephrotoxicity, and neurotoxicity. Etoposide may cause thrombocytopenia. Cyclophosphamide and ifosfamide may cause hemorrhagic cystitis. Patients must be well hydrated to minimize the risk of hemorrhagic cystitis. Patients receiving ifosfamide should also receive mesna to reduce the risk of hemorrhagic cystitis. Bleomycin causes pulmonary fibrosis. One alternative drug may be carboplatin (Paraplatin), which can cause ototoxicity. Ondansetron (Zofran), dronabinol (Marinol), and metoclopramide (Reglan) and other medications may be used to control nausea. Follow-up is extremely important for patients with testicular malignancies.

Follow-up and Referral

For the first 2 years, tumor markers and chest x-ray films are assessed every month, and a physical exam emphasizing the lymph nodes should be performed monthly. After the first 2 years, tumor markers and chest x-ray films are checked every 2 months; the physical exam should be done every 2 to 4 months for another year. CT scans are usually done every 3 to 4 months for the initial 3 years. After year 3 with no further symptoms, the tumor markers, chest x-ray studies, and physical exams should be done every 6 to 12 months. If a patient had a diagnosis of teratoma, he will need to have a follow-up for at least 5 years, however, and a CT scan every year for 3 years. Radiation therapy can cause extreme fatigue and interfere with sperm production; it can also cause diarrhea, vomiting, and skin reaction at the treatment site. Adverse effects of chemotherapy include hair loss, immunosuppression, loss of appetite, and nausea and vomiting. Complications from retroperitoneal lymph node dissection include loss of seminal emission and/or hypoalbuminemia. Radiation treatment may cause nephritis or enteritis. Nonseminomatous tumors are more likely (50%–70%) to metastasize than seminomas (25%). Men who have been cured of testicular cancer in one testicle have a 2% to 4% chance of developing cancer in the remaining testicle. If cancer develops in the other testicle, it is almost always a new cancer, however, and not a metastasis from the first episode.

Patient Education

The question of life after testicular cancer becomes extremely important to the patient. The patient must be able to cope with the way testicular cancer affects his self-image. A low sperm count may occur after the loss of a testis. Patients who are concerned about their appearance after losing a testis can be educated about the availability of a prosthesis that simulates the weight and feel of a testicle. Although surgery to remove lymph nodes does not compromise a man's ability to have an erection or reach orgasm, it can interfere with ejaculation. Some men naturally regain the ability to ejaculate; others require medication. A patient should also be educated about sterility and hormone supplements. The option of sperm banking should be discussed with patients when the diagnosis of testicular cancer is first confirmed. Open discussions and reassurance are extremely important in patients diagnosed with testicular cancer.

The importance of a monthly testicular self-exam (TSE) cannot be stressed enough. Males aged 15 to 40 should be instructed on TSE at each primary care visit, and the technique should be demonstrated. Advanced Practice Nursing Interventions 13.1 presents information on how to teach the patient to perform a TSE.

Advanced Practice Nursing Interventions 13.1 Teaching the Patient to Perform a Testicular Self-Exam

Teach the patient the symptoms of testicular cancer. No symptoms may occur in the early stages. When symptoms do occur, they may include the following:

- Lumps on the testicle
- Slight enlargement of one of the testes
- Heavy sensation in the testicles or groin
- Dull ache in the lower abdomen or groin

Advise the patient that if hard lumps or nodules are found, or if any of the above symptoms occur, he should contact his health-care provider immediately.

Teach the patient when to perform the exam. The exam is best performed during or after a shower or warm bath, as the fingers glide more easily over the relaxed skin, making it easier to concentrate on the texture underneath. The heat causes the skin to relax, making the exam easier. The exam takes only about 3 minutes and should be performed once a month.

Teach the patient how to perform the exam:

1. Start by examining one of the testicles. Slowly roll the testicle between the thumb and fingers, applying slight pressure. Try to find any hard, painless lumps.
2. Now examine the epididymis. This comma-shaped cord is behind each testicle. It may be tender to the touch. It is also the location of the most noncancerous problems.
3. Continue by examining the vas (the sperm-carrying tube that runs up from the epididymis). The vas normally feels like a firm, moveable smooth tube.
4. Now repeat the exam on the other side.

SEXUALLY TRANSMITTED DISEASES

Sexually transmitted diseases (STDs) are on the rise. In response to that rise, the Centers for Disease Control and Prevention (CDC) has published Guidelines for Sexually Transmitted Diseases, which include information on prevention, diagnosis, and treatment for all known STDs. These guidelines are available online at www.cdc.gov.

STDs are a costly addition to the health-care burden in the United States, not only for the treatment of primary symptoms but also because of the increased risk of further complications from STDs. Open, frank discussions with patients about sexual practices is warranted from the early teenage years through old age. The primary-care clinician who is proactive and informative is the greatest resource that a patient can have. Pamphlets, posters, and patient education materials including videos and informational handouts are extremely helpful as a way to open a discussion on the topic.

Epidemiology and Causes

It is estimated that approximately one in five Americans is infected with a viral STD other than HIV. Perhaps even more alarming is that the United States, with the most educated population and highest standard of living, has the highest STD rates in the world. Increased risks for STDs are associated with gender, marital status, race and ethnic background, level of education, number of sexual partners, and lack of availability of health care. The long-term effects of STDs can be devastating and, at times, lethal. Improved advances in treatment, screening tests, and diagnostic procedures aid in discussion of the patient's symptoms and treatment therapies.

Pathophysiology

STDs consist of a heterogeneous collection of causative infectious agents (see Table 13.3). However, the unifying principle of these disorders is their propensity for spread by intimate person-to-person sexual contact, particularly after exposure of the mucous membranes to infected bodily fluids. This typically occurs within the genitalia; however, the oral and anal mucosa are also highly susceptible entry points, as exemplified by the incidence of gonococcal pharyngitis after receptive oral intercourse.

Given the length of the male urethra and the relatively smaller area of exposed genital mucosa via the urethral meatus, men had traditionally been thought of as being less susceptible to STD infection. However, microabrasions in the outer skin of the penile shaft sustained during sexual intercourse have been well documented as another important entry site for sexually transmitted organisms to reach the subcutaneous tissue. Moreover, the presence of one STD increases the chances of becoming infected with another—especially HIV. This is likely due to compromise

(Text continued on page 677)

Table 13.3 Sexually Transmitted Infections

Infectious Agent	Clinical Presentation	Diagnostic Reasoning	Treatment as Recommended by the CDC
Bacterial Infections			
Chancroid *(Haemophilus ducreyi)*	Single painful ulcer (irregular, erythematous, and undermined edges) with a unilateral painful abscess. Painful lymphadenopathy.	Probable diagnosis is made if: patient has one or more painful genital ulcers; no evidence of syphilis on serological test performed at least 7 days after onset of ulcers; the clinical presentation is typical for chancroid; and test for HSV is negative.	azithromycin (Zithromax) 1 g PO × 1 OR ceftriaxone (Rocephin) 250 mg IM × 1 OR ciprofloxacin (Cipro) 500 mg PO 2 times daily for 3 days OR erythromycin (E-mycin) 500 mg PO 4 times daily for 7 days
Chlamydia *(Chlamydia trachomatis)*	Most commonly, no reported symptoms. Patient may note an increase in mucopurulent discharge and bleeding with intercourse.	Yellow, mucopurulent discharge. Wet mount: >10 WBCs per high-power field (hpf). DNA probe—concurrent testing for *Neisseria gonorrhoeae* can be done with the same probe. Direct chlamydia enzyme immunoassay.	azithromycin (Zithromax) 1 g PO × 1 OR doxycycline (Vibramycin) 100 mg PO 2 times daily for 7 days
Gonorrhea *(Neisseria gonorrhoeae)*	Usually asymptomatic; partner may have an infection. Purulent yellow/green discharge. Gonococcal pharyngitis manifests as any bacterial pharyngitis, but 60% are asymptomatic.	Gonococcal culture, DNA probe. Urine DNA (initial 15 mL of a urinary void). Urine will typically have WBCs or epithelial cells infected with *N gonorrhoeae*.	ceftriaxone (Rocephine) 125 mg IM in a single dose OR cefixime (Suprax) 400 mg PO × 1 PLUS azithromycin (Zithromax) 1 g orally in a single dose OR doxycycline (Vibramycin) 100 mg PO 2 times daily × 7 days
Granuloma inguinale *(Klebsiella granulomatis)*	Chronic, progressive papule that ulcerates to a beefy red, painless granular area with clean, sharp rolled edges; inguinal swelling; late painful abscesses (buboes).	History of travel and sexual contact in endemically infected area. Cannot be cultured; stained tissue sample may show Donovan bodies (bacteria-filled vacuoles).	doxycycline (Vibramycin) 100 mg PO 2 times daily for at least 3 weeks and until all lesions have completely healed OR azithromycin (Zithromax) 1 g PO every week for at least 3 weeks and until all lesions have completely healed OR ciprofloxacin (Cipro) 750 mg PO 2 times daily for at least 3 weeks and until all lesions have completely healed OR

Table 13.3 Sexually Transmitted Infections—cont'd

Infectious Agent	Clinical Presentation	Diagnostic Reasoning	Treatment as Recommended by the CDC
			erythromycin (E-mycin) 500 mg PO 4 times daily for at least 3 weeks and until lesions have completely healed.
Lymphogranuloma venereum [LGV] *(Chlamydia trachomatis)*	Lymphadenopathy, anorectal swelling, and fistula formation.	History of travel and sexual contact in endemically infected area. Serological LGV complement fixation test: suspect disease if titer is above 1:16; test is diagnostic if titer is above 1:64.	doxycycline (Vibramycin) 100 mg PO 2 times daily for 21 days
Nongonococcal urethritis [NGU] *(Chlamydia trachomatis)*	Dysuria and urethral discharge (40% of patients); sparse, mucoid penile discharge, usually only after "milking" penis.	Gram stain smear of urethral exudate; culture for sugar fermentation reaction for NGU. Chlamydial DNA probe.	azithromycin (Zithromax) 1 g PO × 1 OR doxycycline (Vibramycin) 100 mg PO 2 times daily for 7 days
Syphilis *(Treponema pallidum)*	**Primary:** Painless ulcer at initial site of contact (chancre), adenopathy **Secondary:** Maculopapular rash on palms and soles, condyloma lata/moist, flat wart-like lesions, adenopathy **Tertiary/late:** Cardiac, neurological, ophthalmic, auditory, and gummatous lesions	Dark-field microscopy: Positive for spirochetes. Direct microhemagglutination-treponema pallidum (MHA-TP): Antibody test. Fluorescent treponemal antibody absorption (FTA-ABS): Antibody test reported as positive. Venereal Disease Research Laboratory (VDRL) rapid plasma reagin (RPR): Reported as reactive with a titer; indicates degree of infection.	benzathine penicillin G 2.4 million units IM × 1 **Early latent:** benzathine penicillin G 2.4 million units IM in a single dose **Late latent or latent syphilis of unknown duration:** benzathine penicillin G 7.2 million units total, administered as three doses of 2.4 million units IM at 1-week intervals **Neurosyphilis (CSF) (infection confirmed):** Aqueous crystalline penicillin G 18–24 million units per day, administered as 3–4 million units IV every 4 hours or continuous infusion for 10–14 days

Table 13.3 Sexually Transmitted Infections—cont'd

Infectious Agent	Clinical Presentation	Diagnostic Reasoning	Treatment as Recommended by the CDC
Viral Infections			
Herpes simplex virus (HSV) infection	**First outbreak:** Flu-like symptoms with adenopathy, tingling of the site before outbreak, and very painful vesicular lesions. Ulcers form, with circumscribed erythematous edges and white exudate centrally; lesions may last up to 12 days. **Recurrent outbreaks:** Symptoms may be similar but are usually less severe and of shorter duration (4–5 days).	Viral culture of vesicle fluid most accurate if done within 48 hours of outbreak. Tzanck smear from the base of an early vesicle. DNA probe from lesion scraping.	**First outbreak:** acyclovir (Zovirax) 400 mg PO 3 times daily for 7–10 days OR acyclovir (Zovirax) 200 mg PO 5 times a day for 7–10 days OR famciclovir (Famvir) 250 mg PO 3 times daily for 7–10 days OR valacyclovir (Valtrex) 1 g PO 2 times daily for 7–10 days **Recurrent outbreaks:** acyclovir (Zovirax) 400 mg 3 times daily for 5 days OR acyclovir (Zovirax) 800 mg PO 2 times daily for 5 days OR acyclovir (Zovirax) 800 mg PO 3 times daily for 2 days OR famciclovir (Famvir) 125 mg PO 2 times daily for 5 days OR famciclovir (Famvir) 1,000 mg PO 2 times daily for 1 day OR famciclovir (Famvir) 500 mg PO once, followed by 250 mg 2 times daily for 2 days OR valacyclovir (Valtrex) 500 mg PO 2 times daily for 3 days OR valacyclovir (Valtrex) 1 g PO daily for 5 days **Suppressive:** acyclovir (Zovirax) 400 mg PO 2 times daily famciclovir (Famvir) 250 mg PO 2 times daily valacyclovir (Valtrex) 500 mg PO daily valacyclovir (Valtrex) 1 g PO daily

Table 13.3 Sexually Transmitted Infections—cont'd

Infectious Agent	Clinical Presentation	Diagnostic Reasoning	Treatment as Recommended by the CDC
Human immunodeficiency virus (HIV) infection (For more about HIV, see Chapter 17.)	Fever, malaise, adenopathy. Rash may occur in first few weeks after infection (acute retroviral syndrome). Bloody diarrhea. Opportunistic infections. Increased HPV infections.	Positive enzyme immunoassay (EIA). Positive Western blot (WB).	Treat infections as recommended by CDC. Refer to specialist. Long-term counseling and management. Highly active antiretroviral therapy (HAART) is key for the treatment of HIV. Initiation of therapy is a function of T-cell count, viral load, and concurrent symptoms. Treatment is heavily influenced by the ability to comply with various treatment regimens.
Human papillomavirus (HPV) infection	History of multiple partners or sexual abuse. Positive history of HPV. Itching, foul discharge. May be asymptomatic. Fleshy, soft, pale-colored keratinized growths.	Acetic acid test: lesions turn white with application of vinegar.	**Patient-applied treatments:** podofilox (Condylox) 0.5% applied thinly 2 times daily for 3 days, then rest for 4 days; may repeat up to 4 cycles OR imiquimod (Aldara cream) 5% applied once a day at bedtime, 3 times a week for up to 16 weeks. Wash treatment area with soap and water 6–10 hours after application. **Clinician-applied treatments:** Cryotherapy and liquid nitrogen treatments—repeat every 1–2 weeks. OR podophyllin resin (Podofin) 10%–25% in benzoin—apply thinly, allow to dry; patient should wash off in 1–4 hours. OR trichloroacetic acid and bichloroacetic acid (TCA/BCA) (Tri-Chlor) 80%–90% applied by clinician and repeated weekly as needed OR Surgical removal

Table 13.3 Sexually Transmitted Infections—cont'd

Infectious Agent	Clinical Presentation	Diagnostic Reasoning	Treatment as Recommended by the CDC
Protozoa			
Trichomoniasis *(Trichomonas vaginalis)*	Heavy, odorous, yellow-green watery discharge. May have complaints of itching, swelling, and redness.	Discharge may be frothy. Wet mount: motile protozoa and WBCs.	metronidazole (Flagyl) 2 g PO × 1 OR tinidazole (Tindamaz) 2 g PO × 1

of mucosal and outer skin barriers, as well as interactions on the molecular level, for example, human papillomavirus (HPV) as a cofactor for HIV infection. Infectious organisms themselves may also express various genetic virulence factors that render them more susceptible to sexual transmission, including surface proteins that facilitate epithelial adherence to the urethral lining.

Clinical Presentation/Diagnostic Reasoning/Management

Table 13.3 presents the treatment of male reproductive system infections and STDs commonly seen by primary-care providers. STDs are typically distinguished from one another by their clinical presentation, although many STDs are asymptomatic in men or present with milder symptoms than in women. (Chapter 14 presents information on infections and STDs that are commonly seen in women.)

It is critical that all patients receiving treatment for one STD also be screened for syphilis with a serum rapid plasma reagin, as well as offered screening for HIV infection. In addition, given the frequently asymptomatic nature of *Chlamydia* infection in both men and women, all persons being treated for *Neisseria gonorrhoeae* should be concurrently treated for *Chlamydia trachomatis,* because these two STDs often occur concurrently.

It is a basic tenet of STD treatment that all sexual partners must be notified of their potential for infection (regardless of the original source of infection or index case) and the need for testing and/or empiric treatment with an appropriate regimen. Reporting of many STDs to public health authorities is mandatory, but these laws differ on a state-by-state basis.

There is some debate whether methicillin-resistant *Staphylococcus aureus* (MRSA) can be considered a sexually transmitted disease. It is transmitted primarily through skin-to-skin and other close contact. Although the use of barrier methods such as condoms minimizes the risk of contracting an STD, this method will have no effect on MRSA transmission unless all infected skin surfaces are fully covered. Because at least 30% of the population is colonized with *S aureus* and at least 2% with MRSA, the likelihood of transmission with intimate contact is possible.

Follow-up and Referral

STDs have traditionally been treated in the primary-care outpatient setting unless clinical symptoms meet criteria for hospital admission, such as severe pelvic inflammatory disease in women or initial presentation of HIV infection with or without the presence of opportunistic infection. Advancement in public health practices gave rise to the development of specialized, high-volume STD clinics to serve urban areas with high STD prevalence rates. However, cases that are refractory to established treatment guidelines may be referred to an infectious disease specialist for further diagnostic testing and individually tailored therapeutic regimens. Regardless of the treatment setting, beginning in the early teenage years, patients need to be asked and/or advised at every visit about sexual practices, the consistent use of condoms, and the benefits of abstinence. Patients with previous STD infection or those practicing high-risk sexual practices should be screened on a regular basis for common STDs including HIV, syphilis, *Chlamydia,* and *Neisseria gonorrhoeae.*

Patient Education

A resurgence in public education about sexual health is probably the most effective and efficient way to decrease the risk of this contagion. The clinician, while providing direct treatments, must also accept the responsibility for educating the patient about the need to seek treatment as soon as any symptoms appear. Persons most at risk are those with multiple sexual contacts, adolescents, and individuals who need further education. Patients should understand that active STD infection increases the chance of becoming infected with HIV, as well.

Chapter 14

COMMON COMPLAINTS

BREAST MASS

A breast mass is a lump in the breast, and discovering such a mass is one of the most anxiety-producing events a woman may encounter in her lifetime. Seventy percent of patients with breast cancer present with a lump in the breast; 90% of these breast masses are discovered by the woman herself. Benign breast disorders (e.g., fibroadenoma) are referred to as *fibrocystic disease* or *mammary dysplasia* and are the most frequent breast lesions. In benign breast disorders, the breast masses or lumps are tender and usually bilateral. There may be a rapid fluctuation in the size of benign masses compared with breast malignancies, which slowly increase in size. In premenopausal women, masses should be reassessed in 2 to 3 weeks during a different phase of the monthly cycle. Typically, the tenderness and size of the mass may increase before menses. Fibrocystic breast disease is most common in women aged 30 to 50 years or in postmenopausal women on hormone replacement therapy.

Differential Diagnosis

The symptoms that differentiate a breast cyst from breast cancer are the tenderness, the fluctuations in size, and the multiplicity of lesions. It is difficult to distinguish a breast cyst from cancer based on clinical findings alone; therefore, aggressive testing is warranted. The first step is to rule out benign causes of a breast mass such as infection (e.g., mastitis or cellulitis). A mammogram is usually the first test performed; however, the breast tissue in patients with fibrocystic breast disease may be too radiodense to provide a conclusive diagnosis. A breast ultrasound will differentiate a cystic mass from a solid mass. A definitive diagnosis is made via breast biopsy. Aspiration of a cystic lesion will relieve the pain and will assist in the diagnosis.

Treatment

Treatment of fibrocystic breast disease consists of avoiding trauma; wearing a firm bra day and night; eliminating coffee, tea, and chocolate from the diet; and taking 400 IU of vitamin E daily. Patients may be prescribed diuretics, oral contraceptives, NSAIDs, and supplemental progestin. For patients with severe pain, danazol (Danocrine) 100 to 200 mg two times daily has been found to be helpful. Danazol is an androgen derivative that suppresses pituitary gonadotropins. With its androgenic effects, such as acne, edema, and hirsutism, most women find that the treatment is worse than the condition itself and prefer to try milder forms of pain relief.

Patients with benign breast lumps tend to become complacent about examining their breasts because they know the lumps are there. Breast self-exam (BSE) is just as important with fibrocystic breast disease as it is for women without breast lumps and should be stressed along with instruction on how to perform BSE.

DYSFUNCTIONAL UTERINE BLEEDING

A change in the pattern or volume of menstrual blood flow is a common health concern of women from puberty to menopause. The literature suggests that 10% to 20% of women have abnormal uterine bleeding (AUB) at least once during their reproductive lives. Women may describe abnormal bleeding episodes as infrequent, prolonged in duration, occurring between regular menstrual periods, and/or excessive. Normal duration of menses averages 4 to 5 days. There may be no evidence of genital tract lesions. The causes of AUB are divided into two major categories: organic and dysfunctional (endocrine). The diagnosis of dysfunctional uterine bleeding (DUB) is considered only after organic, systemic, and iatrogenic causes are eliminated.

Abnormal vaginal bleeding is, therefore, considered DUB if it arises from the endometrium of the uterus with no demonstrable organic cause. It is frequently the result of an endocrine abnormality of anovulation or short ovulatory cycles in which estrogen stimulates the growth of the endometrium without the stabilizing effect of progesterone and is not the result of a normal menstruation. In adolescence, anovulatory DUB is commonly caused by an immature hypothalamic-pituitary system that does not respond to the positive feedback

effect of estrogen. In contrast, perimenopausal women experience variable menstrual cycle durations and bleeding episodes secondary to a decrease in ovarian response to gonadotropin stimulation. In addition, DUB is commonly seen during the reproductive years of women who are experiencing stress, are participating in a strenuous exercise program, or have undergone a large weight change.

Differential Diagnosis

Anovulatory bleeding is the cause of DUB in approximately 95% of women younger than age 20 years and in 90% of perimenopausal women who experience DUB for 2 to 3 years before the onset of menopause. In contrast, ovulatory cycles are associated with certain features such as midcycle pain, specific vaginal mucus changes, dysmenorrhea, and premenstrual breast tenderness. Although approximately one-half of ovulating women experience midcycle spotting, it is self-limiting. Irregular endometrial shedding may occur with the prolonged production of progesterone with a persistent corpus luteum resulting in DUB; however, DUB is a diagnosis of exclusion. Emphasis on a thorough history, physical exam, and pelvic exam and selected laboratory tests usually will yield the appropriate diagnosis. One must inquire about the woman's age, date of last menstrual period, birth control method, frequency of menses, amount of menstrual blood flow (e.g., the estimated number of pads or tampons used daily), duration of menses, and if there is a menstrual pattern change. In women who report profuse acute bleeding episodes, the diagnosis of pregnancy (e.g., passing tissue, nausea, vomiting, breast tenderness) must be excluded. In an ectopic pregnancy, the woman may complain of abdominal pain. Complaints of fainting spells may be indicative of a ruptured ectopic pregnancy.

Up to 10% of patients who use oral contraceptives (OCs) report irregular bleeding episodes. Any woman who presents with AUB and is age 35 years or older should be evaluated for cervical and uterine cancer. Malignancy must also be excluded. Endometrial sampling is an office procedure to rule out unchecked proliferation of the endometrium that can lead to hyperplasia and potentially endometrial adenocarcinoma. Similarly, a colposcopy, cervical biopsy, and endocervical curettage are used to diagnose cervical cancer. Women with a history of an abnormal Papanicolaou (Pap) smear test or ulcerated or friable lesions on the cervix should be referred for colposcopy. In addition, benign neoplasms such as uterine leiomyomas (fibroids), endometrial polyps, and adenomyomas are commonly seen in patients aged 25 to 45 years. Trauma and foreign bodies are seen more commonly in children. A less common cause of uterine bleeding is blood dyscrasia, such as von Willebrand's disease or thrombocytopenia purpura.

Laboratory work-up is directed by the history and physical exam findings and usually consists of hematocrit, hemoglobin, platelet count, and Pap and pregnancy tests. In severe bleeding, partial thromboplastin time, prothrombin time, and bleeding time tests are indicated. Hysteroscopy may be performed immediately before a dilation and curettage to assist in diagnosis of polyps, exophytic endometrial cancer, or fibroids. Prolactin level and thyroid function tests are ordered to rule out hyperprolactinemia and hypothyroidism, respectively.

Treatment

Management of DUB is directed toward controlling bleeding and preventing a recurrence. For teenagers, management includes observation for those with mild cases and no anemia, medroxyprogesterone (if the patient is not sexually active), or OCs for sexually active teenagers. For women of reproductive age, treatment is based on the woman's desire for fertility or contraception. For women who cannot take OCs, medroxyprogesterone is offered. OCs containing ethinyl estradiol are used in acute bleeding episodes. For women with severe acute bleeding, but who remain hemodynamically stable, conjugated estrogen is used until bleeding stops.

DYSPAREUNIA

Dyspareunia is painful sexual intercourse that can occur as a result of either introduction of the penis into the vagina or deep penile penetration. Dyspareunia can also be experienced by lesbians with introduction of multiple fingers or sex toys. The pain a patient experiences can be a consequence of vaginal inflammation, structural (anatomical) abnormalities, vaginal atrophy or insufficient lubrication, pelvic pathology, or psychological issues.

Because patients tend not to report painful sexual intercourse, it is difficult to determine the incidence. A review of studies reporting the prevalence of chronic pelvic pain indicates that the rates of dyspareunia ranged from 1.3% to 45.7% in over 154 studies that included over 35,973 women. One study of 313 patients documented that more than 60% had experienced dyspareunia at some point in their lives. Risk factors include history of sexual trauma, history of sexually transmitted infections (STIs), recurrent candidiasis infection, poor hygiene, menopause, psychological issues, and difficulties in the relationship.

Differential Diagnosis

Obtaining a thorough history from the patient is essential in ascertaining the cause of dyspareunia. As noted earlier, pain may occur with initial or deep penetration and may occur with initial intercourse or after a long time of pain-free experience. The patient may complain of vaginal discharge or irritation. There may be a history of unrelated pelvic pain, recent pregnancy and childbirth, trauma, or surgery. The patient may, on questioning, reveal difficulty in using tampons or difficulty with prior pelvic exams.

On physical exam, the patient may present with signs of vulvar or vaginal mucosal irritation, inflammation, lesions, discharge, atrophy, hymenal remnants, Bartholin's cyst or abscess, or vestibulitis. *Vaginismus,* the involuntary contraction of perineal muscles, may

occur during the speculum exam, impeding full visualization and examination of the vaginal vault and cervix. The clinician must proceed with sensitivity, allowing the patient control over the pelvic exam. The bimanual exam may reveal pelvic mass, cervical motion tenderness, uterine prolapse, rectocele, or cystocele.

The laboratory work-up is directed by findings from the history and physical exam and usually consists of urinalysis, wet mount of vaginal discharge, and cervical cultures. Urinalysis is useful in identifying any urinary tract conditions that may be a contributing factor to the source of the pain. The presence of white blood cells, red blood cells, or bacteria may indicate a urinary tract infection. Wet mount examination of vaginal discharge can reveal the presence of bacterial vaginosis *(Gardnerella vaginalis),* trichomoniasis, or candidiasis. Cervical cultures are useful in determining the presence of *Chlamydia* and gonorrhea.

Treatment

Management of dyspareunia depends on the symptoms and etiology. If the cause is atrophic vaginitis, estrogens, especially vaginal estrogens, may be helpful for postmenopausal women. Water-soluble lubricant (Astroglide, K-Y Jelly) can be used for vaginal lubrication and comfort. STIs are treated with appropriate antibiotic therapy. Progressive dilation and muscle awareness exercises such as Kegel exercises are recommended for treatment of vaginismus, hymenal strands, anatomically narrow introitus, and scar tissue. If psychological factors, such as sexual trauma, relationship conflicts, stress, and a restrictive sexual attitude, appear to be the cause, referral to a psychotherapist is indicated.

PELVIC PAIN

Pelvic pain is seen in 1% to 2% of patients in primary-care practice. Pelvic pain is categorized as acute, chronic, or recurrent and presents as both pelvic or lower abdominal pain. Genitourinary, gastrointestinal, or musculoskeletal system diseases or dysfunctions may cause sudden, acute pain in both areas. Chronic or recurrent pelvic pain is described as less urgent. Recurrent pain can be associated with menstruation or unrelated to menses. The origin of chronic pain can be related to benign or malignant neoplasms or characterized as psychogenic.

Differential Diagnosis

An acute onset of pelvic pain may be the result of pelvic disorders including pelvic inflammatory disease (PID); ruptured ovarian cyst; torsion of ovarian cyst, ovary, or fallopian tube; or ectopic pregnancy with rupture. PID accounts for about 20% of acute pelvic pain in women, ovarian cysts for up to 40%, and adnexal torsion for about 16%. Ten percent of women who report acute pelvic pain may have extrapelvic disease such as appendicitis.

Women reporting recurring pain with menstruation may have primary or secondary dysmenorrhea, endometriosis, adenomyosis, chronic PID, and/or pain related to intrauterine devices. Endometriosis is seen in up to 50% of women with chronic pelvic pain. Recurrent pain that is not associated with menses may have many causes, including Mittelschmerz (release of mature ovum from ovary), leaking ovarian cysts, incompletely treated or recurrent pelvic infections, or urinary tract infections. Nongynecological pathology includes adhesions, inflammatory bowel disease, and irritable bowel syndrome. However, for as many as 37% of women with chronic or recurrent pelvic pain, no physiological cause of the pain can be determined.

Treatment

Treatment for pelvic pain depends on the cause. Differential Diagnosis 14.1 outlines the differential diagnosis for pelvic pain and possible treatments.

VULVOVAGINITIS (VAGINAL ITCHING, BURNING, AND DISCHARGE)

Vulvovaginitis is defined as the simultaneous inflammation of the vulva and vagina. The patient complains of vaginal itching, burning, and vaginal discharge, which comprise the triad of vulvovaginitis symptoms and account for some of the most common reasons patients seek health care. Although frequently the result of infection, vulvovaginitis may also have noninfectious causes including allergic reactions, foreign body, atrophic vaginitis, traumatic vaginitis, or collagen vascular disease.

Differential Diagnosis

The delicate vaginal environment can be easily altered by numerous internal and external influences. In addition to the effects of normal changes in the body's hormonal condition, such as ovulatory midcycle mucus production, menstruation, or the atrophic mucosal changes that occur after menopause, the use of antibiotics, presence of diabetes mellitus or glycosuria, and stress can also cause symptoms of vulvovaginitis.

A thorough history should include time of symptom onset and a full description of the vaginal discharge and the relationship of the symptoms to the menstrual cycle, coitus, and use of medications (especially antibiotics). A detailed sexual history helps to identify whether the patient is at increased risk for the development of a sexually transmitted infection. It is important to determine whether the patient's partner has symptoms of infection (penile discharge or lesion) and if the woman has used spermicidal preparations, douches, bubble bath, or feminine hygiene deodorants and if she has done any self-treatment.

The most common cause of symptomatic complaints of abnormal vaginal discharge, itching, and burning is infection from bacteria, yeast, or parasites. Bacterial vaginosis caused primarily by *Gardnerella* accounts for almost 50% of all vaginal infections, followed closely by candidiasis (approximately 25%) and trichomoniasis (approximately 20%). Each infection is diagnosed based on the clinical presentation, which includes the type,

Differential Diagnosis 14.1 Pelvic Pain

Clinical Findings	Diagnosis	Treatment
Lower abdominal tenderness Cervical motion tenderness Adnexal tenderness Oral temperature above 101°F (38.3°C) ↑ Erythrocyte sedimentation rate Abnormal cervical/vaginal discharge abscess or pregnancy. Evidence of *Chlamydia trachomatis* or *Neisseria gonorrhoeae* ↑ WBCs	Pelvic inflammatory disease (PID)	Antibiotics (see CDC guidelines) Hospitalization may be required for uncertain diagnosis, pelvic abscess, or pregnancy.
Smooth mobile adnexal mass Percussive dullness on affected side Diffuse pain/pressure (if ruptured)	Ovarian cyst	Oral contraceptives may hasten cyst resolution. Cysts >6 cm require evaluation via laparoscopy and possible surgical removal.
Localized or diffuse colicky or dull pain Shoulder pain with hemoperitoneum Rebound tenderness/guarding (if ruptured) Abnormal vaginal bleeding Amenorrhea Quantitative serum hCG immunoassay positive (1 week after conception)	Ectopic pregnancy	Surgery
Dysmenorrhea Dyspareunia Pain on defecation Infertility	Endometriosis	Oral contraceptive if contraception is needed. NSAIDs if no contraception is needed. Possible laparoscopy to rule out pelvic pathology.
Flank pain, suprapubic pain, dysuria, frequency Fever, nausea, vomiting	Urinary tract infection	Antibiotics (see Chapter 12 for specific treatment for UTIs).
Acute, progressively severe pain Mass/tenderness on affected side on palpation Symptoms more impressive than exam	Adnexal torsion	Hospitalization/surgery
Initially: Epigastric to midabdominal pain and anorexia Later: Lower quadrant to suprapubic to flank pain and vomiting Rebound tenderness/guarding: tenderness over McBurney's point Psoas/obturator sign Low-grade fever	Appendicitis	Hospitalization and surgery
Palpable mass on uterus Back pain/pressure Dysmenorrhea/menorrhagia Anemia Frequency/constipation	Uterine fibroid (leiomyomas)	Hysterectomy Uterine artery embolectomy
Variable in intensity of pain lasting up to several hours	Mittelschmerz	No treatment. OCs may be offered to inhibit ovulation.

amount, color, odor, and pH of discharge. Physical exam includes visualization of the vulva and vagina for the presence of lesions, discharge, erythema, or atrophy. The cervix is examined for the presence of lesions, erosion, friability, or erythema. During the bimanual exam, the clinician should pay particular attention to the presence of cervical motion tenderness or the presence of adnexal and uterine tenderness or masses.

Laboratory work-up is directed by findings from the history and physical exam and usually consists of a saline wet mount of vaginal discharge to determine the presence of *Gardnerella, Trichomonas,* or atrophic vaginitis and a potassium hydroxide wet mount to determine the presence of *Candida.* A Gram stain of vaginal discharge can reveal the presence of gonorrhea. In addition, a urinalysis should be performed to rule out the presence of a urinary tract infection.

Treatment

Differential Diagnosis 14.2 presents the differential diagnoses for vulvovaginitis. Treatment for vulvovaginitis depends on the cause. Drugs Commonly Prescribed 14.1 lists the treatments for the different causes of vulvovaginitis.

Differential Diagnosis 14.2 Vulvovaginitis

Clinical Findings	Diagnosis
Vaginal discharge, mild or none Vaginal pH: <4.5 No amine odor KOH exam: negative	Physiological leukorrhea
Pruritus Dyspareunia Vulvar erythema and edema Thick white floccular nonadherent vaginal discharge Vaginal pH: <4.5 No amine odor KOH exam: Pseudohyphae Saline microscopy: Pseudohyphae	Candidiasis
Malodorous, gray-yellow-green watery or thick adherent vaginal discharge Burning with urination No dyspareunia pH: >4.5 Amine odor present KOH exam is positive Saline microscopy: Clue cells	Bacterial vaginosis *(Gardnerella)*
Homogeneous, malodorous purulent, green-yellow, thick, frothy vaginal discharge "Strawberry" cervix Vulvovaginal erythema Itching Burning on urination Dyspareunia pH: 5–6 Amine odor is absent KOH exam is negative Saline microscopy: Motile trichomonads	Trichomoniasis
Dyspareunia Vaginal dryness Vestibular and vaginal thinning Vulvular and vaginal burning Bleeding Itching pH: >6 Amine odor is present. KOH exam is negative.	Atrophic vaginitis

Drugs Commonly Prescribed 14.1 Vulvovaginitis

Drug	Indication	Adverse Reactions and Prescribing Considerations
butoconazole 2% (Gynazole-1 or Mycelex-3) cream 5 g intravaginally once at bedtime OR	Candidiasis	Adverse reactions include vulvovaginal burning, itching, irritation, swelling, cramping, abdominal pain, headache.
miconazole 2% cream (Monistat) 5 g intravaginally (1,200 mg at bedtime for 1 day; or 200 mg at bedtime for 3 days; or 100 mg at bedtime for 7 days) OR		Do not use contraceptive diaphragm or condoms within 3 days.
clotrimazole 1% (Lotrimin) cream 5 g intravaginally for 7–14 days OR clotrimazole 2% cream intravaginally for 3 days OR clotrimazole 100 mg vaginal tablet for 7 days OR tioconazole 6.5% (Vagistat-1) ointment 5 g intravaginally in a single application OR terconazole 0.4% cream 5 g intravaginally for 7 days OR		Do not use tampons, douches, or spermicides within 7 days.
terconazole 0.8% cream 5 g intravaginally for 3 days fluconazole (Diflucan) 150 mg PO ×1 for uncomplicated; if severe 150 mg every 72 hours ×2 doses; for recurrent 150 mg weekly ×6 months	Recurrent or chronic candidiasis	Adverse reactions include headache, nausea, abdominal pain, GI upset, dizziness, taste perversion, and hepatotoxicity. Use with caution in the elderly. Pregnancy Category C Not recommended for use with nursing mothers.
Metronidazole 500 mg PO 2 times daily ×7 days	Bacterial vaginosis (BV)	Avoid ingestion of alcohol with metronidazole and for 24 hours after treatment is complete.
OR		Adverse reactions include GI upset, metallic
metronidazole gel 0.75% one full applicator (5 g) intravaginally daily for 5 days OR clindamycin cream 2% one full applicator (5 g) intravaginally at bedtime ×3 or 7 days		taste, dysuria, cystitis, incontinence, *Candida* overgrowth, seizures, peripheral neuropathy, neutropenia. Pregnancy Category B during 2nd and 3rd trimesters. Preferred orally in pregnancy. Do not use in patients with a history of enteritis or colitis. Do not use contraceptive diaphragm or condom for 72 hours after treatment. Pregnancy Category B Not recommended for nursing mothers.
metronidazole 2 g PO single dose OR metronidazole 500 mg PO 2 times daily ×7 days for recurrent infection.	Trichomoniasis	Must treat partner. Avoid alcohol for 24 hours after treatment is completed.
estrogen cream (Premarin vaginal cream) 0.5 g twice-weekly continuous OR 21 days of therapy followed by 7 days off therapy.	Atrophic vaginitis	Decrease or eliminate based on symptoms.

FAMILY PLANNING

From menarche to menopause, a woman's health concerns may include controlling fertility. Women need to be able to prevent pregnancy, plan intervals between pregnancies, and find help if a desired pregnancy is not achieved. These decisions are related to one's values, professional role, friends, family, cultural and religious beliefs, self-perception, health status, economics, sexual lifestyle, options accessible, and partner status. Ideally, the birth control option should be affordable, easy to use, easy to obtain, 100% effective, safe, mutually acceptable, and reversible. The most popular birth control methods are oral contraceptives (OCs), the diaphragm, and condoms. Other popular choices include Depo-Provera injections and the copper intrauterine device.

Although preventing pregnancy is a major concern, some lifestyle behaviors may also cause concern for acquiring a sexually transmitted infection (STI). To control both pregnancy and disease, routine health care is important. The gynecological history and physical exam are essential to address both issues.

The gynecological history reviews risks for STIs, as well as past and current birth control methods, and identifies needs for health promotion. It also identifies sexual dysfunction or sexual concerns. Reviewing anatomy and physiology with the patient may help her understand her body and result in healthier lifestyle choices. Other items important in history taking include menstrual cycle information; age at menarche; use of tampons or pads; change in menses; number of sex partners in the past year and lifetime; age at initiation of coitus; dyspareunia; orgasms; history of STIs; medications used; results of previous Papanicolaou (Pap) smears and resolutions; and cigarette, drug, and/or alcohol use or abuse. It is important to obtain a basic health history as well to identify potential contraindications to new or previous birth control methods.

Wording questions in a nonjudgmental, supportive, accepting manner enables the patient to be open and honest in an area of great sensitivity and possible pain. The clinician addresses areas of concern, such as poor body image, depression, poor nutrition, emotional or physical problems, myths, abuse from others, smoking, obesity, alcohol or drug abuse, and family problems.

Physical exam includes blood pressure, weight, height, last menstrual period, breast cancer and breast self-exam (BSE) teaching, bimanual pelvic, a Pap smear, and culture for STIs and other infections as appropriate to the patient's risk factors and presenting information. During the initial examination, baseline lab studies should be done including a lipid profile and complete blood count (CBC). Other tests (dependent on presenting history) are thyroid profile, fasting blood sugar, or liver profile. In addition, after a 10-year period of OC use, a liver profile should be obtained.

Some facilities require signed consent for the birth control method selected that ensures that the patient has been given, in writing, full information on the use, risks, benefits, and follow-up needs of the method. Other facilities educate the patient at the time of the visit and give her the product insert and educational material to read at home. Ideally, both partners, if possible, need comprehensive information on birth control methods so that their choice is an educated decision based on their lifestyle and needs. The success or failure of any birth control method depends on the woman's motivation, adherence, partner support, consistency, and comfort. The main methods of birth control are listed in Table 14.1.

Barrier Methods

Barrier methods include male and female condoms, the diaphragm, and cervical cap. Some barrier methods have the dual advantage of preventing pregnancy and STIs. The most common STIs are caused by herpes simplex virus, human papillomavirus (HPV), HIV, *Neisseria gonorrhoeae,* and *Chlamydia.* Controlling HPV also reduces the risk of cervical cancer. Adverse effects of barrier methods are similar in some ways: messiness, handling of genitalia, precoital interruption of spontaneity, and allergy or contact dermatitis. The use of barrier methods requires motivation on the part of both partners.

Male Condom

The *male condom* is the most common barrier method and is most effective when combined with a spermicide such as nonoxynol-9. Condoms are available in various sizes, colors, flavors, strengths, and lubrication. They should not be applied tightly. The tip should extend one-half inch beyond the penis to collect ejaculate. Care must be taken during withdrawal of the penis to prevent the condom from coming off and spilling the semen. Other adverse effects include irritation, allergic reaction, unfavorable oral sex, and accidental splitting of the condom. Condoms are very effective, and when used with a spermicide the failure rate is equivalent to that of OCs. However, condoms may not be the best choice for the under-25-year-old group because of noncompliance, inconsistent use, and low motivation.

Female Condom

The *female condom* is a device that is disposable and made of seamless polyurethane. It fits loosely inside the vagina and covers the perineum. There are flexible rims on both ends. The inner rim sits on the closed end and is compressed for placement into the vagina over the cervix, which prevents contact between body secretions. The condom is soft, lubricated by spermicide, and inexpensive and may be purchased over the counter. Many patients state that it is difficult to handle, however. Adverse effects include irritation and allergic reaction. The

Table 14.1 Methods of Birth Control

Method	Type	Mode of Action	Duration	Rate (%)*
Barrier Methods	Male condom	Prevents sperm from entering vagina.	Each use	3–12
	Female condom	Prevents sperm from entering cervix.	Each use	5–21
	Diaphragm	Prevents sperm from entering cervix.	Each use	2–20
	Cervical cap	Prevents sperm from entering cervix.	48 hours	2–20
	Vaginal contraceptive sponge	Prevents sperm from entering cervix.	24 hours	18–28
	Spermicide nonoxynol-9	Immobilizes and kills sperm.	Each use	2–30
Hormonal Methods	Combination oral contraceptives	Inhibits ovulation, hostile environment, slows tubal transport.	Continuous	0.1
	Progestin-only pills	Inhibits ovulation, hostile environment, slows tubal transport.	Continuous	1–4
	Depo-medroxyprogesterone (Depo-Provera)	Blunts LH, inhibits sperm penetration, endometrium unreceptive.	90 days	0.3
Intrauterine Devices (IUDs)	Copper T-380A	Prevents fertilization and implantation.	10 years	0.8
	Mirena	Prevents fertilization and implantation.	5 years	
Regulated Abstinence	Calendar calculation	Prevents fertilization.	Each cycle	9
	Temperature and mucous changes	Prevents fertilization.	Each cycle	4
Postcoital Controls	Chance	No protection.	N/A	85
	Withdrawal	Prevents sperm from entering vagina.	Each use	18
	Postcoitus douche	Flushes sperm from vagina.	N/A	—
	Emergency contraception	Interferes with fertilization or implant.	Each use (Plan B)	2
Sterilization	Female	Fallopian tubes cut/tied to prevent ovum moving to uterus or sperm entering tube.	Permanent	0.4
	Male	Vas deferens cut to prevent sperm from leaving male.	Permanent	0.15

*Percentage of women experiencing an accidental pregnancy in the first year of use.

failure rate of the female condom is 5% to 21% when used correctly and comparable to the efficacy of the diaphragm.

Diaphragm

A *diaphragm* is a latex hemisphere with a flexible rim that fits over the cervix. The failure rate is 2% to 20% when used with spermicidal jelly. This method allows the woman control and has no systemic side effects. The largest size that covers the cervix comfortably is best. Once the device has been fitted, the patient should insert and remove the diaphragm, then return for a recheck after 1 week of practice while using a backup contraceptive method. Before insertion, 1 teaspoon of spermicide is placed in the cup and a small amount is spread around the rim. The diaphragm must be left in place for 8 hours after intercourse; if additional intercourse is desired, additional spermicide is instilled in the vagina. The diaphragm should not be left in place for more than 12 to 18 hours. Once removed, the diaphragm is washed with a mild soap, dried, and stored. Before the diaphragm is used again, it should be held up to the light to check for holes, tears, and breaks. The patient should be instructed to urinate before inserting and after removing the diaphragm to reduce the risk of urinary tract infections (UTIs). Under normal circumstances, the diaphragm is fitted during the annual gynecological visit; however, if the patient has pelvic surgery, pregnancy, or a weight change of 10 to 20 pounds, the diaphragm must be refitted.

Cervical Cap

The *cervical cap* is a cup-shaped plastic or rubber device that fits snugly around the cervix with a failure rate similar to that of the diaphragm. Like the diaphragm, the cap is used with a spermicide. Because the cap is smaller than the diaphragm, it may be more difficult to insert and remove. The advantage of the cervical cap is that it can be used in women who are unable to use a diaphragm because of a relaxed anterior vaginal wall or in those who have recurrent UTIs with the use of the diaphragm. The cervical cap should not be left in place

for longer than 12 to 18 hours and should not be used during menstruation because of the slight risk of toxic shock syndrome (TSS). Only women with normal Pap smears should use the cap, and a repeat Pap smear should be obtained 3 months after its use is initiated. Adverse effects of the cervical cap are similar to those associated with the diaphragm: allergic reactions, irritation, and displacement.

Spermicidal Methods

Vaginal Contraceptive Sponge

A *vaginal contraceptive* sponge is a one-size-fits-all disposable sponge of polyurethane treated with nonoxynol-9, which protects against pregnancy but not against STIs. The sponge is placed under tap water and rinsed, then inserted into the vagina. Adverse effects include displacement, irritation, and a slight risk of TSS (1 per 2 million sponges). It should be left in place for 6 hours after intercourse, but not more than 24 to 30 hours (depending on product) to minimize the risk of TSS. It is not recommended for use during menses or puerperium to decrease risk of TSS.

Contraceptive Foam, Cream, Film, Jelly, and Suppository

Nonoxynol-9 is the spermicide contained in contraceptive foam, cream, film, jelly, and suppositories. These products have an overall failure rate of 2% to 30% when used correctly. The advantages to these forms of contraception are that they are available without a prescription, easy to use, readily available, and relatively inexpensive. Nonoxynol-9 may have some virucidal and bactericidal activity but does not offer any protection against HIV, as once thought. The disadvantage of these products is that they can cause irritation and allergic reactions.

Hormonal Methods

Hormonal methods include oral contraceptives—both combination and progestin-only pills and medroxyprogesterone (Depo-Provera) injections. The implantable progestin contraceptive levonorgestrel (Norplant) is no longer available in the United States.

Oral Contraceptives

Oral contraceptives (OCs) contain either a combination of estrogen and progestin or progestin only (commonly called the "mini-pill"). The most popular OCs are the 4-week cycle combination pills. These contain estrogen and progestin and are taken each day for 3 weeks, with inert (placebo) pills for the fourth week. The nonhormonal (fourth) week is the time when withdrawal uterine bleeding occurs. A recent introduction is the cycle of OCs that contain 84 active and 7 inert pills (Seasonale). This results in menses only every 3 months (4 times a year).

The estrogen-progestin OC prevents pregnancy by suppressing the hypothalamic releasing factor that inhibits the release of follicle-stimulating hormone and luteinizing hormone from the anterior pituitary, thereby preventing ovulation; estrogen in the pill inhibits implantation by changing normal uterine lining maturation, and the progestins slow ovum transport and uterine motility. Progestins also cause the cervical mucus to become thick and scanty, slowing sperm transport and capacitation. In addition, pH is altered, and the cervical and uterine environment becomes hostile to sperm. If taken as directed, OCs have a failure rate of less than 0.5%; however, the typical failure rate is 3%.

Ethinyl estradiol (EE) is currently the most popular estrogen used in OCs in the United States. The progestins used today include desogestrel (in Mircette, Cyclessa, Ortho-Cept, Desogen), levonorgestrel (in Alesse, Nordette, Seasonale, Trivora, Triphasil), norethindrone (in Estrostep, Norinyl 1/35, Ortho-Novum 1/35 and 7/7/7, Necon 1/35, Modicon, Ovcon 35, Loestrin 1.5/30, Tri-Norinyl), norgestimate (in Ortho-Cyclen, Ortho-Tri-Cyclen), drospirenone (in Yasmin), and *dl*-norgestrel (in Lo-Ovral, Low-Ogestrel).

All progestins, even in low doses, offer excellent cycle control and minimal metabolic changes. Progestins have variable estrogenic, androgenic, and progestational effects. The third generation progestins (desogestrel, drospirenone, norgestimate) are the least androgenic and are particularly good for women with acne or hirsutism. Progestins may also affect plasma levels of clotting factor, blood vessel disease, diabetes, lipids, and other changes discussed separately in the chapter.

The amounts of estrogen and progestin in OC pills have been greatly reduced since their inception. The lower the effective dose, the lower the adverse effects; the lowest acceptable dose is guided by the ability of the pill to prevent breakthrough bleeding. Breakthrough bleeding is an undesirable adverse effect. Estrogen content is usually 20 to 35 mcg of EE per tablet, with no more than 50 mcg available in the United States. Progestin content ranges from 0.1 to 1.5 mg. Both the estrogen and progestin doses may either be constant in a cycle pack (in monophasic contraceptives) or vary (in multiphasic contraceptives). The ratio of estrogen to progestin in combination pills can be 1:5 or 1:50; most commonly, it is 1:10 to 1:30. In the normal menses cycle, the ratio is 1:10 (early follicular), 1:5 (preovulation), and 1:30 (luteal phase). Multiphasic OCs are used in an attempt to emulate the menstrual cycle but may be associated with a higher incidence of breakthrough bleeding than monophasic pills.

To prevent ovulation, the OCs should be started either with the onset of menses (same-day start) or on the first Sunday of the week the menses starts (Sunday start). In a Sunday start, a backup method (e.g., condom or abstinence) should be used for at least 7 days.

The effectiveness of OCs is dependent on patient adherence. Each pill must be taken at the same hour, every day. Once the start date is established and the pack

started, there is no waiting or menstrual impact to start the subsequent pack. As soon as the initial pack is completed, the next pack is started on the next day. Patients may need suggestions on how to take the pill on time and every day, whether it is when brushing teeth or at meal time or bedtime, as long as it is the same hour, every day. For women who experience nausea when taking OCs, taking them at bedtime can minimize this adverse effect.

The combination pills are provided in 28-day pill packs, color-coded by dose and time, and include the 21 active and 7 inert tablets. Some manufacturers include iron supplements in the 7 inert (placebo) pills; some eliminate the 7 inert pills and provide a 21-day pack. To keep a patient adherent and on time, it is usually best to recommend the habit of a pill a day and without stopping the last 7 days, to prevent forgetting when to restart again.

If the patient forgets to take one or more doses of the OC, the following guidelines are recommended:

- One dose missed at any time in the cycle: Take the missed dose as soon as remembered and the next dose at the usual time.
- Two doses missed during the first 2 weeks of the cycle: Take two doses daily for 2 days, then resume one dose a day. Use a backup form of birth control for the balance of the cycle.
- Two doses missed during the third week of the cycle: Take one dose daily until the last day (day 21), dispose of the remaining pills, and begin the new OC pack that day. Use a backup form of birth control for 7 days.
- Three or more doses missed at any time in the cycle: Take one dose daily until the last day (day 21), dispose of the remaining pills, and begin the new OC pack that day. Use a backup form of birth control for 7 days.

Some patients experience breakthrough bleeding with missed pills and doubling of pills. Some practitioners do not advocate using the methods outlined above but instead tell their patients to discontinue the pack, use a barrier method, and restart with a new pack when the regular menses begins. If menses does not occur as usual, a pregnancy test must be performed.

Patients need special instructions when starting OCs if they had a recent full-term delivery, are nursing, had a recent abortion or miscarriage, have infrequent or irregular menses, or are using other medications.

Many patients inquire about starting or restarting OCs postpartum. The Food and Drug Administration (FDA) package insert indicates that because the postpartum period lends itself to a higher risk of thromboembolism, OCs should be started no earlier than 4 to 6 weeks after delivery in nonnursing mothers. Ovulation rarely takes place before 4 weeks postpartum of a full-term pregnancy; however, if a patient is using drugs (such as bromocriptine [Parlodel]) to suppress lactation, ovulation may occur earlier, and the pill should be started by day 14 postpartum.

Similarly, many patients who are breastfeeding inquire about starting on OCs. Because estrogen decreases the amount and quality of breast milk, OCs are not recommended for lactating women. Conversely, progestins actually promote breast milk production, so that progestin-only OCs should be used in women who are breastfeeding and desiring contraception. Combination estrogen and progestin oral contraceptives should not be prescribed until at least 6 weeks postpartum.

Because ovulation is a possibility within 14 days after either a recent abortion or miscarriage, OCs should be started either immediately or no later than 7 days after a first-trimester (5–13 weeks) abortion. After a midtrimester abortion, the OC should be started the same way as after a full-term pregnancy.

If a patient is not pregnant (as confirmed by test), OCs may be started at any time, with backup contraception for the first cycle of pills. In women with amenorrhea or infrequent cycles, discontinuance of the OC may leave them anovulatory or fully amenorrheic if their history includes secondary amenorrhea, oligomenorrhea, or irregular cycles. These patients should, therefore, consider another method of birth control.

Ineffective contraception and breakthrough bleeding may occur as the result of an interaction between the OC and drugs taken simultaneously. Table 14.2 presents common drug interactions. The exact mechanism of action is not clear, but it may be the result of the alteration of the gastrointestinal tract's absorption ability or alteration of enzymatic action on medication (either accelerating or decelerating metabolism). It is often difficult to modify drug prescriptions in illness and far simpler and safer to consider another form of birth control.

The combination OC is the most effective reversible form of birth control, relatively inexpensive, and least invasive method of correcting painful and irregular cycles. Some of the other benefits include reduced blood loss, resulting in lower incidence of anemia; less risk of ectopic pregnancy and salpingitis; fewer ovarian cysts; reduction in dysmenorrhea; reduction in risk of ovarian and endometrial cancer; improvement in acne; decreased risk for developing myomas in long-term (greater than 4 years) users; and a beneficial effect on bone mass. In general, these benefits reduce the need for costly hospitalizations.

The benefits and safety of OCs are dependent on adherence, but are also affected by other factors such as smoking. There is an increased risk of cardiovascular disease and thromboembolic disease in women who are older than 35 years of age and who smoke while taking OCs. Women older than 40 years of age who are nonsmokers may safely continue low-dose OCs. OC use is safest throughout the menstrual life in women who are

Table 14.2 Oral Contraceptives: Drug Interactions

Drug Interactions	Effectiveness	Drugs
Drug effect on OCs	Increased effectiveness	Carbamazepine
	Decreased effectiveness	
	Possible decreased effectiveness	
OC effect on drugs	Decreased effectiveness	Acetaminophen, benzodiazepines, guanethidine, methyldopa, oral anticoagulants, oral hypoglycemics
	Increased effectiveness	Alcohol, antidepressants, benzodiazepines, beta blockers, corticosteroids, theophylline

of normal weight, are nonsmokers, have normal blood pressure (BP) and cholesterol, have no diabetes, and have no family history of heart disease. Consequently, a full history, gynecological exam, Pap smear, infection checks, lipid profile, and CBC lab tests should be performed before an OC is prescribed. Evaluation of the history, physical exam, and lab results is necessary to prevent adverse effects.

OCs have a wide range of adverse effects, from simple to more serious. Primarily, the constant presence of low-level hormones creates a pregnancy-like environment in the body. Thyroid hormone and cortisol levels may be elevated. Progestins may alter the lipid profile. Estrogens decrease glucose tolerance, and women with diabetes should be monitored closely if using OCs. Estrogen-related increases in clotting factors result in an increased risk of thromboembolism. Women who will be undergoing surgery and postoperative bed confinement should discontinue OCs at least 4 weeks before surgery.

The risk of developing hypertension in OC users increases with the duration of use and also in older women. If a woman develops hypertension while taking OCs, the pills should be stopped and another form of contraception adopted. However, if a woman is younger than 40 years of age and has mild hypertension that is controlled with medication and does not smoke, OCs may be used as long as BP is closely monitored.

Other adverse effects of OC use are an increased risk of cervical dysplasia and cancer in long-term (greater than 3–4 years) users. There is some evidence that there is a higher incidence of liver (usually benign) tumors or gallstones, but this is usually associated with higher dosages, long-term use, and older age. The use of OCs can precipitate migraine or vascular headaches or make existing migraines worse. Another form of contraception should be used if headaches increase in severity or frequency. Other problems that have been reported with OC use are depression and fluid retention.

It is unclear whether OCs contribute to breast cancer. FDA packaging inserts imply an association related to duration of use and history. Fibrocystic breast discomfort has been found to be less in OC users. Breast swelling and tenderness are common premenstrual complaints. Low-dose OCs seem to decrease this complaint, as does reducing caffeine intake, avoiding smoking, and reducing sodium intake.

Because the cervical mucus is affected by the progestin component and estrogen can cause cervical mucorrhea, it is not uncommon for OC users to experience mucus-causing irritation, including *Candida,* of the vagina and vulva. Antibiotic therapy may also cause this condition.

Patients who use OCs may have increased pigmentation of the face and forehead. Combination pill users find this in the areola and perineum as well. Weight gain may or may not be an OC effect; it may be simply overeating, lack of exercise, fluid retention, thyroid problems, or poor nutrition, but a gain of 2 to 5 pounds is not uncommon.

To metabolize OCs properly, certain vitamins are utilized and not necessarily stored. Women should be instructed to take a daily multivitamin and extra vitamin C while taking OCs to prevent deficiency of these nutrients.

When combination OCs are discontinued, 90% of women resume ovulation and menses within 3 months. A pregnancy test should be done to ensure the patient is not pregnant if normal cycles are not established after 3 months. If a woman does not wish to become pregnant, another form of contraception should be used when the OC is discontinued. If a woman becomes pregnant while using the OC, most studies show no increased incidence of congenital defects. However, it is best not to use OCs if a patient believes she is pregnant but to use another method until it is established whether or not she is pregnant.

The progestin-only pill, the "mini-pill," contains progestin only and has a reported failure rate of 1% to 4%, slightly higher than that of combined OCs. Progestin-only pills contain either 0.35 mg norethindrone (Ortho Micronor, Nor-QD) or 0.075 mg *dl*-norgestrel (Ovrette) and are taken continuously beginning on the first day of the menstrual cycle. The progestin inhibits ovulation inconsistently but does cause thickening of the cervical mucus (makes it hostile to sperm), alters ovum transport (higher risk of ectopic pregnancy), and inhibits implantation. The advantages of the mini-pill are that it is safe during lactation and may actually increase the

flow of milk; it can be used in women older than 35 years of age; it can be used in women with sickle cell disease; and it can be used in women with myomas. The progestin-only pill is less likely to cause headache, high BP, depression, cramps, premenstrual syndrome, or glucose elevation than combination OCs.

Disadvantages of the mini-pill include contraceptive failure and ectopic pregnancy. Irregular bleeding (amenorrhea, breakthrough bleeding, prolonged flow) is common in progestin-only users and may necessitate frequent pregnancy tests. Absolute contraindications include pregnancy, current or past history of thromboembolic disorders, stroke or heart disease, breast cancer, liver mass, and undiagnosed abnormal vaginal bleeding.

If the woman taking OCs complains of any of the adverse effects typically associated with OCs (nausea, abdominal bloating, hair changes, weight gain, leg pain, cramps, swelling), often switching the patient to a pill with a lower estrogen dose or one with a less androgenic progestin will relieve the problem. For example, switching to an OC with less progestational activity relieves hypoglycemia. If the patient complains of abdominal bloating, a lower estrogen dose or different progestin may relieve this problem. Bowel irregularity can also cause bloating, so this should be evaluated. If a patient complains of nausea, she should be instructed to take the pill with food or at bedtime. If the nausea persists or worsens, the patient may need to consult a gastroenterologist.

Regarding hair changes, excessive facial and body hair is usually less obvious in OC users. Hair loss is not usually related to OC use and should be referred to a dermatologist for evaluation.

Progestin, especially at high androgenic activity levels, and estrogen may cause weight gain. The patient should be switched to an OC with lower progestin/androgenic activities and provided with a diet that is lower in calories. If weight gain is mainly in breasts, hips, and thighs; is cyclic; and causes bloating, a pill with lower estrogen content should be tried.

Leg pain, cramps, and swelling usually disappear after three cycle packs. A severe pain, especially unilateral pain, can indicate a thrombosis and requires immediate discontinuation of the OC and immediate medical evaluation.

Medroxyprogesterone Acetate Injections

Medroxyprogesterone acetate, or Depo-Provera injectable, consists of 150 mg of deep intramuscular (IM) injections given every 3 months and has an efficacy rate of 99.7%. The initial injection is given on day 5 of the menses, and once injected it may take 8 to 9 months for fertility to be restored. The mode of action, adverse effects, and contraindications are the same as those for progesterone-only OCs. After 5 years of use, bone density loss has been observed, and patients should be advised to have adequate calcium intake daily (1,200–1,500 mg) at the onset of use. The thinning of the uterine lining tends to lend some protection against endometrial cancer but also makes it more difficult for the patient to conceive for up to a year after discontinuing the injection. Depo-Provera may be used for patients who smoke and who are not candidates for the oral combination pill. All patients, however, should stop smoking as soon as possible.

Intrauterine Device

The *intrauterine device* (IUD) is a highly effective method for most women, and contrary to previous thought, nulliparity is not a contraindication to IUD use. Available in the United States today are the Mirena IUD, which releases levonorgestrel slowly, and the Copper T-380A. The Mirena is effective for about 5 years, and the Copper T-380A is effective for about 10 years. The mechanism of action of an IUD is not totally understood, but it is believed to act either as a spermicide or to have inhibitory effects on sperm capacitation and transport. Clearly, however, the IUD is not an abortifacient.

The IUD is inserted by a clinician trained in the procedure and is done at midcycle to prevent implantation. A 6- to 8-week wait is customary postpartum before insertion. The IUD has two long, off-white monofilament tails that project from the cervix into the vagina. The patient should be instructed to check this string after each menstrual period to ensure the IUD is still in place. A Pap smear and cultures are done during pelvic exam before insertion to be sure there are no abnormalities or infections.

Adverse effects include heavier menstrual periods, bleeding between periods, and cramping, and women with these problems should seek an alternative form of contraception. In 10% to 20% of cases during the first year of use there is spontaneous expulsion of the IUD. During the first month after insertion, there is an increased risk of pelvic infection. There does not appear to be any greater risk for infection other than that for acquiring an STI. Fertility is not affected by the use of an IUD.

Absolute contraindications for the use of an IUD include pregnancy, acute pelvic inflammatory disease, and purulent cervicitis. An IUD should be used with caution in women with a history of pelvic inflammatory disease, menorrhagia or severe dysmenorrhea, cervical or uterine neoplasia, or an abnormal uterus.

Regulated Abstinence

Regulated abstinence is another form of birth control used for both preventing and achieving pregnancy. Abstaining from sexual intercourse during the days of the menstrual cycle when the ovum is most vulnerable to fertilization is one way of avoiding pregnancy. Likewise, if achieving pregnancy is the desired outcome, engaging in sexual intercourse at this time is desirable. There are several techniques used to predict the best time for

abstinence. The *rhythm method* or *calendar method* is based on the assumptions that the ovum is viable 24 hours after ovulation, spermatozoa are viable 48 hours after coitus, and ovulation occurs 12 to 16 days before menses. The woman records the length of her cycle for several months and establishes her fertile period by deducting 18 days from her shortest cycle and 11 days from her previous longest cycle. Each subsequent cycle, abstinence occurs during this calculated fertile period. The patient must have regular cycles to use this method.

The *natural family planning method* is another technique used to predict the best time for abstinence. There are three types: the basal body temperature method, the cervical mucus method, and the symptothermal method. When used in combination, the period of abstinence can be reduced and the effectiveness is increased for both preventing pregnancy or achieving pregnancy (if this is the goal). In the *basal body temperature method,* the patient measures basal body temperature daily. Abstinence is observed from menses to 3 days of elevated temperature. The lengthy abstinence plus abstinence in anovulatory cycles make this an unfavorable method.

In the *cervical mucus method,* an interpretation and recognition is made of changes in the cervical mucus consistency, which occurs in response to the changes in estrogen and progesterone levels. Abstinence begins in menses (and every other day thereafter to reduce risk of confusing mucus with semen) until the first day of slippery, copious mucus. Abstinence is observed every day thereafter until 4 days after the last day that mucus is present, or the peak mucus day.

In the *symptothermal method,* the fertile period is determined by calendar calculation and cervical mucus changes to decide on the fertile period; changes in mucus and basal temperature are used to decide on the end of this period. This method is difficult to learn but is the most effective natural method to prevent pregnancy.

The greatest obstacle to acceptance of these techniques is the need to avoid sexual relations for many days each cycle. Some couples use the barrier method during fertile times for greater acceptance and reduced failure rate.

Recent developments have produced self-administered tests (ovulation prediction kits) for the detection of hormone changes, reducing abstinence to several days per cycle. Urine evaluation for hormones is another method of family planning.

Postcoital Controls

Postcoital controls are another method of birth control. There are three different types: withdrawal, postcoitus douche, and emergency contraception. The simplest, most practical method of preventing implantation after unprotected sex is the administration of emergency contraception. Several regimens are effective in preventing implantation if the ovum has been fertilized, and all have about the same failure rate, 1% to 3%. The first method is to give two doses 12 hours apart of levonorgestrel 0.75 mg (called Plan B in the United States). An alternative is levonorgestrel 1.5 mg in a single dose. Both of these methods must be instituted within 72 hours of intercourse. Another regimen is ethinyl estradiol 50 mcg with 0.5 mg of norgestrel and is prepackaged as Preven. Two tablets are given and then two more 12 hours later. A regimen that is comparable is to give two tablets now and two more 12 hours later of Lo/Ovral, Nordette, or Levlen. An alternative to this is to instruct the patient to take the yellow pills of either Triphasil or Tri-Levlen in the same regimen, two pills followed by two pills 12 hours later. The third regimen is for the patient to take ethinyl estradiol 2.5 mg 2 times daily for 5 days, but this method tends to cause more nausea, vomiting, and breast tenderness than the other regimens. It is good practice to check for pregnancy pretreatment in the event that the woman inadvertently became pregnant earlier in her cycle and then posttreatment because the effects on the fetus worsen as the treatment and pregnancy continue, although it is uncertain that birth defects are directly related to steroid exposure in early pregnancy. Again, careful menstrual history should be reviewed, and a consent form may be obtained before prescription. Some women elect to continue the pregnancy if the treatment fails, and 10% of such cases have been later diagnosed with ectopic pregnancies. Contraindications to emergency contraception are pregnancy and those as listed for OC pills.

Sterilization

The most permanent method of birth control is sterilization. After risks and benefits of sterilization are reviewed with the patient, consent is obtained. The presence of two witnesses is recommended for patients younger than age 25 or those who are childless and older than 40 years of age. One percent of 1,000 patients who undergo the procedure later request reversal of sterilization.

Male sterilization consists of vasectomy performed on an outpatient basis; the procedure typically takes 20 minutes under local anesthesia. The major complication is hematoma (5%), sperm granuloma, and spontaneous reanastomosis. After vasectomy, the man is not considered sterile until two sperm-free ejaculates have been produced. Semen analysis should be performed 1 to 2 months after the procedure. About 15 to 20 ejaculations are required postvasectomy for absolute sterility.

Female sterilization is performed under general anesthesia by transperitoneal incision for tubal ligation. If sterilization is performed postpartum, a small infraumbilical incision is made and a tubal ligation is performed in the delivery room immediately or in the operating room the next day. The failure rate is 1 per 1,000.

Complications are hemorrhage, puncture, and cautery of the bowel (0.6%).

Abortion

An elective abortion is one of the most common gynecological procedures in the United States and has been legal since 1973. In accordance with the landmark *Roe v. Wade* Supreme Court decision, the state may not interfere with the practice of abortion in the first trimester. To protect the health of the mother, a second-trimester abortion may be performed, and limiting restrictions have been declared unconstitutional. In fact, since legalized abortion in the United States, the maternal mortality rate has fallen considerably.

The primary method used for elective abortion in the first trimester is vacuum aspiration under local anesthesia. Dilation and evacuation can be used in the second trimester and is done under either local or general anesthesia. For pregnancy after 18 weeks, hypertonic saline solution is instilled into the amniotic cavity, or prostaglandins may also be used to induce labor. The prostaglandins used most often are E_2, as a vaginal suppository, and 15-methyl prostaglandin F_{2alpha}, as an IM injection. They are given at 2- to 3-hour intervals until evacuation. Both instillation of hypertonic saline and prostaglandin administration are difficult for the patient. Abortions are rarely performed after 20 weeks, because fetal viability is considered to be at 24 weeks.

Complications from abortions increase as gestation increases and include retained products of conception and unrecognized ectopic pregnancy. Currently, most abortions (90%) are performed before 12 weeks of gestation, and there is an overall mortality rate of 1:100,000. Patients should be counseled to obtain an abortion as early as possible if this is their choice.

In September 2000 the U.S. FDA approved mifepristone (RU486), a synthetic antiprogestational-antiglucocorticoid pill as an oral abortifacient. RU486 is used to induce abortion during the first 9 weeks of pregnancy. RU486 is given as a single dose of 200 mg and has a success rate of 85%, but if it is followed in 36 to 48 hours with a prostaglandin vaginal suppository the success rate in terminating pregnancy is 95%. Adverse effects include nausea, vomiting, bleeding, and abdominal pain.

Patient Teaching

Contraception is not just a method; it is part of a life decision and future plan. There is no ideal method for every woman, but because so many options are available today, contraception can be tailored for each person's lifestyle, motivation, and partner's participation. Research in reproductive biology may provide less invasive and more effective methods in the future. Maximum outcome still depends on consistent and accurate use—the human element.

Every heterosexual woman should consider contraception as part of her overall personal health maintenance just as every woman should include the following in her health regimen: an annual gynecological exam, BSE, balanced nutrition, smoking and alcohol cessation, weight control, mental health, exercise, and risk reduction. Fertility control and good health work hand in hand for the patient and her future plans.

COMMON PROBLEMS

BREAST CANCER

Cancer of the breast is the most common cancer in American women and accounts for approximately 30% of all cancers in women in the United States. Centers for Disease Control and Prevention (CDC) statistics indicate that 230,480 women were diagnosed with breast cancer in 2011, and in that same year, 39,520 women were expected to die from it (most recent statistics available). Breast cancer is second only to lung cancer as the leading cause of cancer death among women and is the main cause of death in women aged 40 to 44 years. During the 1980s, there were yearly increases in breast cancer incidence rates, probably as a result of an increase in screening; but this rise has slowed over the past few years. Mortality rates have been decreasing since 1990, most likely because of earlier detection and advances in treatment.

Epidemiology and Causes

In general, the lifetime risk of a woman getting breast cancer is 1 in 8, and the lifetime risk of dying from breast cancer is 1 in 28. In North America, the lifetime odds of a woman getting breast cancer are 1 in 6 for non-Hispanic white women, 1 in 14 for African American women, 1 in 21 for New Mexican Hispanics, and 1 in 40 for New Mexican American Indians. The risk increases with age: It is low in women in their 20s and 30s and continues to rise each decade, with the median age for breast cancer diagnosis at 64 years of age. Increasing age and other risk factors (see Risk Factors 14.1) have been associated with the development of breast cancer, but these factors explain only 50% of cases. All women have the potential for the development of breast cancer. Screening recommendations and guidelines are presented in Screening Recommendations/Guidelines 14.1.

Pathophysiology

Breast cancer is a disease of various cell populations, with different growth rates, cell surface markers, and tendencies to metastasize. It is often considered a systemic disease at the time of first diagnosis, because many patients with "early" breast cancer already have established but clinically occult micrometastases, reflecting the importance of adjuvant hormonal therapy (e.g., tamoxifen, anastrozole). Invasive breast cancer is often preceded by carcinoma in situ (CIS) lesions of either ductal or lobular

Risk Factors 14.1 Breast Cancer

Major Risk Factors

- Female gender
- Increasing age (>50 years)
- Personal history of breast cancer (in situ or invasive)
- Family history of breast cancer in a first-degree relative (parent, sibling, or child)
- Residing in North America or Northern Europe

Moderate Risk Factors

- Biopsy-confirmed atypical hyperplasia
- Early menarche (<age 12 years)
- Late menopause (>age 55 years)
- Nulliparity or first live-birth at a late age (>30 years)
- Long-term use of postmenopausal hormone therapy, especially unopposed estrogen
- Exposure to high-dose radiation
- History of ovarian or uterine fundus cancer
- Higher education and socioeconomic status

Possible Risk Factors

- High-fat diet and weight gain
- Alcohol consumption (two or more drinks/day)
- Physical inactivity
- Cigarette smoking, especially during adolescence
- Exposure to pesticides and other chemicals

Screening Recommendations/Guidelines 14.1 Breast Cancer

The American Cancer Society (ACS) recommends the following screening for the early detection of breast cancer in those who are asymptomatic (ACS does not specify an age at which screening should be terminated). Women age 20–39:

- Clinical breast exam performed by the practitioner every 3 years.
- BSE performed by the patient monthly.

Women age 40 and older*:

- Clinical breast exam performed by the practitioner annually. (This should be performed close to the scheduled mammogram.)
- Mammogram performed annually.
- BSE performed by the patient monthly.

The National Cancer Institute (NCI) recommends screening (mammogram and clinical breast exam) every 1–2 years for women in their 40s. A review of clinical trials by the NCI showed there to be insufficient data to evaluate the effectiveness of screening mammography in women age 70 and older.

*U.S. Preventive Services Task Force new recommendation is age 50; however, it has sparked much controversy.

distribution, as discussed under Prognosis. However, a malignant breast mass may be present for many years before the initial diagnosis, and it is not uncommon for invasive disease to be identified at the time of diagnosis, rather than a premalignant lesion. Breast cancers spread by contiguous, lymphatic, and/or vascular channels. The most common areas of metastasis are the regional lymph nodes, lung, skin, bone, liver, and brain.

The development of frank breast cancer may also be preceded by a variety of benign breast conditions characterized by multicentric proliferation of breast tissue. Several genetic mutations have been recognized in both precancerous and cancerous lesions, including genes affecting cellular proliferation, DNA mismatch repair, or the conversion of procarcinogens to carcinogenic compounds. Two of the most widely publicized breast cancer susceptibility genes are the tumor suppressor genes *BRCA1* and *BRCA2,* first cloned in the mid-1990s. These gene products are involved in the repair of double-stranded DNA breaks, and mutations predispose individuals not only to breast cancer in women and men, but also to cancers of the ovary, pancreas, and even prostate. However, *BRCA1/BRCA2* mutations are quite rare, accounting for only one-fifth of familial breast cancer cases.

The Knudsen hypothesis of malignant transformation is often credited with the pathogenesis of breast cancer. In this model, at least two sequential genetic "hits" or mutations that interfere with DNA repair are thought to underlie malignant transformation of normal breast tissue, which ultimately loses its capacity for programmed cell death (apoptosis). In familial cancers, the first of these hits is thought to be the inherited germline mutation, and the second mutation may be induced by an environmental carcinogen or related to one of many other predisposing risk factors.

Clinical Presentation

Subjective

History and risk assessment should include age, ethnicity, education and socioeconomic status; breast lump or area that feels denser (with or without pain), tenderness, dimpling, nipple retraction, nipple ulceration, erythema or *peau d'orange* ("orange peel"); change in breast shape, breast enlargement, and/or an alteration in the vein pattern of the breast tissue; nipple discharge; and one or more palpable enlarged axillary lymph nodes. The date of onset, location, and duration of any change in the patient's breast and if trauma occurred should also be elicited.

Assessment should also include any systemic symptoms, especially those that may indicate metastases to the skeleton (bone pain, fracture), spinal cord (localized and radicular back pain, lower extremity weakness, paresthesias, paralysis, bladder/bowel dysfunction), brain (headache, seizure, mental status changes, vision and

speech defects, sensory loss/muscle weakness, ataxia, persistent nausea/vomiting), bladder or bowel (incontinence), lungs (chest pain, dyspnea on exertion, shortness of breath, cough), and liver (abdominal pain or distention, jaundice, weakness, fatigue, nausea, vomiting, appetite, weight loss, lower extremity edema).

The medical history should include illnesses, especially a previous breast cancer, a benign or preinvasive breast condition, or another cancer such as ovarian cancer; prior radiation exposure; medications; allergies; diet and other health habits (fat intake, alcohol consumption, cigarettes, weight gain, exercise); and past surgical history, especially breast biopsy and/or surgery. Questions should be asked regarding gynecological and obstetric history: age at menarche; age at menopause; last menstrual period; pregnancy history (age when first full-term pregnancy occurred, abortions, miscarriages); and use of hormone therapy, particularly unopposed estrogen. Frequency of mammograms and date of last mammogram; results of previous mammograms, noting any abnormalities; other related diagnostic tests and results; and frequency of clinical breast exams and breast self-exams should be determined. Family history questions should include information regarding a first-degree relative with a history of breast cancer (note age at diagnosis and bilaterality of disease) and a family history of ovarian cancer associated with breast cancer.

Objective

A thorough physical exam with a focus on the breasts and axillary and supraclavicular lymph nodes should be performed. Inspect for contour, symmetry, skin changes, and nipple changes. In premenopausal women, this assessment should be done during the follicular phase of the menstrual cycle, when hormone levels are low and less likely to affect the breast tissue. Examination of the breasts includes inspection and palpation in the upright and supine positions. The size, location, mobility, and consistency of any palpable breast mass or dense area and lymph nodes should be documented. Any breast changes noted on inspection and the characteristics of any nipple discharge are also recorded. Pain is present in fewer than 10% of patients with cancer.

Clinical manifestations of breast cancer include those stated above, but some patients may present only with an abnormality detected on a mammogram. The Patient's Voice 14.1 illustrates the individuality of symptoms.

The Patient's Voice 14.1

A Breast Mass

One Patient's Voice

It was on my 48th birthday that I noticed a slightly tender enlargement in my left breast. I had consistently checked my breasts for years during my period. I had no family history for breast cancer and never experienced breast tenderness or lumps on a regular basis. Even before my one pregnancy at age 34, I had never experienced significant breast soreness. My nurse practitioner saw me the next day and stated that she could feel something. She sent me for a mammogram. I had one 2 years ago, so I was sent to the same place. Two days later, I was told there are "changes" and I was referred to a surgeon. I did not know what that meant, except I knew it could be serious. I wanted to do everything they told me to do. I wanted to get better. I had a biopsy and then shortly after, a "lumpectomy." I was told I was very lucky because although the biopsy was positive for cancer, they said my "nodes" were cancer free. I was told I would need radiation therapy since I only had the lump removed. I experienced too much stress and fear at that time in my life. My yoga classes were very important to me then because they helped me relax and heal. I have been going for 7 years since the surgery and now teach yoga too. I know I was lucky and grateful that my nurse practitioner could see me the day after I felt the lump. Waiting is so stressful.

Another Patient's Voice

I went for my annual mammogram and later got the call; I was referred to a breast specialist and had a biopsy. On my 45th birthday, I got the news that I had bilateral breast cancer. I have had a bilateral mastectomy, and almost a year of treatment, first chemo and now radiation. I have a young son and husband. This will be the first Christmas since my diagnosis and I am grateful to be here. Having this diagnosis made me rethink the important things in life. I have slowed down and appreciate all the people in my life. I know people say this, but the diagnosis of breast cancer has really been a gift. I appreciate the small things, like a beautiful sunset, the gentle breeze in my face, and the love of family and friends. I don't take life for granted any more!

Diagnostic Reasoning

Diagnostic Tests

A diagnostic mammogram is necessary in any woman with a palpable breast mass, suspicious nipple discharge, or a suspicious area on a screening mammogram. A spot compression flattens and isolates a lesion. A diagnostic mammogram determines the needs for subsequent testing, and it determines if other suspicious nonpalpable areas are present in one or both breasts.

Suspicious areas on a mammogram include (1) asymmetry with definitive borders or discernible masses; (2) architectural distortion (a "pulling in" of breast structures) not resulting from previous surgery; (3) a nodule that is more radiodense, irregularly shaped, and has unclear margins; (4) calcifications that are irregularly shaped, clustered, and of varying sizes; (5) skin changes such as a thickening or retraction; (6) spiculations (needle-like); and (7) axillary lymph nodes more than

2 cm and/or intramammary lymph nodes more than 2 cm in diameter.

Additional studies that may be scheduled to further delineate the abnormality are ultrasound, ductal lavage, and galactography or ductography. An ultrasound, which differentiates solid from fluid-filled masses, may distinguish between benign and malignant disease. It may better visualize abnormalities in patients with dense breast tissue (women younger than age 30–35 years) and is used in place of mammography in pregnant patients. Genetic testing for the *BRCA1* and *BRCA2* gene is expensive and done only in women with a high suspicion of a familial breast–ovary cancer syndrome who have undergone extensive pretest (and posttest) counseling.

Mammography views, using the Eklund technique, are used in a patient with a breast implant to provide additional views behind the implant. Galactography or ductography is used in the presence of serous or bloody nipple discharge without a palpable mass to visualize an intraductal lesion; however, it cannot distinguish between benign and malignant disease.

A biopsy is performed next. Suspicious areas noted on a mammogram or ultrasound must be submitted for biopsy for a definitive tissue diagnosis. A mammogram may not always result in a visible lesion; therefore, all clinically suspicious palpable masses must be submitted for biopsy whether or not seen with mammography.

The patient should be referred to a surgeon for further evaluation at this point. One or more of the following biopsy techniques may be done in the outpatient setting, usually under local anesthesia:

- *Fine-needle aspiration* (FNA). FNA may be performed by a primary-care provider experienced in the procedure. A 21- or 22-gauge needle is used to aspirate a cyst or extract cells from a palpable solid lesion for analysis. It is easy to perform and provides rapid results with little trauma to the tissue. It is highly reliable when used as an adjunct to the clinical exam and mammogram. On the negative side, it requires an experienced cytopathologist, may yield false-negative results, and does not differentiate in situ from invasive cancer. A stereotactic or ultrasound-guided biopsy can be performed on nonpalpable lesions.
- *Core-needle biopsy.* A large-gauge cutting needle is used to provide a large core of tissue from the lesion for histological examination. The results of a core-needle biopsy are as accurate as those of a surgical biopsy, but the procedure is less invasive with better cosmetic results. A stereotactic or ultrasound-guided biopsy can be performed on nonpalpable lesions.
- *Incisional biopsy.* This procedure may be done when a mass is very large and cannot be removed without major surgery. A wedge of tissue is removed for histological examination.
- *Open surgical excisional biopsy (lumpectomy).* This procedure involves the entire removal of a palpable mass or a nonpalpable lesion (after stereotactic or ultrasound-guided biopsy or mammographic needle localization). To qualify as a lumpectomy, lesions suggestive of cancer should be removed with a margin of at least 1 cm of normal tissue. X-ray films of needle-localization specimens are obtained to confirm removal of mammographically detected abnormality. A postexcision mammogram should confirm complete excision. The open surgical excisional biopsy provides complete pathological assessment but may result in poor cosmesis.

If there is suspicion of inflammatory breast cancer or Paget's disease, a skin biopsy or nipple biopsy should be done at the time of the breast mass biopsy.

Prognosis Preinvasive breast cancers include ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS). DCIS has malignant potential but infrequently disseminates; therefore, approximately 98% of patients are cured with local–regional therapy (total mastectomy or breast-conserving surgery and radiation therapy). The addition of tamoxifen (Nolvadex) decreases the incidence of subsequent invasive disease. LCIS has a propensity for bilaterality, multicentricity, and a 25% to 40% risk for development of subsequent invasive cancer. It is managed with close surveillance, a bilateral mastectomy, or chemoprevention (tamoxifen).

Invasive breast cancers have the potential to disseminate through lymphatic and vascular channels to other organs. Most of these cancers are adenocarcinomas. Approximately 80% are infiltrating ductal carcinomas, and 10% are invasive lobular carcinomas. Their prognosis is identical. Invasive lobular carcinoma differs in its slightly greater tendency toward bilaterality and metastasis to meningeal and serosal surfaces. Other histological subtypes are pure mucinous, tubular, medullary, and papillary carcinomas. These subtypes have a slight to somewhat better prognosis resulting from a smaller risk of dissemination. Paget's disease of the breast and inflammatory breast carcinoma are rare. Paget's disease of the breast, unilateral eczema of the nipple, is always associated with DCIS or invasive ductal carcinoma. Inflammatory breast carcinoma has the poorest prognosis of all breast cancers.

Prognostic factors, or tumor-related features, are biological measures done on the breast tissue specimen. They serve as guides for the oncologist in determining systemic adjuvant therapy for the breast cancer patient. In addition to the histological types of invasive breast cancer, lymph node status (0, 1–3, 4 or more, or 10 or more [range of good to poor prognosis]), tumor size (1 cm or less in diameter [good prognosis]), and histological differentiation (range of well differentiated [low grade] to poorly differentiated [high grade]) are the standard predictors of risk of recurrence and survival. High-grade tumors are poorly

differentiated and carry a worse prognosis, whereas lower grade, well-differentiated tumors carry a more favorable prognosis. With reference to these factors, patients with breast cancer have an excellent prognosis if they have the following features: DCIS, negative lymph nodes with an invasive tumor size less than 1 cm in diameter, and special histological subtypes of breast cancer (e.g., pure tubular) less than 3 cm in diameter.

Patients who have potentially high recurrence rates and who would, therefore, greatly benefit from systemic therapy have the following features: positive regional lymph node(s) or invasive tumors more than 2 cm in diameter even with negative lymph nodes. Breast cancer patients who have a tumor that is poorly differentiated have an increased risk of recurrent disease, but they may also have a greater response to chemotherapy.

Hormone receptor status—for example, the presence or absence of estrogen and progesterone receptors—is another important prognostic factor especially in guiding the oncologist in the selection of hormonal therapy. More patients with breast cancer respond favorably if estrogen receptor levels are high and if both estrogen and progesterone receptors are positive. Also, a positive status of the pS2 protein (an estrogen-regulated secretory protein expressed mainly by estrogen receptor–positive tumors) is indicative of a better prognosis in women with both negative and positive lymph nodes.

Other prognostic factors such as those indicative of the proliferative capacity of the tumor (mitotic index, thymidine labeling index, S-phase fraction, ploidy, and Ki-67), nuclear grade, tumor necrosis, tumor microvessel density, peritumoral lymphatic vessel invasion, the protease cathepsin D, and proto-oncogenes (*ERBB2 [HER-2/neu,* c-*erbB-2]* and c-*myc*), and *p53* (a tumor-suppressor gene) expression may be helpful in predicting response to treatment. For example, the overexpression of c-*erB-2* may predict that a breast cancer patient may be resistant to certain chemotherapy agents and possibly to hormonal therapy. It may also predict a shorter disease-free interval.

Reference to these additional prognostic factors, along with the standard ones, may be valuable in determining the need for systemic therapy in women who have an intermediate prognosis, such as node-negative patients with invasive tumors 1 to 2 cm in diameter.

Staging After the diagnosis of breast cancer is confirmed, the stage of the disease is evaluated (Table 14.3). Certain laboratory tests may determine distant metastasis. A complete blood count may show an abnormality of white blood cells and platelets, and a low hematocrit may indicate bone marrow infiltration and occult metastatic disease. Liver enzymes and calcium and phosphorus abnormalities may indicate occult liver metastasis and/or bone metastasis. Tumor marker (e.g., CEA, Ca 27.29) abnormalities may indicate occult metastatic disease. If the tumor marker is abnormal, it will be useful in later assessing response to treatment (disease progression or recurrence). These radiology exams also determine distant metastasis: A chest x-ray abnormality may indicate lung metastasis, and a bone scan/skeletal survey or liver scan, if signs, symptoms, or laboratory tests warrant, may suggest an abnormality.

Differential Diagnoses

Several differential diagnoses should be considered. With breast cancer, a palpable mass is usually persistent, unilateral, solitary, discrete, firm, irregularly shaped, nontender, and may or may not be fixed to the skin or underlying tissue. Breast distortion and skin changes such as diffuse erythema, edema, *peau d'orange,* dimpling, nipple retraction, or nipple ulceration are also indicative of cancer. If present, nipple discharge is spontaneous, persistent, unilateral, localized to a single duct, watery or sticky, and clear, sanguineous, serosanguineous, or serous in color. Lymph nodes suggestive of a malignancy are large, firm, or fixed.

Fibrocystic changes (cystic breast disease, chronic cystic mastitis, or mammary dysplasia) may be difficult to distinguish from breast cancer by palpation alone. *Fibrocystic changes* are so common that they are considered a normal variant of breast tissue. However, if accompanied by significant pain, nipple discharge, or palpable physical exam findings that raise suspicion for breast cancer, the condition is termed *fibrocystic disease.* Cystic areas are unilateral or bilateral, somewhat more diffuse, 1 mm to many centimeters in diameter, soft, and mobile; they may also be tender and painful due to stromal edema, dilation of ducts, and accompanying inflammation. These cysts are hormonally regulated and may be worse premenstrually; this variation with menses usually distinguishes fibrocystic changes from fibroadenomas and breast cancer. Aspiration of clear fluid with complete disappearance of the cyst on follow-up examination or the appearance of a fluid-filled cavity on ultrasound confirms the diagnosis. These changes are most common in patients aged 30 to 55 years.

Fibroadenomas are benign, solid masses of fibrous and glandular tissue that are often confused with breast cancer. These masses may be isolated or multiple and are typically firm, nodular, usually well defined, freely mobile, and possibly tender. Growth of the tumor is hormonally stimulated; thus, it may grow rapidly during pregnancy, lactation, or hormonal manipulation. These are most common in younger patients and are not associated with an increased risk of breast cancer if in their simple form. However, *complex fibroadenomas* (i.e., containing cysts greater than 3 mm in size, calcification on mammography, or histological evidence of sclerosing adenosis or papillary apocrine changes) have been associated with a greater risk of breast cancer when accompanied by proliferation of surrounding glandular tissue.

Table 14.3 TNM Staging of Primary Breast Cancer

Stage	TNM Staging	Description
	TX, NX, MX	Primary tumor (T), regional lymph nodes (N), or distant metastasis (M) respectively cannot be assessed (X)
0	Tis, N0, M0	Carcinoma in situ or Paget's disease of nipple with no tumor
I	T1, N0, M0	Tumor ≤2 cm; no regional lymph node metastasis; no distant metastasis
IIA	T0, N1, M0	No evidence of tumor, metastasis to moveable ipsilateral axillary lymph node(s); no distant metastasis
	T1, N1, M0	Tumor ≤2 cm; metastasis to moveable ipsilateral axillary lymph node(s); no distant metastasis
	T2, N0, M0	Tumor >2– ≤5 cm; no regional lymph node metastasis; no distant metastasis
IIB	T2, N1, M0	Tumor >2– ≤5 cm; metastasis to moveable ipsilateral axillary lymph node(s); no distant metastasis
	T3, N0, M0	Tumor >5 cm; no regional lymph node metastasis; no distant metastasis
IIIA	T0, N2, M0	No evidence of tumor, metastasis to ipsilateral axillary lymph node(s) fixed to one another or to other structure; no distant metastasis
	T1, N2, M0	Tumor ≤2 cm; metastasis to ipsilateral axillary lymph node(s) fixed to one another or to other structure; no distant metastasis
	T2, N2, M0	Tumor >2– ≤5 cm; metastasis to ipsilateral axillary lymph node(s) fixed to one another or to other structure; no distant metastasis
	T3, N1 or N2, M0	Tumor >5 cm; metastasis to ipsilateral axillary lymph node(s) fixed to one another or to other structure; no distant metastasis
IIIB	T4, any N, M0	Tumor of any size with direct extension to chest wall (excluding pectoral muscle) and/or edema (including *peau d'orange*) or ulceration of the skin or satellite skin nodules confined to the same breast, or inflammatory carcinoma; any nodal status as described above; no distant metastasis
IV	Any T, N3, M0	Any tumor status as described above; metastasis to ipsilateral internal mammary node(s); no distant metastasis
	Any T, Any N, M1	Any tumor or nodal status as described above; distant metastasis, including metastasis to ipsilateral supraclavicular lymph nodes

Hamartomas composed of stromal and epithelial tissue and *tubular adenomas* consisting of ductal tissue are less common benign tumors of the breast that may present similarly on physical exam but are not considered cancerous. Fat necrosis or *panniculitis* is another benign condition and is typically trauma induced. The mass is firm and possibly tender, often with calcification seen on mammography. *Diabetic mastopathy* results in a breast lump with a dense mammographic appearance but benign histology consisting of keloidal scar tissue and a lobular, lymphocytic inflammation. This is most often seen in women with type 1 diabetes mellitus who also suffer from additional end-organ microvascular damage such as retinopathy or neuropathy.

Intraductal papilloma is a benign condition with a small, usually solitary and nonpalpable mass in one mammary duct with an associated spontaneous sanguineous or serosanguineous nipple discharge. If large enough to palpate, the mass is most often close to or beneath the areola, soft, mobile, 1 to 3 cm in size, poorly delineated, nontender, and sometimes associated with skin dimpling. It is most common in patients aged 35 to 55 years. Solitary papillomas are not considered premalignant; however, diffuse papillomatosis characterized by the formation of multiple papillomas carries with it a greater risk of eventual breast cancer.

Duct ectasia is a benign condition involving inflammation of a subareolar duct, which may produce subareolar erythema and swelling, a mass with nipple retraction and/or dimpling, dull nipple pain, tenderness, burning, and itching. Nipple discharge is pasty and straw-colored, cream-colored, green, or brown. It is most common in perimenopausal or postmenopausal patients who have had children and have nursed.

Ductal hyperplasia without atypia is distinguished from ectasia, in that it is the most common benign breast lesion clearly associated with an increased risk of breast cancer. Epithelial cell proliferation along the basement

membranes of the ducts, although benign histologically, varies in size and shape. *Atypical ductal hyperplasia* is associated with an even greater risk of breast cancer (up to sixfold in women with a strong family history of breast cancer), especially in premenopausal women. It is characterized by a loss of apical-basal cellular organization within ductal tissue. *Atypical lobular hyperplasia* is even more concerning because it is qualitatively (albeit not quantitatively) equivalent to LCIS, which is considered a precursor lesion to invasive breast cancer.

Sclerosing adenosis, most common in patients aged 35 to 45, is a benign proliferation of the breast epithelium with increased fibrous and glandular tissue, with hard, pea-sized nodules throughout the affected area. There is mild to moderate pain and swelling premenstrually. The presence of this condition has also been associated with an increased risk of breast cancer. *Radial scars* are another benign histological finding consisting of a fibroelastic core from which ducts and lobules radiate outward. If large, these lesions may appear similar to spiculated carcinoma on mammography and are indeed associated with an increased risk of breast cancer.

Mastitis, a benign infectious condition of the breast that may or may not include formation of an abscess, presents with redness, induration, pain, possible purulent nipple discharge, fever, chills, and myalgia. It is more common during lactation.

Management

The patient diagnosed with breast cancer is referred to oncology specialists, such as a surgeon, medical oncologist, and/or radiation oncologist for treatment of the disease (Table 14.4). The choice of treatment is influenced by such factors as tumor stage, estrogen and progesterone receptor levels and other prognostic factors, patient age, menopausal status, and the patient's general health. When detected in early stages, invasive breast cancer that is treatable with surgery, radiation therapy, chemotherapy, and/or hormonal therapy may be highly curable.

Surgical Management

The initial surgical management of stage I and stage II breast cancer includes one of several types of surgery. Breast-conserving surgery involves a partial mastectomy, lumpectomy, wide excision, segmental mastectomy, or quadrantectomy with a separate axillary node dissection and radiation therapy to the breast. A modified radical mastectomy is a total mastectomy with an axillary node dissection. Breast-conserving surgery removes a portion of the breast tissue, whereas a total mastectomy removes all but approximately 2% to 3% of the breast tissue. The survival rates for these two surgical treatment options are equivalent.

The type of initial surgery for a particular patient usually depends on the location and size of the tumor, breast size, characteristics of the disease on mammography, patient age, and the patient's feelings regarding breast preservation. Breast-conserving surgery may not be an option if there is a tumor beneath the nipple; a large tumor-size-to-breast-size ratio; multicentricity; extensive intraductal carcinoma; diffuse malignant-appearing calcifications on the mammogram; or contraindications to radiation therapy such as pregnancy, collagen-vascular disease, or prior radiation therapy to the breast or chest wall.

After a mastectomy, the patient may choose immediate or delayed breast reconstruction with a submuscular saline implant or expander, a transverse rectus abdominis myocutaneous flap, or a latissimus dorsi flap. Depending on the type of breast surgery, the adverse effects may be wound infection, seroma, bleeding or hematoma, phantom breast syndrome (pain, numbness, or nipple itching), paresthesias, muscle atrophy, arm or shoulder weakness or stiffness, lymphedema, phlebitis, or a winged scapula (protruding scapula resulting from intraoperative injury to the long thoracic nerve). A new technique under investigation, lymphatic mapping and sentinel lymph node biopsy, may eliminate the need for an axillary lymph node dissection in some patients and thus prevent some of these adverse effects. The sentinel node (the first lymph node along a lymphatic drainage pathway) is identified after peritumoral injection with a radioisotope or vital blue dye. If the sentinel node is negative for metastatic disease, a complete axillary lymph node dissection is not indicated.

Radiation Therapy

Radiation therapy is indicated for local–regional control of the primary breast cancer or palliation of metastatic disease. After breast-conserving surgery, primary treatment includes external-beam radiation to the entire breast with or without a boost (interstitial radioactive implant or external-beam radiation) to the primary site. After a modified radical mastectomy, radiation therapy to the chest wall and regional lymph nodes is considered in women at high risk of local–regional recurrence, including those with known residual disease or four or more involved lymph nodes. Patients undergoing an axillary lymph node dissection generally do not require radiation therapy to the axilla. Internal mammary lymph nodes may be treated, and patients with four or more positive lymph nodes may require supraclavicular radiation therapy to reduce the risk of supraclavicular lymph node recurrence. A pregnant patient with breast cancer can begin radiation therapy after delivery. Potential adverse effects of radiation therapy include fatigue, edema, breast pain or tenderness, skin reactions, brachial plexopathy, radiation pneumonitis, and myocardial damage if the left breast is treated. Secondary malignancies, such as sarcomas, leukemias, and lung cancer, are rare, although smokers have an increased risk of lung cancer in the ipsilateral lung.

Table 14.4 Management of Invasive Breast Cancer

Stage	Surgery/Radiation Therapy	Adjuvant Therapy
I	Breast-conserving surgery with separate axillary node dissection and radiation therapy (RT) to the breast *OR* Modified radical mastectomy (MRM)	Suitable ER-negative patients: Adjuvant chemotherapy ER-positive patients: adjuvant chemotherapy or tamoxifen 20 mg daily
II	Breast-conserving surgery with separate axillary node dissection and RT to the breast *OR* MRM Consider RT to the chest wall and regional nodes for patients at high risk of local-regional recurrence, including those with known residual disease or four or more involved nodes	*Node-positive patients:* Premenopausal and postmenopausal (ER-negative) patients: adjuvant combination chemotherapy with or without tamoxifen Postmenopausal patients with positive hormone receptors: Tamoxifen alone *Node-negative patients:* ER-negative or ER-positive patients with large tumors: Adjuvant chemotherapy ER-positive patients: adjuvant chemotherapy or tamoxifen 20 mg daily
IIIA	*In operable cases:* MRM with or without RT or radical mastectomy (removal of breast tissue, all axillary lymph nodes, and underlying chest muscle) with or without RT RT should be given because of the high risk of local recurrence; postoperative external beam RT to chest wall with or without boost as necessary for positive or close margins	Combination chemotherapy with or without hormones Neoadjuvant therapy: chemotherapy may be given preoperatively if primary resection is not feasible or technically difficult
IIIB	Biopsy for diagnosis and estrogen/progesterone receptors (ER/PR) If good response to chemotherapy or hormonal therapy: Local therapy with surgery and/or RT If poor response to chemotherapy or hormonal therapy: Palliative RT	Chemotherapy/hormonal therapy: Combination chemotherapy with or without hormones *OR* tamoxifen (if ER/PR receptors positive)
IV	Biopsy for diagnosis and ER/PR receptors External beam RT or palliative mastectomy to control local disease	If visceral disease minimal or absent and ER/PR receptors positive: Hormonal therapy (as initial therapy) For premenopausal patients: Tamoxifen or oophorectomy For patients who relapse after a period of response or prolonged stability on initial hormone therapy: megestrol 40 mg 4 times daily or anastrozole 1 mg daily or letrozole 2.5 mg daily If visceral disease present or ER/PR receptors negative: Combination chemotherapy
Inflammatory Breast Cancer	Refer to options for stage IIIB or IV	Refer to options for stage IIIB or IV

Breast surgery or radiation therapy may make subsequent mammograms difficult to interpret. Masses (postoperative fluid collections and scarring), edema, skin thickening, and calcifications may be seen on these mammograms, especially during the first 6 months after treatment. During the next 6 to 12 months, slow resolution of these changes takes place and stability occurs within 2 years.

Chemotherapy

Antineoplastic chemotherapy as adjuvant therapy is indicated for the eradication of micrometastatic disease that may be present at the time of the original diagnosis. It should be initiated within 6 weeks (preferably less) of surgery (radiation therapy would follow the chemotherapy). Combination chemotherapy is the standard of care for the treatment of primary breast cancer because it most likely would overcome the potential for drug resistance. The most widely used regimens are CMF (cyclophosphamide [Cytoxan], methotrexate [amethopterin], and fluorouracil [Adrucil]), CAF (FAC) (cyclophosphamide, doxorubicin [Adriamycin], and fluorouracil), and AC (doxorubicin and cyclophosphamide) with or without sequential paclitaxel (Taxol). Other regimens are CMFVP (CMF and vincristine [Oncovin] and prednisone [Deltasone]), CFM (CNF, FNC) (cyclophosphamide, fluorouracil, mitoxantrone [Novantrone]), NFL (mitoxantrone, fluorouracil, leucovorin [Wellcovorin]), sequential Dox-CMF (doxorubicin followed by CMF), VATH (vinblastine, doxorubicin, thiotepa [Thioplex], and fluoxymesterone [Halotestin]), and vinorelbine (Navelbine) plus doxorubicin.

Second-line or later therapy, in the event of disease progression or recurrent disease, includes agents such as vinorelbine, paclitaxel, docetaxel (Taxotere), or gemcitabine (Gemzar). Some of the more common potential adverse effects of chemotherapy include myelosuppression, nausea and vomiting, anorexia, mucositis, alopecia, fatigue, and neurotoxicity. Less common toxicities include hemorrhagic cystitis (alkylating agents), cardiomyopathy (anthracyclines), thromboembolic events, and early menopause (in premenopausal patients). Paclitaxel and docetaxel may also produce myalgia and rare allergic reactions; docetaxel may cause cumulative fluid retention and symptomatic pleural effusions. A rare complication of antineoplastic chemotherapy may be the development of secondary leukemia. Hematopoietic growth factors (erythropoietin, granulocyte colony-stimulating factor [Neupogen], granulocyte-macrophage colony-stimulating factor [Leukine], and oprelvekin [Neumega]) and cytoprotective agents such as amifostine (Ethyol) and dexrazoxane (Zinecard) may help to prevent or reduce some of the chemotherapy-related complications. Pamidronate (Aredia), a second-generation aminobisphosphonate, is used in cases of osteolytic bone metastases to prevent pathological fractures, cord compression, the need for radiation therapy or surgery to the bone, and hypercalcemia, and it significantly reduces bone pain. Pregnant breast cancer patients may receive antineoplastic chemotherapy during their third trimester or after delivery.

Monoclonal Antibodies

The newest treatment for metastatic breast cancer, trastuzumab (Herceptin), a recombinant DNA–derived humanized monoclonal antibody, is used as a single agent in second-line or later therapy for those patients with metastatic breast cancer whose tumors overexpress the HER2 protein. The combined regimen of trastuzumab and paclitaxel is used for the same patient populations who have not previously received chemotherapy for their metastatic disease. Potential adverse effects include cardiomyopathy, anemia and leukopenia, diarrhea, and infection.

Hormonal Therapy

Hormonal therapy includes the use of antiestrogens (tamoxifen), progestins (e.g., megestrol acetate), luteinizing hormone–releasing hormone (LHRH) agonists (e.g., leuprolide), or aromatase inhibitors (anastrozole and letrozole). Tamoxifen is the most prescribed of these agents, and the treatment period is 5 years. Because of its antiestrogenic effect, it is beneficial in breast cancer patients whose tumors have positive hormone receptors, with its greatest effect in those who have both estrogen-receptor (ER)–positive and progesterone-receptor (PR)–positive tumors. Tamoxifen also exhibits an estrogenic effect on the endometrium; therefore, it may increase the incidence of endometrial cancer. Potential adverse effects include mild nausea, hot flashes, menstrual irregularities, vaginal discharge, vaginal dryness and irritation, benign ovarian cysts, thromboembolic events, and ophthalmological toxicities.

Local Recurrent Disease

Local recurrent disease is usually indicative of widespread recurrence, especially in postmastectomy patients. Some patients initially treated with breast-conserving surgery and radiation therapy who later develop a local recurrence in the ipsilateral breast may be cured with surgery and/or radiation therapy. Prolonged survival is more likely if there is a chest wall recurrence less than 3 cm in diameter, axillary and internal mammary (not supraclavicular) lymph node recurrence, and a disease-free interval of more than 2 years after initial therapy. Treatment options for recurrent disease include surgery, radiation therapy, chemotherapy, and/or hormonal therapy. Surgery and/or radiation may be used for a local or visceral recurrence. In asymptomatic patients with a positive or unknown ER/PR status, and with absent or minimal visceral disease in one organ, tamoxifen in premenopausal and postmenopausal patients or oophorectomy (or LHRH agonists) in premenopausal patients may be the treatment option. In the event that a patient had an initial response to hormonal therapy but had a subsequent relapse, another type of hormonal therapy may be prescribed, such as tamoxifen, anastrozole, letrozole, Megace, androgens, LHRH agonists (for premenopausal patients), or aminoglutethimide. A subset of patients may respond to hormonal therapy withdrawal for approximately 10 months before switching to another form of hormonal therapy. Patients with positive visceral disease and a negative ER/PR status should receive chemotherapy. If a patient relapses a year or more

after receiving adjuvant treatment with CMF, this same regimen may be readministered. If the patient relapses after treatment with an anthracycline-containing regimen, she may be retreated with other agents mentioned earlier. Recurrent breast cancer treatment may be palliative in nature, such as the use of radiation therapy to relieve the pain of bone metastases.

Clinical Trials

At any stage of breast cancer, patients may be eligible for clinical trials designed to improve survival or decrease the morbidity associated with current standard therapy. Some patients with stages II, III, or IV may be considered as candidates for clinical trials of high-dose chemotherapy with bone marrow transplantation or hematopoietic stem cell support.

Follow-up and Referral

Depending on the breast cancer patient's risk for both local and distant recurrence, a history and physical exam may be done according to the following schedule: every 3 to 6 months during the first 3 years (more frequently during adjuvant therapy), every 6 months for the next 2 years, and annually after the fifth year (more frequently for patients at very high risk for recurrence).

A baseline mammogram should be done 3 to 9 months after tumor excision and at the completion of all treatment. Thereafter, it should be done at least annually to detect a recurrence in the ipsilateral breast of patients who had breast-conserving surgery or to detect a second primary in the contralateral breast of most breast cancer patients. Further testing such as bone scans, chest x-ray films, computed tomography scans, and liver function tests are ordered for symptomatic patients as indicated. Patients treated with tamoxifen should have routine pelvic examinations. If abnormal uterine bleeding occurs, further evaluation is warranted.

The 5-year relative survival rate for patients with localized breast cancer is 98.4%, for regional spread it is 84.6%, and for distant metastases it is 24.3%. The 10-year survival for localized breast cancer declines to 82%, and 15-year survival declines to 75%.

Patient Education

The primary-care clinician may be involved at various phases of the patient's care, for example, prediagnosis, diagnosis, treatment, and posttreatment. Therefore, the clinician is in a valuable position to teach the patient and significant others regarding breast cancer prevention and detection and to reinforce information about a breast cancer diagnosis and treatment options (including benefits and potential complications).

The patient should be taught the breast self-exam technique, which can be found at www.breastcancer.org. Screening recommendations should also be reviewed. If diagnosed at an early stage, breast cancer may be curable with standard treatment.

The breast cancer patient needs to learn how to prevent potential postsurgical and/or radiation therapy complications such as lymphedema. In this situation, the patient should be taught range-of-motion exercises for the involved arm and shoulder. The need to avoid infections, injuries, strains, and constrictions of the arm is stressed. Antineoplastic chemotherapy and other forms of breast cancer treatment can be teratogenic; therefore, the patient must be advised to use effective contraception during treatment.

The breast cancer patient should be taught about the pharmacological and nonpharmacological management for the adverse effects of potential chemotherapy, radiation therapy, or hormonal therapy. For example, the patient may be instructed to take medications such as ondansetron (Zofran) and Decadron to prevent delayed chemotherapy-induced nausea and vomiting and to perform techniques such as relaxation with guided imagery to prevent or minimize these symptoms. The patient may also be directed in the purchase of a breast prosthesis, mastectomy bra, or wig.

The patient diagnosed with breast cancer may face many physical and psychosocial issues, such as an alteration in body image and sexuality, a role change, anxiety, denial, anger, and depression. The clinician is in a prime position to counsel and support the patient and significant others and to direct them to the many breast cancer resources available to the public that offer individual and group counseling, among other services.

There is confusion in the lay literature about the role of dietary soy intake and the risk for breast cancer in both women with no history of breast cancer and those who have had the disease. Some clinicians discourage their patients from consuming soy. (See Nursing Research–Based Practice 14.1.)

MASTITIS

Mastitis is a general term that refers to inflammation of the breast. The terminology for the various types of mastitis can be confusing. There are overlapping definitions and contradictions in the literature. For purposes of this discussion, there are three general categories: puerperal mastitis, nonpuerperal mastitis, and periductal mastitis. Each category is defined further by an explanation of the cause of the mastitis.

Puerperal mastitis is a cellulitis that develops in the lactating or nonlactating breast after parturition. Epidemic puerperal mastitis was a hospital-acquired infection most commonly seen in the preantibiotic era. The most common contagion for epidemic puerperal mastitis is *Staphylococcus aureus. S aureus* is spread by cross transmission from neonate to mother, as well as cross transmission in the nursery. There is multiple duct involvement, which results in inflammation of several nonadjacent lobes of the breast. With the progression of rooming-in and the introduction of antibiotics, epidemic puerperal mastitis has become a rare occurrence.

Nursing Research–Based Practice 14.1

Enderlin, CA, et al. Dietary soy intake and breast cancer risk. *Oncol Nurs Forum* 36(5):531–539, 2009.

Breast cancer affects about one in every eight women at some point in their lives. There have been confusing reports of soy foods. Soybeans and other soy products are high in phytoestrogens and isoflavones. The isoflavones are structurally similar to human estrogen and have estrogenic properties. Members of some cultures who consume large quantities of soy products also have lower prevalence rates for breast cancer.

The researchers conducted a metasynthesis of the literature of the relationship between dietary soy intake and breast cancer risk. They reviewed a total of 34 studies that represented samples from 12 countries and multiple races and ethnicities. The studies were published between 1997 and 2008. The analysis of these studies indicates that the dietary intake of naturally occurring soy foods is safe for women without breast cancer. The safety of soy supplements, however, is unclear.

Sporadic puerperal mastitis is an acute process that is far more common in women who breastfeed rather than in those who bottlefeed. It usually occurs in the second to sixth week postpartum; however, it has been reported in patients even after breastfeeding for 1 year. It is hypothesized that the higher occurrence of mastitis in the earlier postpartum period is due to the prevalence of nipple and feeding problems at this time, a risk factor for the disease. Feeding problems are more likely to occur in first-time breastfeeding mothers.

Nonpuerperal mastitis is a rare disease, which is usually found in patients who are immunocompromised, have undergone radiation therapy, or have had an autoimmune disorder. It can also occur in neonates. It is common in late adolescence or early adulthood. Nonpuerperal mastitis is a ductal abnormality or a local manifestation of a systemic problem. Several pathological pathways may be involved including squamous metaplasia of the lactational ducts, periareolar abscesses, and cellulitis. Squamous metaplasia is the most common nonpuerperal mastitis. Mastitis can also be caused by several obscure pathogens or by a substance in the breast such as silicone. This disease usually presents a clinical picture of a palpable mass and known infectious process such as tuberculosis (TB) or syphilis. Nonpuerperal mastitis must always be examined for the risk of carcinoma.

Periductal mastitis has been referred to and cross-referenced under several other names, such as mammary duct ectasia, mastitis obliterans, plasma cell mastitis, comedomastitis, and secretory disease of the breast. The term *duct ectasia* refers to the dilated lactiferous ducts of the breast being filled with keratin and secretions. Periductal mastitis is the inflammatory process that occurs around these ducts. Some degree of duct dilation normally occurs with aging. Some researchers have suggested that periductal mastitis seen in younger patients represents a different disease from the more chronic clinical presentation seen in older women. The primary event of periductal mastitis is controversial. Some hypothesize that duct ectasia precedes the inflammatory process and vice versa. The disease is characterized by dilation of the subareolar ducts. The ducts become thick walled and surrounded by plasma cells. Inside the ducts there is a pasty, yellow-brown secretion, which is lipid-rich. The periductal regions become fibrotic and inflamed. This may be caused by rupture and leaking of the ducts themselves. Fat necrosis is often evident.

Epidemiology and Causes

The incidence of mastitis in breastfeeding women has been reported from 1% to 9%. One study found an incidence of 26% in a population of long-term breastfeeding mothers.

The causative organism of sporadic puerperal mastitis is *S aureus* in at least 50% of reported cases. *S aureus* is frequently found on skin and cultured from the neonate's mouth. Other organisms implicated in the infection are *Escherichia coli,* group A and group B *Streptococcus,* and *Mycobacterium tuberculosis.* TB mastitis occurs in populations in which TB is endemic.

There are a multitude of contributing factors for puerperal mastitis. Cracked, abraded, or otherwise damaged nipples provide a portal of entry for the microorganism. Patients who are having latch-on and positioning difficulty during feeding also increase their risk for both nipple skin disruption and milk stasis, which can lead to mastitis. Slow milk ejection reflex, engorgement, failure to empty the breast adequately, waiting too long between feedings, supplemental feedings, use of pacifiers, wearing a tight and restrictive bra, sleeping positions that constrict the breast, and weaning also contribute to a woman's risk of developing mastitis. Each of these situations can lead to blocked ducts and milk stasis. Unresolved milk stasis provides a medium for bacterial overgrowth.

Physiological and psychological stress are both significant risk factors for puerperal mastitis. Fatigue, improper nutrition, and life stress are predictors for breast infections. These situations lead to lower maternal immune defenses and an increased likelihood for the illness.

Periductal mastitis/mammary duct ectasia is seen primarily in perimenopausal and postmenopausal women. The peak incidence is between 40 and 49 years of age, but it can occur at any time after the menarche. The inflammatory process has been observed on microscopic exam in 30% to 40% of women older than age 50; however, clinical disease occurs much less frequently.

The actual incidence of the disease is unknown. Duct ectasia has a reported incidence of 5.5% to 25% as demonstrated on postmortem exams. A risk factor for periductal mastitis is cigarette smoking. The mechanism by which smoking increases the incidence of this disease is unknown, but there is a clear statistical link. Inverted nipples have been suggested to be a source of duct obstruction, which could lead to ectasia, but they have not been shown to be a risk factor.

The cause of periductal mastitis and ectasia is unknown. There may be an autoimmune explanation, but this has not been clarified. Infection by anaerobes and other bacteria may play a role, but this has not been verified either. Some patients with this mastitis do have bacteria in their nipple discharge.

Pathophysiology

The causative mechanism of the various forms of mastitis (puerperal, nonpuerperal, and periductal) has been discussed in the preceding text. However, the pathophysiology of the infectious process in the most common form, puerperal mastitis, is a classic example of a breakdown in the body's protective outer epithelial barriers. This results in entry of bacteria from the infant's mouth or mother's skin into her breast through cracked nipple skin or the nipple pores. With one or more lobes of the breast seeded, infection develops. Moreover, the symptoms of the disease, which include pain, tenderness, and maternal fatigue, contribute to further decreases in effective feeding practices and adequate emptying of the breast, thus worsening the infection. Milk of a mastitic breast has a higher than normal sodium and chloride content, and it is not unusual for an infant to refuse to nurse on that breast.

The infection of puerperal mastitis is primarily in the extraductal tissue, and thus breastfeeding through the infectious process generally poses no harm to the infant, provided skin breakdown has not resulted in frank bleeding from the nipples and there is no evidence of purulent nipple discharge. Purulent material may be present within the ducts, however. In addition, although bilateral infection is possible, mastitis is usually unilateral and localized to the upper outer quadrant of the affected breast. The incidence of mastitis progressing to a subareolar breast abscess has been reported to be as high as 4% to 11% in patients treated for the disease. It is much higher for those who do not seek treatment for mastitis.

Clinical Presentation

Subjective

The clinical presentation is acute in nature. The patient's first complaint is fatigue followed by the onset of flulike symptoms and breast tenderness. The involved breast segments may be red and warm. Patients describe the affected area with a range of being tender to painful. A fever of at least 100.0°F (37.8°C) can be expected with myalgia, malaise, and chills. Nausea and vomiting can accompany these symptoms.

Many patients with periductal mastitis are asymptomatic. Others present with breast tenderness or pain, a breast mass, nipple discharge, nipple retraction, a nonpuerperal breast abscess, or a mammary fistula. The pain is usually subareolar and noncyclical. The nipple discharge varies in color and may contain occult blood. It is most frequently green and sticky and occurs spontaneously. The mastitis can be unilateral or bilateral. Nipple retraction and noninflammatory masses occur more commonly in older women. Pain and abscesses tend to occur in younger women. Periductal mastitis and ectasia account for 3% to 12% of benign breast lumps. The pain is usually focused behind the areola and tends to be more severe in younger patients.

Objective

On examination, there are varying degrees of erythema and edema of the affected breast. The erythema is most commonly in a V-shaped distribution and may or may not feel hard. Sometimes there is purulent nipple discharge. There may or may not be a palpable blocked duct.

Diagnostic Reasoning

Diagnostic Tests

Milk cultures are rarely done in first-occurrence cases of mastitis because they are costly and may delay treatment. They are warranted with a recurrence or failure of initial treatment. A breast milk culture can be obtained by manual expression of a midstream, clean-catch specimen. Washing the nipple with water and sterile gauze preps the breast. The first 2 to 3 mL of milk expressed should be discarded. The specimen needs to be fresh when sent to the lab. Breast milk is rarely found to be sterile and naturally contains leukocytes. A normal leukocyte count is 1,000 to 4,000/mL.

With patients symptomatic for mastitis, there are three diagnostic categories when cytology and cultures are performed on breast milk samples. Milk stasis is present with a white blood cell (WBC) count of less than 106/mL and a bacterial count of less than 103 colony-forming units (cfu)/mL. Noninfectious breast inflammation is considered with a WBC count of more than 106/mL and a bacterial count of less than 103 cfu/mL. A WBC count of more than 106/mL with a bacterial count of more than 103 cfu/mL is indicative of infectious mastitis. With the help of a milk culture and sensitivity, appropriate antibiotic treatment can be initiated. There are occasionally situations in which a patient develops a chronic puerperal mastitis. These patients may have anatomical strictures of some lactiferous ducts, which lead to chronic plugged ducts. Long-term antibiotic therapy and impeccable breastfeeding management can improve the outcome.

Ultrasound examination of the breast or mammogram may be helpful in making the diagnosis of periductal

mastitis. The mammogram shows tubular dilated ducts. Calcification may be present in the lumen and walls of the affected ducts. Intense periductal mastitis may simulate carcinoma on the mammogram. Because carcinoma and mastitis can coexist, a biopsy may be warranted with such findings. In older patients, the mass from the ectasia can be hard to differentiate from carcinoma. Both masses can be hard, irregular, fixed or not to the surrounding tissue, and have skin or nipple retraction. When the nipple discharge is bilateral and multiple ducts are involved, the likelihood of malignancy is reported to be remote. Another diagnostic tool can be needle aspiration and culture of areas of inflammation. Fine-needle aspiration may show polymorphs, plasma cells, lymphocytes, and giant cells.

Differential Diagnosis

The first differential diagnosis to consider when presented with a patient symptomatic for puerperal mastitis is to identify that a condition of milk stasis or plugged ducts has led to an infectious process. The clinical presentation is invaluable in this judgment. There have been several cases of breast cancer in patients who are lactating or pregnant. Inflammatory breast cancer is a rare disease, but it can present with some of the same symptoms as a traditional puerperal mastitis. The patient with inflammatory breast cancer may have a red, swollen breast, and sometimes (but rarely) a fever. The patient commonly has no palpable breast mass and may or may not have *peau d'orange* (resembling orange peel). Reports differ on infants rejecting a breast later diagnosed with a cancerous disease. When inflammatory cancer is present, these symptoms do not respond to antibiotic treatment as mastitis generally does. With any suspicion of a cancerous process, the patient must be referred for biopsy and a definitive diagnosis.

Breast engorgement is often mistaken for mastitis but does not have the accompanying systemic symptoms of infection (e.g., fever, erythema, myalgia). If the infant has signs of poor "latch-on" during feeding (infant showing sunken cheeks, clicking sounds signifying breaking of suction, contact between the upper and lower lips at the corners of the mouth while feeding, etc.), this can also predispose the mother to mastitis. Galactoceles (milk retention cysts), which may result from plugged ducts, appear hard and red and may be quite painful (soreness, as opposed to the shooting pains of mastitis) but which lack the systemic signs of mastitis, should be considered as a possible diagnosis. Interestingly, hard, tender breasts with shooting pains but without redness or fever may be more associated with fungal infection of the breasts.

Management

The principle of management in puerperal mastitis is to decrease contributing factors and generally improve breastfeeding management.

Flu-like symptoms should always be treated as mastitis in postpartum patients unless proved otherwise. With a first occurrence, the diagnosis can be made by clinical symptoms alone. If there is no response to antibiotic treatment, or if there is recurrent mastitis, further diagnostics are indicated.

It is vital that the infant continue to breastfeed to avoid milk stasis. Because the infection is extraductal, there is no risk to the infant on continuing breastfeeding (except in HIV-infected mothers). Massage of the breasts during feeding helps to better drain the breast, and additional pumping may be needed, particularly if the infant is not nursing effectively on the affected side. Pumping breasts in addition to frequent infant feeding decreases the duration of symptoms (recommend every 6 hours feed or pump) and sequelae of the disease, notably breast abscess. Breastfeeding management should include correction of any latch-on or positioning difficulties and aggressive discovery and care of cracked or sore nipples.

Bedrest is imperative during the acute phase of the illness. The mother should be assisted with her household duties and rest in bed with her infant. Moist heat to the affected breast can be useful before feeding and pumping to increase milk expression. Cold application may be comfortable between feedings. Of course, stress management should be explored.

Antibiotic therapy is traditionally recommended to treat the infection. With no treatment at all, only 15% of patients recover without recurrent infection or breast abscess. Approximately 50% improve with pumping alone for treatment and more than 95% recover completely with combination therapy of pumping and antibiotics.

The best response is when antibiotics are started within the first 24 hours of symptom onset. A broad-spectrum antibiotic such as dicloxacillin or cloxacillin 500 mg PO every 6 hours is recommended for 10 to 14 days (for gram-negative organisms, use amoxicillin or cephalexin). If there is no response in the first 48 hours after initiation of antibiotic therapy, cephalexin or amoxicillin + clavulanate (Augmentin) is given for broader coverage. In addition, antibiotic sensitivity should be obtained from the milk culture. For those with a penicillin allergy, erythromycin (E-Mycin) (500 mg PO every 6 hours) can be prescribed. The patient must be instructed to continue her pharmacological therapy for the duration of the prescription to avoid a partially treated disease. Pain and other uncomfortable symptoms can be treated with nonsteroidal analgesics such as acetaminophen.

In the management of periductal mastitis, broad-spectrum antibiotics have been successful. They tend to treat the periareolar inflammation associated with this condition and reduce pain. If a mass is present, it must be biopsied to rule out carcinoma. If the nipple discharge is suspicious, a duct excision is necessary to confirm the diagnosis. Symptomatic treatment simply includes good

nipple and areolar hygiene. Some have recommended no oral nipple stimulation.

The wound infection rate after breast biopsies where periductal mastitis and/or ectasia is present is high. The infection rate is 2% after biopsies with no evidence of this disease but 10.2% when it is present. This appears to be unrelated to trends in culture results.

Notable sequelae of this mastitis are breast abscesses and fistulas. Nonpuerperal breast abscesses are seen more frequently than those associated with lactation. The incidence of periareolar abscess is 10% in patients who are symptomatic with duct ectasia. The bacteria cultured are usually *S aureus* and anaerobes. Surgical excision and broad-spectrum antibiotic coverage is the treatment of choice. Needle aspiration may be performed if the risk of malignancy is low, but this treatment frequently needs to be done repetitively.

Abscess is one of the more common sequelae of puerperal mastitis. It can occur when the disease progresses either with or without treatment. The patient presents with worsening local symptoms and may or may not have systemic manifestations. A breast ultrasound can be useful to confirm the diagnosis. Most abscesses are surgically incised and drained under anesthesia. Biopsy of the cavity has been recommended to check for the presence of carcinoma. A drain is put in place, and broad-spectrum parenteral antibiotics should be started with anaerobic coverage pending culture results. A polymicrobial infection is common. The drain can be covered with a sterile gauze. It is not unusual for breast milk to leak around the drain because of severed lactiferous ducts. There are occasions when a breast abscess is treated with recurrent needle aspiration, but this is not currently the treatment of choice.

A recurrence of mastitis may occur for several reasons, including inadequate antibiotic therapy. When a recurrence is evident, a breast milk culture is indicated, as well as further exploration of the patient's breastfeeding management. Chronic mastitis may be treated with low doses of erythromycin (E-Mycin) 500 mg PO daily for the duration of lactation.

After antibiotic therapy, infection of the nipples with *Candida albicans* is not unusual. Topical treatment for the patient and concomitant oral nystatin for the infant is necessary. A fungal or *Candida* mastitis may develop, which is characterized by fiery pain shooting up the duct system. Oral antimycotic treatment would thus be indicated.

Follow-up and Referral

The patient may best be served by referral to an International Board–Certified Lactation Consultant for professional evaluation and assistance with infant feeding. The lactation consultant evaluates and corrects problems related to the infant's feeding, which may be causing or contributing to the occurrence of infection. If a patient's symptoms are not resolved after reasonable treatment attempts, or if there is no change in the size or condition of a breast lump presumed to be a plugged duct after 48 hours of care and treatment, the patient must be referred for further diagnostic evaluation.

Patient Education

Appropriate patient teaching and breastfeeding management in the early postpartum period can be the best prevention tool for puerperal mastitis. Early and frequent infant feedings with correct latch and positioning is necessary. No harsh substances such as soaps and lotions should be put on the nipples, and correct bra sizing, rest, and diet instruction can all help with disease prevention.

Patients with periductal mastitis and duct ectasia need much support. The fear of carcinoma in this age-group is high, and the patient must be reassured that this diagnosis has been considered and ruled out. Because of the prevalence of this condition, unclear cause, and uncertain absolute recovery, the patient only learns palliative and symptomatic treatment with a clear understanding of the disease process.

FERTILITY PROBLEMS

Fertility is the quality of being productive or fertile. Although science has begun to perfect some techniques that facilitate fertility, chance continues to play a large role in conception. *Infertility* is defined as lack of conception despite unprotected sexual intercourse for at least 12 months, because studies have shown a 93% cumulative probability of pregnancy in normal fertile couples after this period of time. Infertility occurs in 10% to 15% of couples in the United States. A woman younger than age 35 is considered infertile if no conception occurs after 1 year of unprotected intercourse. This time frame is shortened to 6 months in women aged 35 or older. A man is considered infertile if he does not produce and deliver enough quality sperm to initiate a pregnancy. Infertility is divided into two categories. *Primary infertility* refers to a woman who has never had a child, whereas *secondary infertility* applies to a woman who has delivered at least one child. *Sterility* is a term applied when there is an absolute factor preventing reproduction. Fecundability is the probability of successful pregnancy within one menstrual cycle.

Epidemiology and Causes

Approximately 10% of couples in the United States have difficulty conceiving a child after a year or more of trying. The American Society for Reproductive Medicine estimates that there are more than 6 million couples with infertility problems in the United States. Twenty-five percent of fertile couples conceive during 1 month of unprotected intercourse. Sixty percent conceive after 6 months, and 85% conceive after 12 months. These conception rates are averages and vary among couples. Primary infertility occurs in about 1 of 12 couples (8.3%). The incidence of

infertility increases as the woman ages. For example, one in seven couples aged 30 to 34 are infertile, one in five aged 35 to 39, and one in four aged 40 to 44. These declines reflect the natural aging process and emphasize the need for rapid evaluation and treatment of infertility, especially in a patient older than 35 years of age.

Fertility patterns are dependent on many factors, including age, sex, and health. A major difference between male and female reproductive potential is that women have a finite reproductive life span (approximately 35 years), whereas men, after puberty, have the capacity to reproduce for the rest of their lives. However, fertility decreases in both men and women with aging. The causes of infertility are divided into categories. Male factors are responsible for a couple's infertility in 40% of cases. Testicular defects are a major cause with 10% to 20% from post-testicular defects (obstruction and disorders of sperm transport), 1% to 2% from hypothalamic-pituitary disease, and 40% to 50% from unidentifiable causes. Female causes are ovarian disease (failure to ovulate), 20%; tubal disease (obstruction), 25%; cervical factors (sperm cannot effectively pass the cervix), 5%; uterine abnormalities, less than 1%; and unexplained, 10%. In practical terms, infertility is caused by one of four conditions: the inability to produce healthy gametes (sperm or eggs); the failure of healthy gametes to come into close physical proximity, thus preventing fertilization; the inability of the fertilized egg to attach to the uterine lining successfully; and the inability to carry a pregnancy to term.

Infertility is a complex issue and is often caused by numerous factors. Couples should be referred for infertility evaluation if they have been unable to conceive after at least 1 year of attempting to achieve pregnancy. If the woman is older than 35 years of age, the couple should be referred after only 6 to 9 months of unprotected intercourse without conception. At age 25, the age at which couples are the most fertile, the average length of time needed to achieve conception is 5.3 months. The average 20- to 30-year-old American couple has intercourse one to three times a week, a frequency that should be sufficient to achieve pregnancy if all other factors are satisfactory. The number of women who give birth to their first child after age 30 continues to increase. Delaying parenthood appears to increase the possibility that one or more physiological processes necessary for conception will be adversely affected.

Even though infertility is defined as no pregnancy after 12 months of trying, evaluation should be initiated after 6 months in women between 35 and 40 years of age, and immediate evaluation is encouraged in women over 40 years, given the rapid increase in follicular atresia that occurs after age 37.

Pathophysiology

The following essential components must be present for normal fertility in women. The cervical mucus must be favorable to the survival of spermatozoa and allow passage to the upper genital tract. There must be clear passage between the cervix and the fallopian tubes. The fallopian tubes must be patent and have normal fimbria with peristaltic movements toward the uterus to facilitate normal transport and interaction of ovum and sperm. The ovaries must produce and release normal ova in a timely manner, and there must be no obstruction between the ovaries and fallopian tubes. Finally, the endometrium must be in a normal physiological state to allow implantation of the blastocyst and to sustain normal growth and development.

The most common cause of tubal infertility is antecedent pelvic inflammatory disease, caused most commonly by *Neisseria gonorrhoeae* and *Chlamydia trachomatis.* In addition, tubal endometriosis, pelvic tuberculosis, and adhesions from previous pelvic surgery or infection affecting any portion of the fallopian tubes may lead to obstruction. Hydrosalpinges, which are large, elongated typically fluid-filled cystic masses located anywhere along the adnexa, may form due to obstruction. These significantly interfere with the success of in vitro fertilization, thought to be due to components in the hydrosalpinx fluid that are toxic to developing embryos.

Uterine anatomical abnormalities have not been consistently identified as causal sources of infertility, because many women with abnormal uteri are able to conceive and carry pregnancies to term. However, septate uteri, synechiae (severe endometrial scarring), and polyps are all more common in infertile women. Similarly, uterine leiomyomata or fibroids (benign smooth muscle monoclonal tumors), which are the most common form of pelvic tumors in women, are observed in greater frequency in infertile women. However, it appears that only those with an intracavitary or submucosal component are associated with lower oocyte implantation and pregnancy rates.

Several other factors may affect the ability of the uterus to maintain a normal pregnancy. Endometriosis is more common in infertile women and, even when located outside the fallopian tubes, may contribute to infertility in a number of ways: pelvic adhesions affecting the reproductive tract; direct damage to ovarian tissue by endometrial implants or subsequent surgical removal; and cytokine and growth factor production by endometrial implants that interferes with ovulation, fertilization, or oocyte implantation. Cervical stenosis may occur congenitally, after trauma, or from infection and subsequent scarring. This, along with alterations in cervical mucus, may impair entry of sperm into the uterus. After implantation of the fertilized oocyte, impaired corpus luteum development may lead to inadequate progesterone production and delayed endometrial maturation, as demonstrated by endometrial biopsy. Likewise, in the presence of adequate progesterone, the endometrium may not be adequately responsive to this hormone. However, the

importance of luteal phase defects as a direct cause of infertility is controversial.

Systemic factors also exist that affect the ability to initiate or maintain pregnancy. Hypercoagulable states, such as from antiphospholipid antibody syndrome, systemic lupus erythematosus, or other autoimmune and connective tissue disorders, are well known to be associated with early, first-trimester miscarriages—likely due to immunological rejection of the developing embryo or microthrombosis of placental vessels leading to placental insufficiency. Genetic anomalies in both women and men have been associated with infertility, the most common being Turner's syndrome (XO) in women and Klinefelter's syndrome (XXY) and fragile X syndrome in men. Defects in several genes capable of affecting fertility have been identified including *KAL1,* which leads to congenital hypothalamic hypopituitary hypogonadism (Kallmann's syndrome); the follicle-stimulating hormone (FSH) receptor, FMR1, which leads to fragile X syndrome; and *DAX1, FGFR1,* and *GPR54.*

For normal fertility to occur in men, the testes must produce an adequate number of morphologically normal, motile sperm. The male genital tract secretions from the seminal vesicles and prostate gland must be normal. The genital tract must not be obstructed, because sperm travel from the testis through the epididymis and vas deferens to the urethra. Finally, ejaculated spermatozoa must be deposited in the female genital tract in such a manner that they reach the cervix and enter the uterus where they may contact oocytes either within the uterus or more commonly within the fallopian tubes.

Primary hypogonadism is the most commonly identifiable cause of male infertility, resulting from congenital causes including chromosomal disorders (e.g., Klinefelter's and fragile X syndrome), azoospermia from cryptorchidism (i.e., failure of testicular descent from the abdominal cavity during in utero development), defects in androgen production (5-alpha-reductase deficiency) or receptor activity, as well as Y chromosome deletions, especially in the long arm at the Yq6 region. Acquired disorders such as testicular infection (e.g., viral orchitis from mumps paramyxovirus, echovirus, or arbovirus), drugs toxic to sperm (e.g., alkylating immunosuppressants such as cyclophosphamide, antiandrogens such as spironolactone and ketoconazole), radiation exposure, tobacco smoking, and hyperthermia have all been associated with decreased male fertility, as well as underlying systemic disease such as chronic renal insufficiency and cirrhosis. Antisperm antibodies have also been identified in some infertile men that presumably affect fertility, but it is not clear whether these form spontaneously or as a result of testicular injury that compromises the testicular–blood barrier.

In far fewer cases, defects exist higher up on the hypothalamic-pituitary-gonadal axis. A failure of hypothalamic gonadotropin-releasing hormone (GnRH) secretion and/or pituitary gonadotropin production may result from congenital defects (e.g., Kallmann's syndrome) or acquired conditions such as secreting or nonsecreting pituitary macroadenomas, prolactinomas, craniopharyngiomas, or infiltrative processes such as sarcoidosis, histiocytosis, or tuberculosis.

Sperm transport may be inhibited anywhere along the male reproductive tract. Intrauterine estrogen exposure may lead to epididymal defects, and infection (e.g., epididymitis caused by *N gonorrhoeae, C trachomatis,* or tuberculosis) and certain chemical toxins (e.g., chlorhydrin) may affect spermatozoal function within the epididymis. The vas deferens may similarly be affected by infection, intentional ligation as in surgical vasectomy, inspissation of thick mucoid secretions (Young's syndrome), or congenital absence due to defects in cAMP-regulated chloride ion channels, as in cystic fibrosis. Although secretions from the prostate and seminal vesicles contain several components (e.g., fructose) that contribute to sperm viability and motility, defects in glandular secretion have not been causally related to infertility. In addition, erectile dysfunction and ineffective ejaculation may result from spinal cord damage or disease, as well as defects in autonomic function from diabetes mellitus. Varicoceles (venous dilation of the pampiniform plexus proximal to the testicle) are also far more common in infertile men, but they may also be present in men with normal fertility. Although no definitive evidence exists, they are thought to impair spermatogenesis via increased testicular temperature, hypoxia, or vascular stasis with delayed clearance of toxic serum metabolites.

Clinical Presentation

Subjective

The patient presents with the complaint of inability to conceive and the desire to have a child.

Objective

Assessment of persons seeking evaluation and treatment of infertility should begin with a detailed comprehensive history. Before tests to determine the cause of infertility are made, a detailed medical, social, and family history must be obtained from both partners. Often the history uncovers important information. The history should elicit information about the duration of the infertility and whether it is primary or secondary; the frequency of sexual intercourse; the regularity, duration, and frequency of menstruation; and any premenstrual signs and symptoms. It should also include information on any vaginal discharge, cervicitis, pelvic infections, surgery, and trauma. General physical condition, illness, allergies, and drug intake (prescription and illicit) should be noted, as should any significant family history. Prior use of contraceptives, including type, duration, and complications, should be recorded. Information on maternal use of diethylstilbestrol (DES) should also be noted, because this can affect fertility.

Necessary information from the man includes any history of mumps, orchitis, trauma, diabetes mellitus, herniorrhaphy, or exposure to x-rays or toxic substances such as lead, iron, zinc, or copper. The male should also be questioned about exercise patterns, drug intake (prescription and illicit), exposure to heat (from the environment or from wearing tight underclothes), duration of infertility, whether the fertility is primary or secondary, frequency of coitus, and history of maternal use of DES (can affect a son's fertility). A complete physical exam of both partners is essential, particularly a thorough pelvic exam of the woman. The male examination should include testicular volume (below 15 mL is small) and testicular length (less than 3.6 cm is small). Certain laboratory tests, such as complete blood count, thyroid-stimulating hormone (TSH), T_4, and urinalysis, should also be included. If findings are negative, an infertility work-up is begun.

Diagnostic Reasoning

Diagnostic Tests

The easiest and least intrusive infertility testing should be used first. Extensive testing should be avoided until data confirm that the timing of intercourse and the length of coital exposure have been adequate. The couple should be informed of the most fertile times to have intercourse during the menstrual cycle. Teaching the couple the signs and timing of ovulation and the most effective times for intercourse within the cycle may solve the problem before extensive testing needs to be initiated. Primary assessment, including a comprehensive history and physical exam for any obvious causes of infertility, is done before a costly, time-consuming, and emotionally trying investigation is initiated. Because infertility is a couple's issue, it is important for both partners to be present. One basic test of ovulatory function is the basal body temperature (BBT) recording, which aids in identifying follicular, ovulatory, and luteal-phase abnormalities. With the additional documentation of coitus, serial BBT charts can be used to indicate retrospectively if, and approximately when, the woman is ovulating and if intercourse is occurring at the proper time to achieve conception. A proposed schedule for intercourse, based on serial BBT charts, might be to recommend sexual intercourse every other day in the period of time beginning 3 to 4 days before and continuing for 2 to 3 days after the expected time of ovulation.

Semen analysis is the single most important diagnostic study of the male and should be done early in the couple's evaluation and before invasive testing of the female. Semen analysis must be done within 1 day of donation, and normal sperm morphology may be as low as 15% to 20% with good results. Also, at least 25% of sperm should have rapid progressive mobility (not just moving in place). Sperm viability should be tested if motility is insufficient. Semen pH is also important (low pH is correlated with decreased fertility). Cellular debris and agglutination are of concern for antibody-mediated autoimmune destruction of sperm. Antibodies may be detected and are considered concerning if they coat more than 50% of spermatozoa. The presence of immature germ cells may represent a maturation defect, and the presence of sperm leukocytes (greater than 1 million/mL) reflects infection within the reproductive tract. Semen culture is often sent, but this is usually not diagnostically useful. It is important to note that an absence of sperm may be due to spermatic duct obstruction, rather than a lack of sperm production by the testes. Patients lacking sperm in the semen should be referred to urology to rule out retrograde ejaculation, congenital absence of the vas deferens, or other forms of obstruction. A postejaculatory urine specimen will reflect retrograde ejaculation if sperm are present, whereas an absence of sperm may reflect obstruction or impaired spermatogenesis.

It is important to assess both partners because of the high incidence of multifactorial infertility. A thorough female evaluation includes assessment of the hypothalamic-pituitary axis in terms of ovulatory function. Progesterone levels are measured at different points along the luteal phase to confirm ovulation. In addition, LH levels can be measured in the serum and with home urine tests to help predict ovulation (as the surge occurs 1–2 days ahead of ovulation) to facilitate the timing of intercourse, but home urine tests are not as sensitive (85%) as serum tests done during formal fertility evaluation, because once-a-day testing can miss the surge because of variations in renal clearance of luteinizing hormone (LH). Examination of vaginal discharge for increased volume and clear, slippery mucus that stretches into strings (Spinnbarkeit) is a strong indicator of preovulatory estrogen effect. The progesterone challenge test, using medroxyprogesterone acetate 10 mg daily for 5 days and checking for induction of uterine bleeding in the week after treatment, confirms adequate production of estradiol (estrogen). An FSH level should be drawn on day 3 of the cycle to check for adequate ovarian reserve—a value less than 15 mIU/mL is suggestive of adequate reserve. Prolactin and TSH levels should also be checked to rule out hyperprolactinemia (which may be treated with a dopamine agonist such as bromocriptine, pergolide, or cabergoline), especially in women with galactorrhea, and thyroid disorders. Magnetic resonance imaging and hysterosalpingogram imaging are done to evaluate the structure and function of the cervix, uterus, fallopian tubes, and ovaries. Laparoscopy is more sensitive for detecting tubal abnormalities than hysterosalpingogram alone but may be unnecessary if the findings from the hysterosalpingogram are normal. Also, the performance of the hysterosalpingogram itself (flushing the tubes with oil-based contrast medium) increases the likelihood of pregnancy.

Evaluation of the man may include at least two semen analyses to confirm or rule out a seminal deficiency. Endocrine evaluation of men includes serum LH, FSH, and testosterone levels. If the LH and FSH are high and the testosterone level is low, this is consistent with primary hypogonadism, whereas a normal to low LH and FSH reflects secondary hypogonadism. In men with low testosterone and normal to low LH levels, prolactin should be measured to rule out prolactinomas.

If the results of both the male and female infertility work-ups are negative, a laparoscopic evaluation may be necessary. Table 14.5 outlines different fertility tests and favorable clinical findings that indicate that the couple is capable of conceiving.

Management

The principle of management is to assist the couple to achieve pregnancy before or during the natural age-related

Table 14.5 Fertility Tests and Favorable Clinical Findings

Gender	Test	How Obtained	Favorable Clinical Findings
Male	Semen analysis	48–72 hr after abstinence from ejaculation	Normal amount of ejaculate (3–5 mL; range 1–7 mL). No agglutination of sperm. (Agglutination suggests infection or autoimmunity.) Normal seminal fluid. Sperm count greater than 20,000,000 cells with at least 50% motility 2 hours after ejaculation and more than 60% normal-appearing cells.
	Karyotyping (in men with severe oligospermia or azoospermia)	Blood sample/bone marrow	Chromosomal abnormalities can be detected.
Female	Basal body temperature (BBT) measurement	Oral temperature taken daily before arising throughout several menstrual cycles	Biphasic pattern with persistent temperature elevation for 12–14 days before menses.
	Postcoital test	Vaginal exam within 8 hours after intercourse, during time of presumed ovulation	Cervical mucus suggestive of ovulation. Microscopic fern pattern present. Watery, slippery, abundant mucus. Spinnbarkeit is present (the act of pulling out a string of cervical mucus and measuring how far it can be stretched before breaking). Presence of normal live and motile sperm in cervical mucus.
	Serum progesterone measurement	Blood sample	3–4 ng/mL in early luteal phase. 10 ng/mL at midluteal phase.
	Serum LH (to predict ovulation)	Blood sample	6.17–17.2 IU/L at ovulation.
	Karyotyping (in women with ovarian failure or repeated spontaneous abortion)	Blood sample/bone marrow	
	Immunoassay tests	Semen and male/female serum	Absence of antibody reaction.
	Hysterosalpingogram	Dye injected through cervix into uterus then fluoroscopic visualization of the spread of dye through fallopian tubes. Done during first half of menstrual cycle before ovulation	Evidence of normal pelvic anatomy and tubal functioning. Patency of fallopian tubes and absence of abnormalities in uterine cavities and fallopian tubes.
	Laparoscopy	Direct visualization of pelvic structures through a small abdominal incision	Normal pelvic structures and absence of signs of infection, adhesions, endometriosis, or lesions.

decline in female fecundity. Several lifestyle changes can increase the chances that a couple will become pregnant. Women should limit caffeine intake to no more than 250 mg (2 cups of coffee) per day. Studies show that consumption of caffeine over 300 mg can delay conception and increase the risk for miscarriage and preterm labor. Caffeine intake in men does not seem to affect fertility. Likewise, alcohol affects fertility in women, and intake should be limited to no more than 4 drinks per week. Increasing sexual intercourse to 2 to 3 times a week is also advisable. These measures should be recommended before any other interventions. If the woman's body mass index is less than 20 or greater than 27, attempts should be made to get the body weight to a normal level. Loss of just 5% to 10% of body weight in obese anovulatory women with polycystic ovarian disease (PCOS) can restore ovulation within 6 months and should be a first-line therapy. For women with PCOS, in addition to weight loss, insulin sensitization with metformin has been shown to improve fertility.

A low percentage of body fat resulting from eating disorders (anorexia nervosa/bulimia) or from extreme exercise can lead to anovulation through GnRH or gonadotropin suppression and must be addressed. Pulsatile GnRH therapy may restore ovulation in these women, but this treatment is available only in Europe at this time.

If an ovulatory defect has been identified during fertility testing, the treatment depends on the specific cause of the problem. In the presence of normal ovaries, a normal prolactin level, and an intact pituitary gland (normogonadotropic normoestrogenic anovulation [World Health Organization class II anovulation], which is 70%–85% of cases), clomiphene citrate (Clomid), a selective estrogen receptor modulator (SERM) with both agonist and antagonist effects at the estrogen receptor level, is effective. Ovulation occurs in approximately 80% of properly selected women, and conception rates approach 40%. The risk of multiple gestation with clomiphene is 5% and is almost exclusively with twins. The woman takes a 50-mg dose of clomiphene each day from days 5 to 9 of the cycle. Ovulation can be expected to occur 5 to 10 days after the last dose. If ovulation is not achieved in the first cycle of therapy, the dose may be increased in 50-mg increments to a maximum of 200 to 250 mg daily for 5 days. After the first treatment cycle, a pelvic exam should be done to rule out ovarian enlargement or hyperstimulation. Ovarian enlargement and abdominal discomfort may result from follicular growth and the formation of multiple corpus lutea. Other adverse effects include hot flashes, nausea and vomiting, vision problems, headache, and dryness or loss of hair. Clomiphene citrate should not be used for more than six cycles, because it is unlikely to work after this many tries. Tamoxifen is another SERM that works with fewer antiestrogen effects, but it has no added fertility benefit over clomiphene citrate.

Aromatase inhibitors such as letrozole (Femara) and anastrozole (Arimidex) have a shorter half-life than the SERMs and fewer antiestrogen effects, producing fewer follicles and lower estradiol levels, reducing the risk of multiple gestations and miscarriage. These agents may be used for patients who do not respond to clomiphene.

Treatment with gonadotropins requires much closer monitoring, is more costly, and has a higher risk of multiple gestations but is considered the most effective medication used with intrauterine insemination for ovarian hyperstimulation. A laparoscopic technique called ovarian drilling may be used in which a laser is used to induce ovulation. This technique seems to work no better than gonadotropins, but it carries less risk of multiple gestations.

Cervical stenosis can be treated via catheter dilation for several days with concurrent antibiotic prophylaxis (doxycycline 100 mg PO 2 times daily). Women with systemic clotting disorders may also benefit from aspirin and heparin anticoagulation therapy to improve the likelihood of pregnancy.

Intrauterine insemination (IUI) just before ovulation (based on LH measurements) is often effective when other methods have failed. IUI may be tried before in vitro fertilization (IVF) because it is often effective and less expensive. IUI done high in the uterus is more effective than intracervical injection, which approximates normal intercourse. With high IUI, the probability of pregnancy is improved through concurrent treatment with clomiphene for three to six cycles, and if this fails, IUI with gonadotropin injections for at least three cycles can be tried.

The last resort for infertile couples is IVF and embryo transfer or, if the tubes are patent and normal, gamete intrafallopian transfer (GIFT). In some cases of tubal occlusion in which the rate of success with tubal repair is low (less than 30%), IVF appears to be preferable to surgery because of the more rapid conception rate. IVF has the highest pregnancy rate in the shortest amount of time, but it is also the costliest intervention, with a price tag of $50,000 to $100,000 per attempt. Intratubal transfer of embryos may improve the success rate over transcervical transfer, but this is unclear and may depend on how good the results are at the particular center with the regular IVF procedure.

The pregnancy rate with IVF has been highly variable from center to center, owing to the complexity of the techniques required, whereas the pregnancy rate with GIFT has been more consistent. The mean live delivery rates per retrieval with IVF and GIFT are approximately 21% and 28%, respectively. Ectopic pregnancy occurs in about 4% to 5% of these pregnancies, whereas the rate of fetal abnormalities is not increased. There are many ethical considerations associated with assisted reproductive technologies; some of these are presented in Table 14.6.

Table 14.6 Ethical Considerations and Assisted Reproductive Technologies

In vitro fertilization (IVF) has been a welcome solution for many couples who have been unable to conceive. Recently, advances in the application of IVF technology have spurred the emergence of even more new avenues of achieving pregnancy and parenting. With hormone replacement therapy (HRT) and donor egg embryos, women past menopause can achieve pregnancy. Other options include cryopreservation, fertilization of donor gametes (donor eggs, sperm, or both), IVF with the use of a gestational carrier, embryo adoption, and the use of surrogacy. All of these options are complicated by the introduction of a third party into the reproductive process and ethical concerns. Some of the issues raised in connection with these techniques include the following:

1. Is it a constitutional right for individuals or couples to be able to utilize donor gametes or to contract with a woman to carry their embryo to treat their infertility?
2. With a multiple pregnancy rate approaching 20% in couples undergoing IVF procedures, the potential (<3%) of having a grand multiple gestation forces some couples to consider embryo reduction (selective abortion) to avoid an adverse obstetric and/or fetal outcome.
3. If excess embryos are frozen and kept, how long can and should they be stored? What should be done in cases of death of one or both of the partners, divorce, or when couples choose not to claim their embryos?
4. Do providers have the right to decide who can participate in using donor gametes, embryos, gestational carriers, and surrogates? What about single women, lesbian couples, or crossing generational lines (daughter being a donor for mother)?
5. Does the use of assisted reproductive technologies take into consideration the best interests of the parties involved, including those of the resulting offspring? For example, what are the effects on a child of knowing or not knowing the identity of the donor?
6. How can the potential for consanguinity (having an ancestor in common) be controlled in the case of gamete and/or embryo donation?
7. Does the existence of new technologies make it more difficult to accept childlessness by increasing pressure on women to follow every avenue in an attempt to conceive?
8. To what extent should health insurance policies cover these modes of treating infertility at a time of growing healthcare costs?

It is also possible to achieve pregnancy with IVF and embryo transfer using donor eggs, with a higher success rate than with regular IVF and embryo transfer (47% per retrieval). The eggs generally come from young fertile women (sisters or anonymous volunteers). The recipient's uterus can be prepared for optimal uterine receptivity by replacement doses of estradiol and progesterone.

Male infertility from hypogonadotropic hypogonadism may be treated with human chorionic gonadotropin (hCG) injections 1,500 to 2,000 IU subcutaneously or intramuscularly three times per week for at least 6 months. hCG acts similarly to LH. If this does not work, human menopausal gonadotropin 37.5 to 75 IU three times per week is added that contains FSH. Thus, this treatment can last more than a year. This combination therapy is typically needed for Kallmann's syndrome (congenital hypogonadotropic hypogonadism). Recombinant LH/FSH is also now available. Pulsatile GnRH treatment delivered via IV pump is also available for hypothalamic hypogonadotropic hypogonadism.

Sperm autoimmunity may be treated with high-dose steroids (prednisone 40–80 mg PO daily) for up to 6 months, but this regimen may be poorly tolerated. Thus, intracytoplasmic sperm injection (ICSI) is an important IVF alternative with a clinical pregnancy rate of up to 20%. Retrograde ejaculation may be treated with IUI, traditional IVF, or ICSI as well. Repair of varicoceles is controversial and is usually recommended only with large defects or in younger men, because prolonged damage to the testes—indicated by testicular atrophy, epithelial damage, and severe oligospermia or azoospermia—is unlikely to be reversed by surgical ligation of the varicocele. Reversal of vasectomy can result in successful pregnancy in a female partner in up to 50% of cases. In cases of obstruction along the reproductive tract, sperm may be retrieved for ICSI via direct microsurgical aspiration from the epididymis or the seminiferous tubules of the testes. In all cases of congenital reproductive tract defects such as absent vas deferens, genetic counseling must take place before microsurgical aspiration and ICSI, given the risk of passing genetic defects, such as the cystic fibrosis gene, Klinefelter's, or deletions in the Y chromosome, onto these men's offspring.

Follow-up and Referral

After the initial exam and counseling regarding the frequency and timing of intercourse, if couples wish to proceed with testing and/or treatment, referral to a fertility clinic is indicated. Infertile couples need a great deal of support and advocacy, as well as education and help in decision making. The options must be presented in a

nonjudgmental way to facilitate the couple's own decision making. Providing referral to other sources of assistance is another way in which the clinician supports the infertile person or couple. One important source of information is RESOLVE, a national organization composed of self-help groups that provide support and information about infertility. Providing anticipatory guidance for the battery of tests to which patients are subjected during infertility evaluation is important.

Patient Education

An important part of care for infertile persons is emphasizing and teaching self-care. Infertility is often experienced as being "out of control." Identifying and using successful coping strategies help the patient regain a sense of control. Stress-reduction techniques, such as exercise, relaxation techniques, and meditation, may be especially useful both for those with general concerns about fertility and for those concerned about specific diagnostic or treatment procedures. Infertility can become an all-encompassing concern, resulting in alterations in health and recreation patterns and a loss of interest in other aspects of life. It should be emphasized that one can be creative, productive, and successful in other areas even if unable to produce children. The emotional problems surrounding infertility illustrate the need for emphasis on family-centered care. Infertility is a highly emotional issue that has far-reaching implications for many family members.

AMENORRHEA

Menarche usually occurs between ages 11 and 15 years, and the average age in the United States today is 12.7 years. Absence of menstruation is considered amenorrhea and can be primary or secondary. *Primary amenorrhea* is the failure to menstruate by age 14 in girls with no secondary sex characteristics (breast development) or failure to menstruate by age 16 years in girls who may or may not have developed secondary sexual characteristics. *Secondary amenorrhea* is the absence of menstruation for 3 or more consecutive months in a woman who has achieved menarche.

Epidemiology and Causes

Primary amenorrhea occurs in about 0.3% of women and may result from hypothalamic or pituitary failure, ovarian failure, or chromosomal or enzymatic abnormalities. Amenorrhea is a manifestation of a pathological process and is not a diagnosis itself. Causes of primary amenorrhea include congenital defects of gonadotropin production; genetic disorders (Turner's syndrome); congenital central nervous system (CNS) defects such as hydrocephalus; congenital anatomical malformations of the reproductive system (absence of vagina or uterus); abnormal outflow tract (vaginal aplasia or imperforate hymen); and acquired CNS lesions, including trauma, infection, and tumors. Females without a uterus or vagina usually have normal ovarian function in which skeletal growth and secondary sex characteristics develop in the proper sequence, but menses does not occur. In cases of uterine hypoplasia, the uterus does not respond to hormonal stimulation during puberty.

If a woman is not pregnant (most common cause), secondary amenorrhea is usually associated with anovulation caused by neuroendocrine dysfunction. Secondary amenorrhea occurs in approximately 1% to 3% of women, with a higher incidence among college students (3%–5%) and athletes (5%–50%). Amenorrhea reflects a disruption in the normal physiological or anatomical function of the hypothalamus, pituitary gland, and ovary or outflow tract. Hormones produced by these structures play major roles in ovulation; any slight change in production may result in anovulation and absence of menstruation. Women taking anabolic steroids (weight lifters, body builders), elite athletes with low body fat, and those with anorexia nervosa may present with secondary amenorrhea.

Pathophysiology

The hypothalamic-pituitary-ovarian-uterine axis needs to function in a coordinated manner for menstruation to occur. The most frequent cause of primary amenorrhea is dysfunction of the ovaries resulting from gonadal dysgenesis. This may be caused by various chromosomal abnormalities that result in a depletion of oocytes and ovarian follicles, subsequently impairing the regulated cycle of menses. Turner syndrome, characterized by an XO (single X-chromosome) genotype, is one of the most common chromosomal disorders. In this condition, the ovaries are replaced by fibrous tissue (known as streak ovaries), which has a very limited or absent capacity for estrogen production. In addition, premature ovarian failure (menopause occurring before age 40 years), polycystic ovary syndrome (characterized by concurrent hyperandrogenism), and estrogen- or androgen-secreting tumors may all produce amenorrhea. Secondary amenorrhea is nearly universally a hormonal problem because, by definition, normal female sexual development has already occurred. By far, the most common cause of secondary amenorrhea is the normal hormonal changes associated with pregnancy, that is, increased progesterone production needed to maintain the pregnant uterus.

Under normal conditions, the hypothalamus produces gonadotropin-releasing hormone (GnRH) in a pulsatile fashion. In response to GnRH, the anterior pituitary gland produces the gonadotropins follicle-stimulating hormone (FSH) and luteinizing hormone (LH). In response to FSH and LH, the ovaries produce estrogen and progesterone, which subsequently drive secondary sexual development and cyclic menstruation. Factors such as stress, weight changes, nutritional deficiencies, strenuous exercise, or infiltrative CNS lesions including hypothalamic tumors (e.g., lymphoma, histiocytosis) or

sarcoidosis may all disrupt the normal pulsatile release of GnRH. Pulsatile production of GnRH may also be affected by rare pituitary tumors including macroadenomas and microadenomas, which consist primarily of hyperprolactinomas and account for 20% of secondary amenorrhea cases. Amenorrhea may occur before or after the treatment of such tumors (i.e., surgical resection), depending on the underlying production of pituitary gonadotropins. Functional hypothalamic amenorrhea (which may be primary or secondary) is characterized by an absence of histological CNS pathology, despite an underproduction or overproduction of GnRH that leads to a decrease in gonadotropin surges and amenorrhea. In contrast, a complete absence of hypothalamic GnRH production may occur congenitally, inherited in an autosomal dominant, autosomal recessive, or X-linked fashion.

Whereas acquired endometrial scarring known as Asherman's syndrome is the only anatomical uterine etiology of secondary amenorrhea, nearly a quarter of primary amenorrhea cases are due to structural abnormalities that prevent menstrual outflow, including imperforate hymen, vaginal agenesis, absent or abnormal uterus, or the presence of a transvaginal septum between the hymen and the cervix. Such conditions may not be connected to any specific event or environmental exposure. However, some conditions may result from biochemical abnormalities in hormone receptor functioning, manifested on either an XX or XY genetic background. Thus, an advanced work-up of patients with primary amenorrhea should also include karyotyping to confirm that the patient is an XX genetic female.

Complete androgen insensitivity syndrome (testicular feminization syndrome) is the prototype for primary amenorrhea occurring in a genetic male who appears outwardly female on clinical exam. In this disorder, the external genitalia of XY males are unable to respond to testosterone because of a receptor defect and thus fail to undergo differentiation into a phenotypically male form, despite their XY karyotype. Internally, however, the testes do produce functional Müllerian inhibiting factor, causing the regression of all internal female reproductive organs, thus leading to primary amenorrhea. A congenital lack of 5-alpha-reductase enzymatic activity causes a similar phenomenon of external sexual ambiguity in which XY males do not undergo full secondary sexual development at puberty, because testosterone cannot be converted into its more potent metabolite dihydrotestosterone.

Clinical Presentation

Subjective

Amenorrhea is a symptom, so this is usually the reason the patient seeks health care. Other subjective data from the patient usually are obtained during the history. The detailed history must include a complete menstrual history including age at menarche, date of last menstrual period and last normal menses, cycle regularity, and flow; obstetrical history, including number of pregnancies, lactation, and birth control methods; developmental data, to evaluate for short stature or growth hormone or thyroid deficiency; nutritional history, including anorexia, diet, stress, and sports activities; family history, especially the mother's onset of menopause; symptoms that may arise from systemic disorders (diabetes, thyroid); the presence or absence of any secondary sex characteristics; and any medications being taken, such as hypertensive medications or oral contraceptive pills. Cyclic pelvic pain in a young teen or preteen could indicate Müllerian outflow tract obstruction.

Objective

The physical exam should include a neurological exam to assess for headaches and visual field abnormalities to rule out pituitary tumor; olfactory testing to screen for Kallmann's syndrome (hypothalamic or pituitary tumor); a pelvic and rectal exam (to assess for the presence of a vagina, condition of hymen, and presence of uterus); the existence of skin lesions, acne, needle marks, and skin darkening, to rule out adrenal insufficiency; and a breast exam, to observe for galactorrhea, which may be a sign of hyperprolactinemia.

Diagnostic Reasoning

Diagnostic Tests

A urine pregnancy test should be the first test performed in the patient with amenorrhea because it is inexpensive and easy. It should be done despite what the patient tells you about her sexual history. If the test is positive, a serum beta–human chorionic gonadotropin for approximate staging of pregnancy should be done. Other tests should include baseline blood chemistry profiles to evaluate for renal or hepatic disease; thyroid function tests; vaginal smears for estrogen effect; and FSH, LH, and prolactin levels.

Tests for secondary amenorrhea include androgen studies of total testosterone and dehydroepiandrosterone sulfate, which are specifically done in women who also have clinical signs of hyperandrogenism (acne, hirsutism, etc.); a progesterone challenge test; and the measurement of prolactin and FSH levels, which evaluate the hypothalamic-pituitary-ovarian axis.

A progestin (or progesterone) challenge indirectly provides information regarding outflow tract patency. This test, given once a negative pregnancy test is obtained, consists of giving medroxyprogesterone acetate 10 mg PO for 5 to 10 days or 200 mg IM once to induce withdrawal bleeding or spotting, which should occur within 14 days after the last dose. If withdrawal bleeding occurs, this indicates pituitary-gonadal function, and amenorrhea is probably the result of anovulation. The test is negative if no withdrawal bleeding occurs and suggests

low levels of estrogen (premature ovarian failure or hypothalamic pituitary failure) or a nonpatent outflow tract.

Differential Diagnosis

Differential diagnoses include pregnancy (intrauterine or ectopic); menopause; premature ovarian failure; hyperprolactinemia related to tumor, stress, or thyroid dysfunction; and some genetic or chromosome-related problems. Outflow-tract abnormalities include Asherman's syndrome, which is characterized by endometrial adhesions and scarring as a result of aggressive dilation and curettage, uterovaginal malignancies, cervical stenosis, or imperforated hymen.

A genetic disorder of male pseudohermaphroditism may result in primary amenorrhea. The patient is male genetically but female morphologically. No male genitalia develop because androgen receptors are absent in undifferentiated target organs.

Management

The goal of management for amenorrhea is to initiate or restore menses while determining the cause. Treatment of amenorrhea is dependent on its etiology and the patient's wishes. For primary amenorrhea, estrogen therapy is indicated for patients to develop secondary sex characteristics and prevent osteoporosis.

For a patient with secondary amenorrhea whose progestin challenge test is negative, treatment consists of oral estrogen 1.25 to 2.5 mg daily for 21 to 25 days, along with oral progesterone 10 mg daily during the last 5 to 10 days of the estrogen doses. The patient should experience bleeding if the endometrium is normally responsive to estrogen and the outflow tract is patent.

For a patient with secondary amenorrhea who is anovulatory and has adequate endogenous estrogen, the common practice is to administer periodic or cyclic progesterone 10 mg PO daily for 10 days each month. These patients must experience withdrawal bleeding for at least 3 months to prevent endometrial hyperplasia or endometrial carcinoma related to unopposed estrogen. If the patient is anovulatory and wants to conceive, ovulation may be induced with clomiphene citrate (Clomid) 50 mg PO on days 5 to 9 of the cycle after induction of bleeding with progesterone.

If the patient wants contraception, oral contraceptives are beneficial for monthly cycle regulation. For patients with hyperprolactinemia, bromocriptine (Parlodel) is the drug of choice. Once hypothalamic failure is established, GnRH may be given in a pulsatile fashion. GnRH is given as a combination with estrogen and calcium because these patients are hypoestrogenic and at high risk for osteoporosis. In patients with thyroid dysfunction, replacement therapy should be initiated, and the amenorrhea should correct itself.

Surgical intervention is possible for women with endometrial scarring (Asherman's syndrome) from endometritis. Diagnosis and treatment are accomplished in the same way, through hysteroscopic inspection and lysis of adhesions. After this procedure, antibiotics are given, and a small Foley catheter is placed in the uterus and left for 1 week. When the catheter is removed, an intrauterine device is inserted and left in place for 2 months while the patient receives cyclic estrogen and progesterone to build the endometrial lining. This treatment usually restores normal menses and fertility, but complications of pregnancy are common, including spontaneous abortions.

Follow-up and Referral

A gynecologist and an endocrinologist should be consulted for further testing. If a CNS problem is detected, computed tomography scanning or magnetic resonance imaging should be performed to rule out pathology. The gynecologist may also consider an endometrial biopsy for patients who are at high risk (those with diabetes, hypertension, and obesity) for endometrial hyperplasia and adenocarcinoma before prescribing medications. Pelvic ultrasound may also be used to measure the endometrial strip and rule out ovarian masses.

Once the work-up is completed, the patient should be evaluated annually. Patients with primary amenorrhea should be referred to a gynecologist. Patients with secondary amenorrhea may need to be referred if initial treatment is unsuccessful.

Patient Education

Frequently, teenagers and their parents are apprehensive when menses do not start "on schedule," but reassurance and watchful waiting may be all that is needed. Patients should be taught about their medication regimen and the importance of taking medications exactly as prescribed. Patients must be aware of the need to notify their health-care provider if they take any new medications, because many drugs interact with others and have a potentiating effect as well as a negative effect on the action of some medications. Encourage patients to maintain a healthy diet and exercise regimen, because having less than adequate body fat can result in amenorrhea.

PREMENSTRUAL SYNDROME

Premenstrual syndrome (PMS) is a cyclic recurrence of a constellation of physical and psychological symptoms that arise during the second, or luteal, phase of the menstrual cycle, starting at day 14 after menses, immediately following ovulation and the midcycle luteinizing hormone (LH) and follicle-stimulating hormone (FSH) gonadotropin surge. The original term for these symptoms was *premenstrual tension syndrome* (PMT). Most women experience minor physical symptoms before their menstrual cycle; however, about 5% of women present with symptoms severe enough to disrupt their daily lives.

Epidemiology and Causes

Premenstrual dysphoric disorder (PMDD) is the term given to a severe form of PMS in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-V). Although PMS may affect up to 75% of women with regular menstrual cycles, only 3% to 8% of women suffer from true PMDD. To apply the DSM-V criteria for PMDD, women must chart symptoms daily for two cycles. Chief complaints must include 1 of the 4 core symptoms (irritability, tension, dysphoria, and lability of mood) and at least 5 of the 11 total symptoms that are listed under the subjective heading in the clinical presentation section later in this chapter. More than 150 distinct signs and symptoms have been ascribed to PMS within the medical literature (Table 14.7).

The psychiatric hypothesis regarding the etiology of PMDD centers around a woman's denial of her body and femininity, negative imprinting about menstruation, and poor coping skills. This associates PMS with other psychiatric disorders. There does not appear to be any difference in the prevalence of this disorder between racial or ethnic groups. PMS usually disappears at the time of menopause.

Many believe that PMS is a physical response to organic changes that occur during the luteal phase of the menstrual cycle and, therefore, is not a psychiatric diagnosis at all. Research has postulated that mood and anxiety disturbances arise from ovarian steroid hormones that affect the synthesis, release, and reuptake of neurotransmitters. Several neuroendocrine processes are also affected during this period that may affect mood. Other diseases that present with mood and mental status changes, such as thyroid disease and vitamin B_{12} deficiency, are not classified as psychiatric disorders, and many believe that PMS should likewise be considered a physical complaint.

Table 14.7 Common Symptoms of PMS

Core Symptoms
• Irritability
• Tension/anxiety
• Dysphoria/depression
• Lability of mood/mood swings
Other Symptoms
• Headache
• Food craving
• Anger
• Backaches
• Tender breasts
• Clumsiness
• Crying
• Dizziness
• Feeling faint
• Fatigue
• Fluid retention
• Forgetfulness
• Bloating
• Hostility
• Joint swelling
• Confusion
• Migraine

Pathophysiology

PMS has no universally accepted definition. As discussed, the American Psychiatric Association has established diagnostic guidelines for PMDD, which are more stringent than criteria for PMS. PMS is a complex clinical somatic entity, and no specific list or number of symptoms has been established that would enable a definitive diagnosis of PMS to be made. However, certain basic facts have been agreed on. Although the medical literature states that PMS is a complex disorder linking ovarian steroid hormones and neurotransmitter release, some feminist authorities feel that PMS may be caused in part by the stressors on women within modern society and the need for women to masculinize their work lives to meet the standards of Western society.

The influence of cyclical ovarian hormones on various neurotransmitters has been cited, including the beta endorphins and gamma-aminobutyric acid (GABA). In fact, the progesterone metabolite allopregnanolone, which potentiates GABA receptor function, is lower in concentration in women experiencing PMS. However, the majority of evidence supports a deficiency in the tryptophan-derived neurotransmitter serotonin as the primary factor in the pathogenesis of PMS. Serum serotonin levels and serotonin uptake by platelets are both reduced during the luteal phase of the menstrual cycle in women with PMS. Moreover, the serotonin agonist fenfluramine and selective serotonin reuptake inhibitors (SSRIs) both improve PMS symptoms, whereas tryptophan depletion and the serotonin antagonist metergoline both worsen the syndrome.

Fluctuations in ovarian steroids are believed to underlie these abnormalities in neurotransmitter levels, as demonstrated by the efficacy of gonadotropin-releasing hormone (GnRH) treatments (e.g., leuprolide) that suppress ovarian hormones and relieve the symptoms of PMS. Interestingly, however, the concentrations of serum estrogen and progesterone do not differ between women experiencing PMS and controls; thus, it is the cyclical nature of the sex hormones that appears to be key.

Several subcategories of PMS have been suggested. PMT-A is categorized by the symptoms of anxiety, irritability, and nervous tension. PMT-B is categorized by fluid retention, abdominal bloating, mastalgia, and weight gain. PMT-C is categorized as premenstrual cravings for sweets, increased appetite, and food binges. PMT-D is categorized by depression, withdrawal,

insomnia, forgetfulness, and confusion. These categories have some overlap.

Clinical Presentation

Subjective

Usual cognitive symptoms during the premenstrual period are crying spells, depression, hostility, anxiety, irritability, relationship conflict and feelings of inadequacy, increased or decreased libido, and inability to cope with ever-recurring symptoms. These symptoms often persist for years; women tend to seek help from a health-care professional only when adverse events are linked with these alterations in mood. A recent crisis or threat from a significant other may precipitate a perceived need for professional help. Often, women seek relief from a sense of desperation. The delay in seeking help could come from a fear of being labeled a hypochondriac or mentally unstable.

A variety of physical symptoms may accompany these alterations in mood, ranging from mild to severe, and may change from month to month. The following is a comprehensive list of symptoms by body system:

- Gastrointestinal: Abdominal bloating (most common [more than 90% of women]), nausea, vomiting, constipation, increased thirst
- Respiratory: Colds, hoarseness, rhinitis, asthma, sinusitis, sore throat
- Urological: Oliguria, urethritis, cystitis
- Ophthalmological: Conjunctivitis, visual changes, glaucoma, styes
- Mammalogical: Breast tenderness (more than 50% of women), swelling, heaviness
- Dermatological: Acne, boils, urticaria, spot bruising, recurrence of herpes
- Neurological: Headaches/migraines (more than 50% of women), aggravation of epilepsy, vertigo, syncope, fainting, paresthesias of hands or feet
- Miscellaneous: Fatigue (affecting more than 90%), backache, joint pain, edema of extremities, weight gain, palpitations, pelvic or low abdominal pain, cold sweats, hot flashes, food cravings, compulsive eating

Other changes perceived as "positive" have been reported by patients during the premenstrual period, including increased libido, more energy, more creative ideas, and increased ability to accomplish tasks. Although physical symptoms may be the presenting complaints when patients first seek medical treatment, mood alterations are the most incapacitating and distressing.

All of the symptoms that any one patient may exhibit and believe to be resulting from PMS will present in one of four cycle patterns:

1. Symptoms appear at midcycle, disappear, and reappear the week before menstruation.
2. Symptoms begin at midcycle, with subtle changes that gradually escalate until menses.
3. Symptoms appear the week before menses and intensify until menstruation ensues.
4. Symptoms appear in the first or second luteal weeks and do not disappear until the end of menstruation.

Objective

Increased age and parity are important indicators when assessing whether symptoms are genuinely PMS related, because both of these factors increase the possibility of PMS. A 3-month diary of symptoms, such as the one shown in Table 14.7, which includes the timing of symptoms in relation to menses and severity, should be obtained from the patient. This diary should also list treatments and what makes symptoms better or worse. The diary should also contain a description of the effect the symptoms have had on a patient's family and colleagues. The patient should be asked, after this diary has been compiled, about her expectations concerning evaluation and therapy.

Diagnostic Reasoning

Diagnostic Tests

The most commonly accepted method to diagnose PMS uses a diary during at least two menstrual cycles (three is preferred). If the intensity of whatever symptoms are present increases at least 30% in the 6 days before onset of menses (compared with days 5 through 10 of the cycle) and if the symptoms occur in 2 consecutive months, a diagnosis of PMS is made. This is a rather subjective method of diagnosis, because women are asked to assess the percentage of increase subjectively, and there is no objective means of comparison with other patients. Other questions relevant to this diagnosis include those asked during the sexual, reproductive, family, medical-surgical, and psychiatric histories. This enables the health-care professional to rule out other possible diagnoses. Dietary habits, drug and alcohol consumption, exercise, and social and occupational histories are also important. Once the diary of symptoms and impairment can be pinpointed to the luteal phase of the menstrual cycle, with abatement of symptoms during other parts of the cycle, a presumptive diagnosis of PMS can be made.

A complete physical exam including a gynecological exam is necessary to assess the health of women with PMS symptoms. This will enable the provider to rule out other possible causes for these symptoms. Diagnostic tests that may be useful to rule out other illnesses are a complete blood count, Pap smear, and urinalysis. Other blood tests can rule out thyroid abnormalities (thyroid-stimulating hormone, T_4), menopause (FSH), hypoglycemia or hyperglycemia (fasting blood sugar), and hyperprolactinemia (prolactin level).

Depression scales are also part of a complete work-up for PMS. These enable the practitioner to rule out depression during the follicular stage of the menstrual cycle and, therefore, to pinpoint the depression and its manifestations to the luteal phase of the menstrual cycle.

Differential Diagnosis

One of the most important assessment parameters in making a diagnosis of PMS is that symptoms occur only during the luteal phase of the menstrual cycle. If symptoms appear during the follicular phase, this may reflect a mood or anxiety disorder. It is important to note that there is a lifetime incidence of psychiatric disorders, especially depression, of nearly 80% in women diagnosed with PMS. Differential diagnoses that are possibly related to the symptoms of PMS are cyclothymic disorder; dysfunctional marital situation; depression; bipolar depression; perimenopausal status; poor diet; endocrine abnormalities, such as hypoglycemia, diabetes, hypothyroidism, hyperprolactinemia, and hyperandrogenism; alcoholism; drug abuse; and tumors of the brain, breast, and ovaries. These must all be ruled out before a definitive diagnosis of PMS can be made. Often it is easy to dismiss vague symptoms and use "PMS" as a catch-all term. This can lead to misdiagnosis, which could have serious consequences. The DSM-V criteria for diagnosing PMDD specify that a woman must have 5 of the 11 symptoms listed, and at least 1 symptom must be 1 of the first 4 on the list. In addition, to be considered as PMDD, the symptoms must occur during the week before menstruation and end a few days after onset of menses. The symptoms must interfere with work, school, usual activities, or relationships and not be merely an exacerbation of another disorder. This must be established for two consecutive menstrual cycles. The symptoms are as follows:

1. Depressed mood or dysphoria (a feeling of low mood, irritability, anxiety, and/or despair)
2. Anxiety or tension
3. Affective lability
4. Irritability
5. Decreased interest in usual activities
6. Concentration difficulties
7. Marked lack of energy
8. Marked change in appetite, overeating, or food cravings
9. Hypersomnia or insomnia
10. Feeling overwhelmed
11. Other physical symptoms (e.g., breast tenderness, bloating)

Management

The principle of management is to assist the patient in developing strategies to gain control over the symptoms, alleviate them as much as possible, and normalize life. Once an accurate diagnosis of PMS is made, appropriate interventions can be individualized. There are two principles to keep in mind when developing this plan. First, PMS is a chronic disorder that lasts until after menopause. This makes cost and adverse effects important issues when planning treatment. Second, patients have different degrees of severity of symptoms and different symptom profiles. Treatments should match both the symptoms and the severity of symptoms. Lifestyle changes should be recommended as first-line therapy.

Lifestyle Changes

Lifestyle changes include regularly scheduled meals that are relatively high in complex carbohydrates and low in salt, sugar, and caffeine; regular aerobic exercise (shown to decrease depression); and stress reduction techniques. Aerobic exercise can cause an increase in endorphin levels and thereby improve mood. Epidemiological studies comparing the severity of premenstrual symptoms in patients who exercise to those who do not have suggested that those who exercise have fewer symptoms. This is especially true for premenstrual depression. Moreover, it appears that the benefits are independent of the intensity of exercise; therefore, low levels of exercise intensity may be beneficial. An activity as simple as sitting quietly for 20 minutes twice a day and deep breathing while listening to relaxation music was shown to reduce mood symptoms of PMS twice as effectively as no active therapy.

Specific dietary interventions that are effective include a reduction in salt, sugar, alcohol, and caffeine intake and an increase in complex carbohydrates. It is hypothesized that carbohydrates are involved in the serotonergic pathway, and an increase in serotonergic activity caused by increased complex carbohydrate consumption may help to relieve symptoms. In one trial, patients were given a carbohydrate-rich beverage during the late luteal phase of the menstrual cycle. The control group was given an isocaloric control beverage. The patients who drank the carbohydrate-rich beverage reported lower adverse mood symptom scores, whereas the control group reported no effect on mood.

Calcium and magnesium supplements have been shown to help control the emotional and physical symptoms of PMS. In several large clinical trials, 1,000 mg of calcium per day decreased all PMS symptoms as well as any other medication or treatment. Women taking magnesium also experienced a reduction in total symptoms. This effect is thought to be due to the reversal of lower than average mononuclear blood cell magnesium concentrations in patients with PMS.

Other dietary supplements have also been tried for PMS, but the results are not conclusive. For example, micronutrients such as pyridoxine (vitamin B_6) 50 to 100 mg daily, folic acid 400 mcg daily, and tocopherol (vitamin E) have been used to treat PMS symptoms. Because the adverse effects of vitamins are minimal, a daily supplement may be helpful as long as the dosage

does not exceed the recommended daily allowance. Vitamin E has been prescribed as a treatment for mastalgia (breast tenderness). Trials have demonstrated that vitamin E (at doses of 150, 300, or 600 IU daily) makes little difference in the mastalgia of patients with PMS but does help some women. Vitamin E can be toxic in high doses, so it is important to prescribe appropriate doses to patients with mastalgia; 400 IU is the most commonly available dose, which gives a minimum effect without danger of toxicity.

Medications

In addition to lifestyle changes, SSRIs such as fluoxetine (Prozac) 20 mg daily (most common) are effective in relieving tension, irritability, and dysphoria. Sertraline (Zoloft) may be used in doses up to 150 mg daily, paroxetine (Paxil) 20 to 30 mg daily, and citalopram (Celexa) 20 to 30 mg daily. These are relatively inexpensive and have limited adverse effects, which include nausea, headache, jitteriness, and decrease in libido. Lowering the dose of the SSRI may eliminate some of the adverse affects. If a therapeutic response is not reached within several cycles, the dose may be increased. Although SSRIs are generally administered daily, these drugs have been shown to be effective when administered only during the luteal phase. SSRIs can then be used advantageously from a cost and adverse effect aspect.

Other antidepressants that inhibit serotonin reuptake but are not selective have also been used. These include clomipramine (Anafranil), nefazodone (Serzone), and venlafaxine (Effexor) (50–200 mg daily), which inhibit both serotonin and norepinephrine reuptake. But they are definitely not first-line therapies, given their side-effect profiles. In fact, several studies have shown that antidepressants outside of the SSRI class are not consistently effective for PMS control.

Benzodiazepines (BZDs) such as alprazolam (Xanax) 0.25 mg three or four times daily are usually reserved for patients who fit the strict criteria of PMDD. Alprazolam is given starting on day 14 and continued through day 28. This will reduce the chances of developing BZD dependence. Thus, BZDs are considered only as a second-line therapy after SSRIs and only in patients with documented PMDD.

Patients who do not respond to the above measures are candidates for a trial of ovulation suppression therapy with danazol 200 to 800 mg daily. Danazol is a GnRH agonist, a nortestosterone hormone derivative with progestin-like effects that induces ovarian suppression. It works by continuously suppressing pituitary gonadotropin secretions (LH/FSH). It must be given continuously because pulsatile administration leads to FSH/LH secretion. When this therapy is used, "add back" therapy is also used to provide some of the hormones suppressed by the GnRH agonist. Estrogen and progestin are given in low doses. For patients on GnRH agonist therapy, long-term alendronate is given to help prevent bone mineral density loss. Danazol has several undesirable adverse effects such as weight gain, increased facial hair, and acne.

Fluid retention is commonly reported during the luteal phase of the menstrual cycle and accounts for some of the physical symptoms of PMS. Spironolactone (Aldactone) 100 mg daily during the luteal phase has been shown to significantly reduce physical and psychological symptoms of PMS over placebo. With the use of spironolactone, participants reported improvement in irritability, depression, feeling of swelling, breast tenderness, and food cravings. Other forms of diuretics, such as thiazides, do not demonstrate effective reduction of the symptoms of PMS.

NSAIDs administered during the luteal phase significantly reduce physical symptoms of PMS. Naproxen sodium (Naprosyn) 500 mg 2 times daily, begun 1 week before the onset of menses and continued through the first few days of bleeding, is effective for both PMS symptoms and dysmenorrhea. This treatment is not recommended for anyone with renal impairment, gastrointestinal (GI) disorders, or inflammatory bowel disorders. As with any NSAID, GI distress and bleeding may occur. Although this is not first-line therapy for patients with PMDD, for patients with moderate symptoms, especially if associated with dysmenorrhea, headaches, or other musculoskeletal symptoms, NSAIDs may be beneficial. This is a relatively inexpensive and safe form of therapy for younger patients and may provide them with the help that they need to function normally during this period of the menstrual cycle.

Many folk remedies and complementary therapies have also been tried by women for centuries with varying degrees of success. Complementary Therapies 14.1 presents some of these measures.

Surgery (bilateral oophorectomy, usually with hysterectomy) is an option for women who respond only to GnRH agonist therapy for documented PMDD. This option should be reserved for women who no longer desire childbearing and is most appropriate for women who are not near menopause and will likely need therapy for several more years.

Follow-up and Referral

The first follow-up visit should be in 2 months to evaluate the data collected by the patient between visits to assess symptom patterns, enabling the diagnosis of PMS to be made and to begin treatment. Frequent visits may be required after that time to evaluate the effectiveness of treatments and to encourage patients to continue to examine and develop treatment plans. Eventually, once symptoms have been controlled, yearly visits should be sufficient.

Referrals to a specialist may be required, depending on findings from the diagnostic tests and physical exam. The diagnosis of PMDD requires referral to a

Complementary Therapies 14.1 Women's Health Problems

Problem	Therapy	Dosage	Comments
Premenstrual syndrome (PMS)	Evening primrose oil	250 mg PO up to 3 times daily 2–3 days before menses	Rare adverse effects: Headache, nausea, diarrhea
	Calcium	1,200–1,600 mg PO daily	Should be taken in divided doses and with optimal daily allowance of vitamin D (400 IU daily) for better absorption
	Vitamin B_6	150 mg PO daily	Those taking levodopa must consult their provider before taking
	Vitamin C	1,500–3,000 mg PO daily	Take in divided doses for better absorption and to avoid diarrhea
	Essential oils: Chamomile, basil, lavender, marjoram	Use as directed on label	Aromatherapy
Menopausal symptoms	Black cohosh	40–200 mg PO daily	Not recommended for more than 6 months
	Chaste tree berry	Extracts or tinctures to provide 20 mg of crude fruit or 30–40 mg of fruits decoction	Possible adverse GI effects; contraindicated in pregnancy
	Vitamin B complex	50 mg PO daily	High levels of estrogen related to hormone fluctuations can deplete vitamin B_6, resulting in anxiety, irritability, and depression
	Vitamin C	1,500–3,000 mg PO daily	Take in divided doses for better absorption and to avoid diarrhea
	Vitamin E	400–800 IU PO daily	Can interfere with anticoagulant therapy; consult with provider before taking or if taking warfarin (Coumadin) or heparin
Breast tenderness	Chaste tree berry	As above	
	Evening primrose oil	As above	
Candidiasis (yeast infection)	Vitamin C	3,000–6,000 mg PO daily	Take in divided doses for better absorption and to avoid diarrhea
Decreased sexual desire	Essential oils: Jasmine, neroli, rose, sandalwood, ylang-ylang, clary sage, patchouli	Use as directed on label	Aromatherapy; aphrodisiac

psychiatrist for treatment. The use of certain treatments for severe PMS, such as GnRH agents, is handled by a gynecologist.

Patient Education

It is important to listen to and evaluate the concerns of patients when they present with symptoms typically associated with PMS. PMS must not be identified with weakness on the part of the patient but rather recognized as a disease entity that must be investigated and treated. It may take time and energy to manage the symptoms and help the patient maintain a good quality of life. When a patient is able to reduce PMS symptoms, whether severe or mild, it helps her to function within her societal role at a higher level and, therefore, benefits everyone.

DYSMENORRHEA

Dysmenorrhea is painful menses. It may be primary, with no pelvic pathology, or secondary, usually accompanied by pelvic pathology.

Epidemiology and Causes

Primary dysmenorrhea usually begins 1 to 2 years after the onset of menstruation, is associated with ovular cycles, and lasts 1 or 2 days each month. The menstrual pain associated with primary dysmenorrhea may lessen for some women as they age or after the birth of children

or it can last until menopause. There is no associated pathology, and from 50% to 75% of women experience this at some time.

Secondary dysmenorrhea is caused by a physical condition. Women who experience this type tend to be older than those who have primary dysmenorrhea, sometimes beginning when a women is in her 30s or 40s. Menstrual pain is the predominant symptom, as in primary dysmenorrhea. Possible conditions responsible for secondary dysmenorrhea include endometriosis, pelvic inflammatory disease (PID), fibroids (uterine leiomyomas), adenomyosis, and endometrial polyps. Secondary dysmenorrhea is most common in women aged 40 to 50 years.

It is estimated that more than 140 million lost work hours are a result of dysmenorrhea. It is the most common gynecological complaint of women and the main cause of missed work, school, or other activities. An estimated 42 million women in the United States suffer from painful menstrual symptoms each month. Risk factors for primary dysmenorrhea include obesity, low body mass index, long menstrual cycles, menarche occurring before 12 years of age, nulliparity, cigarette smoking, and a positive family history for dysmenorrhea. Risk factors for secondary dysmenorrhea include pelvic infection, endometriosis, and sexually transmitted infections.

Pathophysiology

Dysmenorrhea is caused by the production of prostaglandins and leukotrienes, chemical substances that are released when uterine tissue breaks up and is sloughed off during menstruation. Prostaglandin F_2 (PGF_2) and prostaglandin E_2 (PGE_2) are two of the most important players. Elevated uterine levels of these arachidonic acid metabolites, and more specifically an increased ratio of PGF_2 to PGE_2, have been directly correlated with increases in subjective pain. Increased prostaglandin levels found in uterine tissue, but not in plasma, cause dysrhythmic uterine contractions and increased resting tone by stimulating smooth muscle tissue to contract, which compromises blood supply and oxygenation to uterine muscle, thus causing severe pelvic pain known as "cramps."

These uterine contractions may last for several minutes at a time, producing maximal pressures up to 400 mm Hg, with resting pressures as high as 80 mm Hg. In turn, if uterine muscle tone is consistently higher than systemic arterial pressure, uterine ischemia ensues, resulting in the production of anaerobic metabolites that stimulate small type C pain fibers. In turn, pain relief has been directly correlated with decreases in uterine contraction pressure. Because smooth muscle is found in the stomach, intestines, and blood vessels, as well as in the uterus, the excessive stimulation accounts for the nausea, diarrhea, and headache that often accompany dysmenorrhea. Cramps facilitate the release of menstrual tissue, and because the cervical opening is usually widened after childbirth or years of menstruation, cramps may lessen in the older patient. In contrast, worsened cramps are associated with anovulatory menstrual cycles—a common phenomenon in young women, affecting up to half of adolescents within 2 to 4 years after the start of menses.

Clinical Presentation

Subjective

Description of the pain is an important factor. The type, severity, and duration of pain should be noted. A patient with dysmenorrhea may present with sharp stabbing pain and cramping, low back pain, nausea and sometimes vomiting, bowel changes, and fatigue. The pain with primary dysmenorrhea usually starts within 24 hours of menses and may last for 48 to 72 hours. Secondary dysmenorrhea may have the onset of pain a week or more before the onset of menses and continue after cessation of flow for a few days. The patient may state that she is immobilized by her period every month for the first day. Her pain may be so severe that at times she cannot do anything except stay in bed with a heating pad on her abdomen. She may lose her appetite and eat very little during this time. She may complain of pain during intercourse.

Diagnostic Reasoning

Diagnostic Tests

The physical exam (revealing no signs of pathology) and a history of consistent symptoms for 1 or 2 days each month will usually substantiate the diagnosis of primary dysmenorrhea, because the symptoms are fairly typical. Secondary dysmenorrhea may have a slightly varying description of symptoms; some menses are more painful than others, and the level of discomfort may be progressive. If the complaint of painful intercourse is present, a diagnosis of secondary dysmenorrhea, possibly related to endometriosis, should be explored.

Laboratory studies in the evaluation of dysmenorrhea are ordered to rule out potential causes of pelvic pain. They include quantitative human chorionic gonadotropin and complete blood count, urinalysis, erythrocyte sedimentation rate, and stool for occult blood. Serum CA-125 levels are known to be elevated in women with endometriosis (a common cause of dysmenorrhea), as well as ovarian pathology; however, this test is not sufficiently sensitive to serve as a reliable screening tool. Imaging studies are the choice for the initial evaluation of suspected pelvic disease. Gynecological consultation with visualization of pelvic organs via ultrasound is the definitive procedure of choice for evaluation of pelvic pathology. If such testing does not produce a definitive diagnosis, it may be followed up

by laparoscopic exploration to directly visualize pathological conditions such as endometriosis.

Differential Diagnosis

The ultimate goal of the differential diagnosis of dysmenorrhea is to exclude underlying pelvic pathology to differentiate between primary and secondary dysmenorrhea. This includes diagnosing conditions that may produce or mimic dysmenorrhea such as endometriosis, ovarian cysts, ectopic pregnancy, urinary tract infection, vaginitis, dysfunctional uterine bleeding, uterine leiomyomas, appendicitis, lower back pain, trauma from sexual assault, and PID. Endometriosis is the most common cause of secondary dysmenorrhea.

Management

The principle of management for primary dysmenorrhea is to relieve the menstrual pain as much as possible. For secondary dysmenorrhea, the goal is to find a diagnosis.

Ordinary aspirin 325 mg two tablets (650 mg total) PO every 4 hours, started 1 or 2 days before menstruation, is helpful because of its antiprostaglandin activity as an inhibitor of the enzyme cyclo-oxygenase, which converts arachidonic acid into prostaglandin metabolites. Dietary changes such as the avoidance of caffeine during the first few days of menstruation have been shown to be helpful. Exercise may be of some benefit because it raises levels of beta endorphins, chemicals in the brain associated with pain relief. Cigarette smoking has been linked to increasing the duration of dysmenorrhea.

Interestingly, in clinical studies, placebo treatments have been shown to improve symptoms of dysmenorrhea, albeit often only transiently. But the NSAID ibuprofen (Advil, Motrin) 400 to 800 mg PO three to four times daily as needed remains the mainstay of dysmenorrhea therapy and is considered the most effective over-the-counter pain reliever for cramps. Several studies have demonstrated that if ibuprofen fails to relieve a patient's symptoms, it is appropriate to try an alternative NSAID agent such as naproxen sodium (Naprosyn 500 mg or Aleve 220 mg × 2 tablets PO 2 times daily as needed), indomethacin (Indocin), fenoprofen (Nalfon 300–600 mg PO 2–3 times daily as needed), or mefenamic acid (500 mg PO initially, followed by 250 mg 4 times daily for up to 3 days). The latter agent not only inhibits new prostaglandin formation but also inhibits the activity of preformed prostaglandins (Level II; Kaur Bajaj et al, 2012). In contrast, acetaminophen (Tylenol) appears to be less effective because it does not inhibit prostaglandin formation and is not considered an anti-inflammatory agent.

Application of a hot water bottle or heating pad to the abdomen or hot baths may help relieve discomfort and in some studies has been shown to be as effective as NSAID therapy. However, interestingly, the combination of heat therapy and NSAIDs together has been shown to be counterproductive. Acupuncture, transcutaneous electrical nerve stimulation therapy, and specific herbal teas (e.g., mint tea, certain ayurvedic preparations) have all been shown to decrease uterine spasms in small clinical trials. Relaxation or yoga-type exercises may also help to relieve pain. Dietary restriction of both caffeine and salt is also recommended, and vitamin E, vitamin B_1, vitamin B_6, magnesium, and vitamin D were found to reduce symptoms. There is some evidence that vitamin E therapy, 400 IU/day beginning 2 days before the onset of menstruation and for 5 days total for two cycles, decreases dysmenorrhea (Level II; Kashanian et al, 2013). Other research indicates that ingestion of a single high oral dose of vitamin D has a favorable effect on dysmenorrhea (Level II; Lasco et al, 2012).

For some women, even prescribed prostaglandin inhibitors are ineffective. Combined estrogen-progestin oral contraceptive (OC) agents may be considered for these patients because OCs relieve cramping by inhibiting arachidonic acid production and ovulation, in turn hindering high levels of prostaglandin production. These therapies may be given daily as 21-, 63-, or 105-day continuous courses, each followed by 7 days off medication, before repeating the cycle. Longer cycles of OC therapy decrease the frequency of menstruation occurring during the off-therapy week.

If no relief is achieved after NSAID and OC therapy, ultrasonography and even exploratory laparoscopy may be appropriate to rule out pelvic pathology. If endometriosis (the most common cause of secondary dysmenorrhea) is found, a gonadotropin-releasing hormone analog may be prescribed in continuous fashion to inhibit menses (see under Endometriosis).

Follow-up and Referral

Each patient with a case of pelvic pain should have follow-up care because treatment is ongoing and requires further evaluation of relief of symptoms or additional diagnostic evaluation for continued symptoms. Prognosis for primary dysmenorrhea is good with the use of antiprostaglandins, with a 70% to 80% relief of symptoms in some cases.

Patient Education

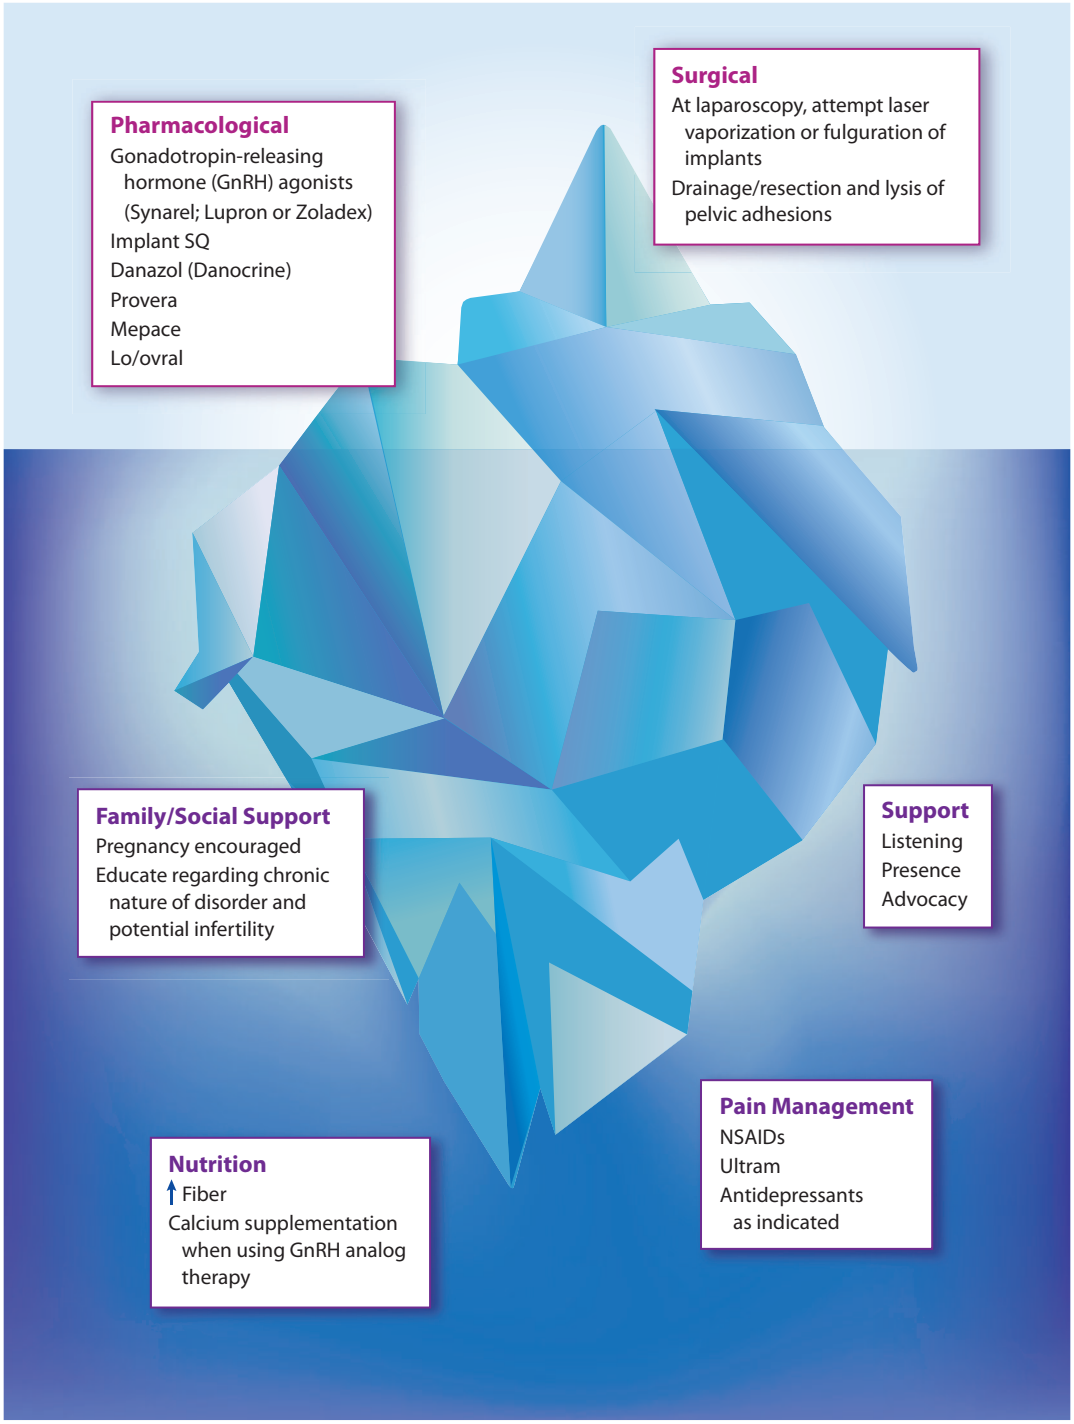
Advise the patient that ordinary aspirin, two tablets every 4 hours 1 to 2 days before menstruation begins, can significantly reduce prostaglandin levels. Education about changes in exercise and diet may also be useful. Dietary supplementation with omega-3 fatty acids has been shown to help provide relief in adolescents. Patients should be encouraged to stop smoking and decrease alcohol intake. Symptomatic treatment with a warm bath or locally applied heat may be helpful.

ENDOMETRIOSIS

Endometriosis is a painful, chronic disease, characterized by the presence and proliferation of abnormally

placed endometrial tissue, which responds to hormone changes in the woman's body. Abnormally placed endometrial tissue has been found outside the uterus, usually in the abdomen, on the ovaries, fallopian tubes, and ligaments that support the uterus; in the area between the vagina and rectum; in the outer surface of the uterus; and in the lining of the pelvic cavity. Other sites for these endometrial growths may include the bladder, bowel, vagina, cervix, vulva, and in abdominal surgical scars. Rarely, endometrial tissue may be located in the lung, arm, thigh, brain, and other locations.

The Iceberg of Endometriosis



This tissue reacts as correctly placed endometrial tissue would during the menstrual cycle. The bloody discharge produced by such tissue has no outlet. The presence of such discharge may cause severe pain with each menstrual cycle, either during ovulation, menstruation, or both. The accumulation of the discharge may form dense fibrous tissue, leading to adhesions, sterility, and destruction of ovarian tissue.

Epidemiology and Causes

Endometriosis affects an estimated 5.5 million women in the United States and Canada. Women at all levels of society and of all races may be affected. A study of 3,684 premenopausal women undergoing laparoscopy or laparotomy found a prevalence of endometriosis varying from 12% to 45%, depending on the indication for surgery. Delay in diagnosing endometriosis is common. Statistical analysis shows the highest level of occurrence reported in women 25 to 29 years of age and lowest incidence found in women over 44 years of age; however, the disease can be found at any age, including adolescents. Research conducted by the Endometriosis Association found that the recognition and diagnosis of endometriosis is still taking a combined average of 9 years (4.67-year delay in seeking medical help and 4.61-year delay in physicians' diagnoses). From the sample of 4,000 respondents, almost half said that they had to see a doctor five times or more before they were diagnosed, referred, or treated. Japanese women are twice as likely to have endometriosis as Caucasian women.

The cause of endometriosis is unknown. The retrograde menstruation and implantation theory suggests that during menses, some amount of menstrual tissue backs up through the fallopian tubes, implants in the abdomen, and proliferates in response to ovarian steroids. In turn, conditions that lead to genital tract obstruction and impede menstrual outflow contribute to reflux through the fallopian tubes. However, this theory has been found inadequate to explain all of the possible sites of endometriosis, and some experts believe that all women experience some menstrual tissue backup. Direct transplantation may account for endometriosis that develops in uterine surgical scars after a cesarean section or episiotomy. Another theory suggests that endometrial tissue is distributed from the uterus to other parts of the body through either the lymphatic or hematological circulatory systems. The coelomic (peritoneal) metaplasia theory suggests that undifferentiated cells lining the peritoneal cavity are triggered to differentiate into endometrial tissue by hormonal irregularities. There may also be a genetic predisposition to endometriosis; in addition, research by the Endometriosis Association has recently linked dioxin exposure to the development of endometriosis.

Pathophysiology

In addition to the etiological theories discussed in the preceding text, a link to immune system dysfunction and the pathogenesis of endometriosis has also been suggested. Reduced T-cell and natural killer cell function are thought to impair the ability of the body to recognize and destroy abnormally implanted endometrial tissue, that is, immunosurveillance. Interestingly, however, an increased number of peritoneal leukocytes and macrophages have been identified within ectopic endometrium. Increased levels of cytokines and chemokines produced by these cells have been identified, including interleukin-1 (IL-1), IL-6, IL-8, tumor necrosis factor, and RANTES (regulated upon activation normal T cell expressed and presumably secreted). These mediators act as growth factors for ectopic endometrium, and vascular endothelial growth factor stimulates capillary proliferation into this tissue. Interestingly, women with endometriosis are also more likely than controls to suffer from autoimmune inflammatory diseases.

Any pelvic organ may be a possible site of abnormal endometrial tissue known as endometriosis. The cyclical production of ovarian sex hormones allows for the proliferation and maintenance of these implants. Thus, endometriosis occurs primarily during a woman's active reproductive phase, rather than during premenstrual, immediately postmenarchal, or postmenopausal phases. This bleeding may cause severe pelvic pain and dyspareunia, infertility, and debilitation. In addition, inflammation of pelvic tissues may lead to adhesions and cyst development.

Endometriosis may be progressively staged from minimal (stage I: isolated implants without adhesions), mild (stage II: superficial implants less than 5 cm in aggregate without adhesions), moderate (stage III: multiple superficial and invasive implants with or without tubo-ovarian implants), to severe (stage IV: multiple superficial and invasive implants with large ovarian endometriomas and dense adhesions).

Clinical Presentation

Subjective

The primary symptom of endometriosis is recurrent abdominal and/or pelvic pain, which may range from very mild to completely incapacitating. The pain may be associated with menstruation (dysmenorrhea), or it may occur slightly before the menstrual period. Pain may be experienced as generalized abdominal or pelvic pain or pain associated with sexual intercourse (dyspareunia), urination, and defecation. Fatigue, diarrhea, constipation, or nausea may accompany the pain. The patient may complain only of premenstrual spotting.

A careful history of menstruation should be taken, with significant attention to any complaints of pain. A history of allergies, chemical sensitivities, and recurrent yeast *(Candida)* infections may be present. Infertility is associated with endometriosis; 30% to 40% of women diagnosed with endometriosis are infertile.

Objective

On physical exam, tenderness in the posterior fornix is the most common symptom. Lateral deviation of the cervix may be due to internal scarring, and bimanual examination may reveal palpable nodules on supporting ligaments and on affected ovaries. However, definitive diagnosis cannot be made via history and physical exam.

Diagnostic Reasoning

Diagnostic Tests

Direct visualization of endometrial implants through laparoscopy is the preferred diagnostic method, because most implants are located on the pelvic organs. A complete blood count may be done to diagnose anemia associated with blood loss resulting from endometriosis, and an elevated white blood cell count may also show evidence of an infection. This would tend to make endometriosis less likely, although it would not exclude abnormal endometrial tissue. Serum CA-125 levels are more likely to be elevated with advanced (stage III to IV) endometriosis, but this serum marker is not particularly sensitive and not a good screening tool.

Differential Diagnosis

The clinical manifestations of endometriosis are associated with many genitourinary disorders. The pain experienced is often discounted because it is a frequent (normal) accompaniment to menstruation. Pelvic and abdominal pain can be caused by gastroenteritis, appendicitis, ovarian cysts, fibroids, or ectopic pregnancy and these diagnoses must be ruled out. Specific differential diagnoses that must be considered are adenomyosis and endometrial polyps.

Adenomyosis is the presence of ectopic endometrial glands and stroma within the musculature of the uterus, which induces hypertrophy and hyperplasia of the myometrium in response to estrogen (and possibly progesterone); it may be microscopic or nodular on gross inspection, but endometrial biopsy is typically negative because of changes in the myometrium. Adenomyosis seems to be more associated with childbearing, but the pathogenesis is unknown. Although a third of women are asymptomatic, adenomyosis may present with abnormal uterine bleeding, dysmenorrhea, and menorrhagia—just as with endometriosis. Abdominal ultrasound may be able to identify these differential diagnoses, but laparoscopy is necessary to diagnose endometriosis.

Endometrial polyps are hyperplastic pedunculated/sessile growths of endometrial glands and stroma at the endometrial surface (millimeters to centimeters in size) and are common in middle-aged women. Metrorrhagia (irregular uterine bleeding) occurs in 50% of cases, and less frequently, menorrhagia, postmenopausal bleeding, prolapse through the cervical os, and breakthrough bleeding on hormonal treatments occur as symptoms. Definitive diagnosis is made on microscopy (after dilation and curettage, biopsy, or hysterectomy), but sonohysterography (instillation of saline into uterus before ultrasound) is preferred to transvaginal ultrasound for noninvasive evaluation (but it cannot be diagnostic). Curettage via hysteroscopy, rather than blindly, is preferred for best detecting polyps.

Management

Currently, there is no cure for endometriosis. Management is linked to relieving or reducing pain, shrinking or slowing endometrial growths, preserving or restoring fertility, and preventing or delaying the recurrence of the disease. In women with mild disease or those who are perimenopausal and will soon stop ovarian cycling and the hormonal fluctuations that trigger bleeding endometriosis, expectant management (observation) is an important option.

Oral contraceptives are used with good results to provide adequate relief for women with mild disease. Studies indicate that low-dose drospirenone/ethinyl estradiol 3 mg/20 mcg, either continuous or cyclic oral contraceptives, are effective in reducing pelvic pain resulting from endometriosis (Level II; Harada et al, 2008; Mabrouk et al, 2012). In addition, pain relief is often achieved with NSAIDs and other prostaglandin inhibitors. Oral contraceptives (OCs) and NSAIDs are usually sufficient only for disease with minimal pain. Typically, the medications include ibuprofen (400–600 mg 4 times daily), naproxen sodium (220 mg 4 times daily), indomethacin, and mefenamic acid (Ponstel) (250 mg 4 times daily to 500 mg 3 times daily). Medication administration should begin with the onset of menstruation to avoid the possible influence of medications on pregnancy. Prescription pain medications may be necessary to control symptoms. Conservative management is to use the least powerful medications first. With consistent reevaluation of symptom reduction, the risks associated with medications can be minimized.

For women with moderate to severe disease, hormonal therapy may help relieve symptoms. Drugs such as nafarelin nasal spray (0.2–0.4 mg 2 times daily), long-acting leuprolide acetate (3.75 mg IM once a month), or goserelin (3.6 mg subcutaneously once a month) are gonadotropin-releasing hormone (GnRH) analogs and suppress ovulation by suppressing pituitary gonadotropin secretion and thus ovarian estrogen secretion. These drugs are used for 3 to 6 months, although the optimum length of therapy is unclear. Adverse effects of this medication are vasomotor symptoms (hot flashes), vaginal dryness, dyspareunia, decreased libido, insomnia, breast tenderness, headache, depression, and bone demineralization, which can be mediated by "add back" therapy with norethindrone, 5 to 15 mg daily.

Another hormonal treatment is danazol (200–400 mg 2 times daily), which is used for 6 to 9 months. Danazol

is a testosterone derivative that acts like progesterone and suppresses menstruation. Adverse effects are androgenic and include weight gain, acne, hirsutism, muscle cramps, lower high-density lipoprotein, and decreased breast size.

Continuous combination OCs may also be given but are most effective in mild disease. Any of the combination OCs discussed earlier in this chapter can be used. Breakthrough bleeding may occur and is treated with conjugated estrogens 1.25 mg daily for 1 week or estradiol 2 mg daily for 1 week. Adverse effects are discussed earlier in the chapter.

Progesterone alone in the form of medroxyprogesterone acetate 100 mg IM every 2 weeks for four doses, then 100 mg every 4 weeks, can be given to inhibit endometrial tissue growth and initiate decidualization and atrophy of the endometrium. Oral therapy of medroxyprogesterone 10 mg three times daily or norethindrone 5 mg daily can also be used. These treatments provide 80% of women with complete or partial relief of symptoms. These treatments are used for 6 to 9 months. Oral estrogen can be added to control breakthrough bleeding.

Aromatase inhibitors, which decrease estrogen production, are still investigational. Regimens may be developed that combine these drugs with progestins or GnRH analogs.

Laparoscopy is used to ablate endometrial implants, which greatly reduces pain. Some women require removal of ovarian endometriomas along with ablation of implants, and this procedure improves fertility. For women who no longer desire to have children, a total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO) will treat the endometriosis definitively, but in women with deep implants, TAH-BSO may not be sufficient.

Medical treatment alone is inappropriate for moderate to severe disease, and in addition, in these women it does not improve fertility. Only surgical interventions are shown to improve fertility. For example, some reviews have shown that with observation alone, pregnancy rates in mild, moderate, and severe disease are 50%, less than 25%, and only 5%, respectively. With surgery, pregnancy rates rise to 50% and 39% in patients with moderate and severe disease, respectively. However, in vitro fertilization is usually needed postoperatively for women with severe disease in whom hysterectomy can be avoided. Infertile women who are trying to improve their chance of pregnancy typically benefit from laparoscopic ablation of endometrial implants.

Alternative therapies are gaining acceptance in the treatment of endometriosis. Visualization techniques, patterned breathing, massage therapy, and others may each have their place in the treatment of this disorder. Diet therapy and therapy to maximize the immune system may also be useful. Therapies must be evaluated for an appropriate match between patient and therapy. Financial issues may be of concern. Hormonal therapies are significantly more expensive than dietary changes and massage therapy (see Complementary Therapies 14.1).

Follow-up and Referral

The signs and symptoms of endometriosis are related to the menstrual cycle. Follow-up visits should be timed to allow prescribed treatments to have affected the symptoms associated with the next menstrual cycle. The patient should be referred to a gynecologist experienced in laparoscopic diagnosis and treatment of endometriosis if the most conservative medical treatments are not sufficient to ameliorate the symptoms.

Patient Education

Each patient must receive appropriately formulated educational materials about endometriosis, including its signs and symptoms and the effects they may produce, because this is usually a lifelong condition. (See The Patient's Voice 14.2.)

The Patient's Voice 14.2

Endometriosis

I had a very painful menstruation from day 1. As long as I can remember, every month I was in bed doubled over in pain. Nothing seemed to relieve the intensity of the pain . . . even taking birth control pills. My periods were not heavy, but I always had pain and even a little spotting, especially after my period every month. About 1 year after the delivery of my third child, I began experiencing great discomfort with intercourse. My gynecologist suggested that since I was almost 40 years old, a surgical intervention was needed. He explained that laparoscopy or laparotomy and eventual hysterectomy was the usual treatment for women with severe pain. My first surgery did reveal that I had endometriosis . . . a small amount . . . but my surgeon said that some of the locations of the endometriosis made it even more painful. I had a difficult time with the hysterectomy . . . a lot of pain. But, since they removed my uterus, the pain I had for almost 27 years is finally gone. Why did it take so long for someone to give me relief?

LEIOMYOMAS (UTERINE FIBROIDS)

Leiomyomas are most commonly called *uterine fibroids.* Fibroids are benign tumors (most common benign tumor of the uterus) and arise from the smooth muscle cells in the myometrium. Most are small and asymptomatic.

Epidemiology and Causes

Leiomyomas are extremely common, and the prevalence increases in women between 30 and 50 years of age. However, the prevalence decreases with menopause. By age 50 years, 50% of African American and Asian American

women have leiomyomas and about 30% of white women have them.

The cause of leiomyomas is unknown, but clearly there is a hormonal link. Girls before menarche do not have leiomyomas, and they shrink after menopause, implicating estrogen. If a pregnant woman has a fibroid, it dramatically increases in size during pregnancy, but decreases after delivery. Risk factors for the development of leiomyomas include nulliparity, age between 30 and 50 years, obesity, and sedentary lifestyle. Interestingly, smoking seems to decrease the risk for developing fibroids.

Pathophysiology

Leiomyomas develop from a single neoplastic smooth muscle cell with abnormal chromosomal patterns. Leiomyomas are classified by location within the uterine wall and can be subserous, submucous, and/or intramural. Rarely, a leiomyoma can be intraligamentous, cervical, or parasitic (deriving its blood supply from an organ to which it becomes attached). Most uterine fibroids are surrounded by compressed (otherwise normal) myometrium. When leiomyomas outgrow their blood supply, they can become necrotic and ulcerate.

Clinical Presentation

Subjective

Most leiomyomas are asymptomatic. When symptoms are present, abnormal uterine bleeding is the most common symptom. The woman may also complain of pain, particularly with intercourse. If the fibroid is large enough, it can cause pressure on the bladder, resulting in urinary frequency, urgency, and possibly dysuria. The complaint of abdominal or genital heaviness is also common with large fibroids.

Objective

Pelvic exam will reveal one or more uterine masses. Leiomyomas are usually firm and nontender. If there are multiple fibroids (most of the time), the uterus will feel irregular and nodular in shape.

Diagnostic Reasoning

Diagnostic Tests

Because most women with leiomyomas have abnormal uterine bleeding, a complete blood count is ordered. The hemoglobin is decreased because of the increased amount and frequency of menstrual bleeding. Occasionally polycythemia may be present. A pregnancy test should be done to rule out intrauterine pregnancy. An endometrial biopsy may be done and will be normal, which helps rule out other diagnoses.

Pelvic ultrasound or magnetic resonance imaging will confirm the diagnosis of leiomyoma, but transvaginal ultrasound is used most often. Occasionally, hysterography or hysteroscopy is used to confirm cervical or submucous myomas.

Differential Diagnosis

Differential diagnoses should include other disorders that cause uterine enlargement and abnormal uterine bleeding, including pregnancy, adenomyosis (presence of endometrial glands and stroma in the myometrium), ovarian neoplasm, tubo-ovarian inflammatory mass, uterine cancer, and possibly diverticulitis.

Management

No treatment is necessary for women with asymptomatic or very small myomas. If the patient is severely anemic, measures should be undertaken to stop the prolonged, heavy menstrual periods and boost her hemoglobin. Medroxyprogesterone acetate 150 mg IM given every 28 days or Danazol 400 to 800 mg PO daily will usually slow or stop the bleeding. The woman should be instructed to take over-the-counter iron preparations (ferrous sulfate, ferrous gluconate, or ferrous fumarate 300 mg) daily. Folic acid 400 mcg PO daily will help boost red blood cell production as well.

The goal of conservative medical management is to shrink the leiomyomas. Oral contraceptives (OCs) may be effective for some women, but for others, the estrogen in the OC causes enlargement, so frequent monitoring is important. Gonadotropin-releasing hormone (GnRH) agonists are given to decrease the luteinizing hormone and follicle-stimulating hormone levels, thereby producing a hypoestrogenic effect that usually causes the leiomyomas to shrink. This is frequently used before surgery, because the risk of surgical complications is increased with large tumors. The GnRH agents that are used are leuprorelin (Lupron) depot injection of 3.75 mg every 28 days for 3 months or a single dose of 11.25 mg IM. Treatment lasts 8 to 12 weeks and is very costly. Because these drugs induce a menopausal state, the adverse effects reflect those of menopause (see under Menopause). These medications are contraindicated in women with undiagnosed abnormal uterine bleeding and in women who are breastfeeding. Insertion of the levonorgestrel intrauterine contraceptive device (Mirena) has been shown to significantly decrease bleeding with fibroids that are associated with menorrhagia. This device is removed after 5 years.

There are several surgical approaches for problematic leiomyomas. Myomectomy is removal of the myoma and is done when preservation of fertility is desired and the tumor is larger than 12-week gestational size. Hysterectomy (with or without removal of the ovaries) is the definitive treatment for very large fibroids, particularly when bleeding is very heavy and the patient is markedly anemic. Few adverse effects occur as a result of hysterectomy; infection, bleeding, and damage to

surrounding organs are always possible with any surgical procedure. Other possible effects are depression, sexual dysfunction, and menopausal symptoms.

Uterine artery embolization is a relatively new alternative to surgery. The uterine arteries are embolized, producing end-organ ischemia and necrosis with subsequent shrinkage. This procedure is effective in reducing menorrhagia, pain, and uterine volume in 80% of patients. However, a large number of women report severe pelvic pain, fever, malaise, and nausea and vomiting resulting from the infarcted uterine tissue.

Follow-up and Referral

Any woman with severe bleeding, marked anemia, and palpable leiomyomas should be referred to a gynecologist for evaluation and treatment. Women with small uterine myomas should be reexamined at 3- to 6-month intervals or more often if symptoms increase. If menorrhagia is present, hemoglobin and hematocrit should be monitored frequently.

Patient Education

Women with leiomyomas should be reassured that this does not increase their chances of developing uterine cancer. If increased bleeding is a problem, the woman should be instructed to take an iron supplement daily and to increase iron-rich foods in her diet. She should report any shortness of breath, palpitations, or increase in fatigue or pain immediately.

ENDOMETRIAL CANCER

Endometrial cancer arises from the lining of the uterus, known as the endometrium. The majority are pure adenocarcinomas. Endometrial cancer accounts for at least 20% of cases of postmenopausal uterine bleeding.

Epidemiology and Causes

Cancer of the endometrium is the most common (50%) of all gynecological cancers. There are approximately 36,000 cases of endometrial cancer per year, with 6,000 annual deaths in the United States. The overall 5-year survival rate is 80% to 85% but is as high as 98% if the cancer is detected early and the depth of invasion is less than 66%. The 5-year survival rate drops to 78% if the depth of invasion is more than 66%. The average age at diagnosis is 60 years, and about 25% of all cases occur before menopause. African American women are at greater risk for most forms of endometrial cancer, and their stage-for-stage survival rates are also worse compared with those for Caucasian women. Oral contraceptive (OC) pills have been shown to have a protective mechanism against ovarian and endometrial cancer. Patients who use OCs have half the risk of developing these cancers. Women who use OCs for at least a year have this protective effect, which remains even after the OCs are discontinued. Risk factors for endometrial cancer include unopposed estrogen, early menarche, advancing age, a high-fat diet, nulliparity, obesity, hypertension, and diabetes mellitus. Routine screening is neither cost-effective nor warranted, except in extremely high-risk women (40%–60% risk) with certain familial malignancy syndromes such as Lynch syndrome II (i.e., endometrial, ovarian, and colorectal cancers) who are at risk for hereditary nonpolyposis colorectal cancer. However, endometrial cancer screening has rarely been shown to be justified in asymptomatic women, even those on unopposed estrogen hormone replacement or the estrogen agonist tamoxifen.

Pathophysiology

The precursor of endometrial cancer is a hyperplastic state that may progress to invasive carcinoma. Endometrial hyperplasia of glandular tissue occurs when estrogen does not have progesterone as a counterbalance, resulting in a greater gland-to-stroma ratio. The mitogenic effect of estrogen on endometrial tissue appears to result from upregulation of the cell cycle protein cyclin D, as well as various proto-oncogenes and cellular growth factors and their receptors. These findings are also consistent with the protective effects of progestin-containing OCs or continuous progestin therapies. An unopposed estrogenic state may occur from multiple etiologies, including chronic anovulation such as in polycystic ovarian syndrome, an estrogen-secreting ovarian tumor, obesity that causes increased aromatization of androstenedione to estrone and testosterone to estradiol in peripheral adipose tissue with decreased levels of sex hormone–binding globulin, or iatrogenic estrogen exposure from older hormone replacement therapy regimens of estrogen monotherapy (10-fold increase in risk) or the selective estrogen receptor modifier tamoxifen (twofold to threefold increase in risk), which is used as adjuvant therapy for breast cancer. The potential for cytological atypia similarly increases with chronic unopposed estrogenic stimulation, creating a persistent proliferative phase within the endometrium, rather than the normal cycling of proliferative and progesterone-induced secretory phases.

This premalignant condition is characterized by either a simple (i.e., cystic dilation of the glands with occasional outpouching) or complex (more abundant and adjacent glands with outpouching and minimal stroma) architectural pattern of the endometrium, as well as the presence or absence of nuclear atypia and glandular mitoses. Simple hyperplasia without atypia is unlikely to develop into endometrial carcinoma (1% of cases), whereas complex architecture with atypia is most likely to progress to malignancy (30% of cases). Atypia is the key negative prognostic factor, because 25% of women with atypia on biopsy have coexistent malignancy on further evaluation. In fact, some pathologists group complex architecture with atypia together with differentiated adenocarcinoma

under the common heading of endometrioid neoplasia. Indeed, 75% to 80% of all endometrial cancers are estrogen-dependent endometrioid carcinomas (type I).

Not all endometrial malignancy arises from hyperplastic tissue. For example, papillary serous endometrial tumors (5%–10% of cases) arise from atrophic rather than hyperplastic tissue and, as with clear cell (1%–5% of cases), mucinous, and squamous cell (fewer than 2% of cases) endometrial cancers, are estrogen independent (type II). These rarer forms of endometrial cancer tend to be more poorly differentiated (higher nuclear grade) than type I cancers, are highly aggressive with lymphatic invasion, and portend a worse prognosis. Uterine sarcoma is a rare form of cancer (5% of uterine malignancies), which may be completely nonepithelial in origin or of a mixed epithelial-nonepithelial phenotype. Most commonly arising from the uterine myometrium (e.g., mixed Müllerian carcinosarcomas of fibrous, vascular, or lymphatic tissue; leiomyosarcoma), uterine sarcoma may also arise from the endometrium and invade the myometrium (e.g., endometrial stromal sarcoma). These cancers are more aggressive than more common hyperplastic endometrial forms, are prone to metastasis to the retroperitoneal and intra-abdominal nodes and hematogenously to the lungs, and carry a poorer prognosis (e.g., 50% 5-year survival rate for stage I disease versus 90% for more common forms of endometrial cancer). They are more common in African American women (except the endometrial stromal form) and in women aged 40 to 60 years, and there appears to be a correlation with prior pelvic irradiation and, possibly, tamoxifen use.

Endometrial cancers may be mediated by mutations in a host of genes, such as the *p53* tumor suppressor gene, which is a late mutation in 20% of endometrioid carcinomas, an early mutation in 90% of serous adenocarcinomas, but rarely mutated in endometrial hyperplasia. Estrogen-dependent cancers also demonstrate mutations in *PTEN* (an early mutation seen in 80% of cases), microsatellite DNA (20%–30% of cases), and K-*ras* (a late mutation seen in 20% of cases). The cancerous cells lining the endometrium may extend directly into the cervix and through the uterine serosa. Both the pelvic (paravaginal) and para-aortic lymph nodes may become involved. Although endometrial cancer metastasizes slowly, malignant cells can be found in the peritoneal cavity.

Clinical Presentation

Subjective

The patient, usually postmenopausal, presents with abnormal bleeding in 80% of cases. Typically, this is the only patient complaint. Patients who are perimenopausal tend to have irregular periods of bleeding; however, irregular uterine bleeding must not be discounted in these women without further exploration.

Objective

The patient does not demonstrate any pain on the exam unless metastasis has already occurred and the pelvic organs are affected.

Diagnostic Reasoning

Diagnostic Tests

Any postmenopausal patient with abnormal uterine bleeding should be referred for endometrial biopsy. Eighty percent of cases of abnormal bleeding are from benign causes. A Pap test is not a reliable diagnostic indicator for endometrial cancer. Any atypical glandular cells reported on the Pap smear should be followed up by endometrial biopsy to rule out hyperplasia or carcinoma; the same may be done for women older than 40 years of age with normal endometrial cells on Pap smear, but this is more controversial. If endometrial biopsy reveals hyperplasia with atypia, a more extensive hysteroscopy with curettage should be done to rule out coexistent endometrial cancer. If abnormal bleeding persists after an otherwise normal endometrial biopsy (i.e., showing only atrophy, proliferative or secretory endometrium, or disordered/dyssynchronous endometrium reflecting irregular shedding of the endometrium seen with unopposed estrogen exposure and endometritis), further assessment should be done with transvaginal ultrasound (TVUS), hysteroscopy, and directed biopsy/curettage. TVUS is helpful in ruling out carcinoma in women not on hormone therapy (HT). A biopsy is done if the endometrial thickness is greater than 4 mm or in any woman with persistent uterine bleeding, regardless of endometrial thickness. However, TVUS cannot replace biopsy as a means of ruling out cancer. CA-125 should be checked to predict extent of extrauterine spread of the cancer. Depending on the results of the endometrial biopsy, the patient should be referred to a surgeon.

Differential Diagnoses

Differential diagnoses may include benign tumor (leiomyomas [fibroids]), ectopic pregnancy, intrauterine pregnancy, gastrointestinal masses, endometriosis, adenomyosis, and pelvic abscess or adhesions. Endometrial polyps should also be considered because they present mostly in middle-aged women, but account for 25% of cases of abnormal bleeding in premenopausal and postmenopausal women. They are hyperplastic pedunculated/sessile growths of endometrial glands and stroma at the endometrial surface (millimeters to centimeters in size). They are only rarely neoplastic (benign in 70%, hyperplasia without atypia in 25%, atypia in fewer than 5%, and cancer in fewer than 1%). Metrorrhagia (irregular uterine bleeding) occurs in 50% of cases of

endometrial polyps; less frequently, menorrhagia, postmenopausal bleeding, prolapse through the cervical os, and breakthrough bleeding on hormonal treatments occur as symptoms. The only definitive diagnosis for endometrial polyps is microscopy (after dilation and curettage [D&C], biopsy, or hysterectomy), but sonohysterography (instillation of saline into the uterus before ultrasound) is preferred to TVUS for noninvasive evaluation (but it cannot be diagnostic). Curettage via hysteroscopy, rather than blindly, is preferred for best detecting polyps.

Adenomyosis is the presence of ectopic endometrial glands and stroma within the musculature of the uterus, which induces hypertrophy and hyperplasia of the myometrium in response to estrogen (and possibly progesterone); may be microscopic or nodular on gross inspection, but endometrial biopsy is typically negative because of changes in the myometrium. It seems to be more associated with childbearing, but the pathogenesis is unknown (it is perhaps related to invagination of the endometrium, or it may arise de novo from Müllerian remnants). The uterus is large and boggy (as opposed to firm with fibroids). Adenomyosis is not related to endometriosis, although this is another form of ectopic endometrium. Although a third of women are asymptomatic, adenomyosis may present with abnormal uterine bleeding, dysmenorrhea, and menorrhagia.

Management

The primary principle of management is to obtain a correct diagnosis as early as possible, because the cure rate for endometrial cancer is very high if treated early.

Because primary prevention is the best management, women with chronic anovulation may benefit from the protective effects of progestin or progesterone-containing regimens (protects against hyperplasia and carcinoma [doses may be decreased from standard recommendations in women with significant side effects from this]). Women with hyperplasia without atypia can be given medroxyprogesterone acetate 10 mg daily for 12 to 14 days each month for 3 to 6 months, whereas women with atypia (premalignancy) need hysteroscopy with D&C and hysterectomy (preferred if childbearing is no longer an issue). If no cancer is found, women can receive megestrol acetate 10 to 80 mg four times daily continuously to suppress the hyperplasia or hysterectomy (if fertility is no longer an issue and the patient can tolerate the surgery). Obviously, any estrogen therapy should be stopped in these cases. In postmenopausal women not on HT who have hyperplasia without atypia, a hysteroscopy and D&C is done to find the source of the estrogen (such as a tumor or obesity). Women can be given medroxyprogesterone acetate 10 mg daily for 3 months, then reevaluated by biopsy as a guide for further management. If the woman is taking HT, it should be stopped immediately and a similar assessment done. In postmenopausal women with atypia, a hysteroscopy with D&C is done to rule out carcinoma, and hysterectomy (preferred) is considered. As an alternative, megestrol acetate 40 mg two to four times daily can be given with a repeat biopsy in 3 months and hysterectomy done if atypia persists. Otherwise, if the atypia regresses, megestrol can be given and repeat biopsies done every 6 to 12 months for the rest of the woman's life.

Treatment of endometrial cancer is based on the International Federation of Gynecology and Obstetrics (FIGO) staging. Stage I is confined to the uterine corpus, stage II involves the cervix, stage III is regional spread to the pelvis, and stage IV is spread outside the pelvis (20%–25% 5-year survival). Node biopsy (lymphadenectomy) is done for clinically suspicious nodes and for anything beyond stage I disease—a tumor greater than 2 cm, type II endometrial cancer, or myometrial invasion beyond 50%—because all these indicate an increased risk of metastasis. Peritoneal cytology is also sent as a part of surgical staging, because a positive result with nonendometrioid tumors may indicate the need for postsurgical adjuvant chemotherapy. Bilateral salpingo-oophorectomy is done to check for adnexal micrometastases and to eliminate endogenous estrogen production.

In contrast to the treatment of early stage type I endometrial CA, uterine sarcoma is treated with total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO) with adjuvant radiotherapy (either external beam or brachytherapy). Although adjuvant chemotherapy has not been shown to be effective for uterine sarcoma, recurrent disease is treated with chemotherapy. Stage II or higher uterine adenocarcinoma is also treated with TAH-BSO, if the patient can tolerate surgery. Pelvic irradiation is an alternative to hysterectomy but entails significant comorbidities from fibrotic tissue damage that is progressive and nonreversible. Adjuvant postsurgical radiation may be used for women at intermediate to high risk of recurrent disease (grade 1 or 2 disease extending greater than 50% beyond the myometrium [stage IC] or stage II to IV disease) or reserved as salvage treatment for recurrent disease. Disease at high risk of recurrence (grade 2 disease extending to the cervix with greater than 50% myometrial involvement, grade 3 disease, involvement of the lymphatic or vascular system or other metastases) should be treated with surgery and adjuvant therapy—either chemotherapy or pelvic irradiation; the choice is individualized depending on potential side effects and patient tolerance. Recurrent or highly advanced disease is treated with a combination of chemotherapy and hormonal therapy, although the choice of regimen is controversial. Localized relapse may be treated with salvage surgery or pelvic irradiation.

Follow-up and Referral

If endometrial cancer is suspected in a postmenopausal patient with abnormal uterine bleeding, an immediate referral should be made to a gynecologist/oncologist for an endometrial biopsy.

Patient Education

The American Cancer Society recommends an endometrial biopsy at menopause for all patients and then occasionally for patients at risk. Healthy postmenopausal patients should be encouraged to seek care at the first sign of any abnormal bleeding. In addition, obese women should be encouraged to lose weight because it may prove protective and possibly therapeutic for women with chronic anovulation. The use of HT for any indication is controversial in women with prior endometrial cancer. All women should be encouraged to follow treatment regimens for any existing diseases such as hypertension and diabetes mellitus.

MENOPAUSE

Menopause has occurred when a patient has not menstruated for a period of 1 year. This takes place most often in women aged 48 to 55 years (average is 51.5 years), but the normal age range for the onset of menopause is wide—anywhere between ages 40 and 60 years. Menopause is not a disease state, but it portends a change in the hormonal, emotional, and reproductive lives of women. Many patients have an increased awareness of and respect for the wisdom of nature; they have philosophical and personal concerns about treating the symptoms and consequences of menopause not as a disease but as a normal part of their life cycle. Patients need to be aware of what is happening to their bodies so that they can make rational decisions about how to manage this stage of their lives.

The management of menopause and its symptoms has received a great deal of attention in recent years. As the life span for women lengthens—currently to an average of 84 years—menopause does not signal the end but rather another phase of life, with its own issues, challenges, and opportunities. Most women spend 30 years of their lives postmenopausal.

Epidemiology and Causes

Perimenopause is a triad of phases that include the climacteric, or menopausal, transition; menopause; and postmenopausal periods in a woman's reproductive life span. Throughout perimenopause, physical changes occur. The years immediately before and the decades after menopause are of much greater clinical significance than the cessation of menses, which identifies menopause itself.

The menopausal transition, or climacteric, is the phase that signals the nearing of menopause; it occurs approximately 10 years before the onset of menopause, usually between ages 38 and 42 years. The period of menopausal transition may have either an insidious or relatively abrupt onset. During this time, ovulation becomes less frequent, and the numbers of ovarian follicles are decreased and less likely to mature. Women note the beginnings of this phase usually with changes in the menstrual cycle, which can be a shortening of the menstrual cycle and an increase in menstrual bleeding.

Immediately before menopause, menstrual bleeding may occur after a short luteal phase or after an estradiol peak without ovulation. In approximately 70% of patients, menses then become lighter and farther apart until they stop. Another 10% of patients simply stop menstruating without any other symptoms.

The remaining 20% of patients experience heavier bleeding, which is often unpredictable. This group of patients is at risk for anemia and endometrial hyperplasia, a precursor for endometrial cancer. The diagnosis of endometrial hyperplasia is made by an endometrial biopsy. Other reasons for abnormal bleeding in this age-group can be endometrial cancer, endometrial polyps, uterine leiomyomas, and systemic clotting disorders. In the past, many patients were treated for increased menstrual bleeding with hysterectomies.

Premature ovarian failure is cessation of ovarian function before age 35 years. To determine true ovarian failure, two follicle-stimulating hormone (FSH) levels must be above the normal limit of 40 mIU/mL.

Pathophysiology

Menopause is the permanent cessation of menses and ovarian function in a woman. To understand menopause properly, however, knowledge of normal ovarian development is required. This is first characterized by germ cell differentiation (i.e., oocyte development) and primordial ovarian follicle formation, both of which begin during embryonic development, with a peak of 6 to 7 million oocytes present in a growing fetus at just 5 months in utero. FSH drives this process by stimulating granulosa cell formation in ovarian follicles and inducing luteinizing hormone (LH) receptor formation, which will eventually allow for ovulation to occur later in life in response to surges in LH at the time of menarche. In a sexually mature ovulatory female, follicular release of an oocyte leads to transformation of the follicle into a corpus luteum cyst, which produces less estrogen but increasing amounts of progesterone, capable of maintaining a pregnancy after fertilization and implantation of an oocyte into the uterine lining.

However, even during the fetal stages of development, follicular atresia and destruction of oocytes within the ovary itself are normal, continuous processes, which account for the reduction in oocyte number from its peak to 1 to 2 million at the time of birth and down to approximately 300,000 at the onset of puberty. Animal and human studies have shown this may be driven by reductions in FSH, decreased androgen production by ovarian thecal cells (reducing substrate for estrogen production via androgen aromatization), the upregulation of pro-apoptotic genes such as *Bax,* and the downregulation of anti-apoptotic genes such as *bcl-2* in both oocytes (primarily a fetal process) and follicular granulosa cells (primarily in adults).

Perimenopause, 2 to 8 years before and 1 year after the complete cessation of menses, is characterized by the waxing and waning of ovarian function, reflected in both ovulatory and anovulatory (estrogen-only) menstrual cycles of unpredictable duration and intensity, extended periods of estrogen deficiency, and heightened FSH/LH secretion with occasional follicular development and estradiol production. Over time, estrogen feedback to the hypothalamic-pituitary axis declines. In some women, estrogen positive feedback no longer leads to an LH surge capable of triggering ovulation, whereas in others, estrogen negative feedback fails to suppress LH production during the follicular phase. Moreover, the failure of corpus luteum cysts to form after ovulation leads to a decrease in progesterone and increased exposure to unopposed estrogen, which accounts for the increase in dysfunctional uterine bleeding (DUB) and endometrial hyperplasia observed during this period.

Although some degree of follicular atresia occurs continuously throughout a woman's reproductive lifetime and increases rapidly after age 37 years, the permanent cessation of both ovarian function and menses known as menopause is an event rather than a period of time. Occurring on average at age 51 years, factors that influence the timing of menopause have been the subject of much research. Whereas the age at menarche has steadily declined over recent decades (having been linked to nutritional status, environmental factors, and general health), the average age at menopause has remained remarkably constant since ancient times. Today, several factors have been well documented to lower the age at menopause, including smoking (which decreases the onset of menopause by 2 years on average), nulliparity, menstrual regularity and a shorter cycle length, a family history of early menopause, increased galactose intake, concurrent type 1 diabetes mellitus, and certain genetic variants in the estrogen receptor and galactose-1-phosphate uridyl transferase gene. Menopause occurring past age 55 years is defined as late menopause.

With the depletion of ovarian follicles that are able to respond to gonadotropins, both follicular development and cyclical estrogen production cease during menopause. FSH levels rise as the body tries unsuccessfully to stimulate follicular production of estrogen. FSH levels above 40 mIU/mL signal the approach of menopause, even though a patient may still experience occasional menstrual bleeding. LH concentration is also elevated, but menopausal levels are difficult to distinguish from LH elevations seen during preovulatory gonadotropin surges in the normal menstrual cycle. Persistently high LH levels lead to continued androgen production by ovarian thecal cells, namely androstenedione, contributing to some of the undesirable physical changes experienced by postmenopausal women such as increased facial hair. Biochemical studies have revealed that the gonadotropins in older women have a longer half-life (contributing to their increased serum levels) but also contain higher levels of carbohydrate that tend to render them less biologically active. Moreover, although residual oocytes and differentiating follicles have been identified in postmenopausal women, the follicles are typically atretic and eventually become cystic in the absence of viable oocytes.

Without a follicular source, circulating levels of estrogen fall significantly during menopause—particularly the active form estradiol, produced from the aromatization of testosterone. High gonadotropin levels stimulate the ovarian stroma to produce the less potent hormone estrone, rather than estradiol, while androstenedione produced by the adrenal glands is converted to estrone by aromatization in the periphery, particularly within adipose tissue, which contains significant levels of the aromatase enzyme. In addition, serum levels of the hormone inhibin B also decline, closely correlating to the rise in FSH, implying an inhibitory action of inhibin B on FSH. Estrone and androstenedione levels remain relatively constant as the patient ages, whereas testosterone levels decline. Obese women, with larger amounts of adipose tissue, typically display higher levels of circulating estrogens; however, they are still subject to vasomotor symptoms triggered by estrogen deficiency. Patients who are thin tend to experience vaginal dryness and other symptoms associated with low estrogen levels, whereas obese patients are at greater risk of experiencing symptoms associated with unopposed estrogen, such as DUB, endometrial hyperplasia, and endometrial neoplasms. In turn, women who do not experience the vasomotor symptoms of estrogen deficiency during menopause (e.g., hot flashes) should be monitored yearly for endometrial pathology with vaginal ultrasound and biopsy as appropriate.

Clinical Presentation

Subjective

Many women do not seek medical attention while going through menopause; they simply stop monthly menstrual bleeding. Their first presentation may be for a yearly gynecological exam. If the patient has not menstruated for 12 months, she can be considered to be menopausal. Women should be counseled about the risks and benefits of hormone replacement therapy (HRT), calcium supplementation, and other steps necessary to remain healthy during the postmenopausal decades. If less than 12 months has passed, a reevaluation should occur at the next yearly gynecological exam.

Several factors have been identified that may alter menopause timing. Genetics and family history are factors that influence the age at which a woman experiences menopause. There is a similarity in menopausal age between mothers and daughters. Hysterectomy (removal of the uterus but not the ovaries) hastens the cessation of follicle stimulation and ovulation by 1 to 2 years. Women who smoke tend to have an earlier menopause.

Menopause can also be induced with chemotherapy and radiation treatments.

Most patients go through menopause without experiencing symptoms debilitating enough to make them seek medical attention. About 20% of patients seek attention for one or more symptoms related to menopause. The most common symptoms of menopause are the vasomotor symptoms of hot flashes, night sweats, and insomnia. Vasomotor symptoms are caused by thermoregulatory dysfunction in which inappropriate peripheral vasodilation, cutaneous blood flow, and perspiration lead to a rapid heat loss and a fall in core body temperature with chills/shivering as an involuntary reaction to increased body temperature; up to 75% of menopausal patients experience this symptom (more likely after surgical menopause). Hot flashes contribute to sleep disturbances commonly experienced by perimenopausal women; this has been linked to mood disorders including depression, irritability, and fatigue, although many studies have failed to show a direct connection between menopause and depression. It is postulated that menopause makes preexisting depression worse, rather than creating it de novo. Ten percent to 15% of all postmenopausal patients report frequent, severe episodes of symptoms that completely disrupt their lives.

Vaginal dryness or atrophy is a common complaint among menopausal women. Vaginal dryness results from decreased blood flow to the vaginal mucosa and vulva caused by estrogen deficiency contributing to the complaints of dyspareunia, or painful intercourse. Lack of estrogen also leads to thinning of the vaginal epithelial lining, decreased rugae, loss of elasticity, and decreased vaginal mucus. Atrophy can become so severe that a woman may complain of postmenopausal bleeding. Although an endometrial biopsy is needed to rule out hyperplasia, the bleeding may be a result of the vaginal dryness.

Five areas of change involving sexual relations have been described: diminished sexual responsiveness, dyspareunia, decreased sexual activity, decline in sexual desire, and a dysfunctional male partner. A decrease in estrogen influences peripheral blood flow responses to sensory stimulation, affecting the timing and degree of vasocongestive response during sexual activity.

Vaginal atrophy is a major contributor to both stress and urge incontinence in the menopausal woman, particularly atrophy of the urethral epithelium with atrophic urethritis, loss of compliance, and irritation interfering with adequate seal of the urethral meatus. Atrophy of the bladder trigone (outlet tract) and decreased responsiveness of alpha-adrenergic receptors at the bladder neck and urethral sphincter all impair continence as well. Detrusor instability is also a cause of urinary symptoms. Patients will report that they either leak urine when they laugh, cough, or sneeze or that when they feel the urge to urinate they cannot make it to the bathroom in time. This can be very disconcerting and uncomfortable and lead to urinary tract infection and urinary odor problems. Done correctly, Kegel exercises (described in Chapter 12) reduce incontinence in 50% to 90% of patients within a few months.

Objective

The only documented objective manifestation of menopause is bone demineralization and resultant osteoporosis. Postmenopausal osteoporosis is one of the most common and disabling diseases affecting North American patients today. During the climacteric, patients may lose 2% to 5% of bone mass per year. Predisposition to falling created by an unsteady gait and poor eyesight are significant factors equal to low bone density as cause for hip fractures in postmenopausal patients.

Until 2001, it was widely believed that hormone therapy would prevent heart disease in menopausal women. As a result of the Heart and Estrogen/Progestin Replacement Study (HERS) and the more recent Women's Health Initiative Randomized Control Study (WHI), it is fairly clear that hormone replacement does not prevent cardiovascular disease and in some cases can precipitate an adverse cardiac event, especially in the first 5 years of treatment. Critics of these studies argue that the women in the study were well past menopause when the study began. Clearly, hormone replacement had deleterious effects on older women, whereas the effect on younger women remains unclear. Current research on the relationship between menopause, hormone replacement, and cardiovascular disease remains controversial at best.

Diagnostic Reasoning

The diagnosis of menopause is based on a history of amenorrhea and the presence of associated symptoms including hot flashes, flushes, night sweats, and sleep disturbances in age-appropriate women. If these symptoms are present, laboratory testing is not necessary. Other causes of amenorrhea must be considered whenever the history is not consistent with estrogen deficiency. Such history would be amenorrhea without vasomotor symptoms. An FSH level above 40 mIU/mL with a history of prolonged amenorrhea is diagnostic.

Diagnostic Tests

The first test that should be done in a woman whose menses has ceased is a pregnancy test, because an elevated beta–human chorionic gonadotropin level could reflect pregnancy, molar pregnancy, ectopic pregnancy, or even certain germ cell tumors. It is simple and inexpensive.

Serum FSH and LH levels are elevated in menopause. FSH levels greater than 10 to 25 mIU/mL suggest relative ovarian resistance consistent with menopausal transition. FSH levels of greater than 40 mIU/mL are consistent with complete cessation of ovarian function. LH levels are less sensitive for hormonal and ovarian function. During the menopausal transition, LH levels begin to rise; however, LH may also be elevated during the midcycle surge and in cases of chronic anovulation.

In patients with amenorrhea who do not have menstrual bleeding after progestin withdrawal, measurement of a serum estradiol may be helpful. Normal estradiol levels range between 40 and 300 pg/mL. A level of greater than 30 pg/mL may indicate some degree of residual ovarian function. Levels less than 30 pg/mL indicate cessation of ovarian function.

Patients on combined oral contraceptives (OCs) should have levels drawn on days 5 to 7 of the placebo-pill week to get accurate FSH and estradiol levels. Patients on progestin-only contraceptive pills can have levels drawn at any time because these pills do not affect FSH and estradiol levels.

Menopausal status can also be determined by vaginal cytological examination. On microscopic examination, parabasal cells will predominate, indicating a lack of epithelial maturating resulting from low estrogen levels.

Differential Diagnosis

The differential diagnoses for patients presenting with menopausal symptoms are pregnancy, spontaneous abortion, anovulation, endometrial hyperplasia, carcinoma, infection, and abnormalities of the uterus such as fibroids or polyps, endometriosis, adenomyosis, injury, and ovarian abnormalities such as tumors or cysts.

Management

Management of menopause focuses on symptom management and includes lifestyle modifications and a variety of medications.

Lifestyle Modifications

Vasomotor Symptoms Lifestyle modification can assist in the management of vasomotor symptoms. These modifications include aerobic exercise, dietary, vitamin, and mineral therapies, and herbal therapies.

The North American Menopause Society (NAMS) recommends aerobic exercise, because physically active women have 50% fewer hot flashes than their sedentary counterparts. As with any strenuous activity, this may precipitate perspiration and hot flashes until the woman becomes physically fit or conditioned. The insomnia that often accompanies these vasomotor problems may be relieved with exercise. Physical conditioning also decreases cardiovascular risk.

In addition to aerobic activity, weight loss for women who are overweight may be beneficial. Women with a high body mass index (BMI) report having more hot flashes than those with a lower BMI. Weight loss, too, is beneficial for cardiac risk reduction.

Other lifestyle changes that can be helpful for hot flashes and night sweats include dressing in layers, avoiding becoming overheated, limiting intake of alcohol and caffeine, reducing stress, and smoking cessation.

Dietary habits are very personal and often very difficult to change. It is prudent to recommend a diet that is high in complex carbohydrates and fiber (25–30 g daily), low in fat (less than 30% of calories from fat), particularly animal fat, and high in antioxidants (fresh fruits and vegetables).

Herbal therapies include those that are similar to estrogen. Isoflavonoid phytoestrogens are contained within plant fibers and are functionally similar to estradiol. They produce estrogenic effects that may reduce vasomotor symptoms. This type of estrogen-like substance is found in soy products such as tofu and soy milk. An alternative herbal preparation that may alleviate vasomotor symptoms is black cohosh (40 mg PO daily) or red clover (40–160 mg PO daily), which has an estrogenic effect and reduces hot flashes. Selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine (noradrenaline) reuptake inhibitors have been used with success in providing relief of hot flashes.

Vaginal Dryness For patients who complain of vaginal dryness, a Pap smear and urine analysis should be done to make sure the symptoms are a result of cellular changes and not infection. If positive for infection or cellular abnormalities (other than parabasal cells), these must be addressed and then symptoms must be reassessed. The most effective treatment for vaginal dryness or atrophic vaginitis is topical vaginal application of an estrogen product. The estradiol vaginal ring has little systemic absorption and is suitable for long-term use and is effective for vaginal atrophy and dryness. Progesterone therapy is not necessary with the ring because there is little systemic absorption of estradiol and therefore no need to protect the endometrium. Estrogen vaginal cream can be used for short-term therapy. Creams are inserted into the vagina daily for 4 to 6 weeks and can be continued for a few months if necessary to resolve symptoms. After initial therapy, use of 1 to 2 g of the cream twice a week will prevent recurrence. Because absorption is variable, the vaginal ring is preferable.

Water-soluble vaginal lubricants are alternatives to topical estrogen or may be used in conjunction with the estradiol ring or estrogen creams as needed. Lubricants (e.g., Astroglide, K-Y Jelly) used before intercourse to decrease dyspareunia do not alleviate the symptoms of vaginal atrophy. Other alternative therapies that may be useful for vaginal dryness include sitz baths, vinegar douches, and intercourse.

For the symptoms of urinary frequency and incontinence, Kegel exercises remain the first line of therapy. These exercises are a natural nonpharmacological therapy that improve the tone of the urethral sphincter in patients with stress incontinence.

Psychological Problems Many women experience emotional problems with menopause including depression, irritability, and anxiety. As previously stated, depression occurs more often in menopausal women who have experienced depression at other times in their lives. In addition to relieving symptoms of depression, many antidepressants also have a favorable effect on

other symptoms such as hot flashes. For example, SSRIs may relieve hot flashes as well as hormone therapy can. Paroxetine (Paxil) 12.5 to 25 mg controlled released or venlafaxine (Effexor) 37.5 to 75 mg is given PO daily. The antiseizure medication clonidine 100 to 150 mcg daily can be given orally or transdermally to relieve hot flashes, but the adverse effects of dry mouth, drowsiness, and hypotension make is less desirable.

Regular aerobic exercise improves cognitive function, enhances mood, and promotes daytime alertness and nocturnal sleepiness. Recent studies have shown that a brisk daily walk enhances wellness and promotes a sense of well-being.

Hormone Replacement Therapy

Because of recent research, hormone replacement therapy is not a first-line treatment for menopausal symptoms and certainly is not prescribed to prevent heart disease. Hormone therapy (HT) can be estrogen therapy (ET) alone or estrogen plus progestin therapy (EPT). These are the new nomenclature promoted by NAMS to clarify different therapies. In mid-2001 the EPT arm of the Women's Health Initiative (WHI) was halted prematurely because of evidence that it increased women's risk for a cardiac event. However, the ET arm of the study is ongoing with no increase in cardiovascular disease noted. In the WHI, there was definitive evidence that EPT decreased the risk of postmenopausal osteoporotic fractures, but the ET did not show this. Also, these results are in postmenopausal women. Improvement in osteoporotic fracture rates for perimenopausal women has not been established in clinical trials. From these results, it is clear that HT is not a first-line treatment for osteoporosis; there are other nonhormonal therapies with proven efficacy in improving bone mineral density.

NAMS recommends HT only for women with moderate to severe menopausal symptoms, particularly hot flashes and sleep disturbances, but only for a short period, no longer than 5 years. In addition, NAMS clearly states that HT should not be used for prevention of heart disease or stroke or for prevention of dementia, but it does state that not all data apply to all women.

If, after reviewing the benefits and risks with the patient, the patient and clinician decide that HT would be the best option, factors such as frequency of dosage, mode of delivery, and convenience should be considered and the appropriate drug prescribed. See Drugs Commonly Prescribed 14.2 for different forms of HT and dosage. Different types of HT are as follows:

- Estrogen therapy (ET)—start with the lowest dose of estrogens (0.3 mg). Estradiol can be given in a transdermal skin patch (lowest dose 0.025 mg/day). The patch is changed once or twice a week. This is usually limited to women who no longer have a uterus.
- Estrogen plus progestin therapy (EPT) (used to be referred to as HRT)—this therapy can be delivered either continuous-sequential (CS-EPT) or continuous-combined (CC-EPT). In the case of CS-EPT, estrogen is given days 1 to 21 of each month, and a progestin is given on days 7 to 21. Hormones are withheld from days 22 to 30, causing endometrial sloughing and bleeding. Many women find this method unacceptable. In CC-EPT estrogen and a progestin are given every day continuously. There may be some spotting initially, but after a few months, the endometrium is atrophic and will not bleed.

Exogenous estrogen is contraindicated in patients with estrogen-dependent cancers, such as breast, endometrial,

Drugs Commonly Prescribed 14.2 Menopause

Estrogen Therapy (ET) (oral)	Dosage available (use lowest possible dose to relieve symptoms for the shortest period of time)
Conjugated estrogen (Premarin)	0.3, 0.625, 0.9, 1.25 mg; can be given cyclic or continuous (0.625 mg usual if continuous)
Micronized estradiol (Estrace)	0.5, 1.0, 2.0 mg; can be given cyclic or continuous (1.0 mg usual if continuous)
Esterified estrogens (Estratab, Meneset)	0.3, 0.625, 1.25, 2.5 mg; used mostly for cyclic hormone therapy
Estropipate (Ogen, Ortho-Est)	0.75, 1.5, 3; ; given cyclic
Estrogen Therapy (ET) (topical)	Dosage and form
Transdermal estradiol	Released in mg/day
Climara	0.025, 0.0375, 0.05, 0.06, 0.075, 0.1 mg; change once weekly
Estraderm	0.025, 0.0375, 0.05, 0.06, 0.075, 0.1 mg change once weekly; may use 3 weeks on and 1 week off

Drugs Commonly Prescribed 14.2 Menopause—cont'd

Alora	0.25, 0.05, 0.075, 0.1 mg; change twice weekly
Vivelle	0.25, 0.0375, 0.05, 0.075, 0.1 mg; change twice weekly
Vaginal estrogen creams and tablets	
Estradiol	
Vagifem	25 mcg tablets; inserted vaginally daily for 2 weeks then 1 tablet twice weekly
Estrace	0.01 mg/g cream; given cyclically—3 weeks on, 1 week off
Estropipate	
Ogen	1.5 mg/g cream; given cyclically—3 weeks on, 1 week off
Conjugated estrogen	
Premarin	0.625 mg/g cream; given cyclically—3 weeks on, 1 week off
Estrogen ring	
Estring	2 mg with 7.5 mcg released per 24 hours; remains in place for 3 months
Estrogen plus Progestin Therapy (EPT)	Dosage available
Continuous-sequential (CS-EPT)	Estrogens given as above on days 1–21 of cycle
Estrogen	
See the ET above	
Progestins	
medroxyprogesterone acetate [MPA] (Amen, Cycrin, Provera)	2.5, 5.0, 10.0 mg; on days 14–25
norethindrone	2.5, 5.0 mg; on days 14–25
norethindrone acetate (Aygestin)	5.0, 10.0 mg; on days 14–25
Continuous combined (CC-EPT)	
Estrogen	
Conjugated estrogens	0.625 mg daily
Estropipate	0.625 mg daily
Micronized estradiol	1.0 mg daily
Progestins	
medroxyprogesterone acetate	2.5, 5.0 mg daily
norethindrone	0.35 mg daily
norethindrone acetate	1.0 mg daily
Micronized progesterone (Prometrium)	100, 200 mg daily
Combination Products	Dosage available
Premphase	Conjugated estrogens 0.625 mg for 14 days; conjugated estrogens 0.625 and MPA 5 mg for 14 days
Prempro	Conjugated estrogens 0.3 and MPA 1.5 mg OR conjugated estrogens 0.45 and MPA 1.5 mg; OR conjugated estrogens 0.625 and MPA 2.5 mg OR conjugated estrogens 0.625 and MPA 5.0 mg; continuously
Ortho-Prefest	Estradiol 1.0 mg and estradiol 1.0 mg with norgestimate 0.09 mg in alternating sequence of 3 tablets each
FemHRT 1/5	Ethinyl estradiol 5 mcg and norethindrone acetate 1.0 mg
Activella	Estradiol 1.0 mg and norethindrone acetate 0.5 mg

and ovarian cancer, or undiagnosed vaginal bleeding. Patients with liver disease, active thrombosis, or history of stroke should not take estrogen. Pregnancy is another absolute contraindication for estrogen or progestin therapy. Migraine headache is a relative contraindication for the use of estrogen because of the vasoactive properties of estrogen in some patients. Estrogen use has also been associated with a small increased risk of gallbladder disease. Recently, studies have demonstrated an association between estrogen therapy and adult-onset asthma. Increased risk for development of systemic lupus erythematosus exists when taking estrogen; however, the incidence is low.

There are many types of estrogen products. These include 17-beta estradiol, estrone, and estriol. Conjugated equine estrogens (Premarin) are commonly prescribed. Conjugated equine estrogen is derived from the urine of pregnant horses. It contains naturally occurring estrogens such as estradiol and estrone, as well as products not native to humans. Synthetic estrogens used for replacement therapy have a higher potency and increased deleterious effects on hepatic globulins.

Levels of androgens decrease slowly in patients who experience natural menopause and more rapidly in patients who have undergone oophorectomy because the majority of androgens are produced in the ovary. Androgens are also produced in skin, muscle, and bone tissue. A positive correlation may exist between reduced androgen production and decreased libido in postmenopausal patients. Androgens have been shown to decrease high-density lipoprotein levels, an undesirable effect; however, they have also been shown to decrease triglyceride levels, a factor in cardiovascular disease. Because the effects of androgen depletion on libido occur only in patients with testosterone levels of less than 20 to 60 ng/dL, a testosterone blood level is indicated before initiation of therapy. Androgens are available in synthetic form, either alone as methyltestosterone (Oreton, Android), or combined with estrogen. A natural micronized testosterone may be procured from a compounding pharmacy. The long-term effect of testosterone administration in postmenopausal patients is unknown.

Raloxifene HCl (Evista) is a selective estrogen receptor modulator and is a first-line therapy for prevention and treatment of postmenopausal osteoporosis. It protects patients from bone loss associated with decreased levels of estrogen. It does not affect breast or uterine tissue and, therefore, cannot cause breast tenderness, spotting, and other symptoms that can occur with the initiation of estrogen therapy. In initial studies, raloxifene did not demonstrate an increased risk for breast or uterine cancer. Raloxifene does not decrease hot flashes and may actually cause hot flashes in early treatment.

Bisphosphonates are a relatively new class of medications that are first-line therapies for the prevention and treatment of postmenopausal osteoporosis and include alendronate (Fosamax) and risedronate (Actonel). These drugs have been shown to increase spine and hip bone mineral density and decrease the risk of postmenopausal fracture. The patient should be instructed to take these drugs on an empty stomach in the morning and wait at least 30 minutes before eating or drinking. The patient must remain upright for 30 minutes after taking the medication. If heartburn or difficulty swallowing occurs, the patient should be instructed to stop the medication and seek medical attention.

Calcitonin can be used to decrease bone resorption in postmenopausal women. It can be used alone or in conjunction with hormone therapy. It is the drug of choice for women who cannot take HT, bisphosphonates, or raloxifene (Evista). The dose of calcitonin is 100 IU/day subcutaneously or 200 IU intranasally daily.

Bone mineral density can also be increased with teriparatide (Forteo, Parathar), which is an analog of parathyroid hormone. It is administered subcutaneously in 20 mg/day doses. A serious adverse effect is osteosarcoma when teriparatide is administered in high doses.

Vitamin D and calcium should be taken as supplements by most women. The recommendation is 1,200 to 1,600 mg of daily calcium and 400 to 1,000 IU of vitamin D to maintain bone health. The form of vitamin D should be ergocalciferol (vitamin D_2). Calcium supplements can be either calcium citrate or calcium carbonate. Some sources indicate that calcium citrate is better absorbed from the gastrointestinal tract.

Bioflavonoids are thought to have estrogenic activity. One study showed that grapefruit juice increased bioavailability of administered estradiol and estrone. Black cohosh, blue cohosh, ginseng, and wild yam have all demonstrated estrogenic effects. These compounds may result in endometrial hyperplasia, however, if unopposed with progesterone in patients with intact uteri.

Follow-up and Referral

When therapies recommended for the abatement of symptoms are followed without relief of symptoms, a referral to a gynecologist is recommended. Any patients with suspected abnormalities, especially carcinoma, should be referred to a gynecologist. Any perimenopausal or postmenopausal bleeding requires further evaluation with endometrial surveillance and biopsy to rule out endometrial hyperplasia or other pathology. Vaginal ultrasound may be used first, however, to avoid biopsy in women whose endometrial thickness is 4 mm or less. Estrogen-progestin therapy usually treats DUB, but intermittent ovulation may call for low-dose OCs as well. In smokers or women with contraindications to OCs (blood clots, breast or uterine cancer history) and no significant symptoms of estrogen deficiency, progestin therapy with medroxyprogesterone

acetate 5 to 10 mg daily for 2 weeks a month can induce withdrawal bleeding and prevent endometrial hyperplasia. A depressed patient who does not respond to lifestyle changes and medications should be referred to a mental health specialist for counseling. Patients who are not responsive to therapy for insomnia may be referred to a sleep disorder clinic.

Patient Education

Pregnancy is still possible during perimenopause. When a patient presents with amenorrhea, it is important to perform a pregnancy test before assuming that the patient may be menopausal. Patients should be counseled about methods of birth control during this time so that undesired pregnancies do not occur.

The decision about the type of menopausal symptom treatment is made in conjunction with the patient. The following tests should be performed before a final decision to initiate therapy: Pap smear, blood chemistry, lipids, blood pressure, mammogram, endometrial biopsy in patients with breakthrough bleeding, and FSH and thyroid hormone levels.

Patients undergoing menopause may have deep feelings about what is happening. The clinician must assess and evaluate these feelings to understand better how to assist the patient. Studies show that fear, lack of knowledge about menopause, and the lack of an informed decision-making process are some of the factors leading to a woman's reluctance to seek treatment for menopausal symptoms. With much conflicting information in the media and among clinicians, patients may be especially interested in clarification of risks and benefits of all the treatments for menopausal symptom relief.

OVARIAN CANCER

Tumors of the ovary are common and most are benign. But malignant ovarian tumors are the leading cause of reproductive system death. *Ovarian cancer* has three main classifications: surface epithelial–stromal tumors, sex cord–stromal tumors, and germ cell tumors. The classifications are based on ovarian embryology and the differences in tissue origin.

Epidemiology and Causes

The cause of ovarian cancer is unknown. The risk factors for developing ovarian cancer include advancing age (more than half of the patients are older than 65 years of age); family history of a grandmother, mother, or sister with ovarian, breast, or colon cancer; father or brother with colon cancer (5%–10% are familial); nulliparity, early menarche, and late menopause ("incessant ovulation" increases possibility of ovarian epithelial damage and inactivation of tumor suppressor genes); lifestyle (high-fat diet, smoking history, lack of exercise); and a history of prolonged use of fertility drugs.

Ovarian cancer is quantitatively the rarest but most deadly of the gynecological cancers. In the United States, more than 25,000 cases of ovarian cancer are diagnosed annually, with approximately 14,500 deaths. It is the seventh most common woman's cancer in the world, with the greatest incidence in industrialized countries. It is most commonly diagnosed in white women with a northern European background and a strong family history. This familial predisposition may be strictly genetic or multifactorial, including environmental causes. The highest incidence occurs in the postmenopausal years, with a gradually rising incidence after age 45 years. Ovarian cancers have been associated with the number of ovulations in a woman's lifetime; therefore, nulliparity increases the number of ovulations and thereby the risk of a cell mutation occurring. Likewise, infertility drugs, which are known to hyperstimulate the ovaries, increase the chances of cancerous mutation.

Although the public is aware that early detection is crucial for cancer in general, no mass screening test has proved effective enough to be recommended at this time. For women who have risk factors for ovarian cancer, however, a pelvic exam, a cancer antigen 125 (CA-125) assay test, and a transvaginal pelvic ultrasound can be used at yearly intervals to increase the chance of early detection.

Pathophysiology

There are several distinct types of ovarian malignancies: epithelial cell, germ cell, and sex-cord stromal cell. By far the most common and life threatening are the malignancies of epithelial origin (80%–90% of ovarian tumors), which are derived from the epithelial layer of cells covering the surface of the ovary, continuous with the peritoneal mesothelium. These in turn are divided into several types, including papillary serous cystadenocarcinoma, which resembles the cells lining the fallopian tubes (75%); mucinous cystadenocarcinoma, which simulates the endocervical epithelium (10%); endometrioid tumors (10%), which are similar to endometrial cancers; and the much rarer clear cell, Brenner transitional cell, undifferentiated, and mixed cell–type tumors. Germ cell tumors comprise 20% to 25% of ovarian tumors, with fewer than 5% of these being malignant. Dysgerminomas are most common (30%–50%), followed by yolk sac (endodermal sinus) tumors and immature/mature teratomas—each of which accounts for approximately 20% of germ cell tumors. Much rarer forms of germ cell tumors include embryonal carcinoma, polyembryoma, choriocarcinoma, and carcinoid tumors.

Stromal cell tumors are less common, comprising only 5% to 8% of primary ovarian neoplasms. Neoplasms of stromal cells originate from the cells of the supporting structure of the ovary. These can be divided into gonadal support structures, which are the cells that support the ova or egg, and nongonadal stromal cells that are the nonspecialized support structures of the ovary. The gonadal cells are further divided into two specialized subgroups called the granulosa-theca and the

Sertoli-Leydig cells. Granulosa-theca cells surround the site on the ovary where the ovum is released and produce the female hormones. The second subgroup, the Sertoli-Leydig cells, is responsible for producing the male hormones. The nongonadal stromal cell tumors are derived from the smooth muscle and ligaments that give the ovary its basic structure and form.

Various germline mutations have been associated with epithelial ovarian tumors, such as *BRCA1, BRCA2,* and the hereditary nonpolyposis colorectal cancer gene, but only in a small minority of cases with serous ovarian adenocarcinomas predominating. These cancers, which appear to run in families, have an earlier age at onset than those in the general population. Mutations in well-characterized oncogenes including *HER-2/neu,* c-*myc, Akt,* and the tumor suppressor genes *p53, p16,* and *PTEN* have also been cited in noninherited forms of ovarian cancer. However, the precise pathogenetic mechanisms implicating these mutations, as well as most ovarian cancer risk factors, have yet to be determined.

A likely mechanism appears to be the increased frequency of genetic mutations associated with repeated injury and repair to the ovarian epithelium that occurs with cycled ovulation, thus explaining the correlation of ovarian cancer with nulliparity and early menses and the protective effect of oral contraceptives (OCs) that suppress ovulation. Hormonal stimulation of ovarian tissue by high estrogen and possibly also androgen levels has also been cited as a factor in malignant transformation, whereas progesterone has been shown to have protective effects. Interestingly, some case-controlled studies have demonstrated a connection between ovarian carcinogenesis and environmental agents believed to enter through the genitourinary tract that travel retrograde to the ovaries (e.g., perineal talc).

Clinical Presentation

Subjective

Symptoms can be vague or nonexistent in the early stages of the disease or seemingly unrelated to the ovaries. Such early symptoms include back pain, bloating, and constipation. As the tumor enlarges and the disease progresses, commonly expressed symptoms include a sense of pelvic pressure or discomfort; urinary frequency, pressure, and urgency; abdominal swelling and bloating; nausea and vomiting; gas and indigestion; rectal pressure; painful intercourse; diarrhea or constipation; abnormal vaginal bleeding; unexplained weight loss; and jaundice.

Objective

During the pelvic exam, a pelvic mass, decreased mobility of the cervix and uterus, fullness in the adnexal areas of cul-de-sac, and pain on palpation of the ovaries may be detected. A rectal exam may confirm a pelvic mass as well.

Diagnostic Reasoning

Diagnostic Tests

A comprehensive diagnostic work-up begins with a complete history and must include questions and discussions regarding the woman's current complaints, past health experiences, obstetric history, family history, and dietary habits. Further information that could be useful would be bowel and bladder habits and menstrual history.

If an ovarian neoplasm is suspected, a bimanual pelvic exam is the first step in the diagnostic work-up. Malignant ovarian tumors are usually large with irregular contour and decreased mobility, unlike benign tumors and cysts, which usually have smooth borders, are relatively small (less than 5 cm), and are mobile.

When a mass is palpated and suspicious of malignancy, subsequent diagnostic testing should include a pelvic ultrasound to evaluate the size, shape, and consistency of the mass. A serum CA-125 level is done. If the CA-125 is greater than 35 units, there is a greater likelihood that the ovarian mass is malignant, but the level may also be elevated in postmenopausal women with benign disease (e.g., endometriosis). CA-125, however, is most helpful for following the response to therapy and to help determine prognosis, but it is not an effective screening tool. A transvaginal ultrasound can help differentiate malignant ovarian masses from those that are benign. An intravenous pyelogram shows if the mass is impinging on the ureters or bladder. A barium enema determines involvement of the rectum or colon. In some cases a diagnostic laparoscopy can be used for direct visualization of the mass. Abdominal/pelvic computed tomography (CT) and magnetic resonance imaging are not useful to establish the diagnosis for pelvic masses, but these imaging tests are helpful in establishing the presence or degree of metastases from ovarian cancer or determining whether a primary cancer site exists outside the ovaries. A biopsy is not routinely recommended when an ovarian mass is present because this may cause the tumor cells to disseminate into the peritoneal cavity.

As part of a preoperative evaluation to further rule out other nonovarian primary cancer sites, a colonoscopy or barium enema should be done if the Hemoccult is positive or if the patient is obstructed. An upper gastrointestinal (GI) series is done if an upper GI site is suspected, bilateral mammography if any breast mass is present, and endometrial biopsy with curettage if uterine bleeding is present.

Differential Diagnosis

Differential diagnoses include ovarian cysts, benign tumors, ectopic pregnancy, hydrosalpinx, GI masses, pelvic kidney, endometriosis, tubo-ovarian abscess or adhesions, and intrauterine pregnancy. Other differentials

include metastases to the ovaries from other primary sites, such as breast, uterus, or GI tract.

Management

The principle of management is early diagnosis and referral for treatment (surgery and oncological). Ovarian cancer is surgically staged, and the staging determines the specific treatment approach. Staging is done using the International Federation of Gynecology and Obstetrics (FIGO) staging, and this guides treatment. Stage I is confined to the ovaries. In stage II, there is extension to the pelvis, and stage III indicates spread beyond the pelvis to the peritoneal cavity or para-aortic/inguinal lymph nodes (but within the abdomen). Stage IV is distant metastasis. Seventy-five percent of women with epithelial disease present in stages III to IV, and 25% present in stages I and II. The 5-year survival rate for stage I ovarian cancer is 90%, but only 25% are diagnosed at this early stage. The 5-year survival rate declines rapidly as the stage increases. For example, 5-year survival for stage II is 40% to 60%, for stage III is 15% to 20%, and for stage IV is less than 5%.

Unlike other cancers, surgical resection for optimal cytoreduction is the standard of care for both early and advanced ovarian cancer. Therapy is based on appropriate surgical staging, unless there are clear contraindications to surgery. Surgery improves disease-related symptoms, improves response to chemotherapy (if cytoreduction leaves a tumor of less than 2 cm in the widest dimension), and decreases tumor-produced immunosuppressive cytokines. Surgical staging is done via laparotomy, checking for fluid in the cul-de-sac, as well as exploring the entire abdomen for disease. The para-aortic and pelvic lymph nodes are dissected as well, to look for microscopic extension into the nodes (stage III disease), which can occur in up to a third of cases that initially appear to be stage I.

Surgical removal usually includes hysterectomy and bilateral oophorectomy (because there is a large risk of contralateral disease) with appendectomy (which may be a site of isolated metastasis) and then additional resection of pelvic/abdominal structures as needed (especially the omentum). In very early stage disease, unilateral oophorectomy may be performed only if future fertility is desired, but endometrial biopsy should be done.

After surgical treatment, the patient is usually given a course of chemotherapy, with or without radiation. The amount and type of chemotherapy are based on the surgical finding and staging and subsequent pathological diagnosis and grading. Carboplatin plus paclitaxel is the standard of care for stage III to IV epithelial cancers. This same chemotherapy regimen may also be used for stage I to II epithelial cancers after surgery. It may suffice to just observe low-grade stage I disease after surgical resection, rather than treat with chemotherapy, as long as higher grade 2 or 3 disease is not noted. Chemotherapy is started 4 to 6 weeks after surgery and continues for three to six cycles, depending on extent of disease and response to therapy (follow with physical exam/history, CA-125, imaging via CT scan, etc.). Most patients respond with first-line chemotherapy, but if recurrence occurs, chemotherapy may be used for palliative care. Patients with bulky residual disease survive a median of 26 months, whereas for those with small-volume residual disease, median survival is 60 months. Both maintenance chemotherapy (longer regimens of single or combination chemotherapeutic agents) and intraperitoneal (IP) chemotherapy are not current standards of care and are under investigation. IP chemotherapy has the advantage of direct contact with cancer cells, less systemic adverse effects, and less collateral damage to nonmalignant tissue. At present for stage III and IV disease, surgery followed by systemic chemotherapy is indicated, but a trial is currently ongoing to evaluate neoadjuvant (preoperative) chemotherapy. Currently, it is used for patients with poor performance status who would not tolerate surgery before treatment. Secondary cytoreduction after initial surgery and first-line systemic chemotherapy might be beneficial, however.

Diagnosis and treatment for ovarian cancer (and other gynecological cancers) is devastating. Several phenomenological studies have identified the themes of uncertainty, perceived lack of control, feelings of isolation, and hopelessness. These feelings can affect recovery and manifest in physical symptoms. Researchers at Yale University School of Nursing conducted a single-blind randomized clinical trial to determine if a specialized nursing intervention designed to help patients develop and maintain self-management skills and participate in decisions affecting their treatment would improve the quality of life (QOL) scores over those women who did not have the intervention. The women in the intervention group had less uncertainty, less symptom distress, and better scores on the QOL instrument than the control group (Level II; McCorkle et al, 2009).

Follow-up and Referral

When an adnexal mass is detected, the patient should be referred to a surgeon for prompt treatment. Patients who have been diagnosed with ovarian cancer and have undergone surgical and chemical treatment often are encouraged to have a second-look surgical procedure to assess the results of the prior treatments, both surgical and medical.

Patient Education

As mentioned previously, the number of ovulations in a patient's lifetime increases the risk of ovarian cancer; therefore, both pregnancy and use of OCs lower the risk of ovarian cancer. Patients should be aware of screening techniques, especially if they have any risk factors. Annual gynecological exams should be encouraged, and the

importance of a low-fat diet and weight control should be stressed.

CERVICAL CANCER

Cervical intraepithelial neoplasia (CIN) has been explored and studied more than any other premalignant lesion of the genital tract. The accessible anatomical location of the upper vagina and cervix facilitates investigation. In addition, the development and use of colposcopy to identify sites of potential dysplasia and assist in directing biopsy have positively affected patient outcomes in the management of CIN. Several terms have been used to describe premalignant lesions of the cervix. These changes are described on a continuum from mildly atypical with a potential to progress to invasive carcinoma.

The grades of severity are CIN I (mild dysplasia), CIN II (moderate dysplasia), and CIN III (severe dysplasia to carcinoma in situ). Alternate nomenclature, as noted, is used to describe similar histological characteristics by using the term *dysplasia.* Hence, early premalignant changes in cervical epithelium are described as mild, moderate, or severe dysplasia. Mild involvement includes one-third of the cervical epithelium, moderate involvement includes two-thirds of the epithelium, and severe involvement includes the full thickness of the epithelium. Carcinoma in situ is considered the most advanced premalignant change.

Epidemiology and Causes

Cervical cancer is the 14th most common cancer in women in the United States and the most common cancer in women worldwide. With the prevalence of Papanicolaou (Pap) test screening in the United States, mortality rates have fallen by more than 45% since the 1970s. The American Cancer Society estimates that there will be 12,360 new cases of invasive cervical cancer and that more than 4,020 women will die of the disease in 2014. More than 20% of cases are found in women over age 65 years. Hispanic women in the United States have the highest incidence of cervical cancer followed by African American women. American Indians and Alaskan native women have the lowest risk.

Precancerous dysplasia, or CIN, occurs more often in younger women, with the incidence peaking in the early 30s. About 12% of women will have cervical dysplasia by age 20. However, the American College of Obstetricians and Gynecologists has issued new recommendations for cervical cancer screening. Screening should begin at age 21 years regardless of sexual history and is recommended every 2 years.

The cause of CIN remains unknown; however, studies implicate several factors that may be related to the development of CIN. In particular, the human papillomavirus (HPV) is believed to support the development of premalignant cervical lesions. Several different HPV types have been associated with various genital lesions. Three specific types have been associated with neoplasia (higher grades of dysplasia and cervical cancer). Condom usage is promoted based more on general principles than on epidemiological data, and protection against HPV transmission is not 100% effective. HPV can be found in many genital areas (e.g., genital tract skin and mucous membranes). Hence, condoms do not protect the vulva from microscopic HPV particles on the skin. Although flat HPV cervical lesions are strongly associated with cellular transformation to CIN, most HPV infections are subclinical. Women may be unaware of their HPV status. In addition, women who have a history of early intercourse (age 14 or 15 years), begin to have children at an early age, and/or have a history of multiple sexual partners are at a greater risk for developing carcinoma of the cervix. A list of cofactors that may contribute to enhanced risk for cervical cancer is shown in Risk Factors 14.2.

Pathophysiology

A normal transformation zone includes columnar epithelium and squamous metaplasia. The squamocolumnar junction (SCJ) of the cervix is viewed via the colposcope, which magnifies the epithelium of the transformation zone. Colposcopic examination of this landmark site is important because this area is most vulnerable to neoplastic changes.

Risk Factors 14.2 Cervical Neoplasia

History

- Early intercourse
- Early marriage
- Multiple sex partners (more than two)
- Early childbearing
- Prostitution
- Immunosuppression
- Prior exposure to radiation
- Intrauterine DES exposure
- OC use
- Cigarette smoking
- Vitamin A, B, C, and folic acid deficiencies

Male Partner

- History of genital cancer, especially penile carcinoma; STIs, especially penile or urethral condylomas; CIN or cervical cancer in a previous partner; low socioeconomic status; multiple sex partners

Infections

- STIs (venereal infection)
- HPV infection (serotypes 16 and 18)
- HSV infection
- HIV infection
- *Chlamydia trachomatis*
- Cytomegalovirus infection

Examination of the exocervix reveals where the cervical glandular, grape-like in appearance, columnar epithelium meets the native squamous epithelium distal to the external os in young adult women. After childbirth this area may enlarge and move farther away from the os. The junction usually recedes after menopause into the endocervical canal. Throughout a woman's reproductive life, squamous metaplasia, a physiological process involving squamous tissue replacing columnar tissue, occurs. This process is most active during fetal development, adolescence, and pregnancy. The SCJ is first delineated in utero; however, metaplasia is an estrogen-dependent process that accelerates during puberty and pregnancy. As noted, SCJ cells are more vulnerable and especially prone to damage at these particular times in a woman's reproductive life. Abnormal colposcopic patterns that characterize an abnormal transformation zone are caused by neoplastic squamous epithelium, thus explaining why exophytic tumors are the most common presentation of cervical cancer.

HPV infection may also alter morphology of the cervical epithelium, leading to nuclear enlargement and multinucleation, hyperchromasia, and perinuclear cytoplasmic halos. Cellular findings of HPV infection on biopsy can be histologically similar to dysplasia, and misdiagnosis can occur. However, the diagnosis of HPV does not imply clinical disease. Thus, treatment is limited only to symptomatic patients (e.g., those with condylomas) or those with demonstrated evidence of neoplasia (e.g., positive colposcopy findings). There are two vaccines (Cervarix and Gardasil) for HPV infection prevention. Both of the vaccines protect against cervical cancer in women, but Gardasil also protects against genital warts and cancer of the anus, vagina, and vulva that are associated with HPV infection. Females should be vaccinated at age 11 but can be vaccinated up to age 26 years. Males should be vaccinated at age 11 but can be vaccinated through age 21 years. In some worldwide studies, the epitheliotropic HPV infection has been identified in greater than 99% of cervical neoplasias. Certain viral serotypes that undergo vegetative episomal replication without integrating into the host genome typically lead to condylomata acuminata or low-grade squamous intraepithelial lesion (LSIL; see discussion later in this section) (e.g., HPV-6, HPV-11), whereas more oncogenic forms of the virus (HPV-16, HPV-18, HPV-58, HPV-52, and HPV-31) that integrate into host DNA are more likely to contribute to malignant transformation—high-grade squamous intraepithelial lesion (HSIL; see discussion later in this section), invasive squamous cell carcinoma, or adenocarcinoma. The HPV E6 protein degrades the cell cycle inhibitory protein p53, and the HPV E7 protein interacts with the retinoblastoma protein Rb, causing dissociation of E2F, which also leads to dysregulated cell cycle progression. E7 protein also leads to upregulation of interleukin-6 (IL-6) and IL-8, both of which contribute to cervical cancer progression. Importantly, HPV serotypes HPV-16 and HPV-18 most strongly correlate with invasive squamous cell carcinoma, with HPV-18 portending a worse prognosis. It is clear, however, that HPV infection alone is insufficient to lead to cervical neoplasia, and further insult by cigarette smoking, immunosuppression, or other risk factors appears necessary.

Although squamous cell carcinoma comprises 80% of all cervical cancers, at least 15% are attributed to adenocarcinomas, with another 3% to 5% being of a mixed adenosquamous phenotype. The incidence of adenocarcinoma of the cervix has steadily increased in women younger than 35 years since the 1970s, but this may be due to improved screening and early treatment of squamous cell disease. In addition, however, a greater association of adenocarcinoma with oral contraceptive use seems to imply the importance of underlying hormonal mechanisms in its pathogenesis. Far rarer forms include neuroendocrine tumors, small cell carcinomas, or rhabdomyosarcomas.

Clinical Presentation

Subjective

Patients with premalignant cervical lesions may present with one or more of the following: a history of one or more epidemiological risk factors associated with the development of cervical cancer; a concurrent vaginal infection with symptoms; a history of no recent gynecological care; and no Pap smear for a long time.

In contrast, women with invasive carcinoma may describe a brownish discharge or a history of abnormal vaginal bleeding occurring spontaneously or after intercourse. Women with a history of postcoital bleeding or irregular vaginal bleeding that cannot be explained should be referred to a gynecologist for further evaluation. Only with an extensive disease spread would other symptoms be manifested (e.g., weight loss, decreased appetite, and back pain).

Objective

Women with abnormal Pap smears are usually asymptomatic with normal cervical, vaginal, and abdominal findings on physical exam. Even if Pap smear findings are normal, any cervical or vaginal lesion that appears abnormal or is friable, is raised, or has the appearance of condyloma requires a referral for colposcopy. The location of the dysplasia directs the treatment.

The Pap smear report should include a statement on the adequacy of the specimen for examination, a general categorization, and the descriptive diagnosis. Pap smear results are described as follows:

- Satisfactory but limited (less than optimal; may be secondary to partially obscuring inflammation)
- Unsatisfactory (not acceptable for diagnostic evaluation and may require a repeat Pap or follow-up)
- Within normal limits

- Other (may require follow-up care; the report will have an additional notation if further action is required)

Protocol for triage of the patient with abnormal cytology is presented in Advanced Practice Nursing Interventions 14.1.

Diagnostic Reasoning

Diagnostic Tests

The American Cancer Society's (ACS's) Pap smear screening guidelines are supported by the American Medical Association, National Cancer Institute, American Nurses Association, American College of Obstetricians and Gynecologists, and American Academy of Family Physicians. An issue that is the subject of ongoing debate concerns the mandated frequency for performing Pap smears. The ACS recommends that screening begin 3 years after the first vaginal intercourse or at age 21 years, whichever comes first. It also recommends that women older than age 30 be screened at longer intervals after three consecutive annual normal/negative Pap smear results, unless the woman has a history of diethylstilbestrol exposure in utero, is HIV positive, or is immunocompromised (organ transplant, chemotherapy, corticosteroid therapy). The ACS also recommends that screening be discontinued in women older than age 70 if they have had no abnormal Pap smears in the previous 10 years. If women have had a hysterectomy with removal of the cervix, they do not

Advanced Practice Nursing Interventions 14.1 Pap Smear Results: Treatment Protocols

Pap Smear Results	The Bethesda System (TBS) Category	Treatment Protocol
Sufficient number of cells were present to determine normalcy: Within normal limits.	Within normal limits	Repeat Pap test annually.
Sample was not prepared correctly or too few cells to be evaluated: Inadequate.	Less than optimal Unsatisfactory	Repeat Pap test in about 8 weeks.
Benign cellular change; may be caused by infectious agent such as *Trichomonas*, fungal organisms, *Gardnerella* and *Chlamydia*, or HSV.	Infection	Treat infections that present as symptoms or identified with Pap smear results, or do confirmatory study. Repeat Pap test after infection in 3–6 months; repeat annually if results are normal.
Benign cellular change secondary to inflammatory process and repair by body of injured tissue; may be caused by mechanical or chemical irritations (inflammation, atrophy, IUD use), trauma, or bacterial or viral infections.	Reactive/reparative	For inflammatory changes of unknown cause, repeat Pap test in 6–12 weeks. For repeated inflammatory changes on Pap test, refer to possible colposcopic examination. For Chlamydia or gonorrhea, treat as recommended and repeat Pap test in 1 year. For postmenopausal women with atrophic vaginitis and Pap test result of ASCUS or low-grade squamous intraepithelial lesion (LSIL), treat with topical estrogen cream for 4–6 weeks, then repeat Pap test.
Cellular changes from HPV or mild to moderate dysplasia.	Squamous epithelial cell abnormalities: Atypical squamous cells of undetermined significance (ASCUS) Squamous intraepithelial lesion: LSIL or high-grade squamous intraepithelial lesion (HSIL)	Refer for colposcopic examination.

Advanced Practice Nursing Interventions 14.1 Pap Smear Results: Treatment Protocols—cont'd

Pap Smear Results	The Bethesda System (TBS) Category	Treatment Protocol
Cellular changes from high-grade or squamous cell carcinoma.	Squamous cell carcinoma Adenocarcinoma	Refer to gynecologist.
Glandular cell findings–atypical glandular cells (AGC); considered less severe than adenocarcinoma but associated with a greater risk for cancer.	AGC	Refer to gynecologist.
Atypical glandular cells from endocervical, endometrial, or glandular not otherwise specified in origin (AGC-NOS); considered at lower risk for neoplasm than AGC women.	AGC–NOS	Refer to gynecologist.
Atypical glandular cells—favor neoplasm (AGC, favor neoplasm); high risk for high-grade CIN.	AGC–favor neoplasia	Refer to gynecologist.
Endocervical adenocarcinoma in situ (AIS); high risk for invasive cervical adenocarcinoma.	AIS	Refer to gynecologist.

need to be screened if the reason for the surgery was for a condition other than cancer or precancer.

It is important that the cytology laboratory comply with state and national regulations, utilize a sufficient number of reputable cytologists, maintain a quality assurance program, and support open, clear communication between health-care professionals and the laboratory. Historically, several reporting systems have been developed to enhance communication between the cytopathologist and the clinician performing the Pap test. The oldest system was the class system that provided limited information and did not reflect the newer risk factors such as HPV infections. See Therapeutic Procedure 14.1 for specific techniques for obtaining a Pap smear.

Therapeutic Procedure 14.1 Pap Smear and Liquid-Based Cervical Cell Collection

Technique for Obtaining a Routine Pap Smear

1. Complete the cytology request form with all pertinent data.
2. Label the slide.
3. Insert the dry or water-lubricated speculum. Direct the speculum in a downward posterior direction.
4. Expose the cervix.
   - Avoid sampling if a vaginal infection is present.
   - Take the Pap smear sample before any other cervical sample.
5. Insert the cytobrush or cotton-tipped applicator in cervical os.
6. Use a vigorous rotary endocervical technique (clockwise fashion).
7. Use a paintbrush motion to place the sample on the glass slide.
8. Scrape the external os area with the cytology spatula.
9. Note the individual topography of the squamocolumnar juncture.
10. Obtain a vaginal specimen if needed (e.g., DES exposure, hormone evaluation, history of hysterectomy).
11. Smear the slide and fix immediately.

Technique for Obtaining a Liquid-Based Cervical Cell Collection

1. Complete the cytology request form with all pertinent data.
2. Label the container.
3. Insert the dry or water-lubricated speculum. Direct the speculum in a downward posterior direction.
4. Expose the cervix.
5. Insert cervical broom with central portion into the cervical os.
6. Rotate one-quarter turn only.
7. Place broom in fixative container and vigorously move about to dispel all particles into solution.

The Bethesda System (TBS) currently uses only two terms to describe the wide spectrum of squamous cell precursors: *low-grade squamous intraepithelial lesion* (LSIL) and *high-grade squamous intraepithelial lesion* (HSIL). TBS has also established a category called *atypical squamous cells* (ASC) and this is further qualified into two categories: *atypical squamous cells of undetermined significance* (ASC-US) and *atypical squamous cells; cannot exclude high-grade SIL* (ASC-H). TBS has also developed a classification for *atypical glandular cells* (AGC) that may be endocervical, endometrial, or glandular cells. There is *atypical glandular cells not otherwise specified* in origin (AGC-NOS), and these women are at lower risk for neoplasia than women with AGC. If the Pap smear shows AGC, this favors neoplasia. More worrisome is endocervical adenocarcinoma in situ (AIS) or true adenocarcinoma. These glandular findings are associated with a high rate of premalignancy, or true neoplasia, and thus these women should be referred for colposcopy; women older than 35 years of age and those with significant anovulatory unexplained bleeding should also get endometrial biopsy. If all cells are endometrial in origin only, colposcopy may be avoided in favor of initial endometrial biopsy.

LSIL is a combination of cytological changes consistent with HPV without evidence of dysplasia and changes consistent with mild dysplasia (CIN I). ASC-US is delimited to epithelial abnormalities of uncertain significance and usually represents about 5% of the smears in most populations screened. When cells are described as atypical, further evaluation is necessary. (Table 14.8 presents a comparison of cytopathology reporting systems.)

Obtaining endocervical cells becomes more difficult as the patient ages and the SCJ migrates inwardly with age. An optimal smear contains squamous cells, endocervical cells, and potentially metaplastic cells. Absence of endocervical cells may indicate an inadequate sample and needs to be repeated. Table 14.9 presents factors affecting Pap smear results.

VULVOVAGINAL INFECTIONS AND SEXUALLY TRANSMITTED INFECTIONS

Several different sexually transmitted infections (STIs) affect the female reproductive tract and genitalia. STIs are transmitted through sexual intercourse between heterosexual or homosexual persons by intimate contact with the genitalia, mouth, or anus. STIs, called venereal diseases in the past, include infection by herpes simplex virus (HSV), *Chlamydia trachomatis, Neisseria gonorrhoeae, Treponema pallidum* (syphilis), human papillomavirus (HPV), trichomonads, and human immunodeficiency virus (HIV). Other vulvar lesions include chancroid, lymphogranuloma venereum (LGV), granuloma inguinale, and molluscum contagiosum lesions. Cervical infection known as mucopurulent cervicitis is also largely caused by community-acquired sexually transmitted agents, namely *C trachomatis* and *N gonorrhoeae.*

In contrast, vulvovaginal infections affecting the female genitalia that are not officially considered STIs include both vulvar disorders and selected vaginal and

Table 14.8 Comparison of Cytology Reporting Systems for Pap Smears

Class System	World Health Organization (WHO) System	Cervical Intraepithelial Neoplasia (CIN) System	The Bethesda System (TBS)
I	Normal	Normal	Within normal limits
II	Inflammation	Normal	Other: Infection, reactive and reparative
III	Dysplasia		Squamous epithelial cell abnormalities Atypical squamous cells of undetermined significance
	Mild	CIN-1	Squamous intraepithelial lesion Low grade (includes cellular changes associated with HPV)
	Moderate	CIN-2	High grade
	Severe		High grade
IV	Carcinoma in situ	CIN-3	High grade
V	Invasive squamous cell carcinoma Adenocarcinoma	Invasive squamous cell carcinoma Adenocarcinoma	Squamous cell carcinoma Adenocarcinoma Nonepithelial malignant neoplasma

Table 14.9 Factors Affecting Pap Smear Results

Patient History
- Previous treatment and/or surgery of reproductive tract
- Previous abnormal Pap test
- Diethylstilbestrol (DES) exposure in utero
- Current or recent vaginal or cervical infection and PID
- Any medications, especially hormones
- Bleeding abnormalities
- History of any malignancy
- Pregnancy suspected or current
- Partner history of genital or urological problems (e.g., discharge, infection, or bumps on penis or scrotum)

Patient Factors
- Intercourse
- Douching
- Birth control methods
- Menses
- Infection
- Accurate history

False-Negatives
- Rate for properly performed cytology smears is 1%–80%
- Rate of sample error (diagnostic cells not on the slide) is 60%; 40% for screening error (cells present on slide but missed by cytotechnologist)
- False or less than optimal reports are caused by clinician, patient, or cytopathologist factors

False-Positives
- Rate is <1%.

cervical infections. Painful vaginal disorders (vulvodynia) go by several names, including vulvar pain syndrome, chronic vulvar pain, vestibulitis, focal vulvitis, vestibular adenitis, and burning vulva syndrome. These may be caused by candidiasis (yeast infection), bacterial vaginosis (BV), atrophic vaginitis, allergic vaginitis, and irritation from foreign bodies or chemicals found in soaps, shampoos, or lotions.

Epidemiology and Causes

STIs are the most prevalent communicable diseases in the United States, with the exception of upper respiratory infections. STIs affect more than 12 million patients annually in the United States alone, with 25% being adolescents. Although STIs disproportionately affect adolescents and young adults (largely because of increased sexual encounters and risk-taking behaviors), no age-group is considered "safe." It is estimated that approximately one American out of five is infected with a viral STI other than HIV. Perhaps even more alarming is that the United States has the highest STI rates in the world despite being one of the most educated populations in the world and having the highest standard of living.

The causative agents of the most common vulvovaginal infections and STIs, as well as the clinical presentation, diagnostic reasoning, and recommended management, are presented in Table 14.10. Inadequately treated STIs have far-reaching implications for future health, including long-term fertility. Mucopurulent cervicitis may extend retrograde through the uterus and out the fallopian tubes to the ovaries and throughout the pelvic cavity, causing widespread inflammation, scarring, and adhesions. Known as pelvic inflammatory disease (PID), this condition may occur in up to 15% of mucopurulent cervicitis cases, requiring hospitalization and IV antibiotics in its most serious form and leading to obstruction anywhere along the reproductive tract. PID is the most common cause of tubal infertility (see section on infertility earlier in this chapter). Untreated syphilis may lead to a tertiary form of infection with serious central nervous system (CNS) insult (general paresis and dorsal motor column defects known as tabes dorsalis); aortitis; and nodular, granulomatous lesions on the skin, bone, and solid organs known as gummas. Untreated HIV infection progresses to clinical AIDS over 2 to 10 years, destroying the immune system and leading to increasing numbers of opportunistic infections of the lungs, genitourinary tract, and CNS, which eventually prove fatal. Even BV has been shown to be a risk factor in pregnant women for preterm delivery of low-birth-weight infants.

Pathophysiology

The female reproductive tract is normally protected from infection by several mechanisms, including a low, acidic pH resulting from vaginal secretions and the presence of commensal, nonpathogenic microbial flora, namely hydrogen peroxide–producing *Lactobacillus.* The normal flora environmentally compete and protect against the overgrowth of potentially pathogenic anaerobic and gram-negative bacteria. Disruptions of the mucosal surface either by trauma or preexistent infectious lesion predispose the reproductive tract to infection. In addition, although BV is not considered sexually transmitted (because it is caused by overgrowth of pathogenic vaginal flora), vaginal intercourse may raise intravaginal pH and predispose the woman to the development of BV. Ascending cervical infections, as seen in PID, also appear to be more common in the week following menses, possibly owing to the absence of endometrial sloughing mechanisms that protect against retrograde infection.

Although the pathogenesis of some vulvar and vaginal pain syndromes has not been fully elucidated, STIs are known to stem from a heterogeneous collection of causative infectious agents (see Table 14.10). However, the unifying principle of these disorders is their propensity for spread by intimate person-to-person sexual contact, particularly after exposure of the mucous membranes to infected bodily fluids. This typically occurs within the genitalia. However, the oral and anal mucosa are also

(Text continued on page 751)

Table 14.10 Vulvovaginal Infections and Sexually Transmitted Diseases

Problem	Clinical Presentation	Diagnostic Reasoning	Treatment: as Recommended by CDC
Vulvar Lesions			
• Chancroid *(Haemophilus ducreyi)*	Single painful ulcer (irregular, erythematous, and undermined edges) with a unilateral bubo If vaginal lesion, may be asymptomatic Painful lymphadenopathy	Risk factors: coinfection with HIV, HSV, and syphilis	azithromycin (Zithromax) 1 g PO × 1 OR ceftriaxone (Rocephin) 250 mg IM × 1 OR ciprofloxacin (Cipro) 500 mg PO 2 times daily for 3 days OR erythromycin (E-mycin) 500 mg PO 4 times daily for 7 days
• Lymphogranuloma venereum (LGV) *(Chlamydia trachomatis)*	Lymphadenopathy, anorectal swelling, and fistula formation	History of travel and sexual contact in endemically infected area Serological LGV complement fixation test; suspect if titer above 1:16; diagnostic if above 1:64	doxycycline (Vibramycin) 100 mg PO 2 times daily for 21 days OR erythromycin (E-mycin) 500 mg PO 4 times daily for 21 days OR azithromycin (Zithromax) 1 gram per week for 3 weeks; no recommended dosage from CDC
• Granuloma inguinale (granuloma venereum, Donovanosis) *(Klebsiella granulomatis)*	Chronic, progressive papule that ulcerates to a beefy red, painless granular area with clean, sharp rolled edges; inguinal swelling; late painful abscesses (buboes)	History of travel and sexual contact in endemically infected area Cannot be cultured; stained tissue sample may show Donovan bodies	doxycycline (Vibramycin) 100 mg PO 2 times daily for 3 weeks OR azithromycin 1 g PO once a week for 3 weeks OR trimethoprim 160 mg plus sulfamethoxazole 800 mg (Bactrim) 1 tablet PO 2 times daily for 3 weeks OR erythromycin (E-mycin) 500 mg PO 2 times daily for 4 weeks (during pregnancy) OR ciprofloxacin 750 mg PO 2 times daily for at least 3 weeks
• Molluscum contagiosum (large DNA virus from the Poxviridae family)	Pearly, raised, painless lesions with umbilicated center; diffuse or singular; may be self-limiting	Based on characteristic lesions	No treatment. Lesions may last months to years and often heal spontaneously. Once healed, the person has a lifetime immunity to the virus.
Vaginal Disorders			
• Vulvodynia	Burning and itching of vulva; tenderness at vaginal opening; dry and swollen vulva; associated with inflamed and painful	Diagnosis of elimination Changes in touch test Vulvar biopsy for inflammation	Treat symptomatically Mild pain: Topical lidocaine (Xylocaine) Antidepressants such as amitriptyline (Elavil) 50–100 mg

Table 14.10 Vulvovaginal Infections and Sexually Transmitted Diseases—cont'd

Problem	Clinical Presentation	Diagnostic Reasoning	Treatment: as Recommended by CDC
	Bartholin's, vestibular, and Skene's glands	Colposcopy for microfissures	PO at bedtime or fluoxetine (Prozac) 20 mg PO every morning or 20 mg PO every morning and noon Surgery (50% success rate)
• Candidiasis	Pruritus, redness, swelling, "curdy" (white, thick) vaginal discharge; occasional burning with urination, vaginal wall redness	Risk factors: previous antibiotic therapy, chronic vulva moisture, diabetes, HIV infection, immunosuppression Wet prep with saline, KOH, pH 4–5	fluconazole (Diflucan) 150 mg PO × 1 OR butoconazole 2% cream 5 g intravaginally at bedtime × 3 days OR miconazole 2% cream 5 g intravaginally at bedtime × 7 days OR clotrimazole 1% cream 5 g intravaginally for 7–14 days OR clotrimazole 100 mg vaginal tablet for 7 days OR tioconazole 6.5% ointment 5 g intravaginally in a single application OR terconazole 0.4% cream 5 g intravaginally for 7 days OR terconazole 0.8% cream 5 g intravaginally for 3 days
• Bacterial vaginosis (BV)	Thin discharge, malodorous, increased odor after intercourse, pruritus, edema, erythema	Based on symptoms, including homogenous white discharge with "fishy" odor, pH >4.5, clue cells on microscopic exam and a positive amine test (KOH applied to discharge releases fishy odor—"whiff" test)	metronidazole 500 mg PO 2 times daily × 7 days OR metronidazole gel 0.75% one full applicator (5 g) intravaginally daily × 5 days OR clindamycin cream 2% one full applicator (5 g) intravaginally at bedtime × 7 days
• Atrophic vaginitis	Dry, thin vaginal tissue; dyspareunia	History of perimenopause or menopause, pH 6.5–7, wet prep: negative for pathogens	Treat symptoms Vaginal lubricants Estradiol vaginal ring—50–100 mcg/24 hr; change every 3 months Estrogen vaginal cream—0.625 mg/g: Insert 0.5–2 g into the vagina once daily at night for 1–2 weeks. After initial therapy, use of 1–2 g of the cream twice a week will prevent recurrence.

Continued

Table 14.10 Vulvovaginal Infections and Sexually Transmitted Diseases—cont'd

Problem	Clinical Presentation	Diagnostic Reasoning	Treatment: as Recommended by CDC
• Allergic vaginitis	Excessive or malodorous vaginal discharge, pruritus, external dysuria	Obtain accurate history, pH normal (3.8–4.2)	Avoid offending substance Sitz baths Hormone-free vaginal creams and gels to restore vaginal pH and increase vaginal moisture
Cervical Disorders • Mucopurulent cervicitis (MPC)	Yellow mucous discharge, possible bleeding with intercourse, cervical tenderness, "beefy red" friable cervix	Wet prep: increase in WBCs	azithromycin (Zithromax) 1 g PO × 1 OR doxycycline (Vibramycin) 100 mg PO 2 times daily for 7 days OR erythromycin (E-mycin) 500 mg PO 4 times daily for 7 days OR erythromycin ethylsuccinate (EES) 800 mg PO 4 times daily for 7 days OR ofloxacin (Floxin) 300 mg PO 2 times daily for 7 days OR levofloxacin 500 mg PO daily for 7 days
STIs • HSV Infection	**First outbreak:** Flu-like symptoms with adenopathy, tingling of the site before outbreak, and very painful vesicular lesions Ulcers form with circumscribed erythematous edges and white exudate centrally; may last 12 days **Recurrent outbreaks:** Symptoms may be similar, usually less severe and shorter length (4–5 days)	Viral culture of vesicle fluid most accurate if within 48 hours of outbreak Tzanck smear from the base of an early vesicle DNA probe from lesion scraping	**First outbreak:** acyclovir (Zovirax) 400 mg PO 3 times daily for 7–10 days OR 200 mg PO 5 times a day for 7–10 days OR famciclovir (Famvir) 250 mg PO 3 times daily for 7–10 days OR valacyclovir (Valtrex) 1 g PO 2 times daily for 7–10 days. **Recurrent outbreaks:** famciclovir: 125 mg every 12 hours for 5 days OR famciclovir 1,000 mg PO 2 times daily ×1 day valacyclovir: 500 mg PO every 12 hours for 3 days OR valacyclovir 1 g PO daily for 5 days **Suppressive:** acyclovir 400 mg PO 2 times daily famciclovir 250 mg PO 2 times daily

Table 14.10 Vulvovaginal Infections and Sexually Transmitted Diseases—cont'd

Problem	Clinical Presentation	Diagnostic Reasoning	Treatment: as Recommended by CDC
			valacyclovir 1 g PO daily Evaluate after 1 year for recurrent episodes.
• *Chlamydia*	Most commonly no reported symptoms. Patient may have an increase in mucopurulent discharge and bleeding with intercourse.	Yellow mucopurulent discharge on cervix Cervix friable and inflamed May or may not have cervical motion tenderness Wet mount: >10 WBCs per high-power field (hpf) DNA probe (cervical swab)	azithromycin (Zithromax) 1 g PO × 1 OR doxycycline (Vibramycin) 100 mg PO 2 times daily for 7 days OR erythromycin base (E-mycin) 500 mg PO 4 times daily for 7 days OR ofloxacin (Floxin) 300 mg PO 2 times daily for 7 days
• *Syphilis*	Primary: Painless ulcer at initial site of contact (chancre), adenopathy Secondary: Maculopapular rash on palms and soles, condylomata/moist flat wartlike lesions, adenopathy	Dark-field microscopy: positive for spirochetes Direct microhemagglutination–*Treponema pallidum* (MHA-TP): Antibody test Fluorescent treponemal antibody absorption (FTA-ABS): antibody test reported as positive	**Early (less than 1 year duration):** benzathine penicillin G 2.4 million units IM × 1 OR doxycycline 100 mg 2 times daily for 14 days
	Tertiary/late: Cardiac, neurological, ophthalmic, auditory, and gummatous lesions	Venereal Disease Research Laboratory (VDRL), syphilis test, rapid plasma reagin (RPR): with titer indicating degree of infection	**Latent or late (duration longer than 1 year or unknown length):** benzathine penicillin G 2.4 million units IM once a week for 3 weeks **Neurosyphilis (CSF) (infection confirmed):** aqueous crystalline penicillin G 3–4 million units IV every 4 hours for 10–14 days Penicillin-allergic patients: doxycycline 100 mg PO 2 times daily for 2 weeks OR tetracycline 500 mg PO 4 times daily for 2 weeks
• *Gonorrhea*	Usually asymptomatic; partner may have an infection Purulent yellow/green discharge May have Skene's and Bartholin's gland inflammation	Gonococcal culture, DNA probe (cervical swab)	ceftriaxone (Rocephin) 250 mg IM × 1 OR cefixime (Suprax) 400 mg PO × 1 PLUS azithromycin (Zithromax) 1 g PO × 1 OR

Continued

Table 14.10 Vulvovaginal Infections and Sexually Transmitted Diseases—cont'd

Problem	Clinical Presentation	Diagnostic Reasoning	Treatment: as Recommended by CDC
			doxycycline 100 mg PO 2 times daily for 7 days Follow CDC guidelines for complicated or refractory gonorrhea.
• HPV	History of multiple partners or sexual abuse Positive history of HPV Itching, foul discharge May be asymptomatic Fleshy, soft, pale-colored keratinized growths on the vagina, cervix, vulva, or perianal area	Acetic acid test: Lesions turn white with vinegar application.	**Patient-applied treatments:** podofilox (Condylox) 0.5% applied thinly 2 times daily for 3 days, then rest for 4 days; may repeat up to 4 cycles OR imiquimod (Aldara cream) 5% applied 3 times a week for up to 16 weeks. **Clinician-applied treatments:** Cryotherapy and liquid nitrogen treatments—repeat every 1–2 weeks. podophyllin resin (Podofin) 10%–25% in benzoin—apply thinly, allow to dry; patient should wash off in 1–4 hours. TCA/BCA (trichloroacetic acid and bichloracetic acid, Tri-Chlor) 80%–90% applied by clinician every 4–7 days. Other therapies: Laser therapy, surgery, interferon lesion injections.
• *Trichomoniasis*	Heavy, odorous, yellow-green watery discharge May have complaints of itching, swelling, and redness on the vulva	Discharge may be frothy, with occasional characteristic "strawberry cervix" pH >5 Wet mount: motile protozoa and WBCs	metronidazole (Flagyl) 2 g PO ×1 OR metronidazole 500 mg PO 2 times daily for 7 days if pregnant OR clindamycin 300 mg PO 2 times daily for 7 days
• HIV infection	Fever, malaise, adenopathy, rash may occur in first weeks after infection (acute retroviral syndrome) Bloody diarrhea Opportunistic infections Frequent vaginal infections Increased HPV infections	Positive enzyme immunoassay Positive Western blot	Treat infections as recommended by CDC. Refer to specialist. Offer long-term counseling and management. Highly active antiretroviral therapy (HAART) is key for the treatment of HIV. Initiation of therapy is a function of T-cell count, viral load, and concurrent symptoms. Treatment is heavily influenced by the ability to comply with various treatment regimens.

susceptible entry points, as exemplified by the incidence of gonococcal pharyngitis after receptive oral intercourse.

Given the length of the vaginal canal and the relatively larger area of exposed genital mucosa, women appear to be more susceptible to STIs. They are also more likely to display symptoms of infection. The presence of one STI increases the chances of becoming infected with another—especially HIV. This is likely due to compromise of mucosal and outer skin barriers, as well as interactions on the molecular level, for example, HPV as a cofactor for HIV infection. Infectious organisms themselves may also express various genetic virulence factors that render them more susceptible to sexual transmission, including surface proteins that facilitate epithelial adherence to the vaginal or cervical mucosa.

Clinical Presentation

Subjective

The patient with a vulvar lesion may present with a complaint of a painful lymph node. With vaginal disorders, the patient typically complains of burning and itching of the vulva, along with tenderness at the vaginal opening. Usually there is a long-standing history of complaints with little or no response to treatment. There is increased pain with tight clothing such as jeans and panty hose, sitting, and external pressure. The discomfort can be so great that it interferes with or stops intercourse. Patients frequently describe "shards of glass" or "pins and needles" on the vulva and at the introitus and may complain of vulvar soreness for days after intercourse.

From 60% to 80% of STIs are asymptomatic; therefore, most are detected on routine exam. Other patients present with burning, itching, and a vaginal discharge that may range from clear to yellowish-green. Table 14.10 presents specific symptoms.

Objective

The primary lesions of some STIs may be painless and blisterlike, or the patient may have severe pain. All lesions of an ulcerative or wartlike nature should be serologically tested for syphilis. Any ulcer may become secondarily infected and may confuse the diagnosis. Manifestation of vaginal infections may include a slightly dry and swollen vulva with small splits present. There may be chronic inflammation, with possible glandular involvement. Bartholin's, vestibular, and Skene's glands may be inflamed and painful, with reddened areas. Scarring and muscle contracture may be present.

Diagnostic Reasoning

Diagnostic Tests

Diagnostic testing for some vulvovaginal infections is not available; therefore, the diagnosis is made by exclusion. Diagnosis of vaginal infections is made by eliminating other diseases as the cause and homing in on the patient's symptoms. Frequently there will be a history of treatment for chronic yeast infections. Table 14.10 presents specific diagnostic tests.

If initial treatment is ineffective, an incorrect diagnosis may have been made initially. The vaginal exam should be repeated and any tests repeated to confirm the diagnosis. For vulvodynia, vulvar biopsy for inflammation, colposcopy for microfissures, and assessing for uneven hips caused by muscle contraction may confirm the diagnosis. Vulvodynia is not sexually transmitted, nor is it a condyloma. External events or irritants can trigger vulvodynia, so a comprehensive history should be obtained.

Differential Diagnosis

Differential diagnosis should include evaluation for chronic dermatitis, bacterial vaginosis, precancerous changes of the vulva, urinary tract infection (UTI), and vaginitis, along with assessing for any STI. The patient should be evaluated for allergies, urinary calcium oxalate, and increased sensitivity to touch, which may indicate a vaginal infection.

Management

The principle of management is to make the correct diagnosis, prescribe the correct treatment, and sufficiently educate the patient and partner so that there will not be a repeat occurrence. In response to the progressive rise in incidence of STIs, the Centers for Disease Control and Prevention (CDC, 2010) published treatment guidelines for sexually transmitted infections, which include information on prevention, diagnosis, and treatment for all known STIs. Table 14.10 presents the specific management of vulvovaginal infections and STIs.

All of the patient's sexual contacts from the 10 days before the onset of symptoms (30 days for STIs) should be treated. A recheck of symptoms is recommended in 3 to 7 days after the start of treatment. Improvement of objective symptoms is usually evident in 3 days and physical improvement within 7 days after treatment. The patient should be advised to apply warm compresses to promote healing of vulvovaginal infections. Treatment of LGV may include needle-aspirating enlarged lymph nodes to prevent rupture.

The use of the touch test is helpful for patients with vulvodynia to assess concretely the success of their treatment. To perform the touch test, the clinician lightly touches the vulvar area with a saline-moistened, cotton-tipped applicator and asks the patient to rate the pain on a scale from 0 to 5 (5 being the worst pain). A record should be kept of the pain scale and changes noted. Treatment should focus on eliminating the cause and reducing patient discomfort. Evaluate the patient for suicide risk secondary to the severe pain. Educate patients about long-term therapy and resources available, such as the Vulvar Pain Foundation.

If there is no improvement after treating vulvar lesions, the following questions should be considered: Is

the patient HIV infected? Does the patient have a coexisting infection? Was the medication taken correctly? Is the diagnosis correct? Inform the patient that scarring may occur even with adequate treatment. Incision and draining of many lesions will increase scarring and is generally not recommended.

Diagnosis with any genital ulcer can be difficult. With chancroid *(Haemophilus ducreyi),* screening for HSV and syphilis is negative. Dark-field microscopy of bubo aspirate may be positive for the chains of gram-negative bacilli. Cultures are expensive and limited in availability. Polymerase chain reaction testing may be available soon. Preventing long-term sequelae and promoting the patient's optimum health depends on the patient's understanding and adequate treatment. Developing a trusting, compassionate relationship can make all the difference to a patient who may have a problem diagnosis.

Follow-up and Referral

Follow-up and referral depend on the specific diagnosis, cause, and management.

Patient Education

Treatment options have improved and simplified over the last few years, and some treatments are now available over the counter, which may lead to patient self-treatment that can confuse the diagnosis. Education is, therefore, most important.

Lesions of the vulva can be both painful and embarrassing for the patient. Frequently the patient may not realize that a lump or sore can be contagious, as well as evidence of a more serious disease. Another problem exists in the fact that the patient may not perform genital self-exam regularly, if at all. The first line of defense is prevention, which is best done through regular exams. Other preventive measures include patient education, abstinence, monogamy, use of condoms, and screening for infections. Education should include prevention of transmission and treatment of partners, along with medication use. Follow-up patient education can prevent transmission and promote adequate medication adherence for prevention of serious sequelae.

If the patient has HSV infection, long-term education, counseling, and compassion are indicated. Learning how to live with a lifelong disease is critical to decrease transmission of this STI. (See also discussion of HSV in Chapter 13.) The principal treatment for HSV focuses on the immune system, preventing outbreaks, and treating at the first sign of an eruption. Further study on herbal immune system treatments may provide additional help for a patient with HSV.

Genital warts (HPV infection) need aggressive partner follow-up to help decrease the spread of HPV. The patient should be educated that this infection can cause Pap smear changes and (if the patient is pregnant) that HPV can be transmitted to a newborn if the virus is active at the time of delivery, but the incidence is low.

Patients with molluscum contagiosum should be cautioned that scratching and picking can spread the infection. This also increases the chance of secondary infection. Patient education focuses on treatment, including that of the partner. Follow-up in 1 month for evaluation of all lesions is indicated.

General patient teaching should include the following. The patient should use unscented, hypoallergenic care products and wear loose clothing that is made of all-natural fibers, such as cotton. Very mild soap (e.g., Basis), daily sitz baths with baking soda, and vitamin E skin oil can decrease the pain associated with vulvovaginal lesions. Topical lidocaine/benzocaine may help mild pain. Dietary management should include a low–calcium oxalate diet. Teach the patient to avoid nuts, soy beverages and cheese, cocoa, chocolate milk, dark beer, black tea, instant coffee, high-fiber cereal, whole wheat products, and berries and to take vitamins and calcium citrate (Citracal) supplements to decrease urinary burning. Other treatments have had less success and can be disfiguring. The patient should be advised before any surgery for vulvar lesions that historically surgery has less than a 50% success rate and a second opinion is advised. Patient considerations for all these diseases include cost, convenience, lifestyle, pregnancy, other disease conditions, and medication use. Follow-up and testing for HIV and diabetes should be encouraged for patients with recurrent candidiasis.

Considerations when treating pregnant women who have STIs, UTIs, and BV/candidiasis are planning treatment to prevent adverse effects (dosage should be decreased) and evaluating the partner, especially with repeated infection. For foreign bodies, patient education about toxic shock syndrome, and careful use of tampons should be included. Any infection may interfere with the accuracy of a patient's Pap smear, so the patient needs to know that the smear may have to be repeated. For mucopurulent cervicitis, follow-up in some practices is 3 to 4 weeks after treatment to evaluate cervical healing. The CDC recommends treating for the identified STI; however, the tests are frequently negative, and some *Chlamydia* tests are only 60% accurate. Patient education should discuss partner treatment, medication use, and sexual abstinence during treatment. At every visit, safer sex practices should be encouraged.

Chapter 15

OVERVIEW

Musculoskeletal pain and dysfunction are one of the most common reasons for visits to a primary-care provider. Because of the complex and ill-defined nature of these problems and the variable differential diagnoses involved, the actual number of people affected is difficult to ascertain with true accuracy. Musculoskeletal problems in general are known to be the most frequent cause of disability in workers, and population surveys show a greater than 50% prevalence of musculoskeletal disorders among older Americans. Musculoskeletal problems are usually classified as acute (less than 6 weeks' duration) or chronic (more than 6 weeks' duration). Examples of chronic, recurrent musculoskeletal problems include arthritis (osteoarthritis [OA] and rheumatoid arthritis [RA]), fibromyalgia, and gout. Gout, fibromyalgia, and RA are important considerations in making a diagnosis, but given the underlying systemic nature of these disorders, they are covered in detail elsewhere in this text. (See Chapter 16 for gout and Chapter 17 for RA and fibromyalgia.) Osteoarthritis is covered in this chapter.

Musculoskeletal complaints are generally self-limiting. However, some conditions, if left untreated, can lead to a cycle of progressive joint instability and a higher risk of subsequent injury if recovery is not complete. It is essential to rule out any musculoskeletal emergencies (see Table 15.1; see Chapter 19 for assessment of musculoskeletal emergencies).

Delayed recognition of certain diagnoses may lead to permanent disability or death. Once these diagnoses have been excluded, proceed with an orderly evaluation of other diagnostic possibilities.

Musculoskeletal complaints can be a diagnostic challenge for the primary-care provider. There are no routine tests that can be employed in clinical practice to determine the presence of inflammation or muscle spasm. Much of the diagnosis is dependent on patient self-reporting of symptoms. An accurate patient history and clinician knowledge of underlying anatomy and physiology of the musculoskeletal system are essential keys to a correct diagnosis. A useful approach to the initial patient encounter is to determine whether the musculoskeletal complaint is

- Acute or chronic in duration
- Articular or nonarticular in origin
- Inflammatory or noninflammatory in nature
- Localized or systemic in distribution

Many musculoskeletal disorders resemble each other at onset, and some may take time to evolve into an identifiable diagnosis. Differential diagnoses of musculoskeletal problems include trauma, infection, metabolic or circulatory disorders, tumors, synovial conditions, congenital or developmental problems, or degenerative disorders.

Identifying the anatomical location of the musculoskeletal complaint is important. First distinguish between articular and nonarticular structures (see Table 15.2). Articular structures include the synovium, synovial fluid, articular cartilage, intra-articular ligaments, joint capsule, and juxta-articular bone. Disorders of these structures are characterized by deep or diffuse pain, limited range of motion (ROM) on active and passive movement, swelling (caused by synovial proliferation, effusion, or bony enlargement), crepitation, instability, "locking," or deformity. Nonarticular (or periarticular) structures are identified as supportive extra-articular ligaments, tendons, bursae, muscle, fascia, bone, nerve, and overlying skin. Nonarticular disorders are characterized by painful active but not passive ROM, demonstrated point or focal tenderness in regions distinct from articular structures, and physical findings far from the joint capsule. It is unlikely to see crepitus, instability, or deformity associated with these disorders.

Inflammatory disorders may be infectious or idiopathic. These are identified by the presence of all or some of the four cardinal signs of inflammation (erythema, warmth, pain, or swelling); systemic symptoms (fatigue, weight loss, morning stiffness, fever); or laboratory evidence of inflammation (elevated erythrocyte

Table 15.1 Musculoskeletal Emergencies

Clinical Manifestations	Musculoskeletal Emergencies: Differential Diagnoses
History	
Significant trauma	Soft tissue injury, internal derangement, fracture
Constitutional signs and symptoms (fever, weight loss, malaise)	Infection, sepsis, systemic rheumatic disease
Hot, swollen, painful joint	Infection, systemic rheumatic disease, gout, pseudogout
Physical Exam	
Weakness Focal	Compartment syndrome, entrapment neuropathy, mononeuritis, motor neuron disease, radiculopathy
Diffuse	Myositis, metabolic myopathy, paraneoplastic syndrome, degenerative neuromuscular disorder, toxin, myelopathy, transverse myelitis
Neurogenic pain (burning, numbness, paresthesia) Asymmetrical	Radiculopathy, reflex sympathetic dystrophy, entrapment neuropathy
Symmetrical	Myelopathy, peripheral neuropathy
Claudication pain pattern	Peripheral vascular disease, giant cell arteritis (with jaw pain), lumbar spinal stenosis

Table 15.2 Comparison of Articular and Nonarticular Structures

Articular Structures	Nonarticular Structures
Synovium and synovial fluid	Supportive extra-articular ligaments
Articular cartilage, intra-articular ligaments	Bone
Joint capsule	Nerve, overlying skin
Juxta-articular bone	Muscle, tendons, fascia

sedimentation rate or C-reactive protein, anemia of chronic disease, hypoalbuminemia, or thrombocytosis). Noninflammatory disorders tend to be related to trauma (meniscus tear), ineffective repair (OA), neoplasm, or pain amplification (fibromyalgia). There may be pain without swelling or warmth, absence of inflammatory or systemic features, minimal or absent morning stiffness, and normal (for age) laboratory testing.

The differential diagnoses may be narrowed by the identification of the underlying pathological process and the exact site of the complaint. These help to determine whether there is need for immediate diagnostic or therapeutic intervention or for continued observation.

The clinical history should contain the patient profile, including age, sex, race, family history, occupational history, medications, and leisure activities. The chronology of the complaint gives important diagnostic clues and may be divided into onset (e.g., abrupt), evolution (chronic, intermittent, migratory), and duration. The number and distribution of involved articulations should be noted. Articular disorders are classified based on the number of involved joints: Monoarticular (one joint), periarticular (two to four joints), or polyarticular (more than four joints). Nonarticular disorders are classified as either focal or widespread. Precipitating events such as trauma or drug ingestion must be documented, as well as antecedent or current illnesses that may contribute to the patient's complaint. If the problem is chronic, ask the patient why he or she is addressing it at this particular time. A review of systems may provide useful diagnostic information, eliciting systemic features of diseases such as fever (systemic lupus erythematosus [SLE], infection). Musculoskeletal complaints may be associated with other organ systems, for example, such as the nervous system (Lyme disease, vasculitis), eye (sarcoidosis, Reiter's syndrome), and gastrointestinal tract (scleroderma, inflammatory bowel disease), to name just a few. (See Focus on History 15.1.)

Guided by the history, the physical exam helps to distinguish between mechanical problems, soft tissue disease, and noninflammatory and inflammatory joint disease. A major goal of the physical exam is to detect warmth over a joint, joint effusion, and pain on joint motion. These are hallmarks of synovitis. Limitations in movement and instability are also important to assess and are of particular concern in knee and ankle pain. The medial and lateral collateral ligaments of the knee can be assessed by valgus and varus stress of the joint. Excess laxity of the knee on anterior drawer test or Lachman's test may indicate an anterior cruciate ligament tear.

Always begin the exam by inspecting the site, observing for side-to-side symmetry. The patient must be undressed and draped so that visual inspection can be done.

Focus on History 15.1 Musculoskeletal Problems

Questions to ask:

1. Have you injured yourself?
2. Describe exactly how your injury occurred:
   - When the injury occurred, did it make a noise or sound? If so, describe the sound.
3. Where does it hurt? Does the pain radiate, or is it localized, or diffuse?
4. Do you have numbness or tingling?
5. Is there loss of function?
6. Is there swelling?
7. When did the pain first occur?
   - What relieves it?
   - What exacerbates it?
   - What time of day does it occur?
   - Does the pain awaken you at night?
8. Is there joint stiffness?
   - Does activity make it worse or better?
9. Do you have any other symptoms (or systemic processes)?
   - Do you have a fever?
   - Do you have a rash?
   - Do you have general fatigue?
   - Have you recently been traveling or camping?
   - Have you recently been immunized?
   - Have you recently been treated with antibiotics?
   - Do you have a history of upper respiratory infection? Sexually transmitted disease? Chronic disease?
   - Were you ever treated with steroids?
10. Describe your daily activities—work, hobbies, home.

The uninvolved side should be examined initially and compared with the involved side. The painful part should be examined last. The patient should actively perform as much ROM as he or she can.

If the patient complains about a specific anatomical area, examine that area to recognize, for instance, a frozen shoulder or hip trochanteric bursitis with pain over the greater trochanter. If the patient reports a history of hand numbness that awakens him or her at night, this suggests carpal tunnel syndrome, even with no physical findings. Foot pain that begins the first thing in the morning when the patient puts his or her foot out of bed is suggestive of plantar fasciitis or early RA.

The combination of point tenderness, reduced active ROM, and preserved passive ROM suggests soft tissue disorders, including bursitis, tendinitis, or muscle injury. If both active and passive ROM is limited, soft tissue contracture, synovitis, or a structural abnormality of the joint is possible. Tendinitis may be suggested by tenderness to palpation along the course of the tendon or by pain or rub produced when the tendon is stretched or stressed during active ROM against resistance. Inability to actively abduct the shoulder fully is suggestive of a rotator cuff tear. Crepitus (joint noises or palpable grinding during joint motion) may be due to articular surface abnormalities or synovitis. Crepitus not associated with pain or limitation of motion is generally of no clinical significance.

After the target area, if any, has been examined—or if the patient reports diffuse generalized musculoskeletal pain—a simple evaluation may begin with gentle palpation of the hands. Bony enlargements of the distal interphalangeal joints or Heberden's nodes are indicative of OA, whereas soft tissue swelling may indicate RA; inflammation may also be indicated by swelling of the metacarpophalangeal joints. If symmetrical swelling has been present for longer than 6 months, a presumptive diagnosis of RA may be made, regardless of laboratory results. Limitations of flexion and/or extension of the wrist are a sign of prior inflammation and a clue to earlier chronic RA. (See Rheumatoid Arthritis in Chapter 17.)

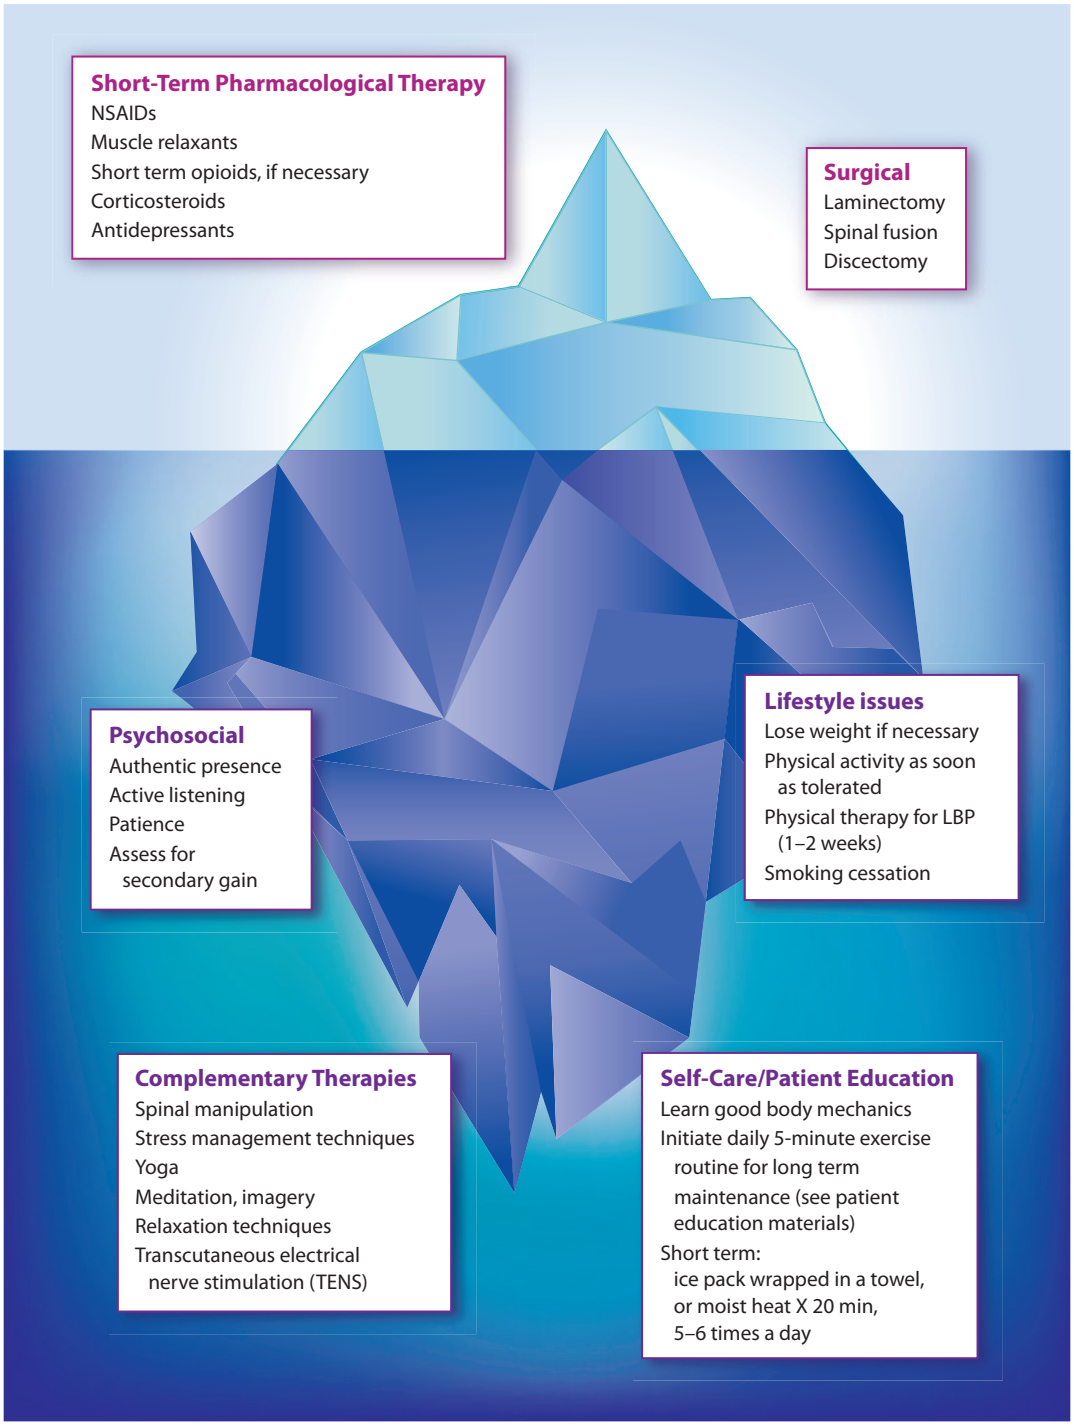
The shoulders can be examined by asking the patient to raise his or her arms above the head, put hands behind the head, and hands behind the back. Tender points in the muscles of the neck, shoulders, and back—a characteristic sign of fibromyalgia—are easily recognized by an experienced examiner. (See Fibromyalgia in Chapter 17.) Ask the patient to rise from a chair without holding on. If the patient cannot do this, there is an abnormality of the joints, nerves, or muscles, which requires further examination, usually by a specialist. Ask the patient to walk a few steps across the room and back and observe the gait. This should be included in all evaluations.

Have the patient lie down to assess ROM of the hips, knees, ankles, and feet. It is important to recognize flexion contractures, which, if not congenital or due to injury (ask the patient), are a sign of prior inflammation. All maneuvers described should take less than 2 minutes and should be included in the "general" physical exam. Note any endocrinopathies (irregular heart rhythms, weight gain, and thyromegaly) and possible malignancy (severe pain, weight loss, or palpable masses). In addition, muscle strength and function should be systematically evaluated. (See Advanced Assessment 15.1.) On physical examination, evidence of tender points and trigger points, as well as the absence of inflammation or swollen joints, increases the likelihood of a soft tissue problem. Many clinicians use a body drawing and mark the affected parts.

Extra-articular abnormalities, such as oral/nasal ulcers; iritis; rash; nodules; pericardial or pulmonary rub; enlargement of liver, spleen, or lymph nodes; and neurological abnormalities, suggest a systemic disease.

An accurate diagnosis of injury and/or rheumatic diseases can best be accomplished with careful history

The Iceberg of Low Back Pain



and physical exam by an experienced clinician. At the same time, it should be recognized that in some patients—perhaps as many as 10%—a definitive diagnosis cannot be established, particularly at the first visit, and sometimes even over time. This is especially true in cases of chronic musculoskeletal pain. The diagnosis is not as important as the approach to treatment, which typically is similar for a range of diagnoses based on the presence or absence of inflammation (see Table 15.3).

Advanced Assessment 15.1 Grading of Manual Muscle Testing

Numerical Grade	Descriptive Grade	Description
5	Normal	Complete ROM against gravity with full or normal resistance
4	Good	Complete ROM against gravity with some resistance
3	Fair	Complete ROM against gravity
2	Poor	Complete ROM with gravity eliminated
1	Trace	Muscle contraction but no or very limited joint motion
0	Zero	No evidence of muscle function

ROM: range of motion.

Table 15.3 Examples of Disorders of Inflammation versus Noninflammation

Inflammatory Musculoskeletal Disorders	Noninflammatory Musculoskeletal Disorders
Infectious Crystal induced Immune related (rheumatoid arthritis, systemic lupus erythematosus)	Ineffective repair (osteoarthritis) Pain amplification (fibromyalgia) Trauma
Idiopathic	Neoplasm

Diagnostic Reasoning

Diagnostic Tests

Laboratory tests may be of limited use. One problem with using laboratory tests in the diagnosis is the fact that many people who have been told that they have SLE, gout, or Lyme disease do not have the disease at all, but simply an abnormal laboratory test such as a positive antinuclear antibody (ANA), elevated uric acid, or positive Lyme antibody test. These tests are abnormal in at least 5% of the general population, whereas the diseases identified are seen in less than 1%. Therefore, most individuals with positive laboratory tests do not have the associated disease. In contrast, many people with RA, for example, often have normal blood tests and x-ray findings, particularly in early disease, when aggressive treatment might be most effective. Some of these tests are useful to research laboratories in the identification and understanding of pathogenic mechanisms, but do not add anything to the meaningful diagnosis and management of the patient. A review of associated laboratory tests is presented here.

- Complete blood count—the presence of anemia may be a clue to inflammation, and leukopenia is seen in active SLE.
- Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)—nonspecific indicators of inflammation. A highly elevated value indicates a likelihood of inflammatory rheumatic disease, infection, or malignancy. ESR increases with age, as does CRP, and some people (as many as 5%–10% of the general population) have elevated values with no explanation. Up to 40% of patients who present with RA have normal ESRs and CRPs. In patients with giant cell arteritis and polymyalgia rheumatica, the ESR is almost always markedly elevated, and therefore diagnostically useful.
- Rheumatoid factor (RF)—25% of patients with RA never have an elevated RF. It may also be elevated with other inflammatory conditions (e.g., SLE, subacute bacterial endocarditis, vasculitis, viral infection).
- Fluorescent ANA test—this test is positive in 99% of patients with SLE; however, it is also positive in 5% to 10% of normal blood donors, meaning only 1 in 100 people with a positive ANA has SLE. A positive ANA can also occur with certain drugs (procainamide, hydralazine); it may be transiently positive in people with a severe infection; and it is positive in a high percentage of people with other inflammatory rheumatic conditions, including RA (30%–50%), scleroderma (20%–50%), polymyositis (10%–30%), and idiopathic pulmonary fibrosis (10%–20%).
- Lyme borreliosis antibodies—Lyme disease is identified serologically by antibodies to the Lyme *Borrelia* organism. From 5% to 10% of normal individuals have a positive Lyme borreliosis titer, even in the best laboratories. A test for Lyme disease is not appropriate in patients with unexplained arthritis unless there are other risk factors such as living in an endemic area and frequent outdoor activities.
- Uric acid—uric acid measurement is often included in evaluation of patients with musculoskeletal symptoms, because elevated uric acid resulting from either overproduction or underexcretion is seen in more than 90% of people with gout. However, most people with elevated uric acid levels do not have

gout. A test for uric acid should be reserved for patients who have clinical evidence of episodic or atypical inflammatory arthritis. Alcohol and diuretics may cause moderately elevated uric acid levels. Asymptomatic hyperuricemia should not be treated. Further, some individuals with gout have normal serum acid levels, particularly at the time of the acute attack. A definitive diagnosis of gout requires identification of uric acid crystals in synovial fluid.

- Screening panels—these tests are available from all national laboratories and are marketed as "rheumatology screening panels" to rule out an inflammatory rheumatic disease. The simplest include rheumatoid factor, ANA, and uric acid, although more elaborate tests are available. These screens tend to be a major source of potential false-positive information in patient evaluations and are not advised for use by the general practitioner.

Imaging studies are indicated (1) when examination cannot localize the anatomical structure that is causing symptoms, (2) after a significant trauma, (3) when there is a loss of joint function (e.g., unable to bear weight), (4) when pain continues despite conservative management, (5) when a fracture or bone infection is suspected, or (6) when there is a history of malignancy. Clinicians who are unfamiliar with what views to order should contact the radiologist for guidance. Plain radiographs will be unrevealing (and are therefore not indicated) for most patients with acute and new symptoms of RA, SLE, gout, mechanical back pain, or tendinitis/bursitis.

Radiographs may confirm the diagnosis of OA and assess its severity, but normal findings on radiographs do not rule out the presence of OA. The earliest radiographic changes in RA are nonspecific and include soft tissue swelling and periarticular osteoporosis, but these features are often absent at the initial presentation. In established RA or long-standing gout, erosions may be diagnostic: Marginal erosions in the former and evidence of reparative process in the latter. Radiography (plain x-ray films) can reveal the following:

- Erosions
- Calcifications and cysts
- Osteopenia
- Narrowing of joint spaces
- Deformity of bones
- Separations (fractures, dislocations)

Repeat radiographs after 7 to 10 days are appropriate when a fracture is suspected despite an unrevealing initial examination because callus formation or abnormal alignment may be evident. Repeated imaging over time in patients with established rheumatic disease may be useful in assessing structural damage. For patients with typical acute mechanical low back pain, a plain radiograph adds little to the management decisions.

Ultrasonography may be useful in the detection of soft tissue abnormalities but has limited clinical value. The foremost application of ultrasound is in the diagnosis of synovial (Baker's) cysts although rotator cuff tears and various tendon injuries may be identified by ultrasound.

Computed tomography (CT) has proved most useful in the evaluation of the axial skeleton because of its ability to visualize in the axial plane. CT is useful in the diagnosis of low back pain syndromes (herniated intervertebral disc, spinal stenosis, spinal trauma), intra-articular osteochondral fragments, and advanced osteonecrosis. Helical or spiral CT can be useful in the detection of obscure fractures.

Magnetic resonance imaging (MRI) or radionuclide bone scanning is useful when specific disorders are suspected, and the management could be altered according to findings. Rotator cuff tear, spinal stenosis, avascular necrosis of bone, or mechanical derangement of the knee are some conditions that may be revealed with an MRI. A bone scan may be useful when osteomyelitis, stress fractures, or bony metastases are a concern. In general, MRI is useful for assessing soft tissue and spinal cord elements, whereas nuclear medicine studies are best for assessing bone turnover. MRI and bone scanning are expensive and the latter exposes patients to significant radiation. Rotator cuff degeneration and disc abnormalities are common in older patients. These studies should be reserved for patients in whom specific disorders are suspected, when the diagnosis cannot be made in a less costly manner, and only after a thorough history and physical exam.

Nerve conduction studies (electromyography) may be indicated when neurological abnormalities or paresthesias are present.

Differential Diagnosis

Joint symptoms of one and up to a few joints may be due to trauma, infection, crystal-induced inflammation (gout, pseudogout), or primary inflammatory arthritis (including spondyloarthropathies and atypical presentation of RA). In acute monoarthritis, it is essential that infection of a joint be diagnosed or excluded, and this can be done only via joint aspiration (see Therapeutic Procedure 15.1) and synovial fluid analysis and culture (see Advanced Assessment 15.2). Chronic monoarticular symptoms with little or no effusion are usually from OA. Tendinitis and bursitis generally involve one joint region, and physical exam is usually diagnostic. Common syndromes include de Quervain's tenosynovitis, olecranon bursitis, medial and lateral epicondylitis, bicipital and rotator cuff tendinitis, rotator cuff tear, trochanteric bursitis, patellar bursitis and prepatellar bursitis, anserine bursitis, plantar fasciitis, posterior tibial tendinitis, and Achilles tendinitis.

Polyarthritis has an extensive differential diagnosis. The presence of prolonged morning stiffness, systemic

Therapeutic Procedure 15.1 Arthrocentesis

Joint	Technique
Ankle	*Patient position:* Supine, with foot in plantar flexion *Needle size:* 20–22 gauge, 1-1/2 in. *Syringe size:* 10–30 mL and 2–5 mL *Procedure:* Locate the space between the medial malleolus and extensor hallucis tendon. Using an anteromedial approach, enter lateral to the medial malleolus, medial to the tendon, and aim the needle downward, laterally. Insert the needle 1-3/4 in. (3 cm).
Elbow	*Patient position:* Sitting, with elbow flexed to 90 degrees with the palm pronated on a table *Needle size:* 20–22 gauge, 1-½ in. *Syringe size:* 10–30 mL and 2–5 mL *Procedure:* Locate the space between the lateral epicondyle of the humerus and olecranon process (3/8 in. below the epicondyle). Using a posterolateral approach, insert the needle and direct it medially and slightly toward the hand. Insert the needle 5/8 in. (1.5 cm).
Knee	*Patient position:* Supine, with knee fully extended or bent slightly to 20 degrees over a rolled towel under the knee *Needle size:* 18–20 gauge, 1-1/2 in. *Syringe size:* 10–30 mL and 2–5 mL *Procedure:* Locate the joint space by moving medially from midpatella to a point halfway between the patella and underlying the femoral condyle. Using an anteromedial approach, aim the needle posteriorly (downward) and laterally. Insert the needle 3/8–5/8 in.
Knee (patient unable to extend knee)	*Patient position:* Sitting, with knee flexed 90 degrees over edge of examining table *Needle size:* 18–20 gauge, 1-1/2 in. *Syringe size:* 10–30 mL and 2–5 mL *Procedure:* Locate the triangle formed by the tendon and condyles. Using an anteromedial or lateral approach, enter distal to apex of patella medially or laterally to the tendon. Direct the needle slightly cephalad to a depth of 1-3/8–1-3/4 in.
Wrist	*Patient position:* Sitting, with palm pronated over a rolled towel, wrist flexed 20–30 degrees and with a slight ulnar turn *Needle size:* 24–26 gauge, 5/8 in. *Syringe size:* 10–30 mL and 2–5 mL *Procedure:* Locate the space between the bony processes of the radius and ulna and just lateral to the tendon. Using a dorsal approach, enter distal to the space and perpendicular to the skin. Insert the needle downward 3/8–3/4 in.

Advanced Assessment 15.2 Synovial Fluid Analysis

	Normal	Grade I: Noninflammatory	Grade II: Inflammatory	Grade III: Infectious
Visual analysis	Clear, straw-colored	Clear or slightly bloody and turbid	Turbid	Turbid, gray or yellow
Viscosity	Normal	Decreased	Decreased	Decreased
WBCs per mm^3	30–150	<2,500	2,500–25,000	>50,000
PMNs (%)	<20	20–50	50–70	70–90
Protein (g/dL)	1–4	1–5	3–6	3–7
Examples		OA, SLE, mechanical derangement	RA, gonococcal arthritis, rheumatic fever, gout, pseudogout, Reiter's syndrome	Septic arthritis, tuberculosis

OA: osteoarthritis; PMNs: polymorphonuclear leukocytes; RA: rheumatoid arthritis; SLE: systemic lupus erythematosus.

symptoms, Raynaud's phenomenon, rash, or sicca symptoms and manifestations of other organ involvement suggest a rheumatic disease. The specific evaluation is guided by the clinical manifestations and should screen organ symptoms that can be involved without overt signs, such as the lung, heart, liver, kidney, and bowel, for potential involvement. Precise diagnosis and management usually requires referral.

Arthralgia and/or myalgia without physical findings has an extensive differential diagnosis. Often, no definitive diagnosis is possible at the initial presentation. Common causes include fibromyalgia, viral infection, an overuse syndrome (tendon strain associated with repetitive motion injuries or muscle fatigue), a neuropathy, or hypothyroidism. If the history and physical exam do not provide a diagnosis, symptomatic management and reassessment over several weeks is more productive initially than is laboratory testing or diagnostic imaging.

After ruling out joint pain, trauma, overuse syndromes, and vascular components, primary differential diagnoses for muscle pain (myalgia) typically include infectious causes, such as viral syndromes, mononucleosis, Rocky Mountain spotted fever, or Lyme disease; systemic disorders such as fibromyalgia (FM) or polymyalgia rheumatica; or psychogenic causes. More than one syndrome may occur concomitantly. For example, bursitis may coexist with pain from FM. If the inflammation from the bursitis is overlooked, the patient may not receive the treatment indicated for the acute disorder (see Fig. 15.1).

COMMON COMPLAINTS

ACUTE MUSCULOSKELETAL INJURY

Acute musculoskeletal injury encompasses a number of common conditions characterized by acute pain and/or muscular spasm (persistent, painful, and reversible contracture of striated muscle). These symptoms may be caused by specific syndromes, such as low back pain and ankle sprain with well-documented and well-tested treatment guidelines; specific syndromes such as torticollis and "tennis elbow" with less-well-tested management guidelines; and a large group of disorders characterized by nonspecific musculoskeletal trauma, which results in tissue derangement that can lead to pain, limitations of movement, spasm, and the inability to perform activities of daily living. Sometimes a traumatic injury, such as from a car accident, or other significant precipitating factor, such as lifting a heavy object, may be identified as the initiating factor. In some cases a trivial movement such as bending over to tie a shoe or coughing may precipitate the injury. Acute musculoskeletal injury implies pain of less than 6 weeks' duration. (See Differential Diagnosis 15.1.)

The following are management principles in acute musculoskeletal pain/injury not requiring emergent treatment (see Chapter 19 for emergency care):

- The acronym RICE is commonly employed: *R*est the affected part, *A*pply ice for 48 hours, *C*ompression (Ace wrap), *E*levate it.
- Reassurance—most injuries are self-limiting and improvement should occur within approximately 2 weeks.
- Limitation of activity—immobilization of injury is appropriate during the diagnostic phase; if appropriate at all, bedrest should be limited to the most acute period (2 days or less) to control spasm and promote healing.
- Physical therapy—may include heat or cold application with the goal of returning the patient to full function as soon as possible with minimal limitation. Commonly cold/ice is recommended for 48 hours; then heat.
- Skeletal muscle relaxants—a 1- to 2-week course is valuable when injury is accompanied by spasm or tightness. Be aware of potential for sedation and abuse (see Drugs Commonly Prescribed 15.1: Skeletal Muscle Relaxants).
- NSAIDs/acetaminophen—first-line choices (see Drugs Commonly Prescribed 15.2: Pharmacological Treatment of Osteoarthritis).
- Opioids—useful for moderate or severe pain or if sedation desired—monitor adverse effects such as constipation, abuse potential.
- Referral—to orthopedic specialist if no relief with conventional methods.
- Imaging studies—radiograph, CT, MRI are usually *not* indicated for acute musculoskeletal injuries.

MUSCLE CRAMPS

Muscle cramps may be described as sudden, involuntary, painful contractions of a muscle or muscle part that last from seconds to several minutes. Cramps may occur spontaneously while at rest or may be precipitated by a brief muscle contraction. The cause is usually related to some hyperexcitability of the motor neurons supplying the muscles. In many cases, the reason for episodic, recurrent muscle cramps may remain unclear, even after complete diagnostic evaluation. Muscle cramps may also occur related to vigorous exercise and during sporting events. Monitor for dehydration.

Differential Diagnosis

The initial history should elicit whether the cramps occur with exercise or at rest. In pregnant women and children, leg cramps tend to occur at rest and are most often benign, requiring no treatment. Certain medications (e.g., some diuretics, some of the statin drugs, and clofibrate [Atromid-S]) may cause muscle cramping. Leg pain and cramps in adults that are precipitated by

Differential Diagnosis 15.1 Classification of Sprains

Grade	Degree of Injury	Treatment
Grade I	Partial tear; no instability or opening of the joint on stress maneuvers	Symptomatic only
Grade II	Partial tear with some instability indicated by partial opening of the joint on stress maneuvers	Immobilization to protect injured part, but full healing expected
Grade III	Complete tear with complete opening of joint on stress	Immobilization; possible repair

Drugs Commonly Prescribed 15.1 Skeletal Muscle Relaxants

Drug	Indications	Adverse Reactions and Prescribing Considerations
meprobamate (200 mg) and aspirin (325 mg) (Equagesic)	For short-term use only Adjunct for musculoskeletal pain, anxiety, tension	CNS depressant; driving and alertness precautions. Do not use with salicylate sensitivity. Caution in patients with depression, renal problems, or hepatic problems. Avoid with alcohol.
cyclobenzaprine HCl (Flexeril)	Maximum of 2–3 weeks Nonneurogenic acute muscle spasm, as adjunct to rest and physical therapy	CNS depressant; driving and alertness precautions. Same profile for toxicity as tricyclic antidepressants—arrhythmias, tachycardia, QT prolongation. Caution in glaucoma, hepatic impairment, urinary hesitancy, elderly. Avoid with MAO inhibitors, alcohol.
orphenadrine (Norflex) (anticholinergic muscle relaxant [central])	Painful musculoskeletal conditions	Potentiates anticholinergics, alcohol, other CNS depressants. CNS excitation, dizziness, blurred vision, dry mouth. Caution in elderly.
orphenadrine citrate 50 mg, aspirin 770 mg, caffeine 60 mg (Norgesic Forte)	Muscle relaxant; short-term use for acute conditions	Potentiates anticholinergics, alcohol, other CNS depressants. CNS excitation, dizziness, blurred vision, dry mouth. Increased risk of GI bleed; caution in elderly.
chlorzoxazone (Parafon Forte DSC)	Adjunct to PT and rest for short-term treatment of acute muscle spasm	May potentiate alcohol, other CNS depressants. Caution in cardiac, impaired renal or hepatic function, elderly. Dizziness, drowsiness.
methocarbamol (Robaxin)	Adjunct treatment of muscle spasm in conjunction with acute musculoskeletal condition	May potentiate alcohol, other CNS depressants. Dizziness, drowsiness, blurred vision, nasal congestion, hypotension. Caution in elderly.
metaxalone (Skelaxin)	Adjunct treatment of muscle spasm in conjunction with acute musculoskeletal condition	May potentiate alcohol, other CNS depressants. Caution with history of seizures, hepatic/renal impairment, elderly. Dry mouth, dizziness, blurred vision, nausea.
carisoprodol (Soma)	Used as adjunct to PT and rest in muscle spasm related to acute musculoskeletal condition	May potentiate alcohol, other CNS depressants. Caution in severe liver, kidney disease and in elderly. Dizziness, drowsiness, agitation, insomnia, irritability, syncope.
diazepam (Valium)	Skeletal muscle relaxant for short-term use in acute musculoskeletal conditions; also used for anxiety	Benzodiazepine; potential for dependence. May potentiate alcohol, other CNS depressants. Caution in hepatic, severe renal dysfunction and in elderly. Dizziness, drowsiness.
tizanidine HCl (Zanaflex)	Skeletal muscle relaxant for treatment of muscle spasticity	May potentiate alcohol, other CNS depressants. Avoid with severe renal, hepatic impairment; caution with elderly. Avoid with other CYP1A2 inhibitors. Visual hallucinations, sedation.

Drugs Commonly Prescribed 15.2 Pharmacological Treatment of Osteoarthritis

Drug/Usage	Indication	Adverse Reactions and Prescribing Considerations
acetaminophen (Tylenol)	Treatment of mild to moderate pain; fever; does not have anti-inflammatory properties	Monitor alcohol intake and limit to <3 drinks/day; hepatotoxicity may occur with chronic use or in doses >4 g/day. Low cost, easy availability, overall safety profile.
capsaicin cream	Topical for pain	Naturally occurring substance that seems to interfere with transmission of painful stimuli.
NSAIDs	Acute and chronic pain due to OA	Renal and/or platelet dysfunction; GI bleeding. Risk factors for GI bleed: Greater age, comorbidity, history of peptic ulcer, history of GI bleed, glucocorticoids, anticoagulation, combination NSAID therapy and increased dose.
tramadol HCl (Ultram; available in immediate and extended release); also available with acetaminophen (Ultracet)	Relief of moderate to moderately severe pain Opioid analgesic	Low abuse potential; nonscheduled; do not use with SSRIs, TCAs, MAO inhibitors to avoid serotonin syndrome. Do not use extended-release form with hepatic or renal disease. CNS depression, caution in elderly, use lowest dose initially.
codeine (Tylenol with Codeine)	Analgesic, opioid. Treatment of mild to moderate pain	Weak opioid; side-effect profile not good for older adults; also increased risk of hip fracture. Use with caution in head injury; constipation.
hyaluronic acid (Viscosupplement injection)—used as joint injection for pain relief for OA of knee only	Either three injections over 15 days or weekly injections for 5 weeks	Expensive; mild adverse effects include injection site inflammatory/allergic reaction, transient worsening of symptoms; systemic include occasional muscle cramps (not common); always risk of infection with intra-articular injection.
Corticosteroids—hydrocortisone (Cortisol)	Symptom relief for weeks to months; Intra-articular injection—dose depends on anatomical site and medication	Duration of relief may be short (1–2 weeks) in lower extremities, shoulder, or elbow; may be effective in hand for several months; always risk of infection with intra-articular injection; local reaction at injection site. Can increase blood glucose in diabetics.
prednisolone tebutate (Hydeltra)		
methylprednisolone acetate	No more than two injections should be given in any weight-bearing joint.	
(Depo-Medrol)		
triamcinolone acetonide (Kenalog)		
triamcinolone hexacetonide (Aristospan)		
betamethasone (Celestone)		

CNS: central nervous system; GI: gastrointestinal; MAO: monoamine oxidase; OA: osteoarthritis; SSRI: selective serotonin reuptake inhibitor; TCA: tricyclic antidepressant.

exercise and relieved by rest are usually caused by peripheral vascular disease. Blood chemistry tests may be necessary, including serum enzymes, to rule out causes such as dehydration (from diarrhea or sweating). (See Differential Diagnosis 15.2.)

PARESTHESIAS

Paresthesia is the sensation of numbness, prickling, or tingling experienced in central and peripheral nerve lesions. Frequently, the patient's understanding and use of the terms will differ from the clinician's; therefore, it is necessary to clearly establish the character of the patient's complaint. During the history, take time to differentiate between the lack of use of a limb from the sensation of tingling and numbness and the total loss of sensation. It is also important to ascertain if the loss or altered sensation ascends onto the abdomen or thorax.

The location of the paresthesia may be focal or generalized. It may also be nonspecific, as in multiple sclerosis, in which the initial presentation may be bilateral diminution of sensation or paresthesia in the upper or lower extremities, or unilateral, as in stroke or transient ischemic attack, in which unilateral extremity or face paresthesias may occur.

Paresthesias are also likely to be a result of anatomical or mechanical peripheral nerve injury, such as entrapment and compression neuropathies. These are most likely to occur at sites that are more susceptible to damage from an increase in pressure and mechanical forces, such as entrapment or compression of the medial nerve at the wrist (carpal tunnel syndrome), the ulnar nerve at the elbow, and the peroneal nerve at the knee.

Paresthesias also occur as a result of nerve-root injury, chlorinated hydrocarbon exposure, respiratory alkalosis, and the use of certain drugs, such as carbonic anhydrase inhibitors (which are used in the treatment of glaucoma).

The physical exam must determine if the sensory abnormality follows the distribution of a peripheral nerve or nerve root. Commonly affected nerves are cervical nerve roots 5 to 8 (C5–C8); ulnar and radial nerves of the hand; lumbar nerves 3, 4, 5, and S1; obturator, sciatic, and femoral nerves in the thigh; and peroneal and tibial nerves of the foot. (See Advanced Assessment 15.3.)

Differential Diagnosis

Cervical Radiculopathy

Cervical radiculopathy is commonly caused by compression of the cervical nerve roots, when the cervical discs place stress on the vertebral bodies. It usually is the result of age-related changes, cervical spondylosis, or a herniated disc. The most commonly involved nerve roots are C6 and C7, which produce paresthesias into the lower lateral arm, thumb, and middle finger.

Diagnostic tests include radiological assessment of the cervical spine, and if radicular pain is severe or if there is motor or sensory deficit or hyporeflexia, MRI is indicated. If only radiculopathy is present, a conservative trial of cervical traction as in the use of a soft cervical collar may be warranted. Newer findings on soft cervical collar usage discourage routine use, especially in cases where cervical radiculopathy is a chronic problem. Use of the soft cervical collar should be intermittent, meaning 1 to 3 hours on and then off for several hours. Usage should never be longer than a few days at most. In severe cases, a myelogram may be necessary to rule out neoplasm and to define the extent of compression. Surgery may be considered, but no long-term outcome studies have compared the benefits of surgery to nonoperative treatments such as heat and cold, ROM exercises, and limiting activity during acute outbreaks.

Brachial Plexus Neuritis or Radiculitis

Brachial plexus injuries include a broad array of neurological dysfunction ranging from momentary paresthesias to completely flail extremities. The mechanism of injury is equally diverse, from high-energy motor vehicle crashes, falls from a height, and gunshot wounds to lower-energy injuries such as most athletic injuries. "Burners" or "stingers" (transient brachial plexopathy)

Differential Diagnosis 15.2 Muscle Cramps

Symptom	Possible Diagnosis
Cramp-like symptoms	Intermittent claudication related to ischemia; drug induced (such as statin-induced myopathy)
Contracture	Thyroid disease, McArdle's disease
Tetany	Hypoglycemia, hypomagnesemia, respiratory alkalosis, hypokalemia
Dystonia	Occupational (such as writer's cramp) Drug-induced (antipsychotics, anti-parkinsonian) metabolic/neurological
True cramps	Ordinary (nocturnal), dehydration, drug-induced (nifedipine, beta agonists), lower motor neuron, hemodialysis (volume and electrolyte shifts), heat induced (volume depletion, hyponatremia)

Advanced Assessment 15.3 Paresthesias and Affected Nerve Roots

Nerve Root	Paresthesia
C6 (6th cervical)	Thumb: Dorsal and lateral aspects
C7 (7th cervical)	Fingers: Index and middle
C8 (8th cervical)	Fingers: Fifth and ulnar half of fourth Hand: Ulnar side
L4 (4th lumbar)	Thigh: Anterior, just above knee
L5 (5th lumbar)	Foot: Dorsal aspect Great toe: Dorsal aspect
S1 (1st sacral)	Foot: Lateral aspect Small toe: Lateral aspect

are transient injuries to the upper trunk of the brachial plexus involving the C5 and C6 nerve roots. The most common mechanism of injury is a traction force when the shoulder is forcefully depressed and the head and neck are tilted toward the opposite side or the upper plexus is compressed between the shoulder pad and the scapula. These injuries are relatively common among college and professional athletes, especially in sports such as football and basketball.

Brachial plexus injuries involving axonal disruptions can be categorized further as occurring proximal to the dorsal root ganglion in the spinal foramen (preganglionic) or anywhere distal to the ganglion (postganglionic). This distinction is important because operative repair is impossible and the prognosis is poor for preganglionic root recovery.

The symptoms are severe—burning upper arm and shoulder pain that radiates down the arm, followed by weakness affecting C5 and T1 (thoracic) nerve root distributions. The patient is often seen holding the arm on the affected side, which hangs limply at the side.

A detailed neurological assessment is required, with examination of the neck and shoulder. Plain radiographs including the cervical spine should be obtained. If radiographs are abnormal, or if symptoms persist, progress to MRI. Cervical spine instability would be evident on radiograph. Depending on the location and severity of the brachial plexus injury, persistent pain, sensory loss, paresthesia, weakness, or paralysis is possible.

An athlete should not return to play while symptomatic. Athletes with prolonged or bilateral involvement should be referred. Treatment options vary from strengthening and stretching exercises to splinting to surgical intervention in some cases. Cervical spine precautions should be followed if cervical spine injury is suspected.

Thoracic Outlet Syndrome

Thoracic outlet syndrome is compression of the brachial plexus and/or subclavian vessels as they exit the narrow space between the superior shoulder girdle and the first rib. These structures can be affected individually or in combination. Women aged 20 to 50 years are most commonly affected. Etiology may be secondary to congenital abnormalities such as cervical rib or abnormally long transverse process of C7 or an anomalous fibromuscular band in the thoracic outlet. Post-traumatic fibrosis of the scalene muscles is also a possibility.

Symptoms may be vague and variable. Common symptoms are color changes in the hand along with sensory changes and weakness in the fourth and fifth fingers. Cervical spine (C-spine) films are necessary to document cervical rib placements, and electromyography (EMG) helps to delineate the specific nerve involvement. Ultrasound of the subclavian artery with the arm in different positions helps define the extent of compression.

Conservative treatment consists of shoulder exercises to improve posture. Orthopedic referral may be needed to evaluate for surgery to remove the offending bony structure.

Peripheral Polyneuropathy

Peripheral polyneuropathy is "stocking-glove" or distal sensorimotor paresthesia, with diminished or variable deep tendon reflexes. Diabetes mellitus is a frequent cause; early symptoms may respond to a regimen with tighter glucose control. A rapid onset of motor polyneuropathy is seen in Guillain-Barré syndrome, in which an ascending weakness occurs after a viral illness. Other etiologies include alcoholism, vitamin B deficiencies, vitamin B_6 excess, Sjögren's syndrome, AIDS, hypothyroidism, amyloidosis, and renal failure.

A complete history and physical exam to exclude muscle disease or weakness is necessary. Paresthesias result in weakness, sensory loss, and altered deep tendon reflexes, whereas primary muscle pathology produces only weakness. Complete blood count, erythrocyte sedimentation rate, blood glucose, liver function, blood urea nitrogen, creatinine, thyroid-stimulating hormone, and immunoelectrophoresis tests are indicated. A chest x-ray film and EMG will help confirm the diagnosis. A neurological consultation is indicated.

Sciatic Nerve Syndrome

Sciatic nerve syndrome is back pain that radiates into the buttocks and produces tingling in the posterior thigh and posterolateral calf to the lateral malleolus. Often the cause is a herniated disc, spinal stenosis, obturator neuritis, sciatic nerve irritation, direct trauma, or osteoarthritis. The pain may also be secondary to lumbar sacral strain but does not necessarily indicate disc herniation or prolapse. Sciatic nerve compression may result from tumors in the pelvis or from prolonged sitting or lying on the buttocks. The history may reveal twisting, bending, or heavy lifting.

The physical exam includes evaluating for point tenderness and ROM in the back. With the patient supine,

perform straight-leg raising. A positive finding is radicular pain that occurs below the knee at less than 60 degrees of limb elevation, with pain in the buttock or posterior thigh. Treatment is usually conservative. Any change in bowel or bladder function (cauda equina syndrome) constitutes an emergency and needs immediate intervention.

Femoral Neuropathy

Arising from the second, third, and fourth lumbar nerve roots, the femoral nerve innervates the quadriceps and terminates as the saphenous nerve. Onset of femoral neuropathy is sudden and painful and is followed by wasting and weakness in the quadriceps, sensory impairment of the anteromedial thigh, and loss of the deep tendon reflex of the knee. Causes include nerve infarction due to diabetes mellitus, retroperitoneal compression by tumor, or hematoma from entrapment. Although improvement may occur, residual weakness is common.

NECK PAIN

Discomfort and limited ROM arising from the structures in the neck is a common complaint. The pain may originate from any of the musculoskeletal structures, including muscles, ligaments, tendons, cervical vertebrae, nerves, and vasculature. Pain referred to the neck from the temporomandibular joint, pleura, or mediastinum may also be seen. Causes of neck pain are generally structural in nature and most often are the result of trauma, degenerative changes, or muscle spasms. Stress, sedentary occupations, and improper biomechanics are frequently found to be contributing factors; questions regarding these factors should be asked during the history taking. The onset (rapid or insidious), location (arm, shoulder, head, or back), and character (sharp, dull, or aching) of the pain are essential in the differential diagnosis. Of particular note is pain (in the absence of trauma) that begins gradually and improves with rest, because infection and malignancy in the vertebrae do occur.

Physical exam of the neck begins with the evaluation of ROM, including flexion, extension, rotation, and side bending to determine limitations and the pain-producing movements. Spurling's maneuver should be used to assess nerve-root compression. (See Advanced Assessment 15.4.) This test is widely used in clinical practice; however, a review of studies assessing inter-rater reliability, sensitivity, and specificity revealed few methodologically sound studies and a need for more research on the usefulness of this test. Palpation of the neck must be done thoroughly, checking for tenderness, muscle spasm, and lymphadenopathy. Lymph nodes in the supraclavicular and axillary regions should be examined carefully; enlarged nodes in the absence of infection may indicate malignancy. Evaluate the vascular structures and the thyroid. The examination must also include a musculoskeletal and neurovascular assessment of the extremities, including assessments of the muscle strength of biceps, triceps, and handgrips. (See Advanced Assessment 15.4.) Abnormalities in sensation of any dermatome and altered deep tendon reflexes indicate cervical nerve-root compression.

Laboratory studies such as erythrocyte sedimentation rate, rheumatoid factor, or antinuclear antibody are necessary only if systemic or bone disease is suspected.

Differential Diagnosis

Torticollis

Often referred to as "wryneck," *torticollis* is a self-limiting condition that usually occurs after excessive exposure to the cold or activities that require unusual or prolonged rotation or twisting of the neck musculature. Torticollis most often occurs in young adults. Pain arises from acute muscle spasm and serves a protective function.

Questioning the patient about sleep positions and the number of pillows used may elucidate the cause of the condition. Physical examination findings in torticollis include limitation of neck flexion away from the affected side. Spasms of the sternocleidomastoid or trapezius areas are common.

Radiographic evaluation is not routinely needed, but x-ray studies may be useful if the symptoms continue past the time when improvement is expected.

Treatment involves decreased activity (which may be easiest to obtain with a soft cervical collar used intermittently for 2–3 hours at a time over the course of 2–3 days), moist heat, muscle relaxants, and any of the NSAIDs. Resolution is expected in 1 week.

Cervical Muscle Sprain/Strain and Spasm

Cervical muscle sprain/strain is a muscle injury in the neck, a common and largely self-limited condition. The soft tissue muscles of the neck are deeply buried and protected, and it is often difficult to differentiate injuries to the neck by either physical exam or more sophisticated imaging modalities. Thus, this term is also used to describe ligamentous injuries of the facet joints or intervertebral discs. After ruling out neurological dysfunction and unstable injuries, the treatments for a neck sprain or strain are similar.

Advanced Assessment 15.4 Spurling's Maneuver

To perform Spurling's maneuver (neck compression), follow this procedure:

1. With the patient's neck in extension, rotate the neck to the affected side.
2. Apply downward pressure on the head.
3. Assess for patient complaint of or accentuation of limb pain or paresthesia (a positive finding). Also observe for obvious atrophy in the neck.

"Whiplash" describes an acceleration–deceleration of the neck with rapid flexion–extension and is a common sequela of motor vehicle accidents. Despite no apparent instability, these injuries may cause prolonged disability, probably related to a combination of relatively severe ligamentous/muscle injury with nonorganic overlay.

Epidemiology and Causes

Cervical pain is common in both men and women and is usually described as lasting 2 weeks or longer. Mechanical disorders of the cervical spine are the most common cause of neck pain. Information on the prevalence and incidence of cervical pain is available from multiple sources but varies across a wide range. Consistent reporting of occurrence rates is also hampered by the lack of a reproducible definition of cervical pain across multiple studies. Terms such as *whiplash, acute neck sprain, neck spasm,* and *cervical strain* are frequently used to describe what seems to be a single condition. The prevalence of cervical pain in men and women is approximately 8% among persons aged 25 to 74 years. The highest prevalence (10%) is among persons aged 45 to 64 years. Rates are higher for whites than for blacks and other racial groups.

It has been estimated that 85% of all neck injuries presenting to primary-care providers result from automobile accidents. The National Safety Council estimates that 20% of all automobile accidents are rear-end impacts that can cause *whiplash*—an acceleration–deceleration injury related to cervical hyperextension, most commonly caused by a rear-end motor vehicle collision (MVC) occurring when the driver of a stationary car is struck from behind by another vehicle. The driver is usually relaxed and unaware of the impending collision. The sudden acceleration of the struck vehicle pushes the back of the car seat against the driver's torso. This force pushes the driver's torso and shoulders forward while the head remains static but moves posteriorly, causing hyperextension of the neck. This injury is most common in Western societies and metropolitan areas, where there are more automobiles. Approximately one-third of people will develop neck pain within 24 hours of the injury. The natural history of hyperextension cervical muscle strain and spasm injuries is that 60% get better within the first year, 32% get better within the next year, and 8% have permanent problems.

The relationship between occupational factors and cervical pain is difficult to study because exposure to those factors is usually difficult to quantify. Workers may be exposed to multiple risk factors both on the job and at home. The majority of work-related cervical injuries are diagnosed as a sprain or strain, and certain occupations appear to have a predisposition to cervical symptoms. Workers who do repetitive tasks with their upper extremities and prolonged sitting with their head in a flexed position are at risk of developing mechanical neck pain; these include machine operators, carpenters, office workers, dentists, and keyboard operators.

Pathophysiology

Cervical sprain is a clinical condition describing a nonradiating discomfort or pain in the neck area associated with a concomitant loss of neck motion and stiffness. The major biomechanical function of the cervical spine is to support the skull and provide movement in flexion, extension, and rotation. The supporting structures of the cervical spine are relatively unprotected; thus, injury to the muscles and ligaments that provide these motions can easily occur. Specific abnormalities in cervical strain can almost never be identified, except in traumatic injury to a specific structure.

Trauma to the cervical muscles that results in a strain may occur from elongation of muscle fibers with subsequent edema related to rupture of muscle tissue and secondary hemorrhage. The response of the muscle to injury is contraction, with reflex recruitment of surrounding muscles for protection (splinting) of the injured muscle. The contracted state may also occur because of poor posture, increases in muscle tension, or environmental trauma.

A *spasm* is caused by increased muscle tone that may be demonstrated by rigidity or spasticity. When a muscle cannot relax, it cannot recover from contracting. Muscle relaxation allows for restoration of internal blood flow, removal of metabolic by-products, and the influx of nutrients. Chronically contracted muscles develop subsequent ischemia and pain.

Normal posture should be effortless and painless. Abnormal forward posture of the head results in chronic strain on the posterior structures of the neck. A variety of daily activities may result in chronic abnormal posture, such as the prolonged use of a computer with a screen below eye level, a faulty sitting position, or the use of bifocal glasses.

Muscle tension is controlled by the interaction of spindle organs, Golgi's tendon organs, and extrafusal nerve fibers. A balance exists between these structures to coordinate muscular length, rate of contraction, and tension and relaxation of opposing muscles. A coordinating system in the spinal cord and the cerebral cortex influences the set point of this balance.

Muscle tone control is a multifactorial process, and the balance can be easily upset. In addition, a variety of factors extraneous to the muscles affect muscle tension, including fatigue, pain, anger, emotional stress, anxiety, and depression. Environmental trauma may lead to an acceleration–deceleration mechanism of energy transfer to the neck. The impact may result in bony or soft tissue injuries. The sternocleidomastoid, scalene, and longus coli muscles may be mildly or severely stretched or, worse, torn. In an MVC, the neck is subject to forced flexion, extension, and lateral flexion, as well as shear forces parallel to the direction of impact.

Clinical Presentation

Subjective

Pain is the most common presenting symptom although the associated complaint of a headache, usually occipital, which may persist for months, is not unusual. The pain is usually located in the middle to lower part of the posterior neck. The area of pain may be limited, or it may cover a large area. The pain may radiate toward the shoulders but usually will not radiate down into the arm. The pain associated with a cervical strain is most often a dull, aching pain that is exacerbated by neck motion and alleviated by rest or immobilization. The pain may follow a significant trauma or may be spontaneous in onset; pain following trauma often persists longer than sprains of spontaneous onset. Nonradicular, nonfocal neck pain is most common and may be noted anywhere from the base of the skull to the cervicothoracic junction. Pain is often worse with motion and may be accompanied by paraspinal spasm and discomfort in the region of the trapezius muscle. Pain may be accompanied by fatigue, sleep disturbance, irritability, and difficulty concentrating. Work tolerance may be impaired.

Cervical pain from an MVC usually does not appear for about 12 to 14 hours after the collision. The driver is often unaware at first of having been injured but later begins to feel stiffness in the neck. The pain at the base of the neck increases and is made worse by head and neck movement. Pain patterns should be evaluated carefully to differentiate muscular pain from radicular symptoms that typically radiate down the upper extremities.

Objective

Physical exam shows decreased neck ROM with poor quality of movement. With typical cervical muscle strain or spasm, Spurling's sign (radicular pain reproduced when the examiner exerts downward pressure on the vertex while tilting the head toward the symptomatic side) is usually negative.

Frequently, there is tenderness to palpation over both the anterior and posterior structures of the cervical spine, specifically the paraspinous muscles, spinous processes, interspinous ligaments, or medial border of the scapula. Pain is often noted at the extremes of motion. The neurological exam is normal in uncomplicated cases. The intensity of pain is variable and the loss of cervical motion correlates with intensity of pain. The presence of true spasm (continuous muscle contraction) is rare. Active motion of the cervical spine against any type of resistance causes an increase in pain. The shoulder exam, as well as the remainder of the physical exam, is typically normal.

Diagnostic Reasoning

Diagnostic Tests

Any evidence of neurological deficit merits further diagnostic testing (such as EMG or nerve conduction studies) to determine the cause. By definition, hyperextension cervical injuries cause only soft tissue damage, but plain x-ray films of the cervical spine should be obtained in all instances. It is important to include radiographic studies so that unsuspected fractures or dislocations of the cervical spine, facet fractures, odontoid fractures, or spinous process fractures that might otherwise be missed in the neurologically intact patient can be identified or ruled out.

All seven cervical vertebrae must be seen. Anterior displacement of the pharyngeal air shadow indicates soft tissue swelling and possible disruption of the intervertebral disc or anterior longitudinal ligament and requires further evaluation. The width of the prevertebral soft tissue at the level of C3 should not exceed 7 mm in normal adults. The normal lordotic curve may be straightened or reversed with muscle spasm, but this limited finding is noted in approximately 10% of normal adults. Preexisting degenerative disease may be noted most frequently at C5 to C6 or C6 to C7 and is usually age related. In a patient with severe pain, the screening radiographs should be examined for signs of instability.

Differential Diagnosis

The diagnosis of cervical muscle strain is based on the history of localized neck pain and a compatible physical exam demonstrating localized pain, muscle spasm, and a normal neurological exam. Trauma to the cervical spine may result in major neural damage with paralysis; if the history reveals a significant trauma, a thorough evaluation with x-ray exam should be performed. Because of the significant consequences of potential damage to the spinal cord, referral to an orthopedic surgeon or neurosurgeon should be sought. Potential differential diagnoses include the following:

- Cervical disc herniation presents with associated radicular pain and neurological findings.
- Cervical spine tumor is accompanied by a history of night pain and weight loss.
- Cervical spine infection is accompanied by fever, sweats, and chills.
- Dislocation or subluxation of the spine would be evident on radiographs.
- Inflammatory conditions of the cervical spine (rheumatoid arthritis) would be accompanied by abnormal radiographs.
- Spinal fracture would also have abnormal radiographs.
- Malingering is accompanied by exaggerated symptomatology and evidence of secondary gain.

Management

Reassurance is a cornerstone of treatment in uncomplicated cases. The treatment of cervical muscle strain includes controlled physical activity and immobilization in a soft cervical collar, worn intermittently for 2 to 3 hours at a time for no more than 2 to 3 days. A decrease in activity allows the injured tissues to heal.

Nonnarcotic analgesics such as NSAIDs are helpful in making the patient more comfortable (see Drugs Commonly Prescribed 15.2). NSAIDs can be continued until symptoms have resolved. Long-term use of NSAIDs can lead to serious gastrointestinal disease, however, such as ulcers, gastritis, and hemorrhage. Thus, patients with gastrointestinal histories should use these drugs cautiously. Using the lowest possible effective dose can help to prevent this problem. It is particularly important to use caution in recommending doses for elderly patients who are more sensitive to the adverse effects of NSAIDs. This class of medicines affects renal and gastrointestinal prostaglandins and may cause fluid retention, edema, and increases in blood pressure; thus, patients should be monitored for weight gain. These problems may be very significant in elderly patients and in people with congestive heart failure.

Muscle relaxants may be helpful if palpable spasms are seen on physical examination, but the practitioner should use caution when prescribing them because they have a potential for addiction, and several studies have failed to show their efficacy beyond NSAIDs alone. Patients need to be aware that this class of drugs is for short-term use because the risk/benefit ratio for prolonged use of muscle relaxants is poorly established. Muscle relaxants cause drowsiness and dizziness, so patients need to avoid hazardous activities such as driving or operating machinery while using these medicines. Because these drugs are central nervous system (CNS) depressants, patients need to avoid taking them with alcohol or other CNS depressants to prevent additive effects. Dry mouth is another side effect of this anticholinergic class of drugs, so frequent mouth rinsing is recommended to prevent dental disease. Topical application of creams such as capsaicin may also help to relieve pain. Narcotic analgesics should be avoided if at all possible because very little research supports the use of narcotics in the treatment of soft tissue injuries.

Manipulation of the cervical spine is contraindicated in patients with osteoporosis, rheumatoid arthritis, carotid or vertebral atherosclerosis, or tumors. It is also contraindicated in the elderly, in patients with associated radiculopathy or myelopathy, and in those on anticoagulants.

Herbal preparations may also be used to treat the pain (see Complementary Therapies 15.1).

Neck pain and mobility are improved with physiotherapy. The goal of therapy is to maximize function of the cervical spine. Physical therapy modalities may take the form of cold (ice) initially or heat (warm bath) to help relieve pain and spasm. Activity should be encouraged as determined by the severity of the symptoms. Cervical traction may also be used to diminish pain and spasm if no improvement is seen with heat and medication. After 2 to 4 weeks of treatment with drugs and rest, if there is no significant improvement, a patient may benefit from an anesthetic injection, with or without the addition of corticosteroids. Administered only by experienced personnel, these injections can relieve pain and block reflex muscle spasms. Aerobic activity, such as walking, should be started as soon as possible. Once improvement is seen, a course of isometric exercises should begin. Encourage an early return to work and activities.

Follow-up and Referral

Usually the course of cervical muscle strain is one of progressive improvement with complete resolution of symptoms over several weeks. Recovery is usually complete without any lasting impairment; however, a small percentage of patients may continue to experience cervical spine pain despite treatment.

Complementary Therapies 15.1 Osteoarthritis and Musculoskeletal Problems

Acupuncture/Acupressure, Massage, and Bodywork Therapy

Acupuncture is used for treatment of osteoarthritis (OA) in Asia and is being used more frequently in other countries as a complementary modality for OA. Uncontrolled studies in which patients were treated with standard medical therapy and acupuncture have demonstrated significant improvement in functional status and pain relief. These findings have not been replicated in controlled studies using sham acupuncture; both groups in the controlled studies experienced marked improvement. Although further controlled studies on efficacy are needed, acupuncture can be used and is safe and well tolerated.

Acupressure is also used as an adjunct, as are various types of massage and bodywork therapy. Building on prior studies of spa therapy, a European randomized, controlled study used 3 weeks of spa therapy for older patients with OA of the lumbar spine, hip, or knee. Participants experienced significant improvement in function, decreased pain, and decreased use of analgesics and NSAIDs for 24 weeks after the final treatment. Tai-chi has also been studied as an intervention for OA.

Herbals may be used to treat the pain associated with cervical muscle sprain/strain and spasm. White willow is considered nature's aspirin and has been used in China since ancient times to relieve pain and inflammation. These herbs can be made into teas by using powder to brew. Care must be taken to follow directions regarding the amount needed and how often they are used, because renal and gastrointestinal side effects may occur. Massage may be especially helpful. Acupuncture or acupressure may also be considered as adjunctive therapy for patients with chronic cervical spine pain.

Continued

Complementary Therapies 15.1 Osteoarthritis and Musculoskeletal Problems—cont'd

The following table describes complementary therapies for different musculoskeletal problems:

Problem and Therapy	Indication	Adverse Reaction and Prescribing Consideration
Arthritis		
Turmeric	Used for anti-inflammatory and antioxidant properties	If allergic or hypersensitive to turmeric, curcumin, yellow food colorings, or plants belonging to the Zingiberaceae (ginger) family, do not use. Caution with a history of bleeding disorders, immune system deficiencies, liver disease, diabetes, hypoglycemia, or gallstones. Caution with blood thinners, such as warfarin and diabetes medications. Stop before surgery. May interfere with cancer chemotherapy agents.
Niacin (vitamin B_3; niacinamide)	Anti-inflammatory properties; decreases joint inflammation	Avoid with a history of liver disease or dysfunction, irregular heartbeats, heart disease, bleeding disorders, asthma, anxiety, panic attacks, thyroid disorders, stomach ulcers, gout, or diabetes.
S-adenosylmethionine (SAMe)	Pain reduction in arthritis; comparable to NSAIDs in efficacy in some studies	Avoid if allergic or hypersensitive to SAMe. Avoid with bipolar disorder. Use cautiously with diabetes, anxiety disorders, or during the third trimester of pregnancy. Avoid during the first trimester of pregnancy or if breastfeeding.
Selenium	Controls free radicals that may destroy cartilage	Avoid with history of nonmelanoma skin cancer; poor evidence of benefit.
Chondroitin	Pain reduction, increased function, and decreased use of anti-inflammatory drugs if used over a 6- to 24-month period	Avoid with prostate cancer or an increased risk of prostate cancer. Avoid if pregnant or breastfeeding. Use cautiously if allergic or hypersensitive to chondroitin sulfate products or with shellfish allergy. Use cautiously with bleeding disorders or if taking blood thinners such as warfarin.
Glucosamine	Pain relief in mild to moderate knee OA. Conflicting results in studies, one specific brand has been used	Avoid if allergic to shellfish or iodine; caution if diabetes or history of bleeding. Avoid in pregnancy.
Green tea	Reduce inflammation and slow cartilage breakdown	Contains caffeine.
Methylsulfonylmethane (MSM)	May inhibit transmission of pain impulses and has anti-inflammatory properties	Used alone or in combination with glucosamine for OA. The combination may provide pain relief and decrease inflammation; further studies needed.
Carpal Tunnel Syndrome		
Turmeric	See previous reference	
Muscle Cramps		
Magnesium	Necessary for muscle contraction and relaxation	
Musculoskeletal Pain		
White willow bark (Salix alba)	Has analgesic and anti-inflammatory properties; salicin is the active ingredient that the body converts to salicylic acid	Similar adverse effects as aspirin but not as pronounced; GI bleeding, abdominal pain, potential (rare) interference with platelet aggregation.
SAMe	See above.	
Sprains/Strains		
Arnica	Pain relief and healing; topical gel, cream, ointment	Do not use orally; toxic.
Glucosamine	Strengthen joints and accelerate healing	See above; further research needed.

If symptoms persist longer than 4 weeks after injury, further evaluation with CT scans or MRI is indicated. If these tests are normal, the patient can be assured that no compression of neural structures is present and can be strongly encouraged to increase activity. If imaging findings are abnormal, a referral to a neurologist, neurosurgeon, or orthopedic surgeon should be made for further evaluation.

If neck pain and restricted ROM are still present after patients have received analgesics and physical therapy and the findings on CT scan or MRI are normal, referrals for psychiatric support or vocational rehabilitation may be indicated to assist in recovery.

Patient Education

Knowing how a healthy neck works can help patients understand their cervical spine problems and how to care for them. It is important for patients to understand the concepts behind their treatments in order to receive the greatest benefits. They must also learn appropriate body mechanics to help protect the cervical spine from further damage by preventing its misuse or overuse. Stress from home or work can also lead to muscle tension and other symptoms, so the patient may need professional guidance in relieving or controlling these stressors.

Cervical Spondylosis

Cervical spondylosis (also known as *degenerative arthritis in the cervical vertebrae*) is a common cause of neck pain in older patients. Degenerative changes on radiography are found in 40% of the population at age 50 and in 70% of the population at age 65. These changes are usually asymptomatic, meaning that a finding on x-ray study does not necessarily account for the patient's pain. Progression of the osteoarthritis may result in subluxation, osteophyte formation, and disc protrusion.

Common symptoms are recurring neck stiffness and mild aching discomfort. There is pain and limited ROM with lateral rotation and lateral flexion of the neck toward the affected side. Paresthesias may also occur.

Radiographs will determine if subluxation and other osteoarthritic components are present, but an MRI will be necessary to identify disc herniation and soft tissue or spinal cord abnormalities.

Hallmarks of treatment are the use of NSAIDs, a conditioning program, and reeducation to result in better care of the neck.

When the secondary bony changes of cervical spondylosis encroach on the spinal cord, a pathological process called *myelopathy* develops. If this process involves both the nerve roots and spinal cord, it is called *myeloradiculopathy.* Regardless of its etiology, radiculopathy causes shoulder and/or arm pain, as well as numbness and/or tingling ("pins and needles"). Fewer than 5% of patients with cervical spondylosis develop myelopathy, and they are usually between ages 40 and 60. Acute myelopathy is most often the result of central soft-disc herniation that produces a high-grade block, which may be visualized on myelogram. This herniation may require surgical decompression and is a medical emergency. If pain is unremitting and cervical nerve-root compression is present, a neurosurgical consultation should be sought immediately.

MYOFASCIAL PAIN

Regional musculoskeletal pain or tender muscles are often the result of minor muscle tears following injury and are referred to as *myofascial pain,* meaning inflammation of a muscle and its fascia. Although the cause may not be readily identifiable, the pain is a result of local inflammation and produces a tender "trigger point" when a particular muscle group is palpated. The pain may radiate to surrounding structures. Even though this is a common cause of nonarticular rheumatic pain, it is often misdiagnosed. The trigger points are not visualized on routine imaging studies and cannot be objectively substantiated. There are commonalities between this disorder and fibromyalgia. (See Chapter 17.)

Treatment includes identifying and eliminating aggravating factors, injecting the trigger points with 1% procaine, and passive stretching of the muscle involved immediately after the local anesthetic has taken effect. Some patients achieve relief with a pharmacological regimen that includes NSAIDs and antidepressants, particularly amitriptyline, which appears to reduce pain and improve sleep. Some sources recommend sedatives such as clonazepam (Klonopin) to help relax muscles affected by myofascial pain syndrome. Sedatives must be used carefully because they can cause sleepiness and can be habit forming.

SHOULDER PAIN

Pain and dysfunction localizing in and around the shoulder girdle are common presenting musculoskeletal complaints. Shoulder pain affects patients of various ages and activity levels. Although shoulder pain can be referred from the neck, chest, or diaphragmatic region, it is most commonly caused by a local process. The shoulder joint includes three large bones (clavicle, scapula, and humerus) and four joints (sternoclavicular, acromioclavicular, glenohumeral, and thoracoscapular). The shoulder is a ball-and-socket joint, like the hip, but the two joints differ significantly in that the hip is a weight-bearing joint and the shoulder is a suspension joint, maximizing mobility. The two chief presenting complaints are usually related to pain and/or instability. Symptoms of decreased motion, power, or function can accompany complaints of pain or instability, but they are rarely the chief complaint.

Common conditions affecting the shoulder include acute injuries (less than 2 weeks' duration; common in younger patients), which include fractures, dislocations,

and acute tendon rupture; chronic or repetitive injuries (impingement syndromes, most rotator cuff tears and biceps tendon ruptures); and degenerative, inflammatory, or idiopathic conditions (glenohumeral and acromioclavicular arthritis, frozen shoulder). Although there have been many technological advances in diagnostic aids, most shoulder disorders can be diagnosed with careful history, clinical exam, and plain radiographs.

In the history, inquire about any precipitating injury and onset of pain. Obtain specific information about the location of the pain and the factors that aggravate or alleviate it. The relationship of the pain to the time of day, to active or passive movement, and to body position is significant. The patient's age, occupation, activities, medical history, and social factors will also be important in making a diagnosis. Patients with acute symptoms (less than 2 weeks' duration) usually have an injury, such as a fracture, dislocation, or rotator cuff tear. For patients with chronic shoulder pain, evaluate the activities related to the onset of symptoms.

Instability, another common complaint, can be classified by the frequency of symptomatic episodes, as well as the direction and degree of instability. Acute injuries may be a first-time dislocation or a recurrent episode. The instability episode may be partial (subluxation) with spontaneous reduction or may be complete (dislocation). The instability may be anterior, posterior, inferior, or multidirectional. Most traumatic dislocations are anterior. Multidirectional instability should be considered in patients who present with recurrent episodes of subluxations or dislocations and no history of significant trauma.

Determine if there is a discrepancy between active and passive motion. Disuse can cause some passive ROM loss; equal losses of active and passive ROM can be secondary to soft tissue contracture, as in frozen shoulder, or the result of joint incongruity from trauma or arthritis.

Muscle strength should be assessed and compared with the opposite shoulder. Pain can affect the accuracy of muscle testing. Tears of rotator cuffs and neurological injury can produce weakness. Assess functional status, although this may be affected by motivation and ability to adapt to impairment. The level of functional disability will depend on the normal intensity of activities that the patient performs.

A concise differential diagnosis is often obtained by evaluating the patient's chief complaint in the context of its chronicity and the patient's age. Patients younger than 30 years of age, for example, commonly present with traumatic injuries or instability such as glenohumeral dislocations and acromioclavicular (AC) joint separation. Impingement syndromes and rotator cuff tears are more commonly seen in middle-aged patients. These must be distinguished from frozen shoulder, which produces a global loss of passive and active ROM. Glenohumeral dislocations are much less common and must be treated with a high index of suspicion for a concomitant rotator cuff tear (50% of patients older than 40 years of age will have an acute tear). Older patients (over 55) are more likely to have rotator cuff tears or degenerative arthritis. Fractures and dislocations related to falls also occur in this age group.

The physical exam of the shoulder should begin with inspection of the shoulder for swelling, color, edema, and symmetry, followed by palpation for tender areas, crepitus, temperature, and deformity. The shoulder should be inspected anteriorly and posteriorly, particularly to observe scapular winging. Both active and passive ROM movements should be tested while comparing the painful shoulder to the unaffected side.

The most common ROM movements tested include the following:

- The Apley scratch test: This measures abduction and external rotation by having the patient reach behind the head and touch the superior aspect of the opposite scapula. Conversely, internal rotation and adduction of the shoulder are tested by having the patient reach behind the back and touch the inferior aspect of the opposite scapula. External rotation should be measured with the patient's arms at the side and elbows flexed to 90 degrees.
- Internal/external in flexion: With the patient's elbow flexed at the side, thumb pointing up, internally and externally rotate the elbow, taking care to keep the elbow against the body.
- Internal/external in abduction: Abduct the patient's shoulder to 90 degrees, keeping the elbow flexed at 90 degrees, and then have the patient lower his or her forearm from the horizontal plane, then raise the forearm, keeping the upper arm parallel to the ground.

Pain with abduction from 45 to 120 degrees (painful arc) indicates supraspinatus tendinitis or subacromial bursitis, which are early rotator cuff injuries. Muscle and bursae involvement produces pain only on active motion, whereas pain with passive ROM may involve tendons, bursae, or restricted joint movement and is generally indicative of more pathology. Resistive muscle testing, reflex testing, and an assessment of the neurosensory and neurovascular status complete the exam.

Specific findings can include inability to shrug the shoulders, which indicates trapezius muscle weakness, and weakness of forward flexion, which is associated with rotator cuff impingement. Because shoulder pain can be referred from other areas, the patient should be evaluated for cardiac, pulmonary, and abdominal causes, as well as neurological disease or injury. Pain caused by bony malignancy is usually gnawing, constant, and unrelated to movement. Malignant tumor is usually evident by a lytic lesion in the bone on x-ray film.

Plain x-ray films, including the anteroposterior (AP) projection and an axillary lateral view, are sufficient to

reveal most fractures and dislocations. Additional views may include a transthoracic lateral, which images the glenohumeral joint at a 45-degree posterior oblique, or a 60-degree anterior oblique (Y view). A new view—the apical oblique—is suggested to reveal shoulder instability. This view is simple to obtain and painless for the patient. In addition to the standard x-ray studies, other diagnostic tests used in diagnosing shoulder pain include MRI, arthrography, and (if nerve involvement is suspected) EMG. Although the standard x-ray studies will often be normal, they should be done to rule out structural abnormalities, especially if there is history of trauma or if the problem is persistent. C-spine films and chest films may also be necessary if involvement in those areas is suspected. Laboratory studies should be done in accordance with the patient's history.

Differential Diagnosis

Shoulder disorders may be separated into acute versus chronic and traumatic versus nontraumatic. Problems in young adults are frequently the result of instability and traumatic injuries and tendinitis. The mature adult usually suffers with degenerative conditions of the tendons and joints.

Adhesive Capsulitis

Often referred to as a "frozen shoulder," adhesive capsulitis is defined as idiopathic loss of both active and passive ROM, with no clear predisposition based on gender, arm dominance, or occupation. Patients aged 40 to 60 years are more likely to be affected; diabetes mellitus (especially type 1) is the most common risk factor. Patients with diabetes tend to be refractory to treatment, and 40% to 50% will have bilateral involvement. Other underlying conditions related to frozen shoulder include hypothyroidism, Dupuytren disease, cervical disc herniation, Parkinson's disease, stroke, and tumors. In a short period of time, immobility will result in a tight, painful shoulder joint that has limited active ROM (a "freezing" phase of pain) and then typically progresses to a "thawing" phase of decreasing discomfort associated with a steady improvement in function. This process may take anywhere from 6 months to 2 years. Although adhesive capsulitis may result from any condition that produces pain and immobility, in older patients and individuals without predisposing factors, the possibility of underlying organic or neoplastic disease should be considered.

Physical exam typically reveals a 50% or more reduction in both active and passive ROM. Pain and tenderness are common with motion and at the deltoid insertion. Diffuse tenderness about the shoulder may also be present. AP and axillary radiographs of the shoulder are indicated to ensure that smooth, concentric joint surfaces with an intact cartilage space are present and to rule out other pathology such as osteophytes, loose bodies, calcium deposits, or tumors. Other studies, such as arthrography, CT, or MRI, are rarely indicated if radiographs are normal.

Adhesive capsulitis is differentiated from chronic posterior shoulder dislocation, tumor, and osteoarthritis (OA) on radiograph. Post-traumatic shoulder stiffness is, obviously, related to a history of trauma. Rotator cuff tear is differentiated because of the presence of normal passive ROM.

Treatment consists of the application of moist heat, use of analgesics (NSAIDs and nonnarcotic analgesics), followed by a gentle stretching program, performed at home three to four times a day (should not cause significant pain). Advise the patient of lengthy recovery time and potential for chronic stiffness and residual pain.

Rotator Cuff Syndrome

Rotator cuff syndrome may include impingement problems, calcific tendinitis, and subacromial bursitis (shoulder bursitis). The term *impingement syndrome* refers to pathological changes that result when the subacromial bursa and/or rotator cuff become inflamed as a result of compression under the acromion or "roof" of the shoulder joint (rotator cuff tendinitis). It is the leading cause of shoulder pain, ranging from bursitis to rotator cuff tendinitis and, eventually, degenerative tears of the rotator cuff. In addition, the biceps tendon may be impinged (in bicipital tendinitis).

The rotator cuff covers the anterior, superior, and posterior aspects of the humoral head and is formed by the coming together of four muscles. These muscles assist in the elevation of the arm. Inflammation of the subacromial bursa and underlying rotator cuff tendons is a common cause of shoulder pain in middle-aged patients. Rotator cuff pathology presents a continuum from edema and hemorrhage to chronic inflammation and fibrosis to microscopic tendon fiber failure progressing to full-thickness rotator cuff tears. The etiology is multifactorial. A loss of microvascular blood supply to the tendon and repeated mechanical insults as the tendon passes under the coracoacromial arch combine to cause damage over time.

The history is usually one of gradual onset of anterior and lateral shoulder pain exacerbated by overhead activity. Night pain and difficulty sleeping on the affected side are also common. Atrophy of the muscles about the top and back of the shoulder may be apparent if the patient has had problems over a period of several months, although this may also indicate a full-blown rotator cuff tear.

On physical exam, palpation over the greater tuberosity and subacromial bursa commonly elicits tenderness and crepitus with shoulder motion. Pain will be elicited by having the patient slowly lower the abducted arm against downward resistance. Neer and Hawkins signs are generally positive. Impingement testing involves locally anesthetizing the shoulder. If the patient is then stronger and without pain after subacromial injection, pain inhibition from inflammation and fibrosis is likely

rather than full-blown tear. AP and axillary radiographs are usually negative; narrowing of the space between the head of the humerus and the undersurface of the acromion suggests a long-standing rotator cuff tear.

Frozen shoulder is ruled out if active and passive ROM loss is not present; a rotator cuff tear will not improve with subacromial injection of local anesthetic; glenohumeral arthritis is evident on radiograph and there is pain on motion; acromioclavicular (AC) arthritis presents with tenderness over the AC joint.

Treatment includes resting from the offending activity and NSAIDs. The patient should begin a stretching program with emphasis on posterior capsule stretching. If home therapy of three to four times a day over a period of 6 weeks does not result in improvement, a subacromial corticosteroid injection can be administered, followed by continued stretching. Steroid injections should not be repeated if the previous injection does not produce significant and sustained (more than 2 months) relief. Significant rotator cuff weakness or failure to improve after 2 to 3 months of rehabilitation (with or without subacromial steroid injection) is an indication for further evaluation and operative consideration.

Calcific Tendinitis

Calcific tendinitis is a degenerative process accompanied by a local deposit of calcium that develops in the rotator cuff. The calcified material often creates inflammatory changes in the subdeltoid bursa and is frequently asymptomatic until an acute event or overuse exacerbates the condition. The symptom of calcific tendinitis is severe, localized pain that occurs with any movement of the shoulder. With the arm in a dependent position, the pain is absent or minimal. The shoulder is acutely tender and can be warm to the touch or swollen. X-ray films usually demonstrate the deposit. A transaxillary view is necessary if the deposit is anterior or posterior to the joint in the subscapularis muscle.

Minor or mild cases of calcific tendinitis rarely need invasive treatment. Anti-inflammatory medications, ultrasound, physical therapy, and rest are usually effective in ameliorating the pain. Some deposits appear soft, fluffy, or irregular on x-ray examination. Aspiration to remove some of the material while concurrently injecting an anesthetic with corticosteroid preparation can provide immediate relief. In more severe cases or those that fail to respond to conservative treatment, consider injection of corticosteroid.

Rotator Cuff Tear

Rotator cuff tear may occur secondary to trauma or from degenerative, calcific changes, chronic mechanical impingement, and altered blood supply to the tendons over time. The rotator cuff muscles insert into the tuberosities of the humerus and tightly hold the ball-and-socket joint of the shoulder together. Rotator cuff injuries are considered to be more serious than other soft tissue injuries of the shoulder. Most full-thickness rotator cuff tears occur spontaneously in patients older than 50 years of age, presumably as a result of age-related changes in vascularity and tissue degeneration. The supraspinatus tendon is most often affected. Older people with rotator cuff tear may have only mild, disabling symptoms, or may even be asymptomatic. This injury can occur in individuals younger than 40 years of age, usually as a result of aggressive physical injury and repeated trauma from contact sports (e.g., football).

The patient will usually report a lateral deltoid pain, and weakness may be present. There may be a history of reaching overhead and feeling "something give" in the shoulder and then noting that the ipsilateral arm drops to the side. Thereafter it is difficult and very painful to abduct the arm. The pain is often worse at night, and the patient may report difficulty sleeping. To reach behind to scratch his or her back causes extreme pain.

The "empty can" test also isolates the mechanism of the rotator cuff. The patient's affected arm is abducted to 90 degrees, in neutral rotation (the thumb is pointed toward the ground). The patient is instructed to turn his or her arm and hand forward as if emptying a can. The examiner places his or her fingers on the outstretched arm near the hand and applies pressure, seeing if the patient can maintain position against resistance.

A suspected rotator cuff tear can be confirmed by performing the "drop arm" test. The examiner abducts the patient's shoulder to 90 degrees and instructs the patient to lower his or her arm slowly. If the arm drops to the side rapidly, the test is considered positive. Most tears are relatively small, however, and the patient is often able to maintain some control. It is clinically very difficult to differentiate tendinitis from a tear. The back of the shoulder may appear sunken, indicating atrophy of the supraspinatus and infraspinatus muscles following a long-standing cuff tear.

Soft tissue injuries do not show up on plain x-rays; therefore, findings are usually reported as within normal limits even though the films may demonstrate calcification from previous or chronic injuries. There may be spurring of the acromion process or calcium deposits in the soft tissue, as well as bony deformities from previous dislocations. Lytic lesions indicating metastatic disease can also show up on radiography. More aggressive diagnostic testing such as MRI, ultrasonography, or arthrography may be indicated in patients with a history of acute trauma or if there is no response to conservative treatment.

Nonoperative treatment includes icing the shoulder (most commonly in cases of acute injury), NSAIDs, physical therapy with stretching and strengthening exercises, and avoiding overhead activities. Ice the entire shoulder for 15 to 20 minutes twice daily. Corticosteroid injections should be used judiciously. Over time, steroid injections further weaken the tendon and can actually accelerate propagation of the rotator cuff tear. Patients

should never receive more than three subacromial injections. Patients with significant failure and failed rehabilitation should be considered candidates for surgery. The exception to this rule is the patient younger than age 60 who has an acute traumatic cuff tear, in whom recovery is best accomplished within 6 weeks of the injury.

Degenerative Arthritis

Arthritis of the glenohumeral or AC joints can occur, but it generally is not isolated to the shoulders unless there is a history of old injury such as a dislocation or fracture. The common complaint is diffuse or deep-seated pain, aggravated by any strenuous activity. As the disease progresses any movement can cause the shoulder pain, and rest and night pain become prominent complaints. ROM may become progressively limited. As a result, activities of daily living, such as dressing, combing hair, and reaching overhead, are increasingly difficult. OA typically involves a single joint in an older patient, and generally there is no apparent relationship between the development of OA in the shoulder and the patient's previous activity level. Physical exam may reveal atrophy of the shoulder muscles; palpation elicits tenderness over the front and back of the shoulder. Crepitus is commonly present with rotation or flexion; ROM is usually decreased.

AP and lateral radiographs are indicated. The axillary view will demonstrate joint space narrowing that is indicative of cartilage destruction; there may be flattening of the humeral head, an inferior osteophyte, and posterior erosion of the glenoid. Treatment includes NSAIDs and application of heat and/or ice to relieve symptoms, and gentle stretching exercises to preserve motion. A trial of glucosamine and/or chondroitin sulfate can be considered, although their efficacy needs further evaluation. Activity modifications are beneficial in reducing pain. For advanced arthritis, total shoulder replacement may offer a very satisfactory solution.

Shoulder Dislocations

Shoulder dislocations are a common injury, occurring most frequently in younger adults. The mechanism of injury may be direct or indirect, usually with the arm in extension. There is often an obvious fullness of the anterior capsule on exam and a positive sulcus sign (space under the acromion). In an acute anterior dislocation, pain is severe and ROM is limited. The patient will usually hold the arm slightly abducted and externally rotated. There may be associated neurovascular and/or neurosensory trauma; therefore, the clinician should check the distal pulses and sensation, especially over the deltoid. Posterior dislocations are less common (2%) and less apparent. Deformity is minimal, but any motion of the extremity will cause severe pain. Recurrent dislocations can occur and do not require as severe a force as the initial injury. Reduction is usually the treatment of choice; occasionally, surgery is necessary.

Shoulder Fractures

Fractures of the humerus, clavicle, or acromion are common. Fracture of the clavicle typically occurs from a moderate fall (such as from a bicycle or down stairs) or from blows during a contact sport. Patients complain of sharp shoulder pain and are reluctant to move the upper extremity. It is important to verify that no neck pain or upper extremity paresthesias are present. These fractures usually best heal spontaneously after proper immobilization; they rarely require surgery.

Shoulder Sprains

Acromioclavicular joint (ACJ) sprain is classified as first, second, or third degree, depending on severity. These shoulder sprains often occur in young men, and are typically associated with a fall while the arm was adducted, causing trauma to the ACJ, although the injury may occur as a result of indirect trauma also. The patient will present with pain, especially on adduction or abduction past 90 degrees, point tenderness over the ACJ, swelling, and possible deformity. First-degree sprains involve a partial tear of the ACJ, whereas second-degree sprains involve a complete tear of the AC ligament and a partial disruption of the coracoclavicular ligament. In a third-degree ACJ sprain, both the AC and coracoclavicular ligaments are torn, and there is obvious displacement of the distal clavicle. X-ray confirmation can be sought. Treatment includes ice, NSAIDs, and a sling or figure-8 splint for 2 to 4 weeks, with daily gentle assisted ROM exercises. Patients with third-degree sprains should be referred to an orthopedic specialist.

Shoulder–Hand Syndrome

Shoulder–hand syndrome, also referred to as *reflex sympathetic dystrophy,* occurs as a complication of minor or major trauma, hemiplegia, myocardial infarction, pneumonia, or peripheral neuropathy. It is more common in elderly patients and is manifested by pain and stiffness in the affected hand. The pain is described as burning and is worsened by light touch and improved with application of cool moisture. The hand or shoulder is often mildly swollen and discolored, and abnormal diaphoresis of the affected areas may be noted. Treatment is early active and passive mobilization and use of NSAIDs. If necessary, a brief course of corticosteroids can be considered.

A summary of common differential diagnoses for shoulder pain is provided in Differential Diagnosis 15.3.

ARM (ELBOW, WRIST, AND HAND) PAIN

Pain in the upper extremity can be caused by problems in the elbow, wrist, or hand. These can be caused by trauma, nerve impairment, joint, muscle, bursa, or

Differential Diagnosis 15.3 Shoulder Pain

Musculoskeletal problems	Adhesive capsulitis (frozen shoulder) Rotator cuff syndrome Impingement Calcific tendinitis Subacromial bursitis Degenerative arthritis: glenohumeral, acromioclavicular
Trauma	Fractures: Humerus, clavicle, acromion Acromioclavicular joint sprains Rotator cuff tear Dislocation: Glenohumeral Nerve injuries: Compression
Neurovascular problems	Reflex sympathetic dystrophy (shoulder–hand syndrome) Thoracic outlet syndrome Cervical root compression Brachial plexus injury
Systemic disease	Inflammatory disease Cancer

tendon disruption or inflammation. Infection is always a possibility, and gout (which can sometimes affect the elbow) is another consideration.

ELBOW PROBLEMS

Usually, elbow complaints in the adult occur as a result of overuse. The most commonly seen complaint is lateral epicondylitis of the humerus. Although this condition is often called "tennis elbow," it occurs frequently in patients who do not play tennis. It is associated with repeated extension of the wrist and pronation and supination of the forearm, particularly against resistance, which occurs in movements such as opening jars, hammering, and turning doorknobs. The common complaint is pain in the elbow that radiates into the forearm. There is pain and weakness with gripping objects ("coffee cup" sign). Tenderness is present over the lateral epicondyle, and wrist extension against resistance produces the pain. Rest, ice, NSAIDs, and physical therapy are generally effective; corticosteroid injections and wrist splinting may be considered in some cases and have been shown to be effective for short-term relief of lateral epicondylitis. Physical therapy is more efficacious than steroid injection if symptoms persist longer than 6 weeks (Stephens et al, 2008).

Medial epicondylitis is less common; this condition is often referred to as "golfer's elbow." It is a result of overuse or strain of the muscle group arising from the medial epicondyle, which is used in wrist flexion. Tenderness and pain is over the medial epicondyle and is exacerbated by wrist flexion. Diagnosis is by clinical exam only, and treatment is the same as for lateral epicondylitis.

Bursitis of the olecranon is often the cause of pain and swelling in the posterior aspect of the elbow. This may occur with forced extension of the elbow joint. Range of motion is generally normal, but caution is needed to rule out a septic bursitis. Monitor for fever, redness, heat, and warmth at the site. Synovial fluid aspiration can provide evidence of infection. Radiography is indicated to exclude bone infection.

Treatment may include ice for 15 to 20 minutes several times a day and rest. Assessment of position of computer keyboards or other workstation corrections may be helpful. NSAIDs are useful, and splinting with an elbow strap may ease pain by exerting counterpressure on the soft tissue below the lateral epicondyle, or short-term use of a wrist splint may reduce pain from lateral epicondylitis. An anterior elbow splint may be useful for medial epicondylitis management. Corticosteroid injection may be necessary. Refer to physical and/or occupational therapy. These measures are effective in 80% of cases. If the patient is still symptomatic, referral to a specialist is warranted. Surgical procedures are a last resort.

WRIST PROBLEMS

Wrist and hand problems may be assessed using Allen's test, Phalen's maneuver, the percussion test for Tinel's sign, and/or Finkelstein's test (see Advanced Assessment 15.5).

Wrist Injuries

Wrist injuries are common after falling on an outstretched hand. Patients present after trauma with pain and swelling in the distal forearm or wrist. Numbness may be present if the medial nerve is affected. The mechanism of injury will often provide important clues to the diagnosis. The exam begins with gentle palpation to locate the area of point tenderness and includes a thorough neurovascular assessment. A radiograph of the wrist (including an oblique view) will be necessary to rule out fracture. Common fractures are the Colles' fracture of the distal radius and the navicular (scaphoid) fracture of the anatomical snuffbox. It is not unusual to have a navicular fracture missed on radiography, so an orthopedic referral should be provided when the presenting complaint is pain and trauma to the soft tissue area of the anatomical snuffbox.

A common wrist ligamental injury is an ulnar collateral ligament tear at the base of the thumb. Often seen with ski-pole injury, this condition is related to repetitive gripping, and surgery is necessary to repair a tear in this area. Therefore, when the presenting complaint is pain and trauma to the proximal thumb, an orthopedic referral for stress testing is appropriate even if the x-ray result is negative.

Advanced Assessment 15.5 Tests for Wrist and Hand Problems

Test	Comments
Allen's test	*Purpose:* Assesses patency of radial and ulnar arteries and the arterial arch. *Procedure:* Compress the radial artery at the wrist. Have patient rapidly open and close his or her hand several times. Then have the patient open the hand. (Hand should be pale or white.) Release pressure from the artery. The hand should flush, indicating patency.
Phalen's test	*Purpose:* Assesses for median nerve compression. *Procedure:* Have the patient maintain forced flexion of the wrist for 1 minute or more, with the dorsal surface of each hand pressed together. If the patient complains of numbness and paresthesias in fingers, the test is considered positive.
Tinel's sign	*Purpose:* Assesses for compression neuropathy. *Procedure:* Percuss the median nerve at the wrist. If the patient complains of tingling in the digits (positive Tinel's sign), compression at the site of percussion is likely.
Finkelstein's test	*Purpose:* Assesses for de Quervain's disease. *Procedure:* Have patient touch thumb into palm and make a fist. Test is positive if moving the wrist into ulnar deviation causes pain.

Ganglion

A *ganglion* is a cyst that develops on or in a tendon sheath. It is filled with a thick, gel-like material that leaks from the joint into the weakened tendon sheath and forms a cyst sac. A ganglionic cyst is usually caused by frequent strains and contusions, resulting in joint inflammation. The most common sites are on the dorsum of the wrist over the radiocarpal joint or on the volar surface of the wrist near the flexor carpi radialis tendon. The ganglion can be asymptomatic, or it may be associated with dull aching and weakness. It can be distinguished from a tumor by its soft consistency and transillumination. Treatment includes aspiration or surgical removal, although a conservative approach is appropriate because spontaneous disappearance may occur.

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is the most common entrapment neuropathy, affecting approximately 3% to 6% of adults. Symptoms are related to compression of the median nerve, which results in pain, paresthesias, numbness and tingling, and associated weakness in the hand and wrist that radiate to the thumb, index finger, middle finger, and radial half of the ring finger. (See full discussion of CTS later in this chapter.)

Hand Problems

When assessing and/or treating a patient with an injured hand, have the patient remove all rings as soon as possible. Inflammation secondary to most injuries will precipitate edema, making removal of rings difficult. A tight-fitting ring may cause arterial compression and ischemia if not removed. Usually soap or lubricant jelly will be sufficient to remove the ring. If this does not work, several other techniques may be used. (See Therapeutic Procedure 15.2.)

Osteoarthritis and Rheumatoid Arthritis

Although both osteoarthritis and rheumatoid arthritis affect the phalanges, the different types of arthritis occur in different locations. *Rheumatoid arthritis* usually presents as bilateral pain, swelling, and stiffness of the metacarpophalangeal and proximal interphalangeal (PIP) joints with characteristic deformities. Generally, other systemic complaints will occur, and joints other than just those in the hand will be affected as well. (See Chapter 17 for a full discussion of rheumatoid arthritis.) *Osteoarthritis* affects the distal interphalangeal joints (Heberden's nodes) and PIP joints (Bouchard's nodes) and presents with swelling, stiffness, pain, and deformity.

LOW BACK PAIN

Low back pain (LBP), also referred to as low back sprain or lumbar sprain, is, strictly speaking, an injury to the paravertebral spinal muscles. The term is also used to describe ligamentous injuries to the facet joints or anulus fibrosus. The disc may not herniate into the spinal canal, but substances can leak from the nucleus pulposus that induce inflammation and cause irritation of the lumbosacral nerve roots. Owing to the deep location of the lumbar soft tissues, localizing an injury to a specific structure is very difficult if not impossible. Whether muscle or ligamentous structures are involved, the treatment is similar.

LBP is also defined as activity intolerance because of lower back or back-related leg symptoms of less than 3 months' duration. LBP occurs in almost 70% of adults at some point in their lives. About 90% of patients with

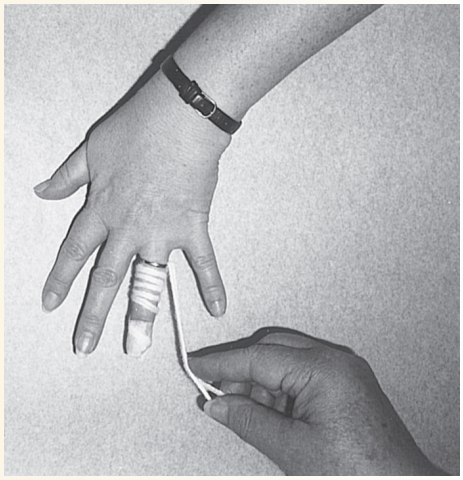
Therapeutic Procedure 15.2 Removing Rings

Equipment: 2–0 or 3–0 nylon suture (string technique), rubber tourniquet (tourniquet technique), lubricant (tourniquet technique), mechanical ring cutter (ring cutter technique)

String Technique

1. In a distal direction, wrap 2–0 or 3–0 nylon suture tightly around the finger just distal to the ring.

2. Slip the proximal end of the string under the ring.
3. Pull the proximal end of the suture over the ring and firmly retract it distally over the axis of the finger. As each coil of the suture unwinds, it pulls the ring slightly over the coiled suture until it is free.



Tourniquet Technique

1. Carefully wrap the finger with a rubber tourniquet, starting at the fingertip and working up to the edge of the ring.
2. Have the patient lie supine on the exam table, with his or her arm pointed straight upward at the ceiling for about 5 minutes.
3. As soon as the patient lowers his arm, remove the tourniquet, apply copious amounts of lubricant, and slide the ring off.

Mechanical Ring Cutter Technique

1. Advise patient that the ring will be cut and obtain his or her consent.

2. Follow the manufacturer's directions.

Postprocedure: Give ring to patient, or secure as per institution policy and document.

acute LBP will spontaneously recover activity tolerance within 1 month. However, back pain associated with a neurological deficit, decreased or absent pulses, or bowel and bladder dysfunction is potentially life threatening and warrants immediate referral. Acute low back pain (ALBP) is pain that persists for less than 3 to 6 weeks. Chronic low back pain (CLBP) is defined as pain lasting longer than 3 months; symptoms are typically recurrent and episodic, but may be unremitting.

Epidemiology and Causes

LBP occurs in almost 70% of adults at some point in their lives. LBP is one of the most frequent reasons that patients visit primary-care providers and is the most common reason for loss of work time and disability in adults younger than 45 years. Most symptoms are of limited duration, with 85% of patients demonstrating significant improvement and returning to work within the month. The 4% of patients whose symptoms persist longer than 6 months generate 85% to 90% of the costs to society for treating LBP. Repetitive episodes, however, are common. Back pain is second only to headache as the reason for a complaint of pain. At any given time, 31 million Americans will be experiencing some sort of ALBP. ALBP occurs most frequently in adults between their 20s and 40s; CLBP typically is seen between the third and sixth decades of life, or even older for women.

The overall incidence of LBP is equal in men and women, but women report more LBP after age 60, most likely due to osteoporosis; these women are at risk for vertebral compression fracture. In addition, a woman's likelihood of experiencing LBP is increased after two or more pregnancies. Approximately 2% of patients with ALBP have lumbar radiculopathy, or "sciatica" and/or disc herniation (see next section on herniated disc).

There are two categories of risk factors that influence LBP: The first group of risk factors is occupational, and the second is patient related. Occupations that require hard labor and heavy exertion have been associated with increased risk of LBP. Lifting, pulling and pushing, twisting, slipping, sitting for an extended period, and exposure to prolonged vibration (such as driving or riding in a motor vehicle for long periods of time, as truck drivers do) have been attributed to the development of LBP. In addition, patients who view their occupations as boring, repetitious, or dissatisfying have been associated with a higher rate of LBP. LBP is the most frequent cause of lost workdays in the United States.

There is a higher risk of LBP in obese persons and in tall persons. No studies have proven posture as a definite risk factor for LBP, but spine pain from scoliosis is well known and is the basis of this risk factor. Many studies have shown decreased strength of abdominal and spinal muscles in patients with LBP. Physical fitness and conditioning have been found to have a preventive effect on low back injuries. Smoking has been shown to increase one's risk of LBP. Aging increases the risk for CLBP. Psychosocial factors such as depression, anxiety, and alcoholism, among others, have been reported with higher frequency in patients with chronic LBP.

The cause of back pain is not always clear, but it may be related to ligamentous or muscular strain resulting from either a specific traumatic episode or an incompetence of the soft tissue structure (ALBP). Degeneration of the intervertebral disc, a physiological event of aging, modified by such factors as injury, repetitive trauma, infection, heredity, and tobacco use, may lead to CLBP. As the hydrophilic properties of the nucleus pulposus degrade, the disc loses height and formerly tight ligaments become loose. Motions such as sliding and twisting create tears in the annulus fibrosus. Osteoarthritis and CLBP may develop.

Pathophysiology

The lumbosacral spine supports the upper body in a balanced, upright position while allowing locomotion. In a static, upright position, maintenance of erect posture is achieved through a balance among the expansile pressure of the intervertebral discs, the stretch placed on the anterior and posterior longitudinal and facet joint ligaments, and the sustained involuntary tone generated by the surrounding lumbosacral and abdominal muscles. The balance of the spine is also related to the reciprocal physiological curves in the cervical, thoracic, and lumbosacral areas of the vertebral column. The balance in curvature results in an individual's posture. Proper alignment is also influenced by structures in the pelvis and lower extremities. Movement of the lumbar spine is associated with a lumbar pelvic rhythm that results in the simultaneous reversal of the lumbar lordosis and rotation of the hips. During flexion and extension of the lumbar spine, tension is produced in the paraspinous, hamstring, and gluteal muscles, the fasciae that surround the muscles, and the ligaments that support the vertebral bodies and discs. In addition to the normal stresses placed on these structures with lowering and raising of the torso, the stresses on these anatomical structures are increased to an even greater degree when an individual is required to lift a heavy object.

LBP that is associated with back strain may be related to anatomical structures that are tonically contracted in the resting position. LBP may also occur during motion if the stress is greater than the supporting structures can sustain or if the components of the lumbosacral spine are abnormal. Although the precise pathophysiology of uncomplicated lumbar strain (back strain) is not well characterized, damage may occur in lumbosacral spinal structures if the amount of force generated exceeds the stress capacity of the spine for an individual patient. If the lumbosacral spine is in a mechanically disadvantaged position (e.g., rotated or flexed) the force may not need to be that great to cause a disruption of annular fibers. These fibers may tear when stressed, which in turn causes degeneration of the disc. An annular tear is associated with the production of pain and may account for the frequent episodes of LBP in patients who eventually

rupture a nucleus pulposus. Protruding or bulging intervertebral disc material may then impinge on a spinal nerve root, imparting specific radiculopathic symptoms depending on the spinal level affected. Disc herniation (herniated nucleus pulposus) is discussed as a separate entity in the next section of this chapter.

Several other less common spinal conditions exist that produce LBP. Spinal stenosis results in nerve impingement with back and lower extremity (calf) pain on extension of the spine owing to the narrowed spinal canal, because this maneuver lengthens and further narrows the canal. Osteoarthritis typically produces erosion with irregular bony deposition known as osteophytes at the articular sites of the vertebrae that may also result in nerve impingement and pain as a result of degeneration of the joint. Significant scoliosis can predispose a person to osteoarthritis and may result in chronic LBP resulting from a fundamental derangement of vertebral biomechanics, that is, the ability of the axial musculoskeletal system to appropriately distribute mechanical loads placed on the spine. Spondylolisthesis is a slipping (displacement) of one vertebral body either anteriorly or posteriorly relative to another and may be a congenital or acquired condition. Spinal hyperextension often causes increased or repeated stress on the bilateral pars interarticularis, the posterior bony plate connecting the superior and inferior articular facets of an intervertebral joint. A lesion or fracture of the pars interarticularis that causes the facet to separate without actual anterior or posterior slippage of a vertebral body is known as spondylolysis. Either of these conditions may result in nerve impingement with lower back and extremity pain. Although spondylolysis may be asymptomatic, this condition may progress to spondylolisthesis.

Focus on History 15.2 Low Back Pain

For the patient who complains of low back pain, focus the history by asking questions that will obtain the following information:

1. Mode of onset (abrupt or insidious?)
2. Characteristics:
   - Provoking factors
   - Aggravating factors
   - Relieving factors
3. Effects of activities
   - Posture
   - Coughing, sneezing, straining
   - Exercise, exertion, rest
   - Sleep
4. History:
   - Similar or different pains
   - Course (progressive, decreasing, increasing, fluctuating, episodic?)
   - Associated limb and/or neurological symptoms (pain, paresthesias, numbness, weakness, atrophy, cramps, fasciculations?)
5. Associated symptoms:
   - Urinary problems (frequency, urgency, retention, incontinence?)
   - Bowel problems (incontinence or constipation?)
6. Previous back pain history and treatment (medications, types of surgery, nonpharmacological management, lifestyle and work modifications, litigation or compensation issues?)

Clinical Presentation

Subjective

An acute onset of LBP often follows a lifting episode or may be precipitated by something as minor as a sneeze or cough. Patients may have difficulty standing erect and often change position frequently for comfort. The pain often radiates into the buttocks and posterior thigh. The condition often occurs for the first time during the young adult years. There may be associated grimacing and generalized hypersensitivity to light touch. Initial assessment of a patient with activity intolerance resulting from LBP consists of a focused medical history, including a history of the present illness and past medical, family, occupational, and social history. A review of systems, especially description of any injury, is essential and may alert the provider to possible "red flags" warranting immediate attention. A history of recent trauma, recent lumbar puncture, concurrent infection, or chronic use of high-dose corticosteroids is significant. (See Focus on History 15.2.) Some questions to consider while evaluating the patient's responses include the following:

- Is there a serious systemic disease causing the pain?
- Is there neurological compromise that might require surgical evaluation?
- Is there social or psychological distress that may amplify or prolong pain?

The hallmark symptom of CLBP is recurrent low back pain that often radiates to one or both buttocks. The pain may be described as "mechanical" in that it is aggravated by activities such as bending, stooping, or twisting. There may be stiffness and a history of intermittent sciatica (i.e., pain radiating down the back of the leg), but discomfort in the lower back remains the predominant symptom. This may be relieved with lying down or a good night's sleep, although if the pain is severe enough it may awaken the patient at night. Psychosocial indicators should be assessed because they can be barriers to recovery in all cases of LBP, both acute and chronic. Consider factors such as fear, financial problems, anger, depression, job dissatisfaction, family problems, or stress that can contribute to prolonged disability.

Objective

There is often diffuse tenderness to the lower back. ROM of the lumbar spine, particularly flexion, is typically reduced and elicits pain. Patients may exhibit a side or forward list from muscle spasm. The degree of

lumbar flexion and the ease with which the patient can extend the spine are helpful parameters by which to evaluate progress. Though not characteristic, nonorganic findings, such as widespread sensitivity to light touch, nonanatomical localization of symptoms, inappropriate grimacing, inconsistent actions, and exaggerated pain behaviors, may be seen. In most cases of uncomplicated LBP, the motor and sensory functions of the lumbosacral nerve roots and reflexes of the lower extremities are normal. Negative straight-leg raise rules out surgically significant disc herniation in 95% of cases. (See Advanced Assessment 15.6.)

Diagnostic Reasoning

Diagnostic Tests

In cases of CLBP, anteroposterior and lateral radiographs often show age-appropriate changes, such as anterior osteophytes and reduced height of intervertebral discs on the lateral view. ALBP does not warrant radiographs except in the following circumstances:

- Unrelenting night pain or pain at rest
- Fever above 38°C (100.4°F) for greater than 48 hours
- Progressive neuromotor deficit
- Pain with distal numbness or leg weakness
- Loss of bowel or bladder control (retention or incontinence)
- Significant trauma
- History of suspicion of cancer
- Osteoporosis
- Chronic oral steroid use
- Immunosuppressed or immunosuppressive medication
- Drug or alcohol abuse
- Clinical suspicion of ankylosing spondylitis

Consider a complete blood count and erythrocyte sedimentation rate (ESR) if there is suspicion of cancer or infection. Routine imaging is not indicated in diagnosis of patients with nonspecific LBP (Chou et al, 2007, 2009).

Differential Diagnosis

LBP is a diagnosis of exclusion. The diagnosis of back strain is based on the history of localized LBP and a compatible physical exam demonstrating localized pain, muscle spasm, and a normal neurological exam. CLBP is recurrent and has lasted for a longer period of time, and the patient may also demonstrate mildly restricted straight-leg raising and spinal motion. (See Advanced Assessment 15.6.) Differential diagnoses for ALBP/CLBP include the following:

- Ankylosing spondylitis (family history, morning stiffness, limited mobility of the lumbar spine)
- Drug-seeking behavior (exaggerated symptoms, inconsistent and nonphysiological exam)
- Extraspinal causes (ovarian cyst, nephrolithiasis, pancreatitis, ulcer disease, abdominal aortic aneurysm)
- Fracture of the vertebral body (major trauma or minimal trauma with osteoporosis)
- Herniated nucleus pulposus or ruptured disc (unilateral radicular pain symptoms that extend below the knee and are equal to or greater than the back pain)
- Infection (fever, chills, sweats, elevated ESR)
- Myeloma (night sweats, men older than 50)

Advanced Assessment 15.6 Assessing the Lower Back—Special Tests

Test	Comments
Straight-leg raising—places the L5 and S1 nerve roots and the sciatic nerve under tension.	With the patient supine and relaxed, elevate the leg until either the leg begins to bend or the patient reports severe pain in buttock or back. Record degree of elevation at which pain occurs. It is considered positive when the pain is elicited below the level of the knee when the leg is raised less than 60 degrees. Next, dorsiflex the ankle to determine whether this motion increased pain (further stretch of the L5 and S1 nerve roots). Plantar flexion of the ankle relieves sciatic tension. Increased back pain with this maneuver is probably nonorganic. The straight-leg raising test is very sensitive, but not very specific. To increase specificity, raise the leg until pain is felt below the knee, then lower the leg about 5 degrees, which should eliminate the pain. Then, have patient dorsiflex the ipsilateral foot while the leg is raised. This should cause more traction on the sciatic nerve and reproduce the symptoms.
Reverse straight-leg raising—places the L1–L4 nerve roots under tension.	With the patient prone, lift the hip into extension while keeping the knee straight. Increased pain suggests compression of the upper lumbar nerve roots.
Prone rectus femoris test—places the L1–L4 nerve roots under tension.	With the patient prone, maintain the hip in a neutral position while flexing the knee. Increased pain suggests compression of the upper lumbar nerve roots.

Differential diagnoses for CLBP that are different than ALBP include the following:

- Depression (abnormal Beck Depression Inventory, sleep disturbances)
- Illness behavior (multiple surgeries, multiple illnesses)
- Inflammatory arthritides (morning stiffness for more than 30 minutes, positive human leukocyte antigen–B27, increased ESR)
- Intervertebral disc infection or vertebral osteomyelitis (history of excruciating pain, recent IV drug use, fever, recent infection/hospitalization, open wound)
- Metastatic tumors, myeloma, lymphoma (pathological fractures, severe night pain, weight loss, fatigue)
- Osteoporosis with compression fractures (female gender, previous fracture)
- Spinal tuberculosis (lower socioeconomic groups, history of AIDS)
- Workplace dissatisfaction (discontent with boss, job)

See Differential Diagnosis 15.4.

Management

Reassure the patient that most episodes of ALBP are mild and self-limited; almost 90% are resolved within 1 to 6 weeks. Symptom control is considered an adjunct to helping the patient to overcome specific activity intolerance. The management of the patient with LBP, especially if pain is recurrent and/or chronic, requires a *Circle of Caring* by the practitioner. Multiple approaches are required to address the "iceberg" of LBP and the ways that it can interfere with the lives of patients and families.

Pharmacological Management

The oral medications used to control the discomfort of LBP primarily include acetaminophen, NSAIDs, muscle relaxants, and opioids. There is fair to good evidence that NSAIDs are effective for reducing pain in patients with LBP. Acetaminophen has also been found to be comparable in efficacy to NSAIDs for treating LBP, with fewer adverse effects. Health-care providers need to be aware that the long-term use of NSAIDs can lead to serious gastrointestinal (GI) disease such as ulcers and hemorrhage; thus, patients with GI histories should use this drug cautiously. Using the lowest possible effective dose can help to prevent this problem. Older adults are more sensitive to the adverse effects of NSAIDs, so it is important to use caution when prescribing NSAIDs for this age group. NSAIDs affect the renal prostaglandins and may cause fluid retention and edema, so it is also important for patients to monitor for weight gain. The risk of fluid retention and edema may be very significant in elderly patients and in those with congestive heart failure. In addition, there is the potential for nephrotoxicity.

There is moderate research evidence showing that muscle relaxants are more effective than placebo but no evidence that they are better than NSAIDs in relieving symptoms of acute LBP. Multiple trials found skeletal muscle relaxants moderately superior to placebo for short-term relief of LBP (duration less than 1 week) (American Pain Society/American Association of Pain Medicine, 2009). Patients need to be aware that this class of drugs is for short-term use because the risk/benefit ratio for prolonged use of muscle relaxants is not known. Muscle relaxants cause drowsiness and dizziness, so patients need to avoid hazardous activities when

Differential Diagnosis 15.4 Low Back Pain

Diagnosis	Spondylolisthesis	Muscle Strain	Scoliosis	Herniated Nucleus Pulposus	Osteoarthritis	Spinal Stenosis
Age	20	20–40	30	30–50	>50	>60
Pain location	Back	Back (unilateral)	Back	Back (unilateral)	Back (bilateral)	Leg (bilateral)
Pain onset	Insidious	Acute	Insidious	Acute (prior episodes)	Insidious	Insidious
Pain increases	When standing, bending	When standing, bending	When standing, bending	When sitting, bending	When standing	When standing
Pain decreases	When sitting	When sitting	When sitting	When standing	When sitting, bending	When sitting, bending
Straight-leg raising	Negative	Negative	Negative	Positive	Negative	Positive (stress)
X-ray (plain film)	Positive	Negative	Positive	Negative	Positive	Positive

taking them. This class of drug is a central nervous system (CNS) depressant, so patients need to avoid taking muscle relaxants with alcohol or other CNS depressants because the combined use will cause additive effects. Dry mouth is another side effect from this antimuscarinic class of drugs, so frequent mouth rinsing is recommended to prevent dental disease.

Research has shown that opioid analgesics did not enhance patients' ability to return to full activity sooner than that of patients taking NSAIDs or acetaminophen. In addition, the adverse effects of opioid analgesics were found to be substantial, including the risk for physical dependence.

Activity

It should be stressed that rest has been proven to have little to no effect on the resolution of LBP. Patients should do whatever activities are tolerable. Weight loss, physical activities, and exercise for 30 minutes a day (walking or biking with lumbar flexion and/or extension exercises) are also important. Deconditioning is a real phenomenon that occurs increasingly quickly with increasing age. Lack of activity, leading to deconditioning, becomes a vicious cycle. Reassurance is always appropriate after ruling out more serious causes of back pain. Avoid labeling patients as "disabled." Actively promote smoking cessation if the patient smokes.

Follow-up and Referral

The course of patients with back strain is one of gradual improvement, usually over a 1- to 2-week period. The recovery is usually complete, without any lasting impairment. The small percentage of patients who do not make a complete recovery may continue to experience LBP associated with muscle strain. Pain may continue for months or years. These patients are experiencing CLBP, which must be evaluated and treated in a manner that takes into account the special difficulties of individuals with chronic pain. Patients with more severe symptoms can have limited vocational and avocational activities, recreation, and sleep disturbances. Mood, sexuality, and concentration can be adversely affected. Deconditioning can be the result of reduced activities, making both symptoms and any occupational dysfunction worse. Suggest a modified work schedule and more recreational activities that improve general conditioning. Narcotic abuse and dependency can be a problem for patients with chronic pain; refer the patient to a pain management center where a variety of evaluation and treatment modalities are available.

In all patients, preventing recurrence of back pain is another important consideration. The first episode of back pain is usually the briefest and least severe. The vast majority of individuals with an episode of back pain are at risk of developing another episode of back pain that will be more severe and of greater duration. Patients with recurrence are usually resistant to therapies that are beneficial in management of acute back pain, and therefore they may require chronic pain assessment and management strategies (including the use of complementary therapies such as acupuncture or acupressure). Consistent evidence from multiple trials demonstrates that acupuncture is moderately effective for short-term pain relief compared with no treatment or sham transcutaneous electrical nerve stimulation in patients with chronic low back pain. There was no difference in effect between acupuncture and sham acupuncture (American Pain Society/American Association of Pain Medicine, 2009).

Referral to a specialist (e.g., neurosurgeon, orthopedic surgeon) is recommended for any patient who has a neurological deficit or if the patient has a trauma history with x-ray exam revealing instability or fracture that could cause damage to neural elements.

Patient Education

Instruct the patient to carefully introduce activities back into his or her day as he or she begins to recover from the worst of the back pain episode. Gradual stretches and regular walking are good activities. Ice or heat, whichever provides more comfort, will help decrease the inflammation. Over-the-counter anti-inflammatory medications (e.g., aspirin, NSAIDs) or Tylenol may be used. Provide information on safe back exercises such as modified sit-ups and low back stretches. Encourage patients to make them a regular part of their lifestyle. Emphasize the need to relax. Patients should call if symptoms persist, worsen, or progress; significant pain persists beyond 1 week; or there is no improvement with home management. There is consistent evidence that application of heat for acute/subacute low back pain is superior to placebo for back functional status and short-term pain relief. There is insufficient evidence to evaluate ice therapy.

Agency for Healthcare Research and Quality guidelines suggest teaching the patient self-application of heat or cold but found insufficient evidence to endorse application of heat or cold products or justify their cost (American Pain Society/American Association of Pain Medicine, 2009).

HIP PAIN

Hip pain is discomfort within or around the hip. The largest joint in the body, the hip is subject to stress from ambulation and weight-bearing; it may suffer trauma and chronic mechanical stress. Possible causes are processes in the hip joint, the surrounding muscles, the soft tissues, or the neurovascular system. Diagnosis needs to consider the patient's age because certain problems are more prevalent in different age-groups. In adults, common problems include OA, RA, fractures, referred pain, bursitis, meralgia paresthetica, avascular necrosis, and malignancy.

Pain in and around the hip can often be felt in the groin or the buttock, or it can be referred to the thigh

or knee. Conversely, pain may be referred to the hip if irritation to the femoral, sciatic, or obturator nerve roots occurs. These may be the result of herniation of lumbar disc, spinal stenosis, retroperitoneal tumor, or femoral hernia. Vascular insufficiency of the aortoiliac area may result in hip and buttock pain as well. The history should ascertain if pain is focal, as in bursitis, or diffuse, as in synovitis. The presence of stiffness should raise the suspicion of degenerative disease. Inquire about trauma, involvement of other joints, infection, fever, and relation of pain to activity.

Physical examination of the hip must first assess position at rest because fracture of the femoral head results in external rotation and flexion, and an internally rotated shortened leg may be a posterior dislocation. These patients should not have the hip moved until radiographic studies have ruled out fracture or dislocation. Performing palpation of the joint allows recognition of focal tenderness and swelling.

The ROM examination begins with assessment of gait, if possible. Next, the extremity should be put through passive ROM to detect crepitus, limitation of movement, muscle spasm, flexion contracture, or guarding. Flexion and extension need to be performed with the knee straight as well as flexed. Abduction, adduction, and internal and external rotation are assessed. Femoral and pedal pulses are auscultated for strength and bruits. Neurological testing for sensation and deep tendon reflexes concludes the exam. Diagnostic testing should include hip x-ray films. Other x-ray studies, such as spine or sacroiliac films or weight-bearing films, may be indicated in special circumstances. MRI, ultrasonography, and joint aspiration are other diagnostic techniques to be considered in special circumstances.

Differential Diagnosis

Osteoarthritis

OA usually causes stiffness or pain with use that is felt in the morning and improves during the day. Pain referred to the groin, thigh, knee, and lateral side of the leg may occur. Often pain or stiffness affects other joints as well. For more information, see the section on osteoarthritis that follows later in this chapter.

Trochanteric Bursitis

The hip area contains multiple bursae. The incidence of trochanteric bursitis peaks between the fourth and sixth decades of life; it is more common in women than in men. It is commonly associated with pain and limited ROM. Onset may be acute or insidious. Bursitis can be associated with trauma or overuse and may be inflammatory, hemorrhagic, infectious, or calcific. Inflammatory bursitis of the hip is the most common type. Trochanteric bursitis is often associated with lumbar spondylosis, degenerative arthritis of the hip, and lower limb–length discrepancy. It is characterized by chronic, intermittent, aching pain over the lateral aspect of the hip, and some patients report numbness in the upper thigh. Pain will increase with movement, especially external rotation and abduction, and can be triggered by prolonged standing or lying on the affected side. Other signs and symptoms include pain on forced hip abduction, distinct tenderness around the greater trochanter, and pain extending down the lateral aspect of the thigh. Trochanteric bursitis is treated with NSAID therapy (e.g., naproxen [Naprosyn] 375–500 mg PO 2 times daily for 1–2 weeks). Persistent cases may require corticosteroid injections.

Rheumatoid Disease

With rheumatoid disease, the hip pain is bilateral, and characteristics include morning stiffness and limited ROM that does not resolve with activity. The hip is generally not the first joint affected. During an acute phase there is tenderness and fullness or thickening seen in the joint.

Proximal Femoral (Hip) Fracture

Hip fractures are one of the most common of all adult fractures, accounting for at least half of all hospital days related to fracture care in the United States. The two primary types of hip fractures are *femoral neck* (intracapsular) and *intertrochanteric,* both of which occur most frequently in older adults who have sustained a fall at home or similar low-energy trauma. The incidence of hip fractures doubles for each decade of life after age 50 years, with women affected twice as often as men are.

Risks for hip fractures include physical activity, previous fracture, visual impairment, institutionalization, and osteoporosis. Pain in the hip area after trauma, such as a fall or motor vehicle collision, especially in patients older than age 50, should give rise to the suggestion of fractures. Neither a lack of trauma nor a long-standing history of hip pain rules out a fracture. In some cases, a fracture may occur as a pathological fracture secondary to an underlying neoplasm or chronic corticosteroid usage. The patient should be admitted to the hospital.

Obtain a history of how the injury occurred and whether the fall was witnessed by anyone other than the patient. A loss of consciousness for any period would necessitate a cardiac and neurological referral, as well as referral for orthopedic care. Determine the patient's mental status, and try to obtain a realistic assessment of the preinjury functional status.

Physical exam typically reveals an externally rotated and shortened injured leg. Any motion to this extremity will produce severe pain centered around the affected groin. Examine the pelvic bony prominences for tenderness because pubis ramus fractures may also be present or may be confused with the hip injury. It is important to check for lower-extremity pulses and neurological function. The entire limb should be assessed for points of tenderness or deformity that may indicate the presence

of other fractures at sites such as the femur, tibia, or ankle. An anteroposterior view of the pelvis and "shoot-through" lateral views of the affected hip can provide definitive radiographic evidence to confirm the diagnosis. In most cases, surgical repair of the fracture is the treatment of choice.

Meralgia Paresthetica

Caused by compression of the lateral femoral cutaneous nerve, meralgia paresthetica is commonly seen in overweight middle-aged men. Symptoms include pain or paresthesias over the anterior superior iliac spine and the anterior lateral thigh, with decreased touch and pinprick sensation. Treatment includes analgesics and avoiding tight clothing around the waist.

Avascular Necrosis

Avascular necrosis appears as abrupt hip pain followed by progressive, intermittent episodes. Pain is worsened with motion and activity and often is worse at night. A limp, along with limited abduction and internal rotation, is present. MRI is needed for diagnosis, and an orthopedic referral is indicated. It often occurs as a serious complication of hip trauma, but it may occur unrelated to trauma.

Malignancy

Initially no signs may be present with malignancy; however, tenderness and palpable swelling may develop later over bony prominences. Night pain, systemic symptoms, and fractures may be seen.

KNEE PAIN

The knee is a complex, modified hinge joint consisting of three bones, three articulations, five major tendons, four major ligaments, and two menisci. The lateral and medial articulations are between the femoral and tibial condyles. The intermediate articulation exists between the patella and the femur. The knee is a relatively weak joint that gains its strength from the strong ligaments that attach the femur to the tibia. There are five intrinsic ligaments that assist in strengthening the articular capsule. The cruciate ligaments connect the femur and tibia within the articular capsule, crossing each other in the form of an X.

As a major weight-bearing joint, the knee is susceptible to many injuries. Torsion is limited in the joint, and any motion that extends beyond the defined range results in a ligamentous injury. Because the knee joint depends on the integrity of the ligaments to provide it with stability, an injury to the knee may be a calamitous event.

The arrangement of three articulations allows a combination of rolling, gliding, and rotation, in addition to flexion and extension. Although it is attached to the lateral tibia, the fibula does not articulate with the knee joint. The anatomy of the knee includes bony structures, ligaments, tendons, bursae, and cartilage. The femoral condyles and the tibial plateaus are capped by the patella and cushioned by the menisci, whereas the ligaments, muscles, tendons, and bursae provide stability.

The knee joint is a common site for discomfort due to trauma (24% of all activity-related musculoskeletal injuries in men, the highest of all sites), degenerative disease, and/or rheumatological conditions. Acute pain in the knee may be related to any of the following:

- Fractures
- Meniscal injuries
- Ligamentous injuries
- Musculotendinous strains
- Extensor mechanism injuries
- Contusions

Many knee complaints by adults are the result of overzealous exercise and sports activity. Fractures can involve the distal femur, patella, proximal tibia, and fibula. Inspect for swelling and deformity, palpate for tenderness in the bone itself, and obtain appropriate radiographs. Patellar fractures can result from indirect forces, such as falls, but fractures of the tibia and femur at the knee usually result from major trauma. Patellar dislocations are often reduced at the scene of injury when the knee is extended for transport.

Obtaining a history of the mechanism of injury is key in diagnosing meniscal tears. A history of a twisting injury sustained with the foot planted on the ground and locking (inability to extend the knee completely) with localized pain and tenderness along the joint are indicative of meniscal pathology. Some patients report that manipulating or pushing on the knee enabled them to "unlock it." Ask the patient if he or she heard or felt a "pop" when the injury occurred.

Patients with ligamentous injuries have acute pain, swelling, and instability. Strains of various musculotendinous structures around the knee also cause acute pain and swelling, but most do not result in instability. Patients with an injury to the extensor mechanism report a fall with a sudden weakness or collapse. Contusions are from direct blows and cause localized pain and tenderness.

Knee complaints are categorized as *injury* (trauma) or *overuse* and are either acute or chronic. Often chronic knee pain cannot be related to any recognized injury or overuse. Conditions that cause chronic knee pain include the following:

- Arthritis
- Tumors
- Sepsis
- Overuse syndromes (including bursitis/tendinitis and anterior knee pain)

Tumors are characterized by night pain and often can be palpated or identified on radiograph. Sepsis in the knee joint is rare; it is more commonly located in the prepatellar bursa. Inspection and palpation of the involved area

easily determine the location of the infection. Bursitis/tendinitis and anterior knee pain have similar characteristics: both usually are chronic, often secondary to overuse, and often bilateral. The pain typically is worse with rising or walking after sitting, at night, and with prolonged exercise or use.

The physical exam of the knee begins with the patient standing. Inspect both knees anteriorly and posteriorly. Observe the gait. Inspect the knees for swelling, ecchymosis, erythema, abrasions, puncture wounds, and active range of motion (ROM). Assess the popliteal space for swelling that may occur with popliteal aneurysm, Baker's cyst, and tumors. It is important to assess movement in both the standing and supine positions and to note any limping, pain, locking, or giving way of the knee. As the patient lies supine, palpate the joint line, muscles, tendons, ligaments, and bones in an attempt to localize tenderness. An effusion may be demonstrated by eliciting the *bulge sign:* As the patient lies supine, massage the medial knee toward the head, then stroke the lateral aspect of the knee toward the medial aspect. A bulge sign or effusion is indicated if fluctuance occurs over the medial aspect. Palpation for crepitus while the knee is passively flexed and extended helps to determine if meniscal injury is present. Do muscle testing of the quadriceps and hamstrings.

A complete physical exam is also important to rule out the presence of systemic disease associated with knee pathology.

There are a number of specialized assessment techniques. Most are specific and technique driven, requiring practice to master them. The Lachman test should be done on most patients with knee pain; it is 94% specific and is helpful in diagnosing anterior cruciate ligament (ACL) injury. The McMurray and Apley tests are indicated in diagnosing meniscal tears. The anterior drawer test has a low sensitivity and high specificity for confirming ACL pathology, so a positive test strongly suggests a problem but a negative test does not rule out an ACL tear. The posterior drawer test is used to diagnose posterior cruciate ligament (PCL) injury. The collateral ligament stress test, also known as the valgus and varus stress tests, evaluates the intact function of the medial collateral ligament (MCL) and the lateral collateral ligament (LCL), respectively. The Fairbank test, also known as the Apprehension test, can identify dislocation of the patella. (See Advanced Assessment 15.7.)

Contusions are injuries to the leg by a direct blow. Disability may be minor; however, contusions can be quite painful, with significant swelling and tenderness. There may be ecchymosis, and active and passive stress will be painful.

Diagnostic testing includes the use of radiographs if mechanical injury or trauma is suspected. Specific weight-bearing views and sunrise or skyline views can be performed. MRI is helpful in diagnosing a torn meniscus or cruciate ligament injury. Arthrography is used for diagnosis of a Baker's cyst, and effusions can be aspirated for diagnostic purposes.

Differential Diagnosis

Inflammatory Arthritis

Knee arthritis, which may cause an inflammatory effusion, may be a primary manifestation in a number of conditions. It is one of the most common manifestations

Advanced Assessment 15.7 Assessing the Meniscus and the Patella—Special Tests

Test	Comments
McMurray circumduction test—to test for meniscal tear	Flex the knee to the maximum pain-free position. Hold that position while externally rotating the foot, and then gradually extend the knee while maintaining the tibia in external rotation. This maneuver stresses the medial meniscus and often elicits a localized medial compartment click and/or pain in patients with a posterior tear. The same maneuver performed while rotating the foot internally will stress the lateral meniscus. Pain-free flexion beyond 90 degrees is necessary for this test to be useful.
Apprehension sign—to test patellar instability	Have the patient seated with the quadriceps relaxed. Place the knee in extension. Displace the patella laterally and then flex the knee to 30 degrees. With instability, this maneuver displaces the patella to an abnormal position on the lateral femoral condyle. The patient often perceives pain and demonstrates apprehension.
Bulge sign—to assess for effusion	Apply lateral pressure to the area adjacent to the patella. Medial bulge will appear if fluid is in the knee joint.
Inspect/palpate—to assess for effusion	First, inspect the suprapatellar region. A large knee effusion will be visible. Subtle knee effusions can be demonstrated by "milking down" the joint fluid from the suprapatellar pouch. Hold the fluid wave in place with one hand and ballot the patella. Excessive fluid will create a spongy feeling as the patella is pushed down.

of osteoarthritis (OA). Often more than one joint is affected, and there is recurrence or chronicity. Gout, pseudogout, Lyme disease, septic arthritis, and avascular necrosis can also be responsible for the inflammatory response. It may be necessary to aspirate the joint and culture the synovial fluid to rule out infection. Treatment will depend on the underlying condition.

Fracture

A fracture is most likely to occur with direct trauma and result in acute onset of pain. Fractures of the knee and leg include those of the patella, tibial plateau, fibular head and shaft, and tibial pilon. Most, but not all, knee fractures are the result of fairly significant trauma; fractures of the knee are often present in conjunction with injury to associated structures. Most fractures around the knee are associated with a large effusion. If the joint is tapped, the presence of hemarthrosis with fat globules is clinically indicative of a fracture. Swelling and significant pain on movement will be present. It is important to ensure that no neurovascular compromise is present in the lower leg. Radiography should be obtained, and immediate referral is indicated.

Patellar fractures are usually the result of a direct blow from a blunt object or can be attributed to a fall or motor vehicle collision (MVC). The patient with a patellar fracture is usually unable to flex the knee. Marked joint effusion is usually present.

Stress Fractures

Stress fractures are common in patients who experience bone pain after initiating or increasing high-impact activity. Stress fractures are a result of repeated subtle bone trauma over a period of time that causes a gradual loss of bony substance. New bone is fragile until it calcifies. The cortex, temporarily weakened, is then susceptible to fracture. Common sites for stress fractures are the legs and feet.

There is point tenderness over the bone on physical exam. There may be ecchymosis and soft tissue swelling. Often the patient has altered his or her gait, causing pain to the knee. Resistive motion of the joint is painless. Radiographs may reveal a periosteal reaction or a hairline radiolucency but are usually negative until 2 to 3 weeks after the injury has occurred. Bone scans may be helpful.

Rest is the best treatment for a stress fracture. Once the patient is pain free, gradually resume activity. The best treatment of stress fractures is prevention. Exercise programs should begin slowly, and the patient should avoid the "weekend warrior" syndrome.

Runner's Injuries

Lateral knee pain frequently plagues runners, whether they are novices or seasoned athletes. When there is an inability to "run through the pain," runners will often seek care. Sometimes the pain occurs when the average running time or distance has been increased.

"Runner's knee," or *iliotibial band tendinitis,* may be related to improper footwear, uneven and bumpy paths, running on very hard surfaces, and lack of warm-up. The pain is based at the lateral edge of the patella, at the point where the iliotibial band crosses over the anterior aspect of the joint. Most runners with this condition have feet that supinate, meaning that they do not get a good push-off. Pain during a run suggests injury; pain after a run suggests an overuse problem.

Treatment includes rest, ice packs or ice massage, and NSAIDs. For runners with foot problems, orthotics may be indicated. Alternative low-impact activities should be encouraged (e.g., swimming, biking, or running in water). The symptoms should resolve in 10 to 14 days; at that time the individual may resume running at half the distance that he or she was running before. After 3 weeks, if the runner is pain free, the distance may be increased.

Collateral Ligament Sprains

Knee sprain or ligament tears often occur as a result of athletic injuries. Joint laxity will be present to a varying degree, depending on the injury. The two collateral ligaments, the MCL and the LCL, provide lateral stability to the knee. The MCL attaches to the medial condyle of the femur and the tibia. The LCL attaches to the lateral femoral condyle and extends to the lateral tibial plateau. The MCL and the LCL are injured when the valgus (MCL) or varus (LCL) stress to the joint extends beyond the defined range. MCL injuries are more common than LCL tears and often include an injury to the medial meniscus. Football players and skiers are more prone to ligamentous injuries, but they may occur just as easily on the dance floor or in the bathroom.

Wrenching the knee with the foot firmly planted causes injury to the MCL. In these injuries, the knee is in flexion and in a slight internal rotation. LCL injuries occur when the varus stress applied to the knee causes a "bend" toward the outside. The knee is painful and often swollen and may be ecchymotic over the body of the ligament. Some patients will report the feeling that the knee is "bent the wrong way." The knee swells within 20 to 30 minutes; more rapid swelling is an ominous sign and should be considered a "red flag."

Examining the knee immediately after the injury is easier and helps to ascertain the severity of the injury. The exam is more difficult once the joint swells. In a suspected collateral ligament sprain, there is tenderness along the body of the ligament, and point tenderness at the attachment sites is frequently present. In the MCL injury, there may be tenderness at the medial joint because the MCL attaches to the medial meniscus. Pain at the lateral joint line is equivalent to a joint injury.

Varus or valgus stress on the knee joint will determine joint laxity. The practitioner should always examine the unaffected knee first to establish the baseline and to allay anxiety about the evaluation.

Obtain plain radiographs to rule out fractures and dislocations. More extensive radiological exams such as stress films, CT scans, and MRI scans are obtained in consultation with an orthopedist. In an acutely swollen joint, MRI is often inconclusive. As in all musculoskeletal injuries, it is important to include fractures, dislocations, and tumors in the differential diagnoses.

Isolated first- and second-degree sprains can be managed with *r*est, *i*ce, *c*ompression (or immobilization), and *e*levation (RICE). The unstable knee requires an external knee immobilizer. No weight-bearing should be allowed on an acutely swollen or painful knee. Once the injury is past the acute stage, the patient should begin adductor-strengthening exercises with physical therapy referral. Once the swelling and pain subside, a more progressive rehabilitation program should begin.

All severe strains and fractures should be referred to an orthopedic specialist. Referral to a physical therapist to assist in complete rehabilitation should also be considered. An incompletely rehabilitated knee will be weak and potentially unstable. Without accurate diagnosis and treatment, the injury can become more extensive, jeopardizing joint stability and other structures. Traumatic arthritis can be the sequela to any joint injury.

Adherence to the rehabilitation process is imperative. In some instances, a knee support is necessary for sports. Pain and swelling are indicators that the knee is being overstressed or reinjured.

Cruciate Ligament Injuries

The two cruciate ligaments—the ACL and the PCL—provide rotational stability to the knee. The ACL attaches to the anterior part of the intercondylar area of the tibia, posterior to the medial meniscus. It rises superiorly, posteriorly, and laterally to attach to the posterior section of the medial side of the lateral condyle of the femur. The ACL restrains the anterior to the posterior translation of the knee, keeping the proper relationship of the femur to the tibia. It is loose when the knee is in flexion and tight when it is fully extended. It is the weaker of the two cruciate ligaments. The ACL is the most commonly involved structure in severe knee injuries. In 70% of the patients presenting with acute, traumatic hemarthrosis, the ACL is the injured structure. The ACL injury frequently occurs in combination with ruptures of the MCL and the medial meniscus. Once the ligament is torn, the knee is unstable. Swelling occurs rapidly in ACL or PCL injuries because of bleeding of the ligament tear.

The PCL originates in the posterior part of the intercondylar area of the tibia. It crosses superiorly and anteriorly on the medial side of the ACL and attaches to the anterior portion of the lateral surface of the medial femoral condyle. The PCL is tight in flexion. The PCL is injured less frequently than the ACL. It is usually injured by trauma to the anterior surface of the proximal tibia, as in hitting the dashboard in an MVC.

With either ACL or PCL injuries, the patient often reports hearing a "pop" or feeling the knee "snap." An instantaneous sensation of something being "terribly wrong" is also commonly reported. Pain from the injury prevents a return to activity. The patient may report a "distrust" of the knee during activities—the knee may give out, especially during exertion.

On examination, the knee is swollen, and the patient is unable to fully flex or extend the knee. There are four standard tests to perform to ascertain the integrity of the ligaments: the valgus and varus stress tests (collateral ligament stress tests), the Lachman test, and the thumb sign (see Advanced Assessment 15.8). Hamstring spasms and the posterior horn of the meniscus can stabilize the knee, so it is important for the patient to relax throughout the exam. Examine the normal knee first to allay anxiety and to establish a baseline because most people have some degree of laxity in the ligaments.

Obtain radiographs of the knee. Plain films will demonstrate effusions, loose bodies, and avulsion fractures. The Segond fracture—an avulsion off the lateral aspect of the tibial plateau—is pathognomonic of an ACL tear. The ligaments can be definitively evaluated by MRI.

Any trauma to the knee can cause fractures as well as cartilage, meniscus, ligament, and muscle damage. The clinician should consider all these injuries when evaluating the knee. The degree of the tear and presence of instability should direct the treatment plan. Partial tears and tears without concurrent fracture or meniscus tear can often be managed conservatively. Immobilize the acutely injured knee to decrease swelling and pain. The patient should avoid weight-bearing on the knee. The quadriceps muscle begins to atrophy with inactivity, so it is important to begin strengthening exercises as quickly as tolerable. The quadriceps muscles are adjunct stabilizers to the ACL, and rehabilitation should stress regaining full ROM and strength.

All patients who have sustained an injury to the cruciate ligaments require an evaluation by an orthopedic surgeon. An unstable knee is in jeopardy of fracture, worsening the initial injury, or falls as a result of the instability, resulting in other injuries. A knee that has sustained severe trauma is susceptible to developing arthritis. It is important that the patient understand that despite reconstruction and rehabilitation, the knee will never be perfectly normal. Nonetheless, it can be functional although it may require the use of a custom-made brace.

Cartilaginous Injuries or Meniscal Tears

Cartilaginous injuries or meniscal tears present with acute or subacute pain. The patient may complain of the knee "locking" or "giving way." Conservative therapy of rest, application of ice, and use of NSAIDs should be the initial treatment. If no improvement occurs, diagnostic evaluation of x-ray films (to rule out

Advanced Assessment 15.8 Assessing Knee Ligaments—Special Tests

Test	Comments
Valgus stress test—assess the medial collateral ligament (MCL) stability.	Support thigh to relax the quadriceps muscle. Apply stress initially with the knee extended and then flexed to 25 degrees. With the thigh supported and the knee extended, place one hand on the lateral side of the knee, grasp the medial distal tibia with one hand on the lateral side of the knee, grasp the medial distal tibia with the other hand, and abduct the knee. If the knee opens up in a valgus direction more than the opposite knee, the patient has either a complete or partial tear of the MCL.
Varus stress test—assess the lateral collateral ligament (LCL) stability	Assess LCL stability with the knee in extension and 25 degree flexion by reversing the stress pattern used for the MCL. If the knee opens up more than the opposite knee in a varus direction, the patient has either a complete or partial tear of the LCL.
Lachman test—anterior cruciate ligament (ACL)	With the patient supine and the knee flexed 15–20 degrees, grasp the calf, wrapping your hand around the leg, with your thumb on the tibial tubercle. With your other hand, stabilize the distal femur, pressing your thumb through the quadriceps tendon while the rest of your hand encircles the thigh above the patella. The knee should be relaxed so that you feel the full weight of it. Simultaneously apply pressure to the tibia posteriorly, attempting to move it forward while pushing backward on the femur, feeling for any anterior excursion of the tibia. The normal response is no forward translation of the tibia. With an ACL tear, there is anterior excursion of the tibia.
Thumb sign—posterior cruciate ligament (PCL)	With the patient supine, flex the knee to 90 degrees with the foot supported. Normally, the anterior tibial plateaus sit 1 cm anterior to the femoral condyles, and you may place your thumbs on top of the medial and lateral tibial plateaus. If the PCL is injured, the proximal tibia falls back and the area available to your thumbs decreases. When the tibial plateaus are flush with the femoral condyles, there is 10 mm or more of posterior laxity, consistent with a complete tear of the PCL.

fractures and OA), MRI, and orthopedic referral are indicated. (See Advanced Assessment 15.8.)

Meniscal Tears

Knee injuries are the most frequent sports-related injury. The knee is an inherently unstable joint held together by ligaments, cushioned by the menisci, and covered by muscles. The menisci are crescent-shaped fibrocartilaginous structures on the articular surface of the tibia. They act as shock absorbers for the knee and help to control normal knee motion. The medial meniscus is injured or torn more frequently than the lateral meniscus because of its more rigid structure, decreased mobility, and more vulnerable sites of attachment, which render it subject to greater stress. Meniscal tears ("torn cartilage" or "locked knee") can occur alone or in combination with ligament injuries such as cruciate ligament disruptions and/or collateral ligament tears. Meniscal tears disrupt the mechanics of the knee, leading to varying degrees of symptoms and predisposing the knee to degenerative arthritis.

Epidemiology and Causes

Meniscal and ligament tears affect two groups of patients primarily—young, athletic adults with a history of trauma and middle-aged or elderly patients with OA. Several case series have indicated that meniscal tears are the most common of all knee injuries, accounting for an estimated 52,000 knees damaged by football injuries alone. Moreover, an estimated 1.7 million people undergo meniscal surgery each year. Traumatic tears may not always involve contact injury; however, most commonly, they are due to sports-related activities, particularly soccer, football, and basketball. In contrast to traumatic tears, degenerative tears result from the progressive weakening of the menisci and articular cartilage associated with aging.

Pathophysiology

The menisci are C-shaped fibrocartilaginous partial rings of tissue that line the surfaces of opposing bones within the mobile knee joint, maintaining the distance between the involved bones—the tibia and the femur. The medial and lateral menisci lie on the tibial plateau, with their curved portions facing outward. They consist of two phases: a liquid interstitial phase and a solid, extracellular collagenous (predominantly type I) matrix phase that is secreted by meniscal fibrochondrocytes. This dense viscoelastic structure allows them to provide nutrition and lubrication to the articular cartilage, as well as to serve a cushioning and stabilizing function, given their cup-like form. As the knee is fully extended from a flexed

position, the distal end of the femur normally rotates slightly medially, with its bilateral bony prominences (femoral condyles) coming to rest within the cupped forms of the two menisci, essentially screwing into place when in the highly stable, fully extended position. When extended, the menisci support 50% of the load placed on the knee joint; when the knee is fully flexed, they support up to 85% of the load.

The menisci of the knee joint are particularly prone to injury when the knee is twisted while in the flexed position, as the femur compresses against the tibia and grinds against the meniscus. This grinding motion tears the meniscus because the force exceeds the strength of the fibrocartilage. The adult meniscus is poorly vascular, except for the peripheral 10% to 25%; thus, it is particularly slow to heal once torn.

Menisci tear either as a direct result of injury or indirectly because of the normal wear and tear on the knee. Traumatic tears are most commonly vertical, longitudinal tears (called bucket-handle tears when displaced), but transverse (radial) tears are also common. They are often associated with ACL or, less commonly, PCL tears. The second type of meniscal tear is known as a degenerative tear, which usually occurs in persons aged 40 years and older and is not preceded by trauma. Horizontal cleavage tears and flap tears are most common. These injuries have particularly poor healing capacity.

Microtears in the menisci heal via the formation of a fibrin clot, containing fibronectin, chemotactic growth factors, and mitogenic growth factors (e.g., platelet-derived growth factor) that cause undifferentiated mesenchymal cells to migrate into the tear, producing a meniscal scar that eventually transforms into fibrocartilage over the course of years. Meniscal chondrocytes act in concert with the scaffolding fibrin clot to contribute to this healing process. Articular damage from the meniscal tear may lead to osteoarthritis with progressive degeneration of the involved joint. Further, because the menisci stabilize the knee, loss of their integrity can lead to more extensive joint injuries.

Clinical Presentation

Subjective Patients with knee problems usually report pain, instability, stiffness, swelling, locking, or weakness. The patient with traumatic tears typically reports a "twisting injury" to the knee. Older patients with a degenerative tear may report a history of minimal or no trauma—they may simply stand from a different position or walk on an uneven surface. The patient may experience the knee "giving way," as well as a painful popping or locking. Typically patients can ambulate after an acute injury and may continue to participate in athletics.

In acute knee pain, obtaining a history of the mechanism of injury is essential to proper diagnosis.

Traumatic tears are typically followed by the insidious onset of knee swelling and stiffness over 2 to 3 days. Mechanical symptoms such as locking, catching, and popping may continue. Patients usually experience pain on the medial or lateral side of the knee, particularly with twisting or squatting activities. Motion is often limited by a feeling of "tightness" secondary to effusion. In some cases, large fragments of meniscal tissue can become incarcerated in the knee joint, leading to a "locked knee." The mechanical symptoms and degree of pain tend to wax and wane.

Objective The most common finding on physical examination is tenderness over the medial or lateral joint line. Young patients who have traumatic tears that disrupt the peripheral blood supply typically present with a large effusion or hemarthrosis. In degenerative tears or tears that involve the avascular central body of the meniscus, effusions are typically small or absent. Knee motion may be limited secondary to pain or effusion in either instance. During provocative testing such as forced flexion and circumduction (internal and external rotation of the foot), pain is frequently elicited on the side of the knee with the meniscal tear. The McMurray test is positive when the flexion-circumduction maneuver is associated with a positive click.

Diagnostic Tests

Anteroposterior (AP), lateral, tunnel, and axial views are indicated for patients with a history of trauma or effusion. For patients with chronic conditions, the AP and lateral views should be weight-bearing. The definitive diagnostic test for a meniscal or ligamentous tear is MRI, which should be done only if the diagnosis is in doubt or if surgery is anticipated. MRI has also effectively supplanted invasive knee arthrography with intra-articular contrast media, except in contraindicated circumstances (e.g., preexisting metallic clips, severe claustrophobia). Aspiration generally yields noninflammatory fluid that may be bloody, depending on the extent of the tear.

Differential Diagnosis

In cases of acute knee pain, the following are diagnostic considerations:

- Fractures (distal femur, patella, proximal tibia, and fibula) may be ruled out on radiograph.
- Meniscal injuries are preceded in most cases by a twisting injury and "locking," inability to extend the knee completely, and localized pain and tenderness along the joint line.
- Ligamentous injuries show acute pain, swelling, and instability.
- Musculotendinitis strains demonstrate acute pain and swelling but rarely instability.
- Extensor mechanism injuries may cause a fall or collapse related to a sudden weakness.
- Contusions present with a history of a direct blow, localized pain, and tenderness.

Conditions that cause chronic knee pain include arthritis, tumors, sepsis, and overuse syndromes (including

bursitis/tendinitis and anterior knee pain). Arthritis is relatively easy to diagnose because symptoms localize to the joint line and are associated with loss of motion and radiographic changes. Tumors are characterized by night pain (relentless and causing sleeplessness), often can be palpated, and should be identifiable on radiographs. Sepsis in the knee is rare in adults; it is more commonly located in the prepatellar bursa. Inspection and palpation of the involved area should determine the location of the infection. Bursitis/tendinitis and anterior knee pain have similar characteristics: Both usually are chronic, often secondary to overuse, and often bilateral. The pain typically is worse with rising or walking after sitting, at night, and with prolonged exercise or use.

Management

In the absence of mechanical symptoms and particularly when a degenerative tear is present, initial therapy should be conservative. RICE and the use of crutches help quiet the acute phase. A short course of oral analgesics, such as acetaminophen or NSAIDs, can facilitate return to normal activities. Rehabilitation to improve the strength of the quadriceps muscle is imperative. Straight-leg raises with the knee extended, but not locked, can be started immediately. Gradually increase weight-bearing, although non–weight-bearing activities such as swimming and riding a stationary bicycle are excellent for increasing ROM and strength.

Traumatic tears on younger patients should be treated aggressively. Sports activity should be restricted until MRI evaluation is made or symptoms resolve. Surgical repair is indicated in younger patients with significant tears in the vascular area (where healing can potentially occur). Other treatments that are being used but are too new to have evidence of long-term effectiveness are meniscal replacement with allogenic or artificial material in younger patients with prior total meniscectomy. For middle-aged or older adults there is no consensus on which treatments yield optimal outcomes. The dilemma is to decide if the meniscal tear will lead to OA or if the degenerative meniscal lesion was caused by OA. Even if the meniscal tear is surgically removed, OA can continue to progress if that was the underlying problem. Current best evidence indicates that medical treatment and planned exercise programs are as efficacious as arthroscopic surgery for middle-aged to older adults. There is a strong need for more research and randomized controlled trials in the area of management of meniscal tears and OA.

Follow-up and Referral

A patient with traumatic effusion, mechanical symptoms, or ligamentous instability requires further evaluation. Patients who do not respond to nonoperative treatment and have persistent joint tenderness or effusion may require further evaluation. Recurrent episodes of locking and damage to adjacent articular cartilage with subsequent OA are possible sequelae. With the exception of the outer rim, the blood supply to the meniscus is poor. Although small peripheral tears can heal, most tears are more central and cannot heal. Patients with recurrent stiffness, locking, or pain have a mechanically significant tear, which suggests ongoing internal damage. Failure to recognize and treat a traumatic tear can lead to progressive damage and a lost opportunity for surgical repair.

Patient Education

Maintaining quadriceps strength is key to minimizing disabilities from this injury. These include "closed-chain" exercises in which the bottoms of the feet are stabilized as they push directly against resistance (e.g., squats, stationary bicycle riding, leg presses). Although the knee will not return to 100% of baseline after healing, participation in sports with proper warm-up exercises and protective equipment can still be enjoyed. Achiness and swelling after a particularly strenuous workout may occur, reflecting the need for increased quadriceps strengthening, as well as the need to return to RICE therapy. Ice and NSAIDs will help control the symptoms but will not address the underlying pathology. Persistent swelling, pain, or episodes of instability should be evaluated further (see Advanced Assessment 15.8).

Patellofemoral Dysfunction

Patellofemoral dysfunction encompasses a continuum of disorders, including chondromalacia patellae and patellofemoral arthralgia. It is an overuse syndrome. Pain typically occurs when climbing stairs or when standing up after a period of sitting. Pain is often reproduced by direct pressure on the patella when the patient is supine with knee extended. X-ray films may reveal irregularity of the patella. Management is conservative; NSAIDs and quadriceps-strengthening exercises, such as tensing of quadriceps and straight-leg raising, are indicated.

Bursitis

Overuse may cause *anserine bursitis,* which produces pain over the inferomedial aspect of the patella, or *prepatellar bursitis,* which is usually a result of direct pressure and produces pain, swelling, erythema, and limited flexion. Initial treatment is the application of ice for 24 hours (then heat), rest, and use of NSAIDs. It is important to rule out infection with fluid aspiration and culture if infection is suspected.

Synovial Growths and Tumors

Pigmented villonodular synovitis is a benign neoplastic disorder, most often affecting young adults. Inflammation of the synovium, which lines the joints, bursae, and tendon sheaths, occurs causing recurrent unilateral pain, erythema, tenderness, and swelling, with intermittent knee locking. An orthopedic referral is necessary for diagnosis.

ANKLE PAIN

Most ankle pain is the result of ankle injury that results in ligamental damage (a *sprain*). A sprain occurs when the ankle is positioned in an unstable way, causing the ligaments to overstretch. A *first-degree sprain* involves stretching of ligamentous fibers; a *second-degree sprain* involves a tear of part of the ligament, with pain and swelling; and a *third-degree sprain* results in complete ligamentous separation (see Table 15.4). The inversion injury is most common, causing damage to the lateral ligaments of the ankle. By contrast, the medial ligaments are very tight and allow for much less motion than the lateral ligaments.

Initiate the history by asking an open-ended question about how the injury happened. Ask what happened after the injury: Was the patient able to get up and walk and continue activity? If so, a serious ligamental injury or fracture is less likely. If the ankle became swollen and discolored within minutes after injury, a severe soft tissue injury or even a fracture can be suspected.

The physical exam should include inspection and palpation. Look for swelling in the area of the internal and external malleoli and compare the landmarks with those of the opposite foot. The location of a deformity helps to localize the injury, and the degree of discoloration is associated with the extent of the injury. The ankle and foot should be palpated to localize the tenderness. It is also helpful to compare the passive ROM in one leg with the opposite extremity. It is important to note crepitus because it is often a sign of fracture. The anterior drawer test should be performed to test the stability of the anterior talofibular ligament, and the varus stress test should be performed to test the stability of the calcaneofibular ligament. (See Advanced Assessment 15.9.)

Radiographic examination of the injured ankle is necessary only in the following cases:

- The patient is not able to bear weight immediately after the injury.
- The ankle develops marked swelling and discoloration soon after the injury.

Table 15.4 Ankle Pain: Sprains

Classification	First Degree	Second Degree	Third Degree
Type of Pain	Stretching, minor tearing of ligament fibers	Partial tearing of ligament fibers	Complete tear of ligament
Clinical Manifestations			
Pain	Minimal	Mild to moderate	Severe
Swelling	Mild	Moderate	Significant; occurs rapidly, usually within the first 30 minutes
Ecchymosis	Mild	Moderate	Severe; occurs rapidly, usually within the first 30 minutes
ROM	Full, nonpainful	Slightly limited, painful	Limited; loss of function
Point tenderness	Mild	Point tenderness	Severe
Joint stability	Stable	Mild joint laxity	Abnormal
Weight-bearing	Able to bear weight	Painful or inability to bear weight	Inability to bear weight
Management	RICE Active ROM Partial weight-bearing activity Return to sports in 2–3 weeks with ankle support	RICE Active ROM Non–weight-bearing activity as tolerated Gradual return to sports with Aircast or taping	Refer to orthopedic specialist; surgery may be required Cast for 4–6 weeks No weight-bearing; rehabilitation Return to sports in 4–8 weeks with support
Complications	Recurrent sprains within 1 month if not fully rehabilitated	Recurrent sprains Joint instability Traumatic arthritis	Persistent instability Traumatic arthritis

RICE: rest, ice, compression, elevation; ROM: range of motion.

Advanced Assessment 15.9 Assessing Ankle Ligaments—Special Tests

Test	Comments
Anterior drawer test—to test stability of anterior talofibular ligament; place the ankle in approximately 20 degrees of plantar flexion	Stabilize the tibia, grasp the hindfoot, and pull forward. Asymmetrical or excessive motion will occur with chronic ankle laxity and severe ankle sprains.
Varus stress test—to test the stability of the calcaneofibular ligament	With the tibia stabilized and the ankle in neutral, grasp the calcaneus and invert the hindfoot. Excessive or asymmetrical motion will occur with chronic laxity of the calcaneofibular ligament.

- Pain occurs with ROM and manipulation of the areas most likely to be stressed in a particular injury.
- Crepitation occurs with palpation or movement of the ankle.
- There is a high risk for litigation.

Management includes application of ice or immersion in an ice water bath immediately after injury and every few hours for 48 hours after the injury, an elastic bandage or splint to stabilize the ankle against inversion and eversion stresses, limited activity until the pain and swelling subside, elevation of the affected foot, and the use of NSAIDs. Strenuous exercise should not be resumed until 2 weeks after the pain and swelling have ceased.

Differential Diagnosis

Nerve Entrapment

Nerve entrapment may occur secondary to ankle fracture, dislocation, or traction injury. If the tibial nerve is affected, there would be a loss of ankle plantar flexion, toe flexion, and weak ankle inversion.

Posterior Impingement Syndrome

Posterior impingement syndrome is most commonly seen in ballet dancers. It manifests with pain and swelling of the posterior ankle and worsens with plantar flexion or dorsiflexion of the great toe. Os trigonum is present on lateral x-ray film.

Referred Pain

Ankle pain may be referred pain secondary to disc herniation at the level of L5 to S1. Signs and symptoms include a sensory deficit over the malleolus, weak eversion, and a decreased Achilles reflex.

Peroneal Tendon Subluxation

Peroneal tendon subluxation may occur secondary to trauma; it will present with pain and a "snapping" over the posterior distal fibula. Pain will increase with active eversion of the dorsiflexed foot, and there may be palpable/visible movement of tendons.

Tendon Rupture

Achilles tendon rupture causes pain and inability to walk normally. Closed tendon ruptures usually result from a sudden excessive load applied to the musculotendinous unit, with failure occurring either within the tendon's substance (torn fibers) or at its insertion into the bone. A tendon rupture can occasionally occur spontaneously in healthy individuals from relatively minor trauma. Achilles tendon rupture is also an uncommon but potential side effect of fluoroquinolones.

Physical exam will usually reveal swelling, tenderness, and often bruising over the site of rupture. Test the tendon's continuity by performing Thompson's test. To do so, (1) have the patient lie prone, (2) bend the knee so that the leg is vertical, and (3) squeeze the calf. The test is positive if squeezing the calf does not produce plantar flexion of the ankle. This means the tendon is ruptured. Treatment is either surgical repair or immobilization with cast with the foot plantar-flexed.

Bursitis

Inflammation of the bursae of the ankle most commonly affects the retrocalcaneal bursa. There will be pain anterior to the Achilles tendon, just above its insertion into the calcaneus; the pain is aggravated by squeezing the area anterior to the tendon, as well as by dorsiflexion of the ankle. This injury is related to repetitive trauma.

Chronic Ligamentous Laxity

Chronic ligamentous laxity may produce few symptoms other than an aching and tenderness over ligaments after prolonged activity. Rest and NSAIDs are the treatment of choice.

Fracture

There will be pain, swelling, or inability to bear weight, decreased ROM, and obvious bony disruption on x-ray film. Stress fractures of the ankle may occur.

FOOT PAIN

The foot contains 26 bones, 33 joints, and more than 100 ligaments. Foot pain is usually related to an

inflammatory process resulting from trauma (13% of activity-related musculoskeletal injuries in men), a deformity, or a foot–shoe incompatibility. The feet are subjected to numerous forces: For example, when an individual is standing, forces exerted on the foot are equivalent to four times the individual's body weight. Any alteration in ability to use the feet for any reason, such as pain secondary to hammer toe or corns and calluses, will have a significant effect on the health and well-being of the patient.

General treatment measures for foot pain include the use of footwear with roomy toes, supportive arches, and low heels. Heel lifts, cushioned inner soles, and arch supports can provide significant relief when used appropriately. Referral to a podiatrist may be necessary.

Differential Diagnosis

Forefoot Problems

Common problems in the forefoot are calluses, corns, plantar warts, bunions, neuromas, and stress fractures. The history in patients with calluses, corns, and warts would reveal discomfort related to pressure, whereas stress fractures cause pain of acute onset involving the metatarsals. An interdigital neuroma causes tenderness in the third and fourth intermetatarsal space with radiation into the toes. Physical exam findings in patients with stress fractures include point tenderness and swelling over the involved bone. The hyperkeratotic lesions of calluses and corns may be indistinguishable from each other, but plantar warts can be distinguished by the punctate bleeding associated with the wart. Interdigital neuromas may sometimes produce a tender nodule in the intermetatarsal space. A *bunion* or *hallus valgus* is the deformity of the first metatarsophalangeal (MTP) joint associated with the lateral drift of the toe. This presents as a painful swelling on the dorsomedial aspect of the first metatarsal head. Foot–shoe incompatibility may produce physical findings such as the toe deformities of hammer toe and mallet toe.

Midfoot Problems

Midfoot problems are generally the result of pes planus, or flat foot. This is likely to produce pain and stiffness in the midfoot region, often associated with degenerative arthritis or laxity of the posterior tibial tendon. Tenderness to palpation usually occurs along the medial plantar border of the sole with flat foot. Flattening of the medial longitudinal arch of the foot and often a valgus deflection of the heel are indicative of this condition.

Hindfoot Problems

Common hindfoot conditions include plantar fasciitis, infracalcaneal bursitis, and posterior heel problems such as Achilles tendinitis and posterior bursitis. The history of individuals with plantar fasciitis includes subcalcaneal pain that sometimes radiates to the arch of the foot while the person is running or walking. The pain is worse in the morning. Infracalcaneal bursitis produces an aching sensation in the midplantar region of the calcaneus that becomes worse the longer the heel is weight-bearing. The pain associated with Achilles tendinitis is at or proximal to the insertion of the Achilles tendon onto the calcaneus. In this condition, the physical exam reveals swelling and erythema. The pain is increased with dorsiflexion of the ankle, and crepitus may be palpated. Infracalcaneal bursitis produces pain and tenderness to palpation in the midplantar aspect of the calcaneus. Plantar fasciitis findings typically include tenderness along the medial plantar aspect of the calcaneus, with forced dorsiflexion of the digits increasing the pain. Differential Diagnosis 15.5 presents common differential diagnoses and their treatment.

COMMON PROBLEMS

ARTHRITIS

Osteoarthritis

Osteoarthritis (OA), also known as *degenerative joint disease* (DJD) or "wear and tear" arthritis, is the most common articular disease in adults older than age 45. It is the most widespread form of arthritis and is a significant cause of functional impairment, chronic pain, and disability in the older population.

OA is a gradual and progressive joint disease typically found in middle-aged to elderly patients. OA is the most common form of joint disease and is the leading cause of disability in the older adult. Although symptoms of OA occur earlier in women, the prevalence among men and women is equal. In addition to age, risk factors include genetics, female sex, joint injury, past trauma, advancing age, obesity, and mechanical stress (Rakel and Rakel, 2011). OA is a joint condition in which loss of articular cartilage and degeneration occur, which leads to pain and often deformity.

Often, OA is classified as "primary" or idiopathic, resulting from one or more of the following:

- Advancing age
- Obesity
- Occupational overloading of joints
- Familial type II collagen gene polymorphisms

This is contrasted to "secondary" OA, which may develop at varying intervals after trauma, infection, osteonecrosis, congenital malalignment, or in the setting of inflammatory arthritis or metabolic disease. In reality, both primary and secondary OA may coexist.

OA actually encompasses a group of subtypes with different etiological factors but a common response pattern in joint tissues. This type of arthritis is primarily noninflammatory and involves a combination of

Differential Diagnosis 15.5 Foot Pain

Differential Diagnosis	Management
Forefoot	
Hallus valgus or bunion	Avoid pressure on the tender bunion, NSAIDs, protective shields, orthotic devices, appropriate footware; if no relief, consider surgery.
Enlarged bone on the medial side of the first metatarsal	
Corns and calluses with keratinized skin	Moleskin protection, gentle rubbing with pumice, separating toes with cushions or orthotics; if unrelieved, consider surgery.
Sesamoid disorders	Protect the injured part by limiting weight-bearing, wearing protective padding or strapping, and NSAIDs.
Localized pain and swelling over first MTP joint	
Neuromas	Shoe modification: wide toe box, metatarsal bar, and soft inner soles; NSAIDs; and in severe cases, corticosteroid injections to reduce inflammation.
Stress fractures	Rest and efforts to disperse weight-bearing away from the fracture such as stiff-soled shoe, metatarsal bar, walking cast.
Infection	Treatment as appropriate.
Flat feet	Orthotics.
Bunion	Pad; surgery.
Peripheral neuritis	Investigate cause.
Midfoot	
Pes planus	No treatment if asymptomatic; if symptomatic: flexible arch support, heel-cord stretching, and toe exercises such as picking up objects with toes and spreading toes.
Hindfoot	
Achilles tendinitis	Initial treatment: Rest, ice and use of NSAIDs, and immobilization. Heel lifts and heel-cord stretching exercises. Corticosteroids are contraindicated.
Plantar fasciitis	Heel lifts, padded heel cups, and orthotic devices. Acute treatment is rest, ice, NSAIDs, and local corticosteroid injections. Heel-cord stretching exercises and use of a nighttime dorsal splint to maintain ankle dorsiflexion and toe extension may be beneficial; surgical release of the plantar fascia is the measure of last resort.
Infracalcaneal bursitis	

MTP: metatarsophalangeal.

biomechanical stresses and biochemical changes in articular cartilage and synovial membrane. There is erosion and fibrillation of cartilage, with joint space narrowing and osteophyte formation. Principal sites for OA are the distal interphalangeal (DIP) joints, the proximal interphalangeal (PIP) joints, and the carpometacarpal (CMC) joint of the thumb in the hand; the first metatarsophalangeal or great toe joint; and the hips, knees, and cervical and lumbar spine. Although hand joints associated with the pincer grasp and lower-extremity weight-bearing joints are affected, the ankle, wrist, shoulder, and elbow are usually not, unless the cause of the arthritis is traumatic or occupational.

Epidemiology and Risk Factors

OA affects approximately 60 million Americans. Radiographic evidence of OA is present in about 33% to almost 90% of people older than age 65. Gender differences are not apparent before age 45. After age 50, however, women are more likely to have OA, with women representing 74% of cases, according to the Arthritis Foundation. The actual numbers are probably grossly underreported because many older adults are asymptomatic or do not report symptoms, which they mistakenly believe to be an inevitable consequence of aging, or for which they believe there is no treatment. Also, the definition of OA may differ among various authorities, leading to variations in reporting prevalence and incidence. Some health-care providers consider symptomatology alone, whereas others use radiographic (x-ray) evidence without symptoms; some include both. Studies stemming from autopsy analyses establish degenerative joint changes occurring as early as the second decade of life. Another confounding factor in interpreting prevalence and incidence is the fact that some sources list breakdowns by anatomical site, whereas others do not.

There is conflicting information on racial differences in rates of OA in African Americans and white Americans. Asian counterparts have a very low prevalence of hip OA, although hand OA is equally prevalent in Hong Kong Chinese and Europeans. Age is a risk factor, with a sharp increase in the middle to late years of life. The

Framingham Osteoarthritis Study and the English twin study have identified a genetic component in hand arthritis in women.

Genetic research on families with a preponderance of arthritis has demonstrated mutations of the *col2A1* gene, the precursor to type II collagen. Other genetic influences also have been identified, but the current approach to the study of genetics and OA is fraught with inconsistencies in defining the disease. Patients who have parents who developed OA at middle age or earlier or parents with polyarticular disease are considered at high risk for developing the disease themselves.

Obesity is a risk factor for arthritis of the knee and, to a lesser extent, the hip. Exercise, including recreational jogging, has not been shown to increase the risk of OA. Muscle weakness around the joints, abnormal gait pattern or weight-bearing, local joint injury, and repetitive occupational joint use are contributing factors. Cruciate ligament damage or meniscal tears, particularly when accompanied by partial or total meniscectomy, increase the risk of knee OA. Low levels of vitamin C and/or vitamin D have also been implicated as a risk factor for OA. Estrogen replacement therapy is associated with a reduced risk of knee and hip OA; it was also shown to have a moderately protective but not statistically significant effect against worsening of radiographic knee OA in a group of white American women enrolled in the Framingham study. Although all of these factors have been cited as having a role in OA, the definitive cause of the disease is not known. In general, biomechanical, biochemical, inflammatory, and immunological factors are all implicated in the pathogenesis of OA.

Pathophysiology

The exact pathophysiology of OA is still under study, with many promising developments on the horizon. Normal cartilage derives its viscoelastic and compressive characteristics from cellular and matrix components. Chondrocytes synthesize type II collagen and glycosaminoglycans to maintain the integrity of the extracellular matrix. These chondrocytes are also responsible for balancing cartilage degradation and repair. In contrast to the autoreactive inflammatory pathology associated with rheumatoid arthritis, systemic lupus erythematosus, and other inflammatory arthritides, in OA articular cartilage is thought to be initially damaged due to repetitive microtrauma or a single inciting macrotraumatic event. Bone and joint malalignment, ligamentous laxity, weakness in muscle groups that provide counterforce against the involved joint (e.g., quadriceps for the knee joint), and any type of underlying structural defect may magnify the damage imparted by this repetitive physical trauma. Proprioception is also impaired in affected knee joints. This diminishes muscular reflexes that normally provide compensatory mechanical mechanisms to counter destructive load-bearing forces on arthritic joints. In addition, underlying genetic defects in cartilage formation (e.g., type II collagen defects, ochronotic cartilage with abnormal pigment deposition) may lead to tissue damage from normal wear and tear in the absence of inciting physical trauma.

Mechanical loading of the joint has been shown to increase macromolecule formation by the chondrocyte within the extracellular matrix as a function of both load intensity and frequency of load-bearing, affecting not only the concentration of matrix proteoglycans but also the integrity of the collagen meshwork. The act of mechanical forces triggering biochemical reactions has been termed *mechanotransduction* and is only now beginning to be characterized within the chondrocyte. Although much of this pathogenesis is poorly understood and stems from preclinical animal studies, we know that cartilage matrix degradation predominates in OA, with greater fluid loss from joint cartilage in response to mechanical loading. In turn, attempts at repair by chondrocytes are ineffectual.

Current focus centers on the role of matrix metalloproteinases (MMPs) in mediating cartilage degradation. This family of proteolytic enzymes includes collagenase-1 (MMP-1), collagenase-2 (MMP-8), collagenase-3 (MMP-13), stromelysin (MMP-3), and gelatinase-A (MMP-2). They are secreted by chondrocytes and synovial cells and are regulated by plasmin, nitric oxide, interleukin-1 (IL-1), and other cytokines such as IL-6 and possibly tumor necrosis factor–alpha (TNF-α). Normally, these substances are tightly controlled by counterregulatory substances including tissue inhibitors of MMPs (TIMPs). However, in OA, pro-inflammatory cytokines, namely IL-1, stimulate MMPs and suppress cartilage self-repair by interfering with chondrocyte proliferation, collagen production, TIMP formation, and MMP inactivation. These processes are normally mediated by transforming growth factor–beta (TGF-β), which is found in decreased levels in OA patients. Dysregulated levels of anabolic cartilaginous growth factors including insulin-like growth factor–1 (IGF-1) and IGF-1 binding protein are also evident, as some studies have revealed lower levels of these factors in OA patients, as well. All these processes result in increased production of type 1 fibrous cartilage, rather than type 2 articular cartilage.

In addition, the disease process of OA includes sclerosis of underlying subchondral bone and abnormalities in the juxta-articular bone marrow. Abnormal bone deposition within the degenerating joint, which impinges on the joint space, is known as osteophyte formation. These osteophytes may give the impression of external bulging within the joint space, which may sometimes be mistaken for the inflammatory joint pathology of rheumatoid arthritis. However, if spinal osteophytes impinge on nerve roots, they may produce radicular symptoms, similar to those seen in intervertebral disc herniation.

Crystal deposition into the synovial fluid of osteoarthritic joints, particularly calcium pyrophosphate dihydrate and basic calcium phosphate crystals, also correlates with worsening degrees of radiographic joint pathology and cartilaginous fissuring. Although evidence for the pathophysiological nature of these crystals is primarily circumstantial, these crystals appear to initiate an inflammatory synovitis, MMP secretion, and synovial proliferation with subsequent cartilaginous destruction. Moreover, patients with an inherited predisposition to calcium pyrophosphate dihydrate deposition also develop severely degenerative OA.

Clinical Presentation

Subjective

Patients typically present with slowly developing, localized pain in the affected joint or joints that interferes with their usual activities. The onset is subtle, and the pain may be ignored initially. Patients with OA in the weight-bearing joints may have early morning stiffness or stiffness after inactivity, which subsides after 30 minutes, also referred to as the "gel phenomenon." Pain and stiffness are also present in hand OA, often accompanied by bony deformities such as Heberden's nodes, which affect the DIP joints, and Bouchard's nodes, which affect the PIP joints. Internal derangement in weight-bearing joints may cause them to "lock" or "buckle," increasing the risk for falls; patients often report that their knee "gave way" or "wouldn't bend." In the later stages of OA, pain may be also present at rest. OA may present as monoarticular or polyarticular.

The history should include information on the onset, location, and duration of pain; any self-care measures the patient has taken to alleviate pain and the effectiveness of these measures; and associated symptoms such as joint stiffness, swelling, or deformity. Does the pain interfere with sleep or awaken the patient at night? Inquire if there is a family history of OA. An occupational history should be explored for evidence of overuse; any trauma or surgery to the joint should be noted. Elicit a history of activity/exercise patterns, any changes in activities of daily living (ADLs) or instrumental ADLs, and weight changes, especially a gain in weight. Socioeconomic factors and vocational issues should be explored. It is also important to obtain a past or present history of any systemic illness or chronic disease state, along with a list of current medications, including over-the-counter (OTC) preparations, herbal remedies, and nutraceuticals. OA of the wrists, ankles, and shoulder is usually related to trauma or other secondary causes.

Objective

Typical clinical findings of OA include minimal or no swelling of affected joints, tenderness on direct palpation, crepitus, and reduced passive and active ROM. Crepitus is a common, although late, finding and a sensitive criterion for OA. There may be effusions in the large joints.

Physical exam findings include the following:

- Hands: Enlargement of the DIP and/or PIP joints. The CMC joint of the thumb may also be enlarged and in general there may be pain on motion.
- Feet: Swelling (bunion) of the big toe and DIP joints.
- Knees and hips: Possible pain and crepitus on passive ROM. There may be tenderness to palpation along the joint line, and some muscle atrophy may be present. Hard swelling, if present, is usually a result of bone spurs, whereas soft swelling is related to effusion. There may be significantly decreased ROM, both active and passive. Carefully examine the hip of any patient who complains of knee pain; pain referred to the knee may be the only symptom of hip OA.
- Spine: Degenerative changes are common. There may be limited motion and stiffness of the neck and/or lower back. Bony spurs at the facet joints may produce pain and compression of spinal root nerves.

The physical exam should include a functional status evaluation in the older adult. Gait abnormalities such as a limp are significant. Evaluation for spinal and hip alignment and leg-length discrepancy is helpful initially to detect contributing factors. Affected joints should be examined for tenderness, bony deformities, swelling, redness, warmth, and ROM. Tenderness along the joint line, crepitus, and limited ROM are typical but nonspecific findings. Knee joint effusion may also be seen, as well as Baker's cysts in the posterior popliteal area. Muscle strength, especially that of the quadriceps muscles, and joint stability should be assessed. The presence of fever or weight loss, especially when accompanied by fatigue and poor appetite, is suggestive of a systemic problem rather than OA; these symptoms need further investigation.

The most common symptom of OA is joint pain. OA pain tends to worsen with activity, more often following a period of rest. OA can also cause morning stiffness and generally lasts less than 30 minutes, unlike rheumatoid arthritis, which can cause stiffness for 45 minutes or longer (Rakel and Rakel, 2011). Frequently, the patient may report joint locking or joint instability. These symptoms result in loss of function, with patients limiting their ADLs due to the pain and stiffness. Early in the disease process, the joints may appear normal. However, the patient's gait may be antalgic if weight-bearing joints are involved.

The joints most commonly affected are the hands, knees, hips, and spine, but any joint can be involved. OA is often asymmetrical. Pain on ROM and limitation of ROM are common to all forms of OA. Table 15.5 explains the unique physical exam findings for common joints.

Table 15.5 Signs and Symptoms of Osteoarthritis

Hand	***Spine***
Pain on range of motion Hypertrophic changes at DIP and PIP joints (Heberden nodes and Bouchard nodes) Tenderness over carpometacarpal joint of thumb	Pain on range of motion Limitation of range of motion Lower extremity sensory loss, reflex loss, motor weakness caused by nerve root impingement Pseudoclaudication caused by spinal stenosis
Shoulder	***Hip***
Pain on range of motion Limitation of range of motion, especially external rotation Crepitus on range of motion	Pain on range of motion Pain in buttock Limitation of range of motion, especially internal rotation
Knee	***Foot***
Pain on range of motion Joint effusion Crepitus on range of motion Presence of popliteal cyst (Baker cyst) Lateral instability Valgus or varus deformity	Pain on ambulation, especially at first metatarsophalangeal joint Limited range of motion of first metatarsophalangeal joint, hallux rigidus Hallux valgus deformity (bunion)

DIP: distal interphalangeal; PIP: proximal interphalangeal.

Diagnostic Reasoning

Diagnostic Tests

Clinicians can make the diagnosis of OA based on the history and physical exam because OA is primarily a clinical diagnosis. Plain radiographs can be helpful in confirming the diagnosis and in ruling out other conditions (Fracture Management for Primary Care Expert Consult, M. Patrice Eiff and Robert Hatch, 2011). No laboratory tests are required to make the diagnosis.

Radiographic testing may be useful in the following situations:

- To establish diagnosis at the hip
- To assess disease severity at other joints
- To screen for other types of bone and joint pathology if pain is severe enough and disrupts sleep
- To determine baseline status to assess change over time

Early changes often do not appear, but as the disease progresses, x-ray findings include asymmetrical joint space narrowing, bony cysts and osteophytes, and subchondral sclerosis. Radiographic findings are poorly correlated to symptomatology. Further x-ray studies may be ordered to document progression of the disease if symptoms increase markedly, ADL levels change dramatically, or the patient is being evaluated for surgical intervention. MRI and CT scans may be ordered for patients with suspected spinal stenosis.

Laboratory testing is helpful in ruling out other conditions such as rheumatoid arthritis (RA), gout, lupus, sepsis, or polymyalgia rheumatica, but has little place in establishing a diagnosis of OA. Complete blood count (CBC), C-reactive protein, and erythrocyte sedimentation rate (ESR) are usually normal; the ESR in older patients is more likely to be elevated. Rheumatoid factor, antinuclear antibody, serum uric acid, or 24-hour urinary uric acid levels may be ordered to rule out RA, lupus, or gout, depending on the clinical presentation, but again may yield significant false-positive results. Synovial fluid analyses may be useful in ruling out inflammatory and/or infectious arthritis. (See Differential Diagnosis 15.6.)

Differential Diagnosis 15.6 Osteoarthritis

- Rheumatoid arthritis
- Crystalline arthropathies (i.e., gout and pseudogout)
- Inflammatory arthritis
- Seronegative spondyloarthropathies (e.g., psoriatic arthritis and reactive arthritis)
- Septic arthritis or postinfectious arthropathy
- Fibromyalgia
- Tendinitis
- Ankylosing spondylitis
- Avascular necrosis
- Patellofemoral arthritis
- Bursitis
- Lupus erythematosus
- Lyme disease
- Neuropathy
- Neuromuscular disease
- Parkinson's disease
- Osteopenia or osteoporosis
- Paget's disease
- Bone malignancy

The American College of Rheumatology (ACR) has identified criteria for the diagnosis of OA of the hand, knee, and hip.

Treatment

The goals of OA treatment include alleviation of pain and improvement of functional status. Optimally, patients should receive a combination of nonpharmacological and pharmacological treatment.

Nonpharmacological interventions, which are the cornerstones of OA therapy, include the following:

- Patient education
- Heat and cold
- Weight loss
- Exercise
- Physical therapy
- Occupational therapy
- Unloading in certain joints (e.g., knee, hip)

Four main categories of treatment choices are nonpharmacological, pharmacological, complementary and alternative, and surgical. In general, treatment should begin with the safest and least invasive therapies before proceeding to more invasive therapies. All patients with OA should receive treatment from the first two categories. Surgical management should be reserved for those who do not improve with behavioral and pharmacological therapy and who have intractable pain and loss of function (Sinusas, 2012).

Nonpharmacological therapy includes exercise and physical therapy that includes strengthening exercises and ROM exercises. The clinician should encourage regular exercise throughout the course of treatment and encourage weight loss for those patients who are overweight or obese. Consider physical therapy referral for supervised exercise and also bracing and splinting to help support painful or unstable joints. Therapeutic ultrasound is a physical therapy modality that is also used in OA treatment.

Pharmacological treatment should include acetaminophen for mild OA. If and when acetaminophen begins to fail in controlling symptoms or if symptoms are moderate to severe, NSAID therapy is recommended. NSAIDs are superior to acetaminophen for treatment of OA. Patients who take NSAIDs should be cautioned about the adverse effects, which may include gastrointestinal (GI) bleeding, renal dysfunction, and blood pressure elevation. COX-2 inhibitors (Celebrex) have an improved safety profile for adverse GI effects; however, they increase cardiovascular risks (Brown, 2012).

Opioids are used often in the treatment of OA pain; however, due to their potential for abuse, opioids should be an option only if the patient has not had a positive response to acetaminophen or NSAID therapy. Opioids should only be prescribed at low dosages and then slowly increased as needed, and the patient should be carefully monitored for potential dependence.

The ACR has issued guidelines for pharmacological treatment of OA of the hand, hip, and knee. For *hand* osteoarthritis, the ACR conditionally recommends using one or more of the following:

- Topical capsaicin
- Topical NSAIDs
- Oral NSAIDs
- Tramadol

The ACR conditionally recommends against using intra-articular therapies or opioid analgesics for hand OA. For patients 75 years and older, the ACR conditionally recommends the use of topical, rather than oral, NSAIDs.

For *knee* osteoarthritis, the ACR conditionally recommends using one of the following:

- Acetaminophen
- Oral NSAIDs
- Topical NSAIDs
- Tramadol
- Intra-articular corticosteroid injections

The ACR conditionally recommends against using chondroitin sulfate, glucosamine, or topical capsaicin for knee OA.

For *hip* osteoarthritis, the ACR conditionally recommends using one or more of the following for initial management:

- Acetaminophen
- Oral NSAIDs
- Tramadol
- Intra-articular corticosteroid injections

The ACR conditionally recommends against using chondroitin sulfate or glucosamine for hip OA.

The Agency for Healthcare Research and Quality (AHRQ) comparison found that acetaminophen was modestly inferior to NSAIDs in reducing osteoarthritic pain but was associated with a lower risk of adverse GI effects. On the other hand, acetaminophen poses a higher risk of liver injury. The AHRQ also noted that topical diclofenac was found to have efficacy similar to that of oral NSAIDs in patients with localized OA.

Management

The principles of management of OA are to control pain and other symptoms, to maximize functional independence and mobility, to minimize disability, and to preserve quality of life. A variety of modalities are utilized to achieve this, including patient education and self-care strategies, nonpharmacological and pharmacological interventions, and surgical management (see Table 15.6).

Pharmacological Management

Acetaminophen The goal of pharmacological management is pain control, with acetaminophen (Tylenol) as the first-line agent. Tylenol two tablets—regular strength

Table 15.6 Management of Osteoarthritis

General Management Pharmacological	Nonnarcotic analgesics Topical agents (e.g., capsaicin) Nonacetylated salicylates NSAIDs Intra-articular corticosteroids
Nonpharmacological	Activity modifications Exercise (biking, walking, swimming) Physical therapy Application of heat/cold Psychosocial support Pain management Self-help programs Surgical
Specific Management OA of the hand	Pharmacological: Analgesics Nonpharmacological: Occupational therapy
OA of the hip	Pharmacological: Analgesics, NSAIDs (at analgesic or anti-inflammatory doses) Nonpharmacological: Occupational therapy, physical therapy Surgical
OA of the knee	Pharmacological: Analgesics, NSAIDs (at analgesic or anti-inflammatory doses), intra-articular corticosteroids (intermittent) Nonpharmacological: Occupational therapy, physical therapy Surgical

(325 mg) or extra strength (500 mg)—may be taken every 4 to 6 hours as needed, or Tylenol Arthritis Extended Relief Caplets (650 mg) two tablets may be taken every 8 hours as needed, not to exceed 4,000 mg in 24 hours. The maximum daily dose of acetaminophen in patients receiving warfarin therapy should not exceed 2,500 mg PO. Several controlled studies have established the efficacy of acetaminophen, although other studies demonstrate that NSAIDs are more effective. However, recommendations begin therapy with acetaminophen, because this is a viable strategy for a long-term treatment plan. Patients should be cautioned about using alcohol with acetaminophen. Hepatotoxicity is a serious potential adverse effect. Patients should also be educated to read the label on OTC cold and sinus preparations because some of them contain acetaminophen. The acetaminophen in these preparations counts toward the daily maximum of 4,000 mg.

Nonsteroidal Anti-Inflammatory Drugs NSAIDs actually comprise several categories of pharmacological agents, all sharing comparable anti-inflammatory properties. Although each class acts in an individual manner, all inhibit the production of prostaglandins, which are inflammatory mediators. Cyclooxygenase (COX), or prostaglandin endoperoxide synthase, is the first enzyme in the prostaglandin synthesis pathway. This enzyme transforms arachidonic acid to other prostaglandin breakdown products. Two forms of COX are present: COX-1 is normally present in blood vessels, stomach, and kidney and promotes the normal functioning of those systems; COX-2 is generated in inflammatory settings by cytokines and inflammatory mediators. Aspirin and NSAIDs inhibit cyclooxygenase enzyme and prostaglandin production, but they have no effect on the arachidonic–lipoxygenase pathway resulting in the formation of leukotrienes. NSAIDs are nonselective COX inhibitors. All possess antipyretic, analgesic, and anti-inflammatory properties. Inhibition of COX-1 is largely responsible for the adverse effects associated with NSAID therapy, including GI bleeding, ulcerogenic activity, fluid retention, and blockade of platelet aggregation. Patients on NSAIDs are four to five times more likely to suffer GI bleeding than individuals who are not taking the drugs. The risk of bleeding is increased during the first month of treatment and with increased dosages of the NSAID; older age and polypharmacy are also risk factors. It was hoped that the use of the COX-2 inhibitors would be equally effective for pain while curbing GI side effects or platelets; however, subsequent data regarding the increased risk of vascular events such as myocardial infarction (MI) or transient ischemic attack (TIA)/stroke have resulted in withdrawal of several of these agents from the market. NSAIDs also interact with several other classes of medication. In addition, NSAIDs are well known to cause fluid retention, as well as having the potential to cause nephrotoxicity.

When initiating NSAID therapy, it is best to begin with the lowest dose possible and increase as needed. It is important to question the patient about use of OTC medications because many patients with OA take ibuprofen (e.g., Advil, Nuprin, Motrin IB) in a nonprescription strength for headache, fever, or other minor discomforts and do not associate the OTC form with prescribed medication. If the patient is intolerant of one medication in a specific class, another one in the same class may prove to be satisfactory. Individualization of therapy is the key to successful management.

Because of emerging data indicating that the COX-2 inhibitor celecoxib may be associated with increased risk of serious cardiovascular events (MI, TIA), especially when used for long periods of time or in very high-risk settings (such as after surgery), the U.S. Food and Drug

Administration (FDA) has issued a recommendation that prescribers consider this emerging information when weighing risks versus benefits for individual patients. According to the FDA, patients who are at high risk of GI bleed, have a history of intolerance to nonselective NSAIDs, or are not doing well on nonselective NSAIDs may be appropriate candidates for COX-2 inhibitor therapy; also, individual patient risk for cardiovascular events and other risks commonly associated with NSAIDs should be considered. There is considerable variability among patients in both effectiveness and tolerance of NSAIDs. If one particular drug proves ineffective or unacceptable, benefit may be obtained by changing to a drug of a different class. The doses of these drugs should be individualized. The addition of a proton pump inhibitor, histamine-2 blocker (H_2 blocker), or the prostaglandin analog misoprostol to NSAID therapy helps protect against gastroduodenal ulceration. In addition, meloxicam (Mobic) is a preferential inhibitor of COX-2, but it is not a true COX-2 inhibitor according to FDA criteria. It seems to be well tolerated with few side effects of drug–drug interaction. The American Academy of Family Practice Physicians has issued the following recommendations regarding NSAID use:

- Initiate therapy with acetaminophen, and if NSAIDs are needed, use the lowest dose for the shortest duration possible.
- Avoid NSAIDs in patients with preexisting renal disease, congestive heart failure, or cirrhosis.
- Avoid NSAIDs and aspirin in patients taking anticoagulants.
- Creatinine should be monitored for patients on angiotensin-converting enzyme inhibitors or angiotensin receptor blockers who are prescribed NSAIDs on a regular basis.

Recommendations from other medical experts emphasize that conservative treatments such as physical therapy and exercise should be first-line management. If NSAIDs must be used, those with the highest COX-1 selectivity should be tried initially (ibuprofen, aspirin, naproxen).

Additional Pain Relievers Tramadol hydrochloride (Ultram) is a nonopioid pain reliever that is indicated for moderate to moderately severe pain. It is available as a combination drug with acetaminophen that works synergistically; it can also be taken with NSAIDs. It is contraindicated with alcohol, hypnotics, and narcotics, and should be used with caution in patients with the potential to abuse it. There is no evidence that this medication is any more effective than NSAIDs. Likewise, although there are times when the prescription of opioids might be appropriate, no evidence exists that these medications provide any more relief than NSAIDs; given the side effects and abuse potential, they should be used only in selected situations. There is no clear evidence that muscle relaxants or benzodiazepines are helpful adjuncts, although some clinicians continue to prescribe them because actual spasms of the paraspinous muscles are elicited on physical exam in the case of vertebral OA.

Other medications such as gabapentin (Neurontin), selective serotonin reuptake inhibitors, and tricyclic antidepressants have also proven effective in the management of patients with OA who have chronic pain.

Glucosamine with or without chondroitin, a dietary supplement not regulated by the FDA, is currently not recommended by the American Academy of Orthopaedic Surgeons (AAOS) for knee OA (Level I; AAOS, 2008).

Topical agents such as capsaicin (Zostrix) cream, applied three to four times daily to the painful areas, either alone or in concert with oral pharmacotherapy, may be helpful. The patient should be cautioned to avoid rubbing the cream in the eyes and to wash hands carefully after using capsaicin to avoid irritation. Some redness and burning at the site of application is normal initially, but it should disappear after 3 to 5 days. If irritation persists, the medication should be discontinued. Other topical agents, such as Ben Gay, Icy Hot, and similar preparations, are menthol based and have a temporary, local effect. Topical preparations also give the patient a sense of control over his or her own treatment. (See Drugs Commonly Prescribed 15.2: Pharmacological Treatment of Osteoarthritis.)

Intra-articular Injections Two groups of drugs are injected intra-articularly, particularly in arthritis of the knee. Intra-articular steroids have been used for some time in the treatment of OA of the knee. Several controlled studies document their efficacy for up to 4 weeks although some patients report a response for up to 6 months after injection. Agents include triamcinolone hexacetonide, triamcinolone acetonide, and methylprednisolone (Solu-Medrol). A 1% lidocaine solution is usually mixed with the steroid before injection. Patients are instructed to rest the joint for a day and to limit physical activity for 48 to 72 hours after the injection. The hip may also be injected. Joint injection is also used in these and other joints for bursitis or tendinitis.

The use of intra-articular injections of corticosteroids should be judicious: No more than three to four injections should be done per year and up to a maximum of 12 injections per joint, and they should be used only in episodes of acute flare-up. If steroid injections are administered excessively, they can accelerate joint deterioration. There is consistent evidence that intra-articular corticosteroid injections of the knee are effective for short-term pain relief (Stephens et al, 2008).

After the introduction of the needle into the joint and before steroid administration, aspiration of as much synovial fluid as possible should be attempted. Aspiration often provides symptomatic relief for the patient and allows laboratory evaluation of the fluid, if necessary. Infected joint fluid and bacteremia are contraindications to steroid injection.

In patients with osteoarthritic knee pain, steroid injections generally result in clinically and statistically significant pain reduction as soon as 1 week after injection. The effect may last, on average, anywhere from 4 to 8 weeks per injection, but the benefit is unlikely to continue beyond that time frame. Corticosteroid injections are effective for hip OA, with benefits often lasting as long as 3 months. Repeat injections are possible in the same joint, but usual practice is limited to four injections yearly.

Viscosupplementation Viscosupplementation with intra-articular hyaluronic acid is also used for treatment of knee OA. Hyaluronic acid is a naturally occurring component of synovial fluid; its purpose is to lubricate the joint for low-impact activities and potentially to prevent mechanical joint damage during high-impact activities. In patients with OA, the viscosity and elasticity of synovial fluid are decreased; there may be a lower concentration and limited distribution of hyaluronic acid. Consequently, all of the rheological features of synovial fluid, such as shock absorption, lubrication, and protection, may be decreased. This further increases damage to synovial tissue and the articular cartilage surface. Hyaluronan (Hyalgan), hylan G-F 20 (Synvisc), and hyaluronic acid (Orthovisc, a highly purified, high molecular weight form of hyaluronic acid, approved for use in the United States only fairly recently) are intended to restore all of the protective functions found in normal synovial fluid. They are indicated for pain relief of knee OA that has failed to respond to conservative measures. Intra-articular injections of hyaluronic acid are marketed as medical devices, not medications, and may be used in conjunction with NSAIDs. Hyaluronic acid is injected once a week for 3 to 5 weeks depending on the preparation, and it may provide benefit for 6 months or longer. Both hyaluronan and hyalin are produced from chicken combs, so patients should be screened for any allergy to avian proteins, feathers, and egg products before injection of hyaluronic acid. Other contraindications for intra-articular injections include knee joint infections, skin diseases, or skin infections at the injection site. If there is joint effusion, aspiration of synovial fluid before injection is advised. Adverse effects of hyaluronic acid injections include transient, localized pain, burning, and swelling at the injection site. Several studies have demonstrated the efficacy of viscosupplementation as equal to or better than continuous NSAID therapy, with significant improvement in pain at night or at rest as well as improvement of pain on motion, including walking pain. Duration of benefit was 8 to 12 months. Intra-articular injection has not been shown to be 100% effective; some studies suggested that the benefit was confined to patients with mild degenerative arthritis. Other conflicting information about viscosupplementation indicates the need for more studies and more rigorous methodology. The AAOS does not recommend for or against viscosupplementation at this time due to inconclusive results. Viscosupplementation is costly and is often not used unless the patient has insurance that will cover this cost.

Surgical Intervention

If nonsurgical strategies fail to provide sufficient pain relief and maintenance of function, referral to a rheumatologist or an orthopedic surgeon for surgical evaluation is indicated. Arthroscopic procedures can include joint lavage, partial medial or lateral meniscectomy or chondroplasty as indicated, lateral patellar retinacular release, fracture drilling of full-thickness defects, or chondral grafts. The AAOS does not currently recommend joint lavage or debridement; partial meniscectomy is advised only when there is strong evidence of a torn meniscus in addition to the OA. Large or open surgical procedures could include osteotomy and partial or total joint arthroplasty. For maximum success, ongoing communication among patients, medical and surgical providers, and physical therapists is essential in identifying appropriate candidates for surgery, treating comorbidities, and establishing rehabilitation goals. Outcomes following total hip and knee replacement demonstrated a higher level of postoperative function and better quality of life in candidates who had surgery earlier rather than waiting until the pain was intolerable and functional abilities had declined. It is also known that psychosocial factors such as motivation and emotional and social functioning (measured at baseline) are strong predictors of postoperative recovery. Annual radiographs to evaluate the position and fixation of the prosthetic components may also be recommended.

Surgery should be reserved for patients whose symptoms have not responded to other treatments. Indication for surgery is continued pain and disability despite conservative treatment. Arthroplasty consists of the surgical removal of joint surface and the insertion of a metal and plastic prosthesis. The prosthesis is held in place by cement or by bone ingrowth into a porous coating on the prosthesis. The use of cement results in faster pain relief, but bone ingrowth may provide a more durable bond; accordingly, prostheses with a porous coating are used in younger patients. Arthroplasty is performed if all other modalities are ineffective and osteotomy is not appropriate or if a patient cannot perform ADLs despite maximal therapy. The most effective surgical intervention is total joint replacement, with excellent patient outcomes following total joint replacement of the hip, knee, and shoulder. Most current joint prostheses function well for 15 to 20 years. After joint replacement, patients require partial weight-bearing, which progresses to full weight-bearing in 1 to 3 months; ROM and strengthening exercises are started within a few days after joint-replacement surgery and continued until the patient has good ROM and strength.

Long-Term Pain Management

For patients who are not candidates for surgery and who have intractable pain, long-term pain management is necessary. Goals of long-term pain management are to

maximize quality of life and minimize pain and functional loss. Consultation with a pain management specialist for collaborative management may be beneficial; the use of alternative treatments, including massage therapy, acupuncture, or acupressure, can further enhance pain management and promote a feeling of relaxation and well-being. Pharmacological management should be individualized; it should take into consideration comorbidities, other medications, age, and functional abilities.

New technologies continue to be developed for this disabling disorder. Newer medications, complementary therapies, different prosthetic joint components, osteochondral replacement procedures, and gene therapy for rare hereditary forms of OA are some promising new directions. (See Nursing Research–Based Practice Box 15.1.)

Nonpharmacological Management

Self-Care Strategies Initial management of OA includes patient education about the nature of the disease, the role of the patient in self-management, and sources of information and support for the patient. The Arthritis Foundation is an excellent resource and offers information sheets, local support groups, and an arthritis self-help course that includes exercise, joint protection, and relaxation techniques, along with information on medications that are typically used to manage symptoms. Weight loss is often an important component of the plan of care (see Table 15.7).

Involvement of the patient's spouse or significant other in the education and support of the individual with arthritis, specifically in helping him or her to develop coping skills, has proven superior to working with the patient alone. In a recent study of patients with OA, an informal network of social support appeared to be effective in mitigating the depression and functional limitations imposed by the disease and significantly enhancing quality of life. Trials of regular monthly phone calls by trained lay personnel to patients, discussing issues such as pain, medication, and treatment adherence, access to medical services, and functional concerns, were also effective. Patients experienced improvement in pain status and function with specific counseling; medical costs were negligible. (See Nursing Research–Based Practice Box 15.2.)

Physical Therapy Nonpharmacological management strategies include weight loss (when appropriate) and physical therapy for muscle strengthening, particularly quadriceps strengthening for patients with knee OA. The physical therapist also evaluates mobility and the need for assistive devices such as canes or walkers to reduce load-bearing on the arthritic joint. The physical therapist may recommend environmental modifications to maximize functional independence and safety. Other orthotic devices, such as shoe lifts, splints, or bracing, may be prescribed to improve biomechanics. Heat, ice, or ultrasound may be applied locally to decrease pain. Whenever feasible, a supervised exercise program incorporating aerobic and resistive components should be instituted. Several significant studies of arthritis patients utilizing comparison groups attest to the safety and efficacy of fitness training programs versus ROM and health education alone. Participants in the fitness program experienced better task performance and reported less physical disability, less pain, and improved psychological functioning. Aquatic exercise programs are also excellent, particularly those that are tailored to the needs of arthritic patients.

Nursing Research–Based Practice 15.1

McCaffrey, R. The effect of music on acute confusion in older adults after hip or knee surgery. *Appl Nurs Res* 22:107–112, 2006.

McCaffrey (2006) used a randomized controlled design to test the effectiveness of music listening as a tool for decreasing acute confusion and maintaining cognitive function in older adults after hip or knee surgery. Twenty-two older adults undergoing hip or knee surgery were randomized into either a control group that received standard postoperative care or an experimental group that received standard care with the addition of the music intervention. Levels of cognitive function were found to be similar preoperatively in both groups when measured by the Mini–Mental State Exam (MMSE). All members of the experimental (music) group listened to lullaby music on transfer to the orthopedic floor from recovery. When alert, participants were asked to choose their own music from a preselected sample. The cognitive function and acute confusion of the control and experimental groups were then compared using the MMSE and NEECHAM Acute Confusion Scale, respectively, on days 1, 2, and 3 postoperatively. McCaffrey (2006) found that older adults who listened to music postoperatively had increased levels of cognitive functioning in comparison to the control group on postoperative days 1 and 2, with no significant difference on day 3. In addition, the music listening group achieved higher scores on NEECHAM on all three postoperative days, indicating decreased levels of acute confusion in comparison to the control group. Although the study was limited by its small sample size, the findings have implications for improving the nursing care of older adults after hip or knee surgery. "Music is a safe, inexpensive, easy-to-use intervention that can be used by nurses to improve cognition and episodes of acute confusion, thereby improving recovery in older adults after hip or knee surgery" (p. 111).

Table 15.7 Nonpharmacological Therapies for Osteoarthritis

Nonpharmacological Therapies	Comments
Continued reassurance and support	Simply telephoning patients periodically can be helpful; support group.
Patient education	Provide materials.
Protection from overuse	Educate.
Exercise: Only 24% of patients with OA report a level of activity consistent with health; >75% sedentary	Gentle, regular joint exercise helps maintain function and manage pain; water exercise especially effective; other non–weight-bearing, bicycling, for example, preserve muscle support; isometric exercises to maintain strength; moderate to vigorous exercise three times a week can lead to dramatic improvements.
Weight loss—BMI should be 25 or lower	Especially important for patients with lower extremity problems; needed after joint replacement also to preserve joint implant.
Surgery—indicated if patient has pain at rest, at night, unable to sleep, unacceptable loss of joint function	Joint replacement (hip and knee replacement especially effective in pain and function); patients who have undergone earlier preemptive procedure such as arthroscopic joint debridement or osteotomy may eventually require joint replacement.
Heat/ice	Application of heat to the OA joint effective—hot shower, bath; ice occasionally.
Shoe inserts, patellar taping, bracing (knee), gait aids (cane)	A variety of mechanical aids useful for support; patellar taping is recommended by the American Academy of Orthopedic Surgeons; shoe inserts and bracing are not recommended (Level II).

BMI: body mass index; OA: osteoarthritis.

Nursing Research–Based Practice 15.2

Davis, GC, and White, TL. A goal attainment pain management program for older adults with arthritis. *Pain Manage Nurs* 9(4):171–179, 2008.

The purpose of this study was to test the effectiveness of the Goal Attainment Pain Management Program (GAPMAP) for promoting the self-efficacy of older adults in managing chronic musculoskeletal pain associated with rheumatic disease. Seventeen older adults living in independent-living residential settings were included in the study, with an average age of 79.29 years. The GAPMAP intervention took place over a 3-month period and initially involved small group meetings to discuss pain management strategies and potential barriers to pain management. Participants then met with the nurse researchers individually to set personalized pain management goals. Attainment of these goals was assessed at the end of the 3 months. Participants received follow-up phone calls at weeks 1, 4, and 8 to assess progress and allow for discussion.

A significant finding of this study was that 13 of the 17 participants either met or exceeded their expected goals, examples of which include "pain reduction, pacing activities, walking, weight loss, performing selected exercises, and community participation" (p. 176). Additionally, participants were more likely to use "exercise" and "a heated pool, tub, or shower" as pain management strategies after the intervention. "Exercise and distraction" were found to be more helpful for participants after intervention, and there was a significant improvement in both the "experience of living with persistent pain" and "expected outcomes of pain management" (p. 177). The results of this study, although preliminary, highlight goal setting as a tool that nurses can use to help older adults take greater control over their own pain management. Supporting older adults to maintain their autonomy and participate in their own care through programs such as GAPMAP is an important part of nursing practice. More research with a larger sample size would be important for assessing the generalizability of these findings when applied to other aspects of the care of older adults.

Transcutaneous electrical nerve stimulation is sometimes used for arthritic pain, but studies to date have not established its effectiveness. Use of pulsed electric and electromagnetic fields (PEMF), more commonly used for the treatment of nonunion fractures, has shown some promise in preliminary studies of patients with knee OA, but further studies are needed before PEMF can be recommended as adjunctive treatment for OA.

Occupational Therapy Short-term occupational therapy to maximize ADL abilities and evaluate the need for

adaptive devices is often overlooked, but it can be very valuable to the patient with arthritis. Devices such as a raised toilet seat, toilet side rails, elastic shoelaces, reachers, and various kitchen accessories can enhance functional capacity and independence.

Complementary Therapy Acupuncture and nutritional therapy (including vitamin supplementation) are other therapies used for the management of OA and other musculoskeletal problems. (See Complementary Therapies 15.1.) Although some studies suggest that acupuncture may be beneficial as adjunctive treatment for OA, results are inconclusive. The AAOS does not recommend for or against acupuncture in OA of the knee due to conflicting evidence. Methylsulfonylmethane and *S*-adenosyl methionine are other dietary supplements some patients find beneficial, although at present no evidence exists to support this. Therapeutic magnets also appear helpful to some patients anecdotally.

Follow-up and Referral

Patients with OA may be referred to a rheumatologist or orthopedic surgeon for collaborative management. When conservative measures fail, the patient's quality of life can be markedly diminished. Frequent or constant disabling pain, especially pain at rest, and functionally limiting symptoms are the most important criteria for orthopedic referral. Patients may also be referred to physical therapy or occupational therapy for functional evaluation, education in joint preservation, and recommendations for environmental modifications to maximize function. Other options include referral to a pain management specialist, a professional massage therapist, or a licensed acupuncturist. Referral to the Arthritis Foundation for patient education and support is also valuable. The patient should be seen for follow-up at 3- to 6-month intervals and should be instructed to contact his or her primary health-care provider if pain increases or functional status declines. ROM and functional status should be assessed at each visit. There are a number of scales, such as the Arthritis Impact Measurement Scale–2, that allow the clinician to monitor the patient's perception of his or her progress with greater accuracy. This scale can be viewed at www.proqolid.org/instruments/arthritis_impact_measurement_scales_aims2. A short version of this scale is available also. A variety of other scales measure function and disability, such as the Pain Disability Index available at www.chronicpainnetwork.com/pdf/Pain_Disability_Index.pdf and the Stanford Health Assessment Questionnaire available at http://aramis.stanford.edu/HAQ.html. It is important to monitor all patients on aspirin or NSAID therapy for GI blood loss and cardiac, renal, and mental status. Practitioners should order periodic CBC, renal function tests, and tests for occult blood in stool.

Patient Education

Education of the patient and support persons is essential to successful management of OA. The Arthritis Foundation is an excellent resource for patient education, as well as a variety of services that are provided at the local and national level. In addition, courses such as the Arthritis Self-Help Course (ASHC) and People with Arthritis Can Exercise are available. Research has shown that patients who complete the ASHC show a decrease in pain and physician visits, even with increased physical disability. The improvements, sustained over a 4-year period, are attributed to these patients' feelings of enhanced self-efficacy.

Exercise programs should be individualized, with protection of the weight-bearing joints. Swimming or water exercise (which minimizes impact on joints) is especially recommended. Rest after exercise is also important.

The patient with OA needs to be aware of potential adverse effects of medications and drug interactions. Key areas for education include acceptance of the chronic nature of OA and lifestyle management to maximize function and minimize pain and the preservation of joint function. Vocational rehabilitation may also be necessary.

GOUT

Gouty arthritis accounts for approximately 3.9 million outpatient visits (Eggebeen, 2007). Gout is a disorder related to hyperuricemia. Urate crystals are deposited in certain joints, causing acute pain and edema. It typically occurs in the first metatarsophalangeal joint of the foot (podagra), but it may affect the wrist, elbow, or finger. Usually only a single joint is involved, with erythema, swelling, heat, and exquisite pain, but 10% to 15% of the patients with gout present with polyarticular symptoms. Attacks spontaneously resolve in 1 week but will recur with more frequency and severity. Diagnosis is made by joint aspiration; clinical symptoms are also used to diagnose. Acute episodes respond to oral ibuprofen; oral or IV colchicines may also be used initially, although GI side effects are a limiting factor. Lifestyle counseling regarding obesity, avoidance of high-purine foods, and alcohol moderation is indicated. Further testing is indicated if episodes recur despite lifestyle medications. Hyperuricemic agents such as allopurinol or febuxostat (Uloric) may be indicated for regular use. Urolithiasis is more common in patients with gout. (See Chapter 16 for a complete discussion of gout.)

OSTEOPOROSIS

Osteoporosis is a generalized skeletal disorder characterized by normal bone mineralization but low bone mass (bone mineral *density*) and disruption of the bony architecture, both of which result in an increased risk of fragility fractures. Its chief clinical manifestations are vertebral and hip fractures, although fractures can occur at any skeletal site. This is contrasted with *osteopenia,* which is a less severe form of decreased bone mineral density, and *osteomalacia,* which denotes a decrease in actual bone mineralization. Osteoporosis is

now recognized as a significant public health concern with potentially devastating consequences in both human and economic terms. Increasing attention to women's health issues, the application of epidemiological research in prioritizing public health problems, and the need to minimize health-care expenditures have all contributed to recent efforts aimed at the prevention, identification, and effective treatment of this condition to avoid fractures. Fractures associated with osteoporosis are not only a physical stress to the individual and a burden for the health-care system; they also inflict great strain on the psychosocial well-being of individuals who suffer fractures and on the family or friends who take on the role of caregiver.

Epidemiology and Causes

Osteoporosis is characterized by microarchitectural deterioration of bone tissue, which leads to low bone mineral density (BMD) and fragility and a consequent susceptibility to fractures. Epidemiological studies in Europe, Japan, and the United States reveal that an estimated 75 million people are affected by osteoporosis. Roughly 4 out of 10 white women older than age 50 in the United States will experience a hip, spine, or wrist fracture during the remainder of their lives. Looking ahead, the lifetime risk of fractures will increase for all ethnic groups as people live longer. Approximately 10 million individuals older than age 50 in the United States have osteoporosis of the hip. An additional 33.6 million individuals older than age 50 have low bone mass, or osteopenia, of the hip and thus are at risk of developing osteoporosis and its potential complications later in life. Common consequences of osteoporosis are vertebral fractures and fracture of the hip and distal radius. In addition, a diagnosis of osteoporosis can lead to depression, a change in role, loss of independence, body deformities, and a real fear of initial or subsequent osteoporotic fractures.

As a result of both the aging of the population and the rise in the age-specific incidence of osteoporosis, the number of osteoporotic fractures has been increasing annually. Approximately 1.5 million osteoporotic fractures of the vertebral body, proximal femur, or distal radius occur each year in the United States. In 2005, osteoporotic fractures accounted for an estimated annual cost in excess of $19 billion per year. Proximal femur fractures, associated with the greatest health-care costs, are accompanied by a 20% risk of dying within 1 year of the fracture and impair the ability to perform ADLs in up to 75% of patients who survive. Women are more likely to have osteoporosis, but men also suffer from this condition. White women are more susceptible than black women; the prevalence of osteoporosis in Hispanic and Asian women is similar to that of white women.

Unless comprehensive prevention, screening, and treatment programs are initiated, as the average age of the American population continues to increase over the next 30 years, costs related to bone fragility could more than double. Women have two to four times greater lifetime risk of sustaining an osteoporotic fracture than men do as a result of the loss of BMD following the cessation of ovarian function at menopause. Bone loss after menopause is caused predominantly by estrogen deficiency and is most rapid (up to 7% per year) in the first decade after menopause. Postmenopausal osteoporosis is more prevalent in white and Asian women than in women of other races, with the majority of white women developing osteoporosis by the end of the first postmenopausal decade. By age 65, one-third of women will have had a vertebral fracture, and by the ninth decade of life, one in three will have had a hip fracture. The incidence, prevalence, and pathogenesis of bone loss in men are incompletely understood, and more research is called for in this area. Fractures of any type from osteoporosis are associated with a significantly higher likelihood of both physical and functional limitations. Patients who have already sustained a fracture from osteoporosis have a more than a fivefold increase in the risk of sustaining another fragility fracture.

The cause of osteoporosis is multifactorial. Although genetic factors are important determinants of bone density, other lifestyle, disease-related, and medication-related factors also contribute to an individual's risk for having osteoporosis, as shown in Risk Factors 15.1.

Risk Factors 15.1 Osteoporosis

Lifestyle	Low body weight Cigarette smoking Excessive alcohol intake Low dietary calcium intake Vitamin D deficiency
Disease-related risk factors	Thyrotoxicosis Hyperparathyroidism Cushing's disease Hypogonadism Rheumatoid arthritis Inflammatory bowel disease Chronic renal insufficiency Malabsorptive diseases Secondary estrogen deficiency resulting from anorexia or overexercise
Medication-related risk factors	Glucocorticoids Excessive thyroxine Long-term use of phenytoin
Other risk factors	Advanced age Family history of osteoporosis Postmenopausal Genetic predisposition

Although genetic factors may account for up to 70% of the variance in peak bone mass, many lifestyle factors play a significant role, and most are amenable to interventions aimed at primary and secondary prevention and treatment of osteoporosis. Regular exercise has been shown to preserve BMD, whereas a sedentary lifestyle probably contributes to osteopenia. Weight-bearing exercise, such as walking, is considered the best form of activity and is associated with higher bone density. There is increasing evidence that muscle strength training may prevent further loss of BMD in postmenopausal women. Further, the improved mobility, agility, and muscle strength that occur in people who engage in regular exercise may help to prevent falls and associated fractures.

The primary dietary risk factor for osteoporosis is lack of adequate calcium intake throughout the life cycle. The majority of cross-sectional studies support the supposition that long-term inadequate dietary calcium has a deleterious effect on skeletal mass. The importance of adequate calcium, phosphorus, and vitamin D intake for children, adolescents, and young adults should not be underestimated, because studies have indicated that women begin losing bone mass (albeit at a rate of less than 1% a year) in their early 30s. There is increasing evidence that vitamin D deficiency is more prevalent than previously thought, particularly among individuals at increased risk, such as the elderly; those living in northern latitudes; and in individuals with poor nutrition, malabsorption, or chronic liver or renal disease. Modest vitamin D deficiency can lead to a compensatory, secondary hyperparathyroidism and is an important risk factor for osteoporosis and fractures.

Cigarette smoking is an established risk factor for loss of bone density, with the proposed mechanism of action being a reduction in circulating estrogen levels, as well as toxic effects on osteoblasts.

Genetics are important determinants of the risk for developing osteoporosis. Although the specific genes that determine bone mass remain largely unknown, some investigators claim that polymorphisms in the vitamin D receptor gene may be associated with up to 75% of the variance in bone density.

A variety of disease-related conditions may be associated with an increased risk for osteoporosis. GI diseases such as inflammatory bowel disease, among others, that lead to malabsorption of minerals and/or vitamin D are associated with low BMD. Other generalized inflammatory diseases that elevate levels of cytokines—substances believed to induce bone resorption—have also been associated with lower bone density. Younger women with eating disorders and women athletes who have altered menstrual function secondary to a hypoestrogenic state are at increased risk for lower bone densities earlier in life and should be targeted for primary prevention interventions as early as possible, as well as treatment of the underlying disease when indicated. Finally, chronic renal impairment with parathyroid dysfunction and vitamin D metabolism abnormalities can lead to bone loss.

Among the medications associated with the development of osteoporosis, long-term use of glucocorticoids (steroids) has been shown to cause bone loss both rapidly and dramatically. Patients who take 7.5 mg or more of prednisone per day for more than 1 month have been identified as being at particular risk. Long-term excessive thyroid hormone may also potentiate bone loss, reinforcing the need to routinely monitor thyroid-stimulating hormone (TSH) levels in patients who require thyroid hormone replacement. Cyclosporine, cytotoxic drugs, anticonvulsants, excessive alcohol intake, heparin, and lithium are medications that have potentially detrimental effects on the skeleton. Long-term use of proton pump inhibitors for gastroesophageal reflux disease has recently been implicated in contributing to osteoporosis by inducing hypochlorhydria that interferes with calcium absorption.

In men, testosterone deficiency from primary or secondary hypogonadism is a common cause of osteoporosis, although few large-scale studies have been done in this area. One small cross-sectional study found that men who had undergone orchiectomy for prostate cancer had significantly higher rates of severe osteoporosis, some of which developed before castration. Research identifying the causes of and treatment for osteoporosis in men is both increasing and necessary, because preliminary data have shown a higher mortality rate in men with hip fractures compared with women. Measurement parameters for osteoporosis and osteopenia in men are different than women and controversy exists regarding the most accurate measurement factors. There is general agreement that osteoporosis in men occurs a decade or so after that in women.

Pathophysiology

Normal bone contains an abundance of intracellular mineral salts (calcium phosphate and calcium carbonate) referred to as *hydroxyapatites.* As hydroxyapatites are deposited in collagenous fibers within immature bone cells (osteoblasts), the tissue becomes hardened, or ossified. Essentially, two types of bone are formed—cancellous or dense. Cancellous bone tissue is spongy, containing many open spaces filled with marrow. It consists of an irregular latticework of thin plates of bone called *trabeculae* and provides some skeletal support. Overlying spongy bone is dense bone that is much more compact, providing substantial skeletal support.

There is a continual remodeling process of bone tissue throughout life, in which osteoclasts release proteolytic enzymes that are responsible for breaking down osseous tissue, and new bone tissue is formed in its place by osteoblasts. At menopause, the remodeling process becomes less homeostatic, and osteoclastic activity begins to predominate while the rate of bone turnover increases. Bony spicules are reduced in number and size,

and horizontal spicules acting as struts do not fully extend to contralateral supporting structures from their sites of origin, thus drastically reducing structural support. This leads to a decrease in cortical thickness and both the number and size of trabeculae in cancellous bone, leading to a decrease in bone density.

Osteoporosis is likely to be a multifactorial process, relating to increased bone resorption, decreased bone formation, and an overall decrease in peak bone mass at baseline (largely determined by genetic predisposition). Each of these physiological processes may predominate to a different extent in different osteoporotic individuals. Studies exploring the genetic basis for osteoporosis have not yet proved definitive, but polymorphisms in the genes of several proteins have been implicated, including collagen, bone morphogenetic protein–2, apolipoprotein E, transforming growth factor–beta (TGF-β), and the estrogen receptor. Normal estrogen function is important in preventing osteoporosis in both men and women because it has been shown to inhibit osteoclastogenesis, induce osteoclast apoptosis, and decrease the erosive activity of osteoclasts. These activities are likely mediated through estrogen's inhibition of macrophages and osteoclasts to secrete tumor necrosis factor–beta (TNF-β), interleukin-1 (IL-1), and their binding proteins. New bone formation also appears to be impaired in estrogen-deficient states because estrogen has been shown to mediate TGF-β secretion by osteoblasts. Interestingly, androgen (e.g., testosterone) deficiency similarly results in increased bone turnover and can predispose an individual to osteoporosis as well.

Because serum hormone levels often do not differ between osteoporotic individuals and age-matched controls, changes in bone resorption and formation appear to be mediated largely by local factors, including mechanical loads on the bones themselves, as well as changes in the concentrations of local growth factors and their receptor proteins. Excesses in both exogenous (therapeutic) and endogenous (stress- or disease-related) glucocorticoids are well-known causes of osteoporosis, but unlike the role of sex hormones, glucocorticoids appear to be most involved in the regulation of new bone formation by osteoblasts. This growth effect is mediated largely by the inhibition of local growth factors including insulin-like growth factor and its cognate receptor binding proteins, as well as prostaglandins.

Research on the effects of prostaglandins and NSAIDs on osteoporosis is not definitive. It appears as though excess prostaglandin (PG) production (especially that of PGE_2) may increase bone resorption, whereas significant inhibition of prostaglandins may lead to reduced bone formation in response to mechanical weight-bearing. IL-6 produced by osteoblasts and other marrow-derived cells has been shown to increase osteoclastogenesis via a prostaglandin-dependent mechanism, leading to increased bone resorption in osteoporotic individuals. In contrast, IL-4 and IL-13 appear to inhibit bone resorption by decreasing prostaglandin synthesis, whereas IL-7 may contribute to bone loss. Finally, excess production of parathyroid hormone (PTH) (as seen in primary hyperparathyroidism) and PTH-related protein (produced by bone and cartilage cells and the mammary gland in lactating women) both lead to increased bone resorption via their effects on downstream growth factors, possibly including fibroblast growth factor. Importantly, however, this complex set of interactions by secreted growth factors on bone resorption and formation has yet to be fully characterized, and the importance of the aforementioned cytokines and growth factors can only be suggested by the current literature.

Clinical Presentation

Subjective

Most often, there are no clinical symptoms with the onset of osteoporosis until a fracture occurs. The only "early" symptom that may be noticed is the gradual development of upper or midthoracic back pain associated with activity or long periods of sitting or standing, which is relieved with rest in the recumbent position. To emphasize the importance of taking a comprehensive history, a strong predictor for future osteoporosis-related fractures is a history of previous fractures, notably those occurring from minimal trauma.

Objective

Acute vertebral compression fractures generally occur in the thoracic or high lumbar region, with the patient experiencing a more sudden, severe onset of pain. With acute compression fractures, point tenderness in the specific area of the fracture can be elicited during the physical exam. As bone density decreases, microfractures of the anterior vertebral bodies in the thoracic spine are likely to accumulate over time, leading to the characteristic dorsal kyphosis (or "dowager's hump"). The resultant exaggerated kyphosis produces a loss of height, which is generally not a "complaint," per se, but may be only casually mentioned by a patient during the course of a health-care visit. This may be the only verbal cue the practitioner receives to help identify that patient as being at risk for having osteoporosis. As the kyphosis worsens over time, impairment of rib mobility, a decrease in lung volumes, and an increase in respiratory complaints may develop.

Diagnostic Reasoning

Diagnostic Tests

Although it is important for identifying patients who may be at particular risk for developing osteoporosis, clinical assessment alone cannot accurately identify patients who do or do not have this condition. For the practitioner, assessing a patient's risk for osteoporosis and signs of the disease based on the physical exam can provide support for the decision to proceed with further

diagnostic testing. Risk assessment tools are currently available and may be used by clinicians as a quantitative means to support the need for additional diagnostic testing. The Simple Calculated Osteoporosis Risk Estimation (SCORE) instrument, for example, is estimated to have 90% sensitivity and approximately 40% specificity for identifying individuals with low BMD at the hip.

The American Association of Clinical Endocrinologists (AACE) recommends BMD testing in all perimenopausal or postmenopausal women who are willing to accept interventions should a low BMD be found. In the current health-care environment, insurance companies are increasingly requiring quantitative justification (e.g., in the form of risk assessments and/or other physical findings) from practitioners before paying for further diagnostic BMD testing. Standard radiographs are considered extremely insensitive for detecting bone loss, with films typically indicating bone loss only when it exceeds 30% or more. No biochemical marker currently exists that is used to detect bone loss; however, preliminary evidence from clinical trials suggests that such markers may be used in the future to evaluate early response to therapy.

The physiological process of bone turnover may be assessed with a variety of serum or urinary markers, allowing the monitoring of bone loss and reformation, although these markers do not provide bone mass density, which is considered the definitive test for diagnosis. However, these markers are useful in monitoring treatment and can serve as useful adjuncts in the original diagnosis of osteoporosis. In general, serum markers provide information about bone formation, whereas urinary markers supply evidence of bone resorption.

Bone alkaline phosphatase (BAP) is the most commonly available serum indicator of osteoblastic activity. These levels should be obtained before the initiation of therapy and then at 3- to 6-month intervals to monitor response. BAP levels that drop significantly may indicate lack of compliance with treatment. Urinary N-telopeptide is the most specific and newest urinary bone resorption marker available. This assay, which measures the urinary excretion of cross-linked N-telopeptide of type I collagen, is useful in identifying individuals with osteoporosis who have high rates of bone resorption and who might be good candidates for antiresorption therapy.

BMD measurement by densitometry is currently considered the gold standard diagnostic test for definitively diagnosing either osteopenia or osteoporosis. *Osteopenia* is the diagnostic term used when BMD is found to be less than normal but not severe enough to be considered osteoporotic. BMD densitometry is noninvasive and can be completed in 5 to 15 minutes. A number of BMD measurement technologies are available, including dual-energy x-ray absorptiometry (DEXA)—the "gold standard" for documenting osteoporosis of the proximal femur and lumbar spine; single-energy x-ray absorptiometry and peripheral DEXA for the radius and calcaneus (heel); ultrasonography for the heel, fingers, and tibia; and quantitative computed tomography (QCT), including peripheral QCT for the spine, hip, and radius.

These technologies use a variety of anatomical sites from which to measure BMD and emit very low radiation doses (less than or equal to a standard chest x-ray study). Although all methods are considered accurate, the DEXA method is most widely accepted because prospective epidemiological studies have found it to be most precise for reproducibility in both the short and long term, making it an excellent method for monitoring responses to interventions over time. DEXA densitometry measures BMD at the central skeletal sites of the lumbar spine and hip (including both the femoral neck and greater trochanter).

BMD measurement reports are interpreted by using the calculated *Z*-scores and *T*-scores. Both use a normally distributed bell curve in determining how any one individual compares to a reference population, with *Z*-scores representing age- and sex-matched distributions and *T*-scores representing mean peak bone mass of a young adult distribution. The *T*-score is the most clinically relevant value on the BMD report and is used to confirm the presence of osteoporosis and to determine fracture risk. For every standard deviation below the young-adult matched mean, there is a significant increase in fracture risk.

Medicare-approved indications for BMD testing include (1) estrogen-deficient women at risk for osteoporosis, (2) patients with vertebral abnormalities, (3) patients receiving or needing to be on long-term glucocorticoids, (4) patients with primary parathyroidism, and (5) patients being monitored for response or efficacy of an approved osteoporosis drug therapy.

Secondary causes of osteoporosis should be considered in all patients with low BMD. The following routine laboratory tests are considered appropriate by the AACE for excluding secondary causes of osteoporosis: CBC, serum chemistry panel (calcium, phosphate, liver enzymes, total alkaline phosphatase, creatinine, electrolytes), and urinalysis, including pH.

Also based on AACE guidelines, additional laboratory analysis may be warranted if there are abnormalities in the aforementioned tests or if there is sufficient other evidence to suspect specific secondary causes for bone loss. These include sensitive TSH, 24-hour urinary calcium excretion, ESR, parathyroid hormone concentration, 25-hydroxyvitamin D concentration, dexamethasone suppression and other tests for hyperadrenocorticism, acid–base studies, serum or urine protein electrophoresis, and bone marrow examination or bone biopsy.

The World Health Organization's diagnostic criteria for osteoporosis are presented in Table 15.8.

Differential Diagnosis

If a fracture has occurred, it is important to distinguish the underlying cause. Was it related to trauma, or was

Table 15.8 World Health Organization Diagnostic Criteria for Osteoporosis

Diagnosis	Diagnostic Findings
Normal	BMD within 1 SD of young adult reference mean
Osteopenia	BMD >1 SD below young adult reference mean (21)
Osteoporosis	BMD >2.5 SD below young adult reference mean (22.5)
Osteoporosis (severe)	BMD >2.5 SD below young adult reference mean (22.5) *and* presence of osteoporotic fractures

BMD: bone mineral density; SD: standard deviation.

there an underlying pathological condition such as osteoporosis or neoplasm? Similarly, skeletal changes could result from a variety of underlying conditions, including a neoplasm, such as multiple myeloma or other neoplasias; osteomalacia; osteogenesis imperfecta tarda (type I); skeletal hyperparathyroidism (primary and secondary); and hyperthyroidism.

Management

The goals for either the prevention or treatment of osteoporosis are to prevent fractures, stabilize or improve bone mass, maximize physical functioning, relieve symptoms of fractures and resulting skeletal deformity, and maximize psychosocial functioning and coping.

The ability to meet these goals is dependent on both the patient and the practitioner's dedication to work as a team, first in determining what therapeutic regimen will be most beneficial and acceptable to the patient. Following this is the long-term commitment to continuing treatment, evaluating the therapeutic response, and assessing for the need to redirect the management plan based on the response. An algorithm outlining prevention, detection, and management strategies for osteoporosis is presented in Treatment Flowchart 15.1.

In addition to the physical and functional limitations that can be quantified, practitioners must also address the human and emotional aspects of being diagnosed with osteoporosis. Although not often the direct cause of death, and often identified as a "silent disease" until the patient sustains a fracture, for many individuals a fracture can lead to a downward spiral in physical and mental health and well-being. There may be an abrupt descent into disease, disability, and deformity. From an individual's perspective, osteoporosis can have a devastating effect on patients and their families, and can dramatically affect functional status, leaving the patient feeling vulnerable, isolated, and uncertain of the future. (See Treatment Flowchart 15.1.)

Lifestyle Management

For both the prevention and treatment of osteoporosis, smoking cessation, moderation of alcohol use, weight-bearing exercise, and adequate calcium and vitamin D intake are advised. In addition, avoidance of falls by eliminating hazards in the home and gait training or other exercises that improve strength and agility through physical therapy are important considerations. Nursing research has found that women with osteoporosis seek interventions that promote the ability to better care for themselves, reduce stress and isolation, and prevent further disability. Weight training and walking are effective interventions for prevention and/or treatment. An active lifestyle, including safe and appropriate exercise, should be actively encouraged by the provider. Protective pads worn around the outer thigh, which cover the trochanteric region of the hip, can prevent hip fractures in elderly residents in nursing homes. Patients with pain from osteoporotic fractures may find therapies such as massage, music, or acupuncture helpful.

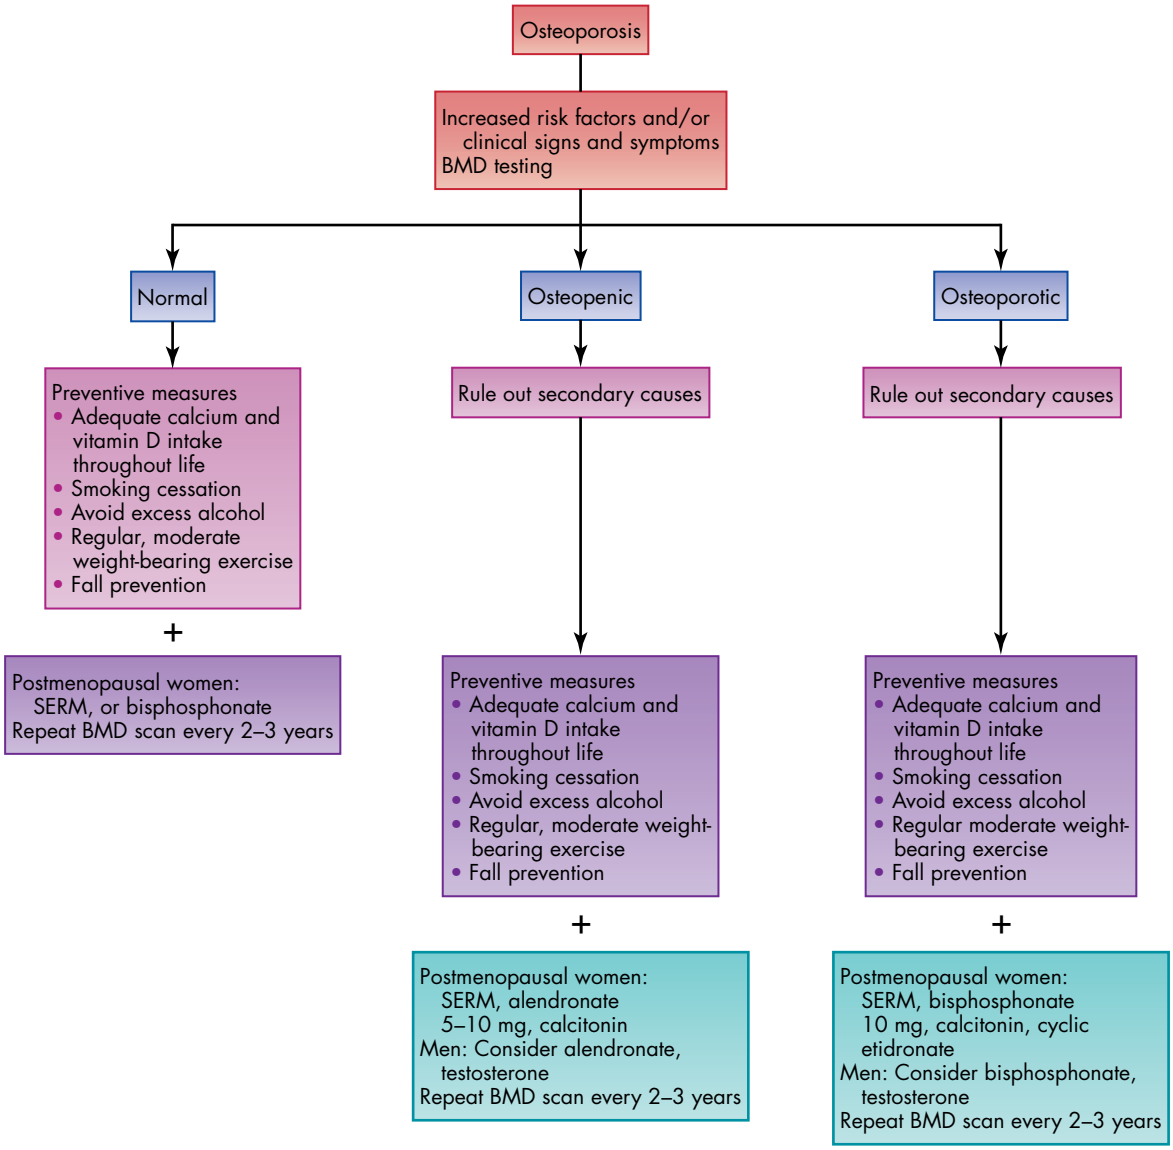
Pharmacological Management

Calcium and Vitamin D Supplements

Optimal calcium intake varies according to age, sex, and other conditions. The recommended daily calcium intake as based on the Office of Dietary Supplements, National Institutes of Health, is as follows:

- Children: 800 to 1,300 mg/day
- Adolescents: 1,300 mg/day, including pregnant/lactating
- Adults aged 19 to 50: 1,000 mg/day, including pregnant/lactating
- Adults older than age 50: 1,200 mg/day
- Adults older than age 50 with low bone mass: 1,500 mg/day

An adequate calcium intake of 1,000 to 1,500 mg/day and sufficient amounts of vitamin D are necessary for both the prevention and treatment of osteoporosis. Supplementation is advised when dietary intake does not consistently meet the recommended amount. Fracture reduction in women aged 75 years and older who use only calcium and vitamin D supplementation has been previously demonstrated. There are many available forms, and patients may be confused about which type or brand is best. In general, the majority of commercially available supplements contain similar amounts of elemental calcium per calcium weight in milligrams (mg), and patient choice should be dependent on affordability, number of tablets per day necessary, and whether it is convenient for the patient to take them with food or not. Calcium carbonate is less expensive and more easily absorbed with meals. Individuals with hypochlorhydria can absorb calcium citrate more efficiently, and it can be taken with or without food. Inadequate levels of vitamin D interfere with the body's absorption of calcium. Recent



Treatment Flowchart 15.1 Osteoporosis

studies have indicated that the 400 IU/day of vitamin D previously recommended were not sufficient. The National Osteoporosis Foundation has updated its recommendations as follows:

- Adults younger than age 50: 400 to 800 IU of vitamin D daily
- Adults older than age 50: 800 to 1,000 IU of vitamin D daily

Estrogen Replacement Therapy Estrogen was the mainstay of treatment for osteoporosis for many years, until the Women's Health Initiative showed increased risk of cardiovascular disease and breast cancer from hormone replacement therapy (HRT). Despite a risk/benefit ratio that is not favorable according to recent, large-scale clinical trials, women may still choose to take estrogen based on their own risk-factor profile.

Selective Estrogen-Receptor Modulators One of the most recent developments in osteoporosis prevention has been the introduction of a selective estrogen-receptor modulator (SERM; e.g., Evista). The approval of this drug by the FDA represents a new class of drugs that are nonhormonal but that modulate selective estrogen-receptor sites in skeletal tissue that decrease resorption of bone that occurs after menopause. The advantage of an SERM over traditional HRT is that it does not stimulate estrogen receptors found in the breast or uterus and therefore does not increase the risk for breast or uterine cancer associated with estrogen use (over 39 months of trials). Although SERMs do not adversely affect lipid profiles, whether they provide any cardiovascular benefit is under investigation. SERMs are currently approved for use in postmenopausal women only for the prevention of osteoporosis but not its treatment. For many

women, the addition of this class of drug into the market may provide an appealing alternative. Tamoxifen is another SERM that, although not FDA approved for osteoporosis, has shown promise in some research.

Bisphosphonates Alendronate sodium (Fosamax), a third generation bisphosphonate, has been approved by the FDA for the prevention and treatment of osteoporosis. It is an aminobisphosphonate that binds to bone hydroxyapatite and specifically inhibits the activity of osteoclasts, thus reducing bone turnover. Treatment with alendronate sodium has been shown to increase BMD of the vertebrae, femoral neck, and femoral trochanter by 5% to 10% and to reduce hip, vertebral, and wrist fractures by approximately 50% over a 3-year study period, making it an effective alternative to HRT for treating osteoporosis in women who either cannot or will not take estrogen therapy. It is also available with vitamin D.

Like other bisphosphonates, alendronate sodium has the potential to irritate upper GI mucosa and is contraindicated in patients who have abnormalities of the esophagus that delay esophageal emptying or in patients who are unable to take the medication exactly as directed. Because of the very specific manner in which alendronate sodium needs to be taken, some individuals initially perceive it as an inconvenience they would rather avoid; with careful patient teaching and the willingness to try this medication, however, many patients find no difficulty incorporating it into their daily routine. Risedronate (Actonel) is another drug in this category, also available in weekly dosing, as is ibandronate (Boniva), which is available in monthly dosing. Only bisphosphonates have been demonstrated in large clinical trials to reduce the risk of fractures in patients being treated with glucocorticoid therapy. Risedronate (Actonel) prevents bone loss and reduces vertebral fracture risk by about 70%. Similar effects have been noted in alendronate (Fosamax) and etidronate disodium (Didronel). Zoledronic acid (Reclast, Zometa) is an IV third generation bisphosphonate. A once-yearly dosage of zoledronic acid (Reclast) 5 mg IV has been noted to reduce the incidence of bone fracture in the hip, spine, and other sites in postmenopausal women with osteoporosis. Adequate calcium and vitamin D must be maintained before, during, and after treatment. Zoledronic acid is approved for prevention and treatment of postmenopausal osteoporosis and glucocorticoid osteoporosis, as well as treatment of osteoporosis in men and treatment of Paget's disease. Concerns about osteonecrosis of the jaw are exaggerated; this complication is most likely when the drug is used in patients with malignancies.

Few studies have examined the effectiveness of bisphosphonates for fracture reduction in men although they have been shown to increase BMD. Currently, few well-designed trials have examined the effects of pharmacological therapy on BMD in men.

Calcitonin Calcitonin is another antiresorptive agent approved for the treatment of osteoporosis. It may be used for women who cannot or will not take estrogens or a bisphosphonate. Although it produces small increases in bone mass, there are conflicting data regarding whether calcitonin reduces fractures, because the quality of bone formed is in question and currently under further investigation. Calcitonin is available for subcutaneous or intramuscular (IM) injection and in a nasal spray preparation. Studies evaluating nasal spray calcitonin have documented an increased lumbar vertebral BMD after 1 year, but no difference from the placebo in BMD at the forearm or hip. Calcitonin has also been found to produce an analgesic effect in the treatment of bone pain and may be useful during the immediate postfracture period. (See Drugs Commonly Prescribed 15.3: Osteoporosis, Paget's Disease.)

Androgen Supplementation Few studies have examined pharmacological therapy effectiveness in osteoporotic men. Preliminary data from one study showed an increase in BMD in men with idiopathic primary osteoporosis when treated with testosterone IM over 6 months. Although no adverse cardiovascular events were found in the treatment group, studies of longer duration are indicated in this area to better estimate the risks versus benefits of testosterone supplementation in men.

Fluoride Oral sodium fluoride has been used extensively in Europe for the treatment of osteoporosis and has been found to significantly increase vertebral bone density by increasing the number of osteoblasts. Large, prospective studies have not shown a concurrent reduction in fractures, however; and until future research shows otherwise, it is believed the quality of bone produced by fluoride is more brittle than that formed by antiresorptive agents. Therefore, in the United States sodium fluoride is currently not approved for the prevention or treatment of osteoporosis by the FDA.

Follow-up and Referral

Perhaps the most important part of managing the treatment of osteoporosis is improving adherence to treatment by individualizing the plan of care according to what is most effective in terms of increasing BMD and preventing fractures and what is most acceptable to the patient. There are currently no well-accepted guidelines for monitoring treatment of osteoporosis. Repeat BMD testing to monitor treatment response in osteoporotic patients should be limited to at least 2-year intervals. For patients with less-than-normal BMD (but who are not osteoporotic) or normal baseline BMD, repeat measurement every 2 to 3 years is indicated to monitor for either stabilization or progression of the disease. Referral to an endocrinologist is warranted any time secondary causes of osteoporosis cannot be excluded or if the response to treatment is less than expected for the type of therapy instituted.

Drugs Commonly Prescribed 15.3 Osteoporosis, Paget's Disease

Drug	Indication	Adverse Reactions and Prescribing Considerations
Bisphosphonates		
risedronate (Actonel) Available in daily, weekly, twice-monthly, and once-monthly dosage forms	Prevention and treatment of postmenopausal osteoporosis, to increase bone mass in men with osteoporosis, treatment of Paget's disease	Swallow whole; take in the morning with a full glass of water before other food or drink; remain in upright position for at least 30 minutes; caution with other GI irritants such as aspirin. Abdominal pain, atrial fibrillation, esophageal ulceration. Hypocalcemia is an absolute contraindication for all bisphosphonates.
alendronate (Fosamax) Also available with vitamin D; daily or once-weekly dosage	Prevention and treatment of postmenopausal osteoporosis and osteoporosis in men	Take on an empty stomach at least 30 minutes before a meal; drink full glass of water and remain upright for at least 30 minutes. Can increase toxic effects of aspirin; can decrease absorption of calcium supplements and vitamin D. See adverse effects above.
ibandronate (Boniva) Available in oral daily or monthly preparations and IV preparation for every-3-month dosing	Prevention and treatment of postmenopausal osteoporosis, osteoporosis in women with breast cancer on specific therapy, Paget's disease treatment, and treatment of hypercalcemia in malignancy	Swallow oral whole; take in the morning with full glass of water; remain upright and eat or drink nothing additional for 60 minutes; take on same day each month. See adverse effects above. Bone pain, arthralgia, and atrial fibrillation can occur in IV form.
zoledronic acid (Reclast)	Treatment of Paget's disease; prevention and treatment of osteoporosis in postmenopausal women and to increase bone mass in men with osteoporosis; hypercalcemia of malignancy	Obtain baseline renal function parameters within 10 days before initial dose. Avoid in renal disease. Adequate hydration is important, also concomitant administration of calcium and vitamin D before, during, and after drug administration. Osteonecrosis of the jaw has been seen; also arthralgia, atrial fibrillation, and bone pain can occur.
Diphosphonate		
etidronate disodium (Didronel)	Treatment of moderate to severe Paget's disease	Give daily (preferred) or in divided doses at least 2 hours before or after food; ensure adequate calcium and vitamin D. Bone pain, GI upset, arthralgias.
Calcitonin		
calcitonin-salmon (Miacalcin) nasal spray	Treatment of osteoporosis	Alternate nostrils—1 spray in 1 nostril daily. Must receive 1.5 g calcium + 400 IU vitamin D daily. Adverse effect of rhinitis in 12% of those treated.
Selective Estrogen Receptor Modulators (SERMs)		
raloxifene (Evista)	Prevention and treatment of postmenopausal osteoporosis Has not been shown to decrease hip fractures	May be taken any time of day, regardless of meals. Decreased effects of warfarin. Thromboembolic disease is a contraindication, as is breast cancer. Adverse reactions include flatulence, abdominal pain, hot flashes, increased risk of thromboembolism. Discontinue 72 hours before immobilization.
Parathyroid Hormone		
teriparatide (Forteo)	Treatment of osteoporosis in postmenopausal women at high risk for fracture (prior fracture and *T* score < –3)	Stimulates bone formation more than bone resorption. Contraindicated in hyperparathyroidism. Adverse reactions include dizziness, orthostatic hypotension, arthralgia, injection site reaction, secondary malignancy.

Continued

Drugs Commonly Prescribed 15.3 Osteoporosis, Paget's Disease—cont'd

Drug	Indication	Adverse Reactions and Prescribing Considerations
Hormone Replacement Therapy		
	Use as second-line therapy only	
Monoclonal Antibody		
denosumab (Prolia)	Treatment of osteoporosis in postmenopausal women at high risk for fracture, prior fracture, or failure on other therapy	Contraindicated in hypocalcemia. Increased risk of serious infection. Subcutaneous injection.

Patient Education

A number of informative patient education materials are available from a variety of sources, including pharmaceutical companies. Extensive, individualized education should be given to individuals when BMD results are available. This is particularly true for patients who are found to be osteoporotic and who have an array of interventions available to them. The amount of information about osteoporosis required for teaching can be overwhelming for patients; therefore, written information is essential. In addition, a number of resources are available to patients through both federal and national organizations. (See the Resources listed at the end of this chapter.)

Reviewing potential hazards that may lead to falls and reinforcing the importance of maintaining agility are equally important in the ongoing care and management of patients who are at increased risk for fractures. Referral to a physical therapist and/or a home-care nursing evaluation is often of value in this area. Referral to local support groups, national osteoporosis education groups, and mental health counseling may also be of benefit for patients who seek further assistance in either learning about their condition or coping with their situation. Active exercise, such as weight training and/or walking, should be encouraged and supported.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome (CTS) is the most common cause of peripheral nerve compression. Pain and/or numbness affects some part of the median nerve distribution of the hand and in some cases may radiate into the arm. Symptoms tend to affect the dominant hand, but more than half the patients experience bilateral symptoms. Women are three times more likely than men are to be diagnosed with CTS.

Epidemiology and Causes

CTS is the most common entrapment neuropathy. It is most common in persons aged 40 to 60 years and affects females significantly more frequently than males, most commonly middle-aged and pregnant women. Roughly 80% of patients are older than age 40 years. Any condition that reduces the size or space of the carpal tunnel can cause compression of the medial nerve. Any movement that causes the wrist to repeatedly flex or extend out of the neutral position or that places pressure on the median nerve may contribute to the development of CTS. Direct compression may result from neoplasms, a misaligned fracture, or trauma to the carpal tunnel. The greatest risk is found in occupations that require repeated flexion or extension of the wrist, use of hand tools that require forceful gripping, or use of hand tools that vibrate. CTS has been reported to occur spontaneously, most often during conditions that affect hormone balance (e.g., pregnancy, menopause, myxedematous hypothyroidism, diabetes mellitus) or in patients with other underlying musculoskeletal disorders (e.g., gout, rheumatoid arthritis, acute injury, acromegaly). Although the mechanism is unclear, it is thought that the generalized fluid increase or deposition of matrix substances (e.g., myxedema, amyloidosis) in the body tissues causes impingement on the median nerve within the carpal tunnel. This is also likely to underlie the association of CTS with fluid overload in end-stage renal disease and chronic dialysis.

Past history of wrist trauma or Colles' fracture, degenerative (and inflammatory) joint disease, ganglionic cysts, obesity, fibromyalgia, and scleroderma are other risk factors for this disorder. There is no universal agreement that CTS is work related. Although no genetic mutations have been identified other than a rare chromosome 17 deletion that leads to an autosomal dominant neuropathic disorder prone to pressure-related nerve palsies, CTS is well known to occur in families. In fact, up to half the risk of developing CTS is thought to be attributable to genetic factors.

Pathophysiology

The anatomy of the wrist extends from the distal radius and ulna to the carpometacarpal joint. The eight small carpal bones of the wrist, arranged in two rows, account for numerous articulations and enable the wrist to perform a wide range of motion (ROM). The wrist is the

second most mobile joint in the body, allowing for the exceptional mobility of the hand. Radial ligaments and the triangular fibrocartilage complex maintain the stability of the carpal bones. The carpal tunnel is formed by the arrangement of the wrist bones and the inelastic flexor retinaculum ligament. Through this tunnel run the finger flexor tendons and the median nerve. Any source of inflammation or pressure within this canal can result in symptoms of CTS.

Patients with CTS are exquisitely prone to developing increases in pressure within the carpal tunnel during wrist flexion and extension. In turn, this may lead to edema within the nerve tissue. Some studies have also demonstrated increased connective tissue proximal to the median nerve with a notable reduction in nerve fiber caliber following nerve impingement. These mechanisms may also result in venous congestion and stasis, compression of the median nerve, and resultant ischemia, leading to the pain and paresthesias associated with CTS.

Clinical Presentation

Subjective

Typically, the patient will present with an aching sensation that radiates into the thenar area; it may also be perceived in the proximal forearm, and occasionally the pain can extend to the shoulder. Paresthesias and numbness in the median distribution (thumb and index, long, and radial half of ring fingers, or some combination thereof) typically accompany the pain. Patients often report that they frequently drop objects and that they cannot open jars or twist off lids. Repetitive motions of the hand or stationary tasks with the wrist held flexed or extended for a period of time (such as when driving) worsen pain and numbness. A hallmark symptom is nighttime awakening with pain and numbness. Patients report that they must rub or shake the hand to "get the circulation" going. Persistent numbness and thenar atrophy can occur when the compression is severe and/or long-standing.

Objective

Examination of the patient with suspected CTS should include inspection of the wrist and hand for swelling, redness, nodules, deformity, and muscle atrophy. The thenar eminence (at the base of the thumb) is the best location to assess for atrophy. If the thenar eminence is atrophied or flattened, chronic CTS should be suspected. Palpation of the hand and wrist should be done to check for swelling, bogginess, or tenderness. Each distal interphalangeal (DIP), proximal interphalangeal (PIP), and metacarpophalangeal (MCP) joint should be palpated, as well as the wrist bones. Capillary refill time should be determined, and the radial and ulnar arteries should be assessed for patency. Allen's test should be performed to determine individual patency of both the radial and ulnar arteries.

ROM of the fingers and wrists should be assessed as follows:

- Have the patient make a fist with the thumb across the knuckles.
- Have the patient extend and widely spread the fingers.
- Have the patient touch each finger with the thumb of the same hand.
- With the palms facing down, passively move the fingers laterally and medially.
- Have the patient flex and extend the hands, with and without resistance.

Assessment may also include the following:

- Phalen's maneuver: Have the patient acutely flex the wrists by pressing the backs of the hands together for 60 seconds. An abnormal or positive Phalen's maneuver is present when the patient reports numbness and tingling in the thumb or first two digits.
- Tinel's sign: Lightly percuss the palmar surface of the wrist with a percussion hammer. An abnormal or positive Tinel's sign occurs when the patient reports tingling or a shocklike sensation that travels across the palm into the thumb and first two digits, a sign of nerve compression. There is broad variability in reported sensitivity and specificity of Tinel's sign in the literature, and it should not be relied on as a primary diagnostic modality.
- Carpal compression test: Place the thumbs over the flexor retinaculum and apply even pressure over the area of the median nerve for 30 to 60 seconds. A positive test is indicated by the occurrence of paresthesia in the hand or first three digits.
- Have the patient draw the pattern of numbness and tingling in his or her hand or indicate it on a preprinted picture of the hand and wrist.

The performance of sensory testing to aid in the diagnosis is of little clinical value. Many patients who do not have CTS have diminished ability to differentiate sharp and dull sensations on the fingers and therefore yield a high false-positive rate for this testing. Also remember that occupation and handedness may affect the muscular symmetry of the hands and wrists in the absence of a musculoskeletal condition.

Diagnostic Reasoning

Diagnostic Tests

Radiographs should be done if the patient has limited wrist movement; however, the most useful diagnostic test is a median nerve conduction velocity study. By measuring the velocity of sensory conduction, nerve entrapment may be conclusively validated. It is important to remember that this is an invasive test and that it is considerably more expensive than other diagnostic methods. In addition, a patient may have an abnormal nerve conduction velocity study but have no clinical

symptoms; conversely, 5% to 10% of patients with CTS have normal test results.

Differential Diagnosis

The following is a list of differential diagnoses:

- Arthritis of the carpometacarpal joint of the thumb (painful motion)
- Cervical radiculopathy affecting the C6 nerve root (neck pain, numbness in the thumb and index finger only)
- Diabetes mellitus with paresthesias (determine on history)
- Median nerve compression at the elbow (tenderness at the proximal forearm)
- Wrist arthritis (limited motion, evident on radiograph)

Management

Conservative treatment is recommended for patients who present with acute symptoms. It has been reported that 50% to 75% of conservatively treated patients will attain symptom relief. The goal of treatment is to prevent the flexion and extension movements of the wrist. This is best accomplished through use of a splint that allows free movement of the fingers and the thumb while maintaining the wrist in the neutral position. Recommendations for wearing of the splint vary from constantly (day and night) to nighttime only. Some providers recommend using the splints day and night for 3 weeks, then nightly only for 3 more weeks. Splinting can be a cost-effective method for symptom control. Maximum results from splinting are attained if it is instituted within the first 3 months of symptom onset.

Oral NSAIDs are another conservative measure that can be used in conjunction with splinting. These drugs are often prescribed for patients who experience pain as part of the syndrome, but they may have some general usefulness in controlling edema in the carpal tunnel.

Corticosteroid injections, although used by some providers, are discouraged for treatment of CTS. Although the injections provide temporary relief, there is a concern that the median nerve could sustain damage and scarring or that infection may occur.

The use of vitamin B_6 (pyridoxine) in CTS has been reported in the literature over the past several years. Although there are no conclusive studies on the utility of this medication in treating or preventing carpal tunnel syndrome, use of this vitamin is becoming more prevalent. Care should be taken with dosing, because larger doses may result in neuropathies. It is also important to determine whether the patient is on any other medications that may be affected by pyridoxine; for example, serum concentrations of phenytoin and phenobarbital may be decreased with pyridoxine.

Management of concurrent disease (e.g., hypothyroidism, diabetes mellitus) is an important aspect of the conservative treatment of CTS. Treatment that diminishes fluid retention, when used with other conservative methods, will produce better results in relieving the symptoms of CTS.

CTS that occurs during pregnancy usually resolves when the pregnancy is over. Treatment consists of splinting and other nonoperative measures such as corticosteroid injections. CTS that is work related may respond to ergonomic modifications.

Follow-up and Referral

The presence of thenar atrophy or unremitting symptoms with conservative treatment warrant referral for surgical evaluation. Carpal tunnel release is one of the most commonly performed hand surgeries; it is usually done under local anesthesia on an outpatient basis. The surgery may be performed by a hand specialist, plastic surgeon, or neurosurgeon. Although small incisions are being used more frequently, some surgeons state that visual inspection of the entire carpal space is necessary. The use of a longitudinal incision must be weighed against the risks of wound infection, scarring, and diminished motor abilities.

Postoperatively, patients can expect to have the hand splinted for 8 to 14 days while the sutures remain in place. Depending on the type of surgical intervention, healing will occur within 4 to 10 weeks. Passive and active ROM exercises are encouraged to promote healing. Patients should be cautioned that subjecting themselves to the same risks that caused the CTS may curtail healing and cause the problem to return. Modification of the work environment may be necessary to reduce this possibility.

Patient Education

Workers who are exposed to occupational risks for CTS should be educated on the causes and prevention of CTS. The work environment should be assessed for ergonomic risks to workers; often an ergonomic specialist is needed to perform these assessments. *Ergonomics* means fitting the job to the worker, as opposed to the worker accommodating to the workspace. Special attention should be paid to jobs with a known ability to produce extreme or repeated flexion of the wrist. Ergonomic evaluations and recommendations include the following:

- Evaluating the workstations of computer keyboard workers in regard to the height of the keyboard, chair, and monitor.
- Teaching lifting techniques and reviewing them annually.
- Rotating jobs for workers who perform repetitive tasks.
- Resting frequently or wearing specially designed hand wear; for example, workers who use vibrating tools should wear antivibration gloves or should be given frequent, short rest breaks.

Outside of workplace risks, patients should be educated to consider the stress on the wrist during everyday

activities such as gardening and cleaning. Knitting, sewing, and playing musical instruments may put tension on the wrist. Patients should be advised to avoid carrying heavy briefcases, packages, or purses with the hands. Bags with shoulder straps, backpacks, or bags with wheels should be recommended to patients with risk factors for CTS.

DUPUYTREN'S CONTRACTURE

Sometimes referred to as "Viking disease," or palmar fibromatosis, this condition affects the palmar tissue between the skin and the distal palm and fingers, most often in the fourth and fifth fingers but also in the thumb–index finger web space. Visible, palpable fibrous bands, reminiscent of tendons, can extend from the palm to the proximal interphalangeal joint of Dupuytren-affected fingers. It is a progressive condition that results in flexor contracture while not affecting the flexor tendons. As the contractures increase, patients have trouble grasping objects, pulling on gloves, and putting hands in pockets. Sensation in the affected fingers usually is normal. It occurs most frequently in persons aged 40 to 60 years and is a familial disorder, most commonly affecting males of northern European ancestry. It is dysfunctional and disfiguring but does not cause pain. Surgery is the only therapeutic option; recurrence is not uncommon.

BOUTONNIÈRE DEFORMITY

Another term for *boutonnière deformity* is "jammed finger" or "central slip extensor tendon injury." This deformity is caused by a rupture of the central portion of the extensor tendon at its insertion into the middle phalanx. The patient typically reports a history of trauma; the finger is held partially flexed at the PIP joint and extended or hyperextended at the DIP joint. With a recent injury, the PIP joint is painful and tender. Boutonnière deformity may not be apparent initially but can develop in 7 to 21 days as the intact lateral bands of the extensor tendon slip inferiorly. Ask the patient to extend the injured finger and observe the position of the DIP and PIP joints. The PIP joint will be flexed more than 30 degrees, and the DIP joint will be extended or hyperextended. A radiograph can rule out fracture. Flexion contracture of the PIP joint and extension contracture of the DIP joint are possible.

Splint the PIP joint in extension for 6 weeks in a young patient and for 3 weeks in an elderly patient. The DIP joint is left free. Initiate active and passive ROM at the DIP joint. If the injury is already 1 to 2 weeks old, this may not be possible.

HERNIATED LUMBAR DISC (HERNIATED NUCLEUS PULPOSUS)

The most common cause of radicular pain to the lower extremities is a herniated lumbar intervertebral disc. Over time, the lumbar discs are subjected to repeated deformations and large loads with physiological motion of the spine. In some individuals, fragmentation of the disc may result, followed by annular rupture, and finally a herniation of the nucleus pulposus into the lumbar canal. The resultant herniated disc syndrome (commonly called "sciatica" or "lumbar radiculopathy") may cause pain and/or numbness and/or weakness in one or both lower extremities. The pain results in part from direct mechanical compression of the nerve root and in part from chemical irritation of the nerve root by substances in the nucleus pulposus.

Epidemiology and Causes

Low back pain affects a significant portion of the population at some time in their lives, most commonly in persons aged 30 to 50 years. The lifetime incidence of low back pain is between 60% and 90%. Among patients with acute back pain, approximately 2% have nerve-root symptoms, but only 10% to 25% of those patients have symptoms that persist for longer than 6 weeks. Because fewer than 10% have symptoms after 3 months, only a limited number of patients require surgical treatment. Disc herniation occurs most commonly at the L4 to L5 or L5 to S1 levels with subsequent irritation of the L5 and S1 nerve root. Herniations at more proximal intervertebral levels constitute only 5% of all lumbar disc herniations. Fewer than 2% of patients with low back pain have infections, neoplasms, or inflammatory spondyloarthropathies. Spinal stenosis is more likely to be the etiology of radicular pain in patients older than age 55 years. Disc disease affects males and females equally.

Risk factors are normal aging (often difficult to distinguish between normal aging of the spine and pathological changes), cigarette smoking, a narrowed lumbar vertebral canal, obesity, osteoporosis, stress, and muscle tension. Causes include trauma (sudden or over time), frequent lifting without proper utilization of body mechanics, and vibration, such as driving and/or riding in a motor vehicle for prolonged periods of time.

Pathophysiology

An intervertebral disc is located between each vertebra and is connected to the vertebral body. The discs have a strong outer layer, the *annulus fibrosus,* and the inner *nucleus pulposus,* which is a jelly-like material that moves in the center of the annulus and redistributes itself as different stresses are placed on the disc, acting like a shock absorber. Disc anomalies begin when there is injury or degeneration of the annulus fibrosus—the outer portion of the disc. Bulging is an initial indication that the disc is showing signs of wear and tear.

The size of the individual's spinal canal becomes an important consideration when diagnosing a disc problem. A small canal will tolerate less disc material that is bulging or herniated, ruptured, or extruded. A small herniated disc in one patient will not be a problem; in another, the same size disc may cause significant compression of the neural

structures. When a disc herniates, the nucleus pulposus pushes through a tear in the annulus fibrosis. The location and amount of disc material in the canal will determine the symptoms. A small amount of nucleus pulposus in a congenitally small canal can cause significant symptoms. Most discs will rupture more to one side than the other, producing more symptoms in the affected side via compression of a unilateral nerve root. Significant herniations may also bulge bilaterally, producing symptoms on both sides of the body. Thus, the nature of the symptoms is determined by the vertebral level of disc herniation.

In turn, radicular symptoms are the hallmark of disc herniation, and their absence makes this diagnosis highly unlikely. Lesions involving the L5 nerve root produce symptoms extending to the dorsum of the foot with weakened dorsiflexion of the large toe and weakened heel walking. Lesions involving both L5 and S1 nerve roots manifest with symptoms in the lateral and posterior calf, with S1 nerve root lesions extending to the heel, as well as gastrocnemius weakness, impaired toe walking, and a reduced or absent ankle reflex. Less common lesions affecting the L4 and L3 nerve roots include a diminished patellar reflex with symptoms extending to the anterior shin and thigh, with quadriceps weakness and difficulty rising from a squatted position.

The *cauda equina* is a continuation of the spinal cord below the first lumbar level in the adult. The "horse's tail" consists of an array of nerves that exit the conus of the spinal cord and continue down the lumbar spine, exiting at different lumbar and sacral levels through foramina. These nerves are responsible for specific sensory and motor functions, including perineal sensation and both bladder and anal sphincter function. In some instances, an acute herniation of the disc at the L5 to S1 level may cause acute cauda equina compression characterized by bilateral lower extremity weakness, anesthesia, or paresthesia of the perineum and buttocks (saddle anesthesia) and bowel or bladder retention and/or incontinence. This is a medical emergency and requires immediate decompression.

Clinical Presentation

Subjective

The onset of symptoms may be abrupt but is more likely to be insidious. Unilateral radiculopathy is frequently accompanied by low back pain. Some patients report that preexisting back pain disappears when leg pain begins signaling the herniation. The pain is often severe and exaggerated by sitting, walking, standing, coughing, and sneezing. Most often, the pain radiates down from the buttock to the posterior or posterolateral leg to the ankle or foot. These patients typically cannot find a position of comfort. Lying on their side in a fetal position or on their back with a pillow under the knees may afford some relief. Upper or midlumbar radiculopathy (L1–L4 nerve root compression) refers pain to the anterior aspect of the thigh and often does not radiate below the knee.

Compression of the root may also cause paresthesias, loss of deep tendon reflex, and weakness of specific muscle groups. A herniated nucleus pulposus is most commonly seen in patients aged 20 to 50 years.

Objective

Most disc ruptures are posterolateral and press on a lumbar nerve root, which produces radiating pain. There may be paraspinal muscle spasm and lumbar scoliosis, with the trunk tilted away from the affected side. Look for a list with the patient standing. With the patient sitting, look for pain and spinal extension (leaning back) when the leg is raised (flip sign). When coupled with reproduced back pain with supine straight-leg raising limited to less than 45 degrees of leg elevation, these signs are highly reliable for herniated disc.

Evaluate motor and sensory function of the lumbosacral nerve roots and the deep tendon reflexes. Evaluate straight-leg raising on both the involved and uninvolved limbs with the patient in the supine position. This test places stress on the L5 and S1 nerve roots. Ipsilateral restriction on straight-leg raising is common with a variety of lumbar spine problems, but a positive crossed straight-leg raising test (pain in the involved leg or buttock that occurs when lifting the uninvolved leg) is highly specific for nerve root entrapment. To stretch the upper lumbar nerve roots, perform a reverse straight-leg raising test. With the patient prone, either extend the hip or do the prone rectus femoris test. With the patient in the prone position, flex the knee. Limited knee flexion in this position compared with supine flexion indicates tightness of the rectus femoris portion of the quadriceps muscle. With severe tightness, the pelvis will elevate as the hip moves into flexion. (See Advanced Assessment 15.10.)

Diagnostic Reasoning

Diagnostic Tests

Age-appropriate changes are usually demonstrated on radiograph. MRI might be useful if there is an unclear diagnosis or if the patient is being readied for surgery but otherwise is not indicated.

The majority of patients who present with low back pain do not require any imaging studies; however, there are several exceptions that warrant further diagnostic testing and immediate treatment. Patients who have recently experienced a trauma should be considered for radiographic evaluation. Imaging studies are used to evaluate the extent of ligamentous, neural, osseous, and soft tissue injuries. Patients suspected of having an infection or tumor should be initially screen with plain radiographs followed by MRI. Immediate imaging is also necessary for a patient who is suspected of having

Advanced Assessment 15.10 Classic Findings of Disc Herniation

Nerve Root	Findings
L3–L4 (L4 nerve root)	Weakness in the anterior tibialis, numbness in the shin, thigh pain, and an asymmetrical knee reflex (5% of all herniations)
L4–L5 (L5 nerve root)	Weakness in the great toe extension, numbness top of the foot and first web space, and posterolateral thigh and calf pain
L5–S1 (S1 nerve root)	Weakness in the great toe flexor and gastrocsoleus with inability to sustain tiptoe walking, numbness in the lateral foot, posterior calf pain and ache, and an asymmetrical ankle reflex

cauda equina syndrome. Cauda equina syndrome is most commonly seen in patients aged 30 to 40 years following an acute disc herniation. The physical exam reveals low back pain with bilateral weakness of the lower extremities, saddle anesthesia, and bladder and bowel incontinence. These patients should undergo immediate MRI and be referred to a surgeon.

In cases of neurological deficit, CT and/or MRI should be obtained in order to depict the spinal cord and surrounding tissue. The superiority of CT at capturing details of osseous structures allows for thorough assessment of fractures. CT is generally used to complement information obtained from other diagnostic imaging studies such as myelography, MRI, and radiographs. The value of the CT is its ability to demonstrate the osseous structures of the lumbar spine and their relationship to the neural canal. CT is helpful in the diagnosis of tumors, fractures, partial or complete dislocations, and spondylolisthesis. CT is not as useful as MRI in visualizing conditions of soft tissue structure.

Differential Diagnosis

The following is a list of differential diagnoses:

- Cauda equina syndrome (perianal numbness, urinary overflow incontinence or retention, reduced anal sphincter tone, bilateral involvement), which can lead to permanent motor loss if not immediately treated
- Demyelinating conditions (clonus)
- Extraspinous nerve entrapment (abdominal or pelvic masses)
- Hip or knee arthritis (decreased internal rotation of hip, knee deformity or effusion)
- Lateral femoral cutaneous nerve entrapment (sensory only, lateral thigh)
- Spinal stenosis (older population)
- Thoracic cord compression (clonus, spasticity, high sensory pattern, abdominal reflexes)
- Trochanteric bursitis (no tension signs, pain down lateral thigh and leg, exquisite tenderness over trochanter)
- Vascular insufficiency (absent posterior tibial pulse, claudication, trophic changes)

Management

Control of symptoms, relief of pain, and improved mobility are all goals of management. Most episodes improve with conservative treatment.

NSAIDs should be given for pain with 1 to 3 days of bedrest. If the pain is severe in the acute phase, which it can be, consider muscle relaxants and/or narcotics but for no longer than 7 to 10 days. The patient should be taught to limit sitting, prolonged standing, or walking and to take frequent rest breaks when resuming activity. Reassure patients that most disc herniations resolve without residual problems. Even ruptures with a significant inflammatory component should improve within 3 to 6 weeks. Refer if the problem persists longer than that, if pain increases, or if there is evidence of any "red flags." A short course of oral steroids (5 days) or an epidural injection may reduce leg pain within the first 2 weeks after herniation, although some recent studies have indicated that epidural steroids do not significantly alter pain that has persisted for more than 2 weeks or influence the outcome of the syndrome. Persistent numbness, progression of neurological deficits, and weakness can occur despite treatment.

Surgical options may need to be considered if symptoms persist for more than 3 months and other underlying causes are ruled out. Intolerable pain, multiple episodes of radiculopathy, severe postural tilt, and persistent dysfunctional pain are all indications for surgery. If cauda equina compression is confirmed, surgical lumbar decompression is the treatment of choice to halt neurological deterioration unless surgery is contraindicated for other medical reasons.

Follow-up and Referral

The patient should return in about 10 days for evaluation of pain and function. Monitor the patient every 2 weeks until he or she is fully functional. A progressive walking program should be initiated after pain is controlled (usually within 7–10 days). It is best to start with short walks initially, up to four times per day, lengthening the walks as tolerated. The patient should return to full activity as soon as possible but avoid high-risk activities such as heavy lifting and long car rides.

Most cases of acute back pain (90%) and/or radiculopathy (60%–80%) recover with conservative treatment; the same is true of most cases of chronic back pain and radiculopathy.

Progression of any neurological deficits, such as loss of ankle jerk; bladder and rectal sphincter weakness with retention or incontinence; foot drop with weakness of the anterior tibial, posterior tibial, or peroneal muscles; narcotic addiction in cases of chronic pain; limitation of movement; and restricted activity all warrant referral for further evaluation and treatment.

Patient Education

Cessation of smoking, weight reduction, good posture and body mechanics, and adherence to an exercise regimen are all ways to improve health and prevent recurrence. (See Patient Education 15.1 for exercises to recommend.) Modification of work environment may be necessary. Manipulation (chiropractic) and/or physical therapy may prove helpful.

LUMBAR SPINAL STENOSIS

Lumbar spinal stenosis is narrowing of one or more levels of the lumbar spinal canal and subsequent compression of the nerve roots. In the order of descending likelihood, L4 to L5, L3 to L4, and L1 to L2 are the levels most commonly involved. At L1 to S1, the stenosis is usually not central but foraminal, involving the same root (L5) as central canal stenosis at the L4 to L5 level. Typically, the stenosis must be severe before symptoms occur.

Epidemiology and Causes

Anatomically, as many as 30% of the population may have spinal stenosis after age 60, yet only a portion of this population has symptoms. Obesity is a predisposing factor, as is osteoporosis.

Pathophysiology

Lumbar spinal stenosis is defined as narrowing of the spinal canal with compression of the nerve roots. It may be congenital or acquired. It most frequently results from enlarging osteophytes at the facet joints, hypertrophy of the ligamentum flavum, and protrusion or bulging of the intervertebral discs. Lumbar spinal stenosis may produce symptoms by directly compressing nerve roots or by compressing nutrient arterioles that supply the nerve roots.

Clinical Presentation

Subjective

Onset of symptoms may follow a lifting incident or minor trauma or may gradually emerge. Often there is pseudoclaudication causing radicular complaints (with or without associated back pain) in the calves, buttocks, and upper thighs of one or both legs. Symptoms progress from a proximal to distal direction. Walking or prolonged standing causes pain and weakness in the legs and buttocks. In cases of vascular claudication, the pain stops when the patient stops walking, but pseudoclaudication does not immediately subside when walking stops. The patient may obtain short-term relief by leaning forward (manifested as "stooping"); when grocery shopping, the patient will be leaning on the cart. Relief after sitting is variable, depending on the degree of neural compression. Patients who sleep on their backs, meaning with the spine extended, might awaken after several hours with back and leg pain. Lumbosacral pain is associated with walking and standing. A vague aching in the legs or leg weakness may also be present. Spondylolisthesis (degenerative or spondylolytic), vascular insufficiency, and osteoarthritis of the hips are often associated with spinal stenosis, as well as obesity.

Objective

Muscle weakness of the legs is a subtle phenomenon. This may be best elicited after walking on a treadmill. Proprioception can be impaired; there may be a positive Romberg test. There may be sensory changes, and these are usually segmental and may involve more than one spinal level. Reflexes are often diminished. Some patients will have a lumbar scoliosis. With bowel or bladder symptoms, sphincter tone may be decreased. However, because many elderly patients have concomitant prostate problems or urinary incontinence, genitourinary evaluation may be necessary to differentiate these processes.

Diagnostic Reasoning

Diagnostic Testing

Radiographs may provide some evidence of spinal stenosis. AP and lateral view radiographs (up to L10 in the lateral view) may show significant narrowing of the intervertebral disc or spondylolisthesis. There may be osteopenia or an old burst fracture of the vertebral body.

Differential Diagnosis

The following is a list of differential diagnoses:

- Abdominal aortic aneurysm (palpable pulsatile mass)
- Arterial insufficiency (distance to claudication constant, recovery after rest, absent or diminished pulses)
- Diabetes mellitus (abnormal glucose metabolism, nonsegmental numbness, skin changes)
- Folic acid or vitamin B_{12} deficiency (confirmed by laboratory tests, anemia)
- Infection (fever, elevated ESR, intervertebral disc narrowing)
- Tumor (patchy neurological deficit, bone destruction, severe night pain)

Management

Any neurological deficit, gait disturbance, or bowel and bladder dysfunction should be evaluated further. These

changes may not be reversed following surgery for decompression; thus the goal of the treatment is to prevent progression.

Intermittent use of NSAIDs may be helpful, as well as folic acid or vitamin B_{12} supplementation in some cases depending on results of laboratory tests. However, most management revolves around physical therapy or an exercise program that focuses on flexing the spine. Flexion of the spine increases intraspinal volume. Bicycling is one exercise that is done with the spine in flexion. Improving abdominal muscle tone lifts the pelvis anteriorly and flexes the lumbar spine. Reduction of intra-abdominal fat is critical to achieving the objective. Thus, weight loss may be pivotal. Lumbar flexion exercises increase spinal canal volume. Examples include exercise on all fours, arching the back, or in the fetal position. Exercises that extend the spine should be avoided (swayback).

Lumbar epidural corticosteroid injection may provide some immediate relief for approximately 50% of patients and more sustained relief for approximately 25%. When disabling symptoms persist, decompression laminectomy provides at least short-term relief in some patients but does not always rehabilitate lost function.

Follow-up and Referral

The rate of progression is variable from rapid to none. Many patients never develop any neurological deficits and tolerate the condition well. Pain and limited function, however, can become severe and lead to a secondary depression. Standing erect may become impossible, and the patient may be forced to adopt a stooped posture. Claudication may develop after walking only a few feet. Cauda equina syndrome develops in some patients, leading to loss of bowel and bladder function.

If nonoperative treatment is ineffective, specialty consultation is warranted. Night pain that disturbs sleep tends to be a sign of advancing disease and also indicates a need to refer and/or consult. Prolonged use of NSAIDs can cause renal failure, hepatotoxicity, and gastrointestinal ulcer disease and can exacerbate existing cardiac disease.

Patient Education

Educate the patient and family as to any potentially serious symptoms such as changes in bowel and bladder function, change in neurological status, and gait disturbance. Educate as to side effects of NSAIDs or narcotic usage. Support weight loss if necessary with dietary instructions and clear guidelines for activity and exercise. Because many of these patients are older adults, they may need a range of services arranged to accomplish these goals.

Common differential diagnoses for back pain include the following:

- Ankylosing spondylitis: Back pain and stiffness over several months; relief with exercise; reduced mobility of spine; painful or ankylosed sacroiliac joints; reduced chest wall expansion.
- Cauda equina syndrome: Acute urinary or rectal incontinence, with or without paraplegia.
- Dissecting aortic aneurysm: Sudden onset of severe low back pain in older adults; pain that is not relieved with rest; pallor, diaphoresis, and confusion may be present; possible asymmetrical pulses and blood pressure in extremities.
- Gallstones: Pain follows ingestion of a fatty meal and radiates around trunk to right scapula; belching, bloating, and stomach acid are present, along with right upper quadrant pain.
- Gynecological disorders: Vaginal discharge; pain worse around menstruation or ovulation.
- Herniated disc: Often preceded by years of recurrent episodes of localized back pain; leg pain overshadows back pain.
- Infection: Unremitting or progressive pain at rest; tender spinous process at level of involvement; fever; history of drug use; diabetes; immunosuppression or suspected systemic infection; previous genitourinary or spinal surgery.
- Musculoskeletal strain: Often no precipitating event; pain is over lower back and muscles without sciatica; aggravated by sitting, standing, and certain movements; alleviated with rest. Palpation localizes pain and muscle spasms may be seen. Insidious onset; progressive improvement.
- Prostatitis: Constant low back pain; urinary hesitancy; change in sexual frequency.
- Pyelonephritis: Ill-appearing patient with nausea and vomiting; back and flank pain excruciating with direct percussion.
- Sciatica: Pain radiating into the buttocks, thighs, and/or below the knees as the result of L5 or S1 nerve-root irritation, compression, or disc prolapse.
- Spinal fracture: Pain felt near the site of injury; history of major trauma to the back or (in older adults) a history of strenuous lifting or a minor fall.
- Spinal stenosis: Gradual onset in older adults; often mimics intermittent claudication, except pain is usually in buttocks, thigh, or calf, worsens with exertion and back extension (leaning backward or walking downhill), and is relieved with sitting, walking uphill, or leaning forward; weakness and/or bowel and bladder dysfunction may be present.
- Spondylolisthesis: Systemic inflammatory condition of the vertebral column and sacroiliac joints; most frequently affects men aged 20 to 30; chronic low back pain, worse in morning; excessive thoracic kyphosis is present.
- Tumor: Unremitting or progressive pain at rest, night pain; tender spinous process at level of involvement; variable neurological findings; weight loss, fever, or other systemic symptoms; known or suspected malignancy.

OVERUSE SYNDROME (REPETITIVE MOTION SYNDROME)

Overuse syndrome describes a constellation of cumulative soft tissue trauma disorders that develop in the absence of acute injury. All major tissues in the musculoskeletal system are subject to overuse injuries. Overuse syndromes may be referred to as *repetitive strain injury, chronic microtrauma, cumulative trauma disorders, soft tissue rheumatism,* and *work-related pain disorder;* all of these terms refer to syndromes that result in chronic localized pain and dysfunction. It may manifest itself as well-defined pathology of a single periarticular site or a regional myofascial pain syndrome. Examples of single-site periarticular pain generators include bursitis, tendinitis, or fasciitis (e.g., plantar fasciitis). Finding several pain generators in the absence of articular involvement suggests a chronic, low-grade, repetitive trauma disorder or an acute overexertion syndrome that one may find in "weekend warrior" athletes.

Proper diagnosis of overuse syndromes may be difficult because they often involve more than one type of tissue. Overuse problems usually develop in the muscles and tendons. Although it is common to divide the muscles and tendons for ease of presentation, it is important to remember that they function together as a unit—the musculotendinous unit. Other soft tissues, including the bursa, fascia, synovium, and nerves, may also be affected by overuse. *Muscle overuse injuries* may be divided into muscle strains and muscle soreness (acute and delayed); there are overuse injuries of the tendons and bursa; any joint that is subject to abnormal loads, ranges of motion, or activity may develop a reactive synovitis. Chronic compartment syndromes may occur related to entrapment of fluid in the fascial sheath. Common anatomical sites and types of overuse syndromes are described in Table 15.9.

Table 15.9 Common Anatomical Sites: Overuse Syndrome

Anatomical Site	Overuse Syndrome
Shoulder	Rotator cuff tendinitis Thoracic outlet syndrome
Forearm	Lateral epicondylitis Medial epicondylitis Ulnar nerve entrapments
Hand and wrist	Carpal tunnel syndrome de Quervain's syndrome "Trigger finger"
Leg and foot	Chondromalacia patellae Iliotibial band syndrome Shin splints Achilles tendinitis Plantar fasciitis Stress fracture

Epidemiology and Causes

Overuse injuries are common in both athletes and nonathletes. It is difficult to determine the true incidence because frequently overuse injuries are not brought to the attention of a health-care provider. Despite this, such injuries account for more than 50% of the injuries seen in a primary-care setting and are the most frequently encountered athletic injury. Whereas individuals seem aware of the benefits of exercise, they do not always seem aware that these same activities can also bring problems with injury. Overuse injuries of soft tissue include damage to tendons, muscles, bursa, fascia, and nerves. They include impingement and snapping syndromes and compartment syndromes.

Given that repetitive stress can traumatize tissue, the potential for injury is enhanced by a wide variety of predisposing factors. Female sex, youth and old age, pregnancy, smoking, menopause, diabetes, poor physical conditioning, underlying anatomical imperfections aggravated by exercise or repeated motions, and obesity have all been identified as risk factors. In addition, poor cardiovascular or musculoskeletal conditioning, underlying cardiovascular disease, arthritis (osteoarthritis or rheumatoid arthritis), gout, and stress may all contribute to the development of overuse syndrome. In athletes, overtraining, running on uneven surfaces, poor equipment, inadequate footwear, and leg-length discrepancy may all contribute; in workers, unhealthy work environments both physically and emotionally are thought to contribute. Repeatedly performing arm and hand movements with a very short repetitive cycle of less than 30 seconds in the course of one's daily job is a risk factor. Repeatedly performing the same task over and over in a short period of time in a factory can impose the same level of risk. Dancers, musicians, grocery clerks, computer keyboard operators, and dental hygienists are all particularly susceptible. Vibration, cold environment, and use of some specific hand tools also are considered risk factors. (See Risk Factors 15.2.)

Sitting all day in an awkward body position may lead to muscle fatigue, for example. This may lead to generalized muscle inflammation and nerve compression throughout the upper extremities. Poor neck and shoulder posture places skeletal bone pressure on the nerve and blood supply to the arms, wrists, and hands, thereby diminishing circulation and nerve conduction to these areas. Fresh nutrient blood supply is diminished, thereby slowing recovery from microtrauma. Independent of whether muscle, tendon, cartilage, or hard tissue is involved, injury results from a simple mismatch between stress on a given tissue and the ability of that tissue to withstand the stress. There are two basic mechanisms behind tissue trauma: single-impact macrotrauma and

Risk Factors 15.2 Overuse Syndrome

- Arthritis (osteoarthritis and rheumatoid arthritis)
- Congenital defects
- Diabetes mellitus
- Ganglia
- Gout
- Hobbies (knitting, musical instruments, electronic games)
- Hormonal factors (pregnancy, oral contraceptive use, menopause, thyroid disorders, hysterectomy with bilateral oophorectomy)
- Hypertension
- Impaired circulation
- Inflammation of tendons and tendon sheath
- Obesity
- Occupational activities (computer usage, cash registers)
- Paget's disease
- Raynaud's phenomenon
- Renal disease
- Sports (racquet sports, golf, softball, running)
- Underlying anatomical abnormalities

repetitive microtrauma (damage at the microscopic or molecular level). Overuse injuries therefore can be defined as the level of repetitive microtrauma sufficient to overwhelm the tissue's ability to adapt or heal.

Pathophysiology

Overuse syndrome results from repetitive microtrauma to bones, ligaments, and musculotendinous units. This repetitive microtrauma causes a local inflammatory process, leading to pain and loss of function. In vitro studies have demonstrated that tendinous fibroblasts produce elevated concentrations of prostaglandin E_2 and leukotriene B_4 in response to repetitive stretch maneuvers. Thus, repetitive microtrauma is believed to lead to repeated cycles of inflammation and tissue regeneration, characterized by fibroblast proliferation, collagen production, and resultant tissue contraction.

Overuse syndrome most commonly involves the musculotendinous unit, resulting in tendinitis or tenosynovitis. Repetitive mechanical trauma to a joint may result in synovitis or arthritis, and repetitive overuse stress on bones can result in periostitis or stress fractures. Bone has the ability to constantly remodel and repair itself. However, if the degree of repetitive microtrauma exceeds the bone's capacity for repair, an overuse injury in the form of a stress fracture may occur. Stress fractures occur most commonly in the weight-bearing bones of the lower extremities, such as the tibia and metatarsals, but are sometimes seen in the upper extremities of athletes who throw (e.g., baseball pitchers).

Histopathological studies of muscle biopsies have also revealed differences in limbs affected by overuse syndrome. These include an increased number of type 1 muscle fibers (smaller, slow-twitch or red fibers) with a decreased number of hypertrophied type 2 fibers (larger, fast-twitch or white fibers). Muscle fibers affected by overuse syndrome also display mitochondrial changes with an increased number of muscle cell nuclei. These changes become increasingly evident at higher grades of overuse syndrome. Decreased blood flow to affected muscles has also been noted in some studies.

Clinical Presentation

Subjective

In general, overuse injuries are insidious in onset. Typical complaints include pain, fatigue, numbness, or any combination of the same. Patients often have difficulty localizing the pain and may report swelling and sensation not apparent on physical exam.

Often, the symptoms have existed for some time; it is when the symptoms occur more frequently or have become more intense and last longer that they may begin to interfere with function. This is most likely the point at which the patient seeks help.

Objective

Specific findings will vary depending on the joints and body area involved. However, in general, overuse syndrome may be categorized by grade. (See Advanced Assessment 15.11.)

Diagnostic Reasoning

Diagnostic Tests

The diagnostic tests indicated will vary depending on the body part involved. Radiographs are necessary with a history of trauma. A bone scan may be necessary to rule out stress fractures. Likewise, nerve conduction velocity studies can be ordered to rule out carpal tunnel syndrome or ulnar nerve entrapment at the elbow, but the results are usually negative. X-ray results are usually negative. MRI may help to visualize soft tissue injury.

Differential Diagnosis

The differential diagnoses will vary, depending on the joints and body area involved. Possible diagnoses include the following:

- Angina with referred arm pain (abnormal electrocardiogram)
- Claudication (decreased peripheral pulses)
- Deep vein thrombosis (abnormal venogram)
- Fibromyalgia (11 of 18 pressure points in four body quadrants)
- Herniated cervical or lumbar disc (abnormal spine radiograph, myelogram, and MRI)

Management

There are two primary goals in the management of overuse injuries: reducing inflammation and improving

Advanced Assessment 15.11 Grading Overuse Syndrome

Grade	1	2	3	4
Pain history	Hours after activity	Late, or just after activity	Early, or in middle of activity	At rest
Clinical manifestations	Tenderness (generalized)	Tenderness (localized)	Point tenderness Erythema Swelling	Point tenderness Erythema Swelling ROM decreased Function impaired
Management	Ice	Ice Decrease activity (25%)	Ice Decrease activity (50%)	Ice Rest NSAIDs

vascular blood flow. Overuse injuries can be very difficult to treat. Treatment should be initiated as early as possible because once chronic, they become even more difficult to treat both physically and psychologically. Exercise and physical therapy are the keys to successful recovery. Initial management should include *protection* from further injury, abstaining from the irritating activity, and, in some cases, splinting for immobilization; *rest; ice* applied for 10 to 30 minutes with an equal period without ice; *compression,* such as with an elastic bandage to provide support to injured tissue; and *elevation* to decrease swelling (*PRICE*). An individualized rehabilitation program should be designed and implemented as soon as possible. Flexibility, strength, proprioception, and endurance must be addressed and encouraged.

Pharmacological approaches may include NSAIDs during the acute phase and, in some cases, muscle relaxants; occasionally, antidepressant therapy may be used in chronic situations. Acupuncture is often effective, and some patients may benefit from the use of transcutaneous electrical nerve stimulation. Injured muscles, tendons, and nerves may require significant amounts of rest to allow healing to take place.

Follow-up and Referral

The degree of follow-up will depend on the location and severity of the injury. Once a diagnosis is made, treatment by a team of health-care professionals may be warranted. Considerable psychological sequelae may be involved. Better results are obtained when there is a specific, clearly identifiable syndrome such as carpal tunnel syndrome. Lack of job satisfaction and depression are also important predictors of recovery. Poor prognosis is associated with both long-standing disability (longer than 6 months) and litigation. With these disorders, patients often lose time from work and experience psychological changes. They may change occupations or never return to work.

Patient Education

The patient needs to be educated as to the precipitating activity and the need to refrain from that activity for a certain period of time. This can be especially difficult to reinforce with athletes. Patience and assistance in designing alternate activities will help so that the patient may remain active. If the cause is work related, monitor for chronicity and issues of secondary gain.

PAGET'S DISEASE

Paget's disease (*osteitis deformans*) of the bone, first diagnosed by Sir James Paget in 1877, is a disease of the osteoclast and is the most exaggerated example of disordered bone remodeling. It is characterized by excessive osteoclastic bone resorption followed by excessive bone formation from osteoblasts, resulting in bone that is architecturally unsound. This can lead to bone pain, bone deformity, and skeletal fragility and can involve a single bone or multiple bones.

Epidemiology and Causes

Prevalence of the disease is difficult to determine because it is often asymptomatic (70%–90% of cases). Older adults are most commonly affected; it is the second most common bone disorder after osteoporosis in older adults. It is estimated that the disease affects more than 10% of people older than 80 years of age. Ethnic and geographic clustering of cases has been well described for Paget's disease, and 40% of patients report a family history of the condition. This disease is common in England, with statistics indicating a prevalence as high as 5% of the general population in some areas. Australia, New Zealand, and Argentina are also high-prevalence areas. In the United States, the prevalence varies between 1% and 3%.

Although Paget himself felt the disease was caused by chronic inflammation, the etiology remains unknown to date. Bone biopsy data have identified various viral

antigens, which suggests that a "slow virus" infection by a member of the paramyxovirus family (e.g., rubeola, which causes measles, respiratory syncytial virus, canine distemper) may be responsible for the disease.

Pathophysiology

The disease affects all aspects of bone metabolism and may be divided into three phases: lytic, mixed, and sclerotic. It begins with the lytic phase characterized by increased activity of multinucleate (up to 100 nuclei compared with 5–10 normally) osteoclasts, which leads to greatly increased resorption of bone (up to 20-fold). Hypercalcemia may manifest, particularly if the patient experiences prolonged immobilization. The mixed phase then follows, in which bone remodeling is abnormally increased, due to a greater number of osteoblasts of normal morphology. This leads to an abnormal, irregular deposition of collagen fibers. The final phase, known as the sclerotic phase, is notable for a predominance of abnormal bone formation. This is characterized by disorganized bone that takes on a mosaic pattern known as "woven bone," which is recognizable on x-ray exam. Eventually osteoblastic activity quiets, leaving sclerotic lesions. As the hypercellularity decreases, this bone becomes known as burned-out Paget's disease.

There are no Haversian systems within pagetic bone, and the bone marrow is eventually replaced by hypervascular fibrous tissue. Bones that are commonly affected with these sclerotic lesions include the cranium, long bones, and clavicles. These affected bones will change in shape, enlarge in size, and undergo changes in predominant direction of growth due to increased osteoid volume—all of which lead to considerable morbidity. Pagetic bone is weaker and less compact than normal adult lamellar bone, and bones affected by this change may be painful and, over time, may develop deformities, fractures, or nerve entrapment. Cytokines and growth factors that have been implicated, albeit inconclusively, in the pathophysiology of Paget's disease include IL-6, RANK-ligand (a member of the TNF-α superfamily), and macrophage-colony stimulating factor.

A rarer juvenile form of Paget's disease also exists. However, this form is fundamentally different from the adult form because it is typically polyostotic with widespread skeletal involvement. In addition, both histological and radiological findings differ from the adult form and may be readily distinguished.

Clinical Presentation

Subjective

The clinical presentation of Paget's disease is a function of the actual extent of disease, bones involved, and any complications present. Most (70%–90%) patients are asymptomatic. Although the affected bone may be larger than other bones, pagetic bones are weaker and more susceptible to fracture. The bones most commonly affected, in order of decreasing frequency, are the femur, sacrum, vertebrae, skull, tibia, and pelvis. Involvement of the tibia and humerus is less common, but the disease may occur at any site and may involve one (monostotic) or many (polyostotic) bones. Hands and feet are rarely involved.

The most typical complaint is one of pain at the involved site. The pain is usually dull or boring, but it can be shooting or knife-like, and often occurs at night. In some cases, a swelling or deformity of a long bone is noticed or the development of a change in gait. Back pain, with radiation to the buttocks or lower extremities, is another common complaint. Headache is a common complaint when the skull is involved.

Pagetic bone is of a highly vascular nature, and there may be increased warmth of the skin over the affected bones. The incidence of high-output cardiac failure may be tied to the increased vascularity of the involved bone, manifesting the classic symptoms of "dropsy" (generalized fluid overload). Though rare, this condition correlates with greater than 15% of skeletal involvement.

In patients with involvement of the ossicles of the inner ear or impingement of bone on the eighth cranial nerve, hearing loss may occur. Vertigo and tinnitus may also develop with skull involvement, as well as cranial nerve involvement resulting from compression by deformed bone. Spinal cord compression has also been observed with resultant cauda equina syndrome or paraplegia. Pathological fractures of vertebrae may also produce spinal cord lesions and pain. Articular complications, including asymptomatic hyperuricemia and classic gout, pseudogout, and degenerative arthritis, may occur. Fractures of the long bones occur most commonly in the femur, tibia, and humerus. Significant morbidity may result from heavy bleeding that may result from pathological fractures in these hypervascular bones.

Complications include cardiovascular problems, arthritic and osteoporotic problems, and neoplastic problems. When Paget's disease becomes widespread in the body, blood flow increases and may be associated with high cardiac output. The end result in this situation may be congestive heart failure. Arthritic changes in weight-bearing joints may result in pathological fractures. One dreaded complication is that of sarcoma. Incidence of sarcoma is approximately 1%; it may be in the femur, humerus, skull, facial bones, or pelvis. The extent of neoplastic involvement may be detected by CT and/or MRI.

Objective

Bowing of the long bones may be apparent, as well as enlargement of the skull (e.g., frontal bossing, maxillary enlargement). The sacrum, pelvis, and spine, particularly the lumbar spine, are the most common areas involved. Other less frequently involved sites include the femur

(right more than left), cranium, sternum, and pelvis. Erythema and warmth is often noted over affected bone sites due to the increased hypervascularity.

Diagnostic Reasoning

Diagnostic Tests

Paget's disease is most commonly diagnosed through radiographs, radionuclide bone scanning, biochemical testing of bone resorption parameters, or biochemical testing of bone formation parameters. Biochemical tests reflecting osteoclast activity and resultant bone collagen resorption include measurements of urinary hydroxyproline/creatinine, as well as measurements of urinary and serum deoxypyridinoline, N-telopeptide, and C-telopeptide. Elevated 24-hour urinary deoxypyridinoline and type I collagen N-telopeptide excretion reflect bony destruction (resorption). As a marker of osteoblast activity, the measurement of serum alkaline phosphatase activity provides a general indication of bone turnover and disease activity in Paget's disease. Serum bone-specific alkaline phosphatase activity is helpful in patients who also have liver disease. At least one measurement of bone metabolic activity and x-ray films of affected bones are the minimum recommended level of evaluation to track and monitor the progression of treatment in Paget's disease.

Radiographs may illustrate three distinct stages of Paget's disease. In the earliest stage of the disease, an osteolytic lesion may be observed in the skull or a long bone. In the second stage of the disease, x-ray films reveal both osteolytic and sclerotic changes in the same bone. In the last stage of the disease, the sclerotic lesion dominates the bone and there may be an increase of the bone itself.

Although it is not a specific test, a radionuclide bone scan, using a radiolabeled bisphosphonate, is the most efficient means of detecting Paget's disease in a skeleton. The bisphosphonate is injected intravenously and is concentrated in areas of increased blood flow and high levels of bone formation, both common characteristics of Paget's disease. The test is used primarily to establish the full extent of skeletal involvement.

Diagnosis is often made when x-ray studies are performed or a high level of bone-specific alkaline phosphatase (a marker of bone formation) is found on routine screening. Immobilization in patients with Paget's disease is a primary risk factor for significantly elevated serum calcium and phosphorus, but immobilization alone will not necessarily result in hypercalcemia without underlying pathology. Occasionally, an associated hyperthyroidism can also lead to hypercalcemia. Quantitative histomorphometry of bone biopsies confirms the extent of remodeling present. Imaging studies to rule out malignancy should be performed whenever pathological fractures or elevated bone-specific alkaline phosphatase levels are detected.

Differential Diagnosis

When lesions are noted on x-ray film, metastatic cancer should be considered. Disseminated breast and prostate cancer are the cancers most likely to resemble Paget's disease radiographically and need to be ruled out. Occasionally, a hemangioma of bone may be sclerotic and mistaken for pagetic bone.

When making a diagnosis of Paget's disease, differential diagnoses such as osteoporosis, osteomalacia, hypercalcemia, and compensatory, secondary hyperparathyroidism should be considered. As with Paget's disease, osteoporosis involves the imbalance between bone formation and bone resorption. When bone formation exceeds resorption, the circulatory levels of parathyroid hormone may become increased, thus resulting in compensatory, secondary hyperparathyroidism.

Management

If Paget's disease is discovered incidentally and the patient is asymptomatic, no treatment may be necessary. However, there is an increasing trend to treat even if the patient is asymptomatic. This is based on evidence that failure to treat leads to further bone destruction, and that successful treatment is associated with restoration of normal patterns of new bone deposition. However, there is no direct evidence that aggressive treatment of Paget's disease is associated with prevention of progression or reduction in the risk of future complications.

There are four main approaches to treatment for a patient with Paget's disease:

- Nonpharmacological therapy, focusing mainly on physical therapy as a way to improve muscle strength
- Pharmacological therapy using either bisphosphonates or calcitonin
- Pain management using analgesics
- Surgery

Currently, bisphosphonates are approved by the FDA for the treatment of Paget's disease. Bone resorption is suppressed or reduced by bisphosphonates. They hinder the recruitment and function of osteoclasts, and they are thought to indirectly stimulate osteoblasts to produce an inhibitor of osteoclast formation. Alendronate, risedronate, tiludronate, and zoledronic acid are indicated for patients with Paget's disease of bone with alkaline phosphatase levels two times greater than normal, those who are symptomatic, or those at risk for future complications from their disease. Etidronate and pamidronate are designated for the management of moderate-to-severe disease. Ibandronate is not approved for Paget's disease treatment.

The bisphosphonates alendronate and risedronate have been shown to reduce biochemical indices for bone turnover into the normal range in many patients with a moderate to severe form of Paget's disease. Alendronate (Fosamax) is taken as a daily 40-mg tablet for 6 months;

risedronate (Actonel) is taken as a daily 30-mg tablet for 2 to 3 months. Calcium and vitamin D supplementation is also recommended for patients using either of these drugs. Etidronate (Didronel) is less potent than alendronate and risedronate but is recommended for treatment of symptomatic Paget's disease. It is given once daily (preferred) or in divided doses at least 2 hours before or after food, initially 5 to 10 mg/kg per day for a maximum of 6 months. Pamidronate (Aredia) is given by IV infusion, 30 mg/day for 3 successive days. Zoledronic acid (Reclast), 5 mg IV, is administered as a single infusion. IV treatments may require dosage adjustments in hepatic or renal impairment.

Subcutaneous injection of salmon calcitonin was the first widely used therapy for Paget's disease. Salmon calcitonin (Fortical, Miacalcin) has been shown to reduce elevated indices of bone turnover by 50%, decrease symptoms of bone pain, reduce warmth over affected bones, improve some neurological complications, and promote healing of lytic lesions. It is available in a nasal spray and an injectable (Miacalcin) form. The recommended dosage for the injectable form is 50 to 100 units per day or 3 times per week as subcutaneous or intramuscular injection. Its use today is primarily limited to patients who do not tolerate bisphosphonates. In the case of secondary resistance to salmon calcitonin, a switch to bisphosphonate therapy is necessary.

Pain directly attributable to Paget's disease is generally relieved through anti-osteoclast therapy as described earlier. Pain that is a result of bone deformity or arthritic or neurological complications may be treated additionally with acetaminophen, NSAIDs, and, depending on the circumstances, COX-2 inhibitors.

Surgical intervention is indicated in the face of significant bony deformities, nerve compression, or pathological fractures. Severe osteoarthritis of major joints such as the hip or knee may require artificial joint replacement with preoperative bisphosphonate therapy. Neurological sequelae from vertebral abnormalities may call for laminectomy for spinal decompression in lesions refractory to medical therapy. Osteosarcomas arising in pagetic bone may also require amputation to improve prognosis. In all these cases, extended physical therapy will follow.

Follow-up and Referral

Follow-up will depend on symptomatology, as will referral. Pain status needs to be monitored, as well as any laboratory abnormalities. If started on medication, the patient will need to be followed for therapeutic effects and any adverse effects that may occur secondary to therapy. Serum and urinary markers of disease activity should be followed 2 to 3 months after initiation of therapy and periodically thereafter. Any suspicion of malignancy warrants full evaluation and referral, because prognosis is particularly grim with the development of sarcoma with only a 1- to 3-year survival. Appropriate referrals may include an orthopedic surgeon, neurosurgeon, physical therapist, and/or oncologist.

Patient Education

Patient education is important because so many people with Paget's disease are asymptomatic. The canine distemper virus has been postulated to be an etiological agent for Paget's disease; therefore, owners of unvaccinated dogs are at increased risk. Many of the medications prescribed for Paget's disease have significant adverse effects. Calcitonin analogs produced from other species may induce anaphylaxis and should be used with caution. Hypocalcemia may also result, and serum calcium should be monitored periodically. The bisphosphonates require ingestion on an empty stomach and the ability to stay in an upright position anywhere from 30 to 60 minutes. They can all cause gastrointestinal irritation, and other medications such as aspirin and NSAIDs should be used concurrently with caution. Adequate calcium and vitamin D intake must be maintained, because the bisphosphonates interfere with their absorption. These medications also interfere and interact with a wide variety of other drugs, blocking tetracycline, fluoroquinolone, and levothyroxine absorption. Warfarin must be monitored also.

COSTOCHONDRITIS

Costochondritis, also called *anterior chest wall syndrome,* is an inflammation of one or more costochondral junctions that manifests with chest wall pain. The pain may be sharp and acute or dull and persistent in nature. It is the most frequently occurring nontraumatic type of chest pain in adolescents and young adults. Pain is located over the costochondral and costosternal areas of the anterior chest.

Epidemiology and Causes

Costochondritis accounts for 10% of chest pain complaints in the United States. In the adolescent population, more than 20% of reported chest pain may be due to costochondritis. It is more common in women than in men, with a peak age range of 20 to 40 years. The cause of the problem is poorly understood, although trauma and overuse have been implicated in some cases. It is also sometimes seen in association with upper respiratory infection.

Pathophysiology

Costochondritis is an inflammation of the costochondral junctions manifesting only with pain in the absence of erythema, heat, or swelling. Repetitive minor trauma is currently believed to be the most likely etiology. However, epidemiological research has revealed an increasing incidence of costochondritis resulting from bacterial or fungal infections of the costochondral joints in injection drug users due to needle contamination or in people with postoperative thoracic wound infections.

When symptoms of costochondritis are accompanied by localized nonsuppurative swelling, this condition is termed *Tietze's syndrome,* which is characterized by a firm, palpable, tender fusiform swelling in the sternoclavicular joints or upper costal cartilages.

Clinical Presentation

Subjective

The patient presents with chest pain, which may be sharp and fleeting or intermittent. The patient may report previous episodes and may be concerned that there is something wrong with his or her heart. The onset of the pain is typically insidious and located at the costochondral junctions, most commonly involving the second to fifth costochondral joints. More than one site is involved in 90% of cases. There may be some radiation to the arm, but the pain is unrelated to position, respiration, or activity, although some patients report an increase in pain with trunk movements or deep breathing. The pain may persist for several months, causing the patient to return to the clinician for reassurance that nothing else is responsible for it. Chest tightness or localized muscle spasm may accompany the pain. There may be a history of recent upper respiratory infection, trauma, or unusual activity involving the chest or pectoral muscles.

Objective

In most cases, there are no objective physical findings other than sharply localized tenderness to palpation. These same sites may not be painful without direct palpation. In a few cases, inspection may reveal an area of redness, warmth, and nonsuppurative edema; however, this condition is more appropriately termed *Tietze's syndrome* and is seen most often in teenage girls. It is imperative in the examination of all patients with chest pain that the examiner apply pressure on the pectoralis muscles and each costochondral and costosternal junctions. This maneuver will reproduce the pain of costochondritis.

Diagnostic Reasoning

There are many causes of chest pain, ranging from life-threatening and acute to troublesome but benign etiologies. All of these must be considered in arriving at an accurate diagnosis.

Diagnostic Tests

The diagnosis of costochondritis is based on a thorough history and physical exam that reveal no red flags for more serious pathology. There are no specific diagnostic tests. However, testing may be initiated to rule out other conditions that manifest with chest pain and are part of the differential diagnosis. A chest radiograph is often helpful in this regard to evaluate for more serious lung, cardiac, or bony pathology. Erythrocyte sedimentation rate (ESR) is elevated in some instances of costochondritis, but inconsistently. Moreover, the lack of specificity of a positive ESR means that it cannot be used to exclude other conditions and rule in costochondritis. However, a nonelevated ESR may assist in ruling out more serious pathology.

Differential Diagnosis

Differential diagnosis includes cardiac-related chest pain such as the following:

- Mitral valve prolapse
- Myocarditis
- Pericarditis
- Left ventricular outflow obstruction
- Tachyarrhythmias
- Aortic aneurysm
- Acute coronary syndrome resulting from coronary artery disease or sympathomimetic drugs of abuse such as cocaine

Respiratory causes of chest pain include the following:

- Asthma
- Pneumonia
- Pleuritis
- Pneumothorax
- Pulmonary embolism
- Chronic cough

Gastrointestinal causes of chest pain include the following:

- Gastroesophageal reflux disease
- Esophagitis
- Gastritis
- Peptic ulcer disease (PUD)
- Esophageal spasm

Musculoskeletal causes of chest pain include the following:

- Muscle strain
- Trauma
- Hypersensitive xiphoid pain (xiphodynia or xiphoidalgia)
- Slipping rib syndrome (pain originating in the lower, floating ribs)
- Subacromial bursitis
- Fibromyalgia syndrome

Psychogenic disorders manifesting with chest pain include the following:

- Panic attacks
- Generalized anxiety disorder

Other diagnostic considerations with cutaneous pain include the following:

- Early herpes zoster (characterized by dermatomal clustered skin lesions)
- Pain related to chest wall tumors

Management

Management consists of reassurance and patient education regarding the benign and self-limited nature of the problem. Application of heat to the area may alleviate discomfort. NSAIDs may be prescribed for pain management, given the inflammatory nature of costochondritis. However, patients should be cautioned of the potential gastric and renal toxicities of NSAID overuse and contraindications should be stressed (e.g., PUD, gastritis, acute or chronic renal insufficiency). Drugs from these classes should be taken with food or milk. In addition, to avoid aggravating costochondritis, patients should be cautioned to avoid overuse or trauma.

Follow-up and Referral

The patient can be seen for reevaluation in 7 to 10 days or can be contacted by phone. The patient should be instructed to call the office if pain intensifies or other symptoms appear. One of the most important considerations when making the diagnosis of costochondritis is to rule out pathology of greater morbidity or potential mortality, as discussed earlier. A complete history and physical examination are the most important tools in guiding this evaluation; however, a complete work-up may require follow-up visitations to complete the diagnostic evaluation or assess changes in signs and symptoms over time.

Patient Education

The most critical point in many cases is convincing the patient that his or her condition is benign and self-limited despite the sharp nature of the pain. The patient is often fearful and requires reassurance. The clinician should educate the patient regarding the need to avoid overuse injury if any repetitive motion appears to be involved. It is important to stress the importance of avoiding any sudden, significant changes in activity.

TENDINITIS/TENOSYNOVITIS

Tendinitis is the inflammation of a tendon, which usually occurs at its point of insertion into bone or at the point of muscular origin. The term *tenosynovitis* refers to inflammation involving synovial sheaths surrounding the tendon in addition to the tendons. Common tenosynovitis syndromes, also referred to as "overuse" syndromes, include supraspinatus tendinitis, lateral epicondylitis or "tennis elbow," bicipital tendinitis, de Quervain's tenosynovitis (inflammation of the abductor pollicis longus and extensor pollicis longus and brevis tendons), "trigger finger" (volar flexor tenosynovitis), patellar tendinitis (patellar tendinosis or "basketball player's knee"), and Achilles tendinitis (see section on overuse syndrome in this chapter).

Epidemiology and Causes

This problem occurs commonly, with a slightly increased frequency in males, most likely related to sports. It occurs at all ages. Professional athletes and manual laborers are especially prone to tendinitis as a result of repetitive use. Painful areas of tendon are often labeled *tendinitis,* implying an inflammatory nature of the lesion; however, it is unclear whether inflammation is truly present in all forms of the pathology, especially in more chronic situations, which tend to have a more degenerative component. Some sources advocate the use of the term *tendinosis* for this reason. *Tenosynovitis* may result from inflammatory arthropathies such as rheumatoid arthritis or from gout. Tenosynovitis from amyloidosis is also common in renal dialysis patients. It also may occur for no discernible reason. Adults who overuse a joint with repeated motion are most likely to develop a *tendinitis.* Some classifications are based on degree of function and whether there is a partial or complete rupture of the tendon.

Pathophysiology

Exact pathophysiological entities involved with tendinitis and tenosynovitis have not been clearly established. It is understood that tenosynovitis involves inflammation of the synovial-lined sheath around one or more tendons, whereas tendinitis involves inflammation of the tendinous tissue itself. Because flexor tendons typically run in tight fibro-osseous tunnels, thickening of the surrounding sheath caused by inflammatory changes may in turn limit movement and cause pain as the trapped tendon attempts to glide within the thickened, tight sheath. The parietal and visceral layers of the synovium that surround flexor tendons typically provide nutrition and stability to the tendons, and they also allow for smooth movement of these connective tissues without extensive friction. However, infection may spread to these areas from nearby mucosal tissues, by direct extension from the skin through a puncture wound, or even hematogenously (as is the case with gonococcal tenosynovitis, which complicates 1%–3% of patients with mucosal infection of the pharynx or genitalia), because these synovial compartments normally offer little resistance. Tenosynovitis may also be associated with an inflammatory, infectious arthritis of large joints resulting from similar spread of infectious organisms (especially bacteria).

Tendinitis is usually associated with some degenerative changes in the tendon, including cell atrophy along with the presence of fibrinoid, mucoid, or hyaline degeneration of the connective tissue, which is visible under microscopic examination. Peritendinous scarring is not unusual, because tendons are relatively avascular and particularly sensitive to increased pressure within their synovial sheaths. Calcium deposits may also be noted along the length of the tendon, known as calcific tendinitis; this is especially common in the shoulder joint. These tendons tend to stiffen without treatment. Loss of function often follows, because they become progressively weaker and may eventually rupture.

Clinical Presentation

Subjective

Patients typically complain of pain and swelling over a localized area of tendon, usually in a region where the tendon passes through a tunnel. Pain is usually worse with motion, especially motion that stretches the involved tendon. A squeaking or rubbing and sometimes a triggering or catching sensation will be described by patients who have significant tenosynovitis. Tenosynovitis around the finger flexor tendon in the carpal tunnel region can have the associated symptoms of fingertip numbness from median nerve compression, as noted previously. A thorough history is essential, including all extracurricular activities.

Objective

The diagnosis of tendinitis is clinically driven. Early imaging is usually of minimal benefit. Perform a thorough physical exam that includes palpating any tender areas and ruling out any articular involvement of pain. One may see minimal swelling in tendinitis, although it can be impressive in cases of infection or with inflammatory causes of tenosynovitis. Examination may reveal localized pain, swelling, and tenderness. The pain will be worsened with certain motions, such as stretching the involved tendon, or with active work or activity that involves use of the tendon, especially against a resisting force. Crepitus and sometimes triggering can be palpated if a significant tenosynovitis has developed. These signs vary depending on the anatomical site of the tendinitis.

For example, tendinitis of the shoulder includes the bicep tendon and the tendons of the rotator cuff. This is similar to impingement syndrome. When patients have shoulder tendinitis, one will note tenderness with palpation of the subacromial space. These patients will have tenderness when one palpates the long head of the biceps tendon in the bicipital notch. To do this, have the patient keep his or her elbow at the affected side and externally rotate the shoulder to palpate the bicipital notch anteriorly and medially in the humeral head. When examining these patients, one can also elicit pain with resisted supination or flexion of the forearm. There is often an overlap of impingement syndrome with tendinitis of the shoulder.

If an inflammatory disease is present, associated redness, soft tissue swelling, and warmth may be present. Inflammatory processes of the tendon sheaths most commonly involve the dorsum of the hands, feet, and ankle and may cause marked soft tissue swelling. The ROM of contiguous joints may be limited by pain.

Diagnostic Reasoning

Diagnostic Tests

Diagnostics involve a thorough history and complete physical exam. Plain films may be useful to rule out other potential causes of pain in areas in question, but they will not show a tendinitis. MRI will show any significant tenosynovitis and tender nodules that sometimes develop. However, the diagnosis can almost always be made clinically without the need for MRI. Other options may include arthrography and MRI. In cases of tenosynovitis, there may be an associated anemia or elevation of the ESR.

Differential Diagnosis

Differential diagnoses to rule out include fracture, avulsion of the tendon, inflammatory arthritis, rheumatoid arthritis, and compartment syndrome. In the case of Achilles tendinitis, one must also consider a gastrocnemius strain, soleus strain, or tarsal tunnel syndrome. Tendinitis can be practically impossible to differentiate from bursitis, and the two conditions commonly occur together. The pain in tendinitis is localized to the side of the joint where tendon insertion occurs. Infectious tenosynovitis occurs primarily in the hand. In addition, the tenderness and swelling are located along the synovial lines proximally instead of at the insertion site and the pain is more marked, as are swelling and erythema. The ESR and white blood cell (WBC) count are more likely to be elevated in the case of infection.

Essentially, definitive diagnosis of tenosynovitis requires careful musculoskeletal examination, confirming the tendon source of the symptoms and excluding pathology from other contiguous musculoskeletal structures, including joints, bursae, and nerves. However, an inflammatory tenosynovitis of the dorsum of the hand or foot may require aspiration of synovial fluid, examination, and culture to confirm the diagnosis.

Management

Specific treatment requires an exact diagnosis to prevent further injury. An aggressive exercise program, for example, would be inappropriate for a compartment syndrome, complete tendon rupture, or nerve entrapment. Treatment will also depend on the stage of healing of the damaged tissue of the musculoskeletal system. There are essentially three phases of healing: (1) inflammation, (2) proliferation of new collagen and ground substance, and (3) scar remodeling and maturation.

Initial management should include protection, rest, ice, compression, and elevation (PRICE). The injury should be protected and rehabilitated in parallel with the healing process. The injured tissue needs to be stressed in order to activate collagen remodeling and realignment but also protected from overstress, which will cause reinjury and incite a further inflammatory response. Taping and bracing can both be helpful in providing protection. Ice is useful for treating pain, hemorrhage, and edema. It induces vasoconstriction, which results in a decrease in local blood flow. Ice acts as a topical anesthetic agent to control pain and decreases reflex muscle spasms by reducing the conduction velocity in peripheral nerves. Ice bags, compared with cold gel packs, elicit the greater

decrease in tissue temperature over a longer period of time, and application for 15 to 20 minutes is recommended. Treatment may be repeated every 1 to 2 hours in acute cases. In lowering the temperature, ice decreases metabolism and enzymatic function; further, it slows down the inflammatory process. It is useful during the first 48 hours in acute cases, and in chronic cases it can be applied after activity for 30 to 50 minutes.

Compression in concert with cold therapy helps to reduce the swelling. Elevation decreases edema by aiding lymphatic and venous return. In acute ankle sprains, for example, elevation has been shown to be the most effective method of reducing swelling. The objective is to treat the initial symptoms with these techniques to prevent prolonged inflammation and avoid new tissue disruption. In addition, measures of relative rest are used to protect the tissue from further injury. In some cases, specifically carpal tunnel syndrome, for example, splinting may be effective. Ideally, the splint should be custom-made and fitted for the individual patient; an occupational therapist may assist with this.

In stage 2 of the healing process, the objective is to gradually introduce stress and apply modalities to increase collagen production, size, cross-linking, and alignment. The rate of collagen fiber formation is directly related to the functional state of the affected area. The collagen fibers reorient themselves in line with the tensile force applied to the tissue. In stage 3, the objective is to make the collagen as elastic as possible and decrease formation of scar tissue. Progressive stress is placed on tissue to promote an increase in collagen fibril size and to increase cross-linking in tissues. Flexibility training is needed to decrease cross-linking in the joint capsule.

Immobilization may be counterproductive, and absolute rest should be limited to 1 to 2 days at most until the inflammation response has settled or in the most severe, chronic cases of tendinitis after active rest has failed. *Active rest* means that the injured area can be used, but it should be protected from significant stress, which may cause further damage. The frequency and intensity of an activity may be decreased or altered, for example, but all activity should not be completely eliminated. Physical therapy is a cornerstone of treatment and can aid in the development of an individualized plan for the patient. Ice plays an important role once exercise and activity are resumed. It should be applied at the end of every exercise session to help prevent recurrence of inflammation and swelling.

Heat is effective after 48 hours in the acute phase and in the chronic phase. After the acute phase of the healing process, heat is useful in improving blood flow, relieving muscle spasm, and decreasing tissue stiffness, allowing greater ease of deformation. The most beneficial form of deep heat is ultrasound because the high-frequency waves render the tissues less stiff and more susceptible to remodeling by applied tensile forces. Ultrasound also increases local circulation and has been shown to speed wound healing. Lasers are another modality that has positive effects on wound healing, but unlike ultrasound, they also decrease inflammation.

Two types of electrical stimulation may be used in treatment. Transcutaneous electrical nerve stimulation is used for pain relief and can be a useful adjunctive modality. High-voltage galvanic stimulation not only produces heat in the tissue but also has been reported to be effective in retarding the formation of edema. Deep friction massage is a modality used by physiotherapists to prevent the formation of adherent scars early in healing and later to break down scar tissue. It should be avoided in the first few days after injury because it can produce microtrauma, induce inflammation, and have a deleterious effect on healing.

NSAIDs are useful in the treatment of acute overuse injury, especially if used early, when they can decrease the production of arachidonic acid derivatives in the inflammatory pathway. They are probably best prescribed at maximum dose for 10 to 14 days. If no benefit is noted in the first 3 days, it is unlikely further benefit will be gained. They probably do not have a major anti-inflammatory role in the treatment of chronic injuries because there is scant histological evidence of true inflammatory response. Although widely prescribed, they have not been shown to effectively shorten recovery time; they may be useful in their analgesic effect in supporting a patient's compliance with physical therapy.

Corticosteroids are occasionally indicated in cases of chronic overuse syndromes. They should never be injected directly into a tendon, because this can lead to rupture. In addition, activity needs to be decreased for 5 to 10 days after injection. Tendon sheath injections, by contrast, are quite effective in treating tenosynovitis of the ankle or wrist. Steroid injections can also be given intra-articulately when there is significant reactive synovitis with effusion.

Follow-up and Referral

As noted in the section on overuse syndromes in general, soft tissue injuries cause considerable pain, discomfort, and potential dysfunction. A comprehensive, team approach, structured in a Circle of Caring model, is what is needed for these patients to avoid significant sequelae. As noted in the section on management, interventions need to be geared toward the stage of healing to be effective. The balance between rest and healing and the danger of erring in either direction can be great without thoughtful consideration by a team of providers, as well as maximum hearing of the patient's voice. Athletes may be overanxious and overdo; unhappy employees might have more of a psychogenic component to their pathology.

Referral to physical therapy is essential, as is referral to an orthopedic specialist if there is any question as to nature of pathology. Treatment must be individualized, and the patient must be a chief architect in the plan of care. Patients requiring corticosteroid injections should

be referred. Occupational therapists can assist with fitting of splints if necessary. Adequate sleep is essential to the overall treatment plan and may also require follow-up. Aggressive intervention will potentially offset the possibility of the development of chronic pain syndrome.

Patient Education

It is important that patients understand the nature of their injury and be involved in the plan of care. In the case of athletes, careful evaluation of training schedules and circumstances surrounding the injury is essential so that appropriate preventive measures can be put in place to support healing and avoid future injury. In the case of a work-related repetitive motion injury, evaluation of the workplace may be necessary.

All risk factors should be assessed. In the case of a patient with obesity, nutritional counseling may be necessary. A diabetic patient may need additional assistance in controlling his or her disease and likewise with a patient with hypertension and cardiovascular disease. Managing household chores may be a challenge for individuals with tendinitis. Carrying groceries in a paper bag rather than a plastic bag, driving a car with an automatic transmission, placing hands properly on the steering wheel (at 9 o'clock and 3 o'clock), and using electric kitchen appliances such as a food processor or electric can opener can dramatically reduce strain on injured muscles and nerves. Some hobbies, such as quilting, knitting, gardening, playing certain musical instruments, computer games, frequent Internet usage, and needlepoint may have to be altered during the healing process and in some cases permanently. For many patients, stress management techniques such as yoga or meditation may be effective in promoting relaxation of injured, inflamed, and tense muscles.

In cases in which the patient's job is the source of repetitive strain injury, restrictions on work activity may be necessary. A careful and thorough occupational history can help make determinations about the contributing factors in the patient's job environment. A comprehensive ergonomic worksite evaluation may be conducted by a physical or occupational therapist in identifying specific problems. Ultimately, however, patients with severe forms of repetitive strain injury may be forced to change occupations.

Likewise, a severe tendinitis can potentially spell the end of a promising athletic career. From this vantage point, hearing the patient's voice—his or her concerns and feelings—is critical.

DE QUERVAIN'S TENOSYNOVITIS

De Quervain's tenosynovitis (stenosing tenosynovitis) is characterized by pain at the base of the thumb or at the radial styloid process on abduction and extension of the thumb. Within the wrist, there are six dorsal tunnels that transport the extensor tendons. The first tunnel transports the abductor pollicis longus (APL) and the extensor pollicis brevis (EPB) tendons. These tendons form the radial border of the anatomical snuffbox. De Quervain's tenosynovitis occurs when the synovial lining of the tunnel becomes inflamed, thus narrowing the opening of the tunnel. This results in pain when the tendons move. The APL and EPB tendons are responsible for thumb flexion and extension and for establishing a grip. This condition is seen in patients who perform pinch-grip activities such as using hand tools with extreme pressure, carrying trays with a pinch grip, assembly work, and sewing/cutting activities. It is more common in middle-aged women and is often precipitated by repetitive use of the thumb.

De Quervain's tenosynovitis presents with pain at the radial side of the wrist, usually with lifting. This pain is aggravated by attempts to move the thumb or make a fist. Patients may complain of pain while turning a key or a doorknob or while attempting to open a jar. Often the condition occurs as the result of lifting infants with the second metacarpals (web between the thumb and the index finger) under the baby's axillae. Chronic pain, loss of strength, and loss of thumb motion can occur.

The history and physical exam should proceed as described for carpal tunnel syndrome. In addition, assess for crepitation over the radial styloid. On palpation, the tendon sheath may feel thickened. Allen's test, Phalen's maneuver, and Tinel's sign (see Advanced Assessment 15-5) should be negative. The confirmation test for de Quervain's tenosynovitis is Finkelstein's test. To perform this test, have the patient grasp the thumb in the palm while you deviate the wrist to the ulnar side. If this motion is painful, the test is considered positive. There is usually no need for additional diagnostic testing. Wrist x-ray studies are indicated only if there is a history of trauma. Calcification associated with tendinitis occasionally can be seen on radiographs.

Ask the patient to bring any work tools to the office visit to better evaluate risky hand and wrist positions. Observe if the patient has attempted to modify the tool (wrapping the handle in duct tape, adding a sleeve of rubbery material) to try to reduce the pressure on the hand surfaces. If there is a possible relationship to the patient's occupation/hobby, ask about the specifics of these activities.

The differential diagnoses include carpal tunnel syndrome, carpometacarpal joint arthrosis of the thumb, scaphoid fractures, and arthritis of the thumb and/or wrist.

Noninvasive treatment includes rest, splinting, and NSAIDs. Splints that are used are either a radial gutter splint or a customized long opponens splint. The splint should immobilize both the wrist and the thumb. Splinting is used for 3 to 6 weeks. A 2-week course of NSAIDs is usually helpful (see Drugs Commonly Prescribed 15.2).

Invasive treatments include corticosteroid injections into the tendon sheath. If the symptoms are not relieved with two to three injections, referral should be made for surgical release of the tendon sheath. Patients with unremitting symptoms after 6 to 8 weeks of conservative treatment should be referred for tendon release.

Patients should be educated regarding the cause of de Quervain's tenosynovitis. Modifications to hand tools or the work environment should be made. For example, hand tools may be retrofitted with a larger grip surface, so that pressure is more evenly distributed over the palmar surface of the hand. Avoidance of the precipitating factor is often enough to permanently resolve early symptoms.

TRIGGER FINGER

"Trigger finger" or "locked finger" is a common name for *stenosing tenosynovitis of the flexor tendons.* This problem can be painful and functionally limiting. Any digit can be affected, although it most commonly affects the ring or middle finger. Inflammation at the metacarpophalangeal (MCP) joint pulley causes a size discrepancy between the tendon and the pulley. Because the tendon no longer slides freely through the pulley, there is a snapping or locking phenomenon. The digit remains flexed or extended until the tendon pops through the pulley, causing severe pain. Tenderness with palpation of the flexor tendon over the MCP joint is noted. There is a higher prevalence of trigger finger in patients with carpal tunnel syndrome and de Quervain stenosing tenosynovitis.

Trigger finger may be idiopathic (more common in middle-aged women) or associated with rheumatoid arthritis (RA) or diabetes. Patients typically report pain and catching when they flex the finger and may describe the finger as going "out of joint." They may awaken with the finger locked in the palm although the finger gradually unlocks during the day. Physical exam reveals tenderness in the palm at the level of the distal palmar crease, usually overlying the MCP joint. A nodule may also be palpable. The nodule moves, and the finger may lock when the patient flexes and extends the affected finger. This movement is almost always painful. Full flexion of the finger may not be possible.

The most effective therapy for this problem is local anesthetic and corticosteroid injection into the tendon sheath, plus a modification of activities for about a month. A small number of patients require surgical release of the tendon. Splinting and NSAIDs have not proven effective.

BURSITIS

Bursitis, which is inflammation of a bursa, is a common cause of painful musculoskeletal syndromes. Bursae are sacs filled with synovial fluid, located between muscles, tendons, and bony prominences. Bursae cushion bony prominences from overlying muscles (deep bursae) or surface skin (superficial bursae); they may or may not communicate with the adjacent joint space. The bursa provides lubrication for movement of tendons over bones and can be affected by trauma, as in overuse, and by infection, inflammation, and neoplasms. The total number of bursae varies from person to person, but on average, this figure approaches 160. Some cases of bursitis may result from rheumatic afflictions and others from a pathological condition of adjoining tissues. It may be acute or chronic.

Epidemiology and Causes

Bursitis is a common complaint, seen most often in patients who are skeletally mature. It is more common in males and tends to be more commonly associated with trauma (including overuse syndrome) in patients younger than 35 years of age. Interestingly, up to 85% of septic bursitis cases are in men. It is one of the most common reasons for visits to the primary-care setting; the incidence is clearly related to increasing age. The incidence of bursitis of the lower extremities is increased by obesity.

Bursitis commonly develops in the subdeltoid and subacromial bursa of the shoulder, the olecranon bursa of the elbow, the greater trochanteric bursa that is lateral to the hip, the ischial bursa, the prepatellar bursa of the knee, the anserine bursa, and the heel. The anserine bursa lies between the pes anserine tendons, which insert into the sartorius, gracilis, and semitendinosus muscles, and the medial collateral ligament, which lies over the medial aspect of the tibia.

Trauma in the form of repetitive motion injury is probably the most common cause of bursitis, as a result of constant friction between a bursa and musculoskeletal tissues surrounding it. Friction in turn causes irritation, edema, and, over time, inflammation and subsequent degeneration. The end result is an engorged bursal sac with surrounding tissue that has become tender and painful. Movement around the bursa may result in increased pain and pressure. In turn, flexion and extension of the closest joint may be limited by the affected bursa. Aging connective tissues are at a higher risk for microtears with bursitis.

Pathophysiology

Bursitis is an inflammatory process that may be acute or chronic; the exact etiology is often unknown. Bursitis may be caused by an infectious process, trauma (more common in patients under age 35 years), repetitive movement disorders, pseudogout, gout, or neoplastic disease. Less often, it may be attributed to rheumatoid disease (especially with nodular or bilateral bursitis) or infection by *Mycobacterium tuberculosis* or *Candida* fungal infection. Far more commonly, however, septic bursitis is due to bacterial infection.

Up to 80% of septic bursitis cases are due to infection by *Staphylococcus aureus,* with 5% to 20% due to *Streptococcus* and other gram-positive skin flora, which are typically introduced via direct trauma that compromises the protective skin barrier. Immunocompromised conditions such as diabetes mellitus, HIV infection, chronic steroid use, or autoimmune conditions such as RA may all predispose the individual to septic bursitis, and causative trauma to the overlying skin surface may even be microscopic in nature.

Bursitis is essentially a soft tissue problem rather than a joint problem such as arthritis, and often coexists

with tendinitis or tenosynovitis. Overuse injury is characterized by repeated cycles of degeneration and regeneration with new collagen deposition. Synovial cells increase in thickness, and the normal bursal lining may be replaced by granulation tissue before eventual fibrosis. In turn, the bursa may become filled with transudative fluid with a high concentration of fibrin. At the conclusion of this inflammatory process, calcium deposition may occur proximal to the affected bursa.

Clinical Presentation

Subjective

The presenting symptoms are usually pain and sometimes swelling over the known locations of bursal sacs, which may be accompanied by swelling and warmth over the involved bursa. When the subcutaneous bursal sacs (olecranon and prepatellar) are inflamed by systemic illnesses such as RA, gout, or infection, additional clues to diagnosis may include fever, chills, and arthralgias. The prepatellar and olecranon bursae frequently present with local redness, swelling, and warmth that must be distinguished from septic arthritis. Patients who develop subcutaneous bursitis may have a family history of articular problems. An occupational history may provide a clue to diagnosis. Some examples include "weaver's bottom" (ischial-gluteal bursitis), "miner's elbow" (olecranon bursitis), and "housemaid's knee" (prepatellar bursitis). Bursitis of a deep bursa is manifested by pain over the bursa with activity or direct pressure. The pain may radiate some distance, as in the case of gluteal bursitis, in which the patient may complain of pain in a sciatic distribution.

Objective

Pain may be referred to other musculoskeletal structures contiguous to the bursa; therefore, careful examination is necessary to identify the source of the pain. Clinical signs and symptoms include induration, erythema, and effusion over the olecranon and prepatellar bursae. Gross distention of the bursal sac may be apparent. If there is significant limitation of ROM or pain on flexion, a coincident arthritis must be suspected. Bursitis may also develop from repeated microtrauma, leading to effusion and thickening of the bursal sac. When irritation and inflammation continue, the bursa is at risk for calcification and development of adhesions around the bursa, thereby limiting tendon movement.

Diagnostic Reasoning

Diagnostic Tests

Laboratory findings will usually be normal. The ESR may be elevated by gout, RA, or infection. In cases of gout, uric acid levels would be elevated. In infectious leukocytosis, the WBC count may be elevated.

Differential Diagnosis

When formulating a diagnosis, RA, gout or pseudogout, and septic arthritis must be ruled out. A diagnosis is generally determined from an x-ray film showing the involved joint or bursa, with or without calcified deposits. Further diagnosis is determined from the aspiration of fluid in the affected joint. The fluid is cultured, and a WBC count done to assess the presence of bacterial infection. An elevated red blood cell count is associated with trauma.

Management

Medical management and treatment of bursitis includes avoidance of activities that can lead to constant irritation of the bursa and application of moist heat or ice to the affected area every 4 hours for 20 to 30 minutes. The use of moist heat versus ice is an individual preference. Immobilization of the affected area to reduce edema and provide support is recommended, along with ROM exercises to prevent loss of mobility and to help maintain motion. It has also been recommended in certain cases that an NSAID along with ultrasound therapy be used. If symptoms recur and fluid reaccumulates, an injection of a long-acting corticosteroid (triamcinolone 2–10 mg, hydrocortisone 25–37.5 mg, methylprednisolone 20–40 mg, or dexamethasone 4–16 mg, each mixed with an equal volume of lidocaine hydrochloride 1%) into the affected bursa is recommended, followed by application of ice for 10 to 20 minutes. Injections should not be repeated more than every 6 to 8 weeks, and most clinicians limit the number of intrabursal injections to two to the same site before referral for more invasive interventions, such as surgery, is initiated. In severe cases, surgery may be performed to excise the inflamed portion of bursa and calcified deposits and to aspirate bursal fluid.

Follow-up and Referral

Follow-up is determined by the response to therapeutic interventions.

Patient Education

Patient education is vital to ensure a rapid recovery. Encouraging a patient to decrease certain activities will speed up recovery. Encourage preliminary stretching and warm-up exercises before activities to maintain flexibility and strength. If medications are a part of the treatment regimen, reinforcement of proper administration and a discussion of their side effects are recommended.

Chapter 16

Endocrine and Metabolic Problems

Angela K. Golden, DNP, APRN, FNP-C, FAANP • Debera J. Thomas, DNS, RN, FNP/ANP • Brian Oscar Porter, MD, PhD, MPH

COMMON COMPLAINTS

CARPOPEDAL SPASM (HYPOCALCEMIA)

Carpopedal spasm is a violent, painful contraction of the hands or feet. It is one of the neuromuscular signs indicating hypocalcemia and is a significant sign of tetany. Neuromuscular signs and symptoms occur in the presence of hypocalcemia because calcium is an important mediator in neurotransmission and other intracellular biochemical activities. In response to hypocalcemia, there is an increased secretion of parathyroid hormone, which leads to immobilization of calcium stores from the bone and an increase in the absorption of calcium in the intestines.

Differential Diagnosis

Acute neuromuscular irritability producing carpopedal spasm occurs when the serum calcium drops abruptly by 2 to 3 mg/dL. Parathyroid hormone (PTH) deficiency disease or inadvertent damage to the parathyroid glands during neck surgery may cause acute severe hypocalcemia. Acute transient hypocalcemia may occur in burns, severe sepsis, pregnancy, extensive blood transfusions with citrated blood, acute pancreatitis, and acute renal failure.

Aggressive treatment of hypercalcemia with plicamycin (Mithracin), bisphosphonates, and calcitonin (Cibacalcin, Calcimar) may result in acute hypocalcemia. Other drugs that may produce hypocalcemia include radiographic contrast dyes that contain a calcium-chelating agent, EDTA, and foscarnet (Foscavir).

Chronic hypocalcemia is usually caused by the absence of PTH, ineffective PTH, vitamin D deficiency, chronic renal failure, hypomagnesemia, or hypoalbuminemia. Other potential causes of chronic hypocalcemia include alkalosis, malabsorption syndromes, chronic pancreatitis, laxative abuse, chronic liver failure, phosphate excess, and osteomalacia.

Patients with carpopedal spasm should be immediately assessed for hypocalcemia. Normal serum calcium values in adults range from 9 to 11 mg/dL. Immediate medical treatment is indicated in patients with marked hypocalcemia (less than 6.5 mg/dL).

A focused history, clinical exam, and subsequent laboratory tests may determine the cause of hypocalcemia. In absence of a clearly identifiable etiology such as a medication, chronic liver or renal disease, or an acute disease process, additional laboratory studies are needed. Further laboratory evaluation should begin with serum magnesium, serum phosphorus, and albumin levels. Depending on these findings, the practitioner should initiate treatment if indicated. A serum PTH level will assist in the diagnosis of parathyroid disease. A direct measure of serum vitamin D levels is the 25-hydroxycholecalciferol (25-[OH]D_3) assay.

Trousseau's sign (carpal spasm) is one of two neuromuscular signs indicative of hypocalcemia. It is often preceded by muscle cramps in the legs and feet. Carpal spasm consists of a flexed elbow and wrist, adducted thumb over the palm, flexed metacarpophalangeal joints, adduction of hyperextended fingers, and extended interphalangeal joints. The response is elicited by inflation of a blood pressure cuff to 20 mm Hg above the level of the systolic blood pressure. Inflation is maintained for 3 minutes to elicit the response, which is secondary to ulnar and median nerve ischemia. In severe hypocalcemia, spontaneous spasms may also occur in the lower extremities and feet. *Chvostek's sign* is the second neuromuscular sign associated with hypocalcemia. It is an abnormal unilateral spasm of the facial muscle when the facial nerve is tapped below the zygomatic arch anterior to the earlobe.

Patients exhibiting either Trousseau's sign or Chvostek's sign accompanied by respiratory distress (e.g., stridor, loud crowing noises, and cyanosis) require immediate referral for emergency care because the neuromuscular irritation produced by hypocalcemia may progress rapidly to laryngospasms, seizures, and dysrhythmias. If the serum calcium levels have gradually declined, symptoms are usually subtle.

Other symptoms of hypocalcemia include various neuropsychiatric disorders, including irritability, emotional instability, problems with memory, and psychosis. Complaints of paresthesias, fatigue, muscle cramps, or muscle weakness may be elicited on history. Gastrointestinal

manifestations include dysphagia, nausea, vomiting, biliary colic, and abdominal pain or cramping. Patients may also complain of chronic constipation or diarrhea. Cardiovascular symptoms include hypotension, bradycardia, congestive heart failure, and dysrhythmias. Prolonged QT intervals may be seen on the electrocardiogram.

Chronic hypocalcemia may cause the skin to be coarse, dry, and scaly. Alopecia may present with thinning of the eyebrows and eyelashes. Nails are often rigid, brittle, and thin, with transverse grooves. Subcapsular cataracts, optic neuritis, intracranial calcification, papilledema, and parkinsonian-type movements may also be present in chronic hypocalcemia.

Management

Emergency treatment of hypocalcemia is IV replacement of calcium and is guided by severity of hypocalcemia paired with the patient's signs and symptoms. Patients with tetany, dysrhythmias, or seizures are treated with calcium gluconate (94 mg of elemental calcium) in bolus and maintenance infusion. Patients with hypomagnesemia also require IV magnesium replacement. During acute therapy and the initial therapy of chronic hypocalcemia, patients must be monitored closely for signs of hypercalcemia such as confusion, abdominal pain, dehydration, weakness, polydipsia, anorexia, nausea, vomiting, constipation, pancreatitis, peptic ulcer, polyuria, hypertension, and a shortened QT interval.

The goal of treatment of chronic hypocalcemia is to restore the serum calcium level to the low to normal range, and therapy includes calcium and vitamin D. Various preparations of calcium can be used, including calcium carbonate, calcium gluconate, calcium citrate, and calcium lactate. Calcium carbonate is the least expensive formulation; however, it may not be absorbed as well, especially in the elderly.

GYNECOMASTIA

Gynecomastia is the enlargement of glandular breast tissue in men, resulting in increased breast size. True gynecomastia involves enlargement of the stromal and ductal tissues; it may present unilaterally and progress to bilateral symmetrical or asymmetrical enlargement. Gynecomastia results from an imbalance of androgen and estrogen or an increase in prolactin. Growth hormones, estrogen, and corticosteroids stimulate ductal growth in the breasts. Progesterone and prolactin stimulate alveolar lobular growth of the breasts.

Gynecomastia is estimated to affect 12% to 40% of the male population in the United States and is present in 40% to 60% of men older than age 50 years. Transient gynecomastia occurs in male neonates and at puberty.

Differential Diagnosis

Asymptomatic gynecomastia may be an incidental finding on routine examination. It may also present as an acute unilateral or bilateral painful tender mass beneath the areola or as a progressive painless enlargement of breast tissue. The enlargement may be obvious by observation alone; however, less severe cases are noted only during palpation. Pain in the nipple or breast and tenderness often accompany gynecomastia. Gynecomastia lasting longer than 1 year is usually asymptomatic. Nipple discharge is rare (present in fewer than 5% of cases).

Gynecomastia associated with puberty has an age at onset of 12 to 14 years. The duration is approximately 6 months and then regression is expected. Gynecomastia that presents before or after puberty and cannot be associated with physiological aging, a drug, or chronic disease requires further investigation by an endocrinologist. Associated symptoms may assist in identifying the cause.

When gynecomastia is accompanied by other breast abnormalities, especially if they are unilateral, a mammogram is indicated to rule out a neoplasm. A disc that is greater than 4 cm in diameter should be evaluated via mammography.

True gynecomastia must be differentiated from pseudogynecomastia, which is fatty enlargement of the breast. The patient is examined in a supine position while the examiner grasps breast tissue between the thumb and forefinger and gently moves the two digits toward the nipple. A firm or rubbery, mobile, disclike mound of tissue at least 2 to 4 cm in diameter arising concentrically from beneath the nipple and areolar region confirms gynecomastia. The glandular enlargement of gynecomastia is usually resistive and ropy in texture. Severe cases present with more extensive enlargement. Lack of a disc of tissue suggests the enlargement is the result of adipose tissue deposition (pseudogynecomastia). Mammography will distinguish between the two if the clinical exam is inconclusive.

When true gynecomastia has been established, the patient is evaluated for physiological (developmental) or pathological causes. The most common causes of gynecomastia are puberty (25%), idiopathic (25%), drug related (15%), cirrhosis or malnutrition (10%), and testicular failure (10%). Other causes include renal failure, thyroid disease, neoplasms (including testicular cancer), hyperprolactinemia, Klinefelter's syndrome, and gonadotropin deficiency. Although physiological development of gynecomastia is the most common cause of gynecomastia, pathological causes should always be considered and ruled out via a thorough history and physical exam.

Medications that are implicated in gynecomastia are highly active antiviral therapy, calcium channel blockers, tricyclic antidepressants, and selective serotonin reuptake inhibitors. Less common medications are amiodarone, human growth hormone, amphetamines, and diazepam.

Malignant breast tumors (which represent about 3% of all cases of gynecomastia) in men are typically unilateral, firm, and immobile; grow rapidly; and are often painful. Nipple retraction and discharge, skin dimpling, and axillary lymphadenopathy also may accompany breast neoplasms. Mammography and fine-needle biopsy are essential for confirming the diagnosis.

Decreased libido and impotence may accompany gynecomastia and may indicate the presence of chronic pulmonary, renal, or liver disease; testicular failure; or endocrine pathology.

Management

Idiopathic and pubertal gynecomastia should resolve spontaneously within 1 to 2 years and require no medication. The patient should be followed every 3 to 6 months, and the size of the disc should be measured until it has resolved. Tamoxifen (Nolvadex) 10 mg twice daily may be useful in treating painful gynecomastia. It is generally used for up to 3 months and is an off-label use of tamoxifen. Cold compresses and analgesics may also relieve discomfort. Attention to any impact on body image, especially in adolescents, is important. Low-dose radiation or tamoxifen may prevent gynecomastia in men receiving estrogen or antiandrogen therapy for prostate cancer.

A referral to an endocrinologist is required for all cases in which gynecomastia appears before puberty, if gynecomastia does not resolve 2 years after puberty, if it occurs in the presence of abnormal serum levels of free testosterone and luteinizing hormones, or when gynecomastia is accompanied by the abnormal presence or the absence of secondary sex characteristics; undermasculinization; or small, asymmetrical testes. In a pubertal male, a referral is indicated at any time when physical findings are not consistent with normal growth and development.

The patient should be provided with information about gynecomastia and its cause. Reassurance is very important in a pubertal male. Patients should receive instruction on breast and testicular self-exam.

HIRSUTISM

Hirsutism is an increase in terminal hair growth on the face, chest, back, lower abdomen, pubic area, axilla, and inner thighs. It is present in approximately 5% of the female population in the United States. Almost 25% of these women have terminal hair growth on the face, especially on the upper lip. Hirsutism is caused by increased secretion of androgens by the ovary or adrenal glands or an increased sensitivity to androgens. It is often accompanied by menstrual irregularities.

There are two major types of hair: vellus and terminal. Vellus hair is found over most of the body and is fine, soft, and unpigmented. During puberty, vellus hair often changes to terminal hair in the presence of an increase in androgen. Terminal hairs are characteristically dark, coarse, pigmented, and thicker compared with vellus hair. Terminal hairs are found on the scalp, eyebrows, and the axillary and pubic areas after puberty. They are found in lesser abundance on the extremities.

Differential Diagnosis

The characteristic increase in terminal hair growth occurs in areas most sensitive to androgen: the upper lip, chin, chest, upper arms, upper abdomen, lower abdomen, thighs, and upper and lower back. Accompanying signs of virilization, hoarseness of the voice, clitorimegaly, receding temporal hairline, acne, loss of body fat, and breast atrophy may be due to an ovarian or adrenal tumor. Markedly increased levels of plasma androgens often accompany virilization.

Although most cases (87%) of hirsutism are idiopathic or result from polycystic ovary syndrome (PCOS), more serious underlying disease entities must be ruled out. A targeted history with emphasis on when hirsutism was first recognized and how rapidly it has progressed, a detailed menstrual history, and a review of associated symptoms may provide some insight into the cause of hirsutism. The physical exam should focus on signs of adrenal disease and virilization that may further clarify possible causes.

Laboratory evaluation of hirsutism is indicated in women with menstrual irregularities, a history of sudden onset or rapid progression of hirsutism, associated symptoms of ovarian or adrenal pathology, and moderate to severe presentations. Evaluation of free testosterone levels, androstenedione, total testosterone, 17-hydroxyprogesterone, urine 17-hydroxycorticosteroids, thyroid-stimulating hormone, prolactin levels, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and dehydroepiandrosterone sulfate (DHEA-S) will provide insights into possible causes or the need for further evaluation. Slightly elevated levels of serum androgens (free testosterone) are found in 40% of women with idiopathic hirsutism, whereas LH/FSH levels are increased in 75% of cases of PCOS. Testosterone levels greater than 200 ng/dL (in women) and/or DHEA-S levels above 700 ng/dL indicate the need for an ovarian and adrenal work-up, because these levels are rarely seen in idiopathic hirsutism or PCOS.

Androgen-dependent terminal hair growth may be caused by pathology in the adrenal glands or ovaries or by exogenous androgen administration. The age, associated symptoms, and rapidity of onset are critical factors in differentiating potential causes.
