To our families:
To my husband, Jim—for his patience, support, and affection, which have been ENDLESS...
To my parents, Joan and Arthur, for their immense love, and to my brother, Jim, for his good humor, steadfastness, and vacation planning!
Lynne M. Dunphy

To my husband, Harvey, who is my soulmate.
To my parents, who instilled a sense of purpose in me and never let me give up on myself.
To my children: My sons, who have grown into wonderful friends—Ken, Nathan, Eddie, and Mason—and my daughter Cydney, for all that we've shared in the past and look forward to in the future.
Jill E. Winland-Brown

As with all my professional endeavors, this continued work is ultimately for my family—my elegant and endlessly supportive wife Carolyn, our gifted and talented sons Mitchel and MJ, our creative and artistic daughter Cheyanne, and our brilliant yet goofy little one Brennan.
I also dedicate this work to my mother and professional inspiration, Dr. Luz Sobong Porter, and my dear aunt, Dr. Loreto Calibo Sobong.
Brian Oscar Porter

To my husband, Bob Coan, who has learned to cook, do laundry, and give a great foot massage; you keep me grounded.
To my parents, who inspired me to believe that I could do anything.
To my dog, Miller, who makes sure I get my exercise, and my cat, Neffer Kitty, for never failing to find my lap at the computer.
Debera J. Thomas

PREFACE

"We are not really in doubt about the more serious of our shared aims. We know what they are. We know they are difficult. And we know that we have not achieved them."

—John Gardner, Excellence, *p. 155, as quoted by Martha E. Rogers,* Reveille in Nursing, *p. 1*

This book grew out of a commitment to primary-care practice and a love and valuing of nursing knowledge. Fifty years ago, in 1964, Martha E. Rogers, Chairperson of the Department of Nursing Education, New York University, came out with a small red and white volume, soft-covered and a total of 96 pages, titled *Reveille in Nursing,* published by F. A. Davis. It was a book, she was later to comment, "that scared the pants off a lot of people" (Martha E. Rogers, personal communication, June 22, 1988). F. A. Davis continues to stand on its commitment to nursing knowledge with its publication of this text. The abandonment of nursing knowledge in some primary-care nurse practitioner programs is not a trend that Martha would have favored. One can hear her saying, "Where's the *nursing* in nurse practitioner primary-care practice? 'Where's the beef?'"

What we offer here is the "beef," a text that builds on the *Circle of Caring,* a holistic, caring-based approach to primary-care practice, consistent with nursing's historical base. Unit I contains five chapters that provide the theoretical base to a caring-based primary-care practice, which is operationalized in the remainder of the text. In this first unit, in Chapter 1, we provide a theoretical model of primary-care nursing, the *Circle of Caring.* The caring base of primary-care practice is presented by Drs. Boykin and Schoenhofer in Chapter 2, as a transformative model for our health-care system. A chapter on health promotion by Drs. Dorothy Dunn and Debera J. Thomas provides a base for primary-care practice that situates the patient and family in the context of the community in Chapter 3. Chapter 4, "The Art of Diagnosis and Treatment," by Dr. Susan K. Chase, describes how primary-care practice in a *Circle of Caring* is actualized through decision making and management plans. "Evidence-Based Practice," by Dr. Angela K. Golden, provides essential information for today's care practice environment. It is essential that all clinicians be able to provide care with a good understanding of the standard of care and the ability to meet that standard in a meaningful way.

Unit II uses the traditional system-based approach to provide the essential information necessary to provide safe and effective primary care to patients. Each system-based chapter begins with "Common Complaints," a symptom-based approach to phenomena that lays out the associated differential diagnoses of each symptom-based complaint a patient may present with. Then each chapter develops these various differentials under "Common Problems." Each problem is defined and the associated epidemiology and causes are outlined, as well as the pathophysiological processes. Dr. Brian O. Porter again has provided a thoughtful and in-depth update on the pathophysiology of each disorder developed within the chapters, as well as a thorough review of diagnostic processes and management plans.

The subjective and objective manifestations of each problem are elaborated, as well as the associated diagnostic testing that might be used. A review of potential differential diagnoses is elaborated, as well as the underlying reasoning and critical thinking involved in the decision making used to reach a specific diagnosis, which then determines treatment. As consistent with our model, a holistic database is established, built on the patient's voice and experience. Management strategies, including pharmacological and surgical therapy, when indicated, are outlined. Again, as consistent with our approach, complementary therapies and psychosocial interventions are elaborated providing a holistic plan of care. Follow-up and referral are included, along with long-term management strategies, and patient education—the important teaching/learning component of caring-based primary-care practice—is also included. Tables, figures, and recurring displays are provided in each chapter in Unit II. Displays include drug charts, therapeutic procedures that a clinician in primary care might be called on to perform, risk factors, screening guidelines, differential diagnosis flowcharts, treatment standards, and guidelines, as well as sidebars on focusing the history and advanced assessment techniques. Also, we provide highlights of complementary therapies and holistically-based advanced practice nursing interventions. Included are "Nursing Situations," essentially case studies, along with abstracts of nursing-based research, and anecdotes from patients, called "The Patient's Voice." The provision of this variety of information will assist any primary-care provider, regardless of disciplinary background, in establishing and implementing a holistic, caring practice base. These features assist the student (or current practitioner) in linking ideas to practice and actualizing a *Circle of Caring.*

We gained some new and exciting contributors to Unit II, such as Dr. Susan Kelly-Weeder, PhD, FNP-BC, from Boston College, who assisted us in redrafting Chapter 8, "Eyes, Ears, Nose, and Throat Problems." Building on the excellent work of Lori Martin-Plank, PhD, FNP-BC, GNP-BC, FAANP, we added Terry South, MSN, APRN, FNP-BC to Chapter 15, "Musculoskeletal Problems." We are also pleased to have added scholar-clinician Michael Zychowicz, DNP, FNP-BC,

FAANP, FAAN, noted specialist in the area of musculoskeletal problems, to oversee and finalize this chapter. We have collaborated with another physician, Michael B. Keller, MD, MS, who added valuable contributions to several chapters, specifically the neurological and cardiac content, and will continue to add his clinical expertise in the future. Dr. Keller is the son of our faculty colleague, Dr. Kathryn B. Keller, who coauthored the cardiac chapter, her area of specialization.

Unit III begins with Chapter 20, "Palliative Care," by Susan Derby, RN, MA, GNP-BC, ACHPN, and Mary Layman Goldstein, RN, MS, ANP-BC, ACHPN, of Memorial Sloan-Kettering Cancer Center in New York City, a chapter that includes comprehensive information on pain management. We are very pleased to provide our readers with an update of the popular chapter "The 15-Minute Hour: Practical Psychotherapy for Primary Care," authored by a new contributor, Brandi Parker Cotton, MSN, Psychiatric NP and doctoral student, building on the prior work of Drs. Eliezer Schnall and Marian Stuart. New content includes motivational interviewing as well as current evidence to support practice in this area. These approaches, developed specifically for primary-care practice, will provide primary-care practitioners with additional therapeutic communication skills that will enable them to "hear" the patient's true concerns, again supporting a holistic and caring practice model. "Ethical and Legal Issues of a Caring-Based Practice" is also an essential for practice, updated by leading nurse-ethicist Dr. Jill E. Winland-Brown. Chapter 22, "The Business of Advanced Practice," has been completely redone to integrate the information and implications of the Affordable Care Act. The author of this chapter, Dr. Marcella M. Rutherford, has a PhD in nursing as well as an MBA and years of experience in medical practice administration from which to draw. We conclude with essential information in "Putting Caring Into Practice: Caring for Self." This chapter has also been completely redone, with two new authors from the University of Rhode Island: Mary Lavin, DNP, APRN, FNP-BC, and Rebecca Carley, DNP, APRN, ANP-BC. They have used a different theoretical base from which to examine caring for self, as well as some important ideas for caring for one's own health.

As long-time nurse practitioner faculty, we remain committed to providing an in-depth book with a comprehensive and holistic approach that can be used across the curriculum (and in a variety of different curricula) and that includes participation by practitioners from other disciplines, such as medicine. Primary-care curriculum content exists in master's-level and doctorate of nursing practice programs. While appropriate for either level, we, as authors, are attentive to shifting practice boundaries and feel that the articulation of a largely nursing base for primary care, rooted in caring and holistic approaches, is critical to disciplinary identity and growth. This text provides a high-level pathophysiological base, evidence-based diagnostic and management strategies, and a holistic plan of care that is consistent with this level of practice. The student is able to find a large amount of information in one text. Although we realize that graduate students will always need supplementary texts to provide the currency and depth of information that they require, we nonetheless believe that they (and their faculty!) will appreciate one large, complete text, complemented by an ever-expanding collection of ancillaries for faculty and student use.

What we also provide is the "beef"—the "beef" of caring-based, advanced practice nursing as actualized in the NP role, in the full flowering of all that primary-care practice *could* be. We are answering the call that Jean Watson sounded in her 1995 article, "Advanced Nursing Practice . . . and What Might Be":

> Such a reform calls for nursing to shift its accountability and voice from the medical cure functional tasks and institutional demands and constraints toward making itself directly accountable to the public for its caring, healing, health knowledge, skills, and practices.
>
> —*Jean Watson (in Watson, J.* "Advanced Nursing Practice ... and What Might Be" *in Nursing & Health Care, Vol. 16, Number 2, p. 81)*

It is the most exciting time for advanced practice nursing. Health-care reform is a reality. The demand for new service approaches in health care is high. The professional doctorate—the DNP—is providing primary-care practitioners of nursing with a well-grounded base of pathophysiology, diagnosis and management, and follow-up, situated in a nursing-based model. Consumers are informed and powerful. Now it is time for nurse practitioners to provide consumers with the "beef"—advanced nursing primary-care practice within a *Circle of Caring*.

ACKNOWLEDGMENTS

There are numerous people to thank for helping this book become a reality:

Joanne P. DaCunha, our wonderful, PATIENT, always supportive, always optimistic publisher, whom we have come to know well, and who is, most of all, our friend.

Susan Rhyner, Senior Acquisitions Editor, who joins our team with a fresh eye, an innovative perspective, and infectious motivation.

Echo K. Gerhart, our new Content Project Manager, who has had to work *very* hard to keep us all in line!

Marcia Kelly, our Developmental Editor from afar, who was efficient, enthusiastic, and patient.

Kelly Boutross of Graphic World Inc., who worked tirelessly to "pull it all together" and maintained her composure at all times, even the most trying!

The entire F. A. Davis production team—*all* of whom were always patient, flexible, and terrific!

Dr. Marlaine Smith, Dean of the Christine E. Lynn College of Nursing, Professor, and caring scholar, who was quoted in this text far before she came to FAU—for her support for *all* our work.

Dr. Anne Boykin, Founding Dean of the Christine E. Lynn College of Nursing, who helped shape our vision for nursing and provides the glue that holds it together—caring.

Dr. Mary Sullivan, Interim Dean and Professor of the University of Rhode Island College of Nursing, for her support and encouragement during Dr. Dunphy's years at URI.

All of our students, past and present, who always continue to teach us as much, if not more, than we teach them!

We also acknowledge the following chapter authors of the third edition of this book, without which this new edition would not have been possible:

Sandra Allen, MSN, APRN, FNP-BC

Lisa J. Bedard, MSN, APRN, FNP-BC

Lauren Gallagher, MS, APRN, FNP-BC

Diane Gerzevitz, MSN, APRN, FNP-BC

Ruth McCaffrey, DNP, APRN, FNP, BC

Jacqueline Rhoads, PhD, RN, CCRN, ACNP-CS

Linda Hall Rothery, DNP, MSN, APRN, FNP-BC

Edwin W. Schaefer, ND, APRN, FNP-BC

Karilee Halo Shames, MSN, RN, HNC

Cathy M. St. Pierre, PhD, FNP, BC

And most of all, we acknowledge our patients, who taught us to "hear" their voices.

Lynne M. Dunphy, PhD, APRN, FNP-BC, FAAN Dr. Lynne Dunphy recently re-joined the faculty at the Christine E. Lynn College of Nursing, Florida Atlantic University, Boca Raton, Florida, in the role of Associate Dean for Practice and Community Engagement. In this role she is coordinating and directing the college's nurse-managed practices. Dr. Dunphy spent the last eight years at the College of Nursing at the University of Rhode Island, serving as the inaugural Routhier Chair of Practice and Associate Dean for External Affairs. She has been a Robert Wood Johnson Executive Nurse Fellow and was the founding nursing lead of the Rhode Island Action Coalition, dedicated to the implementation of the Institute of Medicine's recommendations for the Future of Nursing. Dr. Dunphy recently completed four years of service on the Board of the National Organization of Nurse Practitioner Faculties (NONPF).

Jill E. Winland-Brown, EdD, APRN, FNP-BC Dr. Winland-Brown was born in Boston, but raised in Pennsylvania. After high school, she went to Newport Hospital School of Nursing, Salve Regina College, Newport, Rhode Island, for her BSN, Boston College for her MS, and Florida Atlantic University for her EdD and post master's FNP. Her first teaching position was at the University of Rhode Island, after which she moved to Florida. She teaches ethics in the undergraduate program and teaches in the graduate and FNP programs. Children include his, mine, and ours, although after 30 years, all five are ours. In whatever little free time is left, her loves are the beach and tennis. Dr. Winland-Brown is also on the ANA Center for Ethics and Human Rights Advisory Board.

Brian Oscar Porter, MD, PhD, MPH Dr. Porter is a triple Board-certified and licensed Allergist and Immunologist, Internist, and Pediatrician. After completing both his MD and PhD in Immunology and Microbiology at the University of Miami School of Medicine (Miami, Florida), as well as his MPH at the Harvard School of Public Health (Boston, Massachusetts), Dr. Porter completed combined residency training in Internal Medicine and Pediatrics at the Virginia Commonwealth University Medical Center (Richmond, Virginia), followed by fellowship training in Allergy and Immunology at the National Institutes of Health (Bethesda, Maryland), where he also served as an Adjunct Intramural Investigator in the Laboratory of Immunoregulation and Principal Investigator on two NIH-based clinical and translational research protocols in primary and acquired immunodeficiency. Dr. Porter then joined the U.S. Food and Drug Administration's Center for Drug Evaluation and Research as a Primary Reviewer and Medical Officer, before transitioning into the private biopharmaceutical drug development industry as a clinical development physician focusing on biological immunotherapies and global product development strategy. Dr. Porter has held leadership roles in several companies, including Human Genome Sciences, GlaxoSmithKline, and most recently Novartis Pharmaceuticals, where he currently serves as an Associate Global Program Medical Director* (East Hanover, New Jersey). He also continues to work actively as a clinician in the Veterans Affairs New Jersey Health Care System as a Medical House Officer* (Lyons, New Jersey). Dr. Porter credits his multidisciplinary approach to human health largely to the influence and encouragement of his mother,

**The contents of this textbook and the independent contributions of Dr. Porter fall completely outside of his current employment and do not represent official views of Novartis Pharmaceuticals, the U.S. Department of Veterans Affairs, or any other U.S. federal government agency.*

Dr. Luz Sobong Porter, a nurse clinician, educator, and researcher, who always involved him in her work and remains one of his primary collaborators to this day.

Debera J. Thomas, DNS, RN, FNP/ANP Dr. Thomas is Professor and Dean of Nursing at Northern Arizona University in Flagstaff, Arizona. Her teaching career began in 1978 at Augustana Hospital School of Nursing in Chicago, Illinois. She has held numerous faculty and administrative positions at institutions including Kent State University, Case Western Reserve University, Florida Atlantic University, University of Connecticut, and Northern Arizona University. In her free time, Debera is a potter. She prefers wheel throwing and functional ceramics and works in high fire clay. On most weekends, you can find her hiking the trails in Northern Arizona and the Grand Canyon.

Nursing—The Seasons of My Life

Nursing is the spring of my life—
Each experience is fresh and new.
There's wonderment
Like flowers washed with morning dew.

Nursing is the summer of my life—
A time to perfect all I know.
There's confidence
A world where I can grow.
Nursing is the autumn of my life—
Ablaze with experience rich and glowing.
There's compassion
From richness of caring and knowing.

Nursing is the winter of my life—
A tapestry, a mosaic of all I am.
There's challenge
To find the spring again.

—Charlotte Dison, RN

UNIT ONE

Caring-Based Nursing: The Art

Advanced practice nursing is not filling the gap with medical care where it does not exist; it is filling the existing gap in health care with the core of nursing practice. . . . The core of advanced practice nursing lies within nursing's disciplinary perspective on human–environment and caring relationships that facilitate health and healing. This core is delineated specifically in the theoretic foundations of nursing. True advanced nursing practice is theory-based [and] fully integrated into the nurse's way of being and practicing.
—Marlaine Smith: The core of advanced practice nursing. Nurs Sci Q *8(1):2–3, 1995*

Primary Care in the Twenty-First Century: A Circle of Caring

Chapter 1

WHERE WE HAVE BEEN AND WHERE WE ARE GOING

This is a wonderful and exciting time to begin the study of primary care. The road ahead is brighter than ever for advanced practice registered nurses (APRNs). Our health-care system is in the process of reform. It is remaking itself. It is primary-care providers who will implement new and innovative ways of caring for patients. Education models are also in the process of being reformed; interprofessional education (IPE) and team-based approaches are becoming the required norm. APRNs will be a critical part of this reformed health-care team. Heeding the recommendations of the Institute of Medicine's report *The Future of Nursing: Leading Change, Advancing Health* (2011) that all nurses practice to their full scope of practice, states are implementing important changes in APRN practice regulations. This chapter will review the disciplines of nursing and medicine from a historical perspective, highlighting the different strengths that each brings to the care of patients. The *Circle of Caring* practice model on which this text is based will be presented as a way of making primary-care practice, which *must* incorporate aspects of what has been traditionally defined as "medical" practice, richer by the incorporation of nursing-based understanding of the patient's issues and concerns.

Currently, the American health-care system continues to struggle with fiscal realities, as well as questions of quality and access to care. Technological advancements, an aging population, chronic illnesses, and an increasingly educated and informed consumer are additional themes that color the ongoing debate over the American health-care system and, specifically, the Affordable Care Act (ACA). More than 2,000 pages long, the ACA passed both houses of Congress in early 2010, but public opinion about it remains divided.

Nonetheless, major reforms, such as the Patient-Centered Medical Home, are being implemented in many settings. At present, though, it is known that illness continues too often to be treated episodically, outside the context of home, family, community, and people's day-to-day lives, in isolation from the trajectory of the life of the individual. The major goals of *Healthy People 2020* (U.S. Department of Health and Human Services, 2010) of increasing quality and years of healthy life and the elimination of health disparities are far from being met. Health-care reform supports changes in reimbursement that will support health promotion, disease prevention, and chronic disease management in a more meaningful way. However, these areas have not historically been priorities in a technologically driven, acute-care–oriented, specialized health-care system. Despite increasingly strong evidence of the need for strengthening health-promotion and disease-prevention strategies, including behavioral change, as well as the need for caring and interaction in the health-care provider–patient relationship, these shifts are not easily accomplished. Health-care disciplines are in the throes of change, and change is never easy. Disciplinary and professional turf battles abound as health-care reimbursement shrinks.

Increasing access to care for more of the population, though morally essential, will exacerbate this crisis, as occurred in Massachusetts after the passage of that state's health-care reform legislation. There is a rising demand for primary-care services and a decreasing supply of professionals providing these services (Health Resources & Services Administration, 2013). As the population ages and the number of older Americans swells, so will the burden of chronic illness. Increasing numbers of older adults live with *multiple* chronic illnesses; currently 87% of Americans aged 65 to 79 years live with one chronic condition, and more than 45% suffer from three or more (Bodenheimer et al, 2009). By 2020, a projected 157 million patients will suffer from chronic disease.

Cancer, mental disorders, and diabetes will increase by 50% by 2023 (Bodenheimer et al, 2009). The number of individuals with disabilities is projected to grow

from about 5.1 million in 1986 to 22.6 million in 2040, or nearly 350%, even as the elderly population overall will grow by only 175% (Administration on Aging, 2012). For this reason, a range of community determinants of health, empowerment of individuals and families, and a substantially broadened role and impact of primary-care and other community-based services must be harnessed to ensure a seamless journey through the system of care throughout a person's whole life.

In the past, a portion of the burden of chronic-illness care was provided in hospitals and specialty practices, whereas today that care must be provided in primary-care settings and communities. This trend is expected to accelerate and will continue to stress the resources of primary-care systems (Decker et al, 2009). In this milieu, APRN care providers will be needed more than ever. APRNs excel in coordination of community-care services, and their nursing-based models of care support patient and family empowerment.

In a keynote address at the Centennial Conference of the National League for Nursing in 1993, Donna Shalala, former Secretary of the Department of Health and Human Services, stated that patients, families, groups, and communities are calling for the appearance of the "good fairy" in health care—someone who really hears them and their concerns, the nitty-gritty of their day-to-day experiences and struggles. Patients and their families need someone to hear why they did not take the medication that their health-care provider was so quick to prescribe, but that they just could not tolerate, could not afford, could not get to the pharmacy to pick up, or that had directions for administration that they could not understand or read; to hear why they did not have the mammogram—because they were afraid; to hear why the baby was not immunized—because putting food on the table was more important.

The Tip of the Iceberg

The health problems encountered in day-to-day practice are merely the tip of the iceberg that our health-care system, traditionally focused on the easily visible peaks above the water, has "plowed into." Reimbursement streams pay for the "tip" of this iceberg: a visit to a primary-care provider to put a diagnostic label, for billing purposes, on the symptomatology that the patient presents with, and a "treatment"—typically a pharmaceutical product—aimed at treating that symptom or underlying disease. Whether health-care reform will be able to effect meaningful changes in this current reality of the U.S. system remains to be seen. Will the ACA really be able to reverse the dysfunctional fee-for-service payment model?

The true causality of whatever brought the patient into the primary-care setting is the much larger part of the iceberg that lies under the surface. This "understructure" is built of various lifestyle issues, as well as environmental, community, socioeconomic, spiritual, family, and biological–genetic factors that have an impact on health, often referred to as the *social determinants of health.* The nursing perspective—Donna Shalala's "good fairy"—is even more critical in today's world than it was in 1993. Nurses can and must understand the *whole* of the "patient's iceberg" (Fig. 1.1); they are educated to see both above *and* below the water and to intervene accordingly.

The classic medical model focuses on disease, an abnormality in the structure and function of body organs and systems, and is concerned with the malfunction or maladaption of biological or psychophysiological processes in the individual. In his textbook of family practice, Robert Rakel makes a distinction between the terms *disease* and *illness* (Rakel, 2011). *Illness* is "all the sensations of a patient and all the ramifications of a disorder." *Disease,* however, "is a theoretical and taxonomic concept, a useful tool that enables the healthcare provider to make inferences and predictions concerning phenomena." As such, the two concepts of illness and disease belong to two different universes of discourse: one, the world of theory, and the other, the lived experience of the patient. Benner and Wrubel (1989) also distinguish between disease and the experience of disease, or illness. *Illness* is defined as the way the sick person and his or her social network perceive and respond to disease. Illness is inextricable from the context of the patient's life, including the intersections of social, political, economic, spiritual, and cultural factors—in other words, the whole of the iceberg, which includes all of the community determinants of health.

Historically, nursing has been concerned with the whole person, the promotion of health across the life span—what Florence Nightingale referred to as "the Laws of Health." Nurses also have historically focused on people's responses to the illness experience in the

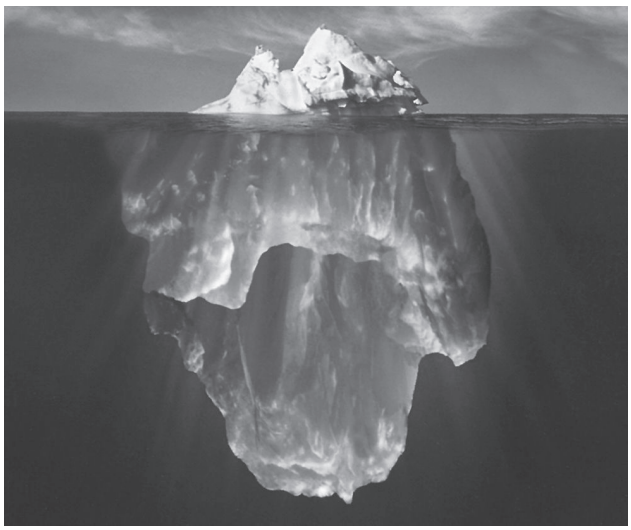

Figure 1.1 Nurses understand the *whole* of the iceberg; they are educated to see both above *and* below the water and to intervene accordingly.

context of their day-to-day lives. Much of the challenge in the role of the APRN has been the negotiation of seemingly disparate worlds: the reconciliation of an essentially holistic nursing model with a health-care system still focused predominantly on disease-oriented care. It is precisely this nexus between more discrete diagnostic categories of disease and a more holistic view of the continuum between health and illness—the iceberg—that gives nursing its identity, richness, diversity, and usefulness. Today's primary-care practitioners dwell in this nexus and must bridge these two realities—the world of disease and the world of illness, including the context of the patient's life in all its complexity. The increasing and necessary placement of APRNs into primary-care settings and teams across the health-care continuum provides nursing with the opportunity to effect change on both the micro and macro levels—in the lives of individual patients and families, as well as in the well-being of communities, including the global community.

A recent Hastings Center Report discussed the difficulty in making prevention a meaningful part of health-care reform because it involves changing behavior. The author notes that changing health behaviors involves changing habits that have "complex developmental, psychological, cultural, and socioeconomic roots" (Blacksher, 2009). In addition, health promotion and disease prevention require comprehensive policy changes and community involvement. In addition to care of the sick, the real-life, day-to-day health needs of people, their social and economic circumstances, and their communities are all part of the traditional domain of nursing practice as stated by Florence Nightingale. Nightingale understood these links and discussed them, as well as care of the sick, in her prophetic *Notes on Nursing* (1860).

Nurse historian Ellen Baer notes that the services demanded of primary-care providers today are broader in scope than those within the domain of medicine before the 1960s. Supportive functions, previously the domain of the clergy or multigenerational families and the like, are now within the purview of the primary-care provider. Likewise, the conceptual shift to health promotion, coupled with increased knowledge about healthy lifestyles, necessitates that primary-care providers be well grounded in their patients' community context. In making her case for the role of the nurse in primary care, Baer concludes: "The best reason for nurses to provide primary care is because they are nurses. Nursing's focus on people; its blend of medical, behavioral, and social science expertise; and its commitment to caring, teaching, counseling, and supporting patients are the characteristics of nursing that make nurses so uniquely qualified to provide primary health care services" (Baer, 1993).

This text provides a nursing-based approach to primary care and includes content on health promotion and disease prevention, as well as the diagnosis, management, and treatment of disease in the primary-care setting. The essentials of disease pathology and management necessary for safe and satisfactory functioning in the clinical area are integrated into a view of the wholeness of persons, an understanding of human responses, and a repertoire of therapeutic options. This information will enable the primary-care provider, regardless of disciplinary background, to become an orchestrator of health and wellness, as well as a skilled negotiator and mediator in the space that exists between health and illness, between disease and the "lived experience of the patient" in the context of his or her community. APRNs must understand the discipline of nursing to effectively fill the gap between health and illness with true nursing care. Nurses on teams and in IPE educational settings must be confident and secure about their knowledge base and its contribution to the care of the patient.

The American Association of Colleges of Nursing (AACN) has called for all APRN preparation to take place in practice-based programs at the doctoral level—the Doctor of Nursing Practice (DNP). In 2006, the AACN *Essentials of Doctoral Education for Advanced Nursing Practice* was approved (American Association of Colleges of Nursing, 2009). Essential VIII, Advanced Nursing Practice, was further defined as a set of advanced nursing practice competencies (Table 1.1).

The DNP is a catalyst, allowing nursing to develop and expand nursing knowledge and practice through health promotion and disease prevention practices, essential for disciplinary distinction and growth (Burman et al, 2009). As noted by Burman et al, "Ultimately our vision is for NP care to be consistently 'different,'

Table 1.1 Essential VIII: Advanced Nursing Practice Competencies

1. Conduct a comprehensive and systematic assessment of health and illness parameters in complex situations, incorporating diverse and culturally sensitive approaches.
2. Design, implement, and evaluate therapeutic interventions based on nursing science and other sciences.
3. Develop and sustain therapeutic relationships and partnerships with patients (individuals, family, or group) and other professionals to facilitate optimal care and patient outcomes.
4. Demonstrate advanced levels of clinical judgment, systems thinking, and accountability in designing, delivering, and evaluating evidence-based care to improve patient outcomes.
5. Guide, mentor, and support other nurses to achieve excellence in nursing practice.
6. Educate and guide individuals and groups through complex health and situational transitions.
7. Use conceptual and analytic skills in evaluating links among practice, organizational, population, fiscal, and policy issues.

yet just as essential as physician care, leading to positive outcomes in health promotion and disease management" (2009).

HISTORICAL PERSPECTIVES ON ADVANCED PRACTICE NURSING

Nursing as a discipline and a profession with a theoretical base can be traced to Florence Nightingale. As long ago as 1860, Nightingale in *Notes on Nursing* proclaimed that there were laws of sickness and laws of health. There was not enough known, she wrote, about the laws of health. Nursing the "room," meaning the environment surrounding the patient, was as important as nursing the patient. She also wrote that nursing and medicine were like "cats and dogs" and should not be mixed.

The early public health nurses of Lillian Wald's Henry Street Settlement House at the turn of the 20th century were an autonomous lot, with their own vision of health and illness. They took this message directly to the community, including both working and living in this community. Lavinia Dock, one of the first Henry Street nurses, evolved a model, shown in Figure 1.2, that is much needed today. New and emerging primary-care models are attempting to recapture population-based care, health promotion, and disease prevention in more meaningful and reimbursable ways, such as team approaches and the ideas of Patient-Centered Medical Homes (PCMHs) and Affordable Care Organizations (ACOs), integrated health-care systems that cross the continuum of care.

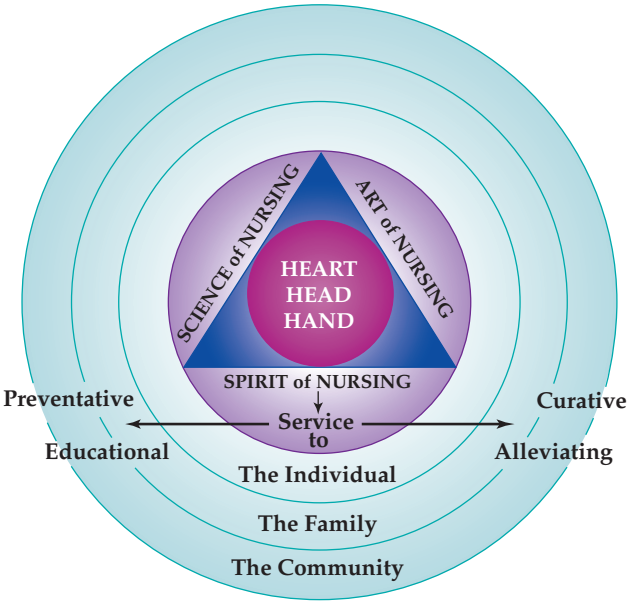

Figure 1.2 The professional equipment of the modern nurse and the scope of her responsibilities. *(Source: Dock, LL, and Stewart, IM.* A short history of nursing: From the earliest times to the present day, *ed 3. GP Putnam's Sons, New York, 1931, p 337.)*

Nurses' functions have always been rooted in population-based, public health approaches, and nursing has always claimed domains that were educational and preventive as well as curative. Nurses alleviated illness and actualized self and "other" through service to the individual, family, and community. As noted by Blacksher in an editorial in the *Hastings Center Report on Prevention,* "Health happens where people live, learn, love, work, and play" (2009). These activities flowed from the spirit, science, and art of nursing or the "heart, head, and hand" of nursing (a phrase popularized by Virginia Henderson [1966]). The first instances of standardized protocols, for example, evolved from the work of the early school nurses and the New York City Public Health Department. These early public health nurses enjoyed an autonomy of practice similar to that exercised by today's primary-care providers. Dock and Stewart (1920) likened the relationship between nursing and medicine to workers on a team who complement and supplement each other; the relationship is based on neither independence nor subordination but on interdependence and cooperation.

Henderson's 1966 book *The Nature of Nursing* was an attempt to provide nursing with its own explanatory model for practice. Building on her own experiences in nursing (Henderson also spent time as a public health nurse at the Henry Street Settlement) and on her understanding of physiology, she tried to place nursing on a continuum with medical care. Henderson argued that nurses had to place themselves (figuratively) "inside" patients in order to become their "counterpart, alter ego, or helper" (1966).

Martha Rogers, another nurse-theoretician, argued for the necessity of an independent basis of nursing science out of which autonomous nursing practice grows. According to Rogers, "Primary care by nurses is as old as modern nursing," citing a number of examples rooted in her early public health nursing experiences (as quoted in Hektor, 1989). She was, however, staunchly opposed to the development of the nurse practitioner role. In a 1975 position statement published in the *American Journal of Nursing,* she boldly asserted, "Not all nurses have succumbed to the blandishments of euphemisms and the increasingly blatant perfidy spawned by such terms as *pediatric associate, nurse practitioner, primary-care practitioner, geriatric practitioner, physician extender,* and other equally weird and wonderful cover-ups—designed to provide succor and profit for the nation's shamans" (Rogers). Those patients that ended up in hospitals were, in her words, "our mistakes" (as quoted in Hektor, 1989).

The early nurse practitioner "movement" evolved with little connection to academia and the flurry of nursing conceptual models and theories that proliferated throughout the 1970s and 1980s. These pioneering nurse practitioners, rooted in practice, usually in a primary-care setting, and often "trained" in certificate programs, had

little patience with the abstractions of nursing theory that provided little meaning for their day-to-day practice. They needed and valued the medical model to care for their patients. Yet most remained nurses at heart, devoted to health promotion, disease prevention, and providing holistic care to their patients. Nurses in today's DNP programs bring 4 years of a nursing baccalaureate base with them, as well as practice as *nurses.* Thus, the DNP is a strong base on which to build advanced nursing practice.

Very few nursing models have addressed or attempted to make sense of the dichotomy of nurse practitioner practice and medical care. Some argue that no dichotomy exists. A number of others, however, identify the relationship between advanced nursing practice and medical practice as an issue requiring ongoing attention. Cody views medicine as still dominating nursing politically, and he states that many nurses "actually value having medical tasks delegated to them" (1994). On a more ominous note, he points out that nursing must realize what is merely delegated from another (more powerful) discipline can also be taken away. He concludes, "Only when nurses everywhere are guided by a theory base specific to nursing will nursing have achieved parity with other scholarly disciplines." In a coauthored article, Barbara Bates, MD, and Joan Lynaugh, NP, venture some thoughts on the relationship between nursing and medicine: Medicine, they speculate, is concerned with structure; nursing is focused on function (Lynaugh & Bates, 1973).

In an unpublished paper, Lynaugh discusses the respective roles of nurses and physicians in greater depth. She notes that the biomedical model of disease and cure, which swept across the Western world, seemed far more compelling and promising than nursing's holism, environmentalism, and "watchful waiting" approach to illness (Lynaugh & Bates, 1973). Nurses, she elaborates, seem to be both inarticulate in explaining their work and "touchingly confident" that altruism will eventually be rewarded. Years of medical dominance have drawn a veil over the work of nursing. Lynaugh stresses that this invisibility is serious because it compromises the public's access to good nursing care in an era in which reimbursement for care is restricted to payment based exclusively on the phenomena of interest to physicians. The power relationships among patient, nurse, and physician are complicated by economic issues, professional territoriality on all sides, and profound questions of disciplinary identity; therefore, Lynaugh suggests, adjustments in these relationships will come slowly, step by step, but inevitably. An essential component of this process is making the "invisible" work of nurses more visible. It is the part of the iceberg that is below the water that takes up so much of nursing's time and energy and is so unnamed and unseen. Demonstration of nursing's contribution to patient care is vital. This is accomplished, in part, through the clear articulation of nursing's theoretical base.

As nursing theory embraces the mode of midrange theory development and testing, with real-life clinical applications for practice, the applicability to advanced practice nursing and the utilization of theory-based practice should increase. This still begs the question, however, of an underlying theoretical basis for advanced practice nursing. It can be argued, as Burman et al do in an article titled "Reconceptualizing the Core of Nurse Practitioner Education and Practice," that "the heart and soul of nursing is health promotion both in healthy persons and those dealing with chronic illness" (Burman et al, 2009). Nursing practice as a DNP should focus more explicitly on health promotion, changing health behaviors, and chronic disease management, thus advancing a unique nursing science. These are traditional nursing domains and strengths. These authors state that advanced practice nurses "can fill the growing societal need for expert clinicians to assume major leadership roles in clinical management and evaluation of outcomes research arenas. Doctor of Nursing Practice (DNP) programs include extensive clinical practicum and have a strong focus on scholarly and evidence-based practice."

ADVANCED PRACTICE NURSING: MODELS OF PRACTICE

Expert practice domains of the clinical nurse specialist and nurse practitioner were originally identified by Fenton and Brykczynski in 1993 and evolved from domains identified in Patricia Benner's 1984 book *From Novice to Expert.* In 1990, these identified domains were used by the National Organization of Nurse Practitioner Faculties (NONPF), the long-time leader in education of nurse practitioners (Zimmer et al, 1990) to create a framework for primary-care nurse practitioner curricula.

In a study by Lewis and Brykczynski (1994), the authors elaborated on the practical knowledge as well as the healing role of nurse practitioners. In the discussion of their findings, the authors state that to bring about healing, nurse practitioners will go beyond the call of duty, going to schools, for example, to fight for a patient's rights, making phone calls, driving patients to appointments, and going to funerals. The practitioners in the study describe both the professional and personal satisfaction derived from their caring practices, even when the rewards of such actions were small. Lewis and Brykczynski (1994) situate their work within a caring paradigm, citing work by Sally Gadow, Jean Watson, and Madeline Leininger. They also cite the 1991 work of Benner, who, in studying the effectiveness of expert nurses, found that mere technique and knowledge were not enough, and that caring, or a certain level of human involvement, was required for expert human practice. Indeed, expert "human practice" should be a goal of all primary-care providers.

Johnson (1993) cites clear evidence of a nursing perspective in nurse practitioner practice in primary care. According to Johnson, nurse practitioner–patient dialogue

incorporates the voice of medicine and the voice of the "lifeworld" (of the patient). The skilled practitioner "knows self" and how to share his or her own personal experience to either enhance the patient's progress or strengthen the provider–patient bond. An element of camaraderie was viewed as positive and not in opposition to maintaining a professional stance. *Coordination, continuity,* and *advocacy* were the major functions the nurse practitioners in this study believed they contributed to the practice. All primary-care practice needs these functions, which constitute some of the foundational ideas of a Patient-Centered Medical Home.

Swanson (1995) proposed "A Spirit-Focused Conceptual Model of Nursing for the Advanced Practice Nurse" in which she identified the core of every person, both patient and nurse, as the spirit. She describes the act of nursing as a goal-directed interpersonal relationship between the patient and nurse, based on traditional nursing process components such as assessing, planning, intervening, and evaluating. Interventions are broad based, ranging from play, music, and stories to utilization of counseling principles such as active listening and anticipatory guidance. The use of this approach in primary-care practice could be adapted by any primary-care practitioner.

The Shuler Nurse Practitioner Practice Model (Shuler & Davis, 1993) is an ambitious attempt to describe the nurse practitioner's integrated role. Building on a holistic nursing assessment, the next step is the mutual identification of unmet patient health needs to identify health problems. The treatment plan must be mutually agreeable and oriented toward self-care; disease prevention and health promotion activities are incorporated into the treatment plan. Nonpharmacological treatments, including alternative and complementary healing practices, are also integrated into the plan. These approaches are framed within the concept of functioning within a multidisciplinary team and could be seen as particularly relevant for today.

In addition, this model is seen as enhancing both the patient's and the nurse practitioner's personal movement toward wellness. Patients are encouraged to examine their lives honestly and to identify areas that are not "balanced." The patient's physical and psychological ability to participate in wellness activities is assessed; creative, uninhibited problem-solving and identification of appropriate wellness activities are pursued. The model emphasizes that the primary-care provider's personal commitment to wellness and health can have a direct impact on the practitioner's ability to influence positive patient outcomes.

Another interesting approach to nursing phenomena, not elaborated as unique for APRNs, but yet with wide applicability to the autonomy of an advanced practice nursing role, is "symptom management." This work has evolved from the University of California, San Francisco, School of Nursing Symptom Management Faculty Group (1994) and has since been revised based on research studies testing the model (Dodd et al, 2001). Proponents of this approach note that when the underlying cause of the patient's problem and the presenting symptoms are managed concurrently, patients are more likely to benefit and remain in treatment.

The Symptom Management group proposes that symptoms be viewed as subjective experiences reflecting changes in a person's biopsychosocial function, sensation, or cognition. They contrast this view of the word *symptom,* a subjective phenomenon, with the word *sign,* which is used to mean an abnormality indicative of disease, which can be observed by another person and sometimes by the patient, and is thus identified as objective. The model they propose for looking at symptoms has three dimensions:

1. The symptom experience (subjective)
2. Symptom management strategies
3. Symptom outcomes

In the revised Symptom Management Model, the nursing domains of nursing science, person, health/illness, and environment are described as having an effect on these three dimensions (Dodd et al, 2001). The model encompasses a multidimensional approach to the experience of the symptom, ways to approach the management of symptoms (always in concert with the patient and family), and outcomes that are gauged on a variety of axes.

Snyder and Mirr (1995) conceptualize advanced practice within a nursing paradigm built around human responses as a focus for nursing interventions. They identify the following foci for advanced practice nursing:

1. Self-care limitations
2. Impaired functioning in areas of rest, sleep, ventilation, circulation, nutrition, and the like
3. Pain and discomfort
4. Emotional problems related to illness and treatment, life-threatening events, or daily experiences, such as anxiety, loss, or loneliness
5. Distortion of symbolic functions reflected in interpersonal and intellectual processes such as hallucinations
6. Deficiencies in decision-making ability to make personal choices
7. Self-image changes required by health status
8. Dysfunctional perceptual orientations to health
9. Strains related to life processes such as birth, development, and death
10. Problematic affiliative relationships

Patient problems, conceptualized in this manner, are amenable to uniquely nursing-based interventions. Attention to human responses, as such, provide the missing link to much that is absent within today's contemporary health-care system. Many of these responses are tied to social determinants of health—such as where one lives and works. Our current health-care system, however, is

not structured in such a way to make many of these practices sustainable: They are not coded for reimbursement.

Ryan's (2009) Integrated Theory of Health Behavior Change (ITHBC) is based on the belief that health promotion activities are an integral part of the long-term health and well-being of both healthy people and those with chronic illnesses. For health promotion to be successful, people must take responsibility for initiating and maintaining both health behavior changes and prevention behaviors. APRNs are in a position to facilitate and support health behavior changes in their patients, and therefore APRNs require knowledge of what drives people to make these changes. This is especially true in today's health-care system, which requires patients and their families to take responsibility for increasingly complex conditions in the home. This trend will continue to escalate as hospital care will be reserved for acutely ill patients.

The ITHBC can be used by APRNs to tailor interventions for individual patients in such a way that positively affects their long-term health status. Health behavior change is directly influenced by "fostering knowledge and beliefs, increasing self-regulation skill and ability, and enhancing social facilitation" (Ryan, 2009). Social facilitation involves both social influence and support, which is of particular importance to APRNs, who are in a unique position to be a source of both for their patients. New research demonstrates that health behaviors are strongly influenced by the health behaviors of those in the patient's social network. Models such as ITHBC have great relevance for APRNs in primary-care settings today.

Cumbie, Conley, and Burman's (2004) Model of Promoting Process Engagement is a patient-centered theory developed to assist APRNs to manage the care of chronically ill patients. In this model, interventions of the APRN are chosen based on each patient's needs and expectations of his or her care and are developed in collaboration with the patient. "Interventions focus on motivational strategies designed to facilitate and support individuals as they make sense of health information, engage in health promoting activities, and sustain health-related behavioral change" (Cumbie et al, 2004). People are influenced by a number of internal and external variables that cause them to either "resist or engage in beneficial health behaviors" (Cumbie et al, 2004). To promote engagement, APRNs must help patients make sense of health information so that this information can become meaningful to them.

APRNs can use the intervention structure of the model to help their patients become actively involved in managing chronic illness. Engagement strategies include patient-centered assessment followed by therapeutic interview, and communication techniques (Cumbie et al, 2004). When the patient's health–illness situation is understood, the APRN works with patients to determine their health priorities and to develop mutually agreed on health goals and a plan of action to meet these goals (Cumbie et al, 2004). Case management, advocacy, and referral are activities of the ongoing collaborative process, which is the part of the intervention that is used to "sustain health process engagement" (Cumbie et al, 2004).

CHANGING MODELS OF MEDICAL PRACTICE

Changes are afoot in medical practice as well. Fiscally unsustainable, the American health-care system *had* to change. Cost-consciousness, the availability of medical information (and misinformation) on the Internet, the move from hospital to community provision of health care, multiculturalism, the growing interest in holistic care and alternative therapies, an increasingly litigious environment, and the ever-expanding use of technology—all of these factors continue to force reexamination of traditional professional roles.

Advances in therapeutics over the course of the 20th century, which are often taken for granted now, were overwhelmingly different than any that had been seen before. Medicine is able to intervene—specifically, powerfully, and radically—in the course of previously fatal diseases. No disorder, however complex, seems beyond the possibility of understanding and cure. As a result, the impact of medicine is felt far beyond the immediacies of the patient–provider encounter. Alcoholism, for example, viewed as a moral disorder in earlier times, is now a phenomenon conceptualized as a disease, with an array of both psychological and pharmacological interventions available to practitioners.

A review of the progress of medicine in combating disease is a journey from an integrated view of illness and therapeutics to one of discrete diseases with distinct causes and an armamentarium of ever-expanding and specific therapeutics. From the time of the ancient Greeks and Romans until well into the 19th century, illness was seen as an imbalance in the economy of the whole body, which could be expressed in the relationships between input or output of food, sweat, secretions, urine, phlegm, and the like. Treatment was focused on restoring harmony and balance between body and environment (a view promulgated by Nightingale, 1860/1969). Specific symptoms were not treated; instead, a systemic physiological effect was sought through such methods as inducing or facilitating sweating, febrilysis, diuresis, and/or vomiting. These interventions, it was theorized, would assist the body to recover its balance.

Throughout the course of the 19th century, however, this integrated view of disease and therapeutics was increasingly challenged by notions of discrete disease states with specific causes. Illnesses seemed less amenable to purges, bleeding, and diuretics (the so-called holistic approaches) than was previously thought. Quite late in the modern era, the first active principles of some of the oldest, most useful botanicals were isolated, and later some were even synthesized. A new dimension was added to the emerging concept of specificity of therapeutics by

the discovery of sulfonamides in the late 1930s and penicillin in the early 1940s. Not only could therapy be directed at particular symptoms, but for the first time, therapeutics could become "radical," matching the power of the surgeon's knife—that is, they could eradicate the primary cause of an illness, in this case, specific microorganisms.

More highly specific measures, such as the use of antisera, the isolation of blood fractions, and the synthesis of polypeptide hormones, are products of the last few decades. Advances in laboratory analysis and diagnostic techniques confer on therapeutics the capability of effecting cure at the molecular loci of disease. The era of specific and radical therapeutics has only just begun. What seems certain is the trend toward even greater specificity in diagnosis and treatment of disease, extending to the genetic level. This will continue to have profound effects on the medical profession, on society, and on inherent power imbalances among patients, nurses, and physicians. Additionally, new diagnostic and therapeutic technologies will surely raise questions of access to care and equitable distribution among all patients.

Medicine's successes have led to a generation of physician-specialists, some of whom are far removed from the day-to-day lives of their patients. The effectiveness of modern therapeutics adds a powerful strain of reductionism and positivism to the 20th-century medical ethos. Although this has been a useful stance for the creation of effective medical interventions, when universalized to all realms of medical practice, this stance may be antithetical to the fulfillment of the more sensitive moral and social responsibilities of medicine. Care—when defined as helping the patient and family to cope, offering reassurance, educating, and relieving worry—does not require a high level of scientific sophistication, but it does require human understanding. When the physician's remuneration was meager and he or she was a member of the community, issues such as those raised above may have been negotiated more successfully between doctor and patient. The doctor of today, however, is more often a stranger with multiple competing priorities. This raises a fearful dilemma for patients: They must trust the physician because of his or her power to heal, but that trust is undermined by the fear of the physician's self-interest. Additionally, social responsibilities in a broader sense—in a public health sense—have become neglected.

Concurrently, there has been a dawning recognition of the *limits* of medical progress and its partner, technological innovation. Beginning with the AIDS epidemic in the early 1980s through the current struggle with multidrug-resistant organisms, it has become increasingly clear that not everything can be controlled solely through medical technology and the development of newer therapeutics. Overwhelming evidence exists that technological innovations are drivers of health-care costs. In numerous studies over time, some 60% of improvement in health status is tied to socioeconomic factors, particularly education and income. With the notable exception of the health care of elders, this means that only approximately 40% of improvements in health result from medical care.

There is an increasing call for a better balance between cure-oriented and care-oriented medicine. Chronic disease continues to emerge as the most difficult and expensive kind of health problem to manage, as demonstrated in the failure of cure-oriented medicine to completely eradicate the most common causes of morbidity, such as heart disease and cancer. People are merely living with them longer; in fact, much of medicine is focused on the long-term management, rather than cure, of chronic disease. Care-oriented medicine reflects well-coordinated medical assistance to patients to enable them to manage disease combined with the marshaling of needed family and social supports—again, traditional nursing strengths and domains. Prevention as an approach can only go so far, however. In the end, sickness and death can be forestalled, but not eradicated, and the costs deferred or minimized, but not eliminated entirely. According to Daniel Callahan, "Serious progress would mean turning back the clock: learning to take care of ourselves, to tolerate some degree of discomfort, to accept the reality of aging and death, and to see our personal doctor as someone as likely to talk to as to have us scanned" (Callahan, 2009).

Medicine is not unaware of this quandary; indeed, these issues are widely discussed in medical circles and among policy makers. A loss of 60% of the nation's hospital beds has been predicted in some reports. There is a converging agreement among health-care and health-care policy experts that allopathic medicine as it has developed across the 20th century does not give the country that much health. Nine-tenths of the health of a community has to do with habits, lifestyles, environment, and genetics. Allopathic medicine only operates at the margin, yet the American health-care system has been structured on this mode of care (Commonwealth Fund Commission on a High Performance Health Care System, 2008).

Over the last decade, American health professional schools were charged with expanding the scientific base of their programs to include psychosocial–behavioral sciences, as well as population-based approaches to clinical work (Whitcomb & Nutter, 2004). The sharing of clinical teaching resources, especially in key areas of preclinical and clinical training, is mandated, as well as cross-teaching and more exploration of the roles played by various professionals, referred to as interprofessional education (IPE). Active modeling of effective team integration in the delivery of efficient, high-quality care is essential to the aims of decreased costs, increased access, and improved quality outcomes that are the hallmark of health-care reform.

In addition, effective interdisciplinary teamwork is essential to bridge the ever-widening chasm between basic science research and the implementation of that research at the bedside. Over the last 30 years, basic science and

clinical research have diverged, and a divide has opened between biomedical researchers and the patients who need their discoveries (Committee on Facilitating Interdisciplinary Research, 2005). This has led to the conceptualization of *translational research* as bridging that gap. Indeed, many of the major strides in understanding disease mechanisms are not resulting in commensurate gains in new treatments, diagnostics, or prevention; conversely, important clinical questions arising at the bedside are not making their way back to the laboratory for investigation. New cures and therapies are ever more expensive to develop and "worryingly thin on the ground". The spectacular success of basic science research, largely funded by the National Institutes of Health (NIH), has led to questions regarding the mandate to apply that knowledge, as consistent with the mission of pursuing fundamental knowledge and applying it "to reduce the burdens of illness and disability" (Committee on Facilitating Interdisciplinary Research, 2005). Biomedical research was previously the domain of physician-scientists, who also cared for patients. However, advances in molecular biology in the 1970s created a new paradigm, in which clinical and basic research began to diverge. Today, the majority of biomedical research is conducted by highly specialized PhD scientists, whereas physician-scientists are a minority. In turn, translational research *demands* collaboration. Large multidisciplinary groups composed of basic scientists and clinicians, as well as bioinformaticians, statisticians, engineers, and industry experts, are needed to work together and bridge the gulf between bench and bedside. Certainly, DNPs and APRNs would be appropriate team members to participate in this enterprise and may be ideally suited to coordinate, if not lead, such teams.

Emerging trends in medicine have included more explicitly the need for relational models of care. In 1995, Dacher espoused the "Whole Healing model," which is rooted in assumptions of dynamism, holism, and purposefulness. He called for a renewed emphasis on the quality and character of the relationships that constitute the healing process—the practitioner to himself or herself, to his or her patient, to other practitioners, and to the community at large—and a careful balance between reductive and holistic perspectives. This integrated model expands the diagnostic process, for example, to include a concern with psychological, spiritual, community, and environmental issues and acknowledges the uniqueness and subjectivity of a person's life circumstances. This approach is totally consistent with a nursing-based approach.

In *Patient-Centered Medicine,* the physician authors (Stewart et al, 1995) address the need for a new method of patient care, founded in new paradigms. On the limitations of the current medical model, situated in the context of disease and curative therapeutics, the authors remind us: "A particular disease is what everyone with that disease has in common, but the illness experience of every person is unique." Patient-centered medicine encourages exploring both the disease and the illness experience, understanding the whole person, finding common ground, incorporating prevention and health promotion, enhancing the patient–doctor relationship, and being realistic. Clearly, these components have been well established in nursing models.

In 2003, the Institute of Medicine published *Health Professions Education: A Bridge to Quality.* This report on reforming education for the health professions emphasized the relationship of high-quality and safe patient care to substantive changes in the way health professionals are educated. Five core competencies were identified:

- Provide patient-centered care
- Work in interdisciplinary teams
- Use evidence-based practice
- Apply quality improvement
- Use informatics

An idea that has gained particular currency in the context of the ACA is the Patient-Centered Medical Home (PCMH). Operational characteristics of this idea include accessible, continuous, comprehensive, family-centered, coordinated, compassionate, and culturally effective care (Payne, 2009). Further statements include a definition of the PCMH as "a health care setting that facilitates partnerships between patients, their personal physicians, and when appropriate, their families."

The American Association of Nurse Practitioners (AANP) supports the concept of the PCMH. The AANP defines the medical home as "a healthcare provider group that provides patients with a single point of access to care, coordinated by a provider who has in-depth knowledge of the patient" (Riffle, 2010). But exactly *who* is that provider? *Must* it be a medical doctor? Important reimbursement decisions for the future—as well as the nature of health care—rest on the question of *which* primary-care providers are qualified and should be defined as the "leader" in this model. It will be up to APRNs in each state to work toward guaranteeing their full inclusion as leaders in various pilot projects, as the effectiveness of the PCMH is evaluated. Additionally, APRNs must *own* their own practices and outcomes in order to share full accountability with physician providers. True data on outcomes of care by APRNs will not be accurate if APRNs bill for reimbursement "incident to" the physician's practice. Being an APRN demands full professional responsibility. Increased responsibility also brings increased liability.

Medicine recognizes the need to incorporate new perspectives of practice, essentially following the long-established lead of nursing. Likewise, it is equally appropriate that nursing incorporate traditional aspects of the medical model into its continually expanding scope of practice. Patient problems, after all, are real and complex, necessitating multidimensional approaches. The *Circle of Caring* model (discussed next) is offered as a

unique approach to patient problems, one that incorporates and builds on both traditional nursing and medical approaches, as well as retaining an openness to a variety of other approaches to phenomena. This model may reflect what most primary-care providers intuitively do, making more visible the so-often "invisible" work of nursing in the health-care encounter—work that is not currently coded or reimbursed but that is there and is often tremendously meaningful for the patient. In this sense, the *Circle of Caring* model may not be considered original but rather is derived from the realities of day-to-day advanced nursing practice in primary care.

A TRANSFORMATIVE TEMPLATE: THE CIRCLE OF CARING

Both the traditional medical and nursing models are predicated on a subjective and objective database, a labeling of the patient's problem and response, a therapeutic plan, and an evaluation of the outcome. The *Circle of Caring* model builds on these features and expands them to include the following:

- A broadened and contextualized database, more typical of a holistic nursing assessment, that gives the health-care provider a more in-depth understanding of the patient's situation, life, strengths, and weaknesses, including social determinants of health.
- A labeling of the patient's concern that more actively incorporates the patient's responses to the meaning of illness in his or her day-to-day life, as well as standard medical diagnostic language.
- A holistic and creative approach to an individualized therapeutic plan that includes nursing interventions based on evidence, including complementary therapies as appropriate, incorporated with standardized pharmacological, surgical, and other nonpharmacological interventions.
- A view of outcomes based on the patient, family, social group, and community perceptions of improvement, as well as the more traditional, quantified outcome measures such as mortality and morbidity, with emerging primary-care quality indicators and costs of care also built into these outcomes. This integrates the health of populations into the outcomes of care.

The *Circle of Caring* model is a synthesized view of the problem-solving methodology that may be used in a variety of settings—primary-care, acute-care, and community-based settings. A linear representation of the problem-solving method necessitated in practice was chosen for clarity of communication of the concepts of the model, and it is embedded in the middle of the schema (see Fig. 1.3).

This process is encircled by caring, a visual representation of the interpersonal process that occurs among the caregiver and the patient, which also reflects the family, social group, and community of the patient. The ability to provide effective and meaningful care for the patient is based on the processes of care. This is what enables the nurse to hear the patient's "call" and to fashion creative nursing responses. Care is actualized through caring processes drawn from Mayeroff (1971) and Boykin and Schoenhofer (2001): patience, courage, advocacy, authentic presence, commitment, and knowing.

A Broadened, Contextualized Database

A contextualized approach—the lived experience of the patient in the context of his or her community—is central to this model and is one that most nurses have learned in their undergraduate nursing programs. Although the patient's subjective perception of this experience is captured in the history portion of the assessment database, the *Circle of Caring* is based on hearing the patient's story in all its complexity, as well as eliciting the patient's own unique meaning of *health.* In addition, increased attention is focused on the interplay among perceptual, psychodynamic, socioeconomic, cultural, and environmental factors that have an impact on the patient's health status—in other words, increased awareness and attention to social determinants of health.

The Nature of Patient Responses

The 1995 American Nurses Association's Social Policy Statement defined nursing as the "diagnosis and treatment of human responses to actual and potential health problems." The *Circle of Caring* model may be used effectively with the traditional tool of nursing diagnosis. Boykin and Schoenhofer (2001) conceptualized the phenomenon of human responses as "calls for nursing." As such, these calls remain unique, interactional, and contextualized, and thus not amenable to any form of generic labeling. It is through coming to know people as caring persons that the nurse is able to fully hear each patient's call.

The importance of the labeling of the patient's problem (i.e., the "call for nursing"), be it in medical or nursing diagnostic terminology or in a more generic format, is that it helps to address the patient responses more effectively. Labeling thus involves the acknowledgment and knowledge of the complex interplay of perceptual, psychodynamic, socioeconomic, cultural, and environmental factors that contribute to health. APRNs are especially skilled at eliciting and understanding this complexity and at fashioning nursing-based responses that are uniquely suited to the individual.

A Creative Approach to Therapeutics

Another hallmark of the *Circle of Caring* model is its broadened approach to therapeutics. This approach should be actualized in day-to-day practice by APRNs, yet remains an especially invisible piece of nursing work. This flexible nursing-based approach entails working with

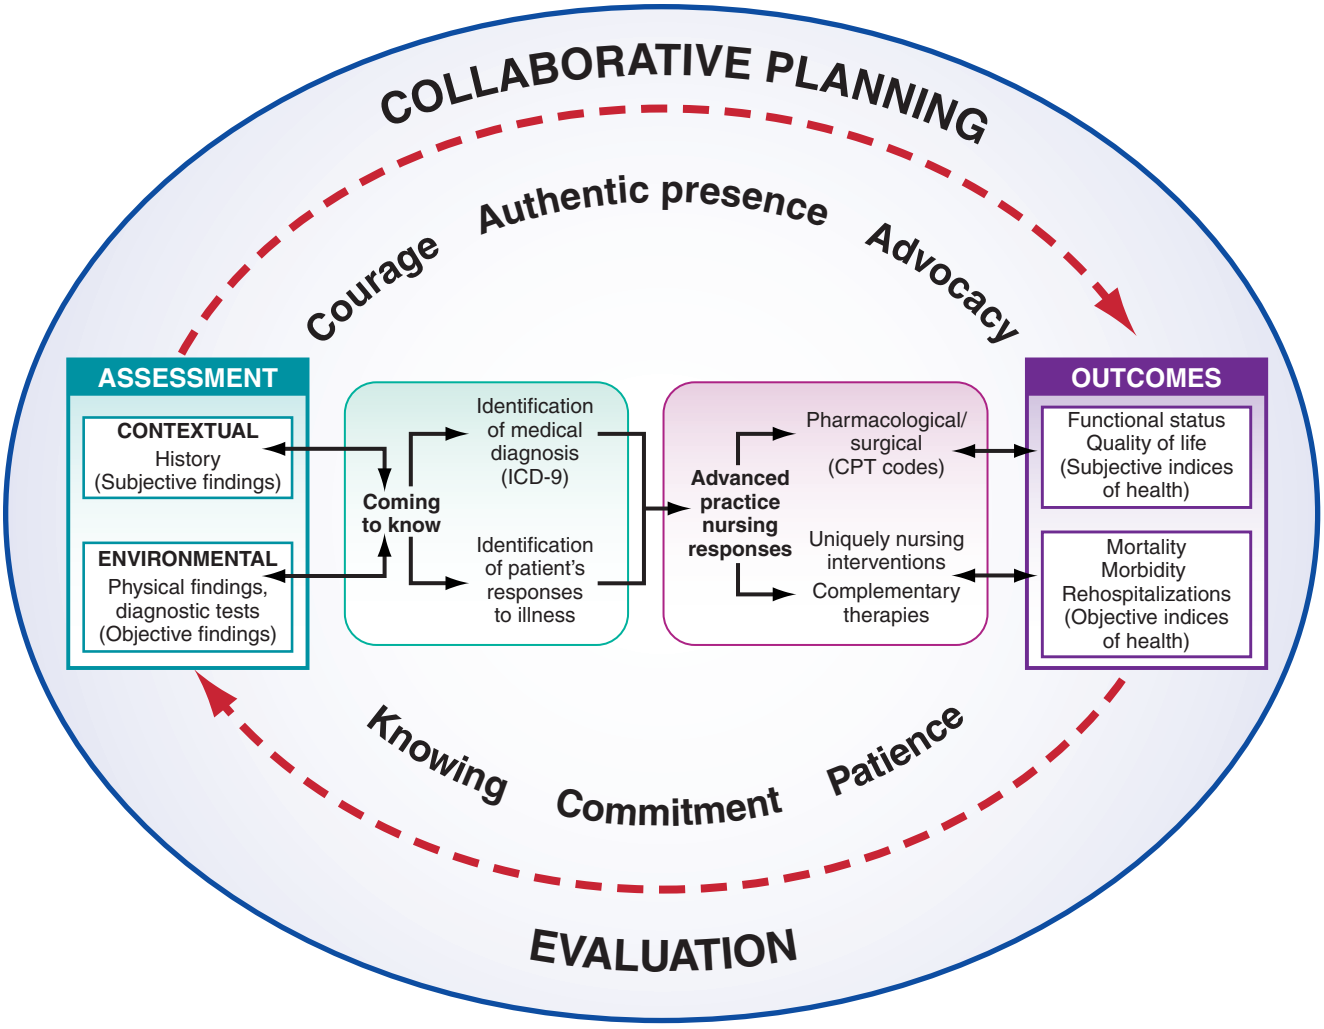

Figure 1.3 The *Circle of Caring* model.

the individual patient to tailor evidence-based interventions geared to the meaning of *health* as defined by that patient. Building on current standards of medical and nursing practice, interventions are fine-tuned for each patient, in the context of community. Although a focus of this text is to provide current evidence-based standards of care, this approach often requires care providers to make decisions through narrowly prescribed filters. As noted by Richard Payne, "there is an art to clinical practice that extends beyond hard science and numbers and often requires swift, sound, decision-making in an environment of incomplete evidence. Sometimes no formula or calculation based on quantified evidence and data can determine the appropriate action" (2009).

Alternative and complementary therapies are considered. This requires a creative approach to therapeutics that includes holistic approaches to healing, as well as a sophisticated understanding of evidence-based practice. Research in this area is proliferating as patients are calling for alternative and complementary approaches (Riffle, 2010).

In nursing as caring, the nurse is an artist who responds creatively to calls for nursing with unique nursing responses. Any taxonomy of nursing must, of necessity, have universal applicability. What distinguishes so many of nursing's interventions, however, is precisely their uniqueness and the tailoring of an individual response to each patient. This is the "artistry" of the APRN.

A broadened approach to therapeutics based on a contextualized database implies attention to the context of the patient's life, and as such the social determinants of health.

POPULATION-BASED APPROACHES

Outcomes: Who Decides What Is Desirable?

Outcomes-based research of today demonstrates the need to incorporate patients' perceptions as measured both objectively (by functional assessments and similar methods) and subjectively. Quality-of-life measures and,

most important, the various and individualistic meanings of health and illness must be taken more fully into consideration. The *patient experience* is a frequently used measure of quality care in both the acute- and primary-care settings. Plans must be assessed according to their potential to assist patients, families, social groups, and communities to meet their goals in ways that are meaningful to them, not just as standard items on a checklist of preventive measures. The voice of an increasingly informed, information-savvy health-care consumer demands no less.

Multiple social and environmental factors on health are recognized as additional pieces of the health-care puzzle—that of public health. Social determinants of health are increasingly acknowledged as one component of the huge understructure of the primary-care iceberg discussed earlier—the "unseen" and often invisible part beneath the water.

Sometimes labeled *community-oriented primary care,* health-care approaches that account for social and environmental factors are now understood to be essential elements of a truly reformed health-care system and are also referred to as *population-based care* or *preventive care.* This holistic approach was largely abandoned by allopathic medical science in the earlier part of the 20th century in favor of technology-based interventions and medical specialization (Brandt, 1997). However, modern medicine recognizes the need for such approaches to provide more effective care with lasting effects and to deal with current health-care realities that highlight the interplay among human health and environmental and social influences (e.g., the health effects of community violence, teen pregnancy, and HIV infection). As with medicine, nursing has renewed its emphasis on population-based approaches, reaffirming its historic roots, and there is now a shared understanding of the importance of these approaches. This is an ideal climate in which to build interprofessional education—shared *core* understandings of care, but with variations in ways to implement or practice these understandings.

Much of the hope for a more responsive, more effective, and less expensive health-care delivery system seems, as of this writing (2014), to be pinned on the PCMH or, as it is described in some circles, "the medical home." Not a physical building of any kind, its architecture is "a philosophical transformation of the way that care is delivered" (Nutting et al, 2009). Patient care within a PCMH should have a whole-person orientation and be coordinated across the health-care system, replacing a fragmented, episodic health-care delivery system. New reimbursement models should reflect the added value of the PCMH to the patient by providing for continuous coordinated care and expanded access to services that fall outside of the fee-for-service system. The process of transition into a PCMH model is a lengthy and complicated one and will require a champion—someone who can allocate resources to this effort and both support and coordinate the process of change. This process requires strong leadership and excellent organizational skills—additional areas in which APRNs excel.

Additionally, someone must lead the team of health-care providers and support staff who work with specific patient populations (e.g., diabetic patients or those with congestive heart failure). This leader might be the same person who advocates for the process of change, or it might be someone different who is focused solely on the provision of care to individual patients. Effective implementation of the PCMH model requires someone to delegate duties among the team of providers and to make decisions, along with the patient, about aspects of care such as referral to specialists. Regardless of who assumes this role, the PCMH leader must be able to move the organization forward to meet the accreditation requirements and to receive enhanced reimbursement as a PCMH practice. Similar to JCAHO or Magnet recognition programs, a PCMH practice must meet specific criteria and inspection requirements by one of four current accrediting agencies: the National Committee for Quality Assurance (NCQA); the Joint Commission (JCAHO); the Utilization Review Accreditation Committee (URAC); and/or the Accreditation Association for Ambulatory Health Care (AAHC). For example, to receive recognition as a PCMH practice by the NCQA depends on meeting specific elements in six standard categories (see Table 1.2).

Evaluation of the PCMH model is just beginning, and thus far, results are mixed. Wide-scale adoption of this model would fundamentally change the primary-care landscape. At present, the physician's skill set is not geared toward care coordination or managing transitions in care, because these functions have been historically performed by nurses.

However, the challenges in our health-care system call for creative thinking and innovative improvements in care. Various technologies will continue to emerge, and health care will continue to evolve, but the interpersonal caring base on which nursing has always been grounded will continue to be widely needed.

FURTHER UNDERSTANDING THE *CIRCLE OF CARING*

The *Circle of Caring* model (see Fig. 1.3) has grown out of, and is rooted in, the assumption that caring is the central concept in nursing and is uniquely known and expressed in nursing. Boykin and Schoenhofer (2001) contend that all nursing takes place within nursing situations, as "shared lived experiences in which caring between the persons of nurse and nursed enhances the process of living and growing in caring."

Watson (1988) viewed caring as an intersubjective human process based on the belief that "persons learn from one another how to be human by identifying ourselves with others or finding their dilemmas in ourselves." Boykin and Schoenhofer (2001) extended this

Table 1.2 NCQA PCMH Specific Elements and Standards

Enhance access and continuity	Accommodate patient's needs with access and advice during and after hours Give patients and families information about medical home Provide patients with team-based care
Identify and manage patient populations	Collect and use data for population management
Plan and manage care	Use evidence-based guidelines Provide preventive, acute, and chronic care management, including medication management
Provide self-care support and community resources	Assist patients and their families in self-care management with information, tools, and resources
Track and coordinate care	Track and coordinate tests, referrals, and transitions of care
Measure and improve performance	Use performance and patient experience data for continuous improvement

concept and defined caring in nursing as "the intentional and authentic presence of the nurse with another who is recognized as a person living caring and growing in caring."

Mayeroff (1971) discussed the primacy of caring as a process in contrast to caring as a product, with caring viewed as an end in and of itself. Mayeroff also identified "ingredients" of caring: knowing, alternating rhythms, patience, honesty, courage, humility, trust and hope. Boykin and Schoenhofer viewed caring in nursing "as a mutual human process in which the nurse responds with authentic presence to a call from another" (2001). The caring attributes of the *Circle of Caring* are based on these—knowing, patience, authentic presence, commitment, courage, and advocacy—and are elaborated by Boykin and Schoenhofer in Chapter 2 of this text. It is the caring attributes that characterize the nurse–patient relationship, enabling healing. Healing is meant in the broadest sense of the word: it might imply a good death, for example.

Neither medicine nor nursing alone can heal the current problems ailing the U.S. health-care system. Both are needed more than ever to shape a healthful future. Both must rethink their roles, functions, and cultures. Moving away from the hierarchical role structures of the hospital setting creates the opportunity for redefining the content and processes of clinical practice and negotiating a new and as yet undefined space. The boundaries of practice continue to expand and contract for both medicine and nursing during this transformative period. The larger questions for both professions include the following:

- How will all health-care professionals be accountable to their patients?
- Are physicians and APRNs willing to share accountability in a responsible manner?
- How can the Institute of Medicine's *Bridge to Quality* become a reality?
- How can disciplines work together in a meaningful way to achieve the goals and objectives of *Healthy People 2020*?
- How can medicine and nursing work together to achieve the triple aim of health-care reform: improving the patient experience of care (including quality and satisfaction); improving the health of populations; and reducing the per capita cost of health care?

Lynaugh, in an unpublished paper from 1989, suggests that both disciplines can occupy the same territory to the benefit of patient care; however, she notes that tension is created by proximity, stating that "physicians and nurses quarrel occasionally when they jostle each other in the narrow passageway of patient care." She makes the case, however, that tension is preferable to the distrust and ignorance that stem from silence and distance between the two disciplines. She advocates a "productive tension" and social parity between the two professions that will benefit the care of all patients. Nurses and physicians are natural allies. Both are needed, working together, for good and effective change to occur in the health-care system. Never did we need both perspectives more.

Daily in practice, primary-care providers hear the frustration of patients and families in dealing with today's health-care system. Although the technology of medical care continues to improve, the interactional and collaborative aspects of care are often underdeveloped. A *Circle of Caring* model is needed for patients, families, social groups, and communities. This model is also a way to document and describe the practice of primary-care providers, who respond to calls from patients and who imaginatively, creatively, and powerfully foster meaningful responses in the context of the situation. These responses may be fashioned on the micro level—the one-to-one clinician–patient relationship in primary or acute care—or on a macro level, as nursing-based knowledge unites with traditional public health approaches and is applied to the care of communities and populations (see Chapter 3). This transformative model, the *Circle of Caring,* incorporates the

strengths of nursing, public health, and medicine, and reformulates them in a new model of care. Primary-care clinicians are the appropriate providers to demonstrate the efficacy of an integrated model of caregiving, rooted in the lived experience of the patient as experienced in the context of community. This text offers you the necessary tools to provide care in ways that will be meaningful for patients, their families, their social groups, and the larger communities in which they live.

Chapter 2

Caring and the Advanced Practice Nurse

Anne Boykin, PhD, RN • Savina O. Schoenhofer, PhD, RN

The role of advanced practice registered nurse (APRN) is a special way of nursing. Although the role often blends elements of medical practice and generic primary care, it is also a form of nursing and is thus characterized by caring as a way of being, knowing, and doing. The prominent place of medical science knowledge and skill in master's and doctorate of nursing science programs to prepare APRNs may tend to obscure the fact that the educational program is intended to facilitate the development of advanced practice nursing.

The advanced practice of nursing must be firmly grounded in advanced knowledge and skill in caring. The framework presented in this text is intended to help students, faculty, and providers retain a nursing focus while addressing advanced practice in the interdisciplinary environment.

Dunphy's advanced practice nursing model, the *Circle of Caring* (see Chapter 1), introduces the term "caring process" as a pivotal element. "Process" in this model is understood to mean "unfolding" (rather than a series of cognitive or psychomotor steps or things to do, as in familiar uses such as nursing process or problem-solving process). Caring processes are ways to express your way of being and living as a caring person in the profession of advanced nursing. There is no defined set or list of caring processes; rather, there are as many caring processes as there are persons and situations.

CARING

Caring is the essence of being human, and nursing is a deeply human relationship; thus, caring is the essence of nursing. The meaning of caring as the essential nature of humanness cannot be encapsulated within a single limiting definition; however, caring can be understood, recognized, and developed both philosophically and practically. Caring expressed in nursing is the intentional and authentic presence of the nurse with another who is recognized as a person who is living, caring, and growing in caring (Boykin & Schoenhofer, 2001).

All human service disciplines are based on caring. Nursing is unique, however, as caring is what most directly characterizes nursing's knowledge base and service. By contrast, in the discipline of medicine, the fundamental commitment to caring is directly characterized in the diagnosis and treatment of human structural and functional problems manifested primarily in physical terms. The nature of the APRN role permits the direct focus on care and caring that is nursing while incorporating the focus of medicine. An APRN does not practice medicine but rather draws on and transforms characteristic medical ways of practice for nursing purposes, just as the practice of holistic medicine draws on and transforms characteristic nursing ways of practice for medical purposes.

The APRN, such as the nurse practitioner, practices a specialized form of nursing practice, which means that specialized opportunities for creating situations of care call forth specialized patterns of caring. What does this mean in a practical sense? It means that the person coming for care presents with an issue that is typically viewed as being within the medical sphere. As in all nursing practice, the APRN is focused on co-creating a relationship in which care is experienced and possibilities for personally meaningful ways of living unfold. Specialized patterns of caring in the role of nurse practitioner blend knowledgeable perspectives of the health situation (diagnosis) and recommendations for characteristically medical ways of ameliorating presenting issues (treatment) with generalized patterns of nursing care. Generalized patterns of nursing care are represented in the *Circle of Caring* model as:

- Courage
- Authentic presence
- Advocacy
- Knowing
- Commitment
- Patience

Specialized patterns of care are incorporated in the uniqueness of caring processes. Knowledge of general patterns of care is important; however, that knowledge must be creatively used in actual, unfolding processes of care if the situation is to be considered nursing.

Caring is the matrix, the medium, the "stuff" within which the APRN–patient relationship is brought to life.

In this relationship, the APRN lives his or her commitment to caring by facilitating a personal connection that communicates "I acknowledge you as a caring person, one who is worthwhile and deserving of my respect, my attention, my commitment, my care." That effort to create a personal connection also communicates the practitioner's acceptance of the trust being placed in him or her as a caring person, as one who is available and able to participate effectively in the life of the other. Within the caring relationship each participant has the opportunity for enhancing personhood, that is, for living life grounded in caring and for growing in one's capacity to express caring in meaningful and satisfying ways. Knowing another as a caring person requires a commitment to entering into the world of the nursed with the explicit intention of knowing the person individually and uniquely. Entering into the world of another with caring intention requires that the practitioner know himself or herself as caring and be open to growing in the relationship. A truly collaborative relationship (in contrast to one in which the collaboration is taken at face value or in some way limited) emerges in the context of this caring intention.

The APRN's involvement with the nursed reflects themes or qualities of caring expressed as courage, authentic presence, advocacy, knowing, commitment, and patience. These themes of caring can serve as a conceptual structure or framework to assist the practitioner in examining, recognizing, and understanding the fullness of caring in practice. Though interconnected, each individual theme is addressed theoretically and then in action in a practice situation to illustrate caring processes.

Courage

Courage is a human act (Tillich, 1952). Courage comes to light in making deliberate choices resulting in acts that express who we are and what is important to us. Courage is the daily application of values, the living out of one's beliefs in spite of obstacles and challenging situations. Expressions of courage affirm our being.

This understanding of courage offers an ethical grounding for the practice of advanced nursing. It requires that, in each nursing situation, the nurse live the values held dear. The nurse risks entering each situation with the fullness of his or her being, willing to be rejected or not understood, or, perhaps equally risky, being accepted and known.

As part of courage, the nurse also understands and acts on the obligation to come to know that which matters to those seeking care. What shapes the moments the nurse has with people is the intention to know them as caring, to hear their stories, and to create nurturing responses reflective of the uniqueness of the situation. Courage manifests itself because of the nurse's deliberate choices to carry out, in a particular time and place, the beliefs that serve as the core of advanced nursing practice. Courage manifests itself in making one's nursing vocation a commitment to these values and beliefs that undergird caring.

Authentic Presence

Nursing is communicated through authentic presence. Authentic presence is a unique way of being with others, unique in that it is a way of ordering and balancing self so as to grow in one's beauty and spirit. Such presence with self requires trust, courage, and the desire to know. One who is authentic with self and others is able to see things from the inside that others see only from the outside. There is an inner genuine awareness that is congruent with feelings, attitudes, and actions lived moment to moment. The commitment to truly know oneself frees one to be with others in authentic presence.

Authentic presence may be understood as intentionally being with another in the fullness of one's personhood. The caring that is communicated through authentic presence is the initiating and sustaining medium of nursing within the nursing situation. Nurses are called to be authentically present in nursing situations. Stories of nursing practice portray the depth of such experiences. The degree to which one knows oneself influences one's presence with others and thus the degree of commitment possible in the situation.

Advocacy

Advocacy is a way in which nurses have traditionally expressed caring. There are many opportunities for advocacy, that is, many situations in which "speaking up for" another is an important aspect of the role. From a depth of knowledge and understanding, the practitioner speaks up for the person as unique and worthwhile, for the person as having personal hopes, dreams, intentions, and preferences that are honorable. In addition, Gadow's (1990) formulation of existential advocacy calls for the nurse to advocate for alternative interpretations of the situation that arise from experience and specialized knowledge. Existential advocacy is contrasted with advocacy that is either paternalistic or consumer oriented. Paternalistic advocacy is characterized by a sense of "as the expert, I know what is best for you and your life." Consumer-oriented advocacy takes the approach that "I'll just give you the facts and options; you sort them out by yourself."

In existential advocacy, self is brought into the situation as a full partner, sharing alternative perspectives for consideration, though not insisting on them or imposing them. The patient enters into the relationship seeking to connect with the practitioner as a whole person, not just as a set of facts. When the practitioner takes the paternalistic stance (dismissive and overbearing, offering an all-or-none option) or the consumer-oriented stance (withdrawn to an objective distance, offering an essentially value-free set of options), the patient experiences the loss of an opportunity to connect with another assumed to be truly concerned, knowledgeable, and

giving. When the nurse offers existential advocacy, the nursed feels truly known, respected, and connected in a way that affirms humanity and being.

Knowing

Knowing as an aspect of caring encompasses "knowing that," "knowing about," "knowing directly," and "unknowing." "Knowing that" and "knowing about" refer to descriptions and analyses of the patient's situation in the context of facts and information. Caring competence requires knowledge of facts and data points that are empirically and objectively derived. "Knowing directly" involves being deeply attuned to the person-as-person and comes through intentionality and authentic presence. "Unknowing" refers to an openness to unfolding, a humble sense that all is not yet known. The practitioner who truly embraces unknowing recognizes that what might be right or timely in general terms may be neither right nor timely for the particular person seeking care in a particular moment.

Carper (1978) described patterns of knowing fundamental to nursing: personal, empiric, ethical, and esthetic knowing. The practitioner draws on the personal way of knowing as essential intuitive knowing. Empiric knowing is an avenue for drawing on science and skilled observation. Ethical knowing prompts the practitioner to ask, "What are the personal and professional values that enter into this situation?" And thus, "What is right for this situation?" Esthetic knowing develops as the practitioner incorporates knowing gained from the other patterns in the context of fully living the situation as she or he co-creates with the nursed an integrated understanding of the unfolding whole picture.

The *Circle of Caring* is developed and strengthened as the practitioner and patient communicate their unfolding knowing of self, of each other, and of the situation. Knowing, as described briefly here, contributes to enhanced personhood, to the affirmation and growth of self and other as caring persons.

Commitment

Is there any greater act of courage than the commitment to another? Commitment is a sign of that which we value. Choosing to be a member of the discipline and profession of nursing speaks to the deep valuing and lifelong commitment of service to humankind. Commitment directs obligations or what "ought to be" in particular situations. Because these commitments are so internalized as values, however, one's obligation is not experienced as a burden but as a response that is right, deliberate, conscious, and caring (Roach, 2002).

Nurses in advanced practice roles frequently face challenges to commitment. Choices made in practice reflect one's devotion to particular commitments. Often the values of an economically based health-care system, of which nursing is such an integral part, do not support or seem to be in line with the substantive nature of caring and its essential relation to practice. A struggle to preserve nursing's values often results. The APRN has the unique opportunity to demonstrate how a commitment to the values of nursing influences the outcomes of care.

The practice of advanced nursing must be firmly rooted in the values of the nurse. In addition to many essential types of knowledge and skills, he or she must be able to draw on the knowledge of nursing, especially knowledge of caring, to create environments for care that honor person-as-person and that humanize care.

Nursing always occurs in a relational context. As a human science, nursing calls for the continued commitment to understand better the lived experience of the nursed, to truly hear their stories, and to respond in ways that matter, ways that nurture and sustain persons as they live and grow in caring. Central to advanced practice is the commitment to know self and others as caring.

Patience

Patience as a key theme in caring refers to trusting people to grow in their own time and in their own way (Mayeroff, 1971). Patience is not passive but rather an active openness to "the moment alive with possibilities." Humility and courage are intimately connected to patience. The ability to remain actively engaged with the person while honoring individual circumstances and freedom of choice is an act of courage and leads to the kind of patience that communicates caring.

CARING PROCESSES

Below are stories of practice shared by two nurse practitioners. These stories illustrate ways in which advanced nursing practice is truly an expression of caring processes. The first story was shared by a family nurse practitioner (FNP) in practice in a family clinic in a small rural southern town.

Nursing Situation 2.1 Like a Pebble in a Pond—The Circle of Caring

The incident that I am describing involved an 18-year-old female college student—I'll call her Lucy—and her mother, Mrs. K. Lucy presented at my clinic with a history of shortness of breath and flu-like symptoms for several months. She and her mother had been to multiple health-care providers seeking a diagnosis and resolution of Lucy's problem. I had never seen this patient, so I went through the usual process of taking a history of the present illness, past medical history, social history, and a thorough physical exam. I then ordered what I determined to be the necessary tests. The outcome was a referral to a pulmonologist in a nearby city with the eventual successful resolution of her illness.

The interesting part of this story is what happened years later regarding this clinical incident. My husband and I went into a newly opened used bookstore in our community. On entering, there was no one but the owner and the two of us in the store. When the owner saw me, she came over and hugged me like a long-lost friend—it was Mrs. K! I did not even remotely recognize her and was sure she had mistaken me for someone else. She looked at my husband and stated, "She saved my daughter's life." She then began to cry as she related her feelings about the event and what had transpired. Mrs. K was embarrassed by her emotions (so was I), but she was determined to tell her story.

Mrs. K said that she had taken her daughter to multiple health-care providers seeking help for her child. She felt they did not take the case seriously and "blew her off" even as her daughter worsened. When Mrs. K and Lucy came to me, Mrs. K was desperate for help for her daughter. Mrs. K described her feelings regarding the clinical visit, grateful that I had listened and believed what she was saying. She then quoted something I had said to her that she said had given her hope and comfort. I told her that "I will do everything possible to find out what is wrong in order to help Lucy get better. We will not give up until we knew what is going on with Lucy." Mrs. K said a burden was lifted from her because at last she felt that "someone cared." Mrs. K told us that with the referral, the problem was diagnosed and resolved. It was her profound belief that I had literally saved her daughter's life. I do not remember Lucy's final diagnosis at this point in time, and I don't know how much actual assistance I was in the final resolution of her illness; but I will always remember Mrs. K's gratitude for a caring response to her feelings of helplessness while dealing with the health-care system. Mrs. K's belated description of her heartfelt feelings regarding her daughter's illness and my interventional actions made a profound impression on me as a provider. The need for a caring response to each of our patients is evident; yet, we may never know how much such caring can impact a life.

As shared by Carolyn B. Dollar, PhD, APRN-BC, FNP

In this story, the most prominent caring processes are authentic presence and commitment, as the FNP offered self in a way that truly communicated caring to this beleaguered family. The FNP's commitment to caring for the family and her courage and patience in tackling an issue that obviously had been given a "pass" by previous health-care providers who had been consulted illustrate the importance of opportunities to hear and respond effectively to calls for caring in advanced nursing practice. Referral is an act of advocacy that is frequently an element of NP practice, and when it is recognized as an opportunity for caring through advocacy, it becomes even more an integral expression of advanced nursing. The fact that the FNP offered this particular story as an exemplar of caring in advanced nursing practice makes evident the merging of knowing in past–present–future: the FNP continues to be open to knowing self and other through appreciating the mother's report of the impact of an act of caring initiated in a rather distant past.

A second story from an APRN practicing in a specialty clinic in an urban health sciences center showcases the centrality of the nurse–patient caring relationship in the midst of treatment situations involving complicated biomedical technology.

Nursing Situation 2.2 Spirited Caring

My APRN role has been a rewarding challenge. The story that I am going to share was pivotal to my development as an APRN. The story focuses on a pleasant, jolly, gem of a patient, with a warm smile—I'll call her Mrs. J. Her energy lit up the room. This independent free spirit also worked as a volunteer at the clinic. She served cookies and other baked goods to the patients undergoing chemotherapy. Her strong faith and compassion for others impressed me as a busy provider. To the nursing staff, she stood out as a patient and volunteer. Her faith helped her in aiding the sicker patients to maintain hope. Her genuine concern for others encouraged nursing staff and family members to have compassion for others. Mrs. J was always the first to ask, "How are you doing?" This unique patient was a beacon of light in a dark, sobering environment.

My favorite patient and I developed a good rapport as I saw her weekly in Coumadin Clinic. She was my first patient on my very first day. When she stepped into my office and noted my frazzled appearance, she grabbed my hands and prayed with me. Because we are in the Bible belt, I considered that to be normal. She later apologized because she did not know my religious beliefs. I assured her that her actions had calmed me and made my day go a little better. Mrs. J had been doing exceptionally well although she had been diagnosed with cancer. She had a history of Stage II breast cancer but had been in complete remission for 2 years.

One Friday, she presented to the clinic at four o'clock in the afternoon. She had been complaining of vision changes and had her son bring her to the clinic. I knew something was wrong because this independent woman always presented to visits alone. Mrs. J's primary-care provider was not available by phone, and her oncologist was out of town. She reported a headache with vision changes, which seemed strange for a woman who had undergone chemotherapy with adjuvant radiation therapy without difficulties. She explained that 4 days before this clinic visit, she experienced the worst headache she had ever had. Her clinical presentation led me to get a computed tomography (CT) scan of the head with contrast. After reading her CT, the radiologist called me immediately. He had identified a large mass that was pressing against her sulcus. At this point, I had to find her hematologist, start her on high-dose steroids, find the neurosurgeon on call, and prepare her for everything that was about to take place. I was so consumed by my actions that I nearly forgot to care for the patient.

Mrs. J demonstrated sincere compassion when I had to give her the hard news. She grabbed my hands and prayed for me and the other health-care providers. She prayed that we would make the right decisions regarding her health care. Just as we had started our relationship, we were ending it. Her demonstration of faith was a unique testament to her life. Her strength in a time of weakness showed the vigor of her faith. Though she was a devout Catholic and I am a Methodist, we had to rely on our genuine concern for each other and our beliefs in a higher being to get us through this difficult time. Compassion and faith were integral components in our provider–patient relationship.

The experience taught us that compassion and faith coupled with therapeutic communication can get you through the toughest of situations. In revisiting this story, I am reminded of the need to foster a sense of caring and respect for patients' beliefs as I mature and develop as a nurse. The patient's actions were surprising. I had been taught about putting my compassion and faith into action. However, I had never seen it done. It was affirming as an APRN to recall how we cried and laughed and came to the sobering realization that this disease might beat her. However, we had given it our best effort. This experience was beneficial to me because it was my first time being the bearer of bad news to a patient. Consumed as we are with time management, compassion and faith are not always exhibited, shared, or utilized in my daily practice. However, by revisiting this story, I am challenged to treat others as I treated my special patient. The core values that guided my practice in the past have been rekindled while reflecting on my nursing experience. Nursing is a rewarding challenge if you allow it to be.

As shared by C'Sara Strong, MSN, CFNP

This story needs no interpretation; it can be easily recognized as an exquisite example of creating a holistic fabric of caring integrating a multitude of harmonious patterns: interpersonal, clinical, and technological.

These stories of advanced nursing practice illustrate the use of caring processes. As situations are studied and relived, students, faculty, and providers discover the limitless ways caring is expressed. As nurses, we live out our personhood—our living grounded in caring—in unique and special ways. We bring to our practice our humanness, our expertise in caring, and our intention to participate fully in the life experiences of those we are privileged to nurse, and thus to bring the benefits of nursing to those seeking care.

Authors' Note: We have elected to make no notable changes to the content of Chapter 2 for this edition of the text. The words of Boykin and Schoenhofer remain as timeless and true today as they did when they were originally written in 1999. They provide an important interpretation of the *Circle of Caring* as described in Chapter 1. The miracle of changing practice and the care of patients, families, and communities through transformative advanced practice nursing remains as vital a need now as it was then. The authors wish to thank Boykin and Schoenhofer for their unfailing commitment to the art and science of caring.

Chapter 3

Health Promotion

Dorothy J. Dunn, PhD, RNP, FNP-BC, AHN-BC •
Debera J. Thomas, DNS, RN, FNP/ANP

HEALTH

The ultimate goal of all health-care providers is to promote health and prevent disease. Patients share this goal. Engaging in health-promoting activities helps individuals live longer and healthier lives. To put this in perspective, the basic tenets of health must first be explored.

What is health? Several disciplines and organizations have tried to define health, and the definition continues to evolve. Many view health as the absence of disease. This definition does not account for the multidimensional characteristics integral to a human being. Humans are physical, social, spiritual, cultural, and emotional beings. To define health only as the absence of disease does not address all the dimensions that makes us human. In 1948, the World Health Organization (WHO, 1948) defined health as a "state of complete, physical, mental and social well-being"; this definition provides a more holistic view of health because it incorporates the social and mental aspects of a human being, as well as the physical dimension. In fact, this definition has not been amended since its inception in 1948. However, this definition does not account for the spiritual and cultural dimensions of a person. According to the American Holistic Nurses' Association (Mariano, 2013), health can be described as a state or process in which an individual experiences a sense of well-being, harmony, and unity of one's body-mind-spirit within an ever-changing environment. Health is therefore a state in which the physical, psychological, social, spiritual, and cultural attributes of a person are in balance, creating harmony within the body (Fig. 3.1).

The balance of each of these dimensions is an important parameter when considering health. A patient whom we care for may be physically healthy, but his or her spiritual, cultural, social, and psychological dimensions may not be balanced, and therefore the patient is not experiencing optimal health. It has been said that the whole is greater than the sum of its parts. We cannot accurately determine someone's health status without evaluating all of these attributes.

Historically, the medical evaluation of a patient was based only on physical signs and symptoms of a disease. If the patient lacked symptoms, we considered him or her healthy. We now know that this type of assessment is incomplete and does not take into account how the other attributes of a person either contribute to or subtract from health status. We also know that many patients have medical problems that have not yet presented as signs and symptoms of a disease.

When assessing a patient, it is imperative to also evaluate his or her social, psychological, spiritual, and cultural well-being, as well as the physical state. In performing a complete health assessment, the provider should ask questions related to the person's social and dietary habits; current living and work situation environment; and feelings, beliefs, values, and life satisfaction, as well as questions about his or her philosophical and spiritual beliefs.

Along with physical signs and symptoms, all these parts of a patient's history inform diagnosis and treatment plans. The focus on all component parts of a person helps to provide a more holistic view that can assist in making a more comprehensive assessment of the

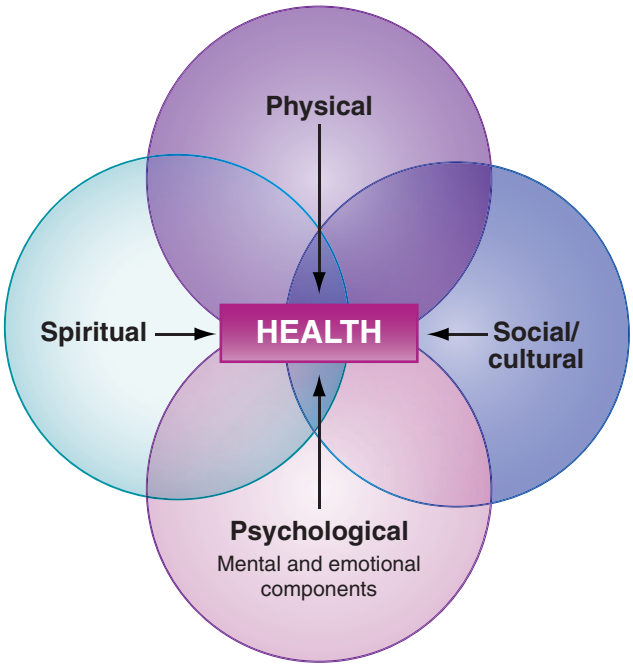

Figure 3.1 The components of health.

current health status of the patient. The determination of health is based on the synthesis of all the parameters of health and should be incorporated into all patient assessments.

HEALTH PROMOTION

Health promotion can be defined as activities and preventive measures that contribute to an individual's state of optimal health. Such activities and preventive measure include immunizations, fitness/exercise programs, breast self-examination, appropriate nutrition, relaxation, stress management, social support, prayer, meditation, healing rituals, cultural practices, and promoting environmental health and safety. Health and well-being are created by a balance of physical, psychological, spiritual, cultural, and social components of health. Health promotion requires a commitment on the part of the individual patient, the health-care provider, and the community. Health promotion efforts are achieved only when everyone works in partnership to achieve goals that will enhance health and well-being.

Health promotion efforts should always begin with the clinician because the clinician plays a pivotal role in educating the patient and the community about health-promoting behaviors. The clinician can help provide insight to each patient about how his or her environment can contribute to health or disease. In addition, the community must understand the impact that environment can have on individuals so that health promotion activities can be a community effort. Health-care providers play an important role by providing consultation to the community and the legislature regarding environmental health.

Consultation with influential members of the community can help in the development of legislation that can support healthy living conditions in a community. In addition, legislative efforts can help to provide funding to maintain or improve environmental health. If patients are trying to promote their own health, living conditions in the community must also be healthy to sustain and support their efforts. Basic community resources such as water and sanitation must be monitored for potential threats to health and well-being, and these resources are the responsibility of community and local government agencies. Health-care providers and patients need to work in collaboration with these agencies to ensure that elements essential to health, such as clean water and street sanitation, are maintained or improved. To be successful, health promotion must be a group effort.

Historically, health promotion has been viewed as an effort to prevent disease and illness. Most sources cite three levels of prevention: Primary prevention is the prevention of disease; secondary prevention consists of early screening and detection of disease; and tertiary prevention is the restoration of health after illness or disease has occurred. Focusing health-care efforts on all three levels of prevention is important to promoting health, but during the last two decades, primary prevention has become the ultimate goal of health promotion.

The focus in health care during the first half of the 20th century was on care for the patient who was already ill. The prevailing belief at the time was that patients should seek health care when they were ill. During this time, most health-care practitioners cared for patients at the tertiary level by (1) preventing further insult or injury after the disease or illness had occurred, by stabilizing the patient's condition to prevent deterioration; (2) helping patients to recover from the current illness or disease through treatment; and (3) whenever possible, to help restore patients to their previous state of health.

Advancements in technology during the second half of the 20th century contributed to better diagnostic testing, helping to shift the focus of health care to secondary prevention. Providers became savvier about the importance of screening "at risk" patients at appropriate intervals for known diseases and illnesses. A focus on secondary levels of prevention led health-care providers to encourage early detection and treatment.

With the focus on screening and early detection, treatment could be instituted before overt signs and symptoms appeared, thereby preventing some of the long-term sequelae associated with illness and disease. For example, blood pressure would be checked in a patient with no symptoms of hypertension, and if elevated, a plan of treatment would be instituted. The goal was and is maintaining the patient's blood pressure within normal limits and minimizing the development of catastrophic complications such as stroke or myocardial infarction. Certain circumstances must exist for a screening test to be useful. These are summarized in Box 3.1.

In determining whether or not screening is appropriate, health-care providers should keep in mind that early signs of chronic disease often surface in midlife, that is, in persons aged 40 to 65 years. In general, the earlier

Box 3.1 U.S. Clinician Handbook of Preventive Services Criteria for Inclusion

1. The condition must have a significant effect on the quality and quantity of life;
2. Acceptable methods of treatment must be available;
3. The condition must have an asymptomatic period during which detection and treatment significantly reduce morbidity and mortality;
4. Treatment in the asymptomatic phase must yield a therapeutic result superior to that obtained by delaying treatment until symptoms appear;
5. Tests that are acceptable to patients must be available, at a reasonable cost, to detect the condition in the asymptomatic period; and
6. The evidence of the condition must be sufficient to justify the cost of the screening.

disease is identified, the easier it is to treat, and the more likely it is to have a successful outcome. In addition, individuals in midlife tend to focus more on behaviors to extend life and prevent disability than do younger people. Adults aged 20 to 40 years focus more on relationships, family, self-image, and career development, whereas those older than 65 spend much time responding to and coping with overt, established illness. As life expectancy increases and older adults anticipate living longer, more attention is focused on health enhancement, adding quality years to the life span of older persons.

Focusing on primary prevention enables providers to assess patients' potential risk factors, including lifestyle and genetic history, and to help them make lifestyle changes that will foster health and prevent disease and disability. Health-care providers are aware that health or wellness is best achieved through primary prevention strategies. However, when this is not possible, secondary and tertiary levels of prevention are employed. Each health-care interaction between a patient and clinician is an opportunity to promote health at the primary, secondary, and tertiary level. Optimal wellness or health for all patients is the ultimate goal.

Health-care providers can use the levels of prevention in several ways: on an individual level, with small groups (families), and with larger groups such as a community. Individual encounters with patients provide an opportunity to educate patients about their individual risk factors and changes they can make to prevent, or at least delay, the onset of disease(s) and the potential sequelae of disease (implementing primary and secondary prevention strategies). Incorporating family members into the educational process of health promotion can provide support and reinforcement for patients during the early phase of risk reduction. This incorporation of family may also serve the individual family members by educating them regarding their own risk for disease. Family members can also serve as advocates for patients by helping to synthesize the information given and providing the patient with a support system to make healthy lifestyle changes.

Health-care providers can be instrumental in developing health promotion strategies in a community. This can be accomplished by developing interventions that include identifying community groups at risk for certain diseases and developing community-wide educational programs that will educate this group about their potential risks. Community-based educational programs reach a broad audience with the potential to have a significant impact on the health status of a community (Fig. 3.2).

Expanding knowledge has increased our awareness that many diseases today can be minimized or potentially avoided with early assessment and management. The effects of diseases such as hypertension, cardiovascular disease, and diabetes on patients' lives can be minimized or avoided with early interventions. For example, most patients diagnosed with diabetes have had the disease for at least 5 years. Diabetes has serious consequences in many organ systems if it is not diagnosed early and treated aggressively. The development of a community-wide diabetes education/screening program can help identify patients who are at high risk for the disease. With early diagnosis and treatment, long-term complications associated with diabetes such as peripheral neuropathy, cardiovascular complications, and retinopathies can be minimized.

Clinicians can take a leadership position within a community by developing targeted programs for early identification and treatment. This type of wide-scale intervention can reduce morbidity and mortality rates. Early diagnosis, before signs/symptoms of a disease are present, can have a significant impact on the outcomes of disease. If patients are identified early, educated about the importance of healthy nutrition and lifestyle, and treated aggressively, the outcome may be a long and healthy life. Table 3.1 provides examples of primary, secondary, and tertiary prevention.

Risk Factors in Health Promotion

The identification of risk factors is an essential component of health promotion. Some patients have no known risk factors, whereas others have many. The key component of effective health promotion is to screen patients for potential known risk factors and intervene. Not all diseases can be prevented, and not every person with unhealthy lifestyle choices will get a particular disease, but the elimination or alteration of certain risk factors can affect disease outcomes.

Some risk factors are modifiable, whereas others are not. Nonmodifiable risk factors, including sex, age, and genetic/family history, are considered nonmodifiable because they cannot be changed in any way (at this time). Because these factors are nonmodifiable, early and aggressive identification of all risk factors should be done so that patients with nonmodifiable risk factors can make any possible changes in the modifiable risk factors and effect a more favorable outcome.

Modifiable risk factors include weight, diet, social habits, lifestyle choices, and stress. For example, 38-year-old Mr. Hart is being seen for a physical examination. He has not had a physical in 20 years. His past medical history is negative for any diseases, surgeries, or illnesses. His social history includes the use of alcohol and cigarettes; he works an average of 60 hours per week as an emergency medical technician and does not exercise. His family history reveals that his father, paternal uncle, and grandfather had all had a myocardial infarction before age 50. Mr. Hart's physical exam reveals the following: height, 69 inches; weight, 230 pounds; and a body mass index (BMI) of 34. Mr. Hart's laboratory results include a cholesterol level of 250 mg/dL, a high-density lipoprotein (HDL) of 30 mg/dL, and a low-density lipoprotein (LDL) of 160 mg/dL. Box 3.2 reviews the risk factors for heart disease for Mr. Hart.

Although Mr. Hart cannot change his age, sex, or family history, there are several factors that he can

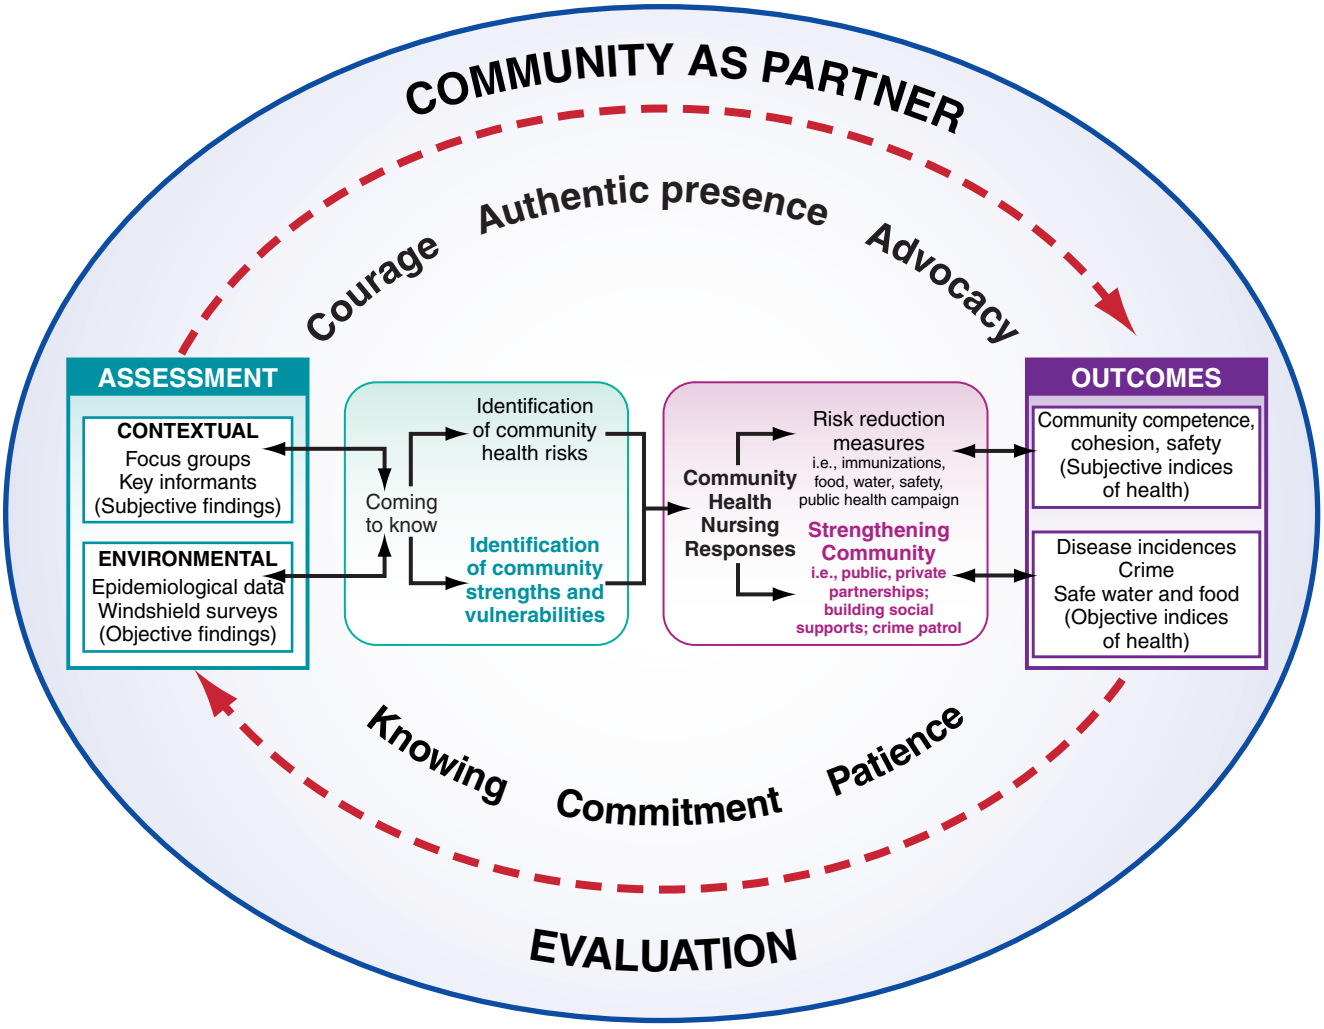

Figure 3.2 The community-based *Circle of Caring*.

Table 3.1 Examples of Primary, Secondary, and Tertiary Prevention

Primary Prevention	Secondary Preventionv	Tertiary Prevention
Immunizations	*Screening for:*	*Treatment to prevent further sequelae of:*
Health education	Skin cancer	Cardiovascular disease
Skin cancer prevention	Oral cancer	Respiratory disease
measures	Lung cancer	Gastroenterology disease
Weight control	Breast cancer	Genitourinary disease
Seat belt use	Testicular cancer	Endocrine diseases
Violence prevention	Prostate cancer	Immunodeficiency disease
Substance abuse	Diabetes	Infectious disease
Education on:	Hypertension	Dermatological disease
Smoking, alcohol, and drugs	Cardiovascular disease	Oncology disease
Environmental hazards	Ovarian cancer	Gynecological disease
avoidance	Cervical cancer	Musculoskeletal disease
Protective hearing equipment	Fecal occult blood	Neurological disease
Protective eye equipment	Sexually transmitted infections	Psychiatric disease
Safety helmets for motorcycles,	Tuberculosis infection	Reproductive disease
skateboards, and bicycles	Pediatric developmental screening	
Nutrition counseling	Lead screening	
Exercise	Anemia screening	
Stress reduction	Height, weight, and body mass index	
Eliminate allergen exposure	screening	

Box 3.2 Risk Factors for Mr. Hart

Nonmodifiable Risk Factors
- Male sex
- Age
- Family history

Modifiable Risk Factors
- Weight
- Sedentary lifestyle
- Elevated cholesterol
- Elevated LDL and suboptimal HDL
- Alcohol consumption
- Smoking
- Stress level

change. With improvements in his diet, regular exercise, stress reduction, moderation of alcohol intake, and smoking cessation, Mr. Hart can reduce his risk for heart disease. This case illustrates the importance of early identification of risk factors for intervention.

Ongoing research has shown the relationship between certain risks such as smoking, consuming alcohol, and ingesting a high-fat diet and the presence of disease. However, the relationship between risk factors and disease can be confounding because often a person may develop a disease without experiencing any risk factors. For example, some patients will have no identified risk factors for a particular disease, yet will still develop the disease. Conversely, some patients may have several identified risk factors and yet never go on to develop the disease. Evidence-based research will continue to focus on efforts to identify as yet unknown risk factors or health-promoting determinants that could influence the outcomes for disease.

INFLUENCES ON HEALTH PROMOTION

Many factors influence health promotion activities today. Government initiatives, community health programs, and media attention all focus attention on the importance of health literacy, health promotion, and disease prevention.

Health Literacy

Most persons will encounter health information when they seek health care, and most persons will encounter health information that they cannot understand. More than a measurement of reading skills, health literacy also includes writing, listening, speaking, arithmetic, and conceptual knowledge. *Health literacy* is commonly defined as the degree to which individuals have the capacity to obtain, process, and understand basic information and services needed to make appropriate decisions regarding their health.

Health literacy is required when acute illness, injury, or chronic disease management necessitates that a person seek health care. Consider that nurses are charged with "the protection, promotion, and optimization of health and abilities, prevention of illness and injury, alleviation of suffering through diagnosis and treatment of human response, and advocacy in the care of individuals, families, communities, and populations" (American Nurses Association, 2010, p. 10). Therefore, nurses must accept the challenge to screen and assess for health literacy levels at each health-care encounter. By identifying those at risk for misunderstanding instructions and the ability to adhere to recommendations in all aspects of care, nurses will have a positive impact on health promotion, prevention strategies, and treatment adherence successes for individuals who seek health care.

Health Promotion and Government Initiatives

Three major government initiatives that have had great impact on health promotion in the United States are the National Prevention Strategy, *Healthy People 2020,* and the U.S. Preventive Services Task Force.

National Prevention Strategy

The Affordable Care Act passed in 2010 created the National Prevention Council, which developed the National Prevention Strategy (NPS). In 2011, the National Prevention Council released the *National Prevention Strategy: America's Plan for Better Health and Wellness,* a comprehensive plan that sets forth evidence-based and achievable means for improving health and well-being for all Americans at every stage of life. These efforts are designed to stop disease before it starts and to create strategies for a healthy and fit nation, recognizing that prevention must be part of daily life. The goal of the NPS is to transform us from a system of sick care to one based on wellness and prevention. *Healthy People 2020* is a foundational resource for the NPS Four Strategic Directions and Seven Priorities.
The Four Strategic Directions are

- Health and Safe Community Environments
- Clinical and Community Preventive Services
- Empowered People
- Elimination of Health Disparities

Within this framework, the Seven Priorities are identified to reduce the burden of the leading causes of preventable death and major illness.

The Seven Priorities are

- Tobacco-Free Living
- Preventing Drug Abuse and Excessive Alcohol Use
- Healthy Eating
- Active Living
- Injury and Violence-Free Living

- Reproductive and Sexual Health
- Mental and Emotional Well-being

Healthy People 2020

Healthy People 2020 is based on the accomplishments of four previous Healthy People initiatives: (1) the 1979 Surgeon General's Report, *Healthy People: The Surgeon General's Report on Health Promotion and Disease Prevention;* (2) *Healthy People 1990: Promoting Health/Preventing Disease: Objective for the Nation;* (3) *Healthy People 2000: National Health Promotion and Disease Prevention Objectives;* and (4) *Healthy People 2010: Objectives for Improving Health. Healthy People 2020* is the result of a multiyear process that reflects input from a diverse group of individuals and organizations.

There are nearly 600 objectives in *Healthy People 2020* with more than 1,300 measures. The topic areas were developed from experts from the following federal agencies: Administration on Aging; Agency for Healthcare Research and Quality; Centers for Disease Control and Prevention; Food and Drug Administration; Health Resources and Services Administration; Immediate Office of the Assistant Secretary for Health; Office of Public Health and Science; Indian Health Services; National Institutes of Health; Office of Global Health Affairs; Office of Minority Health; Office of Population Affairs; Office of the National Coordinator for Health Information Technology; Office of Policy, Strategic Planning, and Communications; Office of the Assistant Secretary for Preparedness and Response; President's Council on Sports, Fitness, and Nutrition; Substance Abuse and Mental Health Services Administration; Department of Agriculture; and Department of Education.

Over the course of the decade, the four foundation health measures will be used to monitor progress toward promoting health, preventing disease and disability, eliminating disparities, and improving quality of life. See Box 3.3.

Healthy People 2020 focuses on identifying, measuring, tracking, and reducing health disparities through a determinants-of-health approach. Over the past two decades, Healthy People's overarching goals have focused on disparities. In *Healthy People 2000,* the goal was to reduce health disparities among Americans; in *Healthy People 2010,* it was to eliminate, not just reduce, health disparities. In *Healthy People 2020,* the goal is expanded further to achieve health equity, eliminate disparities, and improve health for all groups. Currently, *Healthy People 2020* is assessing health disparities in the U.S. population by tracking rates of illness, death, chronic conditions, behaviors, and other types of outcomes in relation to demographic factors, including race and ethnicity, gender, sexual identity and orientation, disability status and special health care needs, and geographic location. See Table 3.2.

There are 13 new topic areas for 2020, and these are listed in Table 3.3. Each of the *Healthy People 2020* topic areas includes related evidence-based interventions and resources from U.S. Preventive Services Task Force Clinical Preventive Services, Guide to Community Preventive Services, and healthfinder.gov's Quick Guide to Healthy Living Information for Consumers. *Healthy People 2020* also hosts an online community using Twitter, LinkedIn, or one of the *Healthy People 2020* webinars. Leading health indicators reflect high-priority health issues and communicate actions that can be taken to address them. These indicators will be used to assess the health of the nation over the decade, to facilitate collaboration across sectors, and to motivate action at the national, state, and community levels to improve the health of the U.S. population.

According to the *Healthy People* initiative, *health promotion* is defined as any strategy that helps individuals make personal choices in a social context about lifestyle that will have a positive influence on the individual's health prospects. *Health protection* is defined as those interventions that are related to the environment made by regulatory bodies to protect a large population group. *Preventive services* include screening for disease, counseling, medication to prevent disease, or immunization interventions for individuals in the clinical setting. The last priority area of surveillance and data systems was essential to track all of the changes that would occur with programs focusing on meeting the goals of *Healthy People 2020.*

The *Healthy People 2020* initiatives continue to have a significant impact on primary health care in the United States. The incorporation of health-promoting and disease prevention strategies has become the foundation for primary care. It is believed that all of the goals of *Healthy People 2020* are achievable with support from individual health-care providers, local and national government

Box 3.3 *Healthy People 2020* Foundation Health Measures

1. General health status measures such as life expectancy at birth and at age 65, healthy life expectancy, years of potential life lost, physically and mentally unhealthy days, self-assessed health status, limitation of activity, and chronic disease prevalence.
2. Health-related quality of life and well-being such as physical, mental, and social health–related quality of life, well-being/satisfaction, and participation in common activities.
3. Determinants of health, a range of personal, social, economic, and environmental factors that include biology, genetics, behavior, access to care, and environment in which people are born, live, learn, play, work, and age.
4. Disparities that include race/ethnicity, gender, physical and mental ability, and geography.

Table 3.2 Topic Areas for *Healthy People*

- Access to Health Services
- Adolescent Health*
- Arthritis, Osteoporosis, and Chronic Back Conditions
- Blood Disorders and Blood Safety*
- Cancer
- Chronic Kidney Disease
- Dementias, Including Alzheimer's Disease*
- Diabetes
- Disability and Health
- Early and Middle Childhood*
- Educational and Community-Based Programs
- Environmental Health
- Family Planning
- Food Safety
- Genomics*
- Global Health*
- Health Communication and Health Information Technology
- Health-care–Associated Infections*
- Health-Related Quality of Life and Well-being*
- Hearing and Other Sensory or Communication Disorders
- Heart Disease and Stroke
- HIV
- Immunization and Infectious Diseases
- Injury and Violence Prevention
- Lesbian, Gay, Bisexual, and Transgender Health*
- Maternal, Infant, and Child Health
- Medical Product Safety
- Mental Health and Mental Disorders
- Nutrition and Weight Status
- Occupational Safety and Health
- Older Adults*
- Oral Health
- Physical Activity
- Preparedness*
- Public Health Infrastructure
- Respiratory Diseases
- Sexually Transmitted Diseases
- Sleep Health*
- Social Determinants of Health*
- Substance Abuse
- Tobacco Use
- Vision

*New for *Healthy People 2020.*

Table 3.3 New and Archived Objectives for *Healthy People 2020*

Objectives Archived from *Healthy People 2010*

Archived objectives are *Healthy People 2010* objectives that are not included in the proposed set of *Healthy People 2020* objectives for data, target, or policy reasons.
Increase in counseling on health behaviors among persons at risk with a physician visit in the past year.
Reduce hospitalization rates for three ambulatory-care–sensitive conditions.
Increase the proportion of persons who have access to rapidly responding prehospital emergency medical services.
Establish a single toll-free telephone number for access to poison control centers on a 24-hour basis throughout the United States.
Increase the number of tribes, states, and the District of Columbia with state-level trauma system facilitation and coordination of statewide defined criteria.
Reduction in proportion of adults aged 65 years and older with long-term-care needs who do not have access to the continuum of long-term-care services.

Objectives New to *Healthy People 2020*

A renewed focus on identifying, measuring, tracking, and reducing health disparities through a determinant of health approach.
New topic areas: Adolescent Health; Blood Disorders and Blood Safety; Dementias; Early and Middle Childhood; Genomics; Global Health; Health-care–Associated Infections; Health-Related Quality of Life and Well-Being; Lesbian, Gay, Bisexual, and Transgender Health; Older Adults; Preparedness; Sleep Health; and Social Determinants of Health.

Source: Retrieved from www.healthypeople.gov/2020/about/new2020.aspx

agencies, and, most important, the active participation of individual patients.

Healthy People 2020 stresses the importance of each individual taking personal responsibility for his or her own health, in partnership with his or her health-care professional. For the public to have an effective role in illness prevention, individuals must work in partnership with clinicians who have been educated in health promotion and disease prevention strategies.

U.S. Preventive Services Task Force

The U.S. Preventive Services Task Force (USPSTF) is composed of private sector experts who make recommendations to the health-care community regarding clinical prevention strategies. This group was first convened by the U.S. Public Health Service in 1984 and since 1998 has come under the umbrella of the Agency for Healthcare Research and Quality (AHRQ). Their

mission, as mandated by Public Law Section 915, is to conduct scientific evidence reviews of a broad array of clinical preventive services; develop recommendations for the health-care community; and provide ongoing administrative, research, and technical support to disseminate the findings.

The USPSTF meets and reviews scientific evidence for each of the current health-care screening guidelines, as well as preventive medications, immunizations, and counseling, and makes recommendations. Through consensus, the task force assigns a grade to each recommendation based on net benefits for patients and the strength of evidence for each of the current recommendations.

The result of the task force's efforts is an online *Procedure Manual* that can be used by clinicians who provide preventive services. The USPSTF *Procedure Manual* is available for distribution from several sources and has its own Web site: www.uspreventiveservicestaskforce.org/uspstf08/methods/procmanual.htm.

An evidence-based prevention resource for nurse practitioners is available at www.uspreventiveservicestaskforce.org/uspstf09/epbnursep/epbnursep.htm. The *Procedure Manual* provides recommendations for screening, including the following: cancer screening and chemoprevention strategies; screening for heart and valvular disease, infectious disease, injury and violence, mental health issues, and substance abuse; metabolic, nutritional, and endocrine screening; and pediatric screening guidelines. Nurse practitioners can use its evidence-based recommendations for clinical preventive services.

The USPSTF not only makes recommendations for screening select populations but also prioritizes services. Some recommendations are not implemented unless the provider feels that they are warranted. Thus, although guidelines are provided and recommendations are made, each health-care provider has the responsibility to assess each patient's history and risk factors and determine whether the current recommendations are appropriate for the individual patient. For example, patients who have a significant family history for a particular type of cancer may need to be screened earlier than recommended for the general population.

The work of this task force continues. Some of the current recommendations, such as lead poisoning and iron-deficiency anemia screenings, have been included as part of the well-child visits in pediatrics for many years. It is important that screening programs be continued or eliminated based on the strength of scientific evidence available and not just on tradition. If the evidence is not strong enough to support current recommendations, practices such as generalized screening for anemia and lead poisoning may need to be eliminated. This type of screening is relatively easy to do and is inexpensive but does cause trauma to the child (and often the parents), so decisions should be based on sound evidence and not just a matter of routine.

With the rapid evolution of technology in health care, it is important to be knowledgeable about current health-care information. Resources such as the NPS, *Healthy People 2020,* and the USPSTF recommendations are essential tools to help clinicians keep up to date with current best practices. All of these initiatives have Web sites that provide updates to the current printed reports. The NPS encourages partnerships among federal, state, tribal, local, and territorial governments; business, industry, and other private sector partners; philanthropic organizations; community and faith-based organizations; and everyday Americans to improve health through prevention. Initiatives such as *Healthy People 2020* and the USPSTF recommendations are excellent examples of well-researched tools that can help to enhance health promotion and disease prevention. The end result will be comprehensive care to patients with the goal of optimal health for all.

Immunization Practices

Immunization administration is one of the best examples of primary health promotion. Immunizations provide the patient's body with the ability to build up antibodies to a potential life-threatening illness before exposure to the offending agent. The guidelines for immunization continue to evolve and change over time. Currently, immunizations begin at birth and are continued throughout life. During early childhood, infants and children (birth through 6 years old) are immunized with a wide variety of vaccines, including hepatitis B (Hep B); hepatitis A (Hep A); diphtheria, tetanus, and acellular pertussis (DTaP); inactivated polio vaccine (IPV); *Haemophilus influenzae* type B (Hib); measles, mumps, and rubella (MMR); varicella-zoster virus (VZV); pneumococcal conjugate vaccine (PCV); influenza (flu); pneumococcal vaccine; and rotavirus (RV). The 2013 Advisory Committee on Immunization Practices (ACIP, 2014) recommends immunizations for children aged 7 to 18 years to protect against tetanus, diphtheria, and pertussis; meningococcal conjugate vaccine (MCV) is recommended at this age as well. At age 11 to 12, boys and girls should receive the human papillomavirus (HPV) vaccine. Either HPV4 or HPV2 may be used for females, and only HPV4 may be used for males. Teens who received MCV for the first time between age 13 and 15 should receive a one-time booster between age 16 and 18. All children should receive approximately 25 vaccines by the time they reach 5 years of age. After this point, they should continue to receive a tetanus, diphtheria, and acellular pertussis (Tdap) booster every 10 years. Recommendations for adults include annual flu immunizations, as well as pneumococcal, meningococcal, Hep A, and Hep B immunizations for those with certain risks related to their health, job, or lifestyle. Older adults should receive a VZV immunization at age 60 to prevent shingles and a pneumococcal polysaccharide vaccine at age 65 to protect them from pneumonia. The immunization schedules

change periodically, so to obtain the most current information, go to www.cdc.gov/vaccines/schedules/index.html, which offers current immunization guidelines for children and adults. Table 3.4 provides a summary of immunization guidelines current as of the publication date.

Immunizations are an effective form of primary health promotion, but they are not without controversy. Over the past several years, some consumers have argued that immunizations are not safe and in fact cause diseases such as autism and attention-deficit hyperactivity disorder. To date, the etiology of these diseases has not been found to be a result of immunization administration. However, there is always the potential for vaccines to cause side effects; therefore, patient education is paramount.

Each clinician must provide patients and their families with accurate information regarding immunization administration, including potential side effects and known contraindications to immunization, and keep a copy of a written consent for each immunization on file. This consent must be obtained for each immunization given, before vaccine administration. If, after administration of a vaccine, a patient develops a significant reaction (such as very high fever, uncontrollable crying for more than 2 hours, lethargy, coma, etc.), the patient should be evaluated in a timely manner, and the potential adverse reaction to the vaccine should be reported. In 1986, the National Childhood Vaccine Injury Act required that all health-care providers report any severe adverse reactions to the Vaccine Adverse Event Reporting System (VAERS) and Centers for Disease Control and Prevention (CDC). The length of time from administration to the appearance of an adverse reaction that is a reportable event is between 7 and 30 days and is

Table 3.4 Summary of Immunization Guidelines for Children and Adults

Pediatric (0–6 Years)	Children (7–18 Years)	Adult
Hep B Three between birth and 18 months		
DTaP Five between age 2 months and 6 years	*Tdap* One between 11 and 12 years	*Td* Every 10 years Substitute 1 dose with Tdap
Hib Four between age 2 months and 18 months		
IPV (polio) Four between age 2 months and 6 years		
MMR Two between age 12 months and 6 years		*MMR* One dose if born in 1957 or later
Varicella Two between age 12 months 6 years		*Varicella* Two doses if no evidence of immunity
	HPV (females and males) Three doses between age 11 and 12 years	*HPV (females and males)* Three doses between age 19 and 26 years if not done earlier
		Zoster One dose after age 60 years
PCV (pneumococcal) Four between age 2 months and 18 months		*PCV* One dose after age 65 years
Influenza Yearly after age 6 months	*Influenza* Yearly	*Influenza* Yearly
Hep A Two between age 12 months and 2 years	*MCV (meningococcal)* 1 between age 11 and 12 years unless in a high-risk group	
RV Two between 2 months and 4 months		

Source: Summary of Immunization Guidelines for Adults and Children (ACIP, 2014). Retrieved from www.cdc.gov/vaccines/schedules

dependent on whether the vaccine contains live virus. When in doubt, it is best to report the event.

The information regarding potential reactions for each vaccine is available in the Red Book developed by the American Academy of Pediatrics (www.aap.org) or on the CDC Web site under the Morbidity and Mortality Weekly Reports (MMWR) (www.cdc.gov/mmwr) section. To file a report on a potential reaction with the CDC, complete the VAERS form, which can be downloaded from www.vaers.org. Immunization is still one of the best methods we have for preventing illness and disease or the serious sequelae that can develop from specific diseases such as polio, diphtheria, *H influenzae,* and others. It is an example of primary prevention at its best.

Individual Influences on Health Promotion

The key to successful health promotion is the motivation and commitment of the patient. To obtain a successful outcome, the patient must be willing to make lifestyle changes. The clinician should provide patients with health education that informs them of their current risk factors, the possibility of reducing or eliminating risk factors by lifestyle changes, and the potential benefits of implementing these changes. Once the clinician has provided the information to the patient, the decision to take action rests with the patient. An ideal scenario for health promotion would involve both patient and clinician working in partnership toward mutually agreed on health goals. However, the choice to engage in this partnership is the patient's decision. For example, 36-year-old K. J. is being seen for a routine physical exam and reveals a smoking history of a pack a day of cigarettes for 20 years. She is counseled about her smoking habit and the associated risk for cardiac, respiratory, and peripheral vascular disease. She states that she understands that smoking is not good for her health but currently is not willing to quit. This scenario illustrates that despite the best efforts of the clinician, the patient still has the right to not engage in health-promoting behaviors.

Many factors can influence a patient's motivation to engage in health promotion activities, such as willingness to alter lifestyle practices, belief that making the changes will affect health, and belief that promoting health can prevent disease. All of these factors will influence whether or not a patient decides to make lifestyle changes. Several health models have been developed to identify factors that influence a patient's willingness to take action and make changes. Nola Pender's 1997 health belief model provides a framework for health-care providers to use in assessing patients' readiness to make lifestyle changes to promote their own health (Pender, 2010). Pender's model describes and defines several factors that affect a patient's decision to take action (Fig. 3.3). She divides these factors into two types: cognitive-perceptual factors and modifying factors. Cognitive-perceptual factors include items such as importance of health, perceived control of health, and perceived barriers to health-promoting behaviors. Modifying factors include biological characteristics, situational factors, and demographic characteristics.

Pender states that all of these factors will affect a patient's willingness to take action (which she terms "cues to take action"). For example, 17-year-old Jonathan had not been consistently wearing a seat belt while riding in or driving a car until 2 months ago. His friend Kyle was involved in a motor vehicle collision (MVC) in which Kyle was seriously injured. Kyle's parents informed Jonathan that Kyle's injury could have been prevented if Kyle had been wearing a seat belt. In this situation, Jonathan has changed his perception (cognitive-perceptual factors) about the importance of wearing a seat belt (health-promoting behavior) based on interpersonal influences (his friend's involvement in an MVC). His "cue to action" was hearing that the injuries incurred by Kyle could have been avoided had Kyle been wearing his seat belt.

This scenario illustrates that although various factors can influence positive health changes, the "cues to action" for patients may vary. In this scenario, it would be interesting to find out if the MVC caused Kyle to change his behavior regarding seat belt use. It is important that clinicians strive to offer patients a variety of scenarios to promote health.

Today's focus on primary disease prevention is empowering for patients, in contrast to the situation 20 years ago, when most patients were not given the option of actively participating in their health care. Health care today provides many opportunities for patients and clinicians to optimize health through health promotion and disease prevention.

Community Influences on Health Promotion

Community efforts can also substantially enhance health promotion efforts. As described previously, the burden of responsibility regarding sanitation, hygiene, and clean water supplies rests with the local community government. A person who lives in a community that lacks appropriate waste disposal, air pollution controls, or law enforcement is exposed to greater health risks than is an individual who lives in a community in which each of these environmental issues has been effectively addressed. Unfortunately, local government agencies are faced with widening budget deficits, and many social and environmental programs are being cut in the wake of the recession affecting the United States.

Health-care providers need to work in partnership with local government agencies to ensure that healthy living conditions are a right for each citizen and not dependent on an individual's race or ethnicity, geography, or socioeconomic status. Clinicians can provide education and expertise to local government agencies for understanding the connection between effective sanitation measures and health. Each health-care provider can also alert the local

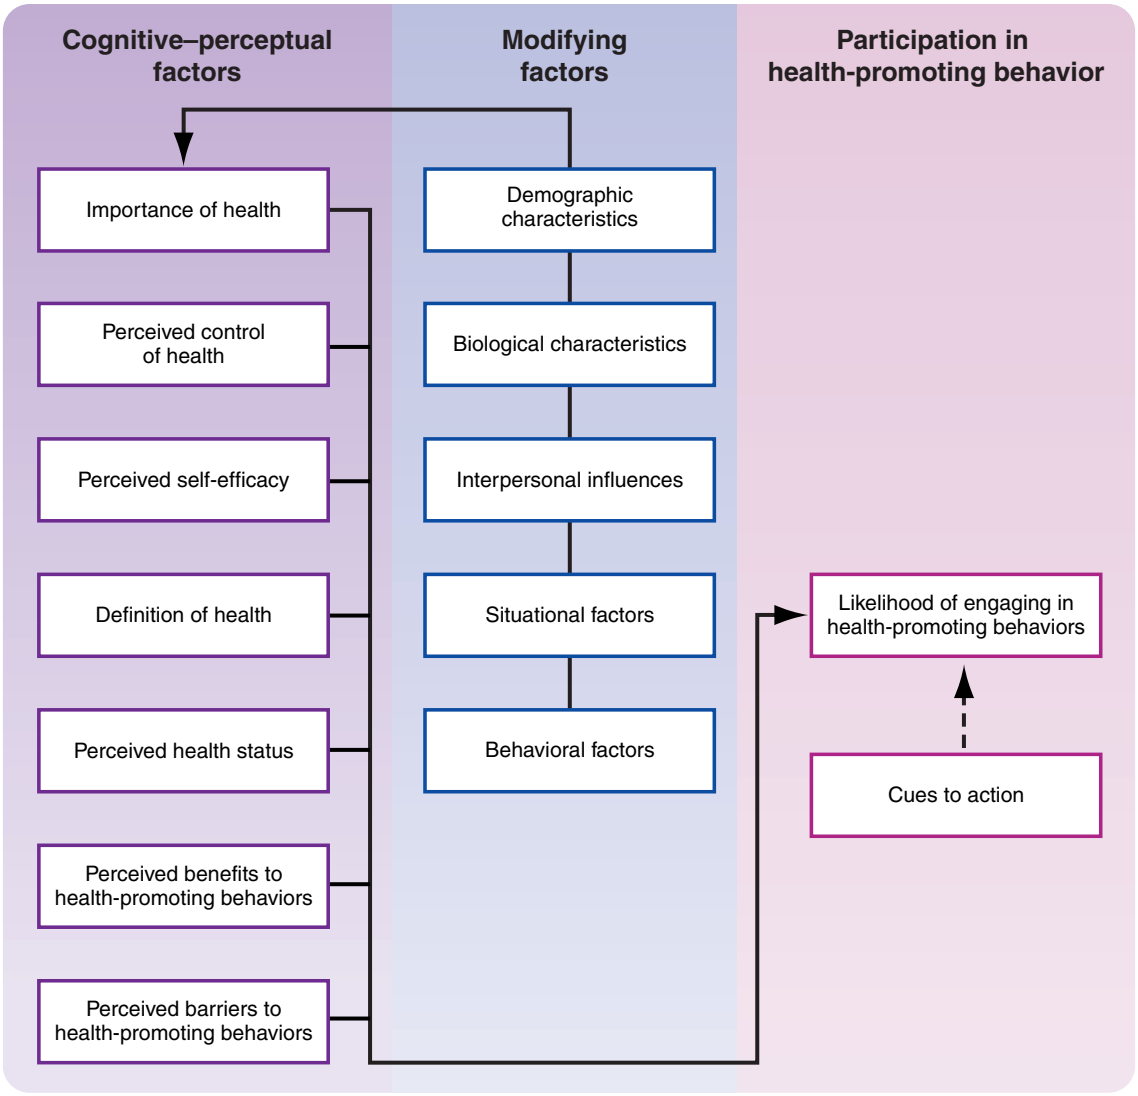

Figure 3.3 Health Promotion Model. *(Source: Pender, N.* Health Promotion in nursing practice, *ed 5. Prentice-Hall, Upper Saddle River, NJ, 2006.)*

community to possible outbreaks of illness and disease that can affect the greater community at large.

One of the major transitions that occurred from the earlier initiatives of *Healthy People* to *Healthy People 2000/2010/2020* was the shift from a largely federal government initiative to more involvement from local and community agencies. It was believed that this shift in responsibility would result in a significant improvement in meeting the goals of the initiative.

Community programs aimed at providing health information are one way that local communities can assist with this initiative. Offering forums for dialogue between health-care providers and local citizens is an excellent way to educate a broader audience. If these types of efforts are supported by community leaders, there will be a larger impact in the community. The development of health-promoting legislation is another way that local communities can help effect change. For example, the passage of smoking restrictions in public areas is an excellent example of how local efforts can improve the health of the communities they serve. Legislative policies and interventions that affect the health of individuals and communities, such as housing, labor, energy, transportation, education, justice, and so forth, can be initiated by local and regional agencies. *Healthy People 2020* encourages the active participation of all civic and community agencies to help meet the goals for 2020.

Communities can also respond to the "call for action" from *Healthy People 2020* by ensuring that their citizens have equal access to health care, which is a priority for the *Healthy People* initiatives. For example, it is often difficult for indigenous populations to access health-care services in their communities because of the rural nature of the Indian Reservations. The Navajo Nation is the largest Indian Reservation in the United States, covering 27,000 square miles and spanning parts of Utah, Arizona, and New Mexico. The nearest health-care facility can be a 3-hour drive away.

In addition, many communities do not have systems in place to support the efforts of patients who have language or financial barriers to seek care in their community. Often, a disadvantaged patient's only access to care is through the hospital emergency department. At that time, tertiary measures of prevention are employed and are very costly. Community hospitals can work together with local government agencies to develop health programs/settings that will provide access to health care for all citizens, not just those who have health insurance or whose primary language is English.

The long-range goals of establishing these types of health programs are a reduction in direct hospital costs and an improvement in the quality of life for all citizens. Saving money is a major concern for both hospitals and local communities, and improving access to nonemergent health care can provide significant savings to both. Providing access to health-care services to groups of people who lack the means to access care in traditional settings will do much to improve the health disparities currently affecting our nation.

The Affordable Care Act (ACA) was signed into law on March 23, 2010, and the Supreme Court rendered a final decision on June 28, 2012, to uphold the heath-care law. The ACA puts consumers in charge of their health care, allowing for improved access to care, stability and flexibility of care, and information needed to make informed choices about their health.

The Patient's Voice 3.1

Looking Back to Move Forward, by Dorothy Dunn

Looking back I was always active, fit, and healthy.
He was born 10 pounds 14 ounces, a vaginal delivery.
"He will be obese, and we need to watch for diabetes."
Truth is that when pregnant, I was the obese one.
Now he is active, fit, and healthy, never having a weight concern.

Now I am aging, moving forward in my life span.
Menopause came and went, a beautiful passage into becoming older with grace.
Now, postmenopausal, my path has been a battle against metabolic syndrome.
As I move forward I slow, dare not to stop.
I learn I have a medical condition, a disease named obesity.
How did this happen to always being active, fit, and healthy?

Choosing to battle metabolic syndrome seemed kinder to the cruelty of being obese.
Is this what it will take to call it what it is?
Is there truth in what my path is, the obesity battle?

I can choose. I choose the path of health and well-being,
A healthy passage as I age.
Enjoy active walking, enjoy colorful eating, enjoy renewed spirit.

Looking back, I was always active, fit, and healthy.
Moving forward, I will enjoy my next passage into quality years to come.

Other Influences

Health promotion strategies can be effective only when we have adequate knowledge of diseases affecting any given population. With this knowledge, individuals, families, health-care providers, community partners, and governmental agencies can work together to alleviate or minimize the impact of disease on patients. The evaluation of current health indicators is important in order to change the course of illness and disease. Evaluating and reviewing the current leading causes of death in the United States is one way to evaluate past trends. Once this evaluation is made, it can be determined whether these diseases can be prevented or reversed with lifestyle changes. The leading causes of death in this country are published by the National Center for Health Statistics. The top 10 causes of death in the United States for 2011 are listed in Table 3.5. Our current knowledge regarding all of these diseases indicates that healthy lifestyles can

Table 3.5 Top 10 Causes of Death (National Vital Statistics Report for 2011)

Cause of Death	Statistics	Amendable to Intervention
Heart disease	596,339	Yes
Cancer	575,313	Some
Chronic lower respiratory disease	143,382	Yes
Stroke (cerebrovascular disease)	128,931	Yes
Accidents (unintentional injuries)	122,777	Yes
Alzheimer's disease	84,691	Early diagnosis to slow progression
Diabetes mellitus	73,282	Yes
Influenza and pneumonia	53,667	Yes
Nephritis, nephrotic syndrome, and nephrosis	45,731	Yes
Intentional self-harm (suicide)	35,539	Yes

indeed positively affect their outcomes. For example, heart disease has been the number 1 cause of death in the United States for many years. A healthy lifestyle can prevent or at least ameliorate heart disease in most individuals. The previously discussed health scenario of Mr. Hart is an excellent example of risk factors for heart disease. As you recall, Mr. Hart had several lifestyle factors that put him at risk for heart disease: smoking, alcohol consumption, overweight, and elevated cholesterol and LDL levels. Making different lifestyle choices could potentially help Mr. Hart to control his heart disease in order to live a long and healthy life, without the devastation of a myocardial infarction or possibly even death from heart disease.

The majority of the current top 10 causes of death could be avoided or delayed with healthy lifestyle choices, providing hope for the future health status for patients. With early health assessment and screenings, clinicians can intervene by helping patients to make healthier life choices and lowering their risk for devastating health consequences.

PRACTICAL EPIDEMIOLOGY

It is essential for clinicians to monitor trends in health and disease that may affect patients' health. In the role of health promoters for both their patients and the larger community, clinicians gather and contribute raw epidemiological data to various health organizations. Clinicians then consume the analyses of these data in the research reports and journals produced by these organizations.

Epidemiology is the evaluation of distribution patterns and determinants of health and disease in populations. The *focus* of epidemiology is to study the trends of disease occurrences in groups rather than in individuals. The *goal* of epidemiological studies is to discover and evaluate the trends of illness or disease in groups of

CASE STUDY 3.1 The Journey to Health Promotion

Delia, a 41-year-old woman, comes in for a complete physical exam. She states that she has completed the questionnaires that were sent to her in anticipation of this appointment. She shows you the completed primary health promotion questionnaire (see Box 3.4) and tells you that she has never had any health-care provider in the past ask her so many in-depth questions about her own health and well-being. She states that she realizes, after completing this assessment form, that there are many factors in her life that contribute to her health status. She relates that completing this survey has made her take a personal inventory of her patterns on an emotional, social, cultural, and psychological level; and she has begun to see how they either contribute to or detract from her current physical health. She indicates that she is willing to work with her health-care provider to begin to change some of her current health and lifestyle patterns to enhance her own health and well-being. She states that completing this questionnaire has been a very enlightening exercise for her and she is excited to begin "her journey" to balancing her life for better health and harmony.

people in order to determine cause and effect and thereby prevent further disease. For example, a single case of swine flu (H1N1) is a concern, but it is not the focus of epidemiology. Instead, increasing numbers of cases of the H1N1 virus become an epidemiological study when they occur in close proximity of time and place. When susceptible populations are studied for the presence of a particular infection or disease, distribution patterns and symptoms may begin to emerge.

When disease statistics are given, reports often refer to the prevalence and incidence rates of a certain disease. The *prevalence* rate refers to the number of cases of a particular disease at a particular point in time divided by the percentage of the population at a point in time (Table 3.6). The prevalence rate does not distinguish between *new* and *old* cases. For example, if the current prevalence rate for a disease was 1 million, it would indicate the number of new and old cases of the disease in the current population. The *incidence rate* is the number of *new* cases of a disease diagnosed at a point in time (e.g., 1 year). Prevalence and incidence rates are commonly used terms to describe disease trends, and the formula is provided in Table 3.6.

Table 3.6 Prevalence and Incidence Rates

Prevalence Rate	Incidence Rate
New and old cases of "B" disease at a specific point in time	New cases of "C" disease at a specific point in time
Number of cases divided by total population at specific point in time	Number of cases divided by total population at a specific point in time

Additional common terms used to study trends include *morbidity, mortality, sporadic, endemic, pandemic,* and *epidemic.* Morbidity and mortality rates are often described together. Morbidity defines the number of people who have been diagnosed with a disease divided by the number of total population at risk. The number of people who have died from a particular disease divided by the total population is the mortality (Table 3.7).

To understand the difference between morbidity and mortality, consider the human immunodeficiency virus (HIV). During 2003, the estimate for the number of persons living with HIV/AIDS in the United States was 1,185,000 (morbidity rate). During the same year, the total number of deaths from AIDS was 17,934 (mortality rate). The current rates for HIV infection indicate that significant strides have been made in improving prevention of HIV, which has in turn influenced the incidence, prevalence, morbidity, and mortality associated with the disease. More people are living longer with HIV as a result of significant advances in its medication and management.

Certain illnesses affect the population during annual predictable cycles. Terminology regarding these cycles includes *epidemic, endemic, sporadic,* and *pandemic.* For example, influenza virus is known to be prevalent during the winter season and can cause significant morbidity and mortality. The ability to predict the active cycle of this virus helps health-care practitioners to educate and inoculate patients before predicted outbreaks. These health promotion efforts are effective means of decreasing the prevalence and incidence of the influenza virus, commonly called the "flu." Each year, predictions are made regarding the number of patients who, without health promotion efforts, will experience the flu. In the past, there have been years in which the number of patients experiencing the flu was significantly higher than expected. This is called an *epidemic* and is defined as the presence of an event (illness or disease) at a much higher rate than expected on the basis of past history.

Although the common cold appears to have some variation, it is known to be present throughout the year. Because it is considered to be present consistently throughout the year, it would be considered an endemic outbreak. *Endemic* is the term used when the presence of an event is constant at or about the same frequency as expected based on past history. A sporadic outbreak occurs when there are occasional cases of an event unrelated in space or time. For example, a gastrointestinal virus may be present in 3 patients this month, 20 patients 2 months from now, and 100 patients in 6 months. The virus is present but is not causing illness at a specific time and place. It is rare to hear of a patient having the flu during the summer season. The last epidemiological term that it is important to understand is pandemic. A *pandemic* is defined as the presence of an event in epidemic proportions affecting many communities and countries in a short period of time. For example, in 2005 to 2006, there was widespread concern regarding avian or "bird" flu. It was found in several countries in a short period of time, and there was concern that it would reach pandemic proportions by affecting many people in many countries. The purpose of all of these epidemiological terms is to clarify the significance of a particular illness or disease at a given point in time (Table 3.8).

The CDC generally monitors and reports the incidence, prevalence, morbidity, and mortality rates of diseases and specifically monitors the rates of infectious diseases. This information is distributed weekly in a report titled *The Morbidity and Mortality Weekly Report* (MMWR), which is available online at www.cdc.gov/mmwr. The report contains useful information about current infectious diseases that are a threat to local and

Table 3.7 Morbidity and Mortality Formulas

Morbidity Formula	Mortality Formula
Number of new cases of "D" disease divided by total population at risk	Number of deaths from "E" disease divided by total population at risk

Table 3.8 Epidemiological Terms

Term	Definition
Sporadic	Outbreaks of an illness/disease that occur occasionally and are unrelated in space and time
Epidemic	Presence of an event (illness or disease) at a much higher rate than expected based on past history
Endemic	Presence of an illness/disease constantly present or present at a rate that is expected based on history
Pandemic	Presence of an event in epidemic proportions affecting many communities and countries in a short period of time

global communities and provides the latest guidelines for treatment of infectious diseases. It is a helpful tool to investigate current infectious disease trends and potential health promotion practices that may minimize or eliminate the threat of infectious disease.

CONCLUSION

Health promotion is one of the most powerful tools available today to prevent disease and disability. Clinicians should use health promotion strategies at the primary, secondary, and tertiary levels of prevention. Each level of prevention is important, but the ultimate goal is primary prevention because it has the most significant impact on disease. Actively engaging in primary prevention strategies such as health promotion creates a wonderful opportunity for patients and health-care providers to work together as a team with the common goal of wellness and the prevention of disease. When primary prevention strategies are not feasible, *Healthy People 2020* and the U.S. Preventive Services Task Force provide clinicians with guidelines to initiate secondary prevention strategies, such as early screening and detection of illness and disease. The utilization of these guidelines and health-focused initiatives will help to improve the health of the nation. With all of the current health promotion strategies in place and a focus on disease prevention, it may be possible to eliminate or minimize the most expensive level of health promotion: tertiary prevention. As we embrace the second decade of the 21st century, we continue to build momentum on primary health promotion strategies with the goal of ensuring optimal health and wellness for all citizens.

Chapter 4

The Art of Diagnosis and Treatment

Susan K. Chase, EdD, RN, FNP-BC

The Affordable Care Act will likely change health-care delivery in the United States over the next few years. Central to the law is granting increased access to health-care services to people who had previously not been able to receive regular primary care. Advanced practice registered nurses (APRNs) will be central in delivering much of the primary care in the new system. APRNs are able to offer unique services in primary care for several reasons. All health-care providers are called to provide evidence-based care, which involves providing care and making treatment and screening choices based on current research findings. Further, evidence-based care works best when systems of care are established so that local protocols and tracking systems support the diagnosis and treatment decisions of providers. Nurse practitioners are able to enact evidence-based care particularly well because they bring a nursing perspective of whole-person care to patient encounters that in some settings have been more disease centered than person centered. As clinicians work with patients to plan how to improve health, they take into account more than a plan for prescription medications. They include considerations of each individual's life situation when choosing regimens that may include medication, but clinicians will also include recommendations for diet, activity, rest, stress management, and health promotion. Evidence-based practice requires more than a "diagnose and treat" mentality. There is more to do in a primary-care visit than set up a treatment plan. Treatment decisions are made based on patient values, preferences, and resources while also considering guidelines and research-based recommendations. Learning to practice primary care in an artful way such as this requires a certain kind of thinking. The kind of thinking that clinicians engage in is the subject of this chapter.

THE CONTEXT OF CLINICAL JUDGMENT IN PRIMARY CARE

Clinical Judgment and the *Circle of Caring*

The *Circle of Caring* model, introduced in Chapter 1, provides a framework for advanced practice nursing. It includes aspects of the more traditional medical model approach within a model that has nursing as its origin. The *Circle of Caring* incorporates elements of the patient's experience, including the context of that experience in the patient's life and the environment in which care is delivered. It includes traditional modes of assessment, such as history taking, that are similar to those of the medical model, as well as a database for a nursing perspective, the functional health patterns, or other more holistic measures. Objective findings include physical assessment data, laboratory test data, and functional measures. The *Circle of Caring* demonstrates that the clinician uses these data as part of a data-collection process that leads to the identification of both medical diagnoses as listed in the International Classification of Diseases, 10th Revision (ICD-10) (www.cms.gov/Medicare/Coding/ICD10) and the human responses to those specific diagnoses or nursing diagnoses as listed in taxonomies such as the North American Nursing Diagnosis Association International (NANDA-I). The NANDA-I list includes consideration of problem prevention and wellness promotion and goes beyond a narrow problem-solving framework. A full understanding of the patient situation provides a basis for planning interventions based on best available evidence. Patient preferences are considered as the patient and provider together design a treatment plan that may include pharmacological measures but will also include lifestyle choices and complementary modalities to approach healing and wellness. The *Circle of Caring* reflects that outcomes of APRN practice include improved mortality and morbidity statistics for aggregates of patients; optimized use of the health-care system that provides early, relatively inexpensive treatments to prevent more expensive problems later; and improved functional status and quality of life, as judged by the patient. All of this occurs in an environment consistent with the Institute of Medicine's recommendations that all patients have access to care based on best available evidence, as well as care that takes into account the patient's preferences and values.

Not only is the *Circle of Caring* an expanded way of thinking of both the nursing and the medical clinical process, but it also denotes the way in which the APRN and patient relate to each other within this model. The APRN is able to make appropriate diagnosis and intervention selections on the basis of knowing the patient, being committed to using appropriate

clinical guidelines, and having patience when working with the patient, who may be required to make substantial lifestyle change as a result of illness or risk factors. In addition, both patient and nurse exhibit courage in that they engage in this most human of endeavors, that of caring. Throughout the assessment, diagnosis, and treatment, the APRN brings an authentic presence, which is in itself humanizing and healing, and is willing to be an advocate for the patient in personal or professional realms. The *Circle of Caring* requires a balance. The nurse and patient working together need to come up with a meaningful treatment plan and a plan for follow-up support. The *Circle of Caring* depicts a complex yet rewarding practice that enriches both patient and nurse.

This chapter focuses on the process aspects of the model. The *Circle of Caring* model includes the medical model perspective that nurses with baccalaureate degrees may not have learned in an academic setting or practiced in hospital or community settings. It also includes a broader sense of nursing than practice at the baccalaureate level allows. Therefore, the APRN role includes elements from the medical realm and from an expanded nursing base.

Essential to high-quality clinical judgment is the ability of the nurse to form a link between the patient's experience of his or her health concerns and the range of diagnostic and therapeutic choices available to achieve a range of possible outcome states. The nurse must be expert at eliciting the true story of the patient and in recognizing patterns that are presented in the data so as to arrive at an appropriate diagnosis and therapeutic plan. This chapter focuses on merging the results of research with diagnostic reasoning and clinical judgment to facilitate their application by the APRN.

Purpose and Goal of Diagnostic Reasoning

From the patient's point of view, the purpose of a visit to a clinician may be to solve a physical problem. Beyond problem-solving, the practitioner must always keep in mind that every visit is an opportunity for disease prevention, for screening for high-risk problems, and for health promotion based on appropriate guidelines. The patient must know that his or her initial concerns are taken seriously and are not ignored. The APRN can establish a tone that attends to body, mind, and spirit in every visit. Diagnostic reasoning to solve problems, to promote health, and to screen for disease or illness all require a sensitivity to complex stories, to contextual factors, and to a sense of probability and uncertainty. At times, the patient will schedule a visit stating one concern, but during the visit other issues arise that become more important. Headache might be caused by a stressful job or family situation, or the patient might not want to tell the scheduler that domestic violence or a sexual concern is really what is bothering the patient. Clinicians learn to pay attention to the "By the way, I was wondering about . . ." lead-ins to real concerns.

The mental tasks of eliciting and sorting through large amounts of data, clustering data elements into meaningful patterns, connecting patterns to reasonable diagnostic statements, considering risk factors, and selecting appropriate interventions require the highest order of cognitive processes. It is these analytical functions that distinguish advanced practice nursing and are the reason patients seek our services. The human element of caring helps elicit rich data and establish the trust necessary to encourage patients to adjust their living patterns in the short or long range.

Primary Care and Its Uniqueness

Many students come to advanced practice programs with extensive experience in acute- or critical-care nursing. They are committed to learning an expanded mode of practice but may be overwhelmed by the amount of new material that must be mastered. Even students with community health experience find that the issues faced in primary care are different from those encountered in their previous practice and require new knowledge and skills. Primary care is a new world with a different set of problems to be solved, different kinds of constraints on choices, and a different culture of care. Entering this world with sensitivity to its differences can help reduce anxiety for new advanced practice students and can explain other reactions to this new nursing setting that might arise.

The types of problems that are solved in primary care are different from those encountered in acute- or critical-care settings. Upper respiratory infections, common abdominal complaints, skin rashes, and vaginal discharges are problems not often encountered in acute-care settings. Even chronic conditions present differently in primary care. Hypertension, congestive heart failure, arthritis, or diabetes present with day-to-day management problems that are different from the crises that acute-care nurses must respond to in tertiary-care settings. Patients with psychosocial problems such as anxiety and depression frequently present with vague, nonspecific somatic complaints.

The pace of care is different in primary care. Nurses who are seeking refuge from busy acute-care duties will be surprised by the mental fatigue that comes from diagnosing and treating up to 30 different patients or families in a day. The sheer variety of possible problems faced in a day's time is exciting and interesting, but it is also challenging. The office visit allows for focused attention with an individual patient, but the former staff nurse will realize that an organized approach to obtaining and processing information is necessary because the patient will not be available to fill in missing pieces of information at the end of the day. On the other hand, the relationship with a growing family or the treatment

of patients with chronic conditions will continue over years. This long-term relationship is very rewarding to both the APRN and the patient and family.

Primary care includes more than problem-solving and symptom management. It involves screening for problems as yet undetected and supporting health promotion and disease and injury prevention at every opportunity. Teaching patients of all ages about how their bodies work, risk reduction, and treatment options helps patients assume more responsibility for their own wellness. These activities support patients in increasing their health literacy so that they can be active participants in their own care. Researchers from Canada are exploring how APRNs help patients participate in their own care more actively through a concern for their comfort and for a sense of coherence in their lives (Sangster-Gormley & Frisch, 2013). Establishing trust and believing that the APRN cares about the whole person promotes true patient-centered care.

Uncertainty

Primary care and the increased autonomy that advanced practice clinicians enjoy also bring an increase in uncertainty. Patient problems are not already labeled when the nurse practitioner sees the patient. Many different conditions present in similar ways. Even the "hard numbers" of laboratory tests must be evaluated for their reliability. Once a diagnosis is made, multiple treatment approaches are available even for simple problems. Further, patients do not always carry out recommended treatment plans (Michaels et al, 2008). Many problems require lifelong lifestyle adjustment. At the end of the day, the clinician may have nagging doubts about the decisions that were made on many levels. New practitioners especially need support to develop confidence in their diagnostic and treatment-planning capabilities, but even experienced practitioners describe learning to live with the uncertainties involved in primary care. Intellectual honesty and humility are important aspects of thoughtful practice and can be cultivated, but they must be balanced with confidence that is based on experience; this serves to increase the effectiveness of the provider.

Nursing versus Medical Model

APRNs perform in both the nursing and the medical domains. The nursing domain contains consideration of individual and family responses to actual or potential threats to health. It involves helping patients cope with disease processes that may be occurring, and it anticipates human distress and works on the level of what an illness experience means to the patient. By becoming an APRN, nurses do not leave their nursing model of practice. As APRNs gain skill in the medical domain of practice, they learn new diagnostic reasoning possibilities and new treatment options for specific medical problems. These new skills are built on the nursing framework, but they do not replace the nursing basis for practice. APRNs have been proven to be effective and efficient care providers for patients with acute and chronic health problems. The process of clinical judgment is unique in primary care because patients and their families will actually carry out the care (Elliott, 2010). Patients are actively involved in their own care, and the clinician must take that into account in designing a treatment or health promotion plan. Though much of this textbook is designed to provide a background for managing medical problems, all that the nurse has learned in caring for patients still applies. An APRN's approach to patient problems is often very individualized and, therefore, less easy to summarize in a textbook. Nevertheless, the nursing model supports and nurtures the APRN's practice. It provides the basis for the *Circle of Caring*.

Patient–Advanced Practice Nurse Linkages

A model for how the provider and patient work together in a clinical encounter is presented in Figure 4.1. Clinical judgment is not a process that happens in the mind of the practitioner alone: It happens in a dialogue that occurs between patient and provider. The quality of communication and the agreement about what the encounter is meant to accomplish will improve both effectiveness and satisfaction with the patient encounter for both parties. The model includes patient factors, provider factors, and environmental factors, all of which have an influence on the clinical judgment process (Chase, 2004).

The Patient–Advanced Practice Nurse linkage model is based on research in diagnostic reasoning in general and the particulars of the primary-care encounter. Johnson (1993) described the discourse between patient and nurse as having several phases: establishing the agenda for the encounter; eliciting information from the patient, including being alert to cues and helping to problem solve; and conducting the physical examination, including attending to comfort level, preparing and informing, and developing a plan of care and using a teachable moment. Teaching in this case is not content centered but patient centered, based on understanding the perspective of the patient. Finally, the APRN personalizes solutions based on knowing the patient. Investigating overall satisfaction with care, a large quantitative study has shown that patients are equally satisfied with care access and overall care experience when care is provided by a nurse practitioner or physician assistant compared with a visit managed by a physician in both adult and pediatric settings. Patients were more satisfied, however, with nurse practitioner and physician assistant care when rating the quality of practitioner interaction (Roblin et al, 2004). A review of the literature on nurse practitioners' communication style (Charlton et al, 2008) characterized nurse practitioner communication style as either biomedical or biopsychosocial. The biopsychosocial

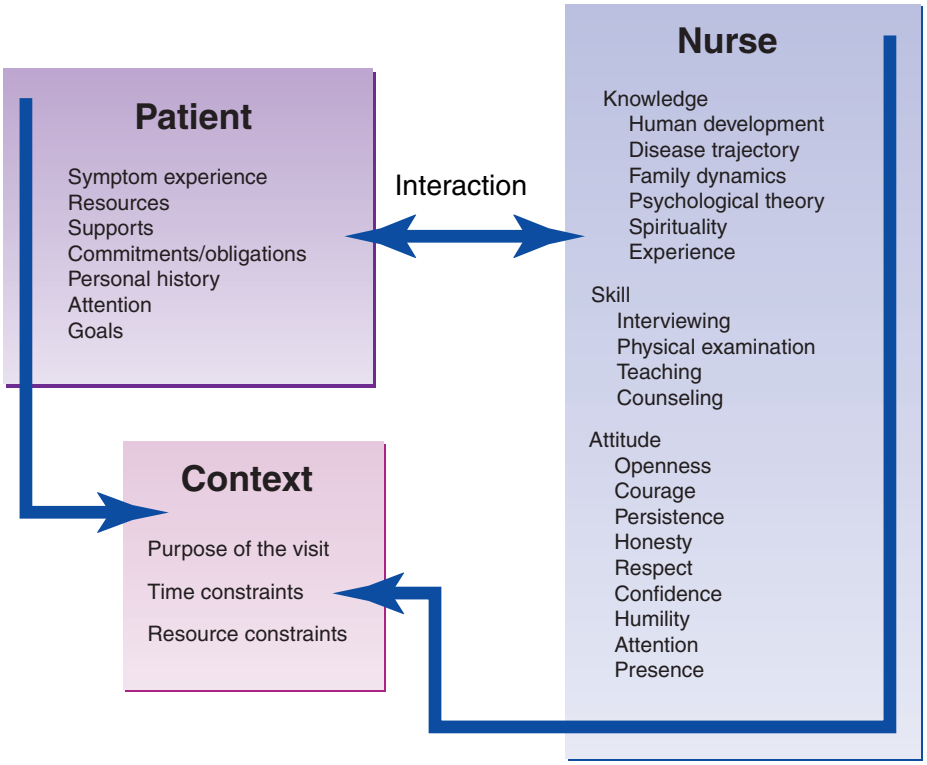

Figure 4.1 Patient–advanced practice nursing linkages. *(Source: Chase, SK.* Clinical judgment and communication in nurse practitioner practice. *FA Davis, Philadelphia, 2004.)*

style was associated with higher patient satisfaction and better adherence to treatment plans. A qualitative study of health outcomes achieved in a home visiting model for young disadvantaged mothers showed that the nature of the relationship between carer and recipient goes beyond protocols with a result of enhanced personhood and new possibilities developed by these young women (SmithBattle, 2009). The personal relationship between APRN and patient within which this work is done is unique.

THE CLINICAL PROCESS AND ITS LIMITATIONS

Human Memory Limitations

One of the most useful models available to understanding diagnostic reasoning is that of the information processing model. This model is built on the premise that the human brain has both short- and long-term memory and that these forms of memory are different from each other. Short-term memory is the processing space that can hold new pieces of information and elements of the patient history and physical data. It has the limitation of being able to hold only approximately seven "bits" of information. Much of the mental activity used in diagnostic reasoning is done to maximize the active processing space and to clustering or "chunking" cues into collections of data that can be managed together, which helps to maximize processing capacity. In contrast, long-term memory is practically unlimited. It can hold vast quantities of facts, sensations, and experiences. To bring these facts or experiences to bear on a given situation, long-term memories must be accessible. Research has shown that the ability to retrieve a fact depends on the frequency with which the fact is brought forward for use. This is why in some cases repetitive exercises assist in cementing long-term memory. Another factor that affects retrievability of facts from long-term memory is the organization structure with which the fact is associated. Body systems and functional health patterns are systems of data organization that help busy clinicians retrieve relevant bits of information as needed.

In actuality, although the information processing model is a useful starting point, the human brain functions differently from a computer. The brain is able to sense patterns of data and to include emotional responses to experiences with human beings. The ability to empathize with a patient, to be available personally, and to be invested with the patient in maximizing health make the human decision-maker much more valuable than any computer or protocol system could ever be. If protocols were enough for effective management, the Internet or other computer system would be sufficient to provide health care to anyone with access to the system. Patients come to a health-care provider for more than a diagnosis, however. They come for a human connection. The human aspect of the nurse–patient relationship adds to, rather than detracts from, diagnostic accuracy. One researcher called this "getting alongside" (Elliott, 2010, p. 2,714) when describing ways the nurse practitioners

listen to the patient's perspective on his or her problem. Technology can assist clinicians by prompting routines and in offering diagnostic and therapeutic options that might have been missed (Lee et al, 2009). The technology system, however, does not substitute for human judgment and should not become a barrier to provider–patient communication.

Critical Thinking

Diagnostic reasoning can be seen as a kind of critical thinking. *Critical thinking* has been defined as reflective thinking because the process involves questioning one's thinking to determine if all possible avenues have been explored and if the conclusions that are being drawn are based on evidence. This kind of thinking supports clinical judgment in several ways. First, it becomes a habit of mind to have humility about one's thought processes and to know that even the most experienced thinker can be mistaken. Second, it becomes a systematic way of generating creative ways of thinking about problems. Third, critical thinking returns one to an examination of the strength of evidence for a given conclusion. "Evidence" in this context means more than "hard" data such as laboratory values. Even laboratory values must be examined critically when they are used to assist diagnostic reasoning. The type of evidence that is useful includes subjective impressions of the ways patients present themselves. The patient's initial complaint may be fatigue, but any patient who describes a bone-chilling inability to generate energy for daily living (compared with a fulfilled fatigue that comes after a challenging situation is completed) is providing data the APRN can use to investigate potentially serious health problems.

Critical thinking can include creative thinking—in this sense, the APRN is creative in developing potential problem lists. A patient may complain of abdominal pain. The pattern is unclear or may indicate irritable bowel syndrome. The creative APRN will explore stress management issues as a way of generating diagnostic and therapeutic choices that could include a diet and symptom log, increased fiber in the diet, a walking program, or a quick follow-up visit to check on symptoms. Creativity may also be required in developing goals with patients for their short- or long-term problems. In addition to creative processing, critical thinking includes systematic thinking that evaluates each new piece of data as it either supports some diagnostic hypotheses or reduces the likelihood of others.

Intuition

Another kind of thinking that develops with experience is that of intuition. Research on intuition shows that it develops after long experience in the particular setting and that it is based on unconscious thought that is probably an exquisite pattern matching. The experienced clinician is reminded of a situation that occurred in the past when presented with a certain new situation. Past experience provides a picture of what will likely happen. The experienced clinician often could not list the specific data points that led to the conclusion. In fact, in some studies of computerized "artificial intelligence," experienced clinicians were asked to "think aloud" as a research device aimed at identifying the steps involved in reaching a diagnosis. Experienced clinicians reported that being asked to do that kind of thinking changed their thought process and slowed them down. Although intuition characterizes expert practice, it is not a goal in itself. Being able to reflect on one's thinking processes opens the process to analysis, sharing, and improvement (Thompson & Yang, 2009).

Developing Expertise

Benner et al (1996) have done extensive work describing differences in clinical judgment based on experience. APRN students, even those who are experts in hospital or specialty care, find it disconcerting to enter a world where they feel like novices again. Even skills that were a part of their old practice feel awkward. Their minds often do not generate ideas smoothly, and they focus on their own performance of skills more than on the patient's situation. With the experience of the clinical practicum, however, the student gains skill and by graduation is probably functioning at the advanced beginner level. Features of diagnostic reasoning used in the various stages of expertise are summarized in Table 4.1.

Table 4.1 Skill Acquisition in Advanced Practice Nursing Practice

Skill Level	Features of Clinical Judgment
Novice	Rule-based actions, unaware of context
Advanced beginner	Sensitive to aspects of the situation, able to formulate principles, needs help setting priorities
Competent	Goal-directed actions, feeling of mastery based on experience, deliberate planning
Proficient	Sees situation as a whole, immediate grasp of meaning, recognizes patterns of normalcy or aberrance, uses maxims to guide action
Expert	Transcends rules, intuitive grasp of the wholeness of situation, creative response to particularities of situation, flexible response to situations

DIAGNOSTIC PROCESS OVERVIEW

Diagnostic reasoning is a process of data generation and clustering, hypothesis generation, probabilistic reasoning, pattern matching, planning, problem-solving, and critical reflection. These processes are commonly summarized by describing the steps in the nursing process or the clinical reasoning process. Research has shown that many clinicians, physicians, nurses, occupational and physical therapists, dentists, and others use a similar method. Although research that uses simulated case studies to examine methods of clinician reasoning tends to oversimplify what happens in real life, it is helpful to review a simplified description of the diagnostic process as outlined here.

Data Collection

Research has shown that expert clinicians generate a list of possible diagnoses or diagnostic hypotheses early in the clinical encounter. Further, the likelihood that the diagnostic choice will be correct is higher if the correct diagnosis is included in the initial hypothesis list. In generating hypotheses, the APRN considers a number of labels that could be associated with the initial complaint and considers potential problems for each patient based on the patient's age and demographics and the setting of the practice.

For experienced clinicians, data acquisition in history taking and physical examination is most effective if it is hypothesis driven—that is, when the information selected and gathered is related to the list of possible diagnoses. For common problems, the data collection approach becomes routine and, therefore, takes less active processing space in short-term memory. In contrast, novices tend to use a "shotgun" approach and ask a little bit about everything that might be possible, not considering which diagnoses are most likely. Hypothesis-driven data collection means that data that would confirm or disprove a specific hypothesis is specifically sought and recorded. It is not enough to note only those data that fit with one possible problem. Competing hypotheses must be ruled out by seeking nonconfirmatory data. In doing this, the clinician must be open to changing the priority list of hypotheses based on new information. For example, rhinitis may present similar to a viral infection, but if, when asked whether the symptoms have occurred before, the patient says, "Yes, I had the same thing two weeks ago," this decreases the likelihood of viral illness and increases the likelihood of allergy.

An approach to data collection that is completely symptom driven, however, can result in leaving out important concepts. The agenda for the visit includes not only the patient's agenda but also expands the visit to provide health promotion.

Hypothesis Evaluation

Data are clustered together into meaningful "chunks" of information that explain and account for the different elements of the history. Clinicians are alert to any data bits that do not fit the pattern of what is expected. They are alert to the feeling in themselves that "something is just not right here." This can indicate that the problem is more serious than initially appeared or that there are data bits that are not yet accounted for. Diagnosticians are persistent in trying to fit the pieces of data into a coherent picture. One must be on guard not to ignore discrepant data. Research has shown that "we see what we expect to see" in many cases, so an openness to the patient situation must be maintained in order to continue "seeing" all the data present.

A maxim of practice is that "common things occur commonly." Students are frequently excited to make a diagnosis for the rare or exotic condition. This can be the result of a rich experience in acute- or critical-care settings where the most serious cases were seen. In primary care, common problems predominate. The maxim that "when you hear hoof beats, think horses, not zebras" applies. In real life, "zebra" diagnoses are rare. Rare conditions can be considered with the differential list, but their lower probability must be taken into consideration.

Experienced clinicians keep their antennae raised for the most serious conditions. Abdominal pain could be from gas, but if it is from a ruptured ectopic pregnancy, a dissecting abdominal aortic aneurysm, or a ruptured appendix, immediate surgical consultation is necessary. The clinician must make it a point to collect and document data that rule out any potentially life-threatening condition.

Diagnoses are frequently interrelated. Obesity, hypertension, hyperlipidemia, and type 2 diabetes mellitus frequently occur together. When evaluating competing hypotheses, the APRN can cluster related problems together. The lifestyle recommendations for all these conditions are the same. The medication approach might differ. For nursing diagnoses, many occur together. Try to approach the core diagnosis, which, if managed appropriately, will ameliorate all the others. For instance, ineffective coping with stress can result in an array of symptoms including altered sleep patterns, constipation, difficulty concentrating, and interpersonal tension. By dealing with the underlying problem, the other problems might not need direct intervention. If the APRN focuses only on the superficial problem level, the problems may still remain. Table 4.2 summarizes habits that promote effective clinical judgment. Table 4.3 describes common errors in diagnostic thinking that are made even by experts.

Clustering history data into a likely problem list helps to focus the physical examination, laboratory test evaluation, and initial management plan. Physical examination for a problem-focused visit serves to rule in or rule out competing diagnostic hypotheses. A new hypothesis rarely emerges during a physical examination, but this might occur for a problem that the patient cannot see or that causes no symptoms, such as a skin lesion. Laboratory

Table 4.2 Habits That Support Clinical Judgment

Phase of Diagnostic Reasoning	Habits That Support Clinical Judgment
Data acquisition	Use systematic or hierarchically organized approach (general to specific). Review multiple systems.
Hypothesis formulation	Generate hypotheses early in encounter. Develop competing hypotheses. Consider life- or function-threatening problems. Consider "zebras" but recognize them as such.
Hypothesis evaluation	Recognize interrelation of diagnoses. Consider probabilities in context. Consider likelihood of altering course of problem with treatment. Rule out life- or function-threatening problems.
Problem naming	Choose most fundamental problem. Include multiple perspectives (biopsychosocial, spiritual; medical, nursing). Include illness prevention and health promotion.
Goal setting	Include patient in goal setting. Make goals explicit and realistic.
Therapeutic option consideration	Include modalities from multiple paradigms. Consider patient preferences. Consider context and cost in economic and human terms.
Evaluation	Plan for follow-up visit or phone call. Consider symptom or treatment logs or diaries. Measure and document the outcome of your practice for the individual. Report the effectiveness of your practice in the aggregate.

tests also provide information that is not available any other way.

Finally, a working diagnosis is reached, even though there might still be some uncertainty. A management plan is discussed with the patient in light of mutually shared goals and guidelines for practice based on published research. Honest conversation about the patient's ability and willingness to follow treatment recommendations will result in more realistic plans. Written instructions often help patients implement complicated treatment directions. Part of the treatment plan always includes a plan for follow-up. Patients need to know when to return for a visit and under what circumstances they should telephone. Documenting these plans in the patient record reduces the possibility of misunderstanding and places appropriate responsibility with the patient. Some patients need support in learning how to engage the health-care system in an

effective way. This is one aspect of health literacy that the APRN can support.

The Diagnostic Process in Action

A simple encounter for a self-limiting acute illness might proceed like this:

A patient requests an appointment for a "sore throat." The patient is known by the APRN as a resourceful, independent young adult. Before even entering the room, the clinician draws from experience with other patients who have complained of sore throat and begins to generate a list of hypotheses. Contextual factors enter into the reasoning: It may be allergy season in that particular area, or the clinician may have seen a large number of other patients with similar complaints who have tested positive for *Streptococcus* infection. The clinician enters the room and notes the general appearance of the patient. Is the patient ill appearing, flushed, fatigued, or mildly irritated? These observations may serve to adjust the hypothesis list. The patient's story is elicited, beginning with history of present illness, along with a review of data already present in the record regarding past medical history and medications. Further questions regarding current life stresses and exposures may also serve to adjust the hypothesis list. The history narrows the hypothesis list to a short one, although experienced clinicians have ways of preventing the common diagnostic error of premature closure and work to consider alternative conditions that could also be represented by the same cluster of symptoms.

The physical exam serves to verify hypotheses and to screen out unlikely, though troubling, alternative diagnoses. The hypothesis list is narrowed further as data are weighed to see whether they fit the pattern of the highest-favored hypothesis; disconfirming data are also elicited to avoid leaping to conclusions too early. Finally, diagnostic tests may be chosen to firm up the diagnosis if the findings of the tests will have a bearing on how the patient's care is to be managed. Once findings of relevant tests have been obtained, treatment decisions are considered, including patient factors such as resources, reliability, and the risk of the patient not following through on instructions. For example, insufficiently treated strep throat could result in rheumatic heart disease. Besides prescribing medication, consider comfort measures that are likely to assist the patient and judge the appropriateness of health promotion and educational opportunities at the moment. For example, is this a good time to give the patient smoking cessation materials? Finally, a plan to evaluate the treatment plan is made. Is a follow-up appointment necessary? Would a telephone call be useful? For which date should the next "well" visit be scheduled? The list of decisions made in this rather simple example is long. Given a few data or situational changes, the management of the patient's care could be quite different, and a new-patient visit requires even deeper background data collection. Patients who present with more complex, long-term problems require even more complex decision making by the clinician. In observing the experienced clinician, many of these mental processes may not be apparent. Many of these processes occur as a kind of internal dialogue, but they occur nonetheless.

FOCUS ON ELEMENTS OF CLINICAL JUDGMENT

A more detailed examination of each step in the diagnostic reasoning process follows.

Focus on Data Collection: History

History of Present Illness

Taking a history is the first step in the diagnostic reasoning process. Problems cannot be found, strengths identified, or appropriate direction known without a real grounding in the life experience of the individual patient. If the patient's visit is for "episodic" care or one in which a new complaint is being addressed, the history begins with a history of present illness (HPI). There are a number of mnemonics that can help the clinician remember the essential data elements. The elements of the "OLD CART" mnemonic are listed in Box 4.1.

Immediately on hearing the chief complaint, the clinician begins to sort out diagnostic possibilities. The list

Box 4.1 OLD CART Mnemonic

Onset	When did this problem start? How did it start? Has it changed over time?	**D**uration	Are the symptoms constant, fluctuating, getting better or worse?
		Characteristics	How are the symptoms experienced? Dull ache, sharp pain, heat, or electrical?
	For an injury, exactly how did the injury occur (the mechanism of injury)?	**A**ggravating factors	What makes the symptoms worse?
Location	Where exactly are the symptoms experienced? Can a specific location be identified, or is the problem more generalized? Has the symptom moved?	**R**elieving factors	What makes the symptoms better?
		Treatment	What have you done so far to try to help the problem?

of possibilities helps to generate questions to follow up on the HPI and in other areas of the history. Specific questions are asked that help distinguish between competing diagnostic hypotheses. For example, the question, "Do you feel the pain more often on an empty stomach or several hours after eating?" helps distinguish between ulcer and gallbladder disease. In general, asking open-ended questions helps the patient give his or her perspective and provides a richer database. An open-ended question is one that cannot be answered by a "Yes" or "No" response. Eliciting the patient's story will assist the APRN in understanding the illness experience from the patient's point of view. Frequently interrupting the patient's story distracts and places the story in the context of the examiner and not in the context of the patient's own life.

The APRN continues to clarify the patient's story until a clear picture of the illness appears. This can require patience because patients do not know which facts "fit together" to support diagnostic hypotheses. Patients may get the chronological order confused or not recall the exact onset of their problems. They may also have more than one problem and may not be able to distinguish which symptoms cluster together. At times, the picture is not completely clear at this point of history taking, but other areas of history can fill in some gaps. Periodically, the APRN can restate the emerging understanding of the story to clarify and summarize it. This summary allows the patient to clarify any misunderstandings. One important issue to address as part of the HPI is what the *patient* thinks may be wrong. Patients know their own bodies, and parents know their own children better than anyone and may have important insights to share. On the other hand, when patients share their fears, the APRN can also explain reasons why many of those fears may be unfounded. A recurring headache does not necessarily indicate a brain tumor.

Visits for periodic health screening, to establish a new patient–provider relationship, or to follow up on an existing problem do not use the HPI in the same sense unless a new problem is also identified. The APRN can ask, "What do you want to accomplish today?" or "What is the most important issue for us to deal with today?" This is particularly useful for the patient with a long list of problems or complaints. Be sure to make a plan for follow-up on other problems. Other elements of patient history are discussed in detail during the visit.

Past Medical History

Past medical history helps to refine the hypothesis list by offering new explanations for symptoms or by ruling out others. The history also gives suggestions of risk factors for other problems that are being considered. If a patient reports that his or her gallbladder was removed 10 years ago, cholecystitis is now off the hypothesis list, but abdominal adhesions might go onto the list. Past medical history is frequently divided into childhood and other illnesses, surgical history, other hospital admissions, history of trauma, pregnancies, and psychiatric diagnoses. Travel outside the United States and any possible exposure to infectious or toxic agents can be explored. Treatment for cancer in the distant past is important in that the treatments may have increased the risk of other conditions. For example, some chemotherapy agents can lead to heart failure in later years.

The history includes information regarding all medications that patients take, including prescription and over-the-counter medications, as well as vitamins and herbal remedies. Patients also need to be asked if they take any medications that have been prescribed for other members of the family. Even for patients who are well known to the practice and whose medications are listed on the chart, asking the patient what medications he or she is currently taking allows the clinician to learn what the patient remembers about the medication regimen. For patients with multiple prescriptions, it sometimes helps to use the "brown bag" method: Ask the patient to bring in all the medications he or she is taking, then go over them one by one. This helps to determine if the medications that have been ordered are really being taken. This review of medications also gives the clinician information about the patient's understanding of his or her medications and helps to determine any difficulties he or she is having with the prescribed regimen. Immunization status is part of the history. Many parents bring their child's immunization cards with them to office visits. This allows any additional immunization series to be documented. Adults often forget that they need immunizations for things such as tetanus or pneumonia.

Allergies can be discussed at this time and reviewed. The kind of reaction the medications or food caused can help to distinguish an adverse effect from a true allergy. By noting the adverse effect, one can avoid confusing it with an allergy, which is characterized by rash, hives, wheezing, or other hypersensitivity reactions.

Health maintenance practices can be questioned, as well as risk reduction techniques such as seat belt use and exercise habits.

Family History

Family history provides information for a part of the risk factor pattern for this patient. The most efficient way to represent the family history is to draw a genogram (Fig. 4.2). This method of representation can be used to record family patterns of births, ages at death, and causes of death. The genogram can also record family members with whom the patient currently lives. Try to include information for at least two generations back, as well as for any children and their health status. The genogram can be used to map difficulties such as alcoholism or the quality of relationships in the family by drawing slashes across the relationship lines that are troubled or by using thick lines to represent relationships that are strongly supportive. Judgment is required

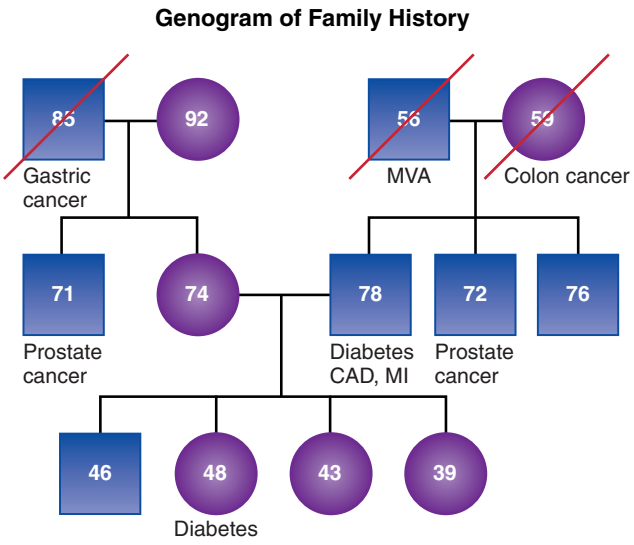

Figure 4.2 Genogram of family history. *(Source: Chase, SK. Clinical judgment and communication in nurse practitioner practice. FA Davis, Philadelphia, 2004.)*

to determine if this level of information is useful. If there is no room in the patient's record for a genogram, list the major diseases that have familiar patterns, such as diabetes, heart disease, arthritis, psychiatric problems, alcoholism, and cancer.

Social History

Social history in a medical model interview includes such things as work patterns. Even if the patient is retired, the type of work in which the patient had engaged is important because worksite exposures can be risk factors for many potential problems. Work background also gives the clinician a sense of how the person might handle new information and what kind of resources he or she might have at his or her disposal. Medical model histories also include the use of alcohol, tobacco, and illegal drugs. Nursing histories are more expanded in this area. Include such information as leisure time activities, risk factors and exposures, and the patient's resources and activity level. If a full functional health pattern is collected, much of this information can be recorded there. If the documentation system in use in a particular setting does not accommodate functional health patterns, expand the social history section to reflect nursing issues.

Review of Systems

This section of the history is often completed by the patient immediately before the physical exam. It is organized by body systems. Advanced Assessment 4.1 presents sample questions that can be used during the review of systems. Whenever the review is completed, it can include problems and symptoms that are current or related to past medical history and prompt the patient to report any past difficulties. This also helps remind patients of conditions they may have forgotten and can help to refine the hypothesis list further or to screen out potential new problems. When introducing a body system, start questions in general terms and then proceed to more specific items. When documenting this section, students frequently forget that these data are appropriately recorded as subjective data because they are reported from the patient's point of view.

Functional Health Patterns

Functional health patterns, developed by Marjory Gordon, serve as a database for determining nursing diagnoses. APRNs engage in some activities that require making medical diagnoses, but their practice base is always nursing. The value that APRNs bring to a practice is an enhanced ability to assist patients with lifestyle changes and an ability to support patients as they cope with illness. The openness and thoroughness that patients report when cared for by an APRN are dependent on the APRN practicing from a database that is broader and more personal than that of the traditional medical model. Even in practice settings using a medically dominated model, the nurse has an obligation to represent nursing's contribution to care. The type of data recorded in the functional health pattern in the medical record can reflect a nursing approach.

For episodic visits, some patterns are more important than others, and the list can be prioritized accordingly. For example, for a patient with a sore throat, important data are nutrition (Is he or she able to eat and drink sufficiently?), sleep and rest (Is sleep interrupted?), activity and exercise (Does he or she feel fatigued?), and role relationship (Is he or she able to work? Are there children in the home?). Inability of the patient to carry out any normal, day-to-day function is often a "red flag"—an indicator for the APRN of a potentially serious disease process that may be developing.

The purpose of the functional health pattern is to determine the extent to which illness is affecting the person's ability to live his or her "normal" life. What accommodations must be made, even for a self-limiting condition? This is nursing's central question. What is the human response to the health problem? Advanced Assessment 4.2 presents the 11 functional health patterns and sample questions that can be used to elicit data for each functional pattern area.

At this phase of history taking, the hypothesis list is taking shape. The initial diagnostic possibilities generated are weighed as each new piece of information is gathered. Some data serve to support one hypothesis in favor of another; some data are noncontributory. Some data serve to rule out specific hypotheses. The problem list may contain physical disorders with signs or symptoms that are visible, along with other physical disorders that are presumed to be present based on the patient's story, emotional distress related to specific disorders, general emotional disorders, family or social disorders, or even spiritual distress. The patient's problem list may

Advanced Assessment 4.1 Review of Systems and Sample Questions

System	Sample Questions	System	Sample Questions
General	How is your general health? Are you sleeping restfully? Is your appetite good? Have you had any recent weight changes? Any fever, chills, or night sweats?	Chest	Any chest pain, cough, difficulty breathing, shortness of breath? How far can you walk before becoming breathless?
Skin	Any rashes, moles, itching, changes in color, easy bruising, changes in hair?	Cardiovascular	Any chest pain, palpitations?
Head	Any headache, dizziness, fainting, history of head trauma?	Gastrointestinal	Any stomach pains, indigestion, nausea, or vomiting? Any blood in your stool? Have your bowel movements changed? Any diarrhea or constipation? Any rectal itching, pain? When, if ever, was your last colonoscopy?
Neurological	Any weakness or paralysis? Any feeling of needles and pins or other loss of sensation? Any trouble walking, any seizures? Any trouble with memory or speech? Any nervousness or depression?	Endocrine	Any intolerance of heat or cold? Frequently thirsty? Do you have problems with frequent urination or getting up to urinate at night? Do you experience unusual fatigue? Have you noticed any unusual hair loss?
Eyes, ears, nose	Any eye problems, blurring, loss of vision? Any trouble hearing, ringing in ears, pain, throat discharge or itching? Any problem with runny nose, change in ability to smell, nosebleeds, or sinus trouble? Frequent sore throats, trouble swallowing, hoarseness?	Urinary	Any trouble passing urine, burning, itching, odor, frequency, loss of control or pain?
Mouth	Any mouth sores, dental problems?	Female genitalia	Any vaginal discharge, itching, or odor? When was your last menstrual period? What is the length of your cycle, the length and amount of flow? Do you engage in sexual relations with men, women, or both? What method of contraception is used? Might you be pregnant now? How many children do you have? How many times have you been pregnant? Are you having any symptoms related to menopause? Do you take any form of hormone replacement? Is your sex life satisfying?
Neck	Any pain, swelling, or stiffness in the neck?	Male genitalia	Any urethral problems such as discharge, burning? Do you do testicular self-exam? Do you engage in sexual relations with men, women, or both? What method of contraception is used? Is your sex life satisfying?
Lymph nodes	Any swelling or painful lymph nodes in armpits, groin, neck?		
Breasts	Any lumps, pain, or discharge? Do you check your breasts regularly? When, if ever, was your last mammogram?	Extremities	Any leg pain or cramping, joint pain, or stiffness? Do your feet get cold easily? Do you have vein problems? Any back pain? Have you ever had a broken bone? A bone density scan?

Advanced Assessment 4.2 Functional Health Patterns: Questions to Elicit Data

Pattern	Sample Questions	Pattern	Sample Questions
Health perception	Do you have a regular health-care provider?	Cognitive/perceptual concept	Any hearing or vision problems? Any memory changes? How do you like to learn new things? Any pain or discomfort?
Health management	How often do you go to your health-care provider? What do you do to stay healthy?	Self-perception/ self-concept	How would you describe yourself? Do you feel good about yourself? Any changes in how you feel about your body? Do you get angry or down at times?
Nutrition/metabolic	What did you eat yesterday or on a typical day? What do you drink? How is your appetite? Any skin problems?	Role relationship self-perception/ self-concept	Who lives with you? Do you have friends? What kind of work do you do? Do you have other responsibilities?
Elimination	What are your bowel and bladder elimination patterns? Do you have unexpected loss of control?	Sexuality/ reproductive Role relationship	Any problems with your sexuality? Any changes? If sexually active, do you practice safe sex? Do you use birth control? What mode of birth control do you use?
Activity/exercise	How far can you walk before feeling tired? Do you have energy to do the things you want? Do you need any assistance with feeding, bathing, toileting, dressing, getting around (activities of daily living)? Do you need any help with cooking, shopping, or cleaning (instrumental activities of daily living)?	Coping/stress tolerance	How do you cope with stress? Any use of alcohol, drugs? Do you have someone to talk things over with?
Sleep/rest	How many hours do you sleep? Any trouble falling asleep or with early waking? Do you feel rested?	Value/belief	What is most important to you in your life? Are you religious? Any values about life that health-care providers should know? Do you have a health-care proxy (medical power of attorney) or living will (advance directive)?

contain more than one diagnosis from any of the biological, psychosocial, or spiritual realms. It may also include health risks. Further data are available to help refine the hypothesis list by performing the physical examination and ordering diagnostic tests.

Focus on Data Collection: Physical Exam

The physical exam serves to clarify diagnostic hypotheses and to detect unanticipated problems of which the patient is unaware. In primary care, there is a wide range of ways of performing the physical exam. Textbooks of physical assessment outline a general head-to-toe model that is useful for an initial visit with a full physical exam or a periodic reassessment. In most practices, an initial patient visit is scheduled for more time, and in coding schemes the visit may be reimbursed at a higher level because of its comprehensiveness. Students in nursing or medical school learn to perform the head-to-toe exam in an organized way. In actual practice, however, clinicians must learn to focus their physical assessment skills and make the physical exam appropriate to the patient's complaint and history. If the patient complains

of headache, a review of head, eyes, ears, nose, and throat and a neurological examination are indicated, as well as a skin survey. For joint pain, a review of musculoskeletal tenderness, range of motion, and strength might be indicated. The body systems that are examined depend on the working hypothesis list that the clinician has generated. Examination skills need to be organized at a general screening level, with subroutines of examination techniques that can be adapted to specific findings and complaints. Positive or negative findings that serve to refine the hypothesis list must be noted and recorded in the documentation system that is in use. At times, a condition is in evolution, and the symptoms may not be clear when the patient comes for a visit. Nonetheless, the rich data reporting from that visit—even though the diagnosis is not clear—can serve to make the diagnosis more accurate later, when the condition evolves further. Full documentation serves to protect both patient and provider. The physical examination can also be a time to provide feedback and teaching about findings and about self-care. There is some evidence that thorough physical exams are becoming more rare in medicine. An overreliance on blood, radiological, and other tests to confirm diagnoses increases costs of care and reduces contact with the patient (Sanders, 2009). The ritual of the physical exam is evidence of person-to-person attention and may be perceived as the kind of professional caring expected in a health-care visit.

Ordering Diagnostic Tests

Diagnostic tests can be used to confirm or to rule out diagnostic hypotheses or as screening devices for conditions with subtle presentations that need to be picked up early, such as lead poisoning in children. Diagnostic tests vary in their usefulness based on their sensitivity, specificity, and predictive value. When considering or evaluating a test, consider that there are patient, test, and disease factors that affect the interpretation of the tests. The prevalence of a condition is the number of cases present in a given population at a particular point in time. The incidence of a condition reflects the total number of cases during a specified time period. For example, the number of cases of flu in a year (incidence) is greater than the number of people who have the flu on a given day (prevalence). Both incidence and prevalence rates are important considerations in making accurate diagnoses. Laboratory tests and radiographic or other imaging can assist in screening for conditions and in making diagnoses. For chronic conditions, tests are used to monitor progress in managing the condition.

No test is perfect. In a given population, a positive test result is found for some people who have the condition and for some who do not. When a patient who does not have the condition has a positive reading on a test, it is called a "false positive." On the other hand, a negative test is found with people who do not have the condition and some who do. A negative test result that occurs when the patient does have the condition is referred to as a "false negative." The sensitivity of a test is greater when it has few false negatives. Sensitivity equals the number of true positives for a test divided by the number of tested individuals who truly have the disease. The specificity of a test is greater when it has few false positives. The specificity of a test equals the number of true negatives divided by the number of all tested individuals who do not have the disease. Table 4.4 represents the relationship between test results and actual conditions.

In clinical practice, the predictive value of a test is the important consideration. Given a positive test result, what is the likelihood that the patient actually has the condition? Positive predictive value equals true positives divided by all positives. Negative predictive value equals true negatives divided by all negatives. Predictive value is in part dependent on the prevalence of the condition. If a condition is highly likely, a positive test result is more likely to be accurate. If a condition is very unlikely, a positive test result needs to be questioned, perhaps with different tests.

When deciding whether to order a test, cost, convenience, sensitivity and specificity, and risk of missing a condition are considered. One can ask whether the test result would affect the potential treatment plan. If not, the test might not be necessary. It is not appropriate to order a test merely to increase the clinician's confidence and comfort. Appropriate screening for life-threatening or life-altering conditions must be considered. Clinicians can use the Clinical Preventive Services Guidelines or other research-based guidelines for deciding on screening tests for specific patients. Always consider the individual patient's situation. For example, the age for first mammogram has changed over the years based on research data and is dependent, in part, on a strong family history or other risk factors for breast cancer.

Table 4.4 Tests: Characteristics and Diseases

Test Reading	Disease Present	Disease Absent	Total
Positive	True positive (TP) A	False positive (FP) B	All positives A + B
Negative	False negative (FN) C	True negative (TN) D	All negatives C + D
Totals	All diseased A + C	All healthy B + D	Grand Total

Differential Diagnosis

A differential diagnosis list is the list of possible diagnoses, usually in priority order. When clinicians discuss a case, the list of differential diagnoses is usually considered. Supports for developing a rich differential diagnosis list include several guides. One approach suggests considering the problem from the "skin in." This means that if the patient complains of chest pain, the clinician can consider all the possible causes of chest pain, beginning at the skin, and visualize all the structures in the area that could possibly be affected. For example, chest pain at skin level could indicate early herpes zoster sensitivity and pain. Below the skin, the musculoskeletal system (including the rib cage) could be causing pain, from costochondritis or from muscle strain. The clinician can consider pain below the rib cage as a source of pain. Could the patient have pneumonia, pneumothorax, or pulmonary embolus? Next is the esophagus. Could the pain be from esophagitis, gastroesophageal reflux, or hiatal hernia? Next consider the pericardium as a possible source of pain, as with pericarditis. Finally, consider cardiac pain. This "skin in" approach keeps the student from jumping to early conclusions without considering a wide range of problems. It thus avoids the common diagnostic error of premature closure.

An evolving problem list can become quite long, even on an initial visit. The Patient's Voice 4.1 describes one approach to differential diagnosis. The Patient's Voice 4.2 illustrates how the diagnosis often involves more than medical problems.

The Patient's Voice 4.1

An Advanced Practice Nurse's Approach to Differential Diagnosis

An APRN describes her approach to a new patient.

My initial diagnosis at that time, just by speaking with him, without any labs and examining him physically, was this: His diabetes was in poor control. His hypertension was in poor control. He had some rhinitis, probably allergic, but he was not having a problem. He has known unequal pupils since he had surgery and had damage to the pupillary musculature, but it does not affect his vision; if you did not happen to know that, you might be very concerned about it, you know? It is real important to put that in the problem list. He had a TUR [transurethral resection] for BPH [benign prostatic hyperplasia]. He had a real bad pars plana with secondary hip pain, and he kept going to people with back pain, and nobody ever stood him up and looked at his feet. He also had seborrheic dermatitis. The guy is an Irishman with pale skin and washed-out blue eyes, and he never used sunscreen. He had lots of skin cancers. The doctor kept calling him back to cut out the skin cancers but never told him to use sunscreen.

For this patient, the APRN goes on to describe her approach to ordering diagnostic tests. Note that the hypotheses precede the test consideration. She describes her initial treatment plan:

OK, first thing you need is your laboratory parameters to check the problems that you have just defined. I would do blood counts, chemistries, thyroid function, glycohemoglobin, urines, PSA [prostate-specific antigen]. The first time I see a patient, I always do the whole gamut. This guy also had had a bilateral total hip replacement, so I reviewed the subacute bacterial endocarditis prophylaxis because he had never been told about it. I started him on Prinivil, an ACE [angiotensin-converting enzyme] inhibitor because he has diabetes and had previously been on Hytrin, but it was not doing the trick, and it was not protecting his kidneys. I started him on Glucotrol. He had not been on anything other than Micronase, which he quit using because he really did not know how to use the stuff. I also talked to him about his seborrhea and sunscreen.

The APRN sees the wholeness of the patient's situation. This is a different approach than treating discrete problems as they come up. The APRN's description of her approach to this patient continues:

He had had previous health care, and he thought he was doing fine. He just had never had it all put together. As far as he was concerned, he happened to have some elevated blood pressure and some elevated blood glucose, but nobody had ever put it all together in terms of the effects on the whole body. He went to someone for his glucose, and he went to somebody for his blood pressure. The guy was not a train wreck, but he had a number of problems that had been overlooked until he saw me and somebody (me) made a list. For example, he had not had a recent eye exam. For any patients with diabetes, I make sure they get an eye exam every single year. And that is how I started. His wife is also a patient of mine—a great cook, which is a tragedy for a diabetic—and he, like most husbands, will eat what he is given. So she needed some education as to what is the proper thing to eat and when and how they could cheat.

The APRN is able to pull all of this patient's concerns and problems together in a way that honors his wholeness and his family dynamics. Her concern is for preventing future problems that are likely to develop, given his pattern of risk factors. Her method of collecting data and clustering it together to form a comprehensive picture of his life results in an effective, personal plan.

The differential diagnosis list should always include any conditions that are life-, organ-, or function-threatening. An APRN describing a different patient situation stated:

I always think in terms of the most dangerous or the most serious thing first—not necessarily the most catastrophic, but the most serious problem. If I know somebody has an AAA [abdominal aortic aneurysm] and he comes in with abdominal pain and it's sensitive, well, he probably has diverticulitis, but if I blow the diagnosis and go that way and it turns out that his aneurysm is dissecting, then

he is dead. So I will treat his diverticulitis, but I will get the abdominal ultrasound right away. I consider the most urgent, deadly thing first. Cancer can be deadly, but it usually is not an emergency. It will kill you, but it is not going to kill you tomorrow. But an AAA can blow at any time. I had someone with an aneurysm blow in here once while I had the surgeon and the OR team waiting for him in the ER. We knew we had an aneurysm that was about to blow because I put my hand on his belly and it was throbbing and the patient was hypotensive and he was sweating. He had come in to the hospital because he was ready to go on vacation and just wanted to check this out before he left. So, you think of the most life-threatening situation first.

The Patient's Voice 4.2

An Advanced Practice Nurse's View of Nursing Versus Medical Problems

One pediatric APRN described her interaction with an immigrant father who brought in a 3-year-old girl with a runny nose. The father was not disciplining the child, even though she was being difficult, because he had been reported to Human Services for hitting this child previously and for hitting a well baby 8 months of age.

I see myself making a dual diagnosis—a nursing diagnosis as well as a medical diagnosis. If the father does not discipline his child at the appropriate time in an appropriate way, that is a knowledge deficit. So I made a nursing decision there, and I intervened on the basis of that nursing decision, but I also made a medical decision, in that the child had an upper respiratory infection and I prescribed what I thought to be the appropriate medication for that. So, I see myself making nursing diagnoses as well as medical diagnoses and trying to somehow mesh these two to care for the family holistically because there is no way you can care for a child without caring for the family. That is my belief.

When asked if her full response was documented in the treatment plan, she responded:

Yeah, well, it sure does not fall under "upper respiratory infection." In this case, I did not know when the family was going to apply for insurance, so I certainly did not want to put "behavior disorder" down. Instead, I put down under my diagnosis, "knowledge deficit, re: discipline." In my treatment plan, I noted that I discussed discipline and that I gave the father 'time out' guidelines and how to reward good behavior. I also noted that the father is coming back to me in 2 weeks to report differences in his approach to discipline and how it worked out. Nobody ever leaves my office without knowing when he or she needs to come back, and I document when I tell them to come back in my treatment plan.

Developing a Management Plan

Once the problem list has been clarified, clinical judgment about how best to manage those problems is addressed. Although APRNs bill for services in the medical realm, they also operate in the nursing domain. One expectation for APRN students is learning to "present the patient" to their preceptor in the clinical area. This skill involves taking all the data collected in history and physical assessment, organizing the content, and presenting the major findings in a coherent way to the preceptor so that the preceptor can review with the student what the treatment options are so that when the preceptor sees the patient he or she can verify and clarify the data collection and move to treatment planning. Initially, students may need to use a template to ensure that they are organized as they begin this process. With experience, the organization of patient data will become more obvious. This same skill of organizing patient data is useful when communicating with consulting providers. They need a clear summary of the case for efficient consultation.

Selection of interventions for APRNs is broader than a consideration of prescription medications. The discussion in Chapter 1 of Engebretson's (1997) contribution is useful to consider here. In addition, Eisenhauer (1994) has argued that different levels of nursing interventions are useful when dealing with patient problems. At the most basic level, interventions deal with symptom relief, such as ice for acute muscle pain followed by heat application for strained muscles or a prescription for pain medication. At a higher level of complexity, interventions address functional patterns, such as stress and coping. The provider could schedule a follow-up visit to determine if a stressful condition is being managed more successfully after a brief teaching or counseling session. At yet another level, an intervention could be concerned with life patterns, such as recommending a course of rehabilitation to help a patient to regain confidence in exercising after a cardiac event. Finally, at the highest level, interventions such as spiritual support could be chosen to help patients and their families cope with life processes such as a terminal condition. This typology of intervention is useful to consider when selecting an approach to a problem. If, for example, a patient has been unable to lose weight using simple diet instruction, a higher-order intervention such as counseling may be required to address the source of the problem at a deeper level.

Evidence-Based Practice

There is an emphasis in health care today to promote evidence-based practice (EBP). In a just society, patients have equal access to the most up-to-date treatment approaches and are also able to make informed choices about their treatment. To justify a treatment approach, proponents of EBP argue that there must be evidence, either from clinical trials or from case studies, that the approach is likely to benefit the patient. Obviously, it is easier to demonstrate the benefit of a certain drug that has been tested on a large number of individuals than it is to demonstrate the effectiveness of individual counseling. Be on guard that your own practice is not limited

to medicine based on clinical trials alone. This may require clinical research to demonstrate case studies of creative nursing intervention success. A research study that investigated how clinicians used guidelines in day-to-day practice showed that practitioners seldom referred directly to guidelines when planning care. They did, however, use internalized guidelines and could discuss what they were and how they were formed. Their own and colleagues' experience were also part of forming this knowledge in practice (Gabbay & LeMay, 2004). Guidelines for practice are available from government agencies (http://guidelines.gov) or from specialty/disease-related groups such as the American Heart Association. These guidelines can form the basis for protocol development and for peer evaluation.

Outcome Considerations

In many instances, the patient's and provider's chosen outcomes for an encounter are clear. The simple, acute health problem is to be resolved. The screening measures recommended for the person's age-group are ordered to rule out the presence of nascent disease. When dealing with more chronic problems or problems that provide the patient with what may be reduced quality of life, the APRN must be more sensitive to outcome determination.

Different settings prompt a different set of concerns. The Patient's Voice 4.3 presents an APRN's approach to outcome considerations.

The Patient's Voice 4.3

An Advanced Practice Nurse's Approach to Outcome Considerations

One gerontological APRN described doing an initial evaluation on an elderly client in a residential hospice situation.

Well, I think in terms of triage—comfort is the priority for me. Is there pain? I try to address that issue, and if the patient is anxious, I try to put that on the same level as psychic pain and physical pain. I try to give my patients as much information as they can tolerate—partly what the plan is, and what we are going to do to relieve their pain and try to make their living more comfortable. So then I work from there. What are some of the problems I see in my patients? Skin problems, incontinence, risk for falls, risk for aspiration—all those kinds of things.

One APRN was treating an 85-year-old patient who had suffered a CVA [cerebrovascular accident; stroke]—and was unable to communicate. The patient also had dysphagia, which meant that she needed a feeding tube. The APRN took time to ask a pertinent question: What would this patient want?

[This patient] would occasionally have bedsores, and sometimes she had a urinary tract infection and occasionally a rash from the urination [she was incontinent]. She also had frequent respiratory infections, and it appeared that she had a very poor quality of life. She could not express herself at all, and every few months, her PEG [percutaneous endoscopic gastrostomy] tube would have to be replaced, which happens with most patients. So after we had replaced about the fourth one, I called the family member, and I posed the question to her this way: "Would it be her wish to continue this way?" I did not ask the family member what she wanted. I asked, "What do you think would be ***her*** *wish?" [emphasis added] This was the first time I had ever talked to this woman, and she acted as if no one had ever posed that question to her before. She said, "Well, I want the tube back in." And I said, "Well, I understand that, but what do you think would be her wish?" It was as if she had never thought about that before. And after she thought about the situation from that perspective, it was very easy for her to come to the answer that her relative's wish would be that her tube not be replaced and that she be allowed to die. She recognized that the patient's wish would not be at all to live like that. After she thought about it and talked it over with her family members, they agreed that the tube should not be replaced, and that is what happened. Without the feeding tube, the patient died in peace. She had a peaceful death.*

This APRN asked the question that made everyone consider the meaning of the experience from the patient's point of view. In this case, the outcome of the care was a peaceful death, an outcome that can be prized.

DOCUMENTATION

Preparing concise, comprehensive, and meaningful documentation of one's thoughts and activities as a provider of primary care is a skill that takes time to develop. The purposes of documentation are to record the patient's report of symptoms, past medical history, lifestyle and family factors, positive and negative findings on physical exam, and the clinician's decisions and actions. An accurate record is essential to remind the clinician of findings and actions for the next follow-up visit. In a large practice, other providers will be seeing the patient and will need the benefit of the clinician's observations and actions during previous visits. The effectiveness of a treatment plan can be judged only if the plan has been adequately described. For example, if teaching about diet was provided at one visit but not recorded, the same teaching might be repeated at the next visit, to the frustration of the patient who was looking for more new information. This frustration might be misunderstood by the next provider as a lack of cooperation with the treatment plan. Finally, documentation can serve as protection for the provider or the practice in the rare case in which litigation is brought by the patient or family. In addition, third-party payers may be auditing the patient's record to determine whether the level of the visit that was billed was justified and whether the interventions billed were actually delivered. Additional details on billing and coding are provided in Chapter 22. In the

student situation, the depth and comprehensiveness of documentation can assist the preceptor or faculty in determining the student's progress in learning judgment.

SOAP Format

General principles for documentation are commonly applied using the SOAP format—*S*ubjective, *O*bjective, *A*ssessment, and *P*lan—of charting. If other systems of charting are used, the principles still apply.

Subjective

The subjective portion of the record includes all data from the patient's report: the HPI, past medical history, family history, social history, functional health patterns data, and review of systems. The clinician can include here, in an easily visible way, current medications, immunization status, allergies to foods or medications, past hospitalizations (if appropriate), and, for women, the last menstrual period and menstrual cycle information. Even when a woman is being treated for simple problems, her pregnancy status must be known before certain medications are prescribed. It is an error to confuse physical findings noticed during the exam with subjective data from the patient. If the patient's particular way of describing a problem seems important, use the patient's exact words and include quotes. This is not necessary if the description is simple and without nuance. Develop an outline form for your documentation that includes all essential data elements in a way that is retrievable. Writing in full sentences and paragraphs does not allow for easy retrieval of data by other providers. An outline template also serves as a memory tool for the new APRN. This template is useful in organizing patient presentation for the preceptor.

Objective

The objective section of the record includes all data obtained through objective means. This is not limited to numerical data. Begin the objective portion of the record with a brief description of the overall impression of the patient. Such phrases as "tired looking," "energetic," or "worried" can convey much of the patient impression that is useful in diagnostic reasoning. Include vital signs and pertinent findings from the physical exam, as well as laboratory data. Do not record diagnostic judgments in this section—think of this part of the record as "just the facts."

At first, students are unable to focus on which pieces of data are significant to a problem and tend to include every piece of data available. All data need not be recorded, but "pertinent negatives" need to be recorded. These include data that by being normal tend to rule out a possible diagnosis. Recording pertinent negatives helps to show that a diagnosis was considered and why it was ruled out. It does not take long, however, for both the subjective and objective sections to be recorded with reasonable skill, even for advanced beginner students. When following patients over time, flow sheets can be useful for tracking data. For example, a flow sheet can show the effect of a change in medication management of hyperlipidemia or blood pressure or track a patient's weight over months or years.

Assessment

The assessment portion is an area of documentation in which much variability can be found. The assessment must include active problems that are being managed in this visit. It can also include chronic problems that may have an impact on the treatment plan. Many practices always include a health promotion line on the problem list to remind each clinician that the visit should reflect the preventive focus of that practice. For the list to serve both patient and practitioner well, a simple diagnostic label may not be enough. For example, if the patient has hypertension that is being managed by lifestyle change and medication, the effectiveness of control of the problem can be recorded in the assessment section. Assessment is ongoing in the management of health problems. For example, a patient's problem list might read as follows: (1) hypertension (HTN) stage 1, well controlled; (2) type 2 diabetes mellitus (DM), poorly controlled; (3) obesity, unchanged. This documentation directs evaluation and intervention adjustment much more clearly than a simple list of "HTN, DM, obesity." Many practices maintain an active problem list near the front of the patient record or in a part of the electronic record. This is particularly useful when dealing with chronic conditions and is recommended. The clinician can initiate such a tool in any practice, even if a blank progress note sheet is filed at the beginning of that section of the patient's record.

When reviewing the assessment part of the record, students can evaluate their own thinking by asking themselves if all data that were used to justify the naming of a problem are included in the subjective and objective section of the note. Further, one can ask whether all data were accounted for in the assessment section. In some cases, a clear problem cannot be identified. Abdominal pain that does not fit a clear diagnostic pattern can be reported in the problem list by simply naming the complaint. The clinician can reflect diagnostic hypotheses by writing "abdominal pain, rule out (R/O) irritable bowel syndrome." Or "cough, viral bronchitis vs. allergy." Students are often reluctant to admit that they cannot name the problem. It is a mistake, however, to name a problem in error, simply to have a problem on the list. The patient will not be well served if the record fails to reveal competing diagnostic hypotheses. In primary care, uncertainty is reasonable and expected. Even if the problem is not completely specified, the problem list is the basis for the intervention schedule in the treatment plan.

Plan

The plan for treatment is most effective if it is described in detail, including specific directions for each

intervention. Three general sections are included in planning: First, any diagnostic testing that is to be conducted should be listed. The results of these diagnostic tests will help to clarify the assessment but, of course, are not yet available to the provider. Second, educational approaches are to be laid out. Every visit is a teaching opportunity. Patient education might include specifics of the problems being managed, such as symptom control for upper respiratory infections, medication teaching, diet and activity recommendations, and risk reduction, such as smoking cessation information or a discussion of seat belt usage. The documentation of the plan includes details regarding any therapeutic plan that is to be carried out—including prescriptions, various therapies, counseling, activity promotion or restriction, dietary changes, or any of the therapeutics discussed earlier. When recording prescriptions, be sure to include all the data that were written on the prescription list, including number or volume of doses to be dispensed and number of refills allowed. This is important because patients may call for refills before they are due, and if a different provider takes the call, he or she may have an unclear idea of how the patient's condition had been managed. This is especially important when prescribing drugs that are prone to abuse.

Finally, the treatment plan is not complete without clear plans for follow-up. When will the patient be seen again, and under what circumstances is the patient instructed to call back? For example, when treating a viral infection, remind the patient to call back if not better in 2 days or if fever develops. By documenting your instructions for follow-up, you allow other providers to manage the patient's care better if the patient calls in when you are not available.

Plans are most effective when they include a sense of the goal of treatment. If the condition is simple and self-limiting, the goal of treatment may be obvious and need not be stated. For chronic or complex problems, however, the short- and long-term goals of therapy need to be discussed and recorded. By engaging the patient in this discussion, the choices that the patient makes in altering lifestyle and in following a treatment plan may be clearer. For example, the patient with hypertension, diabetes, and obesity might have as a goal to lose 4 pounds in a month. The planned intervention to help the patient achieve this goal might be walking three times a week and one less restaurant meal a week. The feedback on the short-term goal at the next visit can help to keep the patient motivated to sustain lifelong change.

Finally, when reviewing the documentation for personal or peer evaluation, the clinician must consider whether the note conveys the scope and tone of the visit. Does it reflect the type of visit that occurred? If the patient were to ask to see the record, would the information be clear? The APRN should write the note in such a way that the patient could agree with what has been stated. Discussions of sensitive issues such as family problems can be left in general terms. This is a useful approach when one considers that others, such as third-party payers or lawyers, might have access to the record in the future. If the provider and the patient disagree on a treatment plan—for example, on the use of medications—the record can reflect the disagreement in nonjudgmental terms, such as "Patient requested prescription for muscle relaxants, which was discussed as being unlikely to benefit the shoulder pain described." This kind of note can assist in determining patterns of behavior or documenting difficulties over time.

Documentation is an opportunity for clinicians at all levels to review the level of their thought. In general, APRNs document visits more completely and less often have charts refused for payment by third-party payers than other clinicians do. It is best to develop a system for maintaining current, accurate records. Saving up quick scratches of notes and writing all formal patient notes at the end of a busy day is not the recommended approach. Dictation and computer systems allow for complete record-keeping and help to keep time spent on the task more manageable.

Documentation systems are usually invented by each practice. If you find that elements of your care are invisible in the record because of restrictive coding or limited space, plan a meeting with the head of the practice or clinic to discuss what you feel is missing in the record. Most systems in which APRNs work are dominated by the medical model. APRNs can ensure that contributions from a nursing perspective are not invisible by claiming credit and billing for the care actually provided. They should not agree to a system of billing "incident to" the physician, except where truly warranted. Unless APRNs "own" their practice through their own, independent billing for services, nursing-based care is lost and outcomes related to APRN practice are not captured. APRNs educated at the Doctor of Nursing Practice level should have the opportunity to shape the practice environment that they manage or share with other providers (Flanagan et al, 2009).

REDUCTION OF MEDICAL ERROR

The reduction of medical error and the support of patient safety are important in the health-care arena. The Institute of Medicine has called for attention to the processes and systems of care in order to reduce error and enhance safety (Kohn et al, 2000). A study of reported medical error in primary care showed that the largest number of errors was considered administrative, such as information filed in the wrong place or at the wrong time, charts not being available at the time of the visit, and lack of documentation. Errors also occurred in obtaining or processing a laboratory specimen. Some errors were reportedly due to lack of clinical knowledge or skills, such as wrong or missed diagnosis or wrong

treatment choices (Dovey et al, 2005). Attention to decision making and follow-through is important to all primary-care providers. APRNs can contribute to shaping the practice in their setting by, for example, developing systems to ensure that important laboratory results are addressed in a timely manner. This is all part of quality-oriented guidelines developed for the patient-centered medical homes (PCMHs) discussed in Chapter 1. These are the health-care systems of the future, and they are still emerging. APRNs have an opportunity and an obligation to participate in and influence that emergence with their own unique knowledge base, to translate their knowledge into systems that support patient engagement.

EMERGING TECHNOLOGIES

The use of electronic media in all facets of the health-care process is a reality. Patients have access to information about health promotion and about specific health-care concerns from the Internet; they can also communicate with health-care providers through e-mail or Web sites. Health records are maintained electronically and made accessible to providers throughout a care delivery system. One such system, the Veterans Administration in the United States, has been a leader in the use of electronic medical records. In addition, some practices send a weekly e-mail to their patients with health-related information. This can be good for marketing as well as for providing information.

Health care providers can participate in federal incentive programs through the Affordable Care Act by adopting electronic health records and demonstrating "meaningful use" of clinical data. To participate, providers must meet specific objectives in their charting, which include lists of patient drugs, computerized order entry, maintaining an active allergy list and an active problem list, and implementing decision support systems. Nurse practitioners, along with physicians, are eligible for incentive payments if a certain percentage of their patient load is in the Medicare or Medicaid system and if objectives are met.

Another new technology, telemedicine, has the capacity to open access to health care for people at remote sites. Health insurance companies are beginning to reimburse practices for telemedicine services, which will likely increase its availability (Reed, 2005). And soon, lack of access to a computer may not be a barrier to participating in telemedicine. Many business leaders predict that the next phase of medical innovation will be the use of smartphones and a variety of mobile apps to monitor our own health and transmit the data to our health-care providers on a regular basis or in advance of an office visit (Topol, 2012). Some speculate that it is only a matter of time until we have purchasable "body scanners" to transmit a wide variety of physical exam data to a distant location where a team of health-care providers is located. Just as in the debate over online education, some speculate that telemedicine can never achieve the same benefits as "hands-on" medical care; others feel that with adept use of technology, in some instances, clinician–patient communication may be enhanced. This debate will dominate future conversation about the value of "human touch" and the benefits of the remote practice of the APRN.

ETHICS

Every clinical judgment is an ethical judgment. Clinical judgment begins with respect for persons and supports each individual's autonomy. Some decisions call for balancing such principles as beneficence against autonomy, for example, as when a patient chooses not to follow a treatment plan. Truth telling by the clinician can do much to establish trust and to develop a plan the patient can accept. Ethical judgments are involved as well in the allocation of scarce resources, the most prominent for APRNs being their own time. If one patient constantly requires more time than is allotted, other patients are made to wait or are given less time for their visits. Being a patient advocate means ascertaining that the health-care system provides for each patient everything that is reasonable to which the patient is entitled; such advocacy is a role of the APRN. A survey of nurse practitioners in one mid-Atlantic state showed that 61% agreed that they sometimes weighed the needs of the patient against the interests of the managed care organization (Ulrich et al, 2003). Fidelity to the patient until the problem has been solved or resolved is another aspect of APRN practice that is based on ethical principles. One could make the case that APRNs have an ethical and professional responsibility to help design and implement systems to collaborate in the establishment of PCMHs that truly reflect the intent of that model, that "hear" the voice of the patient.

The privilege of being an APRN and entering as a partner into patients' lives to support their health and wholeness requires true human presence, clear clinical judgment, and a commitment to do one's best. The *Circle of Caring* includes patient and nurse together as they enter a relationship that has the potential to enhance the humanity of both.

Chapter 5

Evidence-Based Practice

Angela K. Golden, DNP, APRN, FNP-C, FAANP

In health care, evidence originates from research findings used to guide clinical practice, such as decisions regarding which diagnostic tests or treatment approaches are worthwhile. Research findings are used to compile evidence for decision making in practice. Generally, evidence-based practice (EBP) refers to using research findings from multiple studies that are convincing enough to the majority of a community of scientists and providers to recommend that the findings be used for clinical decision making. EBP also involves inclusion of patient and practitioner preferences and patient values in the clinical decision-making process.

The key steps involved in determining EBP are summarized in Box 5.1. Providers during a busy clinical day will unlikely be able to go through the process described; however, they must understand the full process in order to use any abbreviated form of it. Providers must learn to compose clinical questions and to find the best evidence at the point of care quickly.

Although advanced practice registered nurses (APRNs) function primarily from a nursing framework, they also incorporate aspects of the medical model into their practice. Thus, an understanding of the major research methods used in both disciplines and the ability to apply research findings to clinical practice situations are essential. This chapter focuses on EBP across disciplines and the predominant methods used to establish evidence for practice across disciplines.

Box 5.1 Key Steps in Implementing Evidence-Based Practice

1. Ask the burning clinical question.
2. Collect the most relevant and best evidence from a review of the literature including published literature reviews, meta-analyses, and clinical practice guidelines.
3. Critically evaluate the evidence.
4. Integrate the best evidence with personal clinical expertise and values, as well as patient preferences, when making a practice decision or change.
5. Evaluate the change in outcomes after implementing into practice.
6. Disseminate findings.

STRATEGY FOR POINT-OF-CARE EVIDENCE-BASED PRACTICE

This chapter provides specific guidelines for utilizing nursing research, evaluating evidence, and applying it to practice. But every provider needs a go-to strategy to use at the time of patient care. This strategy is based on knowledge of research and evaluation and is presented here to encourage the provider to read carefully the rest of this chapter and then apply all this information to later chapters. The point-of-care strategy is to (1) ask a clinical question, (2) have evidence resources readily available, (3) complete the search using those resources, (4) examine the results of the search, and finally (5) apply the findings to the individual patient—remembering always, as Strauss et al (2011) point out, "evidence does not make decisions." See Box 5.2 for a framework for point-of-care search strategy for EBP.

THE AIMS OF NURSING RESEARCH FOR CLINICAL APPLICATION

There are differences in perspective between nursing and biomedicine; however, the research conducted in each field has a common thread: the systematic pursuit of knowledge to answer questions of importance in the respective professions. Nursing as a discipline is concerned with the human response to health and illness; the use of a few methods to study the complexities of being human is insufficient. Because nursing focuses on the whole person, many of the questions that inform our practice are not easily answered using highly controlled, experimental methods. There is a consensus within the nursing discipline to develop not only the scientific basis of nursing through conducting research but also to develop the understanding and utilization of research by nurses at all levels of practice.

The important question to be asked when using research for evidence-based practice is "What findings constitute evidence?" Perhaps the most useful way of addressing this question is with another: "How will the

Box 5.2 A Framework for Point-of-Care Search Strategy

1. Ask the question.
2. Select your evidence resource. Here is a list. Select two or three that will be the initial sources for your practice:
   - National Guideline Clearinghouse: www.guideline.gov
   - Cochrane Collaboration: www.cochrane.org
   - Essential Evidence Plus (formerly known as Info poems): www.essentialevidenceplus.com
   - Up to date: www.uptodate.com/home/index.html
   - DynaMed: https://dynamed.ebscohost.com
   - Smart phone or tablet options:
     - Skyscape constellation: www.skyscape.com/estore/ProductDetail.aspx?ProductId=1180
     - Pepid primary care: www.pepid.com
3. Search.
4. Examine the evidence found in your search. Think about the level of evidence the search provided (meta-analysis, systematic reviews).
5. Apply the evidence to **your** patient.

Case scenario 1: A 72-year-old man is in the office for recent onset and worsening difficulty breathing. Pulse oximetry reading was 84 (sea level) and he is complaining of difficulty completing ADLs due to the SOB even while at rest. His wife states that he is more lethargic, and this is confirmed on examination. Examination also finds peripheral cyanosis and nonpitting pedal edema that the patient did not have on his last office visit.

1. The question: What are the criteria for admission for COPD exacerbation?
2. Selected search places: National Guideline Clearinghouse (retrieved Jul 7, 2013: www.guideline.gov/index.aspx)
3. Search: National Guideline Clearinghouse. Retrieved from www.guideline.gov/content.aspx?id=43794&search=copd

Examine the evidence: This guideline lists the following that are indications for hospital admission: Marked increase in intensity of symptoms, such as sudden development of resting dyspnea; severe underlying COPD; onset of new physical signs (e.g., cyanosis, peripheral edema); failure of exacerbation to respond to initial medical management; presence of serious comorbidities; frequent exacerbations; older age; insufficient home support.

4. Explain to the patient the results found and discuss his preferences: 72-year-old man states he is willing to go to the hospital. Call for ALS transport.

Case scenario 2: A 3-year-old child is diagnosed in the clinic with AOM, mildly ill appearing, axillary temperature of 100.6°F. Child has no known allergy to medication and is otherwise a healthy 3-year-old. Child is in day care during the day at a camp; parents are migrant workers.

1. The question: What is the recommended antibiotic for AOM in a 3-year-old?
2. Selected search places: DynaMed
3. Search: Information found
4. Examine the evidence: Evidence is as follows: for children >24 months old to provide a wait-and-see approach if non-severe illness, mild otalgia, temperature less than 102.2°F (child is not severely ill and has a temperature less than 102.2°F), and follow-up can be ensured to start antibiotics if symptoms persist or worsen (this child's parents are about to move on to the next migrant camp with unknown available health care). So in the experience of the NP working in this migrant camp, the wait-and-see approach is probably not appropriate. The recommended antibiotic is amoxicillin 80–90 mg/kg per day.
5. Explain to the patient (family) the results found and discuss the family preferences. The mother states that the child had amoxicillin for one other ear infection and had pretty bad diarrhea, and she is asking if another antibiotic could be used instead because it is often difficult to have bathroom facilities while traveling to new camps. She also wonders if there is a medication that can be given just once or twice a day, because she is in the fields often very long days. With this mother's request in mind, the NP has in stock azithromycin suspension and utilizes that for this family.

ADLs: activities of daily living; ALS: advanced life support; AOM: acute otitis media; COPD: chronic obstructive pulmonary disease; NP: nurse practitioner; SOB: shortness of breath.

findings be used?" This approach assumes that it is better to answer the question with the method that fits best rather than applying a few select methods to all questions. If the clinical situation requires a better understanding of what the experience of emergent cardiac catheterization is for postmenopausal women with acute myocardial ischemia, providers need to look for the form of evidence (or findings) that best suits the situation. This evidence will not be found in the results of randomized clinical trials; it will be found in studies specifically designed for understanding human experiences of health in a personal and meaningful way (such as phenomenological studies or those using grounded theory).

APPLYING RESEARCH-BASED EVIDENCE TO CLINICAL PRACTICE

Informed Practice?

Wide variation in practice patterns within and across provider type, specialty practice, and geographic region has been a major impetus for establishing both federal and organization-specific guidelines. Studies of decision-making processes have revealed great variation between practitioners in their approach to diagnosing and treating the same conditions. Many of these studies have demonstrated that providers who observe the same clinical situation will disagree on the assessment findings with each other, and that there is great variation in the management even when evidence-based guidelines exist.

This realization led to a search for a wider consensus on how to diagnose and treat a number of common health conditions that occurred on both national and local levels in the form of clinical practice guidelines, practice policies, and recommendations. Although some providers perceive these attempts to standardize aspects of clinical practice as stripping them of their decision making, the intent is to improve the provider's ability to make better decisions that lead to better, more reliable outcomes for patients.

Practice Standards and Guidelines

Although the terms are often used interchangeably, clinical practice standards and practice guidelines tend to originate from distinct processes, and the purpose of each is somewhat different. Standards relate to a framework for practice. Guidelines focus more on individual patient-care decisions.

Practice Standards

Unlike guidelines, *practice standards* are inflexible and are intended to be used under all circumstances. Practice standards define correct practice rather than a framework that can be tailored to fit different contexts. The American Nurses Association (ANA) has issued a definition of practice standards for nurses, which includes broad requirements for nursing practice in any setting and at any level of practice. As defined by ANA (2013), practice standards are designed to provide guidance to nurses on which to judge their practice. Two types of standards are delineated by the ANA: standards of care for clinical practice and standards of professional performance. Although considered requirements of professional practice, the ANA standards can be broadly interpreted. With respect to EBP, one obligation for nurses is to utilize research findings in practice, which may indirectly refer to the use of clinical guidelines, depending on the methods used to develop the guidelines. The American Association of Nurse Practitioners establishes the standards of practice for nurse practitioners. The standards encompass many aspects of practice, including qualifications, process of care, care priorities, and research as a basis for practice.

Practice Guidelines

Guidelines are not cookbooks taking the decision making away from providers; instead, they allow for flexibility when making individual patient-care decisions. Guidelines are intended to provide a reference point and general direction for decision making and are not to be interpreted as rigid criteria that must be followed regardless of the context in which they are being used. Nonetheless, guidelines should be followed in the majority of cases, unless there is a clear rationale for deviating from them to serve the particular needs of individuals. Tailoring care to the needs of a particular patient is a cornerstone of EBP. The usefulness of applying guidelines in clinical decision making has become increasingly recognized over the past decade and is now an expectation in the delivery of health care.

Processes Used to Design Guidelines

Just as a provider's practice is determined by current guidelines, the quality of the guidelines themselves is determined by the processes used to create them. In general, there are two approaches used to develop such guidelines: the traditional approach (also referred to as global subjective judgment) and an evidence-based approach.

The traditional approach is based on the premise that "common" practice is "correct" practice, despite the scientific evidence available either to support or refute the outcomes of such practice. Under this approach, being common is sufficient evidence that the practice is appropriate. This approach may have been useful in the past, when practice decisions were less complicated and fewer diagnostic tests or interventions were available. Today, with the complexities involved in clinical decision making, research-based evidence is required. Although elements of the traditional approach remain, the majority of guidelines are now developed from available scientific evidence.

The Agency for Health Care Policy and Research was instrumental in leading the way toward EBP, improving

outcomes, and publishing national guidelines on a variety of health-care problems, such as smoking cessation, early detection and treatment of Alzheimer's disease, and caring for HIV-infected patients. The Healthcare Research and Quality Act of 1999 reauthorized this agency and renamed it the Agency for Healthcare Research and Quality (AHRQ). The mission of the AHRQ is to improve the quality, safety, efficiency, and effectiveness of health care for all Americans.

AHRQ clinical practice guidelines are being used not only as references for health-care providers but also as the framework for insurance utilization review, quality assurance, and reimbursement. In addition, adherence or nonadherence to established guidelines (such as those published by the AHRQ) has played an increasing role in influencing medical malpractice litigation outcomes.

The implementation of AHRQ guidelines in clinical practice has not been without significant challenges. Originally, the AHRQ believed that providers would modify their practices to improve care if they were provided with clinically credible and useful information and that practitioner involvement in developing the guidelines would facilitate the use of guidelines in practice. Neither of these assumptions proved accurate: Studies indicated wide variation between a practitioner's knowledge of the recommended management of a particular health problem based on the guidelines and the practitioner's actions. With further studies, a number of barriers to implementing guidelines in practice have been identified, and the AHRQ's role in supporting EBP has been redefined to include keeping relevant information in the public domain; serving as an impartial, neutral broker of the information; encouraging multidisciplinary input in all projects; advocating for patients' perspectives and needs; and protecting special populations.

Implementing Guidelines: AHRQ Program to Address Barriers

Structurally, the AHRQ's role includes promoting initiatives focused on developing effective methods of implementing guidelines and analyzing the outcomes of care when clinical guidelines are widely disseminated and used. There are three parts to the initiatives. Evidence-based practice centers (EPCs) constitute the first part and involve a private–public partnership between the AHRQ and a variety of health-care organizations to produce evidence reports and technology assessments on several priority health-care topics. Topics to be the focus for EPC assessments are nominated by providers or others in the health-care industry and are chosen based on the selection criteria provided in Box 5.3. Final evidence reports are intended for use in practice guidelines, quality improvement programs, and the formation of policy at the state or federal level.

The second part of the AHRQ's initiative is the development of the online National Guideline Clearinghouse (NGC). The creation of the clearinghouse is a result of a private–public partnership among AHRQ, the American Association of Health Plans, and the American Medical Association. It is an electronic repository for clinical practice guidelines and provides widespread access to a number of guidelines from various professional groups. A list of the guidelines can be found at www.guidelines.gov. Box 5.4 lists examples of organizations that have supported/published EBP guidelines. Guidelines published in the NGC are required to meet established AHRQ criteria and can be accessed through

Box 5.3 Criteria for Inclusion of Clinical Practice Guidelines in National Guideline Clearinghouse

A clinical practice guideline must meet all of the following criteria to be included in the NGC:

1. The clinical practice guideline contains systematically developed statements that include recommendations, strategies, or information that assists physicians and/or other health-care practitioners and patients make decisions about appropriate health care for specific clinical circumstances.
2. The clinical practice guideline was produced under the auspices of medical specialty associations; relevant professional societies, public or private organizations, government agencies at the federal, state, or local level; or health-care organizations or plans. A clinical practice guideline developed and issued by an individual not officially sponsored or supported by one of the above types of organizations does not meet the inclusion criteria for NGC.
3. Corroborating documentation can be produced and verified that a systematic literature search and review of existing scientific evidence published in peer-reviewed journals was performed during the guideline development. A guideline is not excluded from NGC if corroborating documentation can be produced and verified detailing specific gaps in scientific evidence for some of the guideline's recommendations.
4. The full text guideline is available on request in print or electronic format (for free or for a fee) in the English language. The guideline is current and the most recent version produced. Documented evidence can be produced or verified that the guideline was developed, reviewed, or revised within the last 5 years.

the Internet. Consistent reference to these guidelines has been used throughout this text.

A final aspect of the AHRQ's initiative involves product research and evaluation. This includes an array of research and evaluation activities aimed at the development of evidence for use in guidelines, implementation strategies, and the quality of practice when clinical practice guidelines are used (e.g., outcome-based research).

These initiatives reflect the new role the AHRQ has with respect to supporting EBP and are meant to improve the scientific basis of guidelines, decrease duplication of efforts, distribute evidence on a national level, enhance uniformity, and reinforce public and private partnerships within the health-care sector.

Development of Evidence-Based Practice Guidelines

The following are essential components of guideline development: (1) identification/clarification of the topic, (2) establishment of an expert panel, (3) a systematic review of the literature, (4) development of evidence-based tables, (5) writing a draft of recommendations based on the evidence, (6) external review of the recommendations, and (7) final acceptance of the revised recommendations by the panel. Panel members chosen to develop guidelines will depend on the focus of the guidelines and may include physicians, nurse practitioners, clinical nurse specialists, ethicists, pharmacists, therapists, and health-care consumers.

A crucial aspect of guideline development is the review of the literature and rating of the available evidence. An adaptation of one of the most common methods of rating evidence is listed in Box 5.5.

An essential aspect in understanding the development and appropriate use of guidelines is to understand the levels of the evidence.

Research Designs for Level I Evidence: Systematic Review or Meta-analysis of Randomized Clinical Trials

Systematic reviews are considered the highest level of evidence on which to base a change in practice. Systematic reviews are also called meta-analyses. The systematic review searches for all *randomized clinical trial* (RCT)

Box 5.5 Quality of Evidence

I. Evidence from a systematic review or meta-analysis of all relevant randomized clinical trials (RCTs), or evidence-based clinical practice guidelines based on systematic reviews of RCTs
II. Evidence obtained from at least one well-designed RCT
III. Evidence obtained from well-designed controlled trials without randomization
IV. Evidence from well-designed case-control and cohort studies
V. Evidence from systematic reviews of descriptive and qualitative studies
VI. Evidence from a single descriptive or qualitative study
VII. Evidence from the opinion of authorities and/or reports of expert committees

Source: Melnyk, BM, and Fineout-Overholt, E. *Evidence-based practice in nursing and healthcare: A guide to best practice.* Lippincott, Philadelphia, 2005.

studies that address a similar clinical question. A review of the literature allows for a compilation of all the studies to give strength to outcomes. This review is a rigorous approach and provides a high level of evidence due to the minimization of bias. The Cochrane Library has an extensive compilation of systematic reviews.

Research Designs for Level II Evidence: Single Well-Designed Randomized Clinical Trials

RCTs are increasingly considered the most respected method for establishing the cause of disease or the efficacy of a treatment/intervention. For example, the Food and Drug Administration requires evidence of a drug's efficacy from two independently conducted randomized trials before approving the drug's use in the United States. The National Institutes of Health (NIH) are increasingly funding RCTs, and agencies or organizations developing clinical guidelines now consider the evidence from RCTs to supersede findings from case-control or cohort studies.

The strength of RCTs to establish cause or efficacy lies in the ability of this design to maintain a high degree of control within experimental conditions. If there are different effects between the groups (e.g., blood pressure, the development of pressure ulcers, the prevention of pregnancy), the differences can generally be attributed to the intervention, exposure, or treatment rather than "extraneous" factors. Moreover, the random assignment of subjects into the treatment or control group allows for a high degree of confidence in making causal inferences about the effects of an exposure, intervention, or treatment.

RCTs also frequently employ the use of double-blinding to further strengthen support for identifying a cause-and-effect relationship. When RCTs are double-blind, neither the principal investigators nor the participants know who is in the control or experimental group until either significant differences are noted in a (blind) analysis of the data or the study is complete. The purpose of double-blinding is to eliminate the potential for participants in the experimental or control groups to treat themselves differently or to be treated differently by investigators.

Research Designs for Level III Evidence: Well-Designed Controlled Trials Without Randomization

Quasi-experimental research designs evaluate the effectiveness of an intervention/treatment, but subjects are not randomly assigned to either the treatment or control group. In these designs, many of the other same methods to ascertain the internal validity of the study, such as control of extraneous variables and standardization of treatment, instituted in RCTs are implemented.

Research Designs for Level IV Evidence: Well-Designed Case-Control or Cohort Studies

These types of studies are especially useful in answering clinical questions that address prognosis or causation. With this design, the study is generally initiated after the disease has developed. A group of individuals (cases) who have the disease and those (controls) who do not are selected and compared in terms of their prior exposures that are thought to be associated with the development of a particular type of disease. Case-control studies are also considered observational studies because they do not manipulate the exposure (what may also be referred to as the intervention). The course of the disease is observed without interference. The lack of control over the exposure in case-control studies (along with other observational studies) risks introducing selection bias into the study, which may confound the results. These potential shortcomings have some researchers arguing that case-control studies are essentially worthless because of the inherent potential for bias.

Despite the arguments against the value of the case-control design, it is the most commonly used epidemiological design in the medical literature today. For example, the association between unopposed estrogen use in postmenopausal women and the development of endometrial cancer was established through several case-control studies.

The Nurses' Health Study at Harvard is an example of a well-known prospective cohort study. It is a large, ongoing cohort study that enrolled more than 120,000 married female nurses who were 30 to 55 years old in 1976. The nurses completed a baseline questionnaire about a number of demographic and health characteristics. Follow-up questionnaires at 2-year intervals asked about the development of disease and any new exposures. By comparing the exposed and unexposed groups on a number of variables (e.g., those who took hormone replacements and those who did not; those who ate high-fat foods and those who did not) and the onset of disease within each group, the study has provided important information about the relationships of these variables with the development of cancer and cardiovascular disease in women.

Perhaps the most renowned example of a prospective cohort study is the Framingham Heart Study. In this study, investigators identified and examined 5,127 men and women from Framingham, Massachusetts, who were 30 to 59 years old in the 1950s. When the study was initiated, all 5,127 participants were determined to be free from coronary heart disease. Participants in the study have provided ongoing lifestyle and health status information and have been reexamined at regular intervals since 1952 for the development of coronary events. Prospective data from this study have been pivotal in identifying a number of major risk factors associated with coronary artery disease (CAD) and have been one of the sources of evidence for recommending lifestyle modifications to prevent CAD.

Research Designs for Level V Evidence: Systematic Reviews of Descriptive and Qualitative Studies

The purpose of descriptive research is to portray accurately the characteristics of a population or a clinical situation. Descriptive research can be quantitative or qualitative in design. In quantitative designs, the findings address the incidence, prevalence, or measurable characteristics of the population using descriptive statistics (frequencies, means, mode, etc.).

In qualitative designs, the population or clinical situation is displayed in a narrative format for the purpose of increasing the understanding of the various dimensions of the phenomena of interest. Common qualitative designs used in nursing research include phenomenology, ethnography, grounded theory, and historical analysis.

Research Designs for Level VI Evidence: Single Descriptive or Qualitative Studies

Case studies fall into this category. They are ranked lower owing to the likelihood of decreased objectivity. These studies describe the history of one individual or a small group of patients. Case studies are generally told in story form. The value of this study type is to alert a provider to an adverse event or a rare disease, or to add to a provider's knowledge base. It is important to recognize that no inferences can made from a case study to the general population.

Research Designs for Level VII Evidence: Opinion of Authorities and/or Reports of Expert Committees

This level of evidence is just as it states; it is the opinion of someone. This follows the traditional approach for "correct" or "common" practice and may or may not be based on strong evidence. This level of evidence should not be a sole determination of changing practice or determining the proper course of treatment. However, there are times when this is the only evidence, and it is utilized to begin treatment in rare situations that do not have higher levels of evidence.

EXAMPLES FROM THE FIELD: STUDIES OF IMPLEMENTING PRACTICE GUIDELINES

The clinician who uses clinical guidelines should evaluate their usefulness by examining the following major characteristics (Box 5.6):

- **Who created the guideline and what is the date of revision or origination?** Authorship and funding of the guideline may be important if there is the potential for bias. In addition, the best guideline will be created using multidisciplinary groups and follow a systematic approach as recommended by AHRQ. The guideline must be current, meaning it was created or revised in the past 2 to 3 years and used the most up-to-date evidence.
- **Are the guidelines clinically important?** To establish clinical importance, guidelines should convince you that following them will provide more benefits for your patients than whatever expected harms or costs are associated with applying them.
- **How strong are the recommendations?** This is largely determined by the strength of available evidence in making recommendations using clinical guidelines. Guidelines will grade the recommendations. This is based on the strength of the evidence the recommendation was based on. Various grading systems for the strength of the recommendations and evidence on which recommendations are based have been used to assist practitioners in determining how "strong" the recommendations are. There is no uniformity in the grading systems, requiring a provider to look at the grading system before reading the recommendations. The *Guide to Clinical Preventive Services* developed by the U.S. Preventive Services Task Force has a section describing the

1. **Who created the guideline, and what is the date of revision or origination?**
   - Authorship: Institute for Clinical Systems Improvement (private nonprofit organization)
   - Funding: The following Minnesota health plans provide direct financial support: Blue Cross and Blue Shield of Minnesota, HealthPartners, Medica, Metropolitan Health Plan, PreferredOne, and UCare Minnesota. In-kind support is provided by the Institute for Clinical Systems Improvement's (ICSI's) members.
   - Currency: March 23, 2011
2. **Are the guidelines clinically important?** The guideline clearly identifies the research basis and the benefits of treatment.
3. **How strong are the recommendations?** The guideline clearly identifies the strength of the various recommendations being made—with Class A–E and acknowledging meta-analysis and systematic reviews.
4. **Are the guideline recommendations applicable to your patients?** The guideline is relevant to any provider caring for children.

Source: Institute of Medicine. Clinical practice guidelines we can trust. Retrieved July 7, 2013, from www.iom.edu/Reports/2011/Clinical-Practice-Guidelines-We-Can-Trust.aspx

methodology for reviewing evidence and how the Task Force members "translated" the science into a five-point scale (with A through E ratings) to allow a quick reference for providers to determine appropriate preventative services. Some guidelines use a Roman numeral scale to define the levels of evidence or recommendations.

- **Are the guideline recommendations applicable to your patients?** Guidelines are developed for a variety of settings and for different practitioners. First, it is necessary to determine the group for which the guidelines were written (e.g., primary-care providers, specialists, or quality assurance reviewers) and whether they suit the intended purpose. Second, a determination is made on whether the individual patient has the characteristics of patients for whom the guidelines were intended. For example, if the patients you care for have a higher or lower prevalence of a disease or different set of risk factors for disease than those in the guidelines, the recommendations may not apply. The patient population for whom the guidelines are intended will likely be dictated by the sample characteristics of the studies used to develop them as evidence. Before applying recommendations to any one patient, first determine whether this patient's characteristics are consistent with those for which the guideline was intended and modify the guidelines when required (remember, they are meant to be flexible and adapted to individual needs when necessary).
- **Case study:** A 52-year-old male patient with hypertension is in the office. The patient is on a diuretic and a beta blocker with well-controlled blood pressure. The provider is trying to determine if the patient should be tested for causes of secondary hypertension. Using the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7), the evidence demonstrates the improved clinical outcomes associated with treating underlying causes of secondary hypertension based on several well-designed studies; however, the costs and risks of adverse outcomes associated with diagnostic tests to rule out a cause such as renal artery stenosis may be greater than the benefits when applied to the entire population. Thus, guidelines do not recommend that every person who develops hypertension undergo extensive testing. Rather, specific characteristics of patients presenting with hypertension assist us in narrowing the population to those individuals who would reap the benefits of screening beyond any potential harm of the tests. A second patient presents with new-onset elevated blood pressure. He is 28 years old with no family history of hypertension. This patient would meet the criteria in the JNC 7 for investigation of possible renal stenosis.

Study Design and the Level of Evidence

Evidence-based health care is widely supported as the new model for practice. Some suggest that the degree of evidence provided by a study is based on its method, or design. There is an increasing trend toward regarding evidence from RCTs as the only valid type of evidence appropriate for use in the practice setting. The danger in this perspective is disregarding what we have learned and can continue to learn from observational studies such as case-control and cohort studies.

The most sobering outcome of reliance on RCTs is the failure to teach providers to think and critically evaluate information. There are many circumstances in which randomization is impossible and where observational methods have provided invaluable information. Take, for instance, how we came to understand the

relationship between alcohol use in pregnancy and fetal alcohol syndrome; smoking and cardiopulmonary disease; birth defects and thalidomide; the transmission of HIV and viral hepatitis; and the development of endocarditis in IV drug use. Knowledge of these associations came from observational studies. Randomizing pregnant women into experimental or control groups to either drink alcoholic beverages or not, or designing an experimental trial to determine how the transmission of HIV in humans occurs, is not ethically possible (or desirable). How we know what we know in practice must be determined through a critical appraisal of the information available. What we need is a framework for appraising the health science literature, for applying research results to practice, and for assessing sufficient degrees of evidence to change the standards of practice.

Practitioners must learn the process of research and how to evaluate the evidence. However, providers also need a way to utilize EBP at the time of patient contact. The learning of the process must occur in the degree programs so that the point-of-care use of EBP can occur in real time.

USING A FRAMEWORK TO EVALUATE HEALTH SCIENCE LITERATURE

Critical appraisal of the health science literature can seem like an overwhelming task, yet it is a professional responsibility within advanced practice nursing. Using a framework for guidance can assist APRNs in taking the appropriate steps toward meeting this obligation. Some of the steps in applying the framework presented here are similar to those used for evaluating clinical practice guidelines. Two of the many sources to find literature are PubMed and CINAHL. A framework for evaluating journal articles in the health science literature is presented in Box 5.7. This framework provides an organized approach to interpreting the information found in a

Box 5.7 A Framework for Evaluating Health Science Literature

Learning to evaluate health science literature is critical. It can be a time-consuming process, but it is necessary to reading an article for use in practice.

1. Look at the title to determine whether it reflects your specific interest.
2. Validate that the content is relevant to your original interest and the title by reading the abstract.
3. Evaluate and determine what is being studied:
   - What are the study questions or hypotheses?
   - What are the specific variables under study?
   - How are the variables defined and measured?
4. Evaluate and determine who is being studied:
   - What are the characteristics of the study sample or subjects?
   - How were subjects selected for the study?
   - Is there an adequate sample size?
5. Evaluate and determine the type of study design and assess its validity:
   - Do the designs of the studies support the statements made?
   - Have other studies in similar (or different) samples found consistent results?
6. Evaluate and determine how data have been analyzed:
   - What are the descriptive statistics used to describe the sample characteristics?
   - Could the degree or pattern of missing data influence the results?
   - Were the inferential statistics used appropriate for the study question and design?
   - Remember that statistical tests of significance do not determine causation or clinical significance.
7. Evaluate what you have determined thus far:
   - Have you been skeptical?
   - Have you judged the quality of the literature based on the journal in which it was published?
   - Do you realize that there is no such thing as a "perfect" study?
   - How have you judged the author's treatment of contradictory results?
   - Remember that validity and reliability are crucial aspects of the study.
8. Discuss your evaluation with colleagues and seek other opinions (such as in a journal club):
   - Do your colleagues agree with your evaluation?
   - Do the results or recommendations suggest a change in your clinical practice? If so, what change is suggested and how will it be implemented?

variety of articles, be it a review of the current knowledge in an area or original research findings.

Evaluating the Evidence to Change Practice

For an example of evaluating evidence to change practice, let's look at the use of angiotensin-converting enzyme (ACE) inhibitors in patients with congestive heart failure (CHF). In the early 1990s, several clinical trials demonstrated that the use of ACE inhibitors improved clinical outcomes in patients with CHF, not only with regard to mortality but also in exercise tolerance, symptom severity, progression to left ventricular dysfunction, and fewer hospitalization rates. The consistency of the findings and the fact that they came from well-designed RCTs provided unequivocal evidence that ACE-inhibitor use was beneficial for the majority of patients with CHF. As a result, the American College of Cardiology, the American Heart Association, and the AHRQ developed clinical guidelines for the treatment of CHF that strongly encourage ACE inhibitors as standard therapy. The use of ACE inhibitors is now considered a standard of care and should be incorporated into the care of persons with CHF. For the provider at the point of care, the clinical guideline produced by these organizations provides point-of-care evidence to utilize with a patient.

Outcomes

Distinguishing between intermediate and clinical outcomes is also critical before applying research findings to practice. Outcome research has been increasingly funded in recent years. An outcome is generally considered the dependent variable of the study. Intermediate outcomes include measurements such as bone mineral density (BMD), hemoglobin levels, and eosinophil level. Clinical outcomes include measures such as the number of hip fractures, a person's functional status, peak flow values, or the number of acute asthma exacerbations experienced.

Improvement in intermediate outcomes does not necessarily lead to improvements in clinical outcomes. For example, in early studies of using fluoride to treat osteoporosis, BMD values improved greatly when given to osteoporotic women, but the number of fractures over time did not differ from those in women who were given placebos. Thus, intermediate outcomes, although important to study to gain an understanding of disease processes and treatment, should not be substituted for clinical outcome data.

NURSING SCIENCE: BUILDING THE EVIDENCE FOR PRACTICE

Historically, nurses have been involved in conducting research. The establishment of the National Institute for Nursing Research marked a new era by aligning nursing science with other respected institutes within the NIH. This development increased both federal funding for nursing research and the visibility of nursing science on a national level. Investment in nursing research continues to grow in terms of resources, funding, training, and the expectation for using research as the basis, or evidence, for practice. Many methods of knowing contribute to our knowledge or understanding of the world, and a combination of methods (or various ways of triangulating) will provide a clearer, more encompassing answer to questions asked within the discipline to provide the best individualized care for patients. The example (Box 5.8) of using multiple

Box 5.8 Example: Integration of Evidence-Based Practice and Nursing Research–Based Practice

The management of the 8-year-old child with type 1 diabetes requires a multidisciplinary approach of which the family is an integral part. Below are two resources available to the APRN to assist in the management of the child with diabetes.

Evidence-Based Practice Guidelines

The American Diabetes Association–Professional Association supports the development of clinical guidelines for the management of diabetes. The foundation of the guideline for the management of diabetes is the recommendations made as to glycemic control. These include the following:

1. Lowering A1C has been associated with a reduction of microvascular and neuropathic complications of diabetes (A).
2. Developing or adjusting the management plan to achieve normal or near-normal glycemia with an A1C goal of <7% is reasonable if it can be achieved without excessive hypoglycemia (B).
3. A lower A1C is associated with a lower risk of myocardial infarction and cardiovascular death (B).
4. Aggressive glycemic management with insulin may reduce morbidity in patients with severe acute illness, preoperatively, after myocardial infarction, and in pregnancy (B).
5. Less stringent treatment goals may be appropriate for patients with a history of severe hypoglycemia, patients with limited life expectancies, very young children or older adults, and individuals with comorbid conditions (E).

Continued

Box 5.8 Example: Integration of Evidence-Based Practice and Nursing Research–Based Practice—cont'd

The panel rated the strength of the evidence supporting the first recommendation as "A." An "A" indicated that there was clear evidence from well-conducted, generalizable, randomized clinical trials that were adequately powered, or at the least supportive evidence from well-conducted randomized controlled trials that were adequately powered, including evidence from a well-conducted trial at one or more institutions. Evidence supporting the second through fifth recommendations were rated as "B." An evidence rating of "B" indicated that there was supportive evidence from well-conducted cohort studies. The final recommendation was given an evidence rating of "E." Evidence rated as E indicated that support for the recommendation was from expert consensus or clinical experience.

The guidelines also addressed nutrition and psychosocial assessment and care. The recommendations listed under psychosocial assessment and care are as follows:

1. Preliminary assessment of psychological and social status should be included as part of the medical management of diabetes (E).
2. Psychosocial screening should include but is not limited to attitudes about the illness, expectations for medical management and outcomes, affect/mood, general and diabetes-related quality of life, resources (financial, social, and emotional), and psychiatric history (E).
3. It is preferable to incorporate psychological treatment into routine care rather than to wait for identification of a specific problem or deterioration in psychological status (E).

Nursing Research

Sullivan-Bolyai et al (2004) conducted a study to describe the experiences of parents managing their child's type 1 diabetes with the use of continuous subcutaneous insulin infusions (CSII), commonly referred to as the insulin pump. In this qualitative study, 14 mothers and 7 fathers were interviewed and asked to describe the day-to-day experience of managing their child's diabetes. The children ranged in age from 2–11 years, and their mean age was 7.2 years of age. Parents in this study agreed that the pump was very effective in managing their child's diabetes and believed that their child's glucose was under much better control with the pump compared with using multiple daily injections (MDI). The results of Sullivan-Bolyai et al's research indicated that some parents are reluctant to change to an alternative method of achieving glycemic control for their child. But all of the parents in their study, once familiar with the device, were very satisfied with the results and reported a better quality of life after they changed methods. Another important finding was that parents reported more freedom and flexibility in their lives once their child was switched from MDI to the insulin pump. Some parents reported that once the child was placed on the insulin pump they often were tempted to impose stricter controls on their child's glucose levels.

Impact on Advanced Practice Nursing

The American Diabetes Association guidelines indicate that there is strong, reliable evidence to support interventions that assist the child with diabetes to maintain normal to near-normal glycemic levels, with less convincing evidence given to support less stringent control in very young children. Two methods currently used to achieve control are MDI and CSII, commonly called the insulin pump.

These guidelines also include a mandate for the primary-care provider to provide psychosocial assessment and care. One assessment needed is the parents' comfort with technology and resources. Technology once limited to secondary and tertiary health-care settings is now available in the community and is often managed by lay persons and caregivers.

The method used to achieve glycemic control of the child is ultimately the parents' decision. However, APRNs who care for these children and families will be influential in the education and support of these families as they make complex health-care decisions for their child. Using the guidelines as the goals for management, APRNs can provide parents with evidence-based rationales for glycemic management of their child and assist them in their choices.

Relaying information to parents based on nursing research, such as the research conducted by Sullivan-Bolyai et al, may relieve some initial hesitancy in parents about switching from MDI to SCII to manage their child's diabetes. One important consideration in using this research in practice is that the sample for the above research was described as Caucasian and well-educated. Will these same experiences be similar in other samples? However, perceptions of parents that their child's diabetes is under better control with the insulin pump and that this method has improved their quality of life can be useful to APRNs in their care of families managing this complex health condition.

This brings the evidence to the point of care, and using the providers' confidence in the evidence, their own experience with MDI or SCII, and the parents' comfort with technology demonstrates the essence of EBP.

types of research to care for the family with a child diagnosed with diabetes demonstrates the value of multiple methods of evidence.

There are numerous other examples of nursing research that have contributed to the knowledge base of nursing. Familiarity with nursing research findings is as important for advanced practice as familiarity with medical research findings. Critically appraising studies regarding the appropriate use of results is one of the most important skills APRNs will be required to use in practice.

CLINICAL DECISION MAKING AND THE PATIENT'S HEALTH-CARE DECISIONS

The decisions APRNs make in practice are fundamental to the quality of care given. Eddy (1996) expresses the importance of critically evaluating the components of clinical decision making. The importance of taking into consideration the patient's beliefs and desired outcomes is basic to making any health-care decision. Eddy (1996) identified two main steps of a decision: (1) collecting and analyzing evidence (or data) on the benefits, potential harms, and costs of various options and (2) making a judgment about how to use the available evidence to achieve the health outcome desired. This step includes the provider's experience with the population of patients served and his or her knowledge of available resources in the community.

Applying analytical procedures for determining the credibility or reliability of data to be used as evidence is only one aspect of the decision-making process, however. An equal challenge in making practice decisions lies in the second part of the process, which involves making a judgment about how to use the evidence available. This second step is not a question of facts but of patient values or preferences. One of the most substantial qualities of advanced practice nursing is establishing a relationship with our patients, providing them with the most current information we can, and allowing them to make health-care decisions they determine are best for them. In this respect, Eddy (1996) further reminds us that it is not entirely important what you as a clinician prefer for your patients; rather, it is as important to understand the patient's perspective. To clarify this point, consider Ms. Jones, a 47-year-old woman with type 2 diabetes. She is in the office for a quarterly visit. She has not met her A1C goal through metformin and lifestyle changes. The provider recognizes that the evidence supports the addition of insulin. However, the patient absolutely refuses, despite significant explanations of the benefits. With this patient's refusal, the nurse practitioner revisits the current guidelines and selects an oral medication to add to the patient's regimen. The patient agrees to add another oral medication.

There will be times, however, that what the patient desires is not appropriate. Ms. Smith, a 22-year-old, comes to the office asking for Synthroid. The patient explains that she has tried everything to lose weight and has a friend who was started on Synthroid and lost 30 pounds. The nurse practitioner does a review of systems and a physical exam and orders the appropriate diagnostics. When the patient's lab results do not confirm a need for thyroid replacement, she educates the patient about the results and does not prescribe the patient a medication just because she is asking for it. Clearly, these cases identify the use of patients' preferences when the evidence will support a change in the "best" options, while not prescribing based solely on patient preferences (Fig. 5.1).

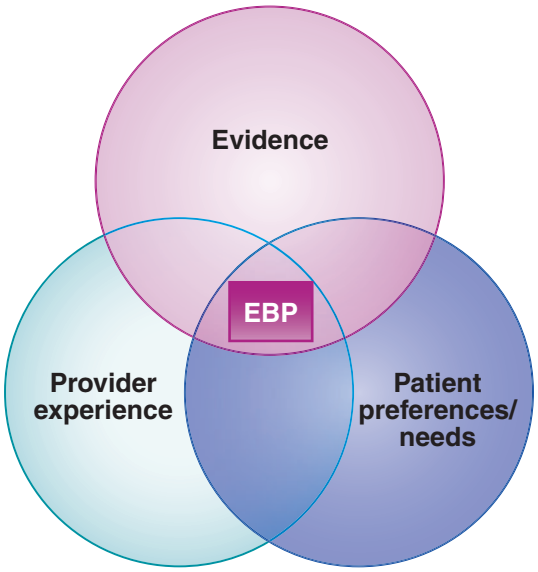

Figure 5.1 Schematic of triangulation of evidence-based practice.

Chapter 6

COMMON COMPLAINTS

CONFUSION

Confusion is not a disease process or disease state but rather a symptom. *Confusion* is an inability to think quickly or coherently. A confused patient is disoriented to time, place, or person and usually demonstrates impairment of cognitive functioning. It is usually demonstrated by inappropriate reactions to environmental stimuli and can arise suddenly or gradually and may be either temporary or irreversible. Stressful events, lack of sleep or food, or sensory deprivation may precipitate confusion. Age is not a reliable predictor; however, older adults are most at risk because of polypharmacy (multiple prescription drugs), the aging process, and the presence of chronic disease.

Differential Diagnosis

Confusion is a key sign of neurological disorders. The clinician must be diligent in determining its cause. The physical exam will provide clues. The Mini–Mental State Exam (MMSE) can help the clinician determine the degree of confusion, which helps to isolate possible causes. One major difficulty lies in disentangling symptoms of delirium from dementia. The clinician must establish whether the patient has delirium, a delirium superimposed on another condition such as Alzheimer's disease, or another neurocognitive disorder apart from delirium, such as dementia. Once the disease has been identified and treatment started, the symptom of confusion may disappear. Differential diagnoses for confusion involve almost all body systems (Differential Diagnosis Flowchart 6.1). Common causes are presented next.

Dementia

Dementia is a decline in mental functioning, affecting memory, cognition, language, and personality. An acute transient disturbance in thought process is a result of delirium, whereas persistent or more severe confusion, with or without psychomotor hyperactivity characterized by a significant timespan between symptom appearance and death, defines dementia. Clinically significant confusional states in older patients would lead the practitioner to suspect dementias such as Alzheimer's disease (AD); multi-infarct dementia as a result of cerebrovascular accident (CVA); depression, which can cause dementia; or excessive consumption of alcohol or drugs, which can also cause dementia. (AD and CVA are discussed later in this chapter.) Plassman et al (2007) estimated that in adults aged over 71 years, more than 13% are affected by dementia; this number rises to almost 40% of individuals aged over 90 years.

Patients with dementia present with an inability to focus or sustain their attention span with at least one of the following cognitive disturbances: aphasia, apraxia, and/or agnosia. The disturbance in cognitive functioning is termed a *disturbance in executive functioning*, which encompasses the following activities: planning, organizing, sequencing, and abstracting. The history and physical exam along with diagnostic studies may reveal the presence of a medical condition or drug toxicity. Screening tests listed in Table 6.1 should be followed up with a comprehensive neurological exam along with lab and diagnostic tests to rule out any reversible causes of dementia. Treatment for dementia should be disease specific. (See Common Problems sections.) Antipsychotic drugs such as haloperidol (Haldol), quetiapine (Seroquel), risperidone (Risperdal), olanzapine (Zyprexa), and aripiprazole (Abilify) can be used to reduce agitation or anxiety. Carbamazepine (Tegretol) is an anticonvulsant that may control impulsivity and aggression. Patients with panic disorders may respond to lorazepam (Ativan) or oxazepam (Serax). Referral to a specialist may help in treatment of agitation and confusion. Management goals for the family and caregivers should be supportive, specific, and consistent.

Delirium

The clinician must distinguish between delirium and dementia when evaluating confusion in the older adult. Patients with a history of delirium have a higher incidence of dementia, whereas delirium may also exist as a state by itself without any evidence of dementia. See Table 6.1 for the differences between delirium and dementia. Both, however, do share common characteristics and causes. Once the cause of the delirium is corrected, the patient should return to his or her previous state of cognitive functioning.

Differential Diagnosis Flowchart 6.1

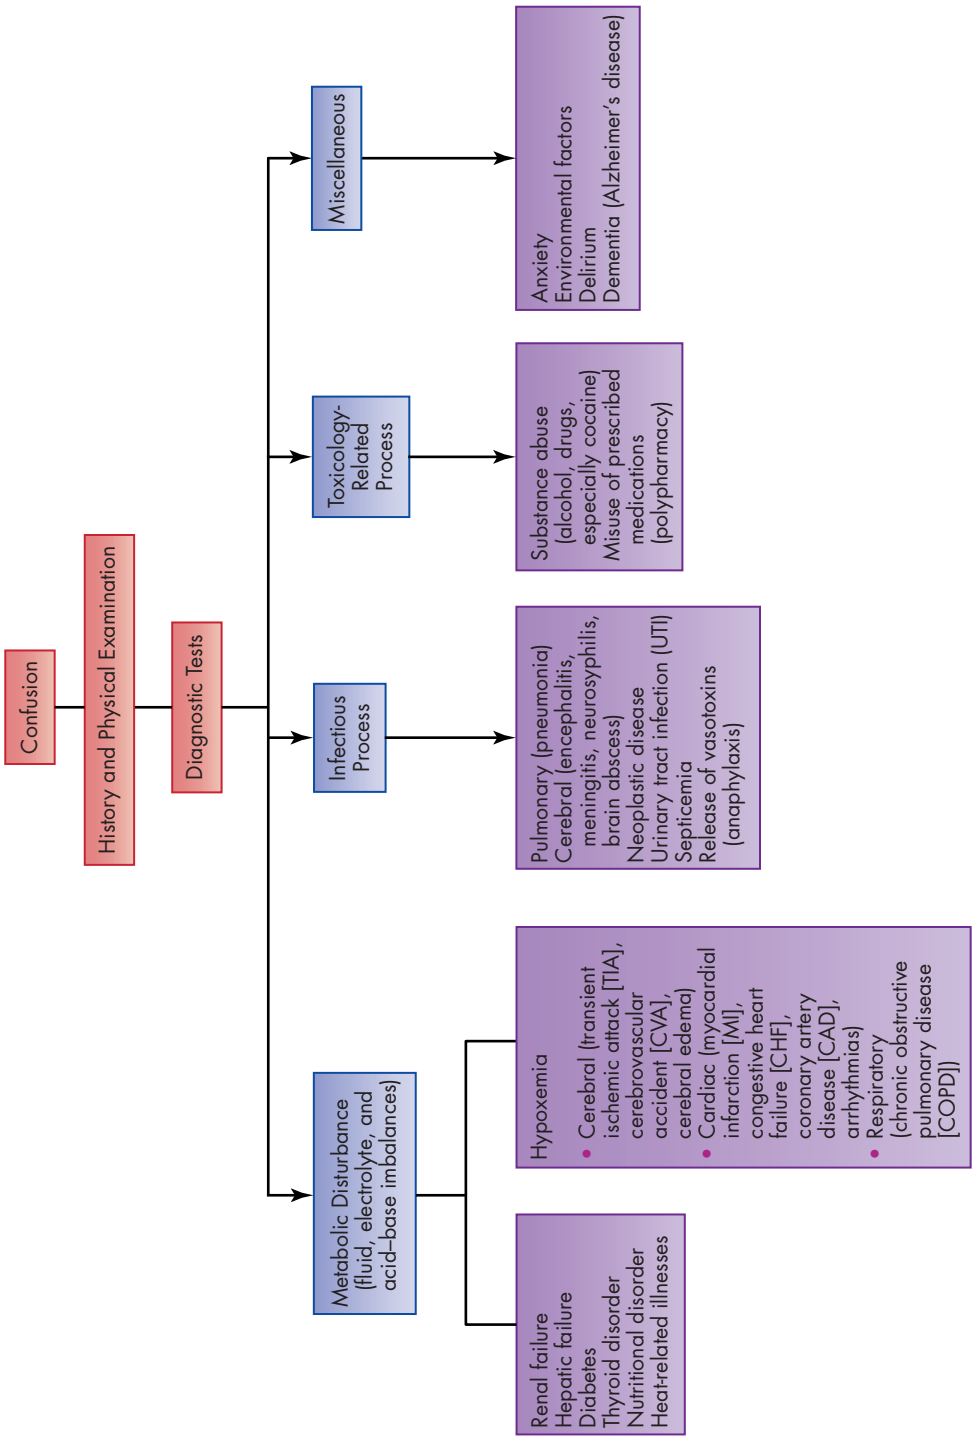

Table 6.1 Delirium versus Dementia

	Delirium (Acute Delusional State)	Dementia (Chronic)
Onset	Abrupt onset over a short period of time—days to weeks	Slowly evident over months or years
Timing	Confusion fluctuates throughout the day	Subtle decline
Duration	Hours to weeks	Months to years
Causes	A cerebral event An acute medical condition Distended bladder, constipation Sensory deprivation (poor eyesight/poor hearing) Fever, infection Actively dying Polypharmacy Adverse reaction/abrupt withdrawal of a medication, serotonin syndrome Hypoxemia Metabolic (thyroid function or organ failure) Stroke	Alzheimer's disease Parkinson's disease Motor neuron disease Medications Metabolic/endocrine disorders Trauma Infections
Symptoms	Hallmark—inattention (73%) Sleep–wake cycle disturbance (73%) Memory problems Psychomotor retardation (37%) Agitation (27%) Perceptual disturbances and hallucinations (26%) Language disturbance (25%)	*Moderate:* Multicognitive deficits—aphasia, apraxia, agnosia, impairment of occupational and social functioning *Severe:* Incontinence, inability to perform ADLs, inability to speak more than 6 intelligible words in a day, progressive weight loss of 10% of body weight in the past 6 months
Screening tools	MMSE	SLUMS MoCA AD8 Informant interview MC-FAQ MMSE: >24 early dementia 12–24 intermediate dementia <12 severe dementia FAST (Functional Assessment Staging): Score of 7: admit to hospice Clock-drawing test
Treatment	Stabilize the environment; glasses or hearing aids if sensory deprivation; antipsychotics (haloperidol, chlorpromazine) if sedation is desired; for long-term prescription—risperidone, olanzapine for sedation	*Nonpharmacological interventions:* Behavior Management Caregiver Intervention Programs Cognitive Stimulation Reality Orientation Therapy Recreational Activities *Pharmacological interventions:* Cholinesterase Inhibitors Antidepressants Antipsychotics

SLUMS: St. Louis University Mental Status exam; MoCA: Montreal Cognitive Assessment; MC-FAQ: Mini-Cog with Functional Assessment Questionnaire; MMSE: Mini–Mental State Exam.

There are many screening tools with a high degree of sensitivity and specificity to detect cognitive changes that may be used to aid the clinician in the first step toward an accurate diagnosis. These are individually available by doing a search on the Internet for each screening tool (Segal-Gida, 2013):

- MMSE
- Modified Mini–Mental State Exam (3MS)
- Mini-Cog
- Montreal Cognitive Assessment (MoCA)
- General Practitioner Assessment of Cognition (GPCOG)
- Saint Louis University Mental Status (SLUMS)
- Memory Impairment Screen (MIS)
- Clock-drawing test

Metabolic Disturbances

Fluid, electrolyte, and acid–base imbalances may be the result of metabolic problems, which can alter a patient's level of consciousness, producing confusion. The extent of the imbalance determines the severity of the patient's confusion. Typically, the patient is dehydrated and has poor skin turgor, dry skin, and a low-grade fever. Additional signs and symptoms such as dizziness, confusion, altered level of consciousness, hypotension, and coma, when evaluated with an extensive history and physical exam, will usually lead the clinician to a diagnosis. Routine laboratory tests, including electrolytes, urinalysis, chest x-ray exam, and electrocardiogram (ECG), may be performed. Treatment should be focused on restoration of appropriate fluid and electrolyte balance—specifically, correction of the primary metabolic disorder.

Infectious Process

Confusion may also be the result of an infectious process that can cause extensive tissue and organ impairment through the release of vasotoxins. If the infectious process is allowed to continue, ischemia often occurs, producing cell injury and death. Severe generalized infections (such as septicemia or bacteremia) can produce symptoms suggestive of delirium, whereas infections that affect the nervous system (such as meningitis) cause confusion, headache, and nuchal rigidity. Specific signs and symptoms of infections include fever, tachycardia, tachypnea, decreased blood pressure, confusion, and irritability. Diagnostic studies should include routine tests and those associated with the suspected infectious agent. Treatment should focus on managing the primary cause of the infection.

Tissue Hypoxia and Ischemia

Cardiovascular disorders can cause confusion as a result of tissue hypoxia and ischemia. Confusion may be insidious and may come and go, as is frequently the case. The patient typically appears ill and has significant changes in vital signs (decreased blood pressure, elevated and/or irregular pulse, and tachypnea), edema, cyanosis, reduced level of consciousness, confusion, severe headache, agitation, vomiting, and motor deficits. Diagnostic examinations should include routine laboratory testing, arterial blood gases, chest x-ray, and ECG. Treatment depends on the problem or disease identified.

Neoplastic diseases that cause confusion include systemic cancers and intracranial lesions to the brain, secondary to the extensive tissue and organ destruction caused by the invading cancers. Signs and symptoms depend on the areas of the body where the cancer is located. Extensive cerebral edema, compression, and cell injury produce ischemic states and result in cell and tissue death. This destruction impairs the circulation, increases intracranial pressure, and results in confusion, headaches, disorientation, tremors, seizures, memory loss, gait disturbances, dehydration, changes in levels of consciousness, vomiting, and sensory and motor deficits.

Diagnostic studies should include basic routine tests. Additional studies and treatment measures will vary depending on the type of cancer.

DIZZINESS AND VERTIGO

Dizziness is the sensation of unsteadiness and a feeling of movement within the head. *Vertigo* is the sensation of rotation or movement of the patient or the patient's surroundings. The terms are often used synonymously, but they do not have the same meaning. Vertigo may result from an inner ear disease or a disturbance of the vestibular center or pathway in the central nervous system (CNS). Dizziness is described as a feeling of lightheadedness, weakness, or faintness. Loss of consciousness rarely occurs, but the feeling of faintness encourages the patient to lie down, which may cause the feelings to disappear. It is important to distinguish between vertigo and dizziness. Episodes of dizziness are brief and may be mild or severe, with an abrupt or gradual onset. Both dizziness and vertigo may be accompanied by nausea, vomiting, nystagmus, and unsteady gait. Dizziness occurs as a result of inadequate blood flow and oxygen supply to the brain and spinal cord. If other neurological symptoms occur, such as numbness or facial, arm, or leg weakness, it is more suggestive of a brainstem problem.

Differential Diagnosis

Differential diagnoses for dizziness are classified into four categories: peripheral vestibular disease, systemic disorders, CNS disorders, and anxiety states (Differential Diagnosis Flowchart 6.2). The history and physical exam are essential to pinpoint a diagnosis. Key questions to ask a patient regarding dizziness include duration, severity, and nature of the episodes and any associated symptoms such as hearing loss and weakness. Key points to assess include physical exam of the ear to rule out cerumen impaction or otitis media; hearing tests, including whisper, Weber, and Rinne; a thorough neurological assessment; and the Hallpike maneuver, to distinguish between benign vertigo and vertigo resulting from a CNS lesion. The Hallpike maneuver is performed by rotating the patient's head to one side and then lowering it slowly to 30 degrees below the bodyline. The patient should be observed for nystagmus during head rotation and vertical positioning. In patients with benign vertigo, there may be rotational nystagmus and possible severe vertigo, which usually occurs in one direction. This resolves quickly and cannot be reproduced after two to three repetitions. The clinician should suspect a central lesion when the vertical nystagmus is of a longer duration and continues with each repetition.

Peripheral Vestibular Disease

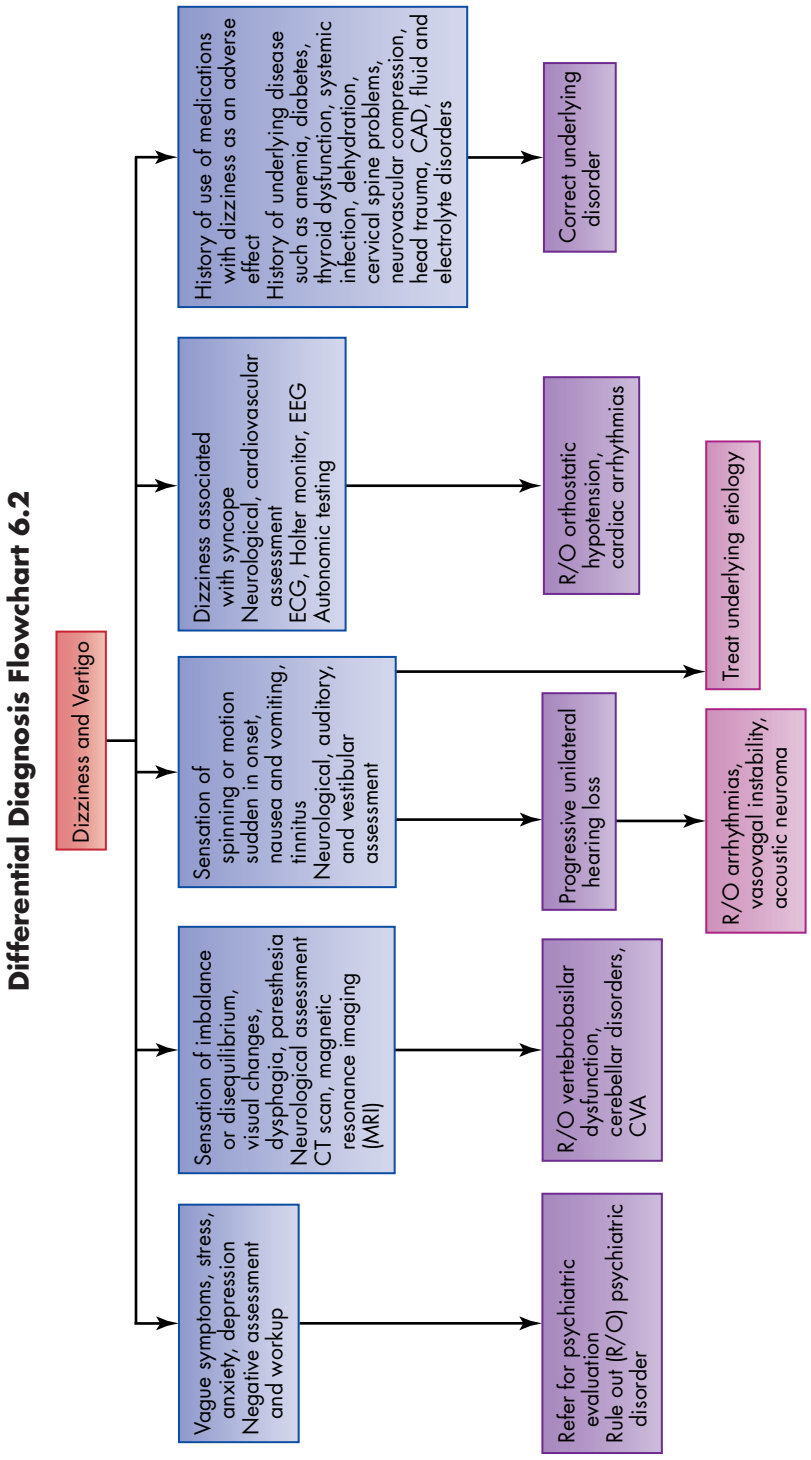
Peripheral vestibular disease accounts for up to 44% of all cases of dizziness and vertigo. Many patients who experience dizziness may have a diseased vestibular nerve. Most often the problem is located in the labyrinth of the middle ear. The problem may be caused by otoliths precipitated in the labyrinth. Signs and symptoms of vestibular disease include dizziness, nausea and vomiting, diaphoresis, difficulty with balance, vertigo, tinnitus, fluctuating hearing loss, feelings of pressure in the ear, and diplopia. Diagnostic studies include audiological evaluation, electronystagmography, magnetic resonance imaging, magnetic resonance angiography, brainstem-evoked responses, and basic laboratory screening as guided by history and physical exam. Antihistamines such as meclizine (Antivert), diphenhydramine (Benadryl), or promethazine (Phenergan) are the most commonly prescribed medications for vertigo. These agents suppress the vestibular end-organ receptors and inhibit activation of vagal responses. Patients are instructed to take the medication for a week, then to try to taper the drug slowly. Diamox is used to decrease edema in the labyrinth. Antiemetics should be considered when nausea and vomiting are severe. These agents suppress central vestibular pathways, which activate the vagal stimulus. Prochlorperazine (Compazine) orally (PO) or by suppository or trimethobenzamide (Tigan) PO or by suppository will usually bring relief to the patient. Vestibular exercises can help the patient with the symptoms of vertigo. Exercises are helpful in dislodging the otoliths. They may also help the patient acclimate to the symptoms. Exercises have been shown to decrease the duration of vertigo or produce longer symptom-free periods. The patient is instructed to reproduce the feelings of vertigo by placing the affected ear down, then assume a supine position and hold that position until the vertigo disappears. The vertigo may return when the patient sits up. The patient must repeat these maneuvers at least five times a day or until the vertigo no longer returns. Patients with persistent symptoms should be referred for assessment of nerve function. Surgery may be indicated when all else fails to relieve the vertigo.

Systemic Disorders

Systemic disorders may cause dizziness or light-headedness. Patients typically complain of light-headedness or feelings that they are about to faint or pass out. Dizziness may be aggravated by postural changes or exertion. Pallor, dyspnea, tachycardia, bounding pulse, weakness, hypotension, blurred vision, decreased breath sounds, headache, diaphoresis, and agitation suggest systemic problems. These symptoms should prompt the practitioner to look for signs of anemia, cardiovascular disease, hyperventilation, drug reactions, endocrine disorders, fluid and electrolyte imbalances, and psychiatric problems. Systemic diseases require diagnostic examination and treatment that is specific for the cause of the dizziness.

Central Nervous System Disorders

CNS disorders that disrupt the pathway between the vestibular apparatus and the brain may cause dizziness. Facial numbness, hemiparesis, diplopia, dysarthria,



Differential Diagnosis Flowchart 6.2
Dizziness and Vertigo
History of use of medications with dizziness as an adverse effect
History of underlying disease such as anemia, diabetes, thyroid dysfunction, systemic infection, dehydration, cervical spine problems, neurovascular compression, head trauma, CAD, fluid and electrolyte disorders
Correct underlying disorder
Dizziness associated with syncope
Neurological, cardiovascular assessment
ECG, Holter monitor, EEG
Autonomic testing
R/O orthostatic hypotension, cardiac arrhythmias
Sensation of spinning or motion sudden in onset, nausea and vomiting, tinnitus
Neurological, auditory, and vestibular assessment
Treat underlying etiology
Progressive unilateral hearing loss
R/O arrhythmias, vasovagal instability, acoustic neuroma
Sensation of imbalance or disequilibrium, visual changes, dysphagia, paresthesia
Neurological assessment
CT scan, magnetic resonance imaging (MRI)
R/O vertebrobasilar dysfunction, cerebellar disorders, CVA
Vague symptoms, stress, anxiety, depression
Negative assessment and workup
Refer for psychiatric evaluation
Rule out (R/O) psychiatric disorder

headache, nausea, and vomiting are some common signs and symptoms suggesting CNS dysfunction. Diagnostic examination and treatment depend on the underlying disorder.

HEADACHE

The most common of all human ailments is the headache. Headache may be localized or generalized and may produce mild to severe pain. About 90% of all headaches are without pathological cause.

Differential Diagnosis

Headaches may be classified into four types: muscle contraction (tension) headaches, vascular (migraine and cluster) headaches, mixed headaches (a combination of muscle contraction and vascular), and traction or inflammatory headaches. Muscle contraction headaches, often referred to as tension headaches, are either primary (without underlying pathology) or secondary (the result of pathology such as trauma, infection, arthritis, or tumor). They occur in 20% to 25% of all new cases of headaches. More than 50% of all headaches seen in primary care are muscle contraction headaches, often referred to as tension headaches. These headaches can occur at any age but are most common in young adults. Females present with the most severe cases, with underlying causes of generalized anxiety or depressive disorders. Forty percent of all patients with muscle contraction headaches have a positive family history of headaches. Any headache that is abrupt, explosive, severe, and described as the worst headache of the patient's life is suggestive of a traction or inflammatory headache and is most often due to intracranial hemorrhage, a medical emergency.

The clinician should ask questions to determine the following factors: onset; location of the headache; frequency; duration; severity; character, such as throbbing versus constant; presence of an aura; an association with sleep patterns; emotional factors; precipitating and alleviating factors; and family history. This information is essential to delineate the diagnosis and rule out other problems. Differential Diagnosis Flowchart 6.3 presents common characteristics, associated symptoms, and precipitating factors of common disorders that present with a complaint of headache. Additional information about headaches is provided later in this chapter; different types of headaches, along with their associated signs and symptoms, diagnosis, and treatment, are compared in Table 6.5 (on page 123).

PARESTHESIA AND PARESIS

Paresthesia is an abnormal sensation described as numbness or tingling, cramping, or pain without a known stimulus, felt along peripheral nerve pathways. Paresis is weakness. It may be local to a single extremity or the face, or it may involve more than one extremity. Paresis may develop suddenly or gradually and may be permanent or transient. Feelings associated with paresthesia are annoying "pins and needles" sensations that often cause the patient to touch or rub the affected area. Paresthesia is a common complaint, especially in patients with certain systemic diseases or those on certain drugs.

Differential Diagnosis

Paresthesia is usually due to damage or irritation to the parietal lobe, thalamus, spinothalamic tract, or the spinal or peripheral nerves that are the usual pathways for transmission and interpretation of sensory stimuli. It is important to explore the symptom of paresthesia by asking the patient to describe when it first began; the character, duration, and distribution of the paresthesia; and any other associated signs and symptoms such as sensory or motor loss. A medical history may reveal any neurological, cardiac, vascular, endocrine, renal, or inflammatory diseases the patient may have had or still has. Recent trauma, surgery, or invasive procedures may reveal possible causes of peripheral nerve injury. The physical exam should focus on the neurological system, assessing level of consciousness; cranial nerve function; reflexes; motor strength; and touch, pain, and temperature sensations. Skin color and the quality of all pulses should also be noted. If the patient has diabetes, symptoms of diabetic neuropathy such as a bilateral loss of pain sensation and diminished touch, temperature sensation, and proprioception may be present. They may present in a stocking-glove distribution.

The most common diagnoses associated with paresthesia symptoms are arterial occlusion, arteriosclerosis obliterans, nerve entrapment syndrome, neuropathy, transient ischemic attacks (discussed in detail later in this chapter), and herpes zoster (Differential Diagnosis Flowchart 6.4).

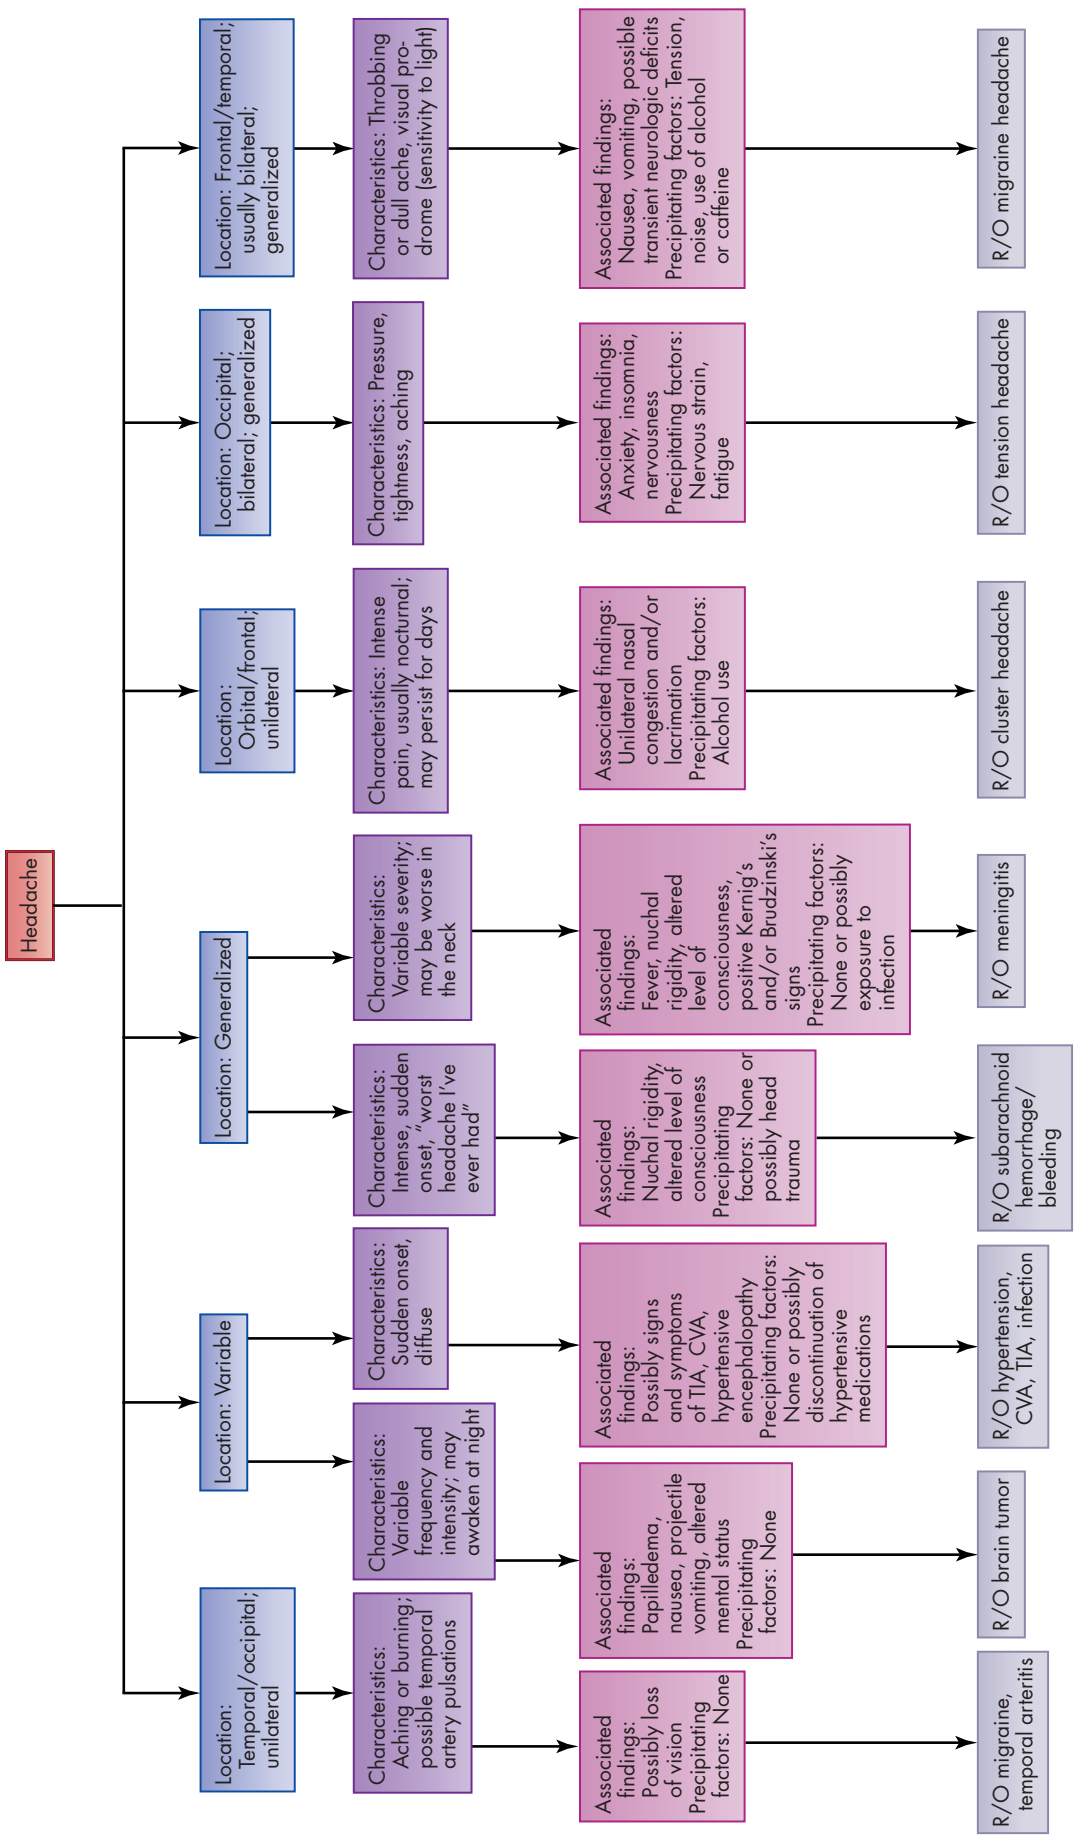
Arterial occlusion is a surgical emergency. An acute occlusion may be either an arterial embolism or a thrombosis. Immediate embolectomy is the treatment of choice in early emboli in the extremities and is preferably performed within 4 to 6 hours of the embolic event.

Arteriosclerosis obliterans is a disorder that involves the pathological process of atherosclerosis, which causes progressive narrowing of the arteries with subsequent obstruction of blood flow, resulting in diminished or decreased flow of blood to the legs and feet.

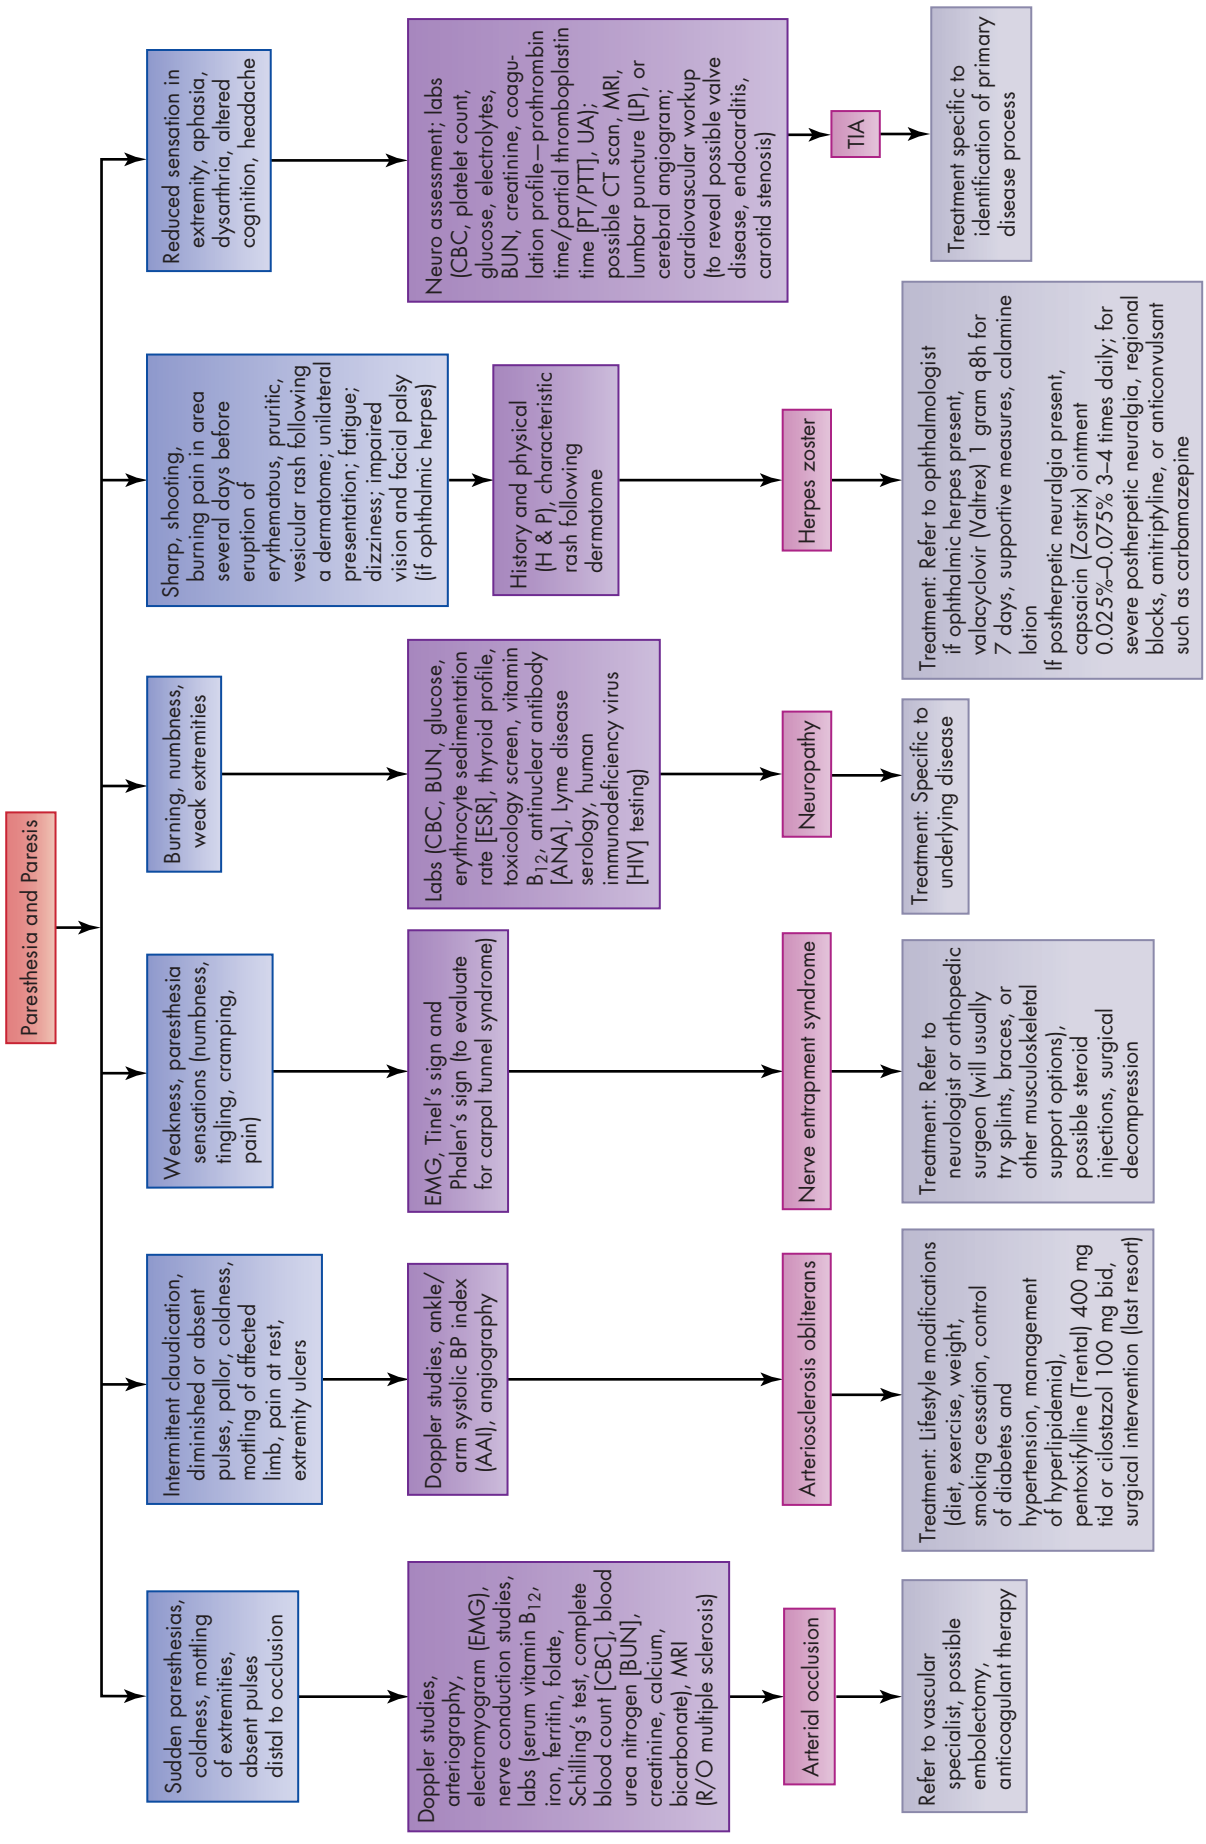
Nerve entrapment syndrome results from compression of a nerve pathway along the root of the nerve, which results in paresthesia or weakness. Trauma causing compartmental syndrome or bruising, rheumatoid arthritis, edema, infection, prolonged standing or sitting, and tight clothing can all cause entrapment of the nerve. The compression diminishes blood supply and can result in cellular changes to the nerve pathway.

Neuropathy is usually the result of underlying diseases such as diabetes, renal failure, multiple sclerosis, cancer, collagen disease, vasculitis, thyroid disease, ingestion of toxins, or nutritional deficiency. Afferent

Differential Diagnosis Flowchart 6.3



Differential Diagnosis Flowchart 6.4



nerve fibers conduct impulses from the skin to the brain. Alterations along these nerve pathways because of disease pathology can cause paresthesia. The majority of the diseases listed involve peripheral nerves.

Herpes zoster is caused by the varicella-zoster virus, which causes an acute vesicular eruption in adults, especially in immunocompromised patients. An early symptom of herpes zoster is paresthesia, which occurs as a result of infection, inflammation, and compression along the dermatomal distribution of a spinal nerve.

A transient ischemic attack (TIA) is a sudden loss of neurological function caused by impaired blood flow to the brain. The loss of function can last from a few minutes to 24 hours; after a TIA, normal function returns. If some residual weakness remains, the patient has had a stroke. TIAs are discussed in detail later in this chapter.

TREMORS

Tremors are rhythmic involuntary muscle movements that result from alternate contraction and relaxation of opposing muscle groups. They are typically evident in patients with cerebellar or extrapyramidal disorders. They are also seen as side effects with certain drug regimens. Tremors are sometimes classified into seven groups: physiological, essential, toxic, cerebellar, parkinsonian, resting, and intentional. A *resting tremor* occurs in a relaxed and supported extremity and ends with purposeful movement, whereas an *intentional tremor* occurs when the patient attempts voluntary movement. Essential tremors are typically underreported because many persons do not seek treatment for mild tremors. It is estimated that at least 10 million persons in the United States have essential tremor. As the most common movement disorder, it is apparent in 1 in 20 Americans older than age 40, and 1 in 5 older than age 65. These patients, when they do present, should be referred to a neurologist.

Differential Diagnosis

A complete history and physical exam are necessary to obtain important subjective data that will provide information on the tremor's characteristics, including duration, onset of action, progression, alleviating factors, and associated symptoms (such as memory loss, agitation, and nausea). It is important to note when the tremor is present (e.g., with rest or activity), what part of the body is affected, whether it is bilateral or not, and the type of movement produced by the tremor (e.g., flexion or extension, pronation, supination, or pill-rolling). The patient's muscle tone should also be assessed: Is it normal or increased (cogwheel rigidity)? The patient's speech, gait, and posture all must be assessed. A thorough drug history is essential, including a list of any over-the-counter (OTC) drugs the patient is taking. The clinician should note whether the tremors affect the patient's activities of daily living (ADLs) and if there is any history of family members having tremors. A review of systems may disclose a history of endocrine, metabolic, or neurological disorders. A complete musculoskeletal and neurological examination must be done to assess range of motion (ROM), mental status, strength and sensitivity, cranial nerve function, deep tendon reflexes, and gait. Differential Diagnosis Flowchart 6.5 presents common differential diagnoses of tremor.

COMMON PROBLEMS

SEIZURE DISORDERS

The terms *seizure disorder, convulsive disorder,* and *cerebral seizures* are synonymous with the term *epilepsy.* They all refer to recurrent paroxysmal episodes of brain dysfunction manifested by stereotypical alterations in behavior. *Epilepsy,* by definition, is a condition in which an individual is predisposed to two or more recurrent seizures because of a central nervous system (CNS) disorder. Seizure disorders referred to in this chapter include the diagnosis of epilepsy.

A *seizure* is a sudden, involuntary, time-limited alteration in behavior, including a change in motor activity, autonomic function, consciousness, or sensation, accompanied by an abnormal electrical discharge in the brain. The major behavioral feature that distinguishes seizures from usual activity is that seizures are stereotypical and repetitive. For example, a *clonic seizure* involves maximal contraction of one group of muscles followed by relaxation, with the cycle repeated three times per second. Table 6.2 presents the International Classification of Seizures and Epilepsies along with guidelines from the International League Against Epilepsy.

Partial seizures are those in which the first clinical and electroencephalographic (EEG) changes indicate initial activation of a system of neurons limited to one part of the cerebral hemisphere. A partial seizure is classified primarily on the basis of whether or not consciousness is impaired during the attack. When there is no loss of consciousness, the seizure is classified as a *simple partial seizure.* When consciousness is impaired, the seizure is classified as a *complex partial seizure.* In patients with impaired consciousness, aberrations of behavior (automatisms) may occur. Automatisms are distinguished by symptoms: eating automatisms (chewing, swallowing); automatisms of mimicry, expressing emotional state; gestural automatisms, crude or elaborate (directed toward either the subject or his or her environment); ambulatory automatisms; and verbal automatisms. Sometimes a partial seizure may not terminate; it may progress to a generalized motor seizure instead.

There is considerable evidence that simple partial seizures usually have unilateral hemispheric involvement and only rarely have bilateral hemispheric involvement; complex partial seizures, however, frequently have bilateral hemispheric involvement. Partial seizures can be classified into three fundamental groups: simple

Differential Diagnosis Flowchart 6.5

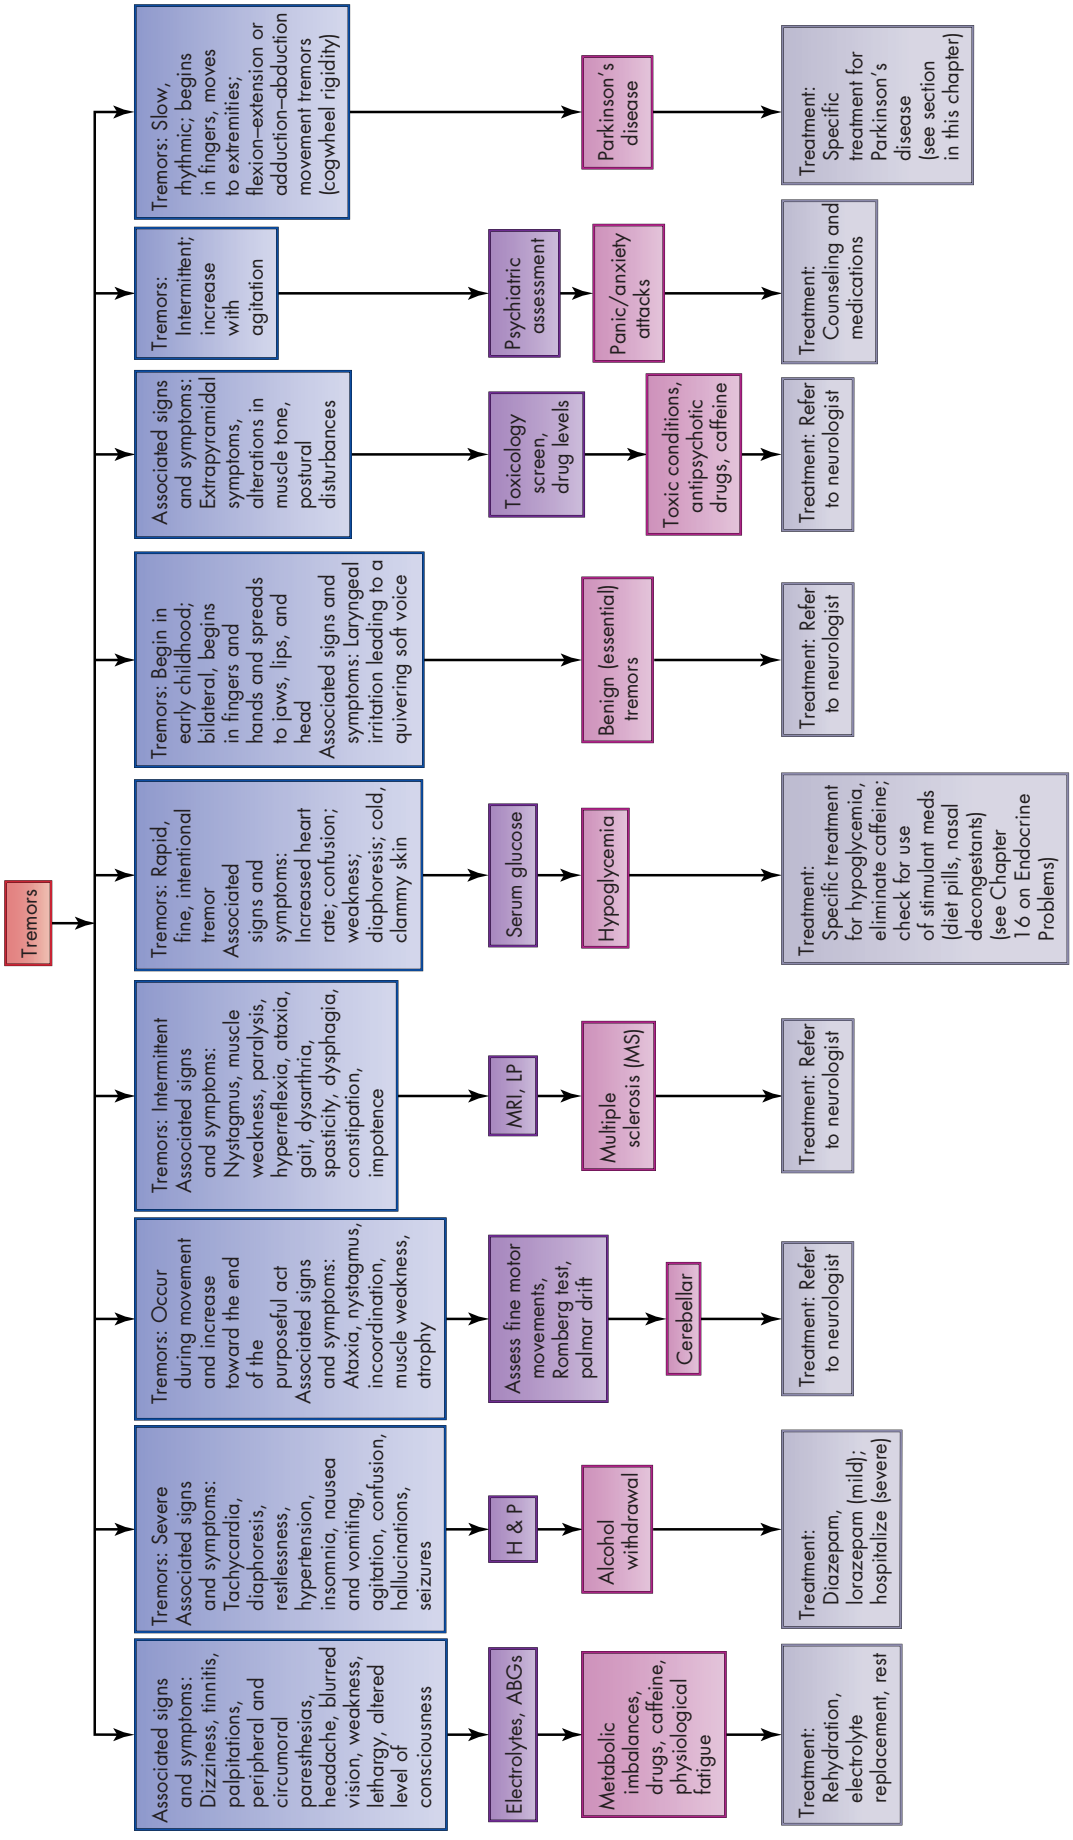


Table 6.2 International Classification of Epileptic Seizures and the International League Against Epilepsy

Seizures	
I. Partial (focal, local) seizures	
A. Simple partial seizures (consciousness not impaired)	1. With motor symptoms 2. With somatosensory or special sensory symptoms 3. With autonomic symptoms 4. With psychic symptoms
B. Complex partial seizures (with impairment of consciousness)	1. Beginning as simple partial seizures and progressing to impairment of consciousness a. With no other features b. With features as in simple partial seizures c. With automatisms 2. With impairment of consciousness at onset a. With no other features b. With features as in simple partial seizures c. With automatisms
C. Partial seizures evolving to secondarily generalized seizures	1. Simple partial seizures evolving to generalized seizures 2. Complex partial seizures evolving to generalized seizures 3. Simple partial seizures evolving to complex partial seizures to generalized seizures
II. Generalized seizures (convulsive or nonconvulsive)	
A. Absence seizures (petit mal)	1. Absence seizures 2. Atypical absence seizures
B. Myoclonic seizures	
C. Clonic seizures	
D. Tonic seizures	
E. Tonic-clonic seizures (grand mal)	
F. Atonic seizures (astatic seizures)	
III. Unclassified seizures	1. Includes all seizures that cannot be classified because of inadequate or incomplete data and some that defy classification as already described; this includes some neonatal seizures, such as rhythmic eye movements, chewing, and swimming movements
Epilepsies	
I. Localization-related epilepsies	1. Idiopathic (age-related) a. Benign childhood epilepsy with centrotemporal spikes b. Benign childhood epilepsy with occipital paroxysms 2. Symptomatic a. Epilepsies involving the limbic system b. Epilepsies not involving the limbic system (frontal, temporal, central, parietal, occipital)
II. Generalized epilepsies	1. Idiopathic (age-related) (benign neonatal familial convulsions, benign neonatal convulsions, West's syndrome [idiopathic cases], epilepsy with myoclonic-astatic seizures [idiopathic and familial cases of Lennox-Gastaut-Dravet syndrome], childhood absence epilepsy [pyknoepilepsy], epilepsy with [myo]clonic absences, juvenile absence epilepsy, benign juvenile myoclonic epilepsy [impulsive mal], epilepsy with generalized tonic-clonic seizures on awakening)

Table 6.2 International Classification of Epileptic Seizures and the International League Against Epilepsy—cont'd

2. Symptomatic
   a. Nonspecific cause (age-related) (neonatal seizures, early myoclonic encephalopathy, West's syndrome [infantile spasms, Blitz-Nick-Salaam-Krampfe], Lennox-Gastaut-Dravet syndrome)
   b. Specific cause (progressive myoclonus epilepsies such as Lafora's disease, Unverricht's disease, Unverricht-Lundborg-Hartung disease, Kufs disease, Zeman's disease)
3. Epilepsies undetermined whether focal or generalized
4. Special syndromes

partial seizures, complex partial seizures, and complex partial seizures that evolve into generalized tonic-clonic convulsions.

Generalized seizures are those in which the first clinical changes indicate initial involvement of both hemispheres of the brain. Consciousness may be impaired, and this impairment may be the initial manifestation of the seizure. Motor manifestations are bilateral. The EEG patterns are bilateral and presumably reflect neuronal discharge, which is widespread in both hemispheres.

The hallmark of an *absence seizure* is a sudden onset, interruption of ongoing activities, a blank stare, and possibly a brief upward rotation of the eye. If the patient is speaking, speech will be slowed or interrupted; if the patient is walking, he or she will stand transfixed; if eating, the food will be stopped on the way to the mouth. The attack may last from a few seconds to a half a minute.

Tonic-clonic, or *grand mal, seizures* are the most frequently encountered generalized seizures. There is a sudden, sharp tonic contraction of muscles, stridor, or a cry, and the patient falls to the ground in the tonic state. The patient lies rigid; during this state, tonic contraction inhibits respiration and cyanosis may occur. The tongue may be bitten, and urine may be voided involuntarily. This tonic stage then gives way to clonic convulsive movements lasting a variable period of time. At the end of this stage, deep respiration will occur, and all muscles will relax, after which the patient will remain unconscious for a period of time. This is known as the postictal period. After this type of seizure, the individual frequently goes into a deep sleep and may have a significant headache when awakened.

Myoclonic jerks are sudden, brief shock-like contractions, which may be generalized or confined to the face and trunk or to one or more extremities. They may occur predominantly during sleep.

Epidemiology and Causes

Seizure disorders are among the most common neurological conditions, affecting more than 2 million people in the United States. Each year, about 300,000 individuals in the United States seek medical attention because of a newly recognized seizure, representing an incidence of about 120 per 100,000. The majority of patients (75,000–100,000) presenting for treatment of seizure are younger than age 5 and have experienced only convulsions associated with a febrile illness. Each year, 50 per 100,000 individuals in the United States are diagnosed as having a seizure disorder, which is approximately 125,000 new cases each year. Although seizure disorders may start at any age, the highest incidence of seizure is among children younger than age 2 and persons older than age 65.

Men are more likely to have a seizure disorder than women. In most newly diagnosed cases, no specific cause is identified. Many factors have been implicated in the etiology of seizure disorders, such as severe head trauma, CNS infections, and stroke. Children with motor disabilities present from birth, such as those with cerebral palsy, have increased risks. Children who are mentally challenged and who may or may not have genetic disorders may have an increased risk for a seizure disorder. When both conditions coexist, 50% or more of patients affected can be expected to develop a seizure disorder by age 20. In addition, children who experience febrile seizures are at increased risk for developing a seizure disorder during their lives.

Seizure disorders frequently occur in families. The parents, siblings, and offspring of a patient with a seizure disorder are more likely (3%–5%) than the general population to have a seizure as a result of both genetic and environmental causes.

Pathophysiology

A seizure is an uncontrollable paroxysm that often includes muscular convulsions. The paroxysm is the bodily effect of abnormal repetitive firing of neurons in the brain. The motor cortex, the hippocampal formation, and the amygdaloid complex are regions that are especially susceptible to developing these abnormal firing patterns.

A great variety of disorders can initiate seizures, including drug overdose (e.g., from antihistamines, cholinesterase

inhibitors, methylxanthines, muscarinic agonists, and tricyclic antidepressants), drug withdrawal (e.g., from alcohol, hypnotics, and tranquilizers), head trauma, strokes, degenerative brain disease (e.g., mesial temporal sclerosis), infections, tumors, and developmental brain defects (e.g., cortical dysgenesis and vascular malformations). The common epileptogenic feature of all these disorders is that they can cause populations of brain neurons to become hyperexcitable.

One category of disorders that cause hyperexcitable neurons includes systemic problems—fever, infection, sleep deprivation, and metabolic imbalances (hypocalcemia, hypoglycemia, hyponatremia, and hypoxia). These problems cause ionic changes throughout the body. For example, hyponatremia causes a relative increase in extracellular potassium concentrations systemically. In the CNS, increased extracellular K^+ at the neuron cell membrane lowers the threshold for triggering axon potentials, and for this reason acute hyponatremia (at levels less than 120 mEq/L) leads to seizures.

The excitability of neuron cell membranes is regulated by intramembrane molecular complexes that either actively move molecules from one side to the other (i.e., ion pumps) or control gated ion channels. Genetic defects in the manufacture of ion pumps or ion channels can cause seizures. Some of the uncommon heritable epilepsies (e.g., *generalized epilepsy with febrile seizures* and *benign familial neonatal convulsions*) are known to be caused by mutations in ion channels. It is believed that other heritable seizure disorders are caused by as yet unidentified genetic defects in ion pumps or ion channels.

The antiepileptic drugs phenytoin (Dilantin), carbamazepine (Tegretol), and lamotrigine (Lamictal) reduce the hyperexcitability of neuron cell membranes by slowing the activation of sodium channels; ethosuximide (Zarontin) decreases the activity of certain calcium channels.

Much of the excitatory activity throughout the brain is via glutamatergic synapses, and increasing the amount or the effect of glutamate in the brain predisposes a person to seizures. Normally, the amount of extracellular glutamate in the brain is minimized by astrocytes, which selectively take up glutamate. Experimental studies have shown that a brain will have seizures if its astrocytes cannot efficiently clear extracellular glutamate from the vicinity of synapses.

Glutamate depolarizes neurons by activating specific receptors that open channels for small cations, such as Na^+ and K^+. These are called *ionotropic receptors,* and the CNS contains at least three different ionotropic glutamate receptors. High brain concentrations of agonists, such as street drugs, cocaine, and angel dust (phencyclidine), may induce seizures. These agonists (chemicals) bind to a receptor and activate it to produce a biological response (the seizure).

Glutamate also activates another family of membrane receptors. These receptors alter cell metabolism and are called *metabotropic glutamate receptors.* Other types of metabotropic glutamate receptor agonists, however, have the opposite effect—activating these receptors decreases the excitability of synapses.

Much of the inhibitory transmission throughout the brain is via GABA-ergic synapses. In general, neurons using the transmitter gamma-aminobutyric acid (GABA) act to prevent the spread of abnormal bursts of neuronal discharges. Reducing the availability of GABA predisposes a person to seizures. Drugs, such as 3-mercaptopropionic acid, that interfere with the synthesis of GABA cause seizures. Vitamin B_6 (pyridoxine) is required for the biosynthesis of GABA, and vitamin B_6 deficiency can lead to seizures. Drugs that interfere with GABA receptors or with GABA binding to receptors can also cause seizures; such drugs include bicuculline, penicillin, and picrotoxin.

GABA agonists have the opposite effect—they counteract a person's tendency to have seizures. Benzodiazepines (e.g., diazepam [Valium]) are GABA agonists and are used to treat seizure disorders. Gabapentin (Neurontin) and pregabalin (Lyrica) are drugs that increase GABA. Barbiturates, which potentiate the actions of both GABA and benzodiazepines, are antiepileptic drugs. Likewise, the antiepileptic drugs tiagabine and vigabatrin both work by enhancing GABA-mediated inhibitory circuitry. Besides the GABA-ergic pathways, noradrenergic circuits (originating mainly in the reticular formation of the brainstem) also appear to play an antiseizure role, because damage to noradrenergic pathways can predispose a person to seizures.

During a seizure, brain metabolism accelerates in the affected areas. Oxygen consumption, glucose use, and lactate levels increase; free fatty acids are released into the blood; extracellular concentrations of neurotransmitters rise; and cerebral blood flow increases. Between seizures, metabolism in the affected areas drops below normal. Prolonged seizures increase the local transcription of certain genes and the synthesis of certain proteins (although the synthesis of most proteins declines). The abnormal metabolic activities associated with repeated seizures produce long-term changes in brain circuitry that make further seizures more likely. One reason for controlling epilepsy is to prevent these lasting increases in neural sensitivity.

Clinical Presentation

Subjective

The patient may or may not be aware of a seizure. He or she may wake up slightly confused, on the floor, or in a different position. The patient may have been incontinent. If an aura was present, the patient will know that a seizure took place.

Objective

The most difficult decision in evaluating a presumed seizure is determining if it was a seizure or another type

of condition (such as syncope, a pseudoseizure, or a panic attack). Pseudoseizures are associated with seizure-like symptoms but are not associated with EEG changes. Up to 80% of pseudoseizures are associated with early sexual abuse, especially in females. Not all events associated with abnormal body movements are seizures. Some events may be mistaken for seizures on initial presentation but must be differentiated from them because their treatment is different. Careful and detailed history taking remains the cornerstone of accurate diagnosis of a seizure disorder. A diagnosis of seizure disorder is primarily a historical diagnosis; the initial assessment and approach to management is based on the patient's clinical history, especially on an accurate description of the event in question. Psychogenic nonepileptic seizures (PNES) are sometimes referred to as pseudoseizures, but that is not the case. PNES are similar to epileptic seizures but arise from psychological disturbances rather than abnormal electrical brain activity. They are most common in women aged 15 to 35 but may affect men.

It is often very useful to ask the patient for a description of specific attacks. This should include the last attack actually witnessed, as well as the first seizure. The setting in which the attacks occurred may be significant for differential diagnosis. A careful review of the events occurring days before the seizure is important. Points of particular interest include relation of events to the sleep–wake cycle. It is important to determine if the seizure was stimulus provoked. Many things can provoke a seizure, such as extensive sleep deprivation or use of stimulants. Questions need to be asked to determine if there is an aura associated with the seizure. The regular presence of an aura indicates that the seizure is probably localized. Obtaining a history of the patient's life, including social, behavioral, and cognitive functioning, as well as a previous health history and family history of seizure disorders or neurological disorders, is crucial. History of postictal behaviors should be elicited—how long did it take to recover to normal function? Other important questions should address any history of neonatal seizures or febrile seizures or history of previous brain injury. The clinician should also ask whether there is a personal or family history of other neurological, mental, or systemic disease.

The physical exam should take into account the interval since the patient's most recent seizure. If the exam is performed within minutes or hours of an attack, the practitioner should look for postictal signs, even of a minor grade. When the examination is performed after some time has elapsed since the last seizure, the practitioner's main objective is to determine whether there are signs of permanent nervous system dysfunction, favoring a diagnosis of symptomatic epilepsy, and if there is evidence of a focal brain lesion. The clinician should look for signs of increased intracranial pressure, although this is rather uncommon. Additional neurological signs of interest include language difficulties and possible evidence of drug toxicity, such as nystagmus, ataxia, diplopia, or tremor.

An eye and visual examination should aim to detect papilledema and visual field loss associated with focal brain lesions. Ocular motor abnormalities may suggest involvement of the brainstem or floor of the third ventricle. Cranial nerves should be assessed to determine if neurological signs or symptoms are present. The findings on the patient's motor exam should be symmetrical. Weakness could indicate a brain lesion. A cardiovascular exam should also be performed to detect the presence of a heart arrhythmia or murmur, which may suggest a syncopal episode rather than a seizure.

Diagnostic Reasoning

Diagnostic Tests

Initial tests should be done to rule out other nonneurological causes of the seizures. Tests may include complete blood count with differential; blood glucose; serum electrolytes; liver function tests; serum calcium, urinalysis; a drug screen or blood alcohol level, if appropriate; and blood levels to assess target levels if the patient is on antiseizure medications.

Subsequent tests that may lead to the cause of the seizure disorder are EEG, computed tomography scan, or magnetic resonance imaging (MRI); lumbar puncture, if CNS infection is suspected; and ECG, if warranted.

To diagnose PNES, the gold standard is video EEG monitoring. In addition, serum prolactin levels may be drawn within 30 minutes of ictus. The levels will be elevated in generalized tonic-clonic seizures and partial complex seizures, but not in PNES. PNES must be accurately diagnosed because these patients do not require seizure medications, but rather mental health counseling.

Differential Diagnosis

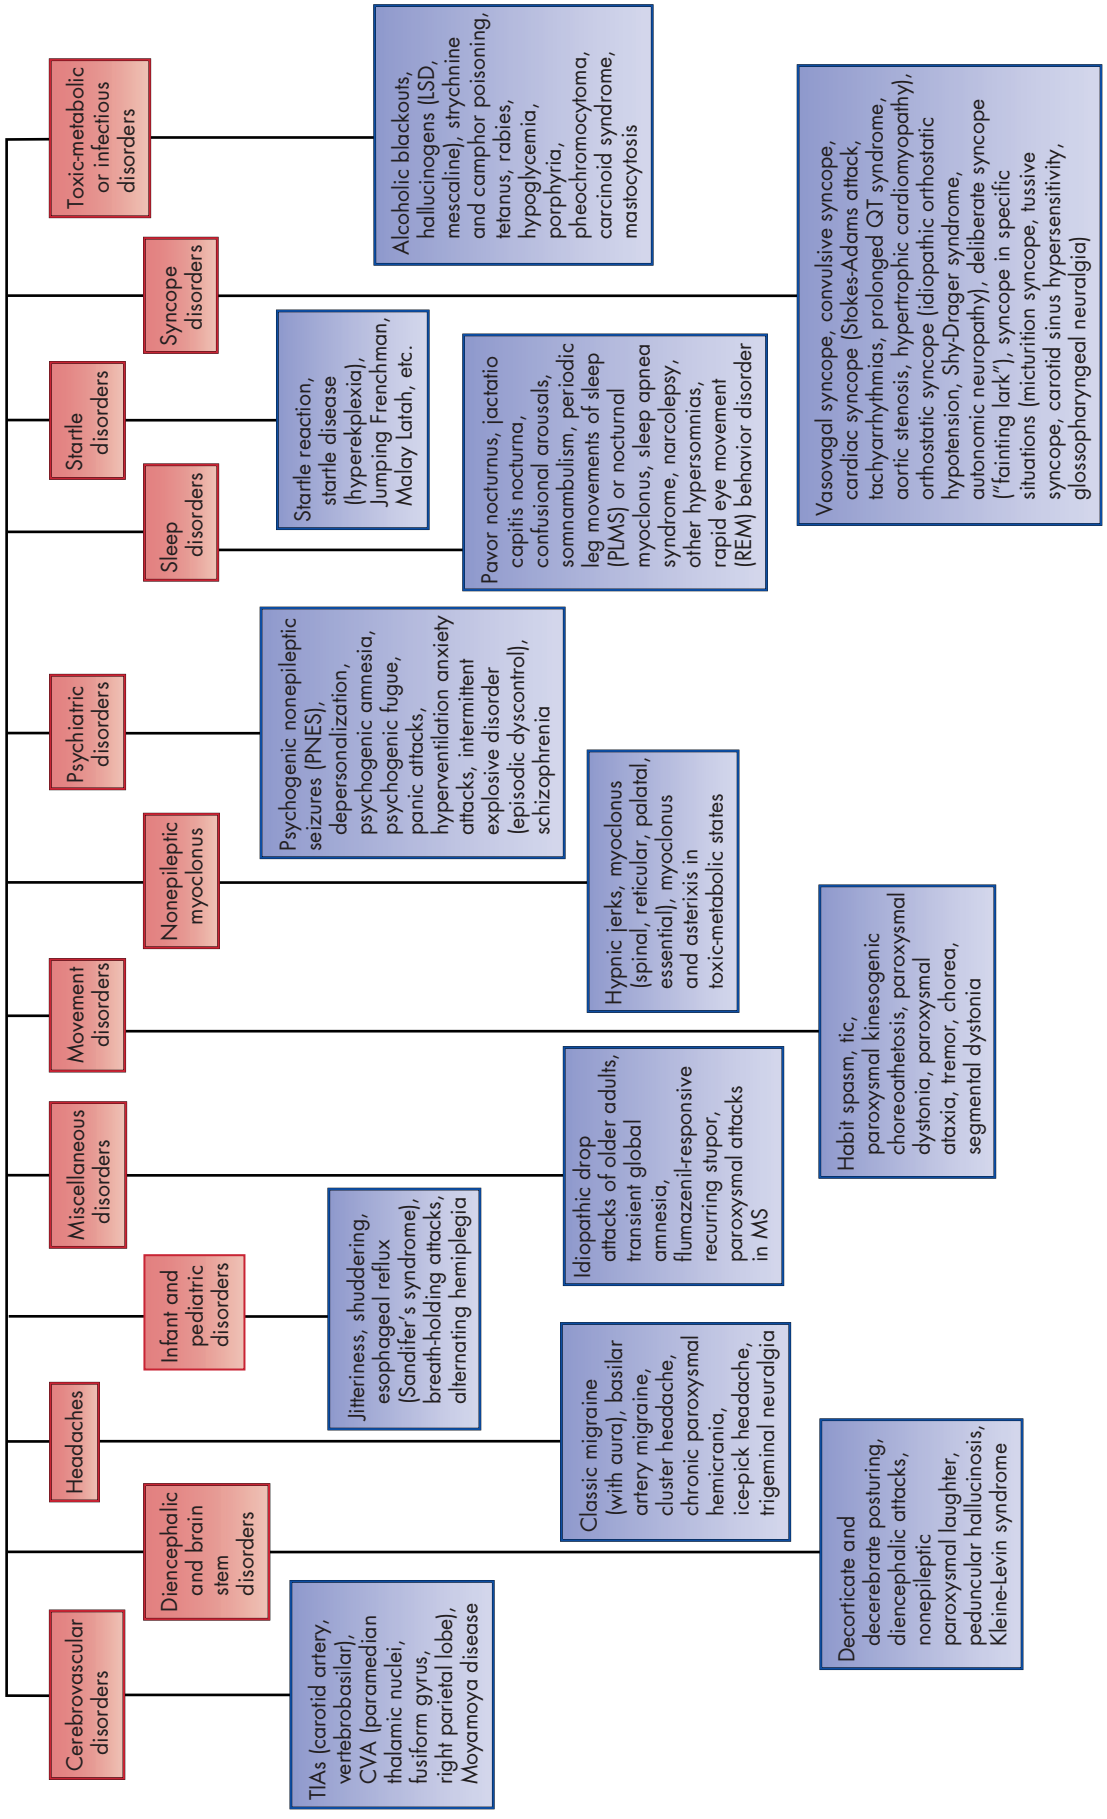
The patient should be reevaluated to confirm the diagnosis and to exclude others in several situations. If the attacks are uncontrolled despite rigorous treatment and if the diagnosis of a seizure disorder has never been supported by EEG or other tests, review and repeat testing are indicated. Drug-seeking behavior, dramatic presentations with multiple attacks in public, and repeated visits to the emergency department should also invite skepticism. Common disorders such as migraine, panic attacks, and sleep apnea can develop in addition to a seizure disorder. Additional differential diagnoses are included in Differential Diagnosis Flowchart 6.6.

Management

The main principle of seizure management is to prevent the recurrence of seizures with anticonvulsant medications while avoiding adverse effects from the drugs. The clinician should refer the patient to a neurologist, who should make the decision to start treatment after a complete review of the risk of further seizures is discussed

Differential Diagnosis Flowchart 6.6

Seizure Disorders



with the patient. Before initiating treatment, the type of seizure the patient experiences should be identified and classified accordingly. Typically, treatment for a single, isolated seizure episode is the identification and treatment of the underlying disorder. Antiepileptic therapy is usually not required unless the patient experiences recurrent seizure activity or a largely resistant/irreversible underlying disorder is revealed. Some structural lesions are clearly associated with recurrent seizures. These include brain tumor and arteriovenous malformation (AVM). When these conditions are diagnosed after a single seizure, there should be no hesitation in initiating pharmacological treatment; however, a much more common situation is the one in which the initial evaluation fails to reveal a specific causative factor for the seizure. Then the neurologist must carefully evaluate the risk of subsequent seizures. The choice of antiepileptic therapy must oftentimes be individualized for each patient. Choice of therapy is contingent on comorbid conditions, medication interactions, adverse side effects, patient age, and type of seizure.

Some patients have only one seizure. For these patients, the probability of a second seizure is less than 10% in the first year following the seizure and approximately 24% by the end of 2 years after the first seizure. The impact of a second seizure depends on the patient's lifestyle. Treatment may be indicated for patients who need to be able to drive or for those who face significant risk of injury or loss of self-esteem from a second seizure. The risk of recurrence is greatest in the first 2 years, so if treatment is initiated, it probably can be halted after this highest-risk period passes.

If the decision to treat is made, accurate identification of the seizure type is very helpful in choosing the drug for the best outcome. Drugs Commonly Prescribed 6.1: Seizures presents suggested medications based on the different types of seizures. Although only the first-line medications are listed, there are many drugs given in combination with these medications. Lacosamide (Vimpat) is one of these adjunctive medications used for added partial-onset seizure control. Others are not included here because a patient will initially be prescribed medications by the neurologist. Some neurologists choose to begin long-term therapy with anticonvulsant medications after a single seizure in the following situations: if the single seizure is rapidly followed by a second seizure; if an MRI or EEG shows evidence of a structural lesion such as a brain tumor, AVM, or infection; if there is a history of a seizure disorder in a sibling; or if there is a history of a brain injury or stroke.

Once the appropriate drug has been chosen based on the seizure type, serum levels should be assessed for baseline hematological and hepatic parameters. Blood levels should be checked two to three times in the first 6 months of therapy to determine if target levels have been attained and are being maintained.

Partial Seizures

The patient may resemble an intoxicated or drugged person. He or she may stare without focusing or speaking, appear to be fidgeting, make chewing movements, or smack the lips.

During the seizure:
- Do not attempt to restrain the patient.
- Gently move the patient away from dangerous objects.

After the seizure:
- Stay with the patient until the patient is fully alert.
- Reassure others that the behavior was medically caused.

Generalized Seizures

The patient may have a warning sign, cry out or scream, then fall down and rhythmically jerk arms and legs in a strong movement that cannot be stopped.

Before or during the seizure:
- Remove the patient's glasses (if wearing) and help the patient lie down in a prone position, but do not restrain.
- Clear the area of dangerous objects.
- Loosen tight clothing around the patient's neck.
- Do not force any object into the patient's mouth.

After the seizure:
- Turn the patient to one side to allow the patient's mouth to drain.
- Stay with the patient until he or she is fully awake.
- If the patient has a known seizure disorder, it is not necessary to call for medical help unless an injury has occurred, the seizure lasts longer than 3 minutes, a second seizure occurs, or the patient requests help.

Follow-up and Referral

If the seizures are controlled and blood levels are adequate, the clinician can monitor them every 6 months (twice each year) for the duration of treatment. If the seizures are not controlled with adequate doses and levels of the medication, the clinician should refer the patient to a neurologist for a second opinion and possible combination therapy.

Patient Education

Education about seizure disorders can provide the patient with understanding and a sense of control over the illness. It is necessary to recognize that to the affected individual, this condition is more than seizures. The patient and his or her family may be overwhelmed by thoughts of disability and impaired quality of life. Such factors as age at onset, duration of seizure activity, frequency, seizure type, associated neurological abnormalities, and associated environmental factors contribute to the degree of disability in each patient. Education is ongoing and should be constantly reinforced. Patients and their families should be referred to seizure literature

Drugs Commonly Prescribed 6.1 Seizures

Drug	Indication	Adverse Reactions and Prescribing Considerations
valproic acid (Depakene)	Absence seizures (petit mal) and myoclonic seizures	Optimum drug level is 50–100 mcg/mL.
divalproex sodium (Depakote)		Take with food. May cause headache, unsteadiness, blood dyscrasias, urticaria.
clonazepam (Klonopin)		Optimum drug level is 20–80 mg/mL. Potentiates CNS depression with alcohol.
phenytoin (Dilantin)	Partial or generalized seizures	Optimum drug level is 10–20 mcg/mL. May cause ataxia, blood dyscrasias, peripheral neuropathy.
topiramate (Topamax)		May cause hyponatremia, weight loss, mental fuzziness, stimulation.
carbamazepine (Tegretol)		May cause dysarthria, ataxia; may exacerbate myoclonic seizures, hyponatremia.
valproic acid		May take with food. May cause nausea and vomiting, indigestion, diarrhea, anorexia, depression, transient hair loss.
phenobarbital (Luminal)		Do not take when pregnant or breastfeeding. May decrease effectiveness of beta-adrenergic blockers, corticosteroids, digoxin, oral contraceptives, warfarin. May cause agitated mood, confusion, low blood pressure, nausea and vomiting.
primidone (Mysoline)		May cause sedation, nystagmus, irritability, megaloblastic anemia.
oxcarbazepine (Trileptal)	Partial seizures	Potentiates CNS depression with alcohol. Potentiates action of phenobarbital and phenytoin, ataxia, fatigue, gastrointestinal upset.

available through the Epilepsy Foundation of America as soon as they are diagnosed, because the well-informed patient is the best advocate for his or her own care. Using the *Circle of Caring* model and coming to know the patient and what matters most to him or her will assist in helping the patient reach his or her highest potential.

A patient with a seizure disorder lives with the fear that a seizure may strike at any moment. Persons with a seizure disorder fear dying during a seizure. They also fear personal injury. This fear is justified; therefore, health-care providers need to counsel patients regarding commonsense safety issues. Persons with a seizure disorder should take showers instead of baths and only when someone else is home. Automatic safety devices that adjust water temperature and shut off water when the shower drain is blocked can be installed. Persons with a seizure disorder should use an occupied sign on the bathroom door rather than locking it. They should swim only with a buddy who is aware of their diagnosis and knows what to do if a seizure occurs while the individual is swimming. When cooking, patients should be instructed to use the microwave or back burners on the stove and keep pot handles turned inward. They should be encouraged not to smoke, but if they must, they should never smoke when alone. Their home should be evaluated to identify any safety hazards and to develop a risk-reduction plan. Families, friends, and coworkers need to be taught what to do in case of a seizure.

Patients with a seizure disorder and their caregivers should be apprised of the risks of harm. In comparison with the general population, children and adolescents with seizure disorders have a 1,000-fold greater risk of drowning during bathing and a 70-fold greater risk of drowning while swimming. Burns tend to occur in the home and are most commonly associated with cooking, showering, and use of space heaters. Driving needs to be discussed at length. The loss of driving privilege is very serious because it restricts a patient's mobility and, therefore, independence. Each state has different laws governing the granting of driver's licenses for individuals with a seizure disorder. At the federal level, the U.S. Department of Transportation has regulations that bar anyone with a history of seizures from being licensed to drive in interstate trucking. The purpose of the driving

restrictions is obvious—to protect the public. Although only six states require health-care providers to report patients who have been diagnosed with seizure disorder, all practitioners have the responsibility to advise their patients of the medical risks, legal requirements, and recommendations regarding driving. Educational and support materials are available through the Epilepsy Foundation of America.

DEGENERATIVE DISORDERS

AMYOTROPHIC LATERAL SCLEROSIS (LOU GEHRIG'S DISEASE)

Amyotrophic lateral sclerosis (ALS) is a progressive neurological disorder that involves destruction of the anterior horn motor cell in the spinal cord or the brainstem. The etiology is not known. It is universally fatal, though the duration of the disease is usually 5 to 6 years. If it begins with brainstem involvement, there is usually a problem with aspiration, and the course is more rapid.

Unlike in multiple sclerosis, the symptoms of ALS are symmetrical. Most commonly, it presents with a simple gait disturbance caused by weakness or a change in voice. The diagnosis is made via electromyographical studies. There is no treatment for ALS.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a chronic, potentially disabling, and demyelinating disease of the CNS that begins most commonly in young adulthood and is most frequently associated with periods of visual changes, intermittent weakness and numbness, and loss of balance. These may occur intermittently, with relapses and remissions, or may be progressive. MS is the most common cause of disability in young adults. Multiple areas of CNS or white matter inflammation, demyelination, and glial scarring or gliosis characterize MS. MS is thought to be a disorder of the T and B lymphocytes that creates an abnormal antibody that invades the CNS and attacks the myelin. There is no known cause for this change.

There are four types of MS, each with its own course and progression. The *relapsing–remitting* type of MS is characterized by acute attacks, with either a full recovery or some residual deficits between episodes. The *primary progressive* type of MS has a steady disease progression, with possibly some plateaus and remissions. *Secondary progressive* MS is a combination of the first two types, beginning as a relapsing–remitting disease but then slowly acquiring the primary progressive characteristics. The *progressive–relapsing* type of MS is a progression of the disease (including relapses and remissions, with or without recovery) on a steady downhill course, compared with the relapsing–remitting variety, in which the disease progression may stop at any point.

The clinical course of MS varies. Prognosis is a common concern. Although there are no definitive prognostic indicators, the following are general guidelines. Good prognostic indicators include minimal disability after 5 years of onset, complete and rapid remission of initial symptoms, onset at age 35 or younger, only one symptom during first year, acute onset of the first symptoms, brief duration of most recent exacerbation, long first remission, optic neuritis, or sensory symptoms. Poor prognostic indicators include late onset, chronic progressive course, motor symptoms, polysymptomatic onset, and vertigo. Patients are concerned about disability. After 15 years, 50% to 60% of patients with MS remain ambulatory, 10% to 20% need assistance devices to ambulate, and 15% to 30% are bedridden.

Epidemiology and Causes

MS occurs worldwide, but there are differences in both incidence and prevalence on the basis of race, sex, genetics, geographical location, and age at the time of probable exposure to a virus or other infectious agent. MS is most commonly diagnosed between ages 20 and 50. The first symptoms of the disease usually occur between ages 20 and 40. If the disease is diagnosed after age 50, it tends to have a more progressive course. The disease affects two to three times more women than men. It is more common among Caucasians and people of northern or central European descent. Asians and Africans/persons of African descent are at lower risk.

Some epidemiological findings suggest a relationship between MS and an unknown environmental factor, possibly a viral exposure during childhood. This exposure may lead to the entry of immune cells into the CNS, where a population of T cells becomes sensitized to a CNS antigen. After years of latency, an environmental trigger may lead to an upregulation of circulating mediators or T-cell activation that may set off an episode of demyelination and clinical disease.

The cause of MS is unknown. There are many theories on possible causes, including genetic susceptibility, autoimmune mechanisms, viral infections, and environmental factors. One leading hypothesis is that of a cell-mediated immunopathological response directed against myelin in genetically predisposed persons.

Studies have suggested that susceptibility to MS is inherited. The higher incidence in twins and in certain families provides support for this genetic susceptibility. The major histocompatibility complex on chromosome 6 has been identified as one genetic determinant for MS. Although genetic factors may contribute to an individual's susceptibility, they are neither sufficient nor necessary for development of MS. Clinical expression of the disease is likely to require additional exposure to one or more environmental factors, which are as yet undefined.

There is evidence of autoimmune mechanisms in the pathogenesis of MS. In a normal immune response, foreign antibodies are processed and presented to T-cell helpers by antigen-presenting cells and macrophages. These T-helper cells recognize foreign peptides bound to major histocompatibility complex (MHC) molecules, become activated, and release various cytokines, tumor necrosis factor, and interleukins that augment the immune response to a particular antigen. These particular class II MHC molecules are usually found only on cells involved in an immune response. In MS, class II MHC induction has been shown to occur in CNS tissue. In peripheral blood of patients with MS, several nonspecific changes are seen that are similar to those in other autoimmune diseases. Suppressor T lymphocytes are decreased in both function and number. Excessive immunoglobulin is present, especially high levels of immunoglobulin G (IgG). Suppressor cell inducers are decreased in many patients with progressive disease.

Pathophysiology

MS is a disease of the CNS stemming from the progressive patchy demyelination of axons. In MS, local immune reactions destroy CNS myelin and cause the death of oligodendrocytes. Astrocytes react to these injuries by proliferating. At the same time, many of the axons remain intact.

MS is most commonly characterized by neurological problems that periodically flare up and then abate. The symptoms reflect repeated episodes of demyelination in new parts of the white matter throughout the CNS. The specific neurological deficits of an MS patient depend on the regions of the CNS that have been affected. For example, lesions in the optic nerve produce blindness, lesions in the corticospinal tracts produce weakness or paralysis, lesions in the posterior columns produce unusual sensations or numbness, lesions in the medial longitudinal fasciculus produce double vision, and lesions in the vestibular pathways produce dizziness.

Areas of MS damage form sharply defined plaques, which are typically found around venules. MS plaques tend to be large (greater than 6 mm in diameter) and oval shaped; over time, the plaques become more and more widely distributed. Newly forming plaques, in which demyelination is not yet complete, are filled with lymphocytes, plasma cells, and macrophages. Older plaques have no myelin in their centers and contain only fibrous astrocytes and unmyelinated axons. Axon damage inevitably follows, but this appears to be a secondary phenomenon and occurs slowly. Between the plaques, myelin is also affected, although here the damage is not as dramatic.

MS plaques are the result of immune reactions, and the state of the disease is reflected in the immune indicators in the cerebrospinal fluid (CSF). When the disease flares up, the CSF has an increased number of lymphocytes (although usually less than 50/mcL). The CSF will also contain elevated levels of immunoglobulins, the majority of which are IgGs. As MS progresses, specific oligoclonal bands are found in the CSF, regardless of the current state of the disease symptoms.

It is likely that MS is an autoimmune disease, but the triggers for the immune destruction of myelin are unclear. Evidence suggests that genetically susceptible individuals develop the disease many years after exposure to certain environmental factors. One hypothesis is that these factors are viruses that happen to consist of molecules with shapes similar to regions of certain myelin molecules. Alternatively, the initial trigger may be a less specific infection that causes leakage in the blood–brain barrier and thus sensitizes peripheral lymphocytes to normal but previously unseen CNS myelin antigens.

Clinical Presentation

Subjective

The most common presenting symptoms in MS include sensory disturbances of the extremities, spasticity and weakness of legs, bladder and bowel dysfunction, ataxic gait, paresthesias in the extremities, fatigue, optic neuritis, and trigeminal neuralgia. Seventy-five percent to 95% of patients with MS experience MS-related fatigue. Exacerbations and remissions occur frequently, and signs and symptoms may indicate more than one lesion. The clinical course is variable and usually occurs in two phases, relapsing–remitting and chronic progressive. In the early phase, the patient presents with symptoms that may last from days to months and may disappear abruptly. The initial symptom is often blurred or double vision, red-green color distortion, or sometimes even blindness in one eye. The next most common complaints are speech impediments, tremors, and dizziness. The patient most often presents with the same chief complaint during the exacerbation, but some of the events will involve new symptoms. After several years, many patients enter the chronic progressive phase of MS, with a mean time from onset of the initial symptom to this phase from 6 to 7 years. In approximately 20% of patients, the disease begins in this phase; 50% of patients enter the phase within 10 years.

Objective

Clinical manifestations of MS may be transient. The patient may experience unusual sensations and have difficulty describing these. Signs and symptoms may be diverse and appear to include all the symptoms that can occur from injury to any part of the spinal cord and cerebral cortex. Symptoms tend to vary in nature and severity. Frequently, complete remission of the first symptoms occurs, but with subsequent attacks, remissions are incomplete or do not occur. The clinical manifestations depend on the areas of the CNS involved. The brainstem, spinal cord, optic chiasm, and cerebellum are common locations.

The clinician should assess the patient for common visual symptoms, including diplopia, blurred vision, diminution or loss of visual acuity unilaterally or bilaterally, and visual field defects. These symptoms may begin to manifest over a period of hours to days. Involvement of the fifth cranial nerve causes pain sensation, impairment, and diminished or lost corneal reflex. The diagnosis of MS should be considered whenever a young adult develops trigeminal neuralgia.

Limb weakness is a common sign of MS, presenting as monoparesis, hemiparesis, or tetraparesis. Fatigue out of proportion to muscle weakness is common. Fatigue may be persistent or related to physical activity or mental exertion. Fatigue interferes with ADLs in 75% of patients with MS. There may be concomitant ataxia and spasticity. Cerebellar involvement causes dysarthria, scanning speech, tremor, gait ataxia, and incoordination of limbs and trunk. Spasticity limits activities, and leg stiffness may interfere with walking or transferring. In patients with severe spasticity, there may be extensor or flexor spasms either spontaneously or on attempted movement. Spasticity may cause pain, interfere with sleep, or prevent movement.

Bladder symptoms are common, including incontinence and frequency or urgency. Patients may have a small-capacity, spastic bladder or a large, flaccid bladder with overflow incontinence. Loss of libido and erectile dysfunction are common in men with MS; in women with MS, sexual dysfunction most commonly involves lack of lubrication and failure to reach orgasm. Although bowel symptoms are uncommon, constipation may occur.

Sensory impairment and paresthesias are common. Patients may complain of tingling or numbness in the face, limbs, or trunk. A sensation of "electricity" down the back after passive or active neck flexion is called Lhermitte's sign and is indicative of a lesion in the posterior column in the cervical spinal cord. Pain is also recognized as a symptom of MS. Pain may be associated with trigeminal neuralgia, flexor–extensor spasms, tonic spasms of the limbs, and local pain syndromes such as constricting pain around a limb, burning pain, pseudoradicular pain, foreign body sensation, headache, neuralgic pain, and pain caused by pressure sores.

Patients may experience depression, euphoria, subtle aphasic manifestations, or cognitive changes. Patients may have difficulty with tasks that require processing new information rapidly, recalling newly acquired knowledge, and problem-solving. Attention deficits may be present early in MS, even before the onset of physical symptoms. In general, the longer the history of MS, the greater the attention impairment. Memory and abstract reasoning may be affected, as well as the capacity to direct attention (CDA). CDA is critical to the management of a chronic illness, and a strong CDA is necessary to learn new information, implement therapeutic self-care, and handle necessary and difficult adjustments in daily life.

Diagnostic Reasoning

Diagnostic Tests

There is no specific test for MS. The diagnosis must be based on multiple signs and symptoms with a history of remissions and exacerbations. The diagnosis is also based on the ability to demonstrate, on the basis of patient history, neurological examination, and diagnostic tests, the existence of lesions involving different parts of the CNS. An initial clinical neurological examination focused on the patient's signs and symptoms is necessary. Tests should be done to assess for increased muscle tone in legs, decreased motor strength, changes in visual acuity, bilateral clonus of ankles and knees, positive Babinski's sign, and a decreased appreciation of vibration or position sense in arms and legs. There are several instruments available to assess functional status. The Mini–Mental State Exam (MMSE) may be administered to screen for global and focal cognitive impairment.

For a diagnosis of MS to be made, two or more parts of the CNS must be involved, and signs of MS must consist predominantly of dysfunction of the optic nerve (affecting vision) or dysfunction of the corticobulbar system (affecting speech, swallowing), the corticospinal system (affecting strength), the cerebellar system (affecting gait, coordination), the medial longitudinal fasciculus system (affecting internuclear ophthalmoplegia, with diplopia and nystagmus), the spinocerebellar system (affecting balance), and the long-tract sensory system (causing position and vibratory disturbances). In addition, CNS involvement must occur in one of the following patterns: two or more episodes of exacerbations, separated by 1 month or longer and lasting more than 24 hours, with subsequent recovery (i.e., relapsing–remitting MS); a slow or stepwise progression of signs and symptoms over a period of at least 6 months (i.e., primary progressive MS); a clinical history of clearly defined exacerbations and remissions, with or without complete recovery, followed by a slow progression of signs and symptoms over a period of at least 6 months (i.e., secondary progressive MS); progression in signs and symptoms and occasional attacks (i.e., progressive relapsing MS); or no relapse or progression of attacks in the past 18 months (i.e., stable MS).

A lumbar puncture with an evaluation of CSF for the presence of immunoglobulins, lymphocytes, and oligoclonal IgG bands may provide supportive data for a diagnosis of MS. Immunoglobulin synthesis within the CSF can be expressed by formulas that adjust for passive transfer of proteins across a damaged blood–brain barrier. Oligoclonal IgG bands can be detected by electrophoresis of CSF and are present in the CSF of 90% of patients with MS, but this finding is not specific to MS. An increase in CSF basic myelin protein

may confirm that an acute MS exacerbation has occurred. Elevated values (greater than 9 ng/mL) suggest demyelination.

Cortical-evoked responses or evoked potentials are of value in demonstrating clinically unsuspected lesions. Visual responses are abnormal in 75% to 97% of patients with MS. Somatosensory responses are abnormal in 72% to 87%, and brainstem responses are abnormal in 50% to 70% of patients with MS.

Magnetic resonance imaging (MRI) is a sensitive, objective measure of plaques and is used to measure the outcomes of treatment. Periodic recording of the volume and number of lesions detected in the brain by MRI can assist the clinician in monitoring the extent of the disease. Pathologically, areas of contrast enhancement observed by MRI correlate with active perivascular inflammatory damage. In addition, the MRI should be obtained as soon as possible in all patients presenting with an isolated demyelinating syndrome involving the CNS to exclude other possible neurological conditions (Level I; Filippi et al, 2011).

A clinically definitive diagnosis of MS requires either (1) evidence from history of two episodes at least 1 month apart, signs of one lesion on examination, and evidence from evoked responses or MRI of other lesions or (2) evidence from both history and neurological exam of more than one lesion. A laboratory-supported definitive diagnosis of MS requires evidence from two lesions in either history or neurological exam. If only one lesion is evident on examination or history, at least one more lesion must be evident in MRI or evoked response testing. The CSF IgG pattern and content should also be abnormal. A clinically probable diagnosis of MS requires that either history or examination, but not both, provides evidence of more than one lesion. If only one lesion is evident by history or neurological exam, MRI or evoked responses may provide evidence of additional lesions. If the collaborating neurologist is uncertain of the MS diagnosis, reevaluation of the patient may be needed.

Differential Diagnosis

Other CNS diseases may resemble MS clinically or radiologically. These are lymphomas and gliomas of the hemispheres, spinal cord, and brainstem; collagen vascular disease such as systemic lupus erythematosus (SLE); human T-cell lymphotrophic virus type I (HTLV-I); HIV infection; encephalopathy; Lyme disease; peripheral neuropathy; Behçet's disease; and sarcoidosis.

It is important to consider Lyme disease as a differential diagnosis because chronic CNS infection with *Borrelia burgdorferi* can cause spastic paraparesis, cerebellar signs, and cranial nerve palsies. Patients with Lyme disease will have a history of erythema migrans plus arthralgias or evidence of cardiac manifestations, as well as positive Lyme titers.

Patients with SLE will have a positive antinuclear antibody and anti-DNA antibody titers, as well as joint or renal involvement.

Patients with suspected MS should be tested for HIV, HTLV-I, and syphilis (human T-cell lymphoma virus) because these diseases may mimic MS. Vascular disease, tumors of the brain and spinal cord, arteriovenous malformations, and arachnoid cysts may have relapsing and remitting signs that mimic MS. MRI is usually the definitive test to rule out these causes.

Management

The principles of management include three major goals: to delay the progression of the disease, manage chronic symptoms, and treat acute exacerbations. There is no known cure for MS. Therapeutic regimens are either disease specific or symptomatic (immunosuppressive or immunomodulatory). Disease-modifying therapy should be considered early in the course of treatment, before neurological deficits have persisted for more than 6 months. Treatment decisions on individual patients should be made based on both the probability of severely disabling disease and the course of disease. Follow-up should be based on progression of disease and the treatment of symptoms and exacerbations. See Drugs Commonly Prescribed 6.2: Multiple Sclerosis.

Glucocorticoids are the mainstay of treatment for acute exacerbations. Glucocorticoids have both immunomodulatory and anti-inflammatory effects, which restore the blood–brain barrier, decrease edema, and may improve axonal conduction. The decision of whether or not to treat an acute exacerbation depends on the functional limitations of the patient, the level of patient discomfort, and objective evidence of neurological dysfunction such as profound weakness/motor dysfunction, visual disturbances, or cerebellar dysfunction. If symptoms of an exacerbation are severe enough to require treatment, IV methylprednisolone (Depo-Medrol) with or without an oral prednisone taper is administered. In sudden, severe exacerbations that do not respond to glucocorticoid therapy, the use of plasma exchange therapy may provide a benefit to patients and should be considered in refractory severe relapsing forms of MS.

Patients with relapsing–remitting MS benefit from early aggressive treatment with disease-modifying agents. The initial treatment of choice for patients with relapsing–remitting MS is either interferon 1a, interferon 1b, or glatiramer acetate. These agents have proved to be equally efficacious in the treatment of relapsing–remitting MS. Interferons are a class of cytokine that halts disease progression and inhibits the accumulation of inflammatory lesions in the CNS white matter as evidenced by MRI; interferons also reduce the number and severity of clinical relapses. Glatiramer acetate is essentially a polymer composed of four amino acid units found in myelin basic protein. It is thought to act as an

Drugs Commonly Prescribed 6.2 Multiple Sclerosis (MS)

Drug	Indication	Adverse Reactions and Prescribing Considerations
methylprednisolone (Depo-Medrol)	Exacerbation	Masks infection. Adverse effects: glaucoma, cataracts, secondary infections, hypokalemia, hypocalcemia, hypernatremia, hypertension, psychotic disorders, myopathy, osteoporosis, peptic ulcer, dermal atrophy, increased intracranial pressure, carbohydrate intolerance.
prednisolone (Deltasone)	Taper after IV therapy	As above.
interferon beta, interferon 1a (Avonex)	Relapsing–remitting MS	Adverse effects: flulike symptoms for 24–48 hours after injection (subsides after 2–3 months); treat with acetaminophen or NSAIDs.
interferon 1b (Betaseron)	Relapsing–remitting MS	As above.
azathioprine (Imuran)	Depression of cell-mediated and humoral immunity	May reduce rate of relapse; has no effect on progression of disability.
glatiramer acetate (Copaxone)	Relapsing–remitting MS resistance to interferon beta–neutralizing antibodies	Adverse effects: reaction at injection site, flushing, sweating, shortness of breath, palpitations, chest tightness, anxiety.
methotrexate (Rheumatrex)	Progressive MS	Do not give in chronic liver disease, pregnancy or nursing women, or in the presence of blood dyscrasias.
baclofen (Lioresal)	Symptomatic treatment for spasticity	May cause drowsiness and confusion.
tizanidine (Zanaflex)	Spasticity	May cause drowsiness. Do not use with clonidine (Catapres).
dantrolene (Dantrium)	Spasticity	Use with caution in patients with impaired hepatic, pulmonary, cardiac function.
diazepam (Valium)	Spasticity	Contraindicated with acute narrow-angle glaucoma; potential for abuse.
carbamazepine (Tegretol)	Tremors	Take with food; use with caution in patients with history of cardiac, hepatic, renal, or hematopoietic dysfunction.
natalizumab (Tysabri)	Relapsing–remitting MS	Monitor for progressive multifocal leukoencephalopathy.
clonazepam (Klonopin)	Tremors	Contraindicated with liver disease or acute narrow-angle glaucoma; withdraw gradually; potential for abuse.
primidone (Mysoline)	Tremors	Potentiated with alcohol and other CNS depressants; antagonizes oral anticoagulants, contraceptives, and steroids.

immunological decoy by diverting the autoimmune response away from the natural host. Other potential mechanisms include the activation of immunosuppressive regulatory Th2 cells that may effectively repress the immuno-inflammatory response.

Physicians who prescribe these medications must be thoroughly familiar with dosage, possible adverse effects, and management of those adverse effects. Patients must be taught the adverse effects, injection techniques, storage, and care of the medications. Once appropriate drug therapy has been stabilized, the clinician may monitor the patient as described under Follow-up and Referral later.

Two types of antibodies occur in patients treated with interferons: binding antibodies and neutralizing antibodies (NAbs). Binding antibodies develop at some time

in 97% of treated patients and are measured by enzyme-linked immunosorbent assay (ELISA) or the Western blot technique. Many of these antibodies do not impair therapeutic effectiveness and have no known function. NAbs are formed in a minority of treated patients but are capable of reducing or abrogating the normal biological treatment effects of interferons. They are measured via a viral cytopathic effect reduction assay. There is no evidence that NAb-positive patients fare significantly worse than placebo-treated patients.

Natalizumab (Tysabri) is an effective agent in the treatment of relapsing–remitting MS; however, it is generally used only for patients whose disease course is refractory to interferons and glatiramer acetate due to the rare risk of fatal progressive multifocal leukoencephalopathy. Natalizumab administered IV monthly prevents the migration of T lymphocytes across the blood–brain barrier.

Treatment for progressive forms of MS has been less favorable to date. An assortment of prospective clinical trials have demonstrated limited efficacy with a host of treatments including pulse glucocorticoid therapy, methotrexate, cyclophosphamide, and cladribine. Further study is required before definite clinical recommendations can be made on the use of these therapies.

Symptomatic management and therapy are important in MS. Spasticity is a major cause of disability in 55% of patients with MS. Antispasmodics are listed in Drugs Commonly Prescribed 6.2. If other noninvasive therapeutic measures for spasticity have failed, the patient may be referred to a neurosurgeon for evaluation as a candidate for an implantable drug infusion pump to administer baclofen (Lioresal) intrathecally. This is highly effective because the drug can cross the blood–brain barrier. Adverse effects are minimal, and a test dose is administered intrathecally before implantation as part of the screening process for candidates.

Selective chemodenervation may be beneficial for localized spasticity in a single muscle or limb. This may be accomplished through administration of botulin *(Clostridium botulinum)* toxin type A (Botox). Only a specialist familiar with the use, adverse effects, and injection sites for botulinum toxin should administer this medication.

The tremors associated with MS are usually cerebellar outflow tremors. Medications recommended for the treatment of tremor are included in Drugs Commonly Prescribed 6.2.

Fatigue is a common problem in patients with MS. The existence of sleep apnea, pain, spasms, restless legs syndrome, ability to sleep, and pattern of sleep should all be investigated. Other medical problems that may cause fatigue should be excluded. Patients should be instructed to take a daytime nap and remain in a cool environment and should be educated in energy conservation techniques. A referral for occupational therapy may be beneficial for this.

Many patients with MS experience pain in the form of unpleasant sensations or overt pain. This pain can assume many forms, and the cause of new pain should be established. Acute pain includes trigeminal neuralgia, Lhermitte's sign, paroxysmal burning, extremity pain, and painful tonic spasms. Acute pain may be treated with carbamazepine (Tegretol), phenytoin (Dilantin), or valproate (Depakote). Chronic pain includes dysesthetic pain in extremities, chronic back pain, and painful leg spasms. Amitriptyline (Elavil), carbamazepine, and phenytoin may be given for chronic pain.

Providers should be aware of issues relating to complementary therapies that may be raised by patients with MS. These therapies have become so widely used that the National Institutes of Health has established an Office of Alternative Medicine that deals with therapies for all kinds of conditions. The following are frequently used complementary therapies for patients with MS: acupuncture, hypnotherapy and imagery, massage, biofeedback, tai chi, and chiropractic therapy. If referring a patient with MS to complementary therapy providers, it is important to suggest those who have an understanding of MS.

Follow-up and Referral

Follow-up and referral should occur soon after diagnosis and should be repeated initially at monthly intervals or more often as symptoms appear to assess level of functioning and effectiveness of medications, and to make dosage adjustments if needed. The patient should be instructed to contact the advanced practice registered nurse immediately for the appearance of symptoms that may signal an exacerbation. Referral to a neurosurgeon may be necessary for extreme spasticity.

Patient Education

Patients should be educated in all aspects of the disease, medications, adverse effects, complications, progression, fatigue management, pain management, diet, and exercise. The weakness that results from MS may be amenable to strengthening exercises. ROM exercise is important to prevent contractures and joint restriction. Referral to a physical therapist who has experience in the treatment of patients with MS may be beneficial. Regular exercise may change the course of the patient's response to illness by minimizing the deconditioning process and maintaining optimal levels of physical activity and functioning. The beneficial effects of prolonged activity are well documented; it can help prevent muscular atrophy and weakness, fatigue, loss of flexibility, cardiovascular deficits, depression, and sleep disturbances. It is important to balance activity and exercise to prevent fatigue. There is no conclusive scientific evidence that any diet or nutritional therapy affects the course of MS. Many of the diets available are not harmful but may be tiring because of the attention to detail required, while offering no benefit. A generally well-balanced diet is recommended.

Patients who have been diagnosed with MS may experience a wide range of emotions ranging from euphoria to depression, including helplessness, lack of hope, mental confusion, stress, and anxiety. These emotions can affect marital relationships and increase child-rearing stress. The chronic nature of MS and the inability to predict level of dysfunction contribute to difficulty in coping with chronic illness and symptoms disruptive to daily living. Patients may also experience job loss, embarrassment, exhaustion, and the feeling of making no contribution to society. It is important to teach patients health promotion behaviors to emphasize emotional and social well-being.

Patients and families should also be educated in coping with possible behavior changes and mood swings. Patients with MS have reported feelings of hopelessness, loss of control, conflict, fear, loss, and uncertainty. Education in the management of problems related to sexual dysfunction may also need to be addressed. Caregivers should be educated not to neglect their own health because coping with a chronic illness may change and stress the dynamics both within a family and within other individual relationships.

PARKINSON'S DISEASE

Parkinson's disease (PD) is a chronic, progressive, degenerative disorder of the basal ganglia in the CNS. The disease usually begins insidiously and eventually leads to disability. PD is the second most common neurodegenerative disorder in the elderly after Alzheimer's disease. Affecting 1% of the population older than age 50, there are approximately 1 million people in the United States suffering from PD, with 60,000 new cases diagnosed each year. It affects people in middle to later life, with a mean age at onset of 57 years. The incidence is slightly greater in men, with a 3:2 ratio of men to women. People in all ethnic groups, all countries, and all socioeconomic classes are affected. The Centers for Disease Control and Prevention's National Center for Health Statistics reports that the complications from PD account for it being the 14th major cause of death in the United States in 2010.

A *parkinsonian syndrome* (parkinsonism) is any disorder that manifests the symptoms of PD. Parkinsonism is divided into four categories: idiopathic, symptomatic, Parkinson-plus syndromes, and other heredodegenerative diseases in which parkinsonism is a manifestation. Patients with idiopathic PD make up the largest subgroup, which represents 78% of the affected population. Symptomatic and Parkinson-plus syndromes are often referred to as secondary parkinsonism when there is a known cause for the disorder such as cerebrovascular disease, drugs, infections, trauma, or exposure to toxins. Parkinsonian syndromes include heredodegenerative disorders such as Huntington's disease and other acquired degenerative diseases.

Epidemiology and Causes

The cause of PD is unknown. The pathogenesis is thought to be multifactorial, resulting from a combination of genetic predisposition, exogenous toxins, and endogenous toxins. The evidence regarding the role of heredity is conflicting. A positive family history is reported in approximately 15% of cases. It has also been reported that a higher prevalence of familial PD is revealed when an informative history is obtained.

There are many theories regarding the role of environmental factors in the development of PD. One theory has suggested increased vulnerability of "old" (i.e., aging) neurons to environmental toxins. There are also theories that have identified the following factors in the development of PD: drug-induced parkinsonism (antipsychotics, lithium), rural living, infections, exposure to heavy metals, and free radical–oxidative stress. Oxidative mechanisms are believed to be important in the pathogenesis of PD. In a normal individual, oxidative stress is balanced by antioxidative protective mechanisms naturally occurring in the brain. In patients with PD, the balance is thought to be tilted toward the oxidative stress side. Other influences, including drinking well water, farming, and industrial exposure to heavy metals, have also been associated with increased prevalence of PD.

One man's depiction of being a victim of Parkinson's disease. (Illustration by Christine Sanders.)

The role of normal aging needs to be considered. During aging, pathways lose neurons. Aging is also associated with a loss of catecholamine-containing neurons and an increase in monoamine oxidase (MAO) types A and B. In addition, there is a progressive loss of more than 60% of the dopaminergic neurons in the substantia nigra. This normal process begins at approximately age 30. There is also a decline in the striatal concentration of dopamine, an increase in the turnover of striatal dopamine, and a loss of striatal D_2 receptors. Compensatory mechanisms are thought to be responsible for the absence of PD until striatal dopamine concentrations drop below 20% of normal. The morbidity and mortality rate for PD is high; an estimated 9% of patients become disabled or die within 1 to 5 years, 21% in 6 to 10 years, and almost 38% in 11 to 15 years.

Pathophysiology

PD is a degenerative disease of the motor systems of the brain. Its neurological effects include tremor at rest, muscular rigidity, slow movements, and difficulty maintaining a steady posture. Characteristically, the motor problems of PD improve when a patient is treated with levodopa.

In Parkinson's disease, there is progressive cell loss in the substantia nigra. There are major neural connections of the substantia nigra to the basal ganglia. The full basal ganglia complex—the striatum, the globus pallidus, the subthalamic nucleus, and the substantia nigra—comprises a set of interconnected nuclei deep inside the cerebral cortex. The basal ganglia are a critical part of the motor system, with which they interact through the motor nuclei of the thalamus. The main output of the basal ganglia is a GABA-ergic inhibitory circuit from the internal segment of the globus pallidus to the ventral anterior and ventral lateral nuclei of the thalamus. This GABA-ergic circuit is itself inhibited (indirectly) by dopaminergic axons from the substantia nigra. PD depletes the substantia nigra of dopaminergic axons. As a result, the globus pallidus output remains unchecked, resulting in a blanket inhibition of the motor activity passing through the thalamus.

Besides cell loss in the substantia nigra, PD kills dopaminergic neurons in the adjacent ventral tegmental area, noradrenergic neurons in the locus coeruleus and the dorsal and medial raphe nuclei in the brainstem, and cholinergic neurons in the nucleus basalis of Meynert. In the process, PD produces a typical intracellular abnormality called a Lewy body inside degenerating neurons. Lewy bodies are spherical, insoluble clumps of neurofilaments, tubulin, synphilin, alpha-synuclein, and ubiquitin. Ubiquitin is normally used in a major intracellular degradative pathway, and evidence suggests that one metabolic abnormality underlying PD is a selective defect in this particular degradative pathway.

Clinical Presentation

Subjective

Presentation of the disease is variable. The patient may present with one or more of the six cardinal features of PD: tremor at rest, rigidity, bradykinesia or hypokinesia, flexed posture, loss of postural reflexes, and the freezing phenomenon. The major manifestations of tremor, rigidity, akinesia (or bradykinesia), and postural disturbances form the mnemonic "TRAP."

A tremor may be the reason the patient or family is seeking care and is recognized as the first symptom of PD in 70% of patients at initial diagnosis. The tremor almost always appears distally in the extremities when the extremity is motionless and as a result is termed a "resting tremor." This resting tremor disappears with action but reemerges as the limbs maintain a posture. A resting tremor is common in the chin, lips, and tongue. The resting tremor of the hands increases when the patient is walking and may be an early sign of PD before other signs are visible. Stress worsens the tremor, but resting tremors are absent during sleep. A classic presentation of PD is a characteristic motion of the thumb and forefinger called "pill-rolling."

A common subjective complaint in patients with PD is fatigue, which may be related to rigidity or bradykinesia. Progressive bradykinesia may contribute to slowness and difficulty in the performance of ADLs. Patients may also suffer from sleep disturbances, contributing to fatigue. Swallowing may be impaired in advanced disease, causing aspiration and choking.

Objective

The four common manifestations of PD may be objectively observed and evaluated by the clinician: tremor, a weak and clumsy limb, a stiff and aching limb, and a gait disorder. Rigidity is a state of increased resistance in muscle tone elicited when the clinician moves the patient's neck, trunk, or limbs. The muscle feels stiff and is difficult to move. This can appear as though the patient is having difficulty initiating movement. Rigidity is equal in all directions and is usually manifested by "cogwheeling," a ratchet-like, rhythmic contraction, especially in the hand, on passive stretching. Cogwheeling can be caused by an underlying tremor in the absence of a visible tremor. When another limb is engaged in voluntary movement, rigidity of the passive limb increases.

The patient with PD often has a flexed posture that involves the entire body. The head is bowed, the trunk is bent forward, and the back posture is kyphotic. The elbows, hips, and knees are flexed. The hands are held in front of the body. There may be hand deformities, including ulnar deviation (fingers flexed at the metacarpophalangeal joints) and striatal hand (extension of interphalangeal joints). Striatal toe (big toe dorsiflexion) and inversion of the feet may be present, along with a lateral tilting of the trunk.

The most common features of PD are slowness of movement, difficulty initiating movement, loss of automatic movement (bradykinesia), and reduction in the amplitude of movement, particularly with repetitive movement (hypokinesia). Bradykinesia has many facets depending on the body parts affected. In addition, walking is slow; patients have a tendency to shuffle, with a shortened stride length. Truncal bradykinesia causes difficulty when a patient attempts to arise from a deep chair, get out of an automobile, or turn in bed.

Loss of postural reflexes may lead to falling. Some individuals are unable to stand unassisted. As postural reflexes become impaired, the patient will collapse into a chair on attempting to sit. The *freezing phenomenon,* also called "motor block," is the transient inability to perform active movements. Most often, the legs are affected, but it may also involve eyelid opening, speaking, and writing. Freezing is transient and occurs suddenly. It typically occurs when the patient begins to walk (start-hesitation), attempts to turn while walking, or approaches a destination (target-hesitation). The patient may be fearful about the inability to handle perceived barriers such as elevator doors and heavily trafficked streets.

Other common manifestations of PD are drooling as a result of decreased frequency of swallowing, dysphagia secondary to the neuromuscular incoordination of the hypopharyngeal musculature, excessive perspiration as a result of a disorder of the hypothalamic heat-regulating mechanism and impairment of perspiration controls, constipation secondary to hypomotility of the gastrointestinal tract, orthostatic hypotension as a result of deterioration of the peripheral autonomic nervous system, and urinary hesitation secondary to autonomic dysfunction. The patient may also demonstrate a "mask-like" face (hypomimia), soft speech (hypophonia), slurred speech (dysarthria), and small, slow handwriting (micrographia).

The clinician may also perform the *pull test,* in which the examiner stands behind the patient; gives a sudden, firm pull on the patient's shoulders; and checks for retropulsion. Obtaining a specimen of the patient's handwriting and comparing it with previous samples may assist in the diagnosis. Most patients with PD exhibit behavioral changes. Personality changes become apparent as the patient becomes fearful, dependent, and anxious. Passivity, lack of motivation, and decreased attention span are common. There may also be confusion, agitation, hallucinations, and mania related to activation of dopamine receptors in nonstriatal regions. More than 50% of patients with PD experience depression, and this may precede motor symptoms.

Patients with PD commonly experience cognitive decline. The MMSE is a simple means of measuring this impairment. This exam assesses temporal and spatial orientation, digit span, and the ability to express and understand language, to follow commands, and to remember complete simple instructions. The severe type of dementia seen in patients with Alzheimer's disease is exhibited in approximately 15% to 20% of patients with PD.

The patient may be slow to answer questions and may be unable to change mental set rapidly. There may also be sensory and autonomic dysfunctions such as pain, burning, and tingling. The patient may report that these sensations diminish or disappear on moving. Autonomic dysfunctions such as cool skin, constipation, inadequate bladder emptying, difficulty in obtaining an erection, and orthostatic hypotension may be present.

Diagnostic Reasoning

Diagnostic Tests

Usually the history and physical exam lead the clinician to the diagnosis of PD. The major features of bradykinesia and akinesia—tremor with the limb at rest or resistance to passive movement of the joints (rigidity) or both of these—usually lead the clinician to the diagnosis. Genetic testing may be used in the diagnosis of PD along with other specific features such as family history and age of onset (Level B; Berardelli et al, 2013). An MRI of the brain may be performed to exclude structural brain lesions but not to demonstrate pathological changes indicative of PD. A serum calcium level may be drawn to exclude hypoparathyroidism. A transcranial sonography is not as universally used and requires some expertise in performing the exam but may differentiate PD from atypical parkinsonian syndromes, may make an early diagnosis of PD, and may detect patients at risk for PD (Level A; Berardelli et al, 2013). Single-photon emission computed tomography will help differentiate between degenerative parkinsonism and essential tremor (Level A; Berardelli et al, 2013).

There are clinical and laboratory clues that suggest that a patient with parkinsonism may have some form of the syndrome other than PD itself. PD often manifests with unilateral symptoms, whereas symptomatic parkinsonism or Parkinson-plus syndromes usually have symmetrical symptoms. Levodopa may be given on a trial basis, and one of the most important diagnostic aids is the patient's response to levodopa. Patients with PD usually have a satisfactory response to levodopa whereas other forms of parkinsonism are most likely if there is no response to levodopa.

The Queen Square Brain Bank for Neurological Disorders holds a large archive of brains donated by patients with neurodegenerative diseases, as well as neurologically normal controls. It specializes in research in PD and parkinsonian movement disorders (UCL Institute of Neurology, 2013).

Differential Diagnosis

Diagnosis is based on the clinical features of PD. These include insidious onset; slow progression; and lack of other findings to explain the symptoms, history, examination, or laboratory tests that point to some other cause

of parkinsonism. PD is commonly mistaken for *essential tremor,* which is characterized by postural and kinetic tremor, not resting tremor. The most common diagnostic difficulty is recognizing progressive supranuclear palsy (Steele-Richardson-Olszewski syndrome) when the PD-like symptoms are accompanied by a supranuclear disorder of eye movements, pseudobulbar palsy, and axial dystonia. Another diagnostic error is confusion with multiple system atrophy, Shy-Drager syndrome, where there are additional symptoms of autonomic insufficiency leading to postural hypotension and widespread neurological deficits. Reversible parkinsonism may be caused by dopamine-blocking or dopamine-depleting medications such as antipsychotics, metoclopramide (Reglan), and reserpine (Serpasil). PD must be differentiated from cerebrovascular accidents, dementia, Wilson's disease, and Huntington's disease. Wilson's disease may be recognized by its onset at an earlier age than PD, the presence of other abnormal movements, gray-green Kayser-Fleischer rings in the cornea, chronic hepatitis, and increased concentrations of copper in the tissues. Patients with Huntington's disease also present with rigidity and bradykinesia, but the family history and accompanying dementia will differentiate it from PD.

Management

The principle of management is to control the symptoms of PD, because no drug or surgical approach prevents the progression of the disease. PD costs are estimated at $100 million per year in the United States, counting medications, treatment, hospitalization, loss of productivity, and disability. Because PD is one of the most expensive neurological diseases, clinicians need to work closely with families to monitor patients' conditions to help them obtain the best quality of life of which they are capable. Each patient has a unique set of signs, symptoms, and responses to medications, so treatment must be individualized. Patients also have social, occupational, and emotional needs to be considered. Treatment is lifelong; the goal is to keep patients functioning independently as long as possible.

The decision of when to initiate symptomatic treatment for PD is controversial. When the diagnosis of PD is made, it is appropriate to consider the introduction of a neuroprotective agent. *Neuroprotection* can be defined as an intervention that protects vulnerable neurons. It may also slow or stop disease progression. Some practitioners advocate early treatment to provide maximal clinical benefit. Others advocate treatment delay, to minimize the risk of developing motor complications or accelerating disease progression because of an increased concentration of oxidant radicals from levodopa metabolism. The major decision is when to introduce levodopa. The most common issues providers consider important in deciding to use symptomatic agents are threat to employability; threat to performance of ADLs; threat to the abilities to handle domestic, financial, or social affairs; and appreciable worsening of gait or balance.

Medications commonly prescribed for the management of PD are presented in Drugs Commonly Prescribed 6.3. Levodopa, a dopaminergic agent, is considered the most effective antiparkinsonian agent and has been shown to improve the symptoms of PD by 40% to 50%. Levodopa/carbidopa should also be considered to treat periodic limb movements of sleep (Level B; Zesiewicz et al, 2010).

Once levodopa therapy is started, the rule of thumb is to administer the lowest dosage that brings adequate symptom reversal. A trial period of 3 months should be given before it may be determined that the patient does not respond to the medication. Ninety percent of patients with true PD respond to levodopa. Patients may also experience the "on–off" phenomenon. After 2 to 5 years of treatment, more than 50% of patients experience fluctuations in their response to levodopa. They may also experience dyskinesia, freezing, and mental and behavioral changes. Selegiline (Eldepryl [L-deprenyl]) is an MAO-B inhibitor and is considered a neuroprotective agent. It has fewer side effects than levodopa, but the effects tend to be only moderate and provide inadequate symptomatic therapy, and thus selegiline typically is not used as monotherapy.

Dopamine agonists presumably act directly on striatal dopamine receptors and do not require metabolic conversion to an active product in order to exert effects. They are slightly less effective than levodopa but are alternative first-line agents for PD. Anticholinergic agents are centrally acting drugs and have been used to treat PD for a long time. These drugs are typically used in patients age 70 or younger in whom tremor is the dominant clinical feature and in whom cognitive function is preserved. These agents are useful for treating resting tremors; however, adverse effects—including memory impairment, hallucinations, and confusion—are common with these drugs. Adverse CNS effects of drugs used to treat PD include dysphagia, sedation, and dyskinesias. These drugs should always be discontinued gradually.

Peripheral catechol-*O*-methyltransferase (COMT) inhibitors such as tolcapone (Tasmar) and entacapone (Comtan) have been studied as adjunctive therapies to levodopa. These drugs are thought to increase the bioavailability of levodopa, thereby extending the duration of levodopa's effect. COMT inhibitors have been shown to be effective in both nonfluctuating and fluctuating patients.

Patients with severe symptoms, such as tremor, that are refractory to medications may require referral to a movement disorder neurologist or neurosurgeon for evaluation. Options of thalamotomy, pallidotomy, and deep brain stimulation may be discussed with these patients. Thalamotomy and thalamic stimulation are best for intractable tremors and drug-induced kinesias. Pallidotomy is helpful in some patients for relief of bradykinesias,

Drugs Commonly Prescribed 6.3 Parkinson's Disease

Class	Drug	Adverse Reactions and Prescribing Considerations
MAO Inhibitors		
	selegiline (Eldepryl L-deprenyl)	After several days, levodopa dosage may be reduced 10%–30%. Adverse effects: nausea, dizziness, confusion, hallucinations, dry mouth. Do not give with meperidine (Demerol) or narcotic analgesics. When given with levodopa, selegiline can increase dopaminergic effects and contribute to dopamine toxicity.
	rasagiline (Azilect)	Avoid tyramine-rich foods. Follow MAO precautions.
Dopaminergics		
	carbidopa/levodopa (Sinemet, Sinemet CR, Atamet) amantadine (Symmetrel)	Gradually titrate to relief of symptoms; may go up to 300–500 mg/day. Monitor for orthostatic hypotension. Adverse effects: dizziness, ataxia, insomnia, leg edema. Do not give at bedtime. May cause postural hypotension.
Dopamine Agonists		
	bromocriptine (Parlodel)	Potentiates alcohol and other CNS depressants. Monitor BP and mental status. Adverse effects: fluctuation of symptoms, dyskinesia, dystonia.
	pergolide (Permax)	As above.
	pramipexole (Mirapex)	As above. Titrate over 7 weeks.
	ropinirole (Requip)	As above. Taper dose over 7 days to discontinue.
Anticholinergics		
	trihexyphenidyl (Artane)	Adverse effects: memory impairment, dysphagia, rigidity. Discontinue drug gradually.
	benztropine (Cogentin)	As above.
COMT Inhibitors		
	tolcapone (Tasmar)	With carbidopa/levodopa, discontinue if no substantial benefit after 3 weeks. Increases dopaminergic side effects. Perform baseline transaminase levels, then recheck every 2 weeks for 1 year, then every 4 weeks for 6 months, then every 2 months; monitor for liver disease. Adverse effects: dyskinesias, nausea, sleep disorders.
	entacapone (Comtan)	Each dose of carbidopa/levodopa increases dopaminergic side effects: nausea and vomiting, dry mouth, postural hypotension.

tremor, and dyskinesias. All of these procedures except deep brain stimulation are destructive in nature. Deep brain stimulation is considered nondestructive and reversible. High-frequency thalamic stimulation may be effective in suppressing the rest tremor of PD. Chronic bilateral stimulation of the subthalamic nuclei or globus pallidus shows promising results as a nondestructive treatment for relief of bradykinesias, tremors, and dyskinesias. Surgical implantation of adrenal medullary tissue or fetal substantia nigra tissue is still under investigation because of mixed results.

A biotechnology company in California, the International Stem Cell Corporation, is developing stem-cell therapies that may provide therapeutic benefit through multiple mechanisms of action (International Stem Cell Corporation announces new data from Parkinson's disease program, 2013).

Follow-up and Referral

The frequency of follow-up and visits is based on the patient's response to treatment, adverse effects of medications, and disease progression. Follow-up should be early

and repeated initially, especially during the introduction of a new medication or dose change. The decision for referral to a specialist should be made based on the practitioner's knowledge level and comfort treating PD and on the severity of symptoms. As the disease progresses, especially in the area of tremor, it may become necessary to refer the patient to a movement disorder neurologist or to a stereotactic neurosurgeon.

Rating scales are frequently used to evaluate and monitor a patient's response to medications. The Unified Parkinson's Disease Rating Scale (UPDRS) is a comprehensive evaluation tool that assesses mental, historical, and motor features and the complications of dopaminergic therapy. A subscale of the UPDRS is the Activities of Daily Living Scale, which assesses speech, salivation, swallowing, handwriting, cutting food, handling utensils, hygiene, turning in bed, falling, freezing, walking, tremor, and sensory symptoms.

Patient Education

Speech therapy may be beneficial to increase the voice volume; effect speech pattern modification; and assist with breathing, memory, and vocal ROM exercises. Occasional swallowing assessments and therapies may be needed to assist with problems of dysphagia and drooling.

Patients should be educated on all issues of the disease, medications, adverse effects, complications, progression of the disease, diet, sleep, and exercise. Patients with PD should be encouraged to exercise regularly. This should be focused exercise, and a referral to physical therapy may be indicated. Patients should be observed for fatigue. Exercises should include swimming, stretching, and walking. These activities can slow the secondary effects of PD. Nutrition in patients with PD is an important component in care. The patient should also be assessed for physical and psychological problems, which may interfere with eating and nutrition. Functional capacity may be limited, hindering the patient's ability to prepare meals. Special table cutlery is available with large nonslip handles that may help with eating. Fiber and fluid may need to be increased. Protein may be taken in the evening to avoid interactions between dietary protein and levodopa.

Patients must also be instructed to continue routine health maintenance and screenings. In addition, both patient and caregiver must be educated to the risk for falls in patients with decreased mobility, as well as other home safety issues. There is an increase in mortality from influenza and pneumonia among patients with PD, so guidance for immunizations must be given. Patient and caregivers may benefit from referral to a support group. Resources are listed at the end of this chapter.

ALZHEIMER'S DISEASE

Alzheimer's disease (AD) is a progressive, neurodegenerative condition and the most common form of dementia in the older population. One in three seniors dies with AD or another dementia. It is characterized by an insidious onset, slow progressive cognitive decline, and an array of emotional and behavioral problems that result from the cognitive decline. AD accounts for about $100 billion per year in medical and custodial expenses, with approximately $27,000 per year for each patient for medical and nursing care. In 2012, 15.4 million caregivers provided an estimated 17.5 billion hours of unpaid care, valued at more than $216 billion. This is stated in the 2013 Alzheimer's Disease Facts and Figures document from the Alzheimer's Association.

According to the American Psychiatric Association, AD is characterized by the impaired ability to learn new information or recall previously learned information and one or more additional cognitive disturbances in language (aphasia), function (apraxia), perception (agnosia), or executive function. Once considered an inevitable result of old age, recent advances in understanding AD have modified both diagnostic and treatment choices. There is a familial as well as a sporadic form of the disease. Most clinicians treat patients with the sporadic form of AD.

Alzheimer's disease was named after Dr. Alois Alzheimer, who in 1906 noticed changes in the brain tissue of a woman who had died of an unusual mental illness. She had symptoms of memory loss, language problems, and strange behavior. On autopsy, he found abnormal clumps and tangled bundles of fibers in her brain. These are now called amyloid plaques and neurofibrillary tangles.

Epidemiology and Causes

The only known cause of AD is genetic mutation, which is an abnormal change in the sequence of chemical pairs inside genes. The incidence of the sporadic form of AD in the general population rises rapidly with age. As many as 5 million Americans are currently living with AD. It affects an estimated 1 in 9 people older than age 65. AD is projected to affect nearly 16 million people in 2050, of whom 60% will be older than 85 years of age. Additional risk factors that have been identified include lower educational and occupational levels, family history, head injury, Down syndrome, and decreased estrogen levels. Because onset is often undetected, it is difficult to accurately predict duration or survival time with the disease. For 60- to 70-year-old patients with AD, the average life expectancy is 7 to 10 years after diagnosis. Alzheimer's disease is the sixth-leading cause of death overall and the fifth-leading cause of death for individuals over age 65. Over 60% of patients with Alzheimer's are expected to die before age 80 compared with 30% of people without Alzheimer's.

The relatively rare familial form of AD is considered a straightforward genetic disease. Onset is typically earlier than in the sporadic form of AD. For example, in an extended St. Louis family with the familial form of AD, the typical age at onset is 26 to 28 years. The

physically fit but demented individuals in this family are considered evidence that the disease is not entirely due to age. Members of another large family from villages outside Medellín, Colombia, exhibit symptoms of AD in their early 30s. Many patients complain of severe headaches before onset of familial AD, but the progression is otherwise similar to that of the sporadic form. If a parent has the familial form of AD, offspring have a 50% chance of developing the disease.

Pathophysiology

AD is a progressive and irreversible cortical disconnection syndrome. The disease depletes the cerebral cortices of neurons, causing generalized cortical atrophy, widened cortical sulci, and enlarged ventricles. Neurons that use the neurotransmitter acetylcholine are especially susceptible to the disease; for example, the nucleus basalis (the basal nucleus of Meynert), a set of large cholinergic neurons in the telencephalon beneath the basal ganglia, is selectively depopulated of neurons. Cortical areas that are especially hard hit include the hippocampus (which loses most of its inputs and outputs), the amygdala (which shrinks as it becomes depleted), the temporal cortex, the olfactory system (including the primary sensory epithelium in the nose), and cortico–cortical (intercortical) connections.

Two pathological lesions are found in large numbers throughout the brain of an Alzheimer's patient: neuritic plaques (also called "senile plaques") and neurofibrillary tangles. Neuritic plaques are macroscopic spherical lesions found throughout the cortex (although they are relatively sparse in the primary motor and sensory areas), the hippocampus, and the amygdala. Each plaque has a core of beta-amyloid, an insoluble peptide. The core is surrounded by swollen and degenerating neurites, and these are encased in a layer of microglia and astrocytes. Excess beta-amyloid is also found diffusely throughout the cerebral cortex, the cerebellar cortex, and the basal ganglia, especially in and around blood vessels.

Neurofibrillary tangles are microscopic collections of intertwined cytoskeletal fibers that form inside neurons. The tangles are best seen in silver-stained tissue, and their density correlates with the degree of the patient's dementia. One major protein in these tangles is an aberrant form of *tau* protein (which, in its normal form, stabilizes microtubules), and patients with AD have elevated concentrations of *tau* proteins in their cerebrospinal fluid. The formation of neurofibrillary tangles immobilizes or otherwise deactivates the neuron's normally dynamic cytoskeleton and leads to the cell's death. The tangles are insoluble and remain after the neurons have degenerated.

The central biochemical problem in AD appears to be a defect in the metabolism of *beta-amyloid precursor protein.* Normally, many types of cells, including neurons, make beta-amyloid precursor protein, the function of which is not yet fully understood. When this protein is broken down by specific secretases, the by-products include beta-amyloid peptides. There are four different forms of beta-amyloid peptide. The form identified as beta-amyloid-42 is insoluble, readily forms fibrils, and is found in neuritic plaques.

In AD, beta-amyloid peptides accumulate excessively in the brain. It is thought that abnormalities in the functioning of the secretases cause the overproduction of beta-amyloids. One current theory proposes that beta-amyloid deposition is the primary problem in AD and that intracellular neurofibrillary tangles are the consequence of the toxic effects of beta-amyloid on neurons.

Clinical Presentation

Subjective

The patient usually presents initially with complaints of memory problems. The boundary between the benign forgetfulness of age-associated memory impairment (AAMI) and the onset of AD is unclear. A complaint of memory problems must be thoroughly explored to distinguish not only AAMI but also emotional disorders, other physical insults to the brain, and early AD. Recognition of cognitive difficulty on the part of the patient or family is often related to a change in pattern: getting lost in familiar places, inability to accomplish a demanding task at work, or increasingly slow response to any cognitive challenge. Word-finding difficulty (anomia) usually occurs. Difficulties with balancing the checkbook, preparing dinner, traveling alone, or maintaining employment are frequent problems reported by family members when the disease has progressed to the point where it is noticeable to others. As the disease progresses to the middle stage, family members report difficulty with simpler tasks: choosing clothes, doing housework, and finishing chores. These behavior difficulties worsen with cognitive decline. In the later stages, the person needs help dressing, bathing, and staying continent. Eventually, the person loses the capacity to converse, walk, sit, or hold up the head. Eighty percent of patients in nursing homes with AD have behavioral problems. These may include hostility, aggression, suspiciousness and paranoia, delusions, agitation, sundowning, incontinence, and inappropriate or impulsive sexual behavior.

Objective

There is no support at present for assessing dementia in asymptomatic individuals. However, if concern about cognitive decline is expressed by the patient or family or changes in behavior or cognition are noted, this should trigger an initial assessment for dementia (Advanced Assessment 6.1).

Cognitive assessment is central to diagnosis and management of dementias and should be performed in all patients. The often heard rule of thumb that if a patient reports memory loss, he or she is not demented, has been refuted. Routine social conversation and questions that

Advanced Assessment 6.1 Alzheimer's Disease: Triggers for Further Assessment

Learning and Retaining
Is more repetitive; has trouble remembering recent conversations, events, new information appointments; frequently misplaces objects.
Handling Complex Tasks
Has trouble following a complex train of thought or performing tasks that require many steps such as balancing a checkbook or cooking a meal.
Reasoning Ability
Is unable to respond with a reasonable plan to problems at work or home, such as knowing what to do if the bathroom is flooded; shows uncharacteristic disregard for rules of social conduct.
Spatial Ability and Orientation
Has trouble driving, organizing objects around the house, finding his or her way around familiar places.
Language
Has increasing difficulty with finding the words to express what he or she wants to say and with following conversations.
Behavior
Appears more passive and less responsive; is more irritable than usual; is more suspicious than usual; misinterprets visual or auditory stimuli.

can be answered automatically will not elicit symptoms of early AD. Instead, ask the person such questions as "Do you remember what you did last Sunday?" or "What did you have for breakfast this morning?" The importance of maintaining the patient's dignity by examining the patient alone before interviewing others cannot be overemphasized. The patient should be informed if others are to be interviewed. It is also important to be alert to the possibility that family members at times may minimize or exaggerate their report of symptoms depending on their motives. Family members can report on the patient's ability to perform independent ADLs using the Functional Activities Questionnaire (Advanced Assessment 6.2).

The clinician should get a focused history documenting signs and symptoms related to the dementia, chronology of the problem (including onset, duration, and stepwise versus continuous progression), family history, and any condition or medications that may mimic or contribute to cognitive impairment. The physical exam should include a neurological evaluation and evaluation of any factors contributing to delirium and evidence of neglect or abuse. Neuropsychological testing can pinpoint the types and severity of impairments in language, reasoning, visuospatial, and memory deficits.

The Mini–Mental State Exam (MMSE) is a well-known, easily administered test of cognition. It should be the initial test done when trying to diagnose AD. Within the possible scoring range of 0 to 30, the median score for adults aged 18 to 59 is 29, but the median score drops to 25 at age 80. A score of 20 to 25 indicates early-stage AD, a score between 10 and 19 indicates middle-stage AD, and a score below 10 indicates late-stage AD. Age; visual, auditory, and other physical impairments; and educational level must be taken into consideration in interpretation of test results. Another test for cognition is the Montreal Cognitive Assessment (MoCA), which may be accessed at www.mocatest.org. Functional assessment tests are also very basic screening tools. These may include the timed get up and go, a gait assessment, or the Functional Activities Questionnaire (FAQ), which may be performed by the clinician. The FAQ is also a useful measure that is reported to discriminate well at higher functional levels. There are other tests previously mentioned at the beginning of the chapter. Probably one of the easiest to administer is the clock-drawing test. Ask the patient to draw a clock face with all the numbers in place and give him or her a specific time to draw on it. Save this drawing in the patient's record and repeat this test on occasion. In addition, have the patient write a sentence and repeat this occasionally. These tests are appropriate for initial assessment. The results also provide a baseline from which any further decline can be noted quantitatively. The clinician should refer the patient to a memory disorder center or a specialist in dementing diseases if the initial assessment is suggestive of AD, particularly when

Advanced Assessment 6.2 Functional Activities Questionnaire

The Functional Activities Questionnaire (FAQ) is an informant-based measure of functional abilities. The caregiver or informant provides a score of dependent (3); requires assistance (2); has difficulty but does by self (1); or normal (0) on 10 functional items. Several other responses could be: Never did the activity but couldn't do it now (0); and Never did the activity but would have difficulty now (1).

The 10 activities are as follows:

1. Maintains financial records.
2. Collects information for IRS purposes.
3. Shops alone for necessities.
4. Does an intellectual activity.
5. Heats water and turns off the stove.
6. Cooks a healthy meal.
7. Has knowledge of what's going on in the world.
8. Carries on a conversation about something in the media.
9. Remembers medications and significant dates.
10. Arranges own travel for activities.

The sum of scores for the 10 items will range from 0–30. The higher the score, the poorer the function.

It is recommended that clinicians go to the source listed below to obtain the exact FAQ and utilize this in the practice setting.

Adapted from Pfeiffer, RI, et al. Measurement of functional activities of older adults in the community. *J Gerontol* 37(3):323, 1982.

atypical presentation, severe impairment, or complex comorbidities are present.

Diagnostic Reasoning

Diagnostic Tests

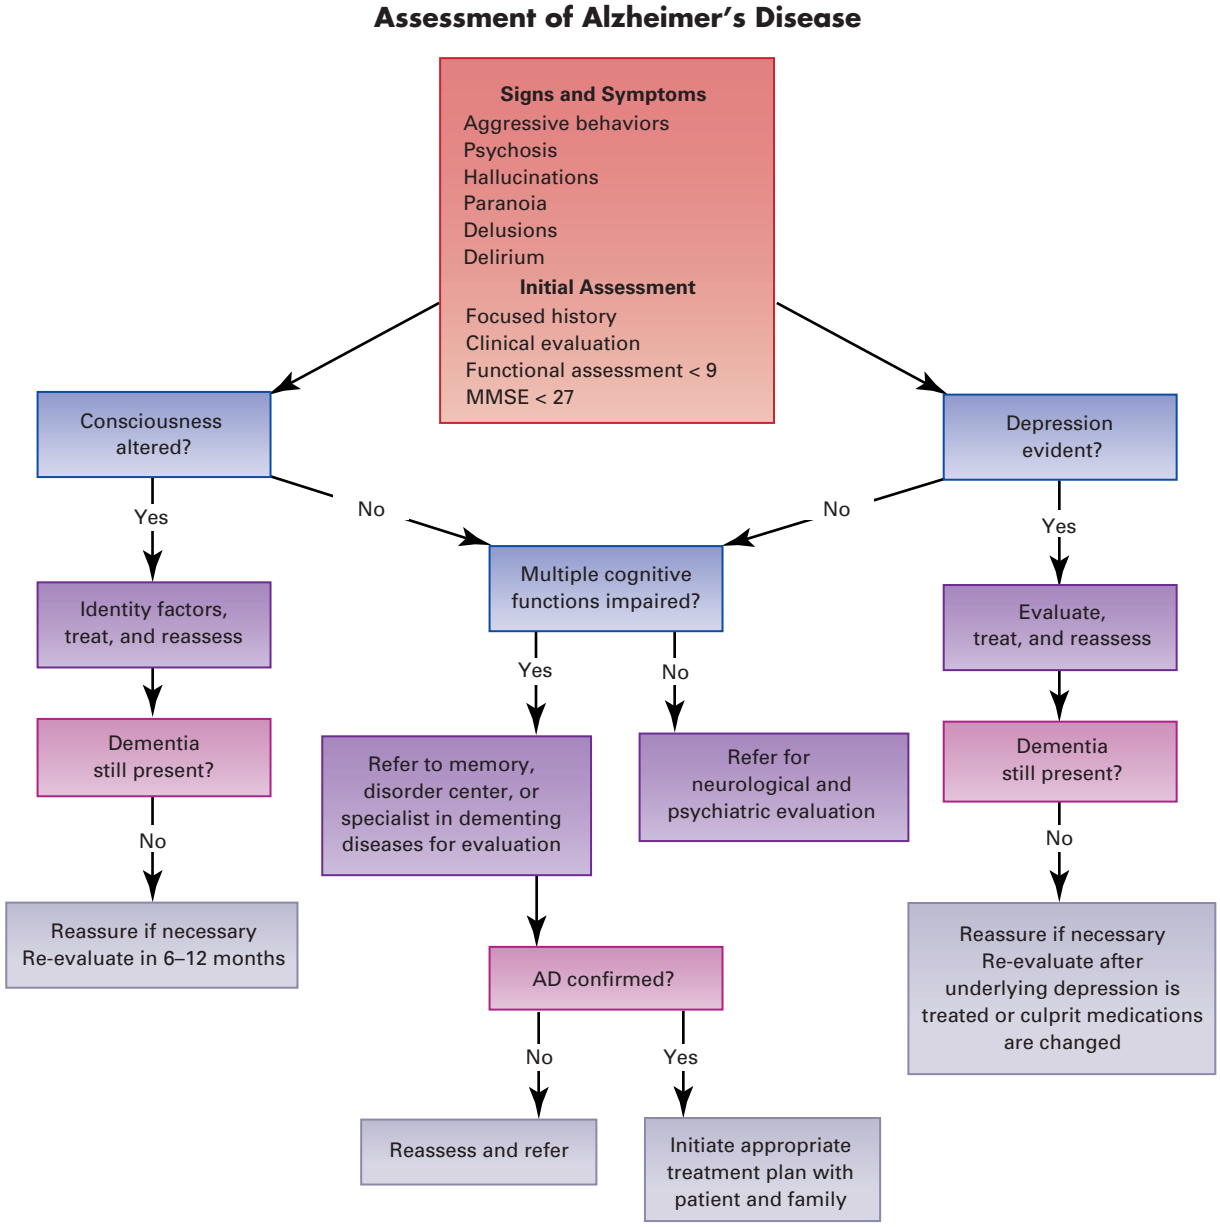
Laboratory tests (complete blood count [CBC], electrolytes, blood glucose, serum calcium, and thyroid-stimulating hormone level, at a minimum) are used to rule out other conditions that may impair brain function. Structural imaging should be used in the diagnostic evaluation of every patient suspected of dementia. Noncontrast computed tomography (CT) can be used to identify surgically treatable lesions and vascular disease. To increase specificity, magnetic resonance imaging (MRI) should be used (Level I; Filippi et al, 2012). Single-photon emission computed tomography (SPECT) imaging is different from the MRI or CT scans. SPECT measures blood flow and activity patterns and can be used to differentiate AD from other possible causes. Pittsburgh compound B positron emission tomography imaging may be used to detect amyloid deposits. Studies show that this test is 86% accurate in predicting which individuals will develop AD within 2 years and 92% accurate in ruling out the likelihood of developing AD. Alzheimer's-related brain changes may occur 20 years before symptoms begin. An individual with early brain changes has preclinical AD or mild cognitive impairment (MCI) due to Alzheimer's. Those patients with symptoms have dementia due to Alzheimer's disease. Two categories of biomarkers in the blood are being studied to determine relevance for diagnostic criteria. The first are biomarkers showing the level of beta-amyloid accumulation in the brain; the second are biomarkers showing that neurons in the brain are injured or actually degenerating. Once these biomarker tests are well established, these will be recommended for individuals with MCI to determine if they have brain changes that put them at high risk for developing Alzheimer's. These biomarkers will also be important in evaluating the effectiveness of treatment. Genetic testing is available, but its value remains controversial; less than 1% of AD cases are caused by the three known genetic mutations.

Differential Diagnosis

To some extent, the diagnosis of AD is still a process of excluding other causes of cognitive impairment (Differential Diagnosis Flowchart 6.7).

Medical conditions and drug-related adverse effects need to be ruled out in patients suspected of AD. Infection, structural CNS conditions, traumatic conditions, metabolic organic failure, and anemia need to be considered. In addition, depression, drug and alcohol abuse, drug-induced delirium, and psychosis need to be ruled out.

The patient should be assessed for deterioration from a higher level of function. Mental retardation should be ruled out. If there is no alteration in consciousness, delirium should be ruled out. Amnesia and aphasia need to be considered if multiple cognitive functions are impaired. If the course of the disease is chronic rather than subacute, the following should be excluded: Creutzfeldt-Jakob



disease, tumor, nutritional deficiency (specifically vitamin B_{12}), drug intoxication, metabolic disorders, and so on. If there is a steady versus stepwise decline, vascular dementia should be ruled out. If there is primarily cortical dysfunction, Parkinson's dementia, Huntington's disease, trauma, vascular dementia, and so forth should be ruled out.

Many patients present with more than one problem. Delirium or depression may be superimposed on AD; PD, vascular problems, or other dementia can also coexist with AD, complicating diagnosis.

Depression can mimic AD and is frequently mistaken for AD in older adults. Information from multiple sources—patient self-report, family members, healthcare provider observations, and patient history—should be used in drawing conclusions.

The Alzheimer's Disease Management Council Clinical Consensus Panel and Scientific Roundtable proposed that the following are highly suggestive of the diagnosis of AD:

- Absence of a precipitating medical illness
- Absence of a drug-related phenomenon
- Presence of objective, well-documented, progressive, and worsening deficits in new learning and memory
- Signs of functional impairment

Management

The principles of management of AD are directed toward slowing progression of the disease pharmacologically, protecting physical health, providing emotional support, and maintaining maximum possible function

through prevention or reduction of excess disability. Maintaining as much normality as possible in relationships and everyday activities may be the most effective way to prevent the development of excess disability, defined as the difference between the observed function and the actual underlying impairment.

Family members have reported that sensitivity to their distress, acknowledgment of their contributions, and information about the disease and its management have not always been dealt with adequately in encounters with primary-care providers. Both patient and family need assistance in understanding and coping with a diagnosis of AD. Most patients are eager to try approved and research-stage drugs. Support group attendance can be very helpful but must be relevant to the stage of the disease. Anxiety and depression should be recognized and treated vigorously because they probably are responsible for much of the disturbing behavior associated with AD. Legal and financial planning and discussion of future care options should take place early in the disease course.

Pharmaceutical agents may improve cognitive function or lessen some of the dementia in mild to moderate AD. Treatment with cholinesterase inhibitors should be considered at the time of diagnosis, taking into account expected therapeutic benefits and potential safety issues. (See Drugs Commonly Prescribed 6.4: Alzheimer's Disease.) The doses for the following drugs are adjusted gradually as tolerated: donepezil (Aricept), galantamine (Reminyl), and rivastigmine (Exelon). An *N*-methyl-D-aspartate (NMDA) receptor antagonist, memantine (Namenda), has been effective in moderate to severe AD by improving cognitive function and has additive effects to cholinesterase inhibitors.

Donepezil does not prevent progression of AD, but it seems to affect the rate of decline. Patients who stop and restart donepezil will not reach the level of function that they had before stopping the drug. Therefore, if the drug is tolerated, it should be continued, because there are no clear guidelines as to when to stop it. Antidepressant drugs have shown an effect in patients with depressive symptoms. Anxious and agitated behavior may respond to anxiolytic drugs; however, use of pharmaceutical agents for noncognitive symptoms such as anxiety, depression, and insomnia should be reserved for instances where behavioral intervention is ineffective.

Because of their side effects, antipsychotics should be used with caution only for patients who exhibit persistent disruptive or dangerous behavior. Precautions include avoidance of drugs that have even a moderate anticholinergic effect and drugs that sedate, affect balance, or are known to cause confusion in older individuals. Atypical antipsychotic medications—risperidone (Risperdal), olanzapine (Zyprexa), and quetiapine (Seroquel)—are usually well tolerated. Risperidone should be avoided in patients with vascular risk factors because it may increase the risk of stroke. Federal regulations require that if antipsychotic agents are used in nursing homes, an effort should be made to reduce the dosage at least every 6 months. Alpha-tocopherol (vitamin E) may help to slow progression of AD in some patients, and an herbal extract of *Ginkgo biloba* has also been reported to have

Drugs Commonly Prescribed 6.4 Alzheimer's Disease (AD)

Drug	Adverse Reactions and Prescribing Considerations
Cholinesterase Inhibitors	
donepezil (Aricept) galantamine (Reminyl) rivastigmine (Exelon)	For mild to moderate AD. May cause diarrhea, nausea, anorexia, and weight loss. Rivastigmine has shown fewer side effects than the other drugs in this category.
***N*-Methyl-D-Aspartate (NMDA) Receptor Antagonist**	
memantine (Namenda)	For moderate to severe AD. Can be used in conjunction with cholinesterase inhibitors. Contraindicated with renal impairment. Requires several weeks to show efficacy.
Anxiolytics	
buspirone (Buspar)	
Atypical Antipsychotics	
risperidone (Risperdal) olanzapine (Zyprexa) quetiapine (Seroquel)	Avoid in patients with vascular dementia or vascular risk factors. Avoid alcohol.

few beneficial effects, with few adverse effects. Research on these supplements is still ongoing.

The failure to institute timely pharmacological management in patients with AD may result in a more rapid need for institutionalization, an increase in aggression, further difficulty with ADLs, and further cognitive decline.

Given the advanced age, compromised brain function, and frequent presence of other chronic conditions in most patients with AD, close monitoring of response to any drug regimen is advisable. In addition, as the patient becomes less able to communicate physical or emotional distress, more careful observation of general health and well-being is needed.

Vigilance in regard to good nutrition, exercise, and preventive care (immunizations, dental, vision, and hearing care) should not be reduced. Patients and their families also need continued support and assistance related to changes that occur as the disease progresses. Recognition of and respect for the patient's humanity can be difficult to maintain in the face of declining cognition, leading to the unfortunate temptation to care for family members while ignoring the patient.

Follow-up and Referral

Referral to a memory disorder center is usually warranted. These centers offer multidisciplinary services ranging from differential diagnosis and access to experimental medications to counseling and support groups. They are excellent sources of accurate information on AD. Most cities have local chapters of national organizations for patients with AD and caregivers that usually offer referrals and support groups as well. Respite care, both at home and overnight in participating health-care facilities, and adult day centers provide social outlets for people with AD and a break in the constant care demands for family members. Family members must be cared for as well; if the clinician is unable to support them, it is essential to find social service agencies that will be able to help.

Patient Education

Both patient and family members need to understand the disease, its ramifications, its future course, and treatment options. Memory aids and environmental modifications can prolong independent function. Specialized communication techniques, memory training, exercise, training in the independent and basic ADLs, and therapeutic recreational activities can all contribute to improved function and quality of life as the disease progresses. Patients need information on legal and financial issues related to the capacity to make decisions, including end-of-life decisions. Driving and living alone are safety issues that arise in the earlier stages; wandering and falls become issues in the later stages. Both patient and family must deal with changes in ability, lifestyle, and relationships with others. Finally, family members need to learn how to help the patient while taking care of themselves as well.

Many patients with advanced disease are taking as many as six to eight medications daily, and many of these medications have side effects that affect cognition and result in falls. Fall precautions need to be taken at home, as well as in long-term care facilities, and clinicians should educate families regarding these at every visit.

NEUROVASCULAR DISORDERS

CEREBROVASCULAR ACCIDENT

Cerebrovascular accident (CVA), commonly referred to as a *brain attack* or *stroke,* is the rapid onset of neurological deficits as a result of decreased blood flow to a focal or localized area of brain tissue. Although the incidence of CVA has decreased in the past 20 years because of risk-factor management and improved treatment, it has continued to be a significant public health problem in terms of both mortality and permanent disability. CVA is the leading cause of disability in adults, incurring major economic burdens on the patient, family, and public as a result of direct medical costs and cost in lost employment. Its impact as a major health problem with demands on health-care and other support systems will continue to grow as the number of CVA survivors living with disabilities increases and the population continues to live longer. The need for continued improvement in the control of risk factors and the prevention of CVAs is critical.

There are two different kinds of CVAs—*hemorrhagic* and *ischemic.* Hemorrhagic CVAs are most often caused by intracerebral hemorrhage from ruptured aneurysms, arteriovenous malformation, hypertensive arteriolar disease, and amyloid deposition. The obstructions that cause ischemic CVAs can be caused by atherosclerosis, embolus, thrombus, hemorrhage, or vasospasm. Up to 85% of CVAs are due to ischemia. Thirty-three percent of all cases of CVAs are caused by atherosclerotic lesions and thrombosis; another 31% are attributed to emboli.

A transient ischemic attack (TIA) serves as a warning of serious underlying atherosclerotic vascular disease. It is defined as an episode of temporary, focal cerebral dysfunction due to vascular disease that lasts less than 24 hours and usually less than 10 minutes. Because most people know the seriousness of a heart attack and the necessity for early treatment, many refer to a CVA as a "brain attack" for similar reasons.

Epidemiology and Causes

CVAs are the third leading cause of death in the United States, after heart disease and cancer, and are highest in the southeastern United States. Although there are approximately 158,000 deaths from CVAs annually (1 in every 15 deaths), an estimated 795,000 people suffer a

CVA each year. Every 53 seconds, someone has a CVA. More women than men (about 3:2) die from a CVA. In reviewing long-term survival, 25% of people who have an initial CVA die within 1 year and two-thirds die within 12 years. Health costs are significant. The average health-care costs per person (inpatient and outpatient) for CVAs have been estimated to be between $8,000 and $16,500. These impressive numbers do not include the additional costs of morbidity-related expenses (lost time from work, additional nursing care, etc.). The direct and indirect costs to the nation are an estimated $53 billion. Age, sex, race, ethnic origin, and heredity have been identified as nonmodifiable risk factors for CVAs, helping to identify those at greatest risk. Compared with whites, young African Americans are at 2 to 3 times greater risk of a CVA and are 2.5 times more likely to die of one. A higher incidence of CVAs is also noted in Hispanics and Asians, particularly Chinese and Japanese, than in white Americans. For people older than age 55, the incidence of a CVA more than doubles in each successive decade. Twenty-eight percent of people who suffer a CVA are younger than age 65. An increased incidence of CVAs in some families has been noted, probably because of a genetic tendency and familial exposure to similar environmental or lifestyle risks.

Important modifiable risk factors for a CVA include hypertension, cardiac disease, diabetes, hypercholesterolemia, smoking, illicit drug use, and lifestyle factors. There is a fourfold increase of a CVA when a patient is hypertensive with a blood pressure (BP) greater than 160/95 mm Hg. Studies show that with treatment for hypertension, there is a 38% reduction in CVAs and a 40% reduction in mortality from CVAs. Atrial fibrillation is associated with a threefold to fivefold increased risk for a CVA. Other cardiac diseases related to increased risk for CVA are cardiac valve abnormalities, such as mitral stenosis or mitral annular calcification. Cardiac structural abnormalities, such as patent foramen ovale and atrial septal aneurysm, increase CVA risk. Myocardial disease, left ventricular hypertrophy, and cardiac failure also increase the risk of a CVA. People with diabetes are more prone to develop atherosclerosis, thus increasing the risk of a CVA.

Although the risk of ischemic stroke that can be attributed to lipids is uncertain, cigarette smoking increases the risk two times. Moderate use of alcohol may actually reduce the risk of a CVA, whereas heavy consumption increases the risk. Drug abuse involving substances such as cocaine, heroin, amphetamines, and marijuana has been linked to CVAs. Lifestyle factors associated with CVAs are obesity, lack of physical activity, high-fat diet, and emotional stress. Recently, studies have shown that there is no increase in risk of ischemic stroke with use of low-dose oral contraceptives. Migraine is also associated as a minor risk factor in men older than age 40. Studies have shown a link between high blood levels of homocysteine (produced from the essential amino acid methionine) and CVAs. However, treatment did not lower the incidence of a CVA. The risk of a CVA may be higher in patients with a progressing and severe stenosis of the carotid artery or in patients who have experienced a TIA. A CVA is an important complication in patients suffering an anterior myocardial infarction (MI) or in patients treated with long-term oral anticoagulants. Complicated atherosclerotic plaques in the aortic wall may contribute to a CVA.

Pathophysiology

Pathologically, there are two distinct categories of cerebrovascular accidents: ischemic and hemorrhagic.

Cerebral Ischemia

Neurons will stop functioning after less than 10 seconds of insufficient blood flow, but they will recover fully if local circulation is restored within a few minutes. After a few minutes without oxygen and glucose, however, neurons begin to die. Cerebral ischemia is caused by a reduction in blood flow that lasts for more than 4 to 5 minutes.

Transient Ischemic Attacks A brief bout of ischemia will produce neurological deficits. If the ischemia is short lived, the neurological signs and symptoms usually resolve within an hour. When the neurological problems take more than 4 hours to improve, some neuron death has probably occurred. Sudden neurological deficits that resolve in less than 24 hours are usually the result of TIAs, fleeting occlusions of cerebral arteries. People who have suffered a TIA are likely later to have a stroke.

Arterial Occlusions Neurological deficits lasting longer than 24 hours indicate that there has been significant neuron death. When the deficits are focal, the ischemic injury is probably due either to atherothromboses or to emboli. Atherosclerosis produces atheromatous plaques, gummy bulges that protrude from the inner walls of arteries. Atheromatous plaques are masses of lipids, cell debris, collagen, fibrin, platelets, and blood cells, covered by smooth muscle cells, macrophages, and lymphocytes. Plaques that fragment send embolic debris downstream, occluding smaller arteries and arterioles and producing areas of ischemia. Plaques that erode can also initiate local blood clotting. When the clot sticks to the plaque, it often grows, occludes the arterial lumen, and leads to ischemia downstream. The specific neurological deficits caused by atherosclerotic plaques reflect the locations of the areas of ischemia.

Occlusive emboli can be generated upstream some distance from the cerebral arteries. Clots and fragments of atherosclerotic plaque in the internal carotids or the vertebral arteries can dislodge and be carried into brain arteries, which then become occluded. Cardiac arrhythmias (atrial fibrillation and sick sinus syndrome), valvular diseases, prosthetic heart valves, and myocardial infarcts can generate emboli. Clots and clumps of platelets formed during angiography and cardiac surgery

can become occlusive emboli. Hypercoagulability syndromes, elevated levels of blood platelets, calcified fragments of plaque and tissue, air, fat, cholesterol crystals, tumor fragments, bacterial vegetations, and foreign material (such as talc and cornstarch injected with illicit drugs) can all clog brain arteries. The occluding emboli are sometimes pushed distally in the affected arteries. This abrades the vessels walls. The injured vessels then bleed and add hemorrhagic damage to the ischemic infarction.

Decreased Brain Perfusion Low cerebral blood flow causes syncope (fainting). If brain perfusion remains low, neurons begin to die in the areas farthest from the main arteries, that is, at the borders between regions supplied by the major cerebral arteries. Hypoperfusion ischemia leads first to loss of vision; decreased alertness; and weakness in shoulder, hand, and thigh muscles. In addition, certain hippocampal neurons are especially sensitive to a temporary loss of cerebral perfusion, and this may explain the memory deficits that occur after the hypoperfusion caused by even a brief cardiac arrest.

Cerebral Hemorrhage

The neurological symptoms of a cerebral hemorrhage result from the pressure of the hematoma. Sometimes, this pressure causes infarcts in the compressed tissue. Other times, however, there is less cell death so that when the hematoma is resorbed, the neurological deficits resolve to some degree. As a rule, the larger the hematoma, the greater and more permanent is the damage.

Epidural Hematomas Epidural bleeding is caused by severe head injuries. Epidural hematomas are most common along the temporal cranial wall and result from tears in the middle meningeal artery. The leaking arterial blood rapidly creates a hematoma between the dura and bone. This increases the overall intracranial pressure, which in turn reduces the cerebral blood perfusion. As the hematoma enlarges, it presses on adjacent brain tissue, causing contralateral hemiparesis. Next, the increasing pressure affects the diencephalon, and the patient becomes lethargic and drowsy. When the midbrain becomes compressed against the dural rim of the tentorium, patients develop ipsilateral oculomotor nerve palsy and an enlarged pupil. Continued expansion of the hematoma compresses the contralateral cerebral peduncle, leading to ipsilateral hemiplegia. Eventually, the diencephalon and ipsilateral temporal lobe can be pushed down through the tentorial notch—such herniations compress the posterior cerebral arteries, press on the brainstem, and can be fatal.

Subdural Hematomas Subdural bleeding is usually caused by blunt trauma that knocks the brain against the skull. Movement of the brain relative to the skull tears the thin superior cerebral veins (the bridging veins), which drain the external cerebral veins into the superior sagittal sinus. Minor repeated injuries can cause chronic venous leakage.

Venous subdural hematomas expand more slowly than the higher-pressure arterial epidural hematomas. Small, self-limited subdural hematomas are often absorbed spontaneously, but subdural hematomas can also continue to enlarge slowly without severe or clear-cut neurological symptoms, especially in the elderly. An untreated subdural hematoma will lead to permanent severe neurological deficits or death.

Subarachnoid and Intraparenchymal Hemorrhages The remaining two classes of intracranial hemorrhages, subarachnoid bleeding and intraparenchymal bleeding, can be caused by trauma and can coexist with epidural and subdural bleeding. They can also happen without apparent external provocation.

Subarachnoid hemorrhages are caused by tears in the arteries running along the subarachnoid space at the surface of the brain. Ruptured arterial aneurysms are the most common source of subarachnoid bleeds. In the brain, these aneurysms usually occur at branch points of the large arteries, especially in the circle of Willis. A less common nontraumatic cause of subarachnoid bleeding is the rupture of a congenital arteriovenous malformation.

Cerebrospinal fluid (CSF) circulates through the subarachnoid space, and blood from a subarachnoid hemorrhage will spread quickly throughout the CSF surrounding the brain and spinal cord. In such cases, a lumbar puncture will produce CSF that contains red blood cells. In this case, the CSF will often assume a yellowish tinge referred to as xanthochromia. Xanthochromia occurs as a result of the breakdown of hemoglobin in the CSF by enzymes producing yellow-pigmented bilirubin. Ruptures of arteries in the subarachnoid space cause a sudden increase in intracranial pressure and produce severe headache, vomiting, and drowsiness.

Sudden rises in cerebral blood pressure or cerebral blood flow can rupture intraparenchymal arteries, especially when the arteries have been weakened by chronic hypertension, aneurysms, or vascular malformations. Clotting disorders, low platelet counts, anticoagulant drugs, vasoconstrictors, and eclampsia during pregnancy increase the risk for intraparenchymal bleeds. Intraparenchymal hemorrhages most often develop from ruptures of arteries to the basal ganglia and the thalamus, although hematomas also form elsewhere in the cerebral lobes, the cerebellum, and the pons. The first neurological symptoms of an intraparenchymal hemorrhage will reflect the specific location of the hematoma—for example, a basal ganglia hematoma pressing on the internal capsule will first cause contralateral motor weakness.

Clinical Presentation

Subjective

A CVA should be suspected when a patient presents with an acute onset of specific signs and symptoms. Patients presenting in the primary-care setting usually complain of weakness, numbness, or paralysis of one or

both extremities on one side of the body. In addition, they usually complain of a severe headache. Impairment is seen in cognitive abilities, level of consciousness, speech, visual fields, extraocular muscle functioning, motor functioning, and gait. Cognitive changes that are exhibited by patients may indicate denial of the illness; neglect syndrome or hemiparesis; spatial and proprioceptive (awareness of body position in spaces) dysfunction; impairment of memory, judgment, problem-solving, or decision-making abilities; and decreased abiity to concentrate on and attend to tasks. The patient may experience emotional lability, especially if the frontal lobe is involved. Aphasia, alexia (reading problems), and agraphia (difficulties in writing) may be apparent. Maximum neurological deficits occur at the onset with paralysis and expressive aphasia.

Objective

Information obtained during the history and physical exam assists in identifying the area of the brain involved and the etiology of the CVA and in determining whether the CVA is hemorrhagic or ischemic. Aspects of the history that are relevant are (1) the nature of the onset; (2) the nature, timing, and duration of the neurological deficit; and (3) whether the deficit is static, improving, or worsening. It is important to inquire specifically about the patient's activity when the CVA began; how the symptoms progressed; the severity of the symptoms; and whether they have worsened, improved, or remained the same. Likely findings for ischemic CVAs caused by thrombus would show that symptoms began during the day and occurred gradually and that the patient had periods of improvement between episodes of worsening. On exam, no seizures are noted, and the patient is awake but confused. Prodromal symptoms are those associated with a TIA. Deficits increase during the first few weeks. Likely symptoms are slight headache, speech deficits, and visual problems. Patients with CVAs caused by embolus typically reveal that their symptoms began during sleep, occurred abruptly, and have progressed steadily. The patient is awake. Symptoms with a hemorrhagic stroke commonly occur during the day with activity and are abrupt in onset, with level of consciousness possibly worsening after the initial onset. Other indicators are vomiting, seizures, severe headaches, coma, and focal deficits. Symptoms also associated with a CVA are seizures or syncope. The patient may complain of feeling "drowsy and dull." The foot on the affected side may be externally rotated, a frequent finding of hemiparesis.

It is important to determine if the symptoms are transient and last no longer than 1 hour, the typical pattern in TIAs. Information can be obtained from the patient as the practitioner observes and interviews the patient for the first time. To assist in differentiating a TIA from a CVA, the patient should describe the event, what precipitated it, the associated symptoms (vision loss, diplopia, paresthesia, aphasia), and how long the event lasted. Table 6.3 presents the different pathologies of TIAs and their symptoms and diagnostic tests.

Patients with carotid atherosclerotic disease are identified by the detection of a carotid bruit or through screening examinations. Detecting the presence of a bruit is significant. Not only does it indicate atherosclerosis and ischemic heart disease, but it may also increase the risk for a CVA. In caring for a patient with asymptomatic carotid bruit, the practitioner should begin with a thorough history for the presence of coronary and peripheral vascular occlusive disease. Most important is the

Table 6.3 Pathologies of Transient Ischemic Attacks (TIAs)

Type of TIA	Signs and Symptoms	Physical Exam	Diagnostic Tests
Carotid Artery Pathology	Paresthesia Weakness of hand, arm, face Aphasia Dysarthria Unilateral neglect Transient blindness or blurred vision in one eye Cognitive/behavioral changes (rare)	Neurological exam: Assess for carotid bruits. Assess for retinal emboli (refer for complete ophthalmological exam). Assess for temporal artery tenderness.	Laboratory tests: CBC, platelets, electrolytes, ESR, ANA, syphilis serology, toxicology screen, coagulation studies (antiphospholipid antibodies, PT/PTT, Russell's viper venom time for lupus anticoagulant) CT scan of the head (10%–20% of patients with TIA have existing infarction) MRI (more sensitive than CT) Vascular evaluation: Doppler studies of temporal and carotid vessels, transcranial Doppler studies of intracranial vertebrobasilar system, magnetic resonance angiography Echocardiography and Holter monitoring to rule out cardiac sources of emboli Transesophageal echocardiography LP CT angiography

Continued

Table 6.3 Pathologies of Transient Ischemic Attacks (TIAs)—cont'd

Type of TIA	Signs and Symptoms	Physical Exam	Diagnostic Tests
Small Cerebral Vessel Pathology	Motor hemiparesis Hemibody sensory loss or paresthesia	As above	As above
Vertebrobasilar System Pathology	Ataxia Dizziness, vertigo Dysarthria Confusion Diplopia, hemianopia, or bilateral vision loss Unilateral or bilateral sensory or motor systems (rare)	As above	As above

identification and management of CVA risk factors. A flattened nasolabial fold and widened palpebral tissue on the same side as the hemiparesis raises the suspicion of a supratentorial lesion. (Facial droop is illustrated at www.cdc.gov/pcd/issues/2008/apr/images/07_0214_01.gif.)

The patient may be confused, agitated, or unresponsive. Difficulties may be noted in speech and cognitive abilities and an increased incidence of incontinence. The practitioner should inquire about a history of similar dysfunctions, especially within the last 2 weeks, or coexistence of cardiovascular diseases, such as hypertension, coronary artery disease (CAD), cardiac valvular disorders, atrial fibrillation, recent MI, or related disorders, such as coagulation and bleeding disorders or diabetes mellitus. A list of current medications should be obtained, including prescribed, OTC, and recreational (illicit) drugs, as well as vitamin and mineral supplements and herbal preparations. The practitioner should be attentive to the use of anticoagulants, aspirin, vasodilators, and illegal drugs, which may provide clues to the cause of the stroke or affect treatment. To complete the history, data should be obtained regarding stroke risk factors, both modifiable and nonmodifiable, with particular focus on gender, ethnic origin, age, familial history, lifestyle (obesity, physical activity, diet), and use of alcohol or cigarettes.

Assessment of visual fields may identify deficits such as horizontal defect, blindness, bitemporal hemianopsia, homonymous hemianopsia, or homonymous quadrant defect. A review of the cranial nerves (CNs) may indicate difficulties with chewing (CN V), facial paralysis or paresis (CN VII), dysphagia (CNs IX and X), an absent gag reflex (CN IX), or impaired tongue movement (CN XII).

The degree of infarction following a CVA varies depending on the severity of the reduction in blood flow, the duration of ischemia, and the adequacy of cerebral circulation.

Signs and symptoms exhibited by the patient may be localized to a particular area of the brain (see Table 6.4).

Bruits become audible when the distal lumen is narrowed to approximately 3 mm or less (about 50% stenosis). The higher the pitch of the bruit, the higher the degree of stenosis. A high-pitched bruit that fades into diastole indicates a hemodynamically important stenosis of the proximal internal carotid artery (ICA) with a residual lumen of less than 1.5 mm (75% stenosis or more). The atherosclerotic plaque commonly forms at the origin of the ICA and at the posterior aspect of the bifurcation of the carotid. The plaque narrows the lumen in a concentric fashion. Occasionally, a thrombus may form near this restricted lumen or blood may penetrate the plaque, creating an ulcer that becomes the source of formation of a thrombus.

Diagnostic Reasoning

Diagnostic Tests

The initial assessment of the patient with a possible CVA should include a CBC with platelet count, prothrombin time (PT)/partial thromboplastin time (PTT), electrolytes, blood urea nitrogen, creatinine, glucose, calcium, magnesium, sedimentation rate, ECG, and chest x-ray study.

A decreased platelet count and prolonged PT/PTT may indicate a bleeding disorder or use of anticoagulants, respectively, leading to a hemorrhagic stroke. Elevated blood glucose levels are sometimes seen in patients with hemorrhagic strokes. An elevated glucose level may be found in patients with diabetes mellitus, a contributing factor toward the development of atherosclerosis. An ECG will detect the presence of a recent MI, atrial fibrillation, or left ventricular hypertrophy, risk factors increasing the probability of a CVA. Left ventricular hypertrophy may be seen on a chest x-ray film. In addition, a high platelet count (greater than 1 million) leads to

Table 6.4 Signs and Symptoms of Occlusion of Specific Areas of the Brain

Specific Areas	Part of Brain Supplies	Signs and Symptoms of Occlusion
Internal carotid artery (carotid system)	Anterior cerebral surfaces (2/5 of CBF)	Unilateral sensory and motor disturbances Hemiparesis, numbness, or paresthesia Visual disturbances (mononuclear blindness [amaurosis fugax], complete unilateral blindness or homonymous hemianopsia) Aphasia with left-sided lesions

hypercoagulability, contributing to the development of a thrombus. A hematocrit greater than 60 causes increased viscosity, resulting in decreased perfusion, and can contribute to cerebral ischemia.

Practice guidelines of the American Heart Association Stroke Council recommend the use of noncontrast CT of the head in patients with suspected acute CVA to exclude a nonvascular lesion as the cause of the manifestations and determine whether the CVA is an ischemic infarction or an intracranial hemorrhage. It is also recommended for early evaluation of young adults with acute CVA.

Ideally, a neurological consultation should also be available within 30 minutes of the patient's arrival. In the practitioner's physical and neurological examination and management of the CVA, the time at onset of symptoms is particularly important to determine the proper use of thrombolytic therapy. It is strongly recommended that emergency CT be the initial brain imaging study for the emergency evaluation of a suspected ischemic CVA. A quick CT during the first hours of symptoms can detect a bleed versus a no bleed for a decision to use early clot busters. Other important information can be obtained from laboratory tests, including CBC, blood chemistry, and coagulation profiles; pulse oximetry; and cranial CT scan without contrast. Other imaging techniques or ultrasonography can help with diagnosis but should not delay treatment. Laboratory data are used to guide intervention and to determine the etiology of the CVA.

MRI is generally recommended for patients with CVAs because it is more sensitive than CT for identifying small ischemic lesions. It also can identify hemorrhagic features, including mass effect. Echo-planar MRI diffusion and perfusion MRI may document changes within minutes, whereas conventional high-field MRI shows changes in 90% of patients after 24 hours. The changes produce increased signals in T2-weighted sequences, indicating the presence of an intraluminal clot. Other signs consist of an absence of flow void in the intracranial arteries, suggestive of occlusion. These signs can be detected almost immediately after onset. Hemorrhage can be detected through high-signal changes in T1-weighted sequences. There is no consensus regarding a method to measure the degree of stenosis from x-ray exams because of the difficulty involved with differentiating one type of lesion from the other (e.g., an atherosclerotic plaque from a thrombus or artery occlusion). Angiography is

considered the test of choice. Magnetic resonance angiography, CT angiography, color duplex ultrasound, and transcranial Doppler are acceptable, noninvasive techniques to screen patients with suspected lesions.

Ischemic CVA caused by embolus has a high incidence in pregnant women. In these women, there are no specific imaging recommendations other than those related to radiation precautions. There is a potential risk of radiation-induced defects during the first trimester, when the patient may be unaware of pregnancy. Detection of an acute ischemic CVA by CT depends on the location and extent of the infarct. Large infarcts are often not documented until 3 hours after onset, but nearly 60% can be detected by 24 hours and 100% by 7 days. In hemorrhagic stroke, the CT demonstrates an irregularly hyperdense, "mottled" infarct. These signs, though subtle, can be seen within 5 hours of onset of symptoms. The most common early signs are anatomical changes, seen in the lentiform nucleus, and especially the loss of the "insular ribbon."

In hemorrhagic CVAs, an early mass effect in cerebral or cerebellar infarcts can be detected on CT within hours from onset. These effects develop before the hypodensity and are indicative of massive infarction. Calcified or hyperdense, cordlike areas in a major artery are suggestive of embolic CVAs. The use of CT with contrast for the evaluation of acute stroke is controversial and does not increase the yield. A concern exists over promoting cerebral "toxicity" when the blood–brain barrier has been disturbed in large infarcts.

An erythrocyte sedimentation rate (ESR) may be warranted in cases of unexplained CVA. If anemia is present and the history suggests ethnic or genetic predisposition to thrombosis, a hemoglobin electrophoresis may be performed. A lumbar puncture (LP) may be an additional test indicated to confirm a diagnosis of subarachnoid hemorrhage if blood is detected in the CSF when the CT is negative. Contraindications to this procedure include papilledema, thrombocytopenia, coagulation disorders, and focal neurological deficit. When common risk factors are not evident, an immune electrophoresis or fibrinogen level may be obtained. Because increased fibrinogen levels appear in early CVAs, as well as increased viscosity, this particular test can help to confirm the diagnosis. All other tests should exhibit normal findings. No laboratory test will definitively confirm the diagnosis of a CVA.

Though it is not meant to be used as a screening tool for CVA, panoramic radiography can also identify asymptomatic patients with carotid calcifications, also revealing a significant correlation with obesity because these patients typically have a high-fat diet leading to carotid blockage.

Differential Diagnosis

CT scanning and MRI assist in the differential diagnosis of CVA. A subarachnoid hemorrhage may present with a severe headache of abrupt onset with a decreased level of consciousness. In subdural hematoma, headache is the single most common symptom and is more common in older adults; however, the headache is generalized and often bitemporal. Neurological signs are usually not present for a long period of time. In most patients with a brain abscess, a headache is present, as well as neurological signs of altered level of consciousness and focal deficit, most often hemiparesis. Nausea and vomiting are frequent, along with a fever. Idiopathic intracranial hypertension (pseudotumor) shows symptoms of papilledema and diplopia, along with a headache and normal CT scan. Transient visual symptoms are present. Headache is present in most patients with brain tumor, along with seizures, weakness, and subtle cognitive changes; however, vomiting and papilledema may be present. No focal neurological signs are seen.

Arterial dissection, although occurring frequently in young adults, has an extremely important symptom of cephalic pain or headache of sudden onset, often preceding retinal or hemispheric ischemic symptoms. Carotid dissection appears initially with occipital headache or acute neck pain and is followed by ischemic symptoms of diplopia, syncope, and amaurosis fugax. Unilateral neck pain that is sudden and radiates to the ipsilateral face or eye is usually present. The headache is related to cervical manipulation, sustained exertion, or trauma. A symptom of new-onset, progressive headache appears as a major feature in temporal arteritis with some cranial symptoms of diplopia and mental sluggishness. Other symptoms are local swelling; tenderness and pulselessness of the temporal artery; and systemic symptoms of fever, anorexia, weight loss, and chills. Systemic markers of inflammation also are present. Because a headache occurs commonly in cerebral venous thrombosis and often is the only initial symptom, cerebral venous thrombosis can be differentiated easily from a CVA. No neurological deficits are seen, and it usually occurs in isolation. Common causes associated with this type of thrombosis are pregnancy and oral contraceptive use. In meningeal irritation, headache is often the most prominent feature, along with lethargy. Encephalitis is associated with a generalized headache of rapid onset, particularly when it is accompanied by confusion, altered level of consciousness, focal neurological signs, or seizures. Fever, meningismus, and signs of myalgia and fatigue are present. Changes associated with these conditions can be detected by either CT or MRI. In addition, a hemorrhagic CVA can be identified via CT, thus differentiating it from an ischemic CVA. Initial diagnostic studies should also rule out other conditions that can masquerade as a CVA (e.g., recent seizures, delirium, syncope, intoxication, suicide attempts, conversion disorders, and possible recent cocaine or amphetamine use).

Management

The main principle in the management of stroke is prevention and early recognition and treatment. Much

remains to be done in order for CVAs to be recognized and managed as a medical emergency, a "brain attack."

Patients with symptoms of a possible stroke require immediate referral to an emergency department for evaluation, CT scanning of the brain, and possible use of thrombolytic therapy. In patients with a cardioembolic source of stroke, a referral to a neurologist is recommended for hospitalization and consideration of the use of heparin anticoagulant therapy. Patients with a high-grade carotid artery stenosis ipsilateral to the side of a TIA should also be considered for hospitalization and may benefit from carotid endarterectomy if they are good surgical candidates or from anticoagulant therapy if they are not. Carotid endarterectomy is established as effective for recently symptomatic (within previous 6 months) patients with 70% to 99% internal carotid artery angiographic stenosis. Symptomatic and asymptomatic patients undergoing carotid endarterectomy should be given aspirin (81 or 325 mg/day) before surgery and for at least 3 months after surgery to reduce the combined endpoint of stroke, MI, and death. Carotid endarterectomy should not be considered for symptomatic patients with less than 50% stenosis. An emergency neurosurgical consultation is indicated in the presence of an intracranial lesion caused by hemorrhage, a mass, or an increase in intracranial pressure. Patients with TIAs should be hospitalized because there is a potential risk of stroke.

Initial management of a CVA is focused on addressing the patient's airway, breathing, and circulation in order to maintain adequate tissue oxygenation. Anaerobic metabolism with depletion of energy stores can increase the extent of brain injury and worsen the outcome. In the prehospital setting, special attention is given to monitoring of the patient's oxygen status through pulse oximetry and the use of supplemental oxygen as needed. Maintaining an adequate airway is crucial, and intubation with mechanical ventilation is initiated when there is decreased level of consciousness or evidence of apparent hypoventilation. Hypotension is treated to maximize cerebral blood flow and minimize complications. Aggressive treatment of hypertension in the prehospital setting is not done in patients with known ischemic disease, because lowering the BP may precipitate hypoperfusion and injury. There is a permissive level of hypertension allowed in the days following the CVA as well. Prehospital evaluation and transport time account for significant delays in initiation of thrombolytic therapy for patients with acute CVA who require it. Aggressive CVA protocols and educational programs keyed to emergency medical services can markedly reduce the time from CVA onset to initiation of treatment.

Once the clinical presentation, the laboratory data, and the results of the CT scan are completed, if they point to a diagnosis of acute ischemic stroke, thrombolytic agents must be considered. The patient and/or family should understand that thrombolytic therapy carries at least a 6.4% risk of intracerebral hemorrhage. Intravenous thrombolytic therapy is effective in reducing the neurological deficit in some patients without CT evidence of intracranial hemorrhage who meet National Institute of Neurological Disorders and Stroke inclusion/exclusion criteria and can be treated within 3 hours after symptom onset (Level A; Edlow et al, 2013). Contraindications to thrombolytic therapy include recent head trauma in the last 3 months, previous intracranial hemorrhage, recent intracranial or intraspinal surgery, active internal bleeding, or evidence of intracranial bleed on CT scan, international normalized ratio greater than 1.7, and platelets less than 100,000. Nursing Research–Based Practice Box 6.1 describes a retrospective study that showed patients on warfarin had larger intracerebral hematomas.

It would be important for the clinician to treat and reduce sources of fever, which can accompany an infectious complication of a CVA, with antibiotics and antipyretics; to prevent recurrent seizures with anticonvulsants; and to prophylactically administer heparin, low molecular weight heparin, or heparinoids (Lovenox) to prevent deep vein thrombosis. The use of corticosteroids is not indicated in the management of cerebral edema and increased intracranial pressure due to CVA.

Once a patient's condition has deteriorated, including development of a herniation syndrome as a result of increased intracranial pressure, osmotherapy and

Nursing Research–Based Practice 6.1

Flaherty, ML, et al. Warfarin use leads to larger intracerebral hematomas. *Neurology* 71:1084–1089, 2008.

Among patients with intracerebral hemorrhage (ICH), warfarin use before onset leads to greater mortality. In a retrospective study, the researchers sought to determine whether warfarin use was associated with larger initial hematoma volume, one determinant of mortality after ICH. ICH volumes were measured on the first available brain scan. Univariable analyses and a multivariable generalized linear model were used to determine whether international normalized ratio (INR) influenced initial ICH volume after adjusting for other factors, including age, race, sex, antiplatelet use, hemorrhage location, and time from stroke onset to scan. Two hundred fifty-eight patients with ICH, including 51 patients taking warfarin, were included in the study. Warfarin use was associated with larger initial ICH volume, but this effect was observed only for INR values >3.0. Larger ICH volume among warfarin users likely accounts for part of the excess mortality in this group.

hyperventilation are used. Surgery is indicated to decompress and evacuate a large cerebellar infarction that compresses the brainstem, although survivors may have severe residual neurological deficits. Early ambulation and preventive measures against aspiration, malnutrition, pneumonia, deep vein thrombosis, pulmonary embolism, decubitus ulcers, contracture, and joint abnormalities are important goals in managing the patient with a CVA.

TIAs with a probable cardioembolic source may be considered for mild anticoagulation. If anticoagulation is contraindicated, antiplatelet therapy may be considered. Medical management is preferred to carotid endarterectomy for symptomatic patients with less than 50% stenosis (Level I; Berardelli et al, 2013). One of the most significant approaches to the medical management of patients with CAD with respect to CVA risk reduction has been the use of antiplatelet drugs, principally acetylsalicylic acid (ASA). Ticlopidine (Ticlid) has shown some improvement over the effects of ASA. Combination therapies, such as ASA plus dipyridamole (Persantine), are better than ASA alone. The dosage of ASA remains controversial—from 81 mg to 650 mg per day—to none at all. Clinicians disagree as to whether high or low doses are efficacious and whether ASA is more effective in women than in men. Clopidogrel (Plavix) 75 mg daily may be used in patients with TIAs to reduce the likelihood of thrombosis and microemboli.

Although ticlopidine is more effective than ASA in decreasing the risk of CVA, the cost and adverse effects are higher. Studies have shown adverse effects such as rash and diarrhea, and thus poor patient compliance. Neutropenia has been known to occur between 3 weeks and 1 month after starting treatment. CBCs should be monitored every 2 weeks for the first 3 months, with therapy continuing for a period of no longer than 6 months.

Clopidogrel (Plavix) is more commonly used than ticlopidine because of lack of neutropenia. A significant number of patients with carotid artery disease have concomitant CAD, and serum cholesterol in patients with CAD should be evaluated and treated. The hydroxymethylglutaryl–coenzyme A (HMG-CoA) reductase inhibitors, or statins, reduce the risk of both nonfatal and fatal CVAs, demonstrating a significant protective effect similar to that conferred by antiplatelet agents. The efficacy of combination therapy is still being researched.

Follow-up and Referral

Follow-up and rehabilitation focus on the return of the patient's optimum level of functioning. The patient may be assessed for the potential for rehabilitation and transferred to a rehabilitation unit. The rehabilitation process involves six major areas of focus: (1) preventing, recognizing, and managing comorbid illness and medical complications; (2) training for maximum independence; (3) facilitating psychosocial coping and adaptation by the patient and family; (4) preventing secondary disability by promoting community reintegration, including resumption of home, family, and vocational activities; (5) enhancing quality of life in view of residual disability; and (6) preventing recurrent CVAs and other vascular conditions, such as MI, that occur with increased frequency in patients with CVAs. Nursing Research–Based Practice Box 6.2 discusses patients' improved quality of life from exposure to interventions designed to increase physical activity.

Patient Education

Adjustments may need to be made in the home environment before discharge, such as building a ramp or removing a door to accommodate a wheelchair. Specific areas of teaching involve exercise and ambulation techniques, dietary requirements, recognition of symptoms of another CVA, and an understanding of the emotional lability and depression that commonly accompany a CVA. Also important are knowledge of appropriate use of medications and the time, place, and frequency of occupational and physical therapy activities. To help prevent caregivers at home from becoming overburdened and thus ill themselves, clinicians should teach caregivers to plan for respite or time away from caregiving activities

Nursing Research–Based Practice 6.2

Conn, VS, et al. Meta-analysis of quality-of-life outcomes from physical activity interventions. *Nurs Res* 58(3):175–183, 2009.

Interventions to increase physical activity among adults with chronic illness are intended to improve quality of life and reduce disease complications or slow disease progression. The aim of this study was to integrate quality-of-life outcomes from primary research studies testing interventions to increase physical activity among adults with chronic illness. Extensive literature searching strategies were used to locate published and unpublished primary research testing physical activity interventions. The researchers synthesized 85 samples from 66 reports with 7,291 subjects. Most design and sample attributes were unrelated to intervention effects on quality of life. Studies that exclusively used supervised center-based exercise reported larger quality-of-life improvements than did studies that included any educational/motivational content. Subjects experienced improved quality of life from exposure to interventions designed to increase physical activity. Future primary research should include quality-of-life outcomes so that patterns of relationships among variables can be explored further.

on a regular basis. Information regarding community, state, and national resources can be a welcome source of support to patients and their families. The National Stroke Association has resource information, including referral services and a quarterly newsletter. The American Heart Association provides a large variety of information regarding risk factors and referrals for assistive devices. The Easter Seal Society also may provide assistance with wheelchairs or other assistive devices. Additional listings of resources for the patient and the practitioner appear at the end of the chapter. Some communities have organizations to help with meals or transportation, along with self-help groups. Education regarding the modification and reduction of risk factors plays a significant role toward the reduction in the incidence of CVAs and TIAs. The most relevant risk factors are the control of hypertension, the use of ASA for prophylaxis in patients with a moderate to high risk of CVA or TIA, and the use of anticoagulants in patients with atrial fibrillation. In a summary of 17 treatment trials of hypertension throughout the world with nearly 50,000 patients, there was a 38% decrease in all strokes and a 40% decrease in fatal CVAs after treatment of hypertension. In the Framingham study, smoking cessation promptly reduced the risk of a CVA, with the major risk reduced within 2 to 4 years. Heavy use of alcohol also should be avoided. Moderate and heavy levels of physical activity have been associated with a decrease in chronic incidence of CVA. The physical activity is believed to exert a beneficial influence on the risk factors for atherosclerotic disease by decreasing BP, weight, and pulse rate; raising high-density lipoprotein cholesterol and lowering low-density lipoprotein cholesterol; decreasing platelet aggregability; increasing insulin sensitivity and improving glucose tolerance; and promoting a lifestyle conducive to changing diet and promoting a cessation of cigarette smoking. A diet low in fat, sodium, and cholesterol and high in fiber, fruits, and vegetables should be encouraged. Patients should also be encouraged to exercise modestly, to avoid weight gain, and to use stress reduction techniques. If the patient has atrial fibrillation, anticoagulant therapy should be initiated to prevent pooling of the blood in the atria that could promote potential microemboli.

Because treatment within 3 to 4.5 hours of onset of a stroke is critical, successful treatment depends on educating the patient and the family to recognize CVA symptoms and to contact and secure access to medical care by calling 911. Delay in treatment has been known to occur for patients who call their primary-care physician instead of 911, live alone, have onset of CVA while asleep, have onset at home rather than work, and who experience a milder severity of a CVA. Studies have documented that 38% of patients and their families did not know a single warning sign of a CVA and that 28% could identify only one sign of seizures. Thus, mild tingling or numbness of the fingers or mild gait clumsiness is attributed to a problem with the arm or leg. Patients may also feel they have dust in their eyes, when in fact they are experiencing amaurosis fugax. Patients may think such symptoms are trivial and may not seek attention, or if they do, they may not mention those symptoms to their practitioner. Older adults may simply forget that any symptoms occurred.

Education of the patient and family should include the importance of reporting any symptoms of graying, darkening, or fogging of vision; a shadow coming over the visual field; or if any episodes of peripheral numbness, tingling, or clumsiness in the upper or lower extremities (e.g., leg giving way suddenly or being weak for a short period of time) occur. Thorough teaching of high-risk patients and their families of the warning signs of a CVA, along with frequent evaluation and a careful review of symptoms by the practitioner, will assist in detecting symptomatic carotid artery stenosis and initiating treatment as soon as possible.

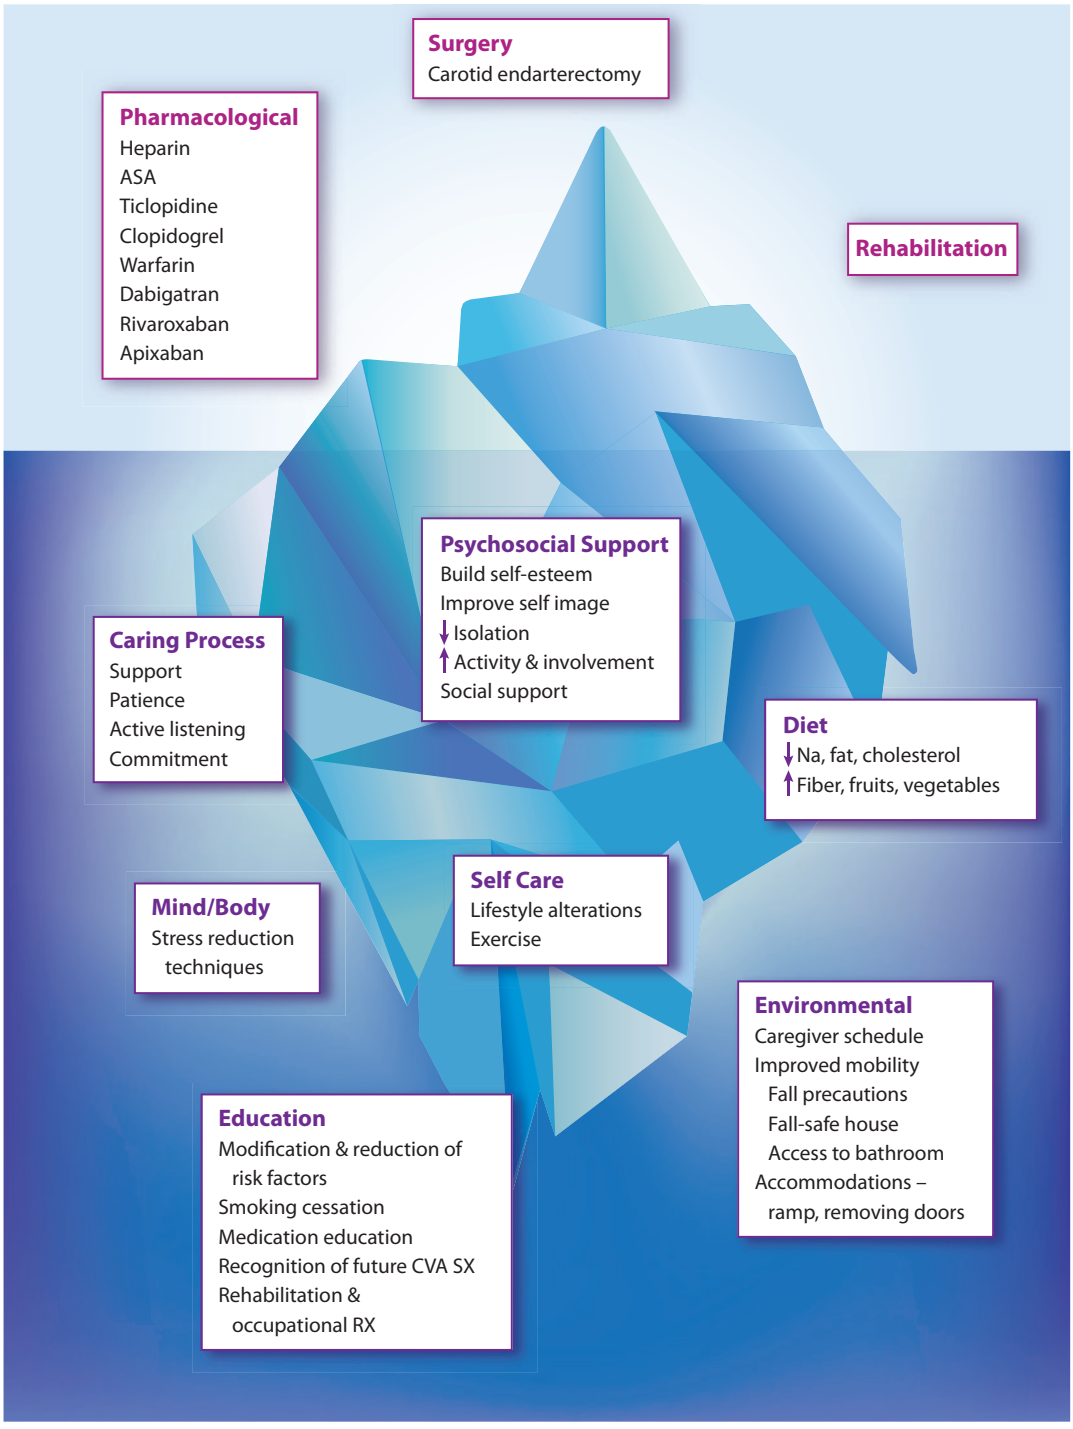
See the Iceberg of Stroke for the intense interactions that need to occur for a patient recovering from a stroke to achieve his or her highest potential.

HEADACHES

Headaches are a pain or ache in the head, sometimes restricting activity, reducing the level of functioning, and decreasing work performance. The prevalence of headaches has a great impact on society because of lost or reduced effectiveness at home, work, or school. Individual burdens result from pain, suffering, and the disabling effects of various headache syndromes. It remains difficult to gain a measure of control over headaches. Headaches pose a challenge to the practitioner to avoid underestimating their significance as an early manifestation of serious neurological disease.

Headaches may be classified into four general categories: muscle contraction headaches (tension); vascular headaches (migraines and cluster headaches); mixed headaches (a combination of muscle contraction and vascular); and traction or inflammatory headaches. A *tension headache* presents as a mild to moderate bilateral, nonpulsating, tightening pain that is not aggravated by routine physical activity. It is usually not accompanied by nausea and vomiting or photophobia. A *migraine headache* may last for 4 to 72 hours and may or may not be precipitated by an aura. It is usually of moderate to severe intensity with a pulsating quality, aggravated by routine physical activity, and accompanied by nausea, vomiting, and photophobia. A *cluster headache* usually occurs at night and may last from 15 to 180 minutes. There is usually severe unilateral orbital, supraorbital, and/or temporal pain that is accompanied on the same side of the face with sweating, lacrimation, nasal congestion, ptosis, rhinorrhea, eyelid edema, and/or conjunctival injection. A *traction or inflammatory headache* is an acute new-onset headache that has an increasing intensity; this type of headache is a medical emergency

The Iceberg of Stroke



because it may be symptomatic of a more serious condition (i.e., subarachnoid hemorrhage or infection). Table 6.5 presents a comparison of the four categories of headaches. These are all considered primary headaches. Secondary headaches are a symptom of an injury or an underlying illness.

Epidemiology and Causes

More individuals complain about headaches than any other condition experienced, and they affect anyone of any age. Each year, approximately 45 million individuals complain of headaches, and more than 8 million individuals of all ages visit a health-care provider with

Table 6.5 Headaches: A Comparison of the Different Types

Type	Muscle Contraction (Tension)	Vascular (Migraine, Cluster)	Mixed	Traction or Inflammatory (Acute Headache)
Signs and symptoms	Nausea and vomiting Bilateral pressure or band-like pain	**Migraine:** Unilateral pulsating episodic pain Nausea and vomiting Photophobia Confusion Disorientation **Cluster** (associated with alcohol use): Periorbital nighttime unilateral nonpulsatile pain Photophobia Tearing Nasal stuffiness	Combination of muscular and vascular headache	New onset Usually older than age 35 Acute, constant, progressive pain that prevents sleep "Worst headache of my life"
History and physical exam findings	Sleep cycle disturbances Depression Appetite changes Relationship difficulties Recent or remote memory loss Limited neck ROM with crepitus	May be similar	May be similar	Acute onset
Diagnostic tests	MRI: lesions, trauma, hematomas CT: hemorrhage LP: to determine presence of organisms	Same	Same	Same
Treatment	Support Biofeedback Stress management Drugs: aspirin, acetaminophen (Tylenol), NSAIDs, muscle relaxants Preventive treatment	**Migraine:** Avoidance education Drugs: beta blockers, ergot alkaloids, NSAIDs, antiemetics, selective serotonin receptor agonists (sumatriptan [Imitrex]), tricyclic antidepressant (amitriptyline) **Cluster:** 100% oxygen by mask Drugs: inhaled ergotamine Preventive treatment (propranolol, amitriptyline, valproate, or lithium)	Combined approach of counseling, migraine prevention, drugs, antidepressants, and stress reduction	Refer to neurologist

this complaint annually, with the incidence decreasing with age. In the United States, some researchers estimate the annual cost of headaches, including costs of direct medical care and lost productivity, to exceed $17 billion. Headaches affect women two to three times more than men across all age-groups, with the incidence in women increasing during adolescence and peaking at menarche.

Muscular traction or a tension-type headache is a highly prevalent condition that can be disabling. It is the most common type of headache, with an estimated 80% to 90% of the population suffering from tension headaches at some period in their lives. It is found more often in women (86%) than in men (65%). Its prevalence peaks at about age 30 to 38. Tension headache occurs more frequently in whites (40%), especially with

increasing educational levels (48%). Although few people who suffer tension-type headaches lose time from work, more than 40% of people affected reported decreased effectiveness at work, home, or school because of this type of headache.

Migraine headaches are the second most common type of headache. Twenty-five percent of women suffer a migraine at least once, and 8% of men are affected by migraine headaches. Racial differences in migraine prevalence are striking: African Americans and nonwhites of Hispanic or other nonspecified ethnic origin are at least twice as likely as whites or Asians to be migraine sufferers. An inverse relationship exists between migraine and age. Prevalence of migraine is highest in adults younger than age 40, and lowest in those older than age 60. Migraine headaches occur in 4% to 5% of school-age children. It is not unusual for migraine headaches to begin during childhood between ages 5 and 8 years. Migraine syndromes are painful and often disabling, accounting for a loss of more than 157 million workdays to headache pain each year. In one study of patients who met the International Headache Society criteria for migraine, fewer than half had actually received a diagnosis of migraine.

Migraine headaches are often hereditary and can be traced to hormonal shifts in women. In familial migraine headaches, the cause is associated with mutations in calcium-channel genes. The causes of menstrual migraine are explained by hormonal fluctuations either before, during, or after menstruation. Falling estrogen levels can trigger a migraine that is either endogenously or exogenously induced (e.g., by a week-off [21-day] oral contraceptive pill or by hormonal replacement therapy). There are multiple and varied precipitating factors or "triggers" of migraine headaches. A migraine headache may occur shortly after or just before a period of stress. One type of migraine, sometimes known as an exertional migraine, is associated with strenuous physical activity, but in general, women who exercise regularly are less likely to get migraines or at least experience them with less severity. Some sports, however, may actually precipitate a headache, resulting in common phrases such as "swimmer's migraine" or "runner's headache." Weight lifting, cycling, and hockey have been identified as other possible culprits. Researchers believe that the relationship between exercise and sports activities and migraine is associated with increased pressure on the head or a strained neck muscle. Physical activity at high altitudes is another factor that may trigger a migraine between 6 hours and 4 days after arrival. Other factors associated with exercise may be an inadequate warm-up or dehydration. Certain foods containing tyramine or phenylethylamine are known triggers of migraine. These vasoactive substances cause both vasodilation and vasoconstriction of the cerebral vessels. Examples of vasodilator agents include alcohol and sodium nitrate. Sodium nitrate is used as a preservative and is present in processed meats and food coloring. Vasoconstrictor agents, on the other hand, stimulate the release of noradrenalin and adrenalin, causing vascular constriction of the cerebral vessels. Caffeine is known to cause a headache after six cups of coffee are consumed. Although consuming smaller amounts of coffee may protect a person from a headache, sudden caffeine withdrawal may trigger a migraine as a result of rebound vasodilation. Monosodium glutamate (MSG) can also produce a migraine. Eighty-five percent of individuals report some sort of trigger that will kick off their headache. Table 6.6 presents common triggers of migraine headaches.

Cluster headaches, another form of vascular headaches, are named for their particular pattern of occurrence: They usually come in groups over the span of several weeks or months, then disappear for months or even years. Cluster headaches are considered to be the most painful of the headaches. They occur in middle-aged men, with the first onset between ages 20 and 30, and typically cluster on a seasonal basis, with anywhere from 3 to 18 months between headaches. Approximately 69 out of 100,000 individuals suffer from cluster headaches. A dysfunction of the hypothalamus may account for the periodicity and clocklike regularity of cluster headaches.

Table 6.6 Common Triggers of Migraine Headaches

Hormonal
• Low estrogen level, increased prostaglandin level
Environmental
• High-pitched noises, excessive sun, bright lights, weather changes, strong odors, video display terminals
Diet
• Vasodilating agents: alcohol, sodium nitrate
• Vasoconstricting agents: caffeine, tyramine (bananas, ripe cheese, nuts, pods of broad beans [Italian pole, lima, or butter beans]), chicken livers, yogurt, avocado, sour cream
Phenylethylamine
• Some cheeses, red wine, chocolate
Monosodium glutamate
• Chinese food, canned soups, frozen dinners
Artificial sweeteners
Lifestyle
• Stress, sports, swimming, cycling, hockey, weight lifting, running, inadequate warm-ups
Physical activity at high altitudes
• Cycling, climbing, skiing
Fatigue
Changes in sleep schedule
• Excessive sleep, too little sleep
Cigarette smoking
Dehydration

Older adults have fewer headaches overall. Unfortunately, about a third of those that occur are traction or inflammatory headaches that are secondary to systemic disease or primary intracranial lesions such as subarachnoid hemorrhages resulting from arteriovenous malformation (AVM) or intracranial aneurysms. These headaches require immediate medical evaluation. Other causes may be temporal arteritis and subdural hematoma.

Temporal arteritis or giant cell arteritis (GCA) affects men and women equally and occurs predominantly in adults older than age 60. Its incidence increases with age and is rare in the young. The headache from a subdural hematoma is of venous origin, typically resulting from a head injury that is usually mild and easily forgotten by the patient. It occurs predominantly in persons older than age 50 and is more common in men. The abuse of alcohol and use of anticoagulants contribute to its occurrence. It rarely is associated with a fractured skull.

The headache from subarachnoid hemorrhage commonly occurs from a ruptured intracranial aneurysm, such as a "berry" aneurysm or dissecting arterial aneurysm of the carotid or vertebral vessels. A berry aneurysm, or berry-shaped aneurysm, results from a congenital abnormality of intracranial vessels, primarily at the circle of Willis. Ruptured intracranial aneurysms are the primary cause of subarachnoid hemorrhage. Less often, a subarachnoid hemorrhage is caused by an AVM or bleeding disorder. An AVM is a congenital disorder that results in the formation of a tangled collection of dilated arteries and veins. Symptoms are usually seen in persons aged 20 to 40 years. Two-thirds of people affected by a subarachnoid hemorrhage are aged 40 to 60 years; women are affected slightly more frequently because of the higher incidence of hypertension among women. In the United States, 10 to 15 cases occur per 100,000 population per year. Activities such as lifting, straining, sexual intercourse, or emotional excitement can precipitate a hemorrhage. However, subarachnoid hemorrhage has also been known to occur during sleep.

Primary Headache Syndromes

Pathophysiology

Head Pain Inside the skull, only certain structures are sensitive to pain; these include the fold of dura between the cerebral hemispheres (the falx cerebri), the middle meningeal artery of the dura, the dural venous sinuses, and the extraparenchymal regions of the larger pial arteries. Increased pressure on and inflammation of the meninges will cause pain, and distention of or traction on the arteries will cause pain. Head trauma usually causes headaches through all these pain-inducing mechanisms.

Besides head trauma, many other medical problems can initiate a headache secondarily—CVAs (hematomas, hemorrhages, and thrombi); intracranial infections, tumors; metabolic disorders (hypercapnia, hypoglycemia, and hypoxia); sudden hypertension; changes in intracranial pressure; drugs and drug withdrawals; cranial nerve pain; and eye, ear, nose, sinus, teeth, and jaw disorders. On the other hand, in certain disorders headaches are considered to be the primary problem. The three primary headache syndromes are chronic tension-type headaches, migraine headaches, and cluster headaches.

Pain signals are transmitted from most structures in the head by branches of the trigeminal nerve (see Fig. 6.1), although pain from the back of the head and the posterior fossa of the skull are transmitted by branches of the first three cervical spinal nerves. First-order pain fibers from these nerves synapse in the brainstem and upper spinal cord, and from there, the second-order pain fibers project

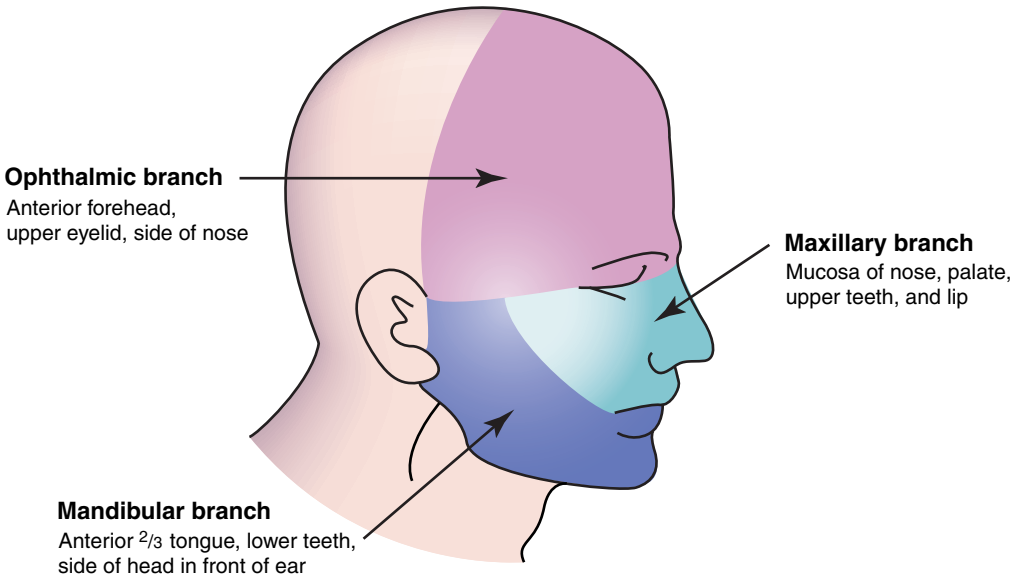


Figure 6.1 The three branches of the trigeminal nerve.

to sensory nuclei in the thalamus. Regardless of its cause, headache pain is the result of activating these trigemino-thalamic and cervico-thalamic pain circuits.

The primary headache syndromes, however, are not caused simply by the normal activation of trigeminal or cervical pain receptors inside the skull. Instead, primary headache syndromes require hypersensitization of the trigemino-thalamic or cervico-thalamic circuitry at one or more points along their route from the primary afferent axons to the thalamic sensory nuclei.

One part of this circuitry on which many headache studies have focused is the thalamus. When pain stimuli pass through the thalamus, the signals are modulated by serotonergic axons coming from the dorsal raphe nuclei in the midbrain. It is thought that an abnormal reduction in serotonergic activity in the thalamus is a part of the hypersensitization in primary headache syndromes. Among the observations consistent with this idea are the following:

- Serotonin agonists (ergotamine, dihydroergotamine, and triptans) can reduce the pain and frequency of migraines and can reduce the duration and frequency of cluster headaches.
- Increasing the effectiveness of serotonergic synapses with a selective serotonin reuptake inhibitor can reduce the frequency of tension-type headaches.
- Reserpine, a drug that depletes CNS synapses of serotonin, can precipitate migraine headaches.

Chronic Tension-Type Headaches Chronic tension-type headaches produce mild to moderate pain that feels like a constant, bilateral head tightness and that lasts from a half hour to a week. These headaches do not pulsate, do not cause nausea, and usually are not made worse by physical activity. Chronic tension-type headaches occur repeatedly (typically many times a month), they come on gradually during the day, and they are more common in people with depression.

Although patients with chronic tension-type headaches have muscle tenderness, their headaches seem not to be caused by unusual muscle tension or contraction. Instead, in patients with this type of primary headache, the head and neck pain circuitry is hypersensitized so that normal stimuli and typical muscle strains lead to headaches. The basic cause of the hypersensitization is not known, although it is thought that chronic tension-type headaches result from abnormalities in the serotonin, norepinephrine, or dopamine pathways that originate in the brainstem and that modulate the trigemino-thalamic or cervico-thalamic pain circuits.

Migraine Headaches Migraine headaches produce moderate to severe unilateral pain lasting from 4 hours to 3 days. These headaches throb, cause nausea, and are made worse by activity. Migraine headaches happen repeatedly (typically one to three times per month) and can be triggered by certain stimuli, most commonly alcohol, stress, menstruation, or diet.

Migraine headaches come as a set of events that unfold in a predictable pattern. First, there is a prodrome, which begins hours or days before the headache. The prodrome is often a psychological change—it can be drowsiness; depression; euphoria; hyperactivity; difficulty concentrating; irritability; or increased sensitivity to noises, lights, or smells. The prodrome is thought to reflect disturbances in the hypothalamic-limbic system.

Patients with the most common type of migraine then develop a unilateral throbbing headache, which is accompanied by anorexia and nausea (with vomiting in a third of the cases) and by a heightened sensitivity to noises, lights, and smells. The basis for the pain is a hypersensitized trigemino-thalamic circuit, which makes the normally innocuous pulsing of cerebral blood flow feel painful. The hypersensitivity can carry over to all trigeminal nerve stimuli on the same side of the head, so that normal pressures (caused by, e.g., combing, shaving, taking a shower, or wearing glasses or earrings) on the skin of the face and scalp also feel painful.

In an experimental model, migraine-like headaches can be initiated by electrical stimulation of areas in the midbrain. In this region, focal stimuli set off a cascade of specific reactions including an increase in local blood flow and a hypersensitization of the trigemino-thalamic pain circuits.

In a less common type of migraine (classic migraine), the headache is preceded by sensory phenomena called an aura. An aura is usually either a set of patterns in the visual fields or a sequence of strange feelings moving from the hand, up the arm, and onto the face. The aura coincides with a slowly spreading wave of chemical and metabolic changes that moves across the cerebral cortex from initial foci in the occipital lobe(s). As the wave reaches a region, it briefly activates the local neurons and increases the local blood flow. After the wave passes, it leaves the neurons refractory and the local blood flow decreased. It is thought that this wave contributes to the hypersensitization of the trigemino-thalamic circuits and that the wave also elicits the headache pain that follows the aura. Experimentally, it has been found that agents that reduce migraine headaches (specifically, the adrenergic agonist norepinephrine, the alpha$_2$-agonist clonidine, and the beta blocker propranolol) also stop or slow this wave of cortical depression.

Like epilepsy sufferers, patients with migraine headaches have cortical neurons that are permanently hyperexcitable. Even between migraine attacks, migraine patients experience other headaches with unusual frequency, and they can get headaches and perceptual distortions from minor visual stresses such as patterns of glare. The neuronal hyperexcitability underlying this continuous sensitivity can be inherited, and there are indications that it is due to abnormalities in certain ion channels in nerve cell membranes.

Cluster Headaches Cluster headaches give severe unilateral pain behind the eye or temple lasting from a half

hour to longer than an hour. The pain is constant, deep, and piercing and can radiate to the forehead, neck, or shoulder. These headaches do not pulsate, do not cause nausea, and usually are not made worse by physical activity. Together with the pain, there are eye or nose symptoms, such as tearing, swollen conjunctivae, runny nose, nasal congestion, eyelid droop, eyelid edema, facial sweating, or pupillary constriction. Cluster headaches come in groups that last 2 to 3 months. During one of these periods, headaches can occur as often as eight per day or as few as one every other day. Typically, a sufferer has one or two clusters of headaches per year.

Cluster headaches appear to be triggered by an abnormality in the ipsilateral circadian pacemaker, which is located in the ventral hypothalamus. The headache pain is caused by a hypersensitized ophthalmic nerve (the ophthalmic branch of the trigeminal nerve). The autonomic symptoms are caused by concurrent excitation of parasympathetic fibers running with the ophthalmic nerve. It is not known what causes these nerve problems.

Clinical Presentation

Subjective

Patients with episodic tension headaches rarely seek health care. Patients with chronic tension headaches present with symptoms of anxiety and depression but do not attribute their headaches to these symptoms. It is the astute clinician who can relate patients' subjective comments to the stress and anxiety that they are experiencing in their lives and help each patient to attribute his or her headache to that cause, thereby encouraging patients to seek treatment for the underlying stress, anxiety, and/or depression.

Two basic types of migraine headaches occur—those with aura and those without. A typical migraine without aura (previously called "common migraine") is often unilateral (60%) but may become generalized. The headache lasts 2 to 72 hours or longer and is of pulsating quality. Most patients describe the pain as intense, throbbing, or pulsating. It is moderate to severe in intensity, inhibiting or prohibiting daily activities. It can be aggravated by routine physical activity and is often relieved by sleep. During the attack, nausea and vomiting, photophobia, and phonophobia are common. Adults often experience both photophobia and phonophobia, whereas children are more likely to have one or the other.

In migraine with aura (previously called "classic migraine"), the aura develops over 4 minutes and usually lasts an hour. Following the aura may be a pain-free period lasting no longer than 1 hour before the headache pain begins. The headache may also start before or at the same time as the aura. Patients typically have one or more symptoms associated with the aura that are characteristically neural in nature, such as unilateral numbness or paresthesia of the face or extremity and speech difficulties. Visual symptoms are common and usually occur 20 to 40 minutes before the headache. These symptoms include scotoma (blind spots), photopsia (flashing lights), fortification spectra (zigzag pattern), and diplopia. The aura phase may include additional symptoms of euphoria or depression, fatigue, hunger, and hyperosmia.

Migraine attacks may occur sporadically, with just a few headaches per year, or may be more frequent, with eight or more occurrences each month. Other symptoms may be associated with migraines, such as anorexia, constipation, pallor, dizziness, tremors, or diaphoresis. Some patients complain of cold hands or feet or experience polyuria, hunger, diarrhea, or body aches following the migraine.

The patient with a headache from a subarachnoid hemorrhage presents a picture of a sudden, abrupt, and unrelenting headache. Associated symptoms include nausea and vomiting, photophobia, and decreased level of consciousness. With small "warning leak" hemorrhages, the patient may complain of severe hemifacial pain spreading to the neck or back. The headache may have begun after exercise or intercourse.

Objective

Careful attention to the headache history is essential, including such particulars as onset, location, character, and severity; frequency and duration; associated signs and symptoms; prodromal symptoms; and precipitating factors. The practitioner should explore the patient's family and social history. Information should be sought regarding other family members who suffer from headaches, the type of headache, and the age at occurrence.

Patients with migraines usually have a parent who suffers from migraines. Information regarding the age at onset with migraines is also important because migraine frequently starts before age 20. A social history may elicit stressors or precipitating factors for the headache. Identifying the possible precipitating factors for the migraine can assist the practitioner in developing an individual prescription plan for the patient to decrease the severity or frequency of the attacks. The patient's lifestyle, dietary habits, possible job-related stress, and environmental factors should be explored. In women, information should be sought regarding the relationship of the migraine to the menstrual cycle. Headaches usually occur after ovulation and before and during menstruation. Migraines that occur before menses are considered premenstrual and associated with the premenstrual syndrome. Women are more likely to have their first migraine in the year of menarche and often cease to have migraine headaches during pregnancy. The use of oral contraceptive pills or hormonal replacement therapy should be explored. Initially, the cycle is more haphazard because of unstable blood estrogen concentration. The use of hormones for the first time may precipitate a migraine and cause the migraine to become more frequent or to be

preceded by auras. Most women who suffer from migraines do not experience an aura. Discontinuing the oral contraceptive does not always resolve the problem. In patients with gynecological disorders, migraines often become more frequent and can improve when the disorder is corrected. Practitioners may consider postponing a complete medical history to a more pain-free period for the patient once more serious disorders have been ruled out. The final step of the medical history is obtaining a record of all previous work-ups and past treatments performed, including their effectiveness.

In contrast to migraine, the patient with a cluster headache experiences severe, unilateral, orbital, supraorbital, or temporal pain lasting 15 minutes to 3 hours. The pain is most commonly sharp and burning in quality. Frequently, the headache occurs at night, awakening the patient. No aura is present, and it is rare to find nausea and vomiting. Attacks commonly occur in "clusters" or groups and can last up to several weeks or even months. One of the following can be demonstrated on the affected side: conjunctival injection, miosis, ptosis and eyelid edema, nasal congestion, rhinorrhea, and forehead and/or facial sweating. Physical findings to detect a headache resulting from a subarachnoid hemorrhage are visual blurring, diplopia, fever, slight decrease in awareness, asymmetrical pupillary response, equivocal extensor plantar response, and pronator drift. Other findings from a subarachnoid hemorrhage may include decreased level of consciousness and nuchal rigidity.

Frequently, a headache is seen in patients with temporal arteritis. The intensity of GCA is severe with the quality of the pain described as deep, burning, and throbbing. A symptom specific to temporal arteritis is "claudication" of the muscles of mastication. Because of ischemia of the muscles, the patient complains of pain in the jaw on prolonged chewing. Localized tenderness of the affected artery is found. The practitioner should be alert to the potential complication of blindness. Diplopia is a common sign seen before visual impairment. Once visual impairment occurs, however, it can progress quickly to blindness in several hours. On physical exam, few abnormalities are revealed. A low-grade fever may appear. The temporal arteries may be tender and more visible or pronounced on palpation but have absent or decreased palpations.

The single most commonly occurring symptom with a subdural hematoma is headache. It is subacute and usually progresses. Characteristically, this secondary headache is generalized, is temporal, and worsens with changes in posture. It can occur during the night and may cause the patient to awaken in the morning earlier than usual. Associated symptoms are nausea, vomiting, confusion, seizures, or weakness. The practitioner should be alert to changes in personality, decreasing level of consciousness, excessive sleepiness, or sensory changes. Less common findings are focal neurological signs, such as hemiparesis or pathological reflexes. Papilledema rarely occurs because of the large volume of CSF.

Diagnostic Reasoning

Diagnostic Tests

An EEG is not useful in the routine evaluation of a patient with a headache and is not recommended to exclude a structural cause for headache. Neither a CT scan nor an MRI is warranted in adult patients whose headaches fit within the broad definition of tension or migraine headache and who have not demonstrated any recent substantial change in headache pattern, occurrence of seizures, or presence of focal neurological signs or symptoms.

A CT scan or an MRI study is recommended if the patient's headache pattern is atypical; has changed in pattern or character; or is accompanied by seizures, personality changes, or an abnormal neurological finding. Patients with migraines commonly have normal physical findings between attacks. Extensive diagnostic testing for a patient with a migraine is not warranted. A CBC, chemistry profile, and urinalysis may be obtained to rule out a systemic illness for the patient with typical migraine with no change in pattern and a normal physical exam. Nonspecific EEG abnormalities can occur; however, some of these findings are normal and others often do not require treatment.

The Headache Classification Committee of the International Headache Society has a headache classification system and operational diagnostic criteria for the different headache syndromes, divided into 14 categories. This system was designed to describe and identify headaches to allow for more accurate diagnosis and research. For example, a diagnosis of migraine with aura must include the presence of one or more fully reversible neurological (visual, motor, or sensory) symptoms. For migraine without aura, two of the following characteristics are required: unilateral location, pulsating quality, moderate to severe intensity, and exacerbation by physical activity. In addition, at least one of the following must be present: nausea or vomiting, photophobia, or phonophobia.

In an older adult patient with late-onset migraines, it is recommended that a CT scan be performed, just in case, even in the presence of a typical migraine with normal physical exam, to rule out organic disease. In a patient who has a history of migraines, the presentation of migraines can often change as the patient ages, and a headache can easily be mistaken for a migraine, overlooking a TIA. In older adults, a good indication of the need for imaging studies is an unusual presentation or change in symptoms associated with migraine.

Physical exam of patients with cluster headaches usually reveals normal physical findings. If there has been no change in the pattern or pain of the cluster headache and a normal physical exam is found, a CBC, chemical profile, and urinalysis may be completed to rule out a systemic illness.

Headaches from a subarachnoid hemorrhage should be identified quickly and an immediate CT scan performed. In a few patients with a small hemorrhage, the result may be negative. The benefit from the CT scan diminishes with time; that is, there is less sensitivity if the scan is obtained more than 7 days after headache onset. If the results are positive, an immediate neurosurgical referral is initiated.

With temporal arteritis, the ESR may be strongly elevated, from 50 to 100 mm, but it may also be normal. The C-reactive protein test (CRP) may also be elevated. These inflammatory markers, ESR and CRP, may, however, be normal and should not be used alone to rule out GCA. In this case, referral is essential, and a biopsy of the temporal artery (the gold standard) is recommended along with excision of a long segment of the artery because lesions typically are not present along the entire artery. Other laboratory findings may include anemia and an elevated alkaline phosphatase level.

A subdural hemorrhage is best evaluated by CT, which has a greater sensitivity to early hemorrhage. The CT reveals the bleeding as hyperdense, isodense, or hypodense. If bleeding is isodense, there may be a shift of midline structures without any further evidence of abnormalities on CT. MRI or angiography may be used to determine if a hematoma is present.

Differential Diagnosis

A complete history is paramount to distinguish and diagnose headaches and to rule out life-threatening events, such as subarachnoid hemorrhage or a TIA that could lead to a CVA. Patients may have more than one type of headache, so each event must be identified. A thorough history should be explored, including the family, social, and medical history. A family history may reveal migraine headaches in other family members. A social history may identify stress or other precipitating factors for the headache. A general medical history, including a review of systems, may lead to a diagnosis other than migraine headache. The clinician should explore any recent or past history of head or neck traumas and previous medical procedures contributing to a headache, such as LP, spinal anesthesia, or surgeries. Following an LP, for example, a bilateral headache may develop after 7 days. It typically worsens in 15 minutes on standing; once the patient is recumbent, the headache is relieved within 30 minutes. Possible causes of headache might be related to current medical conditions, especially hypothyroidism, hypertension, and asthma. Identifying current medications, both prescription and OTC agents, would help in distinguishing the headache. Chronic daily headaches are frequently associated with the daily use of nonprescription "pain killer" drugs, especially compounds containing 50 to 75 mg of caffeine per tablet.

Sudden onset of pain may suggest serious pathology such as subarachnoid hemorrhage, meningitis, or brain tumor. A headache that has been present over a period of years is more likely to be associated with migraine, cluster, or tension-type headaches. The character of pain in migraines also is helpful in distinguishing a migraine headache from a tension-type headache. A tension-type headache is dull and nonpulsating; it changes in intensity. Its duration may be 30 minutes to 7 days, and it is not associated with nausea or vomiting. Patients with tension-type headaches may report phonophobia or photophobia, but not both. Though tension-type headaches may limit some activities, these are generally not aggravated by physical activity and will not incapacitate the individual. Testing should include motor and sensory function to detect serious organic disease. A diagnosis of migraines with aura requires the presence of one or more fully recoverable neurological symptoms (visual, motor, or sensory). This finding helps the practitioner distinguish migraine from a progressive, organic disorder that requires further assessment. An aura that is rapid in onset and short in duration, atypical of migraine, may be caused by a paroxysmal event or specific cardiovascular disease. Prodromal signs (aura) can be differentiated from signs of a stroke by the length of the aural event, which is usually less than 60 minutes. Differentiating a migraine with aura from a TIA may be difficult. Age, for instance, may play a role in the differential diagnosis, because a TIA is rare in the young.

Some warning signs indicative of secondary problems include the following (Beithon et al, 2013):

- Progressive headaches that worsen over time
- Patient states, "This is the worst headache of my life!"
- New-onset headaches after age 50
- Persistent headache precipitated by a Valsalva maneuver
- Fever, hypertension, myalgias, weight loss, or scalp tenderness
- Neurological signs and symptoms: confusion, altered level of consciousness, changes in memory, papilledema, sensory deficits, reflex asymmetry, or gait disturbances
- Seizures

Management

Immediate hospitalization is required for the person with a severe (secondary) headache occurring suddenly with signs of meningeal irritation. A patient claim that he or she is having "the worst headache of my life" is definitely a red flag. Possible causes are intracranial hemorrhage or meningeal infection. If examination reveals evidence of symptoms or signs of increased intracranial pressure or severe intractable migraine, urgent hospitalization is indicated.

Because the majority of headaches (tension-type and migraines) can be recurrent and chronic, the principle of management is to design an individual treatment plan that identifies therapeutic goals for the patient. Goals would include strategies to avoid possible triggers and

the ability to abort an attack, to obtain relief from pain and associated symptoms, and to decrease the frequency and severity of attacks.

Management for a tension-type headache is focused on the use of NSAIDs, cool compresses, and stress-reduction techniques. Aspirin and acetaminophen are recommended for acute treatment in patients with tension-type headache. Triptans are recommended as the agents of choice where prophylactic treatment is being considered in a patient with chronic tension-type headache. Drug therapy for acute headache should generally not exceed more than 2 days per week on a regular basis. More frequent treatment may result in medication-overuse chronic daily headaches.

Migraine treatment can be divided into four methods: nonpharmacological, abortive therapy, pain relief, and prophylactic treatment. Nonpharmacological measures are useful for minor migraines or as an adjunct to pharmacological treatment to prevent or decrease the severity of a headache. These methods include identifying and eliminating known triggers. Maintaining a strict schedule for sleep and meals can prevent a headache related to fatigue and hunger. It is critical to keep from getting too much or too little sleep. If exercise precipitates an attack, an adequate warm-up before working out is recommended. Biofeedback, relaxation techniques, and regular aerobic exercise are encouraged. Deep breathing, massage, and hot or cold therapy sometimes ease the pain, but excessive cold (e.g., ice packs) or caffeine can backfire.

Most migraine attacks vary in the effect on the patient's ability to function. In mild attacks, the effect is minimal. In moderate attacks, visual activities are moderately impaired. In severe attacks, however, the patient is unable to continue normal activities or can continue them only with severe discomfort. In some severe attacks, the patient is incapacitated, requiring treatment in the provider's office or emergency department.

Drug therapy should be added when these measures are not completely effective. Early treatment of migraines with effective medications improves a variety of outcomes, including duration, severity, and associated disability. It is appropriate for the clinician to take a trial-and-error approach to identify medications most successful in the relief of headaches and associated symptoms with the fewest adverse effects and minimal costs and a return to normal functioning for each patient. Some patients may require three different medications: a triptan as an abortive medication, a rescue medication for breakthrough or residual pain, and a daily preventive medication. Initially, aspirin 900 mg or ibuprofen 400 mg is recommended for acute treatment in patients with migraine. Drugs Commonly Prescribed 6.5 presents a listing of medications commonly used to treat migraines. Complementary Therapies 6.1 presents other measures that may be taken to help treat headaches.

Drugs Commonly Prescribed 6.5 Migraines: Adults

Drug	Adverse Reactions and Prescribing Considerations
Abortive	
Triptans (serotonin receptor agonists)	
almotriptan (Axert)	Side effects: Paresthesias, asthenia, nausea, dizziness, chest or neck tightness, heaviness, somnolence.
eletriptan (Relpax)	Contraindicated in ischemic heart disease or other significant cardiovascular disease or cerebrovascular disease.
frovatriptan (Frova)	There is a risk of rebound headache if triptans are used more than twice a week.
naratriptan (Amerge)	
rizatriptan (Maxalt)	
sumatriptan (Imitrex)	
zolmitriptan (Zomig)	
Ergot derivatives	
ergotamine 1 mg/caffeine 100 mg (Cafergot)	Contraindicated in peripheral vascular disease, coronary heart disease, hypertension, and hepatic or renal disease.
ergotamine 2 mg/caffeine 100 mg (Cafergot supp)	IV route preferred when rapid relief is desired.
dihydroergotamine (DHE 45, Migranal)	
Prophylactic Medications	
Beta blockers (Level A; Silberstein et al, 2012)	
propranolol (Inderal)	Contraindicated in asthma, sinus bradycardia, second or third atrioventricular block.
timolol (Blocadren)	Potentiated by alcohol.
metoprolol (Lopressor, Toprol)	May cause weight loss, asthenia, mental fuzziness.

Drugs Commonly Prescribed 6.5 Migraines: Adults—cont'd

Drug	Adverse Reactions and Prescribing Considerations
(Level B; Silberstein et al, 2012)	
atenolol (Tenormin)	
nadolol (Corgard)	
Antidepressants	
venlafaxine (Effexor XR) (Level B; Silberstein et al, 2012)	
Calcium channel blockers	May take several months to be effective. Contraindicated in pregnancy. Adverse effects: Extrapyramidal effects, bradycardia, fatigue, weight gain, constipation, nausea, edema, muscle pain.
verapamil (Calan)	
Antiepileptic agents (Level A; Silberstein et al, 2012)	Adverse effects: Asthenia, back pain, diarrhea, nausea, vomiting, dizziness, somnolence, tremor, weight gain. Has teratogenic effects.
divalproex (Depakote)	
sodium valproate	
topiramate (Topamax)	Adverse effects: Somnolence, dizziness, asthenia.
Rescue Medications	
Triptans	
ergot derivatives (see above)	
NSAIDs	For mild to moderate attacks. Increased risk of GI bleed with alcohol. Adverse reactions: GI upset, GI bleed.
ibuprofen (Advil, Motrin)	
ASA (aspirin)	
naproxen sodium (Aleve, Naprosyn)	
Combination analgesics	For tension or muscle contraction headache. Potentiation with alcohol. Adverse effects: Drowsiness, dizziness, GI disturbances.
butalbital 50 mg/acetaminophen 325 mg/caffeine 40 mg (Fioricet)	
butalbital 50 mg/ASA 325 mg/caffeine 40 mg (Fiorinal)	

GI- gastrointestinal.

Complementary Therapies 6.1 Headaches

Acupuncture/acupressure

Aroma and herbal therapy

- Apply lavender oil to the temples (women).
- Apply peppermint oil to the temples (men).
- Use eucalyptus for sinus headaches.
- Drink rosemary tea or mix the essential oil in hot water and inhale.
- Take evening primrose oil 500 mg.
- Apply cold black tea bags to the eyes for 15 minutes.
- Take *Ginkgo biloba* 120–240 mg of dried extract in 2–3 doses daily.
- Take valerian *(Valeriana officialis)* 2–3 g 1–3 times per day.

Biofeedback

Diet therapy

- At the first sign of a migraine, drink 1–2 cups of strong coffee to prevent vessel dilation (effective for some individuals) or a glass of carrot or celery juice.
- To reduce throbbing and contractions, eat foods high in magnesium such as dark, leafy greens, fresh seafood, sea vegetables, nuts, whole grains, molasses.
- Eat vitamin C–rich foods such as broccoli, hot and bell peppers, sprouts, cherries, citrus.

Continued

Complementary Therapies 6.1 Headaches—cont'd

- Drink green tea.
- Avoid foods known to trigger headache: Additive and chemical-based foods (monosodium glutamate, sulfites [red wine], condiments, nitrates [aged and smoked meats]; pickled fish and shellfish; caffeine-containing foods, including chocolate; cultured foods [e.g., yogurt]; refined sweeteners); red meats; dairy products (cheese); soft drinks (the phosphorus binds up magnesium); alcohol; salty, sugary, and wheat-based foods.

Exercise

Massage or chiropractic manipulation

- Massage the temples for 5 minutes.
- Do 10 neck rolls.
- Pull ear lobes for 5 seconds.
- Rub back of ear and all around ear shell.
- Apply an ice pack to the back of the neck to reduce vasodilation or put feet in a cold water bath.

Poultices

- Rub capsaicin (Zostrix) cream on the forehead.
- Apply onion or horseradish poultices to the nape of the neck or soles of the feet.

Reflexology

- Apply pressure to the inside base of the foot and big toe 3 times for 10 seconds each.

Relaxation therapy

- Perform deep breathing.

Vitamin therapy

- Take magnesium citrate 800 mg daily.
- Take niacin 100–500 mg daily.

Other

- Avoid smoking and secondhand smoke.
- Take a coffee enema to stimulate the liver and normalize bile activity. (Bowel movements may relieve vomiting.)

For the first-choice treatment for the relief of acute attacks of cluster headaches, subcutaneous injection of sumatriptan or intranasal zolmitriptan is recommended. Oxygen inhalation is highly effective for cluster headaches when administered at the beginning of an attack with a non-rebreathing facial mask at 7 to 15 L/min. Most patients will obtain relief within 15 minutes.

Follow-up and Referral

A neurological referral should be considered in any patient with episodes of transient neurological deficits, increasing frequency and severity of unilateral headaches, or atypical auras, as well as changes in personality, excessive sleepiness, and new onset of progressive deficits suggesting a mass lesion, hemorrhage, or structural disorder. The possibility of ischemia must be carefully considered in a middle-aged or older patient with vascular risk factors who presents with a new and unexplained headache. The patient should be monitored regularly with follow-up exams. Surgical referral may be necessary for a temporal artery biopsy and definitive diagnosis or possible use of chronic steroid therapy.

Patient Education

The management of migraine is a team effort in which the patient plays an equal role. Patients must be convinced of the practitioner's interest in their complaints and commitment to their treatment. Realistic outcomes should be discussed because treatment is often ineffective or can be used for only a short period of time. Patients should be educated about the nature of migraine and given additional literature. Patients should keep a diary of any events that may be associated with an attack. This helps to identify and avoid triggers associated with a single episode and distinguish them from triggers that lead to an increase in the frequency and severity of attacks. Though clinicians may not help patients deal with endogenous triggers—endocrine factors, genetic tendencies, and psychological depression—they may help the patient identify other triggers. Exogenous triggers include foods, for example, red wine and other alcoholic beverages, aged cheese, monosodium glutamate, aspartame (dietary sweetener), and chocolate; the frequency and pattern of light; and oral contraceptives. Environmental triggers include stress and stressful family events; air travel; weather changes; odors (bad and good); and meteorological depression. Having an awareness of the

triggers may help the patient avoid them, which should diminish the frequency and intensity of the attacks. The clinician should explain the importance of warming up before exercise and avoiding tight-fitting goggles, sunglasses, helmets, or other headgear and suggest that regular exercise may prevent or decrease the headaches. If exercise is found to trigger an attack, discuss the importance of adequate nutrition and fluids before and after such activities.

Women who have migraines with aura have a much higher risk of stroke with the use of estrogen-containing contraceptives compared with those without migraines. When discussing migraine therapy with women of childbearing age, the clinician should ask what method of birth control the individual is using.

Stress-management strategies and relaxation techniques are commonly taught to patients to manage frequently unavoidable family- or work-related stress and emotional problems. When pharmacological treatment is necessary, the family should fully understand the treatment. Impaired judgment may occur with severe attacks, and the patient may not remember what drugs or dosages were used. The patient should understand each medication type, its proper use, and adverse effects of the medications, including interactions with other medications and any contraindications, such as pregnancy. Ask the patient to record in a headache diary the medications used (including any OTC or other medications), dosages, response to medication, and evaluation of treatment, including adverse effects. Clinicians should advise patients not to take headache medications other than those prescribed. Excessive use of other analgesics may reduce their effectiveness. Using ergotamine and analgesics frequently can lead to rebound headaches or chronic daily headaches. Adverse effects are common, and the patient must keep the practitioner informed in case changes in medicine are needed. Patients should discuss with the practitioner if they desire to become or are pregnant.

INFECTIOUS AND INFLAMMATORY DISORDERS

MENINGITIS

Meningitis is an inflammation of the meningeal membranes surrounding the structures of the CNS and/or the CSF. Although meningitis is typically depicted as an acute process, syndromes of both chronic and subacute nature have been found. The common factor shared by all types of meningitis is an abnormality in the number of white blood cells (WBCs) in the CSF.

Purulent forms of acute meningitis are usually caused by three types of bacteria: *Neisseria meningitidis, Haemophilus influenzae* type B, and *Streptococcus pneumoniae.* Subacute or chronic manifestations occur with fungus, mycobacteria, spirochete, HIV, and neoplasms. Aseptic meningitis (no bacteria found in CSF) is usually associated with a virus or with noninfectious causes such as a brain tumor or CVA. Table 6.7 reviews the types of meningitis.

Epidemiology and Causes

The incidence of meningitis is 15 per 100,000, with a prevalence of 5 cases per 100,000. Since the initiation of the widespread use of antibiotics in the 1950s, the mortality figures have remained steady at 10% to 15%, and those who do survive may experience chronic long-term problems, such as brain damage, kidney disease, hearing loss, or limb amputations. Susceptibility differs with the causative organism, but generally young people, elderly people, and immunocompromised patients are at greatest risk. Fifteen percent of all cases involve adolescents and young adults. One out of seven cases among adolescents will result in death.

The majority of cases of meningitis are attributed to bacteria and viruses, with a much smaller occurrence caused by fungi or parasites. Among the viral causative agents, enteroviruses are leading in incidence. Seasonal occurrence shows a higher incidence of meningitis in the spring and fall. Infants and young children are particularly susceptible because of a lack of immunity and also because of the higher fecal-to-oral transmission that takes place in this age-group. Arboviral infection is another common source during warm months when insect vectors are in abundance. The mumps virus can also be a causative factor in unimmunized populations. Various herpes viruses have been associated with meningitis, although the incidence is low.

Meningitis caused by bacterial sources is predominantly from the organisms *H influenzae, N meningitidis,* and *S pneumoniae. H influenzae* occurs primarily in infants and young children, usually in conjunction with or following otitis media, epiglottitis, or pneumonia. *N meningitidis* is common in children aged 2 to 18. Each year in the United States, about 2,600 individuals get this highly contagious disease. High-risk groups include infants under 1 year old, individuals who are immunocompromised, travelers to foreign countries where the disease is endemic, and college students (particularly freshmen) living in dorms. Between 10% and 15% of cases are fatal. *S pneumoniae* is more frequently observed in adults with concurrent conditions such as pneumonia, sinusitis, otitis media, or endocarditis. *Staphylococcus aureus* can be a causative factor of meningitis in patients who have undergone invasive neurological instrumentation or trauma and in those with shunting of CSF.

Other organisms may be responsible for chronic meningitis syndromes and are generally rarer in occurrence than acute forms. *Mycobacterium tuberculosis*

Table 6.7 Types of Meningitis

Major Type	Description	Organism	Diagnostic Tests	Treatment
Bacterial (purulent)	Rapid onset: hours or days after exposure	**Age 3 months–18 years:** *H influenzae* *N meningitidis* *S pneumoniae* **Age 18–50:** *S pneumoniae* *N meningitidis* **Age 50 or older:** *S pneumoniae* *N meningitidis* *Listeria monocytogenes* Gram-negative bacilli	CSF Gram stain analysis Culture	**Age 3 months–18 years:** cefotaxime IV 50 mg/kg q6h **OR** ceftriaxone IV 50–100 mg/kg q12h **Age 18 or older:** cefotaxime 2g q4h IV **OR** ceftriaxone 2 g q12h IV **PLUS** vancomycin 750–1,000 mg IV q12h ampicillin 2 g IV q4h
Chronic (subacute)	Symptoms develop over months; less acutely ill	*M tuberculosis* Atypical mycobacteria Fungi Spirochetes	CSF analysis Culture	**Mycobacteria:** isoniazid (INH) IV 10 mg/kg/day rifampin IV 600 mg/day **Fungi:** amphotericin IV 0.3–0.6 mg/kg/day flucytosine IV 150 mg/kg/day **Spirochetes:** penicillin G IV 12–18 million units over 21–24 days acyclovir (Zovirax) IV 30 mg/kg/day
Aseptic (viral)	More benign type; self-limited syndrome caused primarily by viruses	Mumps virus Echo virus Herpes virus	Increased immunoglobulins in CSF	Rest, fluids; acetaminophen or ibuprofen

(tuberculosis) and *Treponema pallidum* (syphilis) sometimes produce indicators of meningitis in addition to their primary symptomatology. Other rare forms include fungal meningitis, parasitic meningitis, and rickettsial meningitis.

Pathophysiology

Meningitis is an infection that produces inflammation of the brain's meningeal membranes. Viruses, fungi, and parasites can cause meningitis, but the serious meningitides are most often caused by bacteria. Bacterial meningitis is an acute purulent infection that develops within the subarachnoid space. In adults, its signs and symptoms are fever, headache, and stiff neck, usually accompanied by vomiting, lethargy, confusion, or coma.

In developed countries, adult bacterial meningitis is usually caused by *S pneumoniae* (gram-positive cocci) or *N meningitidis* (gram-negative diplococci). Both types of bacteria first colonize the nasopharynx. From the infected nasopharyngeal epithelium, bacteria then get into the underlying blood vessels. *S pneumoniae* and *N meningitidis* are both encapsulated bacteria, and their capsules protect them from phagocytosis in the bloodstream.

From the circulation, bacteria enter the CSF through the choroid plexuses in the ventricles and through injured or leaky areas of the blood–brain barrier. Bacteria can multiply rapidly in the subarachnoid space because normal CSF has few WBCs, no immunoglobulin M antibodies, and low concentrations of the complement components C3 and C4.

As the number of bacteria increases, they come in repeated contact with the brain and the meninges. Local monocytes, macrophages, astrocytes, and microglia react

to components in the bacterial cell walls by making and releasing inflammatory molecules, such as cytokines, interleukin-1, and tumor necrosis factor. These molecules increase the permeability of the blood–brain barrier and attract polymorphonuclear leukocytes from the systemic circulation. Large numbers of WBCs enter the CSF and form a purulent exudate in the subarachnoid space. The exudate reduces the flow of CSF. Meningeal irritation from the exudate causes nuchal rigidity (meaning that the neck will resist passive flexion), and lumbar punctures in bacterial meningitis produce CSF with a high WBC count.

The invading leukocytes add to the concentration of inflammatory molecules, and the blood–brain barrier becomes sufficiently permeable to cause cerebral edema and significantly increased intracranial pressure. Increased intracranial pressure causes a number of neurological and systemic signs, including a depressed level of consciousness; a triad of bradycardia, hypertension, and irregular breathing; dilated nonreactive pupils; weakness in the abductors of the eyes; papilledema; nuchal rigidity; hiccupping; projectile vomiting; or decerebrate body postures. In addition, under significantly increased intracranial pressure, the mechanisms that regulate intracranial blood flow become ineffective, and systemic hypertension and hypotension will both have disproportionate effects on cerebral blood flow. Lumbar punctures (LPs) of patients with bacterial meningitis yield high CSF pressures.

Clinical Presentation

Subjective

Subjective symptoms of meningitis include headache, photophobia, and neck pain and stiffness (nuchal rigidity).

Objective

Objective signs include fever (usually high, greater than 103°F [39.4°C]) with accompanying chills, tachycardia, and tachypnea. Signs of meningeal irritation such as Brudzinski's sign (hip and knee flexion when the neck is flexed) and Kernig's sign (inability to fully extend the legs) are often present. Occasionally, opisthotonus (severe back spasm, causing arching) is observed. Altered level of consciousness is present and may include confusion, progressive lethargy, stupor, and coma. Cranial nerve dysfunction can occur, resulting in possible diplopia, deafness, facial weakness, and pupillary abnormalities.

History taking may yield clues to possible causative agents or risk factors for meningitis. Major areas to emphasize in taking the history include pertinent exposures (contacts, food consumption, sexual practices, drug use), history of extraneural disease (especially respiratory), evidence of immunocompromise, underlying systemic disorders, and travel history.

Diagnostic Reasoning

Diagnostic Tests

Initially, routine blood studies may show marked elevation of WBCs (neutrophils) in bacterial meningitis or mild elevation in viral meningitis. In addition, electrolytes, especially sodium, are evaluated for a common complication of meningitis, the syndrome of inappropriate antidiuretic hormone secretion (SIADH).

If the clinical signs and symptoms indicate the possibility of meningitis, the collaborating physician will probably refer the patient to a neurologist for LP and CSF studies. Bacterial infection is indicated by cloudy appearance of CSF, increased CSF pressure greater than 20 mm H_2O, protein levels greater than 15 mg/dL, increased neutrophils, and reduced CSF glucose compared with simultaneous serum glucose. Gram stains and cultures of CSF may assist in detecting causative organisms. An LP should not be performed if increased intracranial pressure is suspected because cerebral herniating may occur.

Imaging studies such as MRI may reveal meningeal enhancement, basilar exudate, hydrocephalus, and possible focal lesions as indicators of meningitis. Any other contributing abnormalities such as skin, lung, or sinus lesions should be investigated.

Differential Diagnosis

Many infectious and noninfectious conditions may mimic meningitis. It is also important to establish the specific type of meningitis. Some differential diagnoses include encephalitis, giant-cell arteritis, metabolic or toxic encephalopathy, systemic lupus erythematosus (SLE), and thrombotic thrombocytopenic purpura. Similarities in symptoms include headache and visual disturbances (encephalitis, arteritis), fever (encephalitis, SLE), nuchal rigidity (encephalitis), and headache (encephalopathy). Other diverse processes may also cause changes in CSF (e.g., increased neutrophils but with a normal CSF glucose).

Management

Meningitis can be a life-threatening problem. If meningitis is suspected, the clinician should refer the patient to the collaborating physician for immediate hospitalization for extensive diagnostic examination and treatment. The principal goals for managing meningitis include eliminating infection, symptomatic care, and prevention or treatment of complications.

The first goal and priority is to eliminate infection. This is achieved through the judicial use of specific antimicrobial therapy if the meningitis is bacterial in origin. If the diagnosis of bacterial meningitis is suspected, the administration of empiric antibiotics should not be delayed. Blood cultures and an LP should be performed immediately, and empiric antibiotic therapy should be initiated without delay. Antibiotic therapy

should not be held if there is a delay in the performance of the LP. The choice of empiric therapy is predicated on the demographics of the patient (age, immunocompromised state, recent head trauma, basilar skull fracture). The patient's antibiotic regimen can be narrowed based on the results of cultures of the CSF. The usual course of IV antimicrobials is 10 to 14 days. Specific treatment regimens are included in Table 6.8. Although the concomitant use of corticosteroids has been reported in the care of children with meningitis, this strategy has not been studied thoroughly in adults and is not generally recommended. The main indication for the concomitant use of glucocorticoids is meningitis secondary to *S pneumoniae.* Use of these treatment regimens is thought to decrease inflammation and enhance circulation of the antibiotic.

Chronic meningitis may require prolonged intrathecal and/or IV antimicrobial therapy. Symptomatic treatment includes reduction of fever with acetaminophen and headache management with an analgesic such as codeine. The literature strongly recommends the use of acetaminophen every 4 to 6 hours. If nausea and vomiting are present, an antiemetic such as prochlorperazine (Compazine) may be used. Oversedation should be avoided because it may mask increasing intracranial pressure. Other supportive treatment includes bedrest in a quiet, darkened room, adequate liquids, and a soft, nutritious diet appropriate for the patient's age.

Several vaccines are available for the more common forms of meningitis or contributing infections. In some cases, chemoprophylaxis is advised for documented exposure. The most common preventive measures for meningitis, including vaccine for the unexposed and chemoprophylaxis if exposure has occurred, are listed in Table 6.8.

Of major concern as a complication of meningitis is increasing intracranial pressure caused by cerebral edema brought on by the inflammatory process. Early signs include drowsiness, episodes of confusion, and pupillary changes. Later signs include decreasing levels of consciousness, increase in pulse pressure, bradycardia, and respiratory changes. This serious complication requires ventilatory support, oxygen therapy, close monitoring of circulatory and respiratory status, and careful management of IV fluid replacement. Techniques such as hyperventilation and use of osmotic diuretics, such as mannitol (Osmitrol), and anti-inflammatory agents, such as dexamethasone (Decadron), help reduce intracranial pressure.

Follow-up and Referral

All patients who are suspected of having any form of meningitis should be referred to a neurologist for more definitive care. When the patient's condition is stable, the neurologist will release the patient back to the care of the primary health-care provider to continue

Table 6.8 Prevention of Meningitis

Type	Vaccine	Indications	Chemoprophylaxis
Meningococcal	2 doses of meningococcal conjugate vaccine quadrivalent (MCV4) at least 2 months apart Single dose Meningococcal polysaccharide vaccine (MPSV4) For all of the above: may revaccinate with MCV4 every 5 years	Adults aged 55 and younger with damaged spleen or terminal complement deficiency HIV-infected persons Epidemics High-risk children aged 2 months to 10 years; all children aged 11–12 years Military personnel or travelers to endemic locations College students living in dorms (if not vaccinated after age 16) Adults aged 56 years and older	**Adults:** rifampin 600 mg q12h for 2 days **OR** ciprofloxacin 500–750 mg once For close contacts of known cases
Pneumococcal	Pneumovax: provides immunity up to 5 years	All persons older than age 2 who are immunosuppressed or who have a chronic disease Elderly, especially those in chronic-care facilities	None recommended
H influenzae	HbOC (Hib titer) PRP-OMP (Pedvax Hib)	Children aged 2 months to 5 years, especially with chronic illness and older than 18 months attending day care Children older than age 5 years, according to risk	rifampin IV 20 mg/kg/day for 4 days For household or day-care contacts, especially if younger than age 6 years

follow-up care consisting of completion of antibiotic regimen and monitoring of blood work. Any indication of a complicated course warrants close follow-up and neurological referral. Cases of uncomplicated acute meningitis such as aseptic meningitis may require only home IV antibiotic therapy after discharge. The total course of antibiotics is about 10 to 14 days. Patients with chronic meningitis or with neurological deficits require rehabilitation and continuous follow-up. The facility for this depends on the nature of the patient's needs and family resources.

Patient Education

Education regarding prevention of meningitis through available immunization or chemoprophylaxis, as well as observance for clues to impending complications, should be provided. Home management after hospital discharge should emphasize the need for assistance with routine activities for a period lasting up to several weeks to allow for complete recovery. The patient should be encouraged to have frequent rest periods and to gradually increase activities while looking for signs (e.g., shortness of breath, increased pulse) that the activity is too strenuous. The diet should be well balanced to ensure intake of nutrients such as protein and vitamin C. Soft foods may be better tolerated. Plenty of fluids should be encouraged unless other conditions are present, such as congestive heart failure or kidney disease. Two tablets of acetaminophen (Tylenol) may be given every 4 to 6 hours for pain or headache. The patient may feel more comfortable initially in a darkened, quiet room, which will prevent discomfort related to photophobia. The importance of completing the full course of antibiotic or antiviral medications exactly as prescribed must be stressed to the patient and family. The patient needs to avoid close contact with others to whom he or she may transmit germs orally. The patient needs to be taught about potential complications and when it is necessary to call the health-care provider, for example, if he or she has any signs of an upper respiratory infection, any change in alertness or awakeness, any recurrent fever, or any other sign of a worsening illness.

ENCEPHALITIS

Usually of viral causation, encephalitis is an acute inflammation of brain tissue, which produces inflammation, hyperthermia, altered levels of consciousness, and other focal neurological signs. Often referred to as "sleeping sickness," encephalitis may on rare occasions be caused by nonviral agents, such as bacteria. Table 6.9 presents the types of encephalitis.

Epidemiology and Causes

With more than 25 viral organisms causing the inflammation, encephalitis is relatively common, with an incidence of 15 cases per 100,000 and prevalence of 10 per 100,000. Although several thousand cases of encephalitis are reported each year, many more may actually occur because the symptoms may be mild to practically nonexistent in some patients. Arboviruses (carried by arthropods, such as mosquitos) can occur in epidemic fashion during warm-weather months. With overall mortality due to encephalitis averaging between 5% and 20% and with residual neurological deficits occurring in up to 90% of cases, treatment and supportive care become important. Although most cases of encephalitis are viral, there are many nonviral agents responsible for the other few cases of encephalitis. These include tertiary syphilis, *Rickettsia rickettsii* (responsible for Rocky Mountain spotted fever), *S aureus, S pneumoniae, H influenzae, Bacteroides fragilis, Brucella* species, *Leptospira* species, *Cryptococcus neoformans,* and *M tuberculosis.*

Table 6.9 Types of Encephalitis

Major Type	Description	Organism	Diagnostic Tests	Treatment
Viral	Most common type; progressive altered level of consciousness, seizures, motor weakness, headache	More than 25 viral organisms, including arboviruses	Diagnosed primarily from the clinical picture	Symptomatic treatment Supportive care acyclovir 15 mg/kg q8h
Herpes simplex virus (HSV) (accounts for 10% of cases)	Sudden development of olfactory or gustatory hallucinations, prominent memory loss, bizarre behavior	HSV	CSF analysis EEG CT MRI	foscavir (Foscarnet) 20 mg/kg IV bolus, then 120 mg/kg IV q8h acyclovir 15 mg/kg q8h
Microbial	Selectively attacks CNS cells; varied signs and symptoms	Multiple bacterial organisms	Gram stain of CSF Serum antibody levels	penicillin 20 million units/day chloramphenicol 75–100 mg/kg/day divided q6h)

Encephalitis may occur at any age, but very young children and older adults are at the highest risk. There is no significant ethnic predisposition, and encephalitis occurs equally among men and women.

Pathophysiology

Encephalitis is an infection of the brain parenchyma. Typical symptoms include fever and confusion or drowsiness, which sometimes progresses to stupor and coma. Encephalitis is usually accompanied by inflammation of the meninges; therefore, headache and nuchal rigidity are also frequent symptoms. A bout of encephalitis can produce a range of specific neurological problems, including seizures, muscle weakness or paralysis, isolated cranial nerve palsies, heightened or depressed deep tendon reflexes, and papilledema. Sometimes the infection disrupts the hypothalamic-pituitary axis, and this can lead to diabetes insipidus, SIADH, or the inability to maintain a normal body temperature. When the infective agent is the herpes simplex virus (HSV), the encephalitis can cause personality changes, hallucinations, and aphasia.

Encephalitis is usually caused by a virus—in the United States, the most common cause is HSV—and the neurological signs and symptoms of encephalitis are usually preceded by other signs of viral infection, such as fever, malaise, muscle aches, rashes, gastrointestinal disturbances, or respiratory symptoms. Encephalitis viruses get into the body through a number of routes: HSVs are transmitted through person-to-person contact; enteroviruses are swallowed and invade through the gut; arboviruses are introduced by bites of insects, other arthropods, birds, and rodents; rabies enters through bites of mammals; and varicella-zoster viruses are inhaled. In most cases, the viruses replicate, a viremia develops, and virus particles get into the CNS from the bloodstream. Some viruses (rabies, HSV, and varicella-zoster), however, are carried into the CNS retrogradely inside axons.

A typical case of viral encephalitis comprises a mix of parenchymal inflammation, meningitis, cerebral edema, and hemorrhage. Throughout the brain and meninges, there is perivascular inflammation with local collections of lymphocytes, brain monocytes, microglia, and a lesser number of polymorphonuclear leukocytes. Capillary endothelial cells are injured, especially in the gray matter, causing small hemorrhages. There are areas of neuron cell death. In addition, ependymal cells can be damaged, contributing to the brain swelling.

The brain areas suffering the most damage vary from case to case. Some patients develop seizures, which can be either generalized or focal. Sometimes oligodendroglia are selectively infected, and the main damage is demyelination, which leads to focal neurological deficits. When the brainstem becomes infected, coma or respiratory failure can result. Generalized cortical edema decreases consciousness. The direct cause of these and other major symptoms of encephalitis seems to be the inflammation and immune reactions themselves because when these host responses subside, patients often recover dramatically.

Clinical Presentation

Subjective

A common presentation of viral encephalitis includes alteration in level of consciousness related to parenchymal swelling. The manifestations are usually progressive from lethargy to coma with the swelling and resultant increased intracranial pressure. Other focal neurological signs may develop, including seizures and motor weakness. Generalized headache with abrupt onset often accompanies other signs as a result of intraparenchymal bleeding and swelling. Other complaints may be nausea, vomiting, confusion, drowsiness, sensitivity to bright light, and a poor appetite.

Herpes simplex encephalitis caused by HSV may be heralded by bizarre behavior, aphasia, or hallucinations as the temporal and frontal lobes are selectively attacked by this organism. Other types of infectious agents (other herpes viruses, Lyme disease [*Borrelia burgdorferi*], varicella-zoster virus, *R rickettsii*) may produce a cutaneous rash in addition to neurological signs such as headache, seizures, or nuchal rigidity. The rash is a typical feature of many viral diseases.

Objective

Physical exam may reveal a fever, nuchal rigidity, paralysis, hyperresponsive deep tendon reflexes, and possibly a viral rash.

Diagnostic Reasoning

Diagnostic Tests

Epidemiological clues and assessment of risk factors to identify potential etiological agents should be sought in all patients with encephalitis. In addition, an LP is essential for the diagnosis. When encephalitis is suspected, the patient should be referred to the collaborating physician and to a neurologist. Cultures of body fluid specimens (e.g., from blood, stool, nasopharynx, or sputum), if clinical and epidemiological clues are suggestive, should be performed in an attempt to identify various viral, bacterial, and fungal etiologies of encephalitis. CSF testing reveals increased white blood cells (WBCs, especially mononuclear) and an increased protein level. A Gram stain of CSF may be useful for bacterial infection to provide early guidance for appropriate antibiotic treatment. Serum antibodies taken early in the infectious course and compared with a specimen drawn 1 to 3 weeks after onset of illness will reveal significant antibody increase. This may be helpful clinically to provide confirmation of a viral cause and further therapy guidance. With encephalitis caused by HSV, extensive hemorrhagic necrosis is demonstrated on CT scan and MRI.

Occasionally cell damage occurs that does not demonstrate abnormality on a CT scan or MRI.

Because changes in the CSF may not be apparent at the beginning of the infection, a repeat LP may be indicated. EEG is rarely helpful in establishing an etiology in patients with encephalitis, but it has a role in identifying patients with nonconvulsive seizure activity who are confused, obtunded, or comatose. An EEG taken in the presence of herpes simplex encephalitis often is abnormal because of localized hemorrhage and edema. MRI is the most sensitive neuroimaging test to evaluate patients with encephalitis. CT, both with and without contrast enhancement, should be used to evaluate patients with encephalitis if MRI is unavailable, is impractical, or cannot be performed. An MRI may indicate areas of demyelination or edema.

Differential Diagnoses

Because encephalitis often produces signs of meningeal irritation, the differentiating factor to consider encephalitis over meningitis is usually alteration in level of consciousness. Meningitis has an abrupt onset, and although the condition may show signs of parenchymal damage that are seen in encephalitis (e.g., memory difficulties, confusion, hallucinations, dysphasia, seizures, and focal motor/sensory deficits), these signs are usually seen late in the course of the disease compared with encephalitis, in which they are exhibited from the beginning. Photophobia and severe headache may point to acute meningitis rather than encephalitis. A preceding viral illness such as measles or mumps points to encephalitis occurring as a complication. Patient history of an animal bite in the presence of the typical symptoms may lead to suspicion regarding encephalitis caused by rabies. In addition, seasonal factors may point to an arboviral cause of encephalitis by mosquito or tick bite.

Management

A suspicion of encephalitis requires referral and patient hospitalization for definitive neurological diagnosis and treatment. The principles of treatment include inactivating and eliminating the causative organism, providing supportive care, and preventing complications.

Viral causation is treated with antiviral agents such as acyclovir (Zovirax). Antivirals are most effective when used early in the course of illness, especially before changes in level of consciousness occur. Antivirals act by suppressing replication of the virus. Vigorous supportive care for unconscious patients is necessary to prevent complications of ventilator support, catheters, IV lines, or other invasive treatment. Handling invasive equipment aseptically is essential in preventing infection. It is crucial to be alert for IV infiltration and phlebitis. The patient on a mechanical ventilator must be observed to prevent pressure necrosis, atelectasis, infection, and barotrauma.

Seizure control is achieved by the use of phenytoin (Dilantin), with dosages up to 600 mg/day for adults. Safety must also be a consideration with these patients. Padding should be used to prevent seizure injury. Although some fever can be beneficial, occasionally extreme hyperthermia can cause seizure activity. Acetaminophen (Tylenol) is used to reduce hyperthermia and may be given as a rectal suppository if indicated. Cerebral edema resulting in increased intracranial pressure is another ominous complication of encephalitis. An osmotic diuretic such as mannitol (Osmitrol) is chosen first to reduce edema, but glucocorticoids, such as dexamethasone (Decadron), may be added if necessary. Agents used for the treatment of encephalitis are listed in Table 6.9.

Follow-up and Referral

Patients suspected of having encephalitis are referred to a neurologist for definitive care and follow-up. When the patient is stabilized, the neurologist will release the patient's care to the primary-care provider. The relative degree of neurological deficit determines the nature of follow-up care. Complete convalescence can take weeks.

Patient Education

Prevention of infection vectors through mosquito control and insect repellants should be one important focus of patient and community education. Early detection and proper removal of ticks is another important aspect. For convalescence, the importance of bedrest, fluids, and nutrition is emphasized, as well as clues to impending complications. The patient should be encouraged to take frequent rest periods and to increase activities gradually while looking for signs that the activity is too strenuous, for example, shortness of breath and increased pulse. The patient should be instructed to eat a balanced diet to ensure the inclusion of nutrients such as protein and vitamin C. Fluids should be encouraged unless contraindicated. Acetaminophen may be used for pain or a headache. The patient may feel more comfortable in a darkened, quiet room if photophobia is present. The importance of taking the antibiotics or antiviral medications exactly as prescribed should be stressed to the patient. Patients should be instructed to avoid close contact with others who may be harboring germs. If they notice any signs of an upper respiratory infection, they should seek help from their health-care provider immediately. Patients and families should be instructed to inspect the skin for ticks and to remove them intact. They should wear protective clothing to prevent tick bites. Last, patients should be instructed when to call the health-care provider, for example, if there are any changes in their level of consciousness, recurrent fever, or any other signs of a worsening illness.

HERPES ZOSTER

Herpes zoster, commonly known as shingles, is an infection by the varicella-zoster virus occurring along dermatomal pathways and resulting in a vesicular skin rash, especially in the intercostal areas.

Epidemiology and Causes

Varicella-zoster virus is thought to become latent after the primary infection of chickenpox; it then reactivates, usually in persons who are immunocompromised, as herpes zoster (shingles). One out of every three individuals in the United States will develop shingles. Every year, there are an estimated 1 million cases. Children may get shingles; however, the risk of disease increases as persons get older, and approximately half of all cases occur among men and women aged 60 and over. It is thought to be caused by immunosuppression that often accompanies the aging process. Four percent of patients with herpes zoster may experience a second episode but rarely a third episode.

Immunocompromised patients also have a higher incidence of complications because of their impaired ability to thwart the infectious process. In adults who have no previous history of chickenpox, exposure to the virus (usually transmitted by respiratory route or by direct contact with vesicular fluid) causes herpes zoster. In addition, patients with inflammatory bowel disease are at a significantly increased risk for developing shingles.

Pathophysiology

Varicella-zoster virus, which causes chickenpox, is also responsible for a number of neurological disorders, including encephalitis, meningitis, polyneuritis, multiple cranial neuropathies, and Reye's syndrome. Varicella-zoster virus initially infects people through the mucosa of the upper respiratory tract or the conjunctivae of the eyes. Within a week, the virus has spread throughout the body via the bloodstream, and about a week later, infections of the capillaries of the skin produce the vesicular lesions of chickenpox.

At this point, virus particles are retrogradely transported inside sensory axons to dorsal root ganglia, where the viruses remain latent for the life of the patient. Varicella-zoster virus is most often found in the sensory ganglia of the ophthalmic division of the trigeminal nerve and in the dorsal root ganglia of the mid to lower spinal cord (ganglia T3 to L2). If viruses in a ganglion are reactivated, they replicate, destroy ganglion nerve cells, and migrate through the nerves to the innervated dermatomes, where they again produce vesicular skin lesions.

The destruction of sensory neurons in a ganglion produces pain in the innervated dermatome. This pain usually precedes the skin lesions by a few days, although sometimes pain is the only symptom. Typically, viruses are reactivated in only a single ganglion at a time; therefore, the symptoms are unilateral and affect a single dermatome. When the pain does not resolve within a few weeks, the syndrome is called postherpetic neuralgia (PHN). The pain of PHN can be either constant or intermittent and worsens at night and during temperature changes. Varicella-zoster virus that has been reactivated in the ophthalmic division of the trigeminal nerve can cause eye problems, including lesions of the cornea.

It is not known what triggers the reactivation of latent varicella-zoster viruses. The likelihood of developing this reactivation syndrome (called "herpes zoster" or "shingles") increases as a person ages and when a person's immune system becomes compromised. Herpes zoster is a frequent complication of HIV infection.

Clinical Presentation

Subjective

Initially, the patient with herpes zoster may present with unexplained pain. The pain is described as constant or intermittent, with a stabbing quality. The pain occurs along the involved dermatome, usually 48 to 72 hours before eruption of the classic vesicular skin rash. Pain acuity differs among individuals, but many patients say the pain becomes progressively worse at night or with changes in temperature. When herpes zoster is manifested along the branches of the fifth cranial nerve, herpes zoster ophthalmicus results. This condition can cause blindness and requires immediate referral to an ophthalmologist for evaluation and treatment. If the site of infection is along the trigeminal nerve, lesions will occur on the inside of the mouth, and occasionally in the external ear opening. Lesions on the eighth cranial (acoustic) nerve can cause vertigo, hearing loss, and ear pain.

Another major characteristic of the disease is the occurrence of acute neuritis along the path of the rash dermatome. PHN occurs in approximately 25% to 50% of patients older than age 60. The constant or intermittent stabbing pain worsens at night or with temperature changes.

Objective

Herpes zoster is characterized by a unilateral vesicular rash along a dermatome, most commonly a thoracic or lumbar dermatome. The rash begins as erythema, then changes to papular lesions that rapidly form vesicles. The vesicles rupture, releasing infectious fluid, and then form scabs. Occasionally the vesicles coalesce to form bullae. The skin lesions usually continue to develop for 3 to 5 days, and the entire disease course usually lasts 10 to 15 days. In some individuals, the skin lesions can persist for 30 days or longer. The pain caused by PHN may last much longer and at times may be permanent.

Diagnostic Reasoning

Diagnostic Tests

Diagnosis is made after careful review of data obtained from the history and physical exam. The characteristic appearance and distribution of the lesions along with a history of neuritis helps establish the diagnosis of herpes zoster. Usually the history and physical exam are all that is needed to make a definitive diagnosis.

If the diagnosis is questionable, a polymerase chain reaction assay, which detects the DNA sequence of the virus, may be done, along with antibody titer (which requires more than one test for comparison).

Differential Diagnosis

Other conditions with similar rashes need to be ruled out. Impetigo may present as vesicles around an area of broken skin. The scrapings of these lesions can be sent for a Gram stain, which will reveal gram-positive cocci if herpes zoster is present. Viral cultures may be done to rule out HSV or coxsackie viral infections that can appear with a dermatomal pattern.

Management

The principal goals are to manage the healed vesicles, obtain pain relief, and prevent secondary infection and other complications. Initial management of herpes zoster involves the use of antiviral agents. They reduce the impact of herpes zoster by diminishing neuritis and speeding the healing of the skin lesions. Early intervention in the treatment of herpes zoster produces the best results. Famciclovir (Famvir), acyclovir (Zovirax), or valacyclovir (Valtrex) may be used. Systemic corticosteroids such as prednisone starting at 60 mg/day and tapering over 3 weeks may assist in reducing acute pain when given in conjunction with the antiviral therapy. Lotions such as calamine and dressings soaked with Burow's solution may be used to soothe the lesions and prevent scratching or rubbing, thereby improving healing time, decreasing pain, and preventing secondary infection. Some patients find that corticosteroid cream helps as well. Some report that the pain of lesions in the thoracic area can be diminished by using a tight wrap of the chest to produce a splinting effect. The practitioner should use this method with care, especially in older adult patients or those with pulmonary disease, because the restriction (splinting) of normal breathing patterns could promote pulmonary stasis of secretions and increase the incidence of pulmonary infections. Patients with ophthalmic herpes affecting the first branch of the trigeminal nerve must be referred to an ophthalmologist because this condition may result in blindness. The patient with ophthalmic herpes will usually have a lesion on the tip of the nose.

Postherpetic neuralgia (PHN) is a persistent pain resulting from shingles that lasts more than 3 months after the disease has run its course. PHN rarely occurs in individuals under age 40, is more severe in individuals over age 50, and may occur in up to half of untreated people over age 60. Even with treatment, PHN may occur. Some clinicians think that administering systemic corticosteroids at the earliest onset of the rash reduces the risk of developing PHN. Analgesics (from nonnarcotic to narcotic agents in doses individualized for the patient) are supportive in reducing neuritis and PHN. If PHN is present, the use of tricyclic antidepressants such as amitriptyline 25 to 75 mg taken each night may help if simple analgesics are ineffective. For additional pain relief, gabapentin (Neurontin) starting at 300 mg three times a day up to 3,600 mg daily may help. Gabapentin along with valacyclovir given to patients with acute herpes zoster reduced the incidence of PHN to almost 10% in an initial study. More research is needed in this area. Topical capsaicin cream is approved by the Food and Drug Administration for relief of PHN. There is also a capsaicin 8% patch (Qutenza), which is a one-time treatment applied in the primary-care provider's office. In about half of all patients with PHN, this patch can reduce PHN pain by about one-third. If pain is persistent, chronic PHN may respond to a regional block with or without corticosteroids. Ideally, the patient should be referred to a pain center because PHN can have devastating effects. (See The Patient's Voice 6.1.)

The Patient's Voice 6.1

Postherpetic Neuralgia

My mother died of postherpetic neuralgia (PHN).

My mother was 80 years old and had recently won the golf championship at her club. She had been a widow for 25 years and decided that she wanted to move in with me, her daughter, with her only granddaughter (age 3). We lived 4 hours away. At first she was very independent—driving around by herself and going shopping while I worked. That only lasted a few months. Then the decline began. First, she broke a wrist, which incapacitated her, and then she got pneumonia, which weakened her. Then she got "shingles" (herpes zoster), which did her in. She was diagnosed at the earliest onset of pain, yet treatment wasn't started until the vesicles erupted. She had ophthalmic herpes, so her vision was affected. She developed PHN very early, and due to the persistent pain, she became reclusive. She stopped going out, retreating to her room and eventually wouldn't get out of bed. Nothing helped the pain. I'm convinced it was because preventive treatment wasn't started early. As she became more depressed and stayed in bed, she got weaker and weaker and just gave up. She complained of shooting pain over half of her head that was worse at night, so she'd be awake all night, and sleep all day. Nobody could help; her primary-care provider, neurologist, ophthalmologist, psychologist, nor me. She died in her sleep, and I'm convinced it was the result of PHN.

I've learned two things from this experience. First, if older persons are optimally functioning, don't move them out of their familiar supportive environment. Second, treat all cases of herpes aggressively, as you don't know who is going to develop PHN. As my mom used to say, "An ounce of prevention is worth a pound of cure."

Follow-up and Referral

It is essential that any patient with ophthalmic herpetic lesions be referred to an ophthalmologist. Other follow-up would include a return visit if skin lesions become infected or if PHN is present. Referral to a neurologist may be required at any time if the patient does not respond to primary treatment plans. Patients should be referred to a pain center if PHN results in chronic persistent pain.

Patient Education

Because herpes zoster is usually treated on an outpatient basis, patient and family education is important. The clinician should encourage patients to complete the course of the antiviral agent, even if they feel the disease has abated, or especially if they feel the treatment is not as effective as they had hoped it would be. Patients should be informed that elimination of the disease could take longer than anticipated and careful medication administration and follow-up care could mean fewer complications in the long run. Patients should be instructed that the medication may be better tolerated if taken with food. If adverse effects from the treatment plan occur, patients need to keep the practitioner informed so adjustments can be made. Education on the potential for spread of the herpes zoster virus via fluid from ruptured vesicles is important. Patients should be instructed that before the rash crusts, it can release fluid that will cause an infection in others. Patients must be careful in handling dressings, linens, towels, and clothes that they have used. They should not be around children who have not been vaccinated for chickenpox or those who have not had chickenpox yet; contact with pregnant women should also be avoided. Because patients will have a low resistance to infection, they should not be around those who may have an infectious illness, such as a cold. Patients need to know that scratching the rash can lead to an infection. The clinician should pursue ways to relieve the pruritus, as mentioned previously. Patients should be instructed about the nature of the rash so that when they see it in varying stages of progression, they will not think that it is not healing. Again, the importance of completing all prescribed medications needs to be stressed. Patients need to know the reason they are taking other medications, for example, antidepressants (which may help prevent PHN), so they will continue taking them. Research has shown that the shingles vaccine Zostavax has reduced the occurrence of shingles in people aged 60 and older and offers more than a 50% protection. In addition, it reduces the incidence of PHN by almost 70%. The Centers for Disease Control and Prevention recommends a single dose of Zostavax for adults aged 60 and older, even if they have already had shingles. Immunocompromised individuals should not receive the vaccine.

TRIGEMINAL NEURALGIA

Trigeminal neuralgia is a distressing, painful idiopathic disorder of the trigeminal nerve (cranial nerve V). It is also known as tic douloureux (unbearable painful twitch). This excruciating facial pain is paroxysmal and lasts usually less than 3 seconds. For many individuals the severity of the pain is disabling, and patients will do almost anything to prevent triggering an episode.

The lancinating, sharply cutting pain occurs along one or more of the three branches of the trigeminal nerve. Characteristically, the painful episodes occur when specific trigger zones are stimulated by touch, chewing, talking, shaving, or environmental temperature changes. Patients often describe the pain as "electric" or "stabbing" and penetrating. The pain of trigeminal neuralgia is chronic. Although patients may experience periods of spontaneous pain remission that may last weeks or months, the pain returns with the same or greater intensity.

Epidemiology and Causes

Trigeminal neuralgia occurs more frequently in women than in men and more often in individuals over age 50. The incidence is 12 per 100,000 of the general population per year. A higher incidence of risk occurs in individuals with hypertension and multiple sclerosis (MS). These at-risk individuals are much younger than the characteristic age of patients with trigeminal neuralgia.

Most often with trigeminal neuralgia there is involvement of the muscles of the right side of the face where two or three branches of the trigeminal nerve are affected. The lower and center portions of the face are most commonly affected, and it is rare to have pain in the forehead and scalp areas.

Pathophysiology

Trigeminal neuralgia, which produces episodic paroxysms of sharp facial pain, is caused by demyelination of axons in the fifth cranial nerve, the trigeminal nerve. The trigeminal nerve has three main branches: V_1, the ophthalmic branch, transmits sensation from the eye region and forehead; V_2, the maxillary branch, transmits sensation from the midface and upper jaw; and V_3, the mandibular branch, transmits sensation from the lower jaw. The neuron cell bodies for the sensory axons in these nerves are located in the trigeminal (gasserian) ganglion, which is inside the skull along the floor of the middle cranial fossa.

Trigeminal neuralgia most often affects the mandibular or the maxillary branches of the trigeminal nerve. The problem tends to occur in middle-aged and elderly people. Patients with multiple sclerosis, another demyelinating syndrome, get trigeminal neuralgia with a higher frequency than the rest of the population.

Although it is extremely painful, trigeminal neuralgia produces no obvious neurological deficits. On the other

hand, patients with trigeminal neuralgia have a general sensory hypersensitivity of the face, and 90% of sufferers have trigger points on their faces that will set off paroxysms of pain.

Trigeminal neuralgia is caused by focal demyelination of axons in the affected nerve, ganglion, or roots. Biopsy specimens of affected nerves show patches of demyelination but no significant inflammation. It has been hypothesized that, due to demyelination, axons come in direct contact with neighboring axons so that signals in one axon spread laterally to adjacent axons. A modest stimulation of the nerve will then be amplified into a massive excitation, which is interpreted by the brain as a sudden burst of pain.

Clinical Presentation

Subjective

The patient with idiopathic trigeminal neuralgia presents with complaints of severe paroxysmal pain, most commonly on one side of the face. The pain lasts for a few seconds, with no ache or pain between occurrences, and follows the trigeminal nerve distribution. The patient's history includes the onset of a painful event after trigger points have been stimulated by chewing, talking, brushing teeth, touching the face, or, in some cases, after intense physical activity, lowering of the head, and wind touching the face. The patient's history may include periods of remission with or without medical treatment.

During periods of exacerbation, the patient may be totally disabled by the severity of the pain. Patients may report refraining from eating, sleep deprivation, depression, and even suicidal tendencies, which reflect their willingness to go to great extremes to escape the severe paroxysmal pain.

Objective

On physical exam, the cranial nerves, specifically the trigeminal nerve, have normal motor and sensory function; facial muscle strength and reflexes are normal. Clinically, the cardinal signs of idiopathic trigeminal neuralgia are elicited when a facial trigger point is stimulated; the patient experiences a sharp, electric-type pain that follows the distribution of the trigeminal nerve and lasts for only a few seconds, and the patient's face grimaces. After the painful attack, there is no residual ache or pain. Facial pain, however, that is continuous and varies in intensity must be further evaluated for atypical trigeminal neuralgia that is caused by trauma, tumor, or previous facial surgery. Because of the many pathological and etiological theories regarding trigeminal neuralgia, the clinician must be alert to the characteristic symptoms of typical (idiopathic) trigeminal neuralgia. These are short periods of paroxysmal pain associated with trigger zones, pain limited to the distribution of the trigeminal nerve branches, and negative neurological findings.

Diagnostic Reasoning

Diagnostic Tests

Idiopathic trigeminal neuralgia can often be diagnosed based on clinical history that describes paroxysmal pain episodes triggered by specific activities in patients characteristically older than age 50.

Patients who have prolonged episodes of pain that increases in intensity and occurrence and are younger need to be evaluated further for pathology-related tumors, trauma, MS, and vascular compression. The tests most frequently used for the diagnosis of atypical trigeminal neuralgia are a CT scan and an MRI. The MRI is the method of choice in differential diagnoses of trigeminal nerve pathology.

Another diagnostic method for typical trigeminal neuralgia is the administration of carbamazepine (Tegretol) or a low dose of a tricyclic antidepressant. If either of these medications relieves the pain, this effect may be used to diagnose this disorder.

Differential Diagnosis

There are many causes for the general presentation of orofacial pain. These conditions can be generally categorized as inflammatory (e.g., dental pathology, sinusitis, parotitis, sialolithiasis, temporal arteritis, HSV type I), neurological (e.g., trigeminal, glossopharyngeal, or paratrigeminal neuralgia; cluster or migraine headaches; meningiomas; posterior fossa tumors), or musculoskeletal (e.g., temporomandibular joint pain, myofascial pain dysfunction syndrome). It is important, therefore, to identify whether the clinical presentation is either typical trigeminal neuralgia or some other orofacial pain cause.

Management

The major principles in the management of trigeminal neuralgia are (1) to elicit a remission by drug therapy, (2) to prevent untoward effects in patients resulting from prescribed medications, and (3) to help the patient avoid triggering painful episodes. Trigeminal neuralgia is a chronic condition that results in the need for the patient's chronic pain to be managed. In addition to interventions related to establishing remission and avoidance of painful episodes, the patient's psychological needs—related to depression, isolation, and possible suicidal tendencies—are significant areas in the plan of care.

Initially, pharmacological management is to try to initiate remission of the pain. Carbamazepine or gabapentin may block the nerve firing. The patient experiencing pain relief should stay on the medication for at least 6 months Tricyclic antidepressants such as amitriptyline can also be used to treat pain.

Patients who are taking oral contraceptives should be cautioned that the contraceptives may not be reliable when analgesic drugs are being prescribed. An alternative method of birth control must be recommended. The

patient should also be warned about the hazard of driving a motor vehicle when on these drugs.

Follow-up for complications of drug therapy with anticonvulsants is essential in the pharmacological management of typical trigeminal neuralgia. If carbamazepine becomes ineffective after prolonged use or if adverse effects develop, the dosage must be gradually decreased to prevent withdrawal symptoms. Carbamazepine has many adverse effects, including nausea, vomiting, mouth ulcers, dizziness, diplopia, skin rash, blood dyscrasias (aplastic anemia, agranulocytosis, thrombocytopenia, and leukopenia), fever, and chills.

Fluoxetine (Prozac) may be prescribed for patients who experience psychological depression and difficulty coping with the pain associated with performing normal ADLs. Periods of remission and exacerbation that occur as pharmacological interventions become less effective are also very stressful for the patient.

Other therapies for trigeminal neuralgia include acupuncture, transcutaneous electrical nerve stimulation, and topical application of capsaicin (Zostrix). Some patients have reported modest pain relief after botulinum toxin injections that block the activity of sensory nerves. Patients with trigeminal neuralgia who have few or no periods of remission should be referred for surgical intervention.

The unrelenting paroxysmal pain associated with trigeminal neuralgia is frequently associated with compression of the trigeminal nerve root. Surgical intervention (rhizotomy) is performed to relieve the compression, although recurrence in 1 to 2 years is common after surgery, regardless of the surgical method chosen.

Follow-up and Referral

Because of the intense and chronic pain associated with trigeminal neuralgia, the patient may experience depression, social isolation, and suicidal tendencies. The clinician must recognize these effects of the disease and reinforce coping mechanisms the patient may use during periods of exacerbation. Referral for counseling may be required if the patient is not able to cope with the chronicity and severity of the pain. The patient experiences pain when eating and washing the face and frequently avoids these and other activities. The patient begins to lose weight and becomes dehydrated, and hygiene becomes a problem.

Patient Education

The goals of patient instruction are the avoidance of triggering painful events, pharmacological management, and coping with chronic, severe pain. Nutritional counseling should encourage intake of soft or pureed, high-caloric foods, along with increased fluids. For hygiene, the use of soft washcloths and mouthwashes should be encouraged. Patients should be educated about adverse reactions (e.g., dizziness, sleepiness, ataxia, nausea and vomiting) to their medications and about the necessity for follow-up blood studies to detect any blood dyscrasias. Intense counseling and supportive education is a continuous process in caring for the patient with trigeminal neuralgia. Recognition of the patient's educational needs based on his or her coping mechanisms, search for pain treatment, and the status of the neuralgia will direct the clinician in establishing an individualized plan.

BELL'S PALSY

Bell's palsy (prosopoplegia) is a condition with an acute onset of flaccid paralysis, usually occurring on one side of the face in an otherwise healthy person. The peripheral facial palsy is self-limiting and complete recovery usually occurs in a few weeks or months in 80% to 86% of patients. Initially, the facial paralysis may be incomplete and then worsen within 48 hours after onset. The sudden experience of facial paralysis is very frightening to the patient, who usually seeks medical care immediately.

Epidemiology and Causes

The specific cause of Bell's palsy is unknown. Theories of etiology include viral infections such as herpes simplex virus type I, respiratory infections, and heredity. Approximately 40,000 individuals each year in the United States will get Bell's palsy. It does not discriminate against men or women but is less common under age 15 years or over age 60 years. A higher incidence is seen in individuals with diabetes, hypertension, trauma, toxin exposure, Lyme disease, pregnancy, and those suffering upper respiratory ailments.

A complete recovery from facial paralysis usually occurs in 3 to 6 months or no longer than 12 months. Persons at risk for incomplete recovery are those older than age 55, hypertensive, with pain other than ear pain, with complete facial paralysis, and those who have changes in lacrimation, such as involuntary shedding of tears.

Pathophysiology

Cranial nerve VII—the facial nerve—comprises both motor and sensory axons. Its efferent motor axons innervate the muscles of facial expression and its preganglionic parasympathetic axons innervate the lacrimal and nasopalatine glands and all the salivary glands except the parotid. Its afferent axons carry sensation from the taste buds of the anterior two-thirds of the tongue and from cutaneous sensory receptors of the external ear.

The various classes of axons in the facial nerve peel off group by group as the nerve makes its way through the bony canals of the skull; therefore, pressure on or lesions of the nerve at different locations will produce different deficits. Inside the skull, the facial nerve runs with cranial nerve VIII, the vestibulocochlear nerve, and pressure on the facial nerve here (such as from an acoustic neuroma) will usually cause hearing loss and

vestibular problems in addition to deficits in all the motor and sensory components of the facial nerve.

Within the skull wall, the facial and vestibulocochlear nerves separate. After this, the first components to leave the facial nerve are the lacrimal and nasopalatine axons; therefore, damage to the facial nerve distal to this juncture will not affect a patient's ability to produce tears. The next components to leave the facial nerve are the taste axons and the axons to the salivary glands; therefore, damage to the facial nerve distal to this juncture will cause unilateral paralysis of all the muscles of facial expression but will not affect taste or the production of saliva.

Damage to the facial nerve inside the skull wall can be caused by skull fractures, hemangiomas, tumors, and inflammation. When the facial nerve is damaged and no structural problems are found, the condition is called Bell's palsy. Bell's palsy always produces unilateral facial paralysis, and depending on the location of the nerve lesion(s), it may also include deficits in functions of the other components of the facial nerve.

The majority of cases of Bell's palsy are preceded by systemic symptoms of a viral infection. Most cases are thought to be caused by a reactivated herpes simplex infection of the geniculate ganglion, which leads to inflammation and swelling of the nerve inside its restrictive bony canal. Reactivated varicella-zoster virus can also cause Bell's palsy; these cases probably involve demyelination of the nerve and include severe pain and sometimes hearing loss. In addition, a Bell's palsy–like facial paralysis is the most common neurological problem caused by Lyme disease.

Clinical Presentation

Subjective

Patients with Bell's palsy present with an acute onset of partial or total paralysis on one side of the face, usually involving lower motor neurons. The patient has normal ocular movements and facial sensation and often complains of loss of taste (dysgeusia), postauricular pain, abnormal sensitivity to sound (hyperacusis), and a heavy feeling in the face.

Objective

On physical exam, the motor and sensory functions along the entire facial nerve should be assessed. Bell's palsy can be diagnosed because of its acute onset and the fact that no other CNS symptoms exist. The physical assessment characteristically reveals on the affected side the absence of forehead wrinkles, wider palpebral fissure of the eye, decreased corneal reflex, Bell's phenomenon (the eyeball turns upward when the patient tries to close the eyelid), open eyelid, flattening of the nasolabial fold, narrowed lips, and loss of taste on the anterior two-thirds of the tongue. Lacrimation may or may not be affected.

A patient with Bell's palsy typically is unable to make these movements on the affected side on request: raise the eyebrow, wrinkle the forehead, close the eyelid, whistle, or retract the muscles of the mouth or chin. When talking, the patient's cheek puffs out and there is an inability to clearly pronounce words that require pursing of the lips. There appears to be a deviation of the tongue because of mouth paralysis on the affected side. The patient is unable to suck or hold fluids in the mouth but is able to swallow.

During the history, it is important to ask about pregnancy, diabetes, any recent infection such as upper respiratory infection or herpes simplex virus, and any stress.

Diagnostic Reasoning

Diagnostic Tests

Diagnosis is based primarily on patient history and clinical exam. If the history and physical exam are inconclusive for Bell's palsy, the patient should be referred for further diagnostic work-up, including a CT scan or an MRI. Evoked electromyography or electroneurography can assess the extent of nerve involvement. These tests are helpful when the patient is not recovering from the Bell's palsy as expected.

Documentation of the extent of facial function at the time of initial diagnosis and at subsequent assessments is critical to evaluate the course of the disease. Several methods to assess and document facial function are available to the clinician. Photographs, an automated computer-assisted clinimetric system, or a facial grading system may be used. Regardless of what method is used to assess facial functioning, the progression or lack of progression of the symptoms is important to differentiate Bell's palsy from other pathology.

Differential Diagnosis

Tumors, infections, trauma, drug ingestion, TIAs, CVAs, and trigeminal neuralgia may appear similar to Bell's palsy. The history and physical exam will usually provide conclusive data to support the diagnosis of Bell's palsy. Close inspection of the patient's ears and skin is done to assess for herpes zoster lesions that would indicate Ramsay Hunt syndrome, which is herpes zoster affecting the facial and auditory nerves, causing facial palsy and cutaneous herpes zoster lesions of the external ear and/or tympanic membrane. Associated symptoms include tinnitus, vertigo, and deafness.

Management

The majority of patients with Bell's palsy totally recover without treatment because the lesion is mild and a result of a conduction block. Therefore, management of a patient with idiopathic Bell's palsy is primarily directed at preventing eye injury. Loss of the ability to blink and close the eyelid subjects the cornea to drying and ulceration.

The patient is instructed to keep the eye moist by topical application of artificial tears every 30 minutes during the day and use of an ocular lubricant ointment at night. Wearing wraparound sunglasses and using a moisture shield (self-adhesive eye bubble, cellulose wrap) are ways to provide eye protection. An eye patch may be necessary if eye closure is not possible. An ophthalmologist should be consulted if the patient experiences any signs of corneal irritation or injury.

Pharmacological management of Bell's palsy is controversial because the disorder is a self-limiting condition. Some practitioners recommend treatment with acyclovir (Zovirax); others recommend prednisone to reduce inflammation and swelling. If drug treatment is chosen, the medication should be started as soon as Bell's palsy is diagnosed.

Ear pain control is essential during the first few weeks after onset of symptoms. The patient may try a variety of over-the-counter drugs, such as acetaminophen (Tylenol) and ibuprofen (Advil, Motrin). Rest and decreased auditory stimulation may lessen the effects of hyperacusis.

Follow-up and Referral

The patient should be examined at regular intervals to assess for resolution or deterioration of Bell's palsy symptoms and adverse effects of medication, if prescribed. Special attention should be given to effectiveness of eye care by the patient. If the patient's symptoms have not resolved in 6 months or if other neurological signs are evident, the patient should be referred to a neurologist. In some cases, though rarely, the patient may be advised to have surgery. Surgery may be indicated for cases in which paralysis is progressive and when incomplete involvement of some branch of the facial nerve is evident.

Patient Education

The patient with Bell's palsy is experiencing a physical and psychological crisis. The clinician provides essential teaching that supports the recovery process. The patient is in a state of shock and disbelief at the change in self-image and concern about the causes of the symptoms. Reassurance that Bell's palsy is usually a short-term condition will allay some anxiety.

To help the patient cope with self-esteem issues, the clinician may advise the patient to use cosmetic interventions to decrease objective symptoms. For example, combing hair over the affected side of the face, using make-up to emphasize the unaffected side, growing a beard or mustache, and wearing sunglasses can lessen the appearance of facial paralysis. Drinking from a plastic, spouted bottle may be easier than drinking from a cup or glass, because liquid can be squeezed into the back of the mouth.

In addition to meticulous eye care, the patient should be taught to perform oral hygiene vigorously because food becomes trapped, there is a reduced amount of saliva, and chewing is impaired. The patient should be instructed to use a soft-bristled toothbrush, mild mouth rinses, dental floss, and an oral water-jet machine to remove food particles after each meal. Foods may also need to be spicier than normal to compensate for loss of taste. The clinician should encourage the patient to eat soft foods of high nutritional value because patients often avoid eating because of difficulty chewing and holding food in the mouth.

When muscle strength returns, facial massage and exercise can be started for 15 to 20 minutes at least twice a day. Using a cream or oil, the affected side of the face from forehead to chin should be massaged. The patient should also be encouraged to perform facial exercises, including opening and closing of eyes, winking, smiling, and showing teeth in front of a mirror.

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS) is usually an ascending paralysis most often beginning in the legs and then progressing in an ascending fashion. It only affects about 1 person per 100,000 individuals. There is another form called the Miller Fisher variant that begins with brainstem symptoms such as ataxia, dysphonia, and dysphagia. It may be related to gastric *Campylobacter* infection. There is production of an abnormal antibody that settles on the motor neuron causing it to dysfunction. GBS may be self-limiting over days or in some cases permanent residual such as weakness may occur. Most individuals reach the stage of greatest weakness within the first 2 weeks after the symptoms appear, and 90% will reach this point by the third week. The diagnosis is made by spinal fluid analysis, which shows an elevated protein, especially gamma globulin with little or no cellular response. A nerve conduction velocity test may also help aid in the diagnosis. The treatment involves IV gamma globulin or plasmapheresis. It may progress to a chronic form, chronic inflammatory demyelinating polyneuropathy.

BOTULISM

Botulism is a rare paralytic illness caused by the bacterium *Clostridium botulinum* and usually enters through an infected wound or the oral route. Not pasteurizing milk or adding honey to milk puts infants at risk for infection with botulism. Home canning at elevations above 8,000 feet can fail to sterilize the media and lead to botulism. Wound botulism is on the increase due to IV drug abuse.

Symptoms begin within 72 hours of ingesting the toxin and continue for several days. The bacterium forms an endotoxin that affects nerve endings, preventing the release of acetylcholine at the myoneural junction. This causes paralysis.

The primary management of botulism is preventive. However, acute cases require supportive treatment, most

often with a ventilator, and if the patient is not allergic to horse serum, trivalent antitoxin is given.

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is a disorder of the neuromuscular junction. It is an autoimmune disease in which an antibody occupies the muscle receptor for acetylcholine. Women are more affected than men, and it occurs in approximately 10 to 15 individuals per 100,000.

The symptoms of MG are usually muscle fatigue associated with use. It affects smaller muscles, which have more acetylcholine receptors than larger muscles. Therefore, eye movements and speech are most commonly affected. The symptoms will ameliorate with rest.

Symptomatic treatment is with anticholinesterase agents. This affords temporary relief. The major side effect is gastrointestinal irritability.

For permanent relief of the symptoms, antibody suppression is needed. This may be accomplished by giving immunosuppressant drugs. Plasmapheresis is also used to reduce antibody levels. In some patients thymectomy may help, because the thymus may be the source of the abnormal lymphocytes creating the abnormal antibodies.

Chapter 7

COMMON COMPLAINTS

ALOPECIA

Alopecia (baldness) can occur anywhere on the body where hair is present, although it is commonly associated with absence of hair on the scalp area. Scalp hair loss can occur in patches *(alopecia areata)* or over the entire scalp *(androgenetic alopecia).* Hair loss can occur on the eyebrows, on the beard area, or on the entire body *(alopecia universalis),* and it can be either a temporary or permanent condition.

Hair loss is a gradual process; up to 50% of scalp hair can be lost before the loss becomes clinically apparent. Alopecia is associated with emotional distress even if the hair loss is temporary *(alopecia areata).* The most common cause of permanent hair loss is androgenetic alopecia, or male-pattern baldness (common baldness). Androgenetic alopecia (AGA) has a polygenic inheritance pattern: It is inherited from both parents, not only through maternal genes—a common myth. Another common misconception is that AGA is more common in men; in reality, it occurs in both sexes. Factors that influence normal hair development and cycling include estrogens, growth hormone, glucocorticoids, thyroid hormone, retinoid, prolactin, and androgens; these factors can be adversely affected by certain medications. The most important hair growth factors are the androgens, testosterone, and its active metabolite, dihydrotestosterone. During puberty, when androgen secretion starts, hair follicles become enlarged in certain areas of the body such as the beard area, the chest, and the extremities. Androgens have the opposite effect on the hair follicles of the scalp region: They cause a decrease in the size of the hair follicles (miniaturization) and can alter the hairline on the bitemporal region and the vortex areas. Four cycles of scalp hair growth exist. The growth phase *(anagen)* of scalp hair is the longest cycle, lasting from 2 to 6 years. The majority of hair on the scalp (90%–95%) is in the anagen phase. The latent, or involution, phase *(catagen)* is the shortest cycle, which lasts only 2 to 3 weeks. The resting phase *(telogen)* lasts from 2 to 3 months. Hair is shed during the fourth phase *(exogen).* In an average person, from 50 to 150 hairs are lost daily, and the cycle is repeated. Both topical and systemic medications for hair loss affect some or all of the phases of hair growth.

Thirty-five million men in the United States experience hair loss, and 21 million women do as well. For men, 40% have noticeable hair loss by age 35 years, 65% by age 60 years, 70% by age 80 years, and 80% by age 85 years. Women tend to develop AGA 10 years later than men. Thirteen percent of women develop AGA before menopause and 75% develop it postmenopausally.

In reversible cases of nonscarring alopecia, regrowth of hair usually takes several months. Patients who are reassured of this important fact will have lessened anxiety over their condition. Two important factors that the practitioner should address in the evaluation of alopecia are (1) whether it is scarring or nonscarring alopecia and (2) whether hair loss is in a small, well-circumscribed area (alopecia areata or trichotillomania) or generalized (AGA). Based on these two general categories, the differential diagnosis is made easier for the clinician. Scarring alopecia *(cicatricial alopecia)* causes permanent hair loss and is not reversible. Hair loss from nonscarring alopecia *(noncicatricial alopecia)* can be either temporary or permanent.

Differential Diagnosis

A thorough history is important in the evaluation of alopecia. Information regarding family members—both male and female—with hair loss should be elicited. Because some medications affect hair growth factors, a review of the patient's medication history is important and should not be missed. Drugs that cause hair loss include hormones, anticonvulsants, anticoagulants, oral contraceptives, beta blockers, antimetabolites, antithyroid drugs, and excessive amounts of vitamin A or topical Retin-A.

A potassium hydroxide (KOH) and Wood's light exam is helpful in the diagnosis of tinea capitis in cases of patchy hair loss. Although most cases of tinea capitis do not fluoresce, a fungal culture can provide definitive proof of fungal infection and should be performed if suspicion is high. Some dermatologists utilize the telogen

count, in which 100 hairs (only 50 hairs are needed for accuracy) are removed from different areas of the scalp and the number of hairs in telogen is counted. Telogen hairs are recognized because of the large white club on the end of each hair. The appearance of the skin on the scalp will give the practitioner a clue to the type of alopecia that is involved. In nonscarring alopecia, the scalp will have normal texture and color. In contrast, the scalp of a patient with scarring alopecia has no visible hair follicles (or no follicular openings) and is atrophied and smooth. The affected area of the scalp (or the entire scalp) is sometimes hypopigmented or hyperpigmented. Obvious scarring is seen in some patients, and some have erythema and scaling (in these cases, it is important to rule out fungal infection). Look for fine pitting of the dorsal nail plate ("hammered brass") on the physical exam.

Both systemic and nonsystemic causes are seen in nonscarring alopecia. Nonsystemic causes of alopecia include hair pulling *(trichotillomania),* excessive traction of the frontal and temporal area of the scalp (from tight cornrows or tight ponytails), trauma (both physical and chemical), radiation therapy of the head, local bacterial infection, and local fungal infection. Trichotillomania (compulsive hair pulling) is more commonly seen in children and teens. It is usually on the same side as the dominant hand and may include other than just scalp hair (e.g., eyelashes, eyebrow hair, and beards, although those hairs are usually not long enough to pull).

Systemic causes of nonscarring alopecia include alopecia areata, telogen effluvium, androgenetic baldness (common baldness), vitiligo, Hashimoto's thyroiditis, Addison's disease, systemic lupus erythematosus (SLE), hypothyroidism or hyperthyroidism, secondary syphilis, severe herpes zoster of the scalp, drug-induced alopecia (common in patients on cyclophosphamide therapy), iron-deficiency anemia, and pituitary insufficiency.

Telogen effluvium (TE)—excessive shedding of scalp hair as a result of an increased number of hair follicles entering the resting stage (telogen)—can be caused by fever and certain drugs; therefore, a search for these possible causes should be included in the history taking. TE may also be caused by stress, pregnancy and/or childbirth, extreme weight loss, and general anesthesia. TE is almost nonexistent in men. The classic signs of androgenetic baldness are thinning hairs of various diameters and lengths ("miniaturized" hairs) located in typical areas, which differ in men and women. In men, hair loss usually starts on the hairline and around the temple (bitemporal) area and the vortex or top of the head. In women, hair loss is much more diffuse and occurs mostly on top of the head. Hair loss is sometimes harder to recognize in women because of hairstyles that are used to camouflage the problem.

Alopecia areata is not an uncommon condition in primary-care practice. The cause of alopecia areata is still unknown, although an immunological mechanism is suspected. The typical patient will present with well-circumscribed patches of hair loss on the scalp or sometimes on the face, in areas such as the eyebrows or the beard area. Occasionally only one patch is seen; sometimes multiple patches of hair loss are apparent. Alopecia areata can occur once in a lifetime, or it can be a recurrent problem. Some cases become recalcitrant and are best treated by specialists. Because gray hair is spared, patients may complain of going gray overnight. In alopecia areata, when the scalp is examined closely with a magnifying lens, short, stubby hairs with tapered ends (so-called "exclamation point hairs") are seen on the periphery of the bald patch (or patches). Alopecia areata is associated with autoimmune endocrinopathies such as Hashimoto's thyroiditis, Addison's disease, and pernicious anemia.

Hair regrowth occurs after several months, with new hairs that look thinner and finer than the original hair. There is no cure for alopecia areata, but in most patients hair usually regrows spontaneously after several months. The prognosis for alopecia areata is good if it occurs after puberty: Studies have found that up to 80% of these patients will regrow hair. Occasionally, a case of persistent alopecia areata that is unresponsive to treatment is seen; these cases are best referred to dermatologists for management.

Etiology of scarring, or cicatricial, alopecia can include trauma (physical or chemical), severe bacterial or fungal infections of the scalp, scleroderma, discoid lupus erythematosus, lichen planopilaris, and excessive radiation. Early recognition and treatment of bacterial or fungal infections can help prevent or minimize the incidence of scarring. Severe local infection with either bacteria or fungi can permanently damage hair follicles and cause a patchy (and scarring) alopecia that is permanent.

When an autoimmune disease is suspected, laboratory tests include antinuclear antibodies to rule out lupus or autoimmune disorders; rheumatoid factor; and erythrocyte sedimentation rate (ESR), a nonspecific marker for inflammation. The rheumatology, or arthritis, profile is a panel of tests that may help in the diagnosis of autoimmune disorders that can cause alopecia, such as SLE and scleroderma. Scleroderma (progressive systemic sclerosis) is a multisystemic inflammatory disorder associated with sclerotic changes in the body, including the skin. The skin becomes diffusely thickened with telangiectasia. A scalp biopsy is reserved for difficult and recalcitrant cases of alopecia. For the differential diagnosis of alopecia, see Differential Diagnosis 7.1.

In addition, serum testosterone, dehydroepiandrosterone, iron, total iron-binding capacity, and thyroid function tests, along with a complete blood count (CBC), will identify most other causes of hair thinning in premenopausal women.

Differential Diagnosis 7.1 Alopecia

Type of Alopecia	Differential Diagnosis
Scarring Alopecia (Cicatricial alopecia)	Trauma (chemical, physical, heat) Kerion formation in tinea capitis Chronic discoid lupus erythematosus Scleroderma Excessive radiation to scalp Lichen planopilaris Bacterial infection of scalp
Nonscarring Alopecia (Noncicatricial alopecia)	Alopecia areata Drug-induced hair loss Trichotillomania (hair pulling) Telogen effluvium (after pregnancy, major surgery, major emotional stress) Androgenetic baldness Tinea capitis (with no kerion formation) Hypothyroidism (Hashimoto's thyroiditis) Systemic lupus erythematosus Addison's disease

A biopsy is useful in diagnosing scarring alopecia, but specimens must be obtained from the active border rather than from the scarred central zone.

Treatment

Medical treatment is available but is not a permanent solution for alopecia. Patients should be educated that total return to previous levels of hair growth is not possible, but cosmetically acceptable hair coverage is possible. Medical treatments must be used daily to maintain regrown hair. Stopping treatment will result in shedding of hair and a return to the previous levels of alopecia. Hair shedding is seen rapidly in a matter of days after stopping minoxidil (Rogaine), but is more gradual over several months with finasteride (Propecia). Propecia is for men only. Nonmedical options include hair weaves, toupees, and wigs. Wigs are either worn on top of the head or are interwoven into existing hair as a "weave." As the existing hair (to which the weave is anchored) grows, the weave must be readjusted periodically, which may impart increased stress on hair follicles. The only currently available permanent treatment for alopecia is scalp surgery with hair transplantation.

Topical treatment includes minoxidil 2% solution (Rogaine for Men or Rogaine for Women) and minoxidil 5% solution (Rogaine Extra Strength for Men), which are available over the counter (OTC). At a higher dose, oral minoxidil is a vasodilator and is used to treat hypertension. Topical minoxidil has not been found to cause lowering of systolic or diastolic blood pressure and pulse rate. The best candidates for treatment with topical minoxidil are patients with recent onset of alopecia (less than 5 years), those younger than age 50 years, and patients with smaller areas of hair loss. Up to 40% of patients who use topical minoxidil for a period of 1 year or more will experience moderate to dense hair regrowth. Minoxidil 2% solution has been shown consistently to reduce hair loss and induce new hair growth in females with female pattern hair loss (Level 2; University of Texas at Austin, 2011). Minoxidil 5% solution is more effective, but it is indicated for use by men only. The 5% solution has not produced any demonstrable improvement over that seen with the 2% solution in women. Minoxidil is used twice daily on the affected scalp area. Adverse effects include irritation, itching, dryness, scaling, and redness of the scalp; sometimes minoxidil can cause contact dermatitis. An adverse effect that is more common in women is *hypertrichosis* (excessive hair growth on the body).

Systemic treatment for alopecia with finasteride (Propecia) should not be used in women of reproductive age because this drug can cause abnormalities of the external genitalia of male fetuses. In women not of childbearing age, finasteride does not appear to be effective in treating AGA. Therefore, finasteride, once daily, is used for the treatment of androgenetic baldness in men only. Dihydrotestosterone (DHT) levels are the main issue in men because testosterone is converted to DHT by means of the enzyme 5α-reductase. Finasteride, which blocks the effects of 5α-reductase, is metabolized in the liver and should be used with caution in patients with liver disease. In men aged 60 years or older, finasteride may not be as effective as in younger men because of reduction in alpha-reductase activity. Adverse effects include decreased libido (1.8%), erectile dysfunction (1.3%), and ejaculatory dysfunction (1.2%). In most men, these sexual side effects gradually resolve with prolonged treatment.

The treatment choice is determined by the patient's age and the severity of the hair loss. For patients with hair loss of less than 50%, treatment options include corticosteroid intralesional injections, anthralin, minoxidil solution, or topical corticosteroid creams. Topical treatment with a potent corticosteroid is preferred by primary-care practitioners because it is not invasive and is simple to use, although it is not as effective as intralesional injections. Small amounts of triamcinolone acetonide 5 mg/mL (Kenalog) may be injected intralesionally into the middermal layer, spaced approximately 1 cm apart on bald patches. Hair growth is usually seen in 4 weeks. One side effect of corticosteroid use that patients and practitioners should monitor for is atrophy of the skin. Unfortunately, these injections are only a

temporary solution and do not alter the underlying pathophysiology of hair loss.

PIGMENTATION CHANGES

The skin is the largest and most visible organ of the body. For most people, skin color is an important part of their identity as an individual. Because of the skin's visibility, conditions affecting the skin cause not only physical discomfort but also have emotional overtones. Pigmentation disorders seen in primary care include both hyperpigmentation and hypopigmentation. Either condition can be a sign of disease, or it can be considered a normal finding, depending on the rest of the clinical picture.

Melanin is a skin pigment produced by melanocyte cells that determines skin color. Although there is no difference in the number of melanocytes among the different ethnic groups, the ability of the melanocytes of darker-skinned people to produce and retain melanin (from melanosomes) is much greater than in people with lighter skin. Research has found that melanosome size is directly related to skin color: The larger the size of the melanosomes, the darker the skin color. Asians and whites have fewer and smaller melanosomes, whereas in individuals with darker skins, especially in blacks or people of African descent, melanosomes are much larger and more numerous. Darker skin gives protection from ultraviolet (UV) radiation. Studies of people with darker skin have shown that dark skin has a sun protection factor (SPF) between 5 and 13. Because of the protective aspect of darker skin, the incidence of nonmelanoma skin cancer in blacks or people of African origin is much less than in whites. Studies have shown that basal cell carcinomas are extremely rare in individuals with darker skin.

Pigmentation disorders can be clinical manifestations of diseases that include endocrine, genetic, metabolic, or nutritional problems or a malignancy. Pigmentation disorders seen in primary care include normal variations in color as a result of ethnic differences (e.g., oral hyperpigmentation in darker skins). *Vitiligo,* or the total loss of skin color in patchy areas of the body (rarely over the entire body), is recognized clinically as extremely white macules or patches that are usually located on exposed areas such as the face and the hands. More than half the cases of vitiligo occur in persons aged 10 to 30 years; vitiligo occurs equally in both sexes. It is relatively common and affects up to 1% of the population. Vitiligo is an autoimmune disorder in which the body produces antibodies against its own melanocytes. Vitiligo is associated with a higher risk of other autoimmune disorders such as thyroid disease and diabetes mellitus type 1 but not with diabetes mellitus type 2.

Skin bleaching (or lightening) creams and ointments may be used by some patients wanting to lighten their overall skin tone, particularly those from darker-skinned ethnic groups, such as Asians, African Americans, and Hispanics. These creams, typically not prescribed, are sold OTC and may be prone to misuse or overuse. In turn, their active ingredients are largely unregulated, and some preparations have been known to contain potential toxins, such as heavy metals. Patients should, therefore, be cautioned against the use of such nonprescription bleaching creams. The clinician should be sensitive to the fact that such discussions may also extend to the larger societal implications of skin color valuation as perceived on a personal level by the patient.

Differential Diagnosis

Differential diagnoses to consider in oral hyperpigmentation include Peutz-Jeghers syndrome, pigmented tumors such as melanoma, Addison's disease, heavy metal exposure, and a history of taking antimalarial medications. Peutz-Jeghers syndrome is an inherited disorder that presents with pigmented (dark brown–colored) macules on the lips and inside the mouth on the mucous membranes. It is associated with multiple polyps in the stomach, the small intestine, and large bowel, causing abdominal pain and other gastrointestinal symptoms. Patients who are suspected of having this disease need to be referred to a gastroenterologist for further evaluation.

Normal variations in pigmentation are commonly seen in the clinical area in patients with darker skin. In patients with dark skin or those of African descent, oral hyperpigmentation is considered a normal variant, but underlying pathology should be ruled out. The exception is newborn infants—oral pigmentation should not be present at this early time. The most common site of involvement is the gingivae (the gums), but other sites, such as the inside of the cheeks (buccal mucosa) and the tongue, can be involved as well. The hyperpigmented areas can range from bluish black to a deep brown in color. Another pigmentation change that is considered a normal variant in blacks or people of African descent is hypopigmentation of the midsternal area. It is more common in males; this type of hypopigmentation is seen in up to 70% of black children and in one-third of adults.

Voigt's or Futcher lines are seen in up to one-fourth of blacks or people of African descent and less frequently in Asians. These distinct lines appear down the length of each arm symmetrically, dividing lighter-colored skin anteromedially from the patient's darker skin color (the lighter shade of skin is touching the trunk). The nails of people with darker skin can be pigmented, with involvement of the entire nail plate or in longitudinal bands of streaks of darker color. Normal nail pigmentation should be bilateral and symmetrical. Any asymmetry or new onset of pigmentation should arouse the clinician's suspicion for disease, including acral melanoma. Pigmentation changes in people with darker skin do not necessarily point to pathology, but at the same time the clinician should not neglect the possibility of a disease process.

A physiological hyperpigmentation condition called *chloasma* ("the mask of pregnancy") is caused by increased levels of estrogen, progesterone, and melanocyte-stimulating hormone during pregnancy. Chloasma may

also occur in 30% to 50% of women taking oral contraceptives. Areas commonly affected include the face, especially the malar region and jawline, the nipples, the genitals, and the linea nigra extending midline on the abdomen from the umbilicus to the pubis. The hyperpigmentation is worsened by exposure to sunlight, and patients should be cautioned to decrease sun exposure at this time. Treatment of chloasma can include combinations of a retinoic acid and hydroquinone, beta-hydroxy acid peels, and various laser and intense pulsed light photorejuvenation treatments. Chloasma can be very difficult to treat in Asian and Hispanic clients. A 24-hour skin patch test to rule out an allergy to any bleaching agent should be done before use. The cream can be applied twice a day for 2 months. The patient should be advised to avoid the eye area and to use the cream cautiously in sensitive areas such as the nose and the lips. Unfortunately, hydroquinone is labeled Pregnancy Category C, so the patient should be referred to an obstetrician for management. Certain drugs that are known to cause a diffuse hyperpigmentation (melanosis) include zidovudine and cyclophosphamide. Skin discoloration has also been reported in patients who have been taking amiodarone, chlorpromazine, and certain antimalarials. Photosensitivity reactions resulting in hyperpigmentation after sun exposure can be caused by citrus oils that are present in fruit or certain perfumes.

Although these dark patches on the face that develop during pregnancy are referred to as chloasma, *melasma* is a more general term referring to hyperpigmentation of certain areas of the skin (regardless of pregnancy status) as a result of sun exposure and hormonal influences. It is usually more common in women than in men. First-line treatments are prescription skin bleaching creams (hydroquinone) and strict sun avoidance. Studies are being done to examine the benefit of laser therapy and salicylic acid peels every 2 to 8 weeks.

Addison's disease is caused by inadequate secretion of corticosteroids as a result of partial or complete destruction (70% of cases are due to an autoimmune mechanism) of the adrenal glands. Addison's disease can cause a diffused generalized hyperpigmentation, especially on skin creases, because of increased levels of adrenocorticotropic hormone (ACTH) from the pituitary. Classic areas where hyperpigmentation is seen are skinfolds; palmar creases; pressure points such as the elbows, knees, or knuckles; inside the mouth on the cheeks (buccal area); and on scars. Symptoms of Addison's disease include generalized weakness, amenorrhea, and loss of axillary hair in women. Laboratory findings in Addison's disease include elevated serum potassium and calcium, low serum sodium, anemia, and an elevated ACTH level. Screening laboratory tests to detect autoimmune diseases include thyroid-stimulating hormone (TSH), antinuclear antibody, sedimentation rate, random blood glucose levels, vitamin B_{12} level, rheumatoid factor, and a CBC.

In patients with pigmented nevi (moles), the presence of certain unusual colors on nevi, such as blue, gray, pink, white, and black (or a variegation of color), should arouse suspicion in the clinician. Benign moles are usually a small size (less than 5 mm)—smaller than a pencil eraser—and have a well-defined border. Benign moles should be only a single shade of color—either brown, beige, or pink.

When evaluating nail pigmentation changes, symmetry and bilateral involvement of the nails and a history of no change is reassuring. A variegated color or very dark color on one solitary nail should arouse suspicion for acral melanoma. Melanomas in people with darker skin are more likely to present on the extremities (or acral area) rather than on the trunk area. The nailbeds, the palms, and the soles are sites where acral melanoma is more likely to be seen in darker-skinned people. The differential diagnoses of nail pigmentation change include acral melanoma, Peutz-Jeghers syndrome, a subungual nevus, gold therapy, Addison's disease, hemochromatosis, and a history of taking antimalarial medications. If acral melanoma is suspected, referral to a dermatologist for a nail biopsy and definitive diagnosis is imperative.

Malignant melanoma, the deadliest of all skin cancers, requires a high index of suspicion. Factors that can precipitate the appearance of acquired melanocytic nevus include immunosuppression, pregnancy, puberty, and sun exposure. Any asymmetry and changes in pigmentation, size, or surface of a mole require referral to a dermatologist. Moles that are larger than 5 mm are more likely to be atypical. Persons at higher risk for skin cancer include patients with numerous moles (50 or more countable moles), atypical and large (more than 5 mm) moles, and a family history of melanoma. The American Cancer Society mnemonic to help detect skin cancer is ABCDE: A—Asymmetry, B—Border (irregularity), C—Color (variegation), D—Diameter (greater than 6 mm), and E—Elevation or Evolving. Any patient with a suspicious mole should be referred to a dermatologist for definitive diagnosis and treatment.

PRURITUS

Pruritus—the sensation of itching—is perceived as unpleasant; therefore, people often seek help for this problematic symptom. Pruritus is a frequent symptom of dermatological disease; it can be acute or chronic and is sometimes so severe as to interfere with sleep and daily life activities.

Pruritus is generally caused by either local (e.g., insect bite, contact dermatitis) or systemic (e.g., uremia, hyperbilirubinemia with skin deposition of bile salts) etiology. In Hodgkin's disease, the incidence of pruritus is between 10% and 25%. Senile pruritus is common in people aged 70 years and older. Rashes or other skin lesions generally accompany the sensation of itching on the skin, although in some cases of systemic etiology, no external findings on the skin are ever located. Therefore,

the finding of skin lesions or rashes is most useful in classification of the differential diagnosis of pruritus.

Differential Diagnosis

A thorough and careful history is an important step in the evaluation of pruritus. If skin findings (such as the linear shape characteristic of contact dermatitis) suggest an external causation, the history should be directed toward eliciting an external etiology. If the patient complains of generalized itching with no skin lesions, an internal or systemic causation is more likely. The presence of a generalized rash should also arouse the clinician's suspicion to drug reactions. Some systemic causes of pruritus include conditions such as allergies, drug reactions, malignancy (lymphomas and leukemias), uremia of chronic renal disease, and pruritus from obstructive biliary disease, as a result of elevated blood levels of unconjugated bilirubin. (See Focus on History 7.1.)

Pruritus is a symptom and should elicit an investigation of the possible causation. External causes of pruritus include insect bites, insect infestation (scabies, pediculosis), pinworms (more common in children), larva migrans, contact dermatitis, fiberglass dermatitis, seabather's eruption, and bacterial folliculitis. It is not uncommon for patients to deny the knowledge of insect bites (especially if the event occurred during sleep), because some insects do not have painful bites. The patient should be asked about any history of medication use, including prescriptions, hormones, vitamin supplements, and the use of nutritional and protein supplements. The history should include a review of all detergents, soaps, creams, moisturizers, cosmetics, and perfumes. A history of alternative medicines, including herbs, homeopathic remedies, and oils for aromatherapy, should also be included. Many young women who take oral contraceptives forget that these are prescription drugs and therefore do not mention them unless the practitioner makes a special effort to elicit information about oral contraceptive use. The use of recreational substances, including chewing tobacco, marijuana, and illicit drugs, should be considered as a potential cause of pruritus. Psychiatric illness as a cause of pruritus is a diagnosis of exclusion. Skin markings are seen more often on extremities; the urge to scratch even in the absence of itch is sometimes reported. The clinician should search for symptoms of depression or mood disorder. There is frequently a history of increased stress because of personal, financial, or familial problems.

The most predominant and disturbing symptom of scabies is pruritus, especially nighttime pruritus. The clinician needs to have a high index of suspicion for scabies because it frequently does not manifest in its classic presentation. If the clinician is looking for the mites' burrows, which the patient can obliterate by scratching, the diagnosis can easily be missed. Frequently, the rash has secondary changes, including excoriation, scaling, lichenification, and occasionally nodules (nodular scabies) because of the intense inflammatory response from the mite. Even if skin lesions do not resemble those associated with scabies, the clinician should consider the diagnosis if the location of the rash is on the axilla, under the breast, on the waistline, on the penis, or between the fingers. The clinician should not assume a lack of scabies infection if the classic rash on the interdigital webs is not seen. Scabies is more common in group homes and nursing homes. The management and treatment of scabies are discussed in depth later in this chapter, under Common Problems: Parasitic Infestations.

If a pruritic rash does not respond to symptomatic treatment, a work-up for systemic diseases is in order. Laboratory tests that should be ordered if systemic disease is suspected include CBC with differential;

Focus on History 7.1 Pruritus

History	Questions to Ask
Insects	Have you had any exposure to mosquitoes, fleas, sand flies, ticks, or spiders? (Brown recluse and black widow bites have necrotic centers.)
Outdoors	Have you been to the beach, at a picnic, gone camping or swimming, or attended a sporting event?
Plants	Have you been in contact with plants or done any gardening?
Jewelry/metals	Any new watches, belts/belt buckles, earrings, necklace? Any contact with metals?
Occupation	What is your occupation? (Gardeners and employees of prisons, day-care centers, and schools have the potential for scabies, pediculosis, or impetigo exposure.)
Hobbies and sport participation	Any exposure to hobby paints and glues? Do you participate in any sports? (Weight lifters, athletes are prone to fungal skin infections.)
Chemical exposure	Any use or exposure to pesticides, herbicides, fertilizers, household cleaners?
Medications	Any use of topical medications such as Neosporin ointment, Benadryl topical lotion, anti-itch lotion or spray? (contact dermatitis) Any prescription medicines, over-the-counter, herbs, vitamins?
Family history	Any family members or intimate friends with the same symptoms? (scabies, pediculosis, tinea capitis)

ESR; fasting blood sugar; liver, and renal function tests; a thyroid profile or a TSH level; and a hepatitis profile. If the pruritic area is in the anus, a search for external hemorrhoids should be done. In children or in adults with small children (when pinworm infestation is suspected), a stool sample to check for ova and parasites, or a Scotch tape test, is recommended.

Dry skin, or *xerosis,* is a common finding in the elderly. It is also seen in young adults who have dry skin and are overly meticulous with personal hygiene. Use of strong deodorant soaps or daily hot baths can precipitate dry skin and worsen pruritus. Systemic causes of pruritus to consider include atopic dermatitis (eczema), psoriasis, drug reactions, urticaria (from exposure to any substance, including airborne allergens), urticarial eruptions of pregnancy, lichen planus, lichen simplex chronicus, prurigo nodularis, and a malignancy, such as Hodgkin's lymphoma, cutaneous T-cell lymphoma (mycosis fungoides), and leukemia. A history of similar pruritic lesions in the past (especially if on the same location) should bring to mind an atopic history or urticaria. Atopic skin diseases that present predominantly with pruritus include atopic dermatitis (eczema) and psoriasis. The presence of hives or a history of hives is sufficient to diagnose urticaria. It is often seen with dermatographism, which can be elicited by rubbing a blunt object or finger on the skin firmly. An immediate response is seen, with formation of whealing that resolves within a few hours.

Lichen planus can mimic psoriasis; its cause is unknown. The lesions appear with shiny flat tops that are a red to violaceous color (red violet-tinged). Other presentations include small, flat-topped papules and a netlike lesion on the buccal mucosa (reticular lichen planus), penis, and external female genitalia. Malignant oral lesions occasionally occur, but oral carcinoma is rare. Lichen planus may have several presentations and locations: Lesions may be generalized, or they may be located on the arms, trunk, mouth, and genitalia. This disease may last for months to years; it does not have a cure and is best managed by a dermatologist. See Differential Diagnosis 7.2 for the differential diagnoses of pruritus.

Treatment

The treatment of pruritus depends on making the correct diagnosis. Symptomatic treatment for dry skin consists of avoidance of strong soaps, taking shorter, tepid showers (10–20 minutes) instead of hot baths, and the use of good emollients. Mild bland soaps such as Dove, Basis, Purpose, and Neutrogena are recommended. The patient should be educated to gently towel dry the skin after showering, because rubbing the skin stimulates pruritus. To seal the moisture in the skin, applying a bland emollient such as Eucerin, Lubriderm, or Alpha-Keri immediately after dabbing the skin with the towel is helpful. Waiting too long (more than 5 minutes) after finishing a bath or shower allows moisture to evaporate. The strongest emollients are ointments that are

Differential Diagnosis 7.2 Pruritus, Scabies, and Pediculosis

Condition	Differential Diagnosis
Pruritus—Rash Present	Insect bites/pediculosis
	Burrowing insects/larvae (scabies)
	Tinea (corporis, pedis, cruris)
	Contact dermatitis
	Atopic dermatitis (eczema)
	Drug eruptions
	Transient acantholytic dermatosis (Grover's disease)
	Bullous pemphigoid
	Urticaria (hives)
	Malignancy (cutaneous T-cell lymphoma)
	Pregnancy-induced
	Psoriasis
	Miliaria (heat rash)
	Folliculitis
	Seborrheic dermatitis
	Lichen planus
	Prurigo nodularis
	Dermatographism (Darier's disease)
	Pityriasis rosea
	Dermatitis herpetiformis
	Impetigo
	Ecthyma
	Erythroderma
	Neurotic excoriation
Pruritus—No Rash Present	Uremia from chronic renal disease
	Cholestatic liver disease
	Hyperparathyroidism
	Hodgkin's lymphoma
	Polycythemia vera
	Delusions of parasitosis
Scabies	Pruritus (see above)
	Pyoderma
	Impetigo
	Ecthyma
	Furunculosis
Nodular Scabies	Urticaria pigmentosa (in young child)
	Insect bites
	Darier's disease
	Prurigo nodularis
	Secondary syphilis
Crusted Scabies	Psoriasis
	Eczematous dermatitis
	Seborrheic dermatitis
	Erythroderma
Pediculosis	Pruritus (see above)
	Dandruff
	Scabies
	Pyoderma (impetigo)

petrolatum based, followed by creams (oil in water), and then lotions (powder in water). Gels are alcohol based; they should not be used for pruritus associated with dry skin because of their drying effect. Pruritus of the scalp caused by seborrheic dermatitis (with dandruff and fine scales at the hairline, by the nares, and the ears) should be treated with ketoconazole 2% shampoo (Nizoral shampoo). The rash of seborrheic dermatitis on the hairline, nares, and ears is best treated with hydrocortisone 1% (OTC) used twice to three times a day. Fluorinated topical steroids should not be used on the face because of the risk of skin atrophy. If the etiology is an irritating external agent (such as fiberglass insulation), elimination of irritating external agents may provide clinical relief of pruritus. Treatment of scabies infection is discussed later in this chapter.

Symptomatic treatment of generalized pruritus includes classic oral H_1 antihistamines such as hydroxyzine, one of the most effective treatments for pruritus, given 3 to 4 times per day. Cyproheptadine is used 2 to 3 times per day. OTC antihistamines include loratadine once a day, diphenhydramine, brompheniramine maleate, and chlorpheniramine maleate; all can be taken every 4 to 6 hours as needed. Prescription antihistamines do not cross the blood–brain barrier and cause less (or no) sedation. These include cetirizine taken daily, fexofenadine taken twice daily, and desloratadine taken once daily.

Any patient who is on antihistamines should be warned of possible drowsiness and should be warned against driving or operating dangerous machinery until the effects of the antihistamine are known. Alcohol and other central depressants worsen this effect. For anogenital pruritus, treatment includes the use of hydrocortisone and pramoxine cream 1% or 2.5% (Pramosone) on the anogenital area. Pramoxine preparations are very effective and have a low incidence of sensitivity reactions compared with topical antihistamines and benzocaine. They are effective not only for anogenital pruritus but also for short-term relief of urticaria, insect bites, pruritus vulvae, and nummular eczema. Use of fluorinated and potent topical steroids on the anogenital area is not recommended because it can lead to atrophy and striae. Lichen planus is treated with topical and systemic steroids and retinoids, cyclosporine, and psoralens with ultraviolet A photochemotherapy; the treatment of this disease is best managed by dermatologists.

If Hodgkin's lymphoma is suspected, the clinician should perform a thorough physical exam and should especially look for painless and enlarged lymph nodes and constitutional symptoms such as generalized pruritus, weight loss, night sweats, and fever. Cutaneous T-cell lymphoma (mycosis fungoides) is a malignancy of the helper T cells of the immune system. Onset of lesions may take many years; sometimes intractable pruritus may be the only presenting symptom. The lesions are sometimes misdiagnosed as psoriasis or as nummular dermatitis (eczema) because of their similar appearance. The lesions go through several stages and can present as red and scaly plaques that mimic the appearance of psoriasis. Nodules and tumors can be present, sometimes with ulceration. Diagnostic laboratory testing for suspected malignancy can include a CBC with differential, a peripheral smear, liver and renal function tests, ESR, a chest x-ray film, and computed tomography (CT) scan. Patients with suspected malignancy should be referred to cancer specialists.

RASH

The word *rash* refers to any pink or red-colored skin eruption. Words that are synonymous with rash include *exanthem* and *eruption.* Rashes are clinical manifestations of inflammation and have multiple etiologies.

Skin cells (keratinocytes) originate in the basal layer of the epidermis. These cells take approximately 28 days to mature and migrate to the surface *(stratum corneum).* The epidermis has no blood supply of its own and is dependent on the dermis for its circulation. It is stratified into two main layers—the inner viable layer *(stratum germinativum)* and the outer layer of dead, anucleated cells, called the *stratum corneum* or the horny layer. The stratum corneum consists of up to 25 layers of flat and tightly packed anucleated cells filled with keratin. Keratin, a tough and durable protein, limits the passage of molecules into and out of the skin. Thus, this tough outer layer is relatively impermeable to many external substances and also acts to prevent the evaporation of bodily fluids. It is a protective barrier against numerous microorganisms. When the stratum corneum is damaged by inflammation (rash), it becomes more permeable to external substances, including microorganisms and chemicals. Not only do these substances and microorganisms have a greater chance of gaining entrance into the body, but therapeutic topical creams and ointments applied to inflamed skin also are more likely to be absorbed and thus increase the chance of toxicity.

The dermis, which gives the skin its elasticity and strength, is made up primarily of a complex network of collagen and elastic fibers interspersed with blood vessels, cutaneous nerves, apocrine glands, eccrine glands, the lymphatics, and the pilosebaceous units of the skin. The *dermoepidermal junction* (the topmost section of the dermis) is the interface between the epidermis and the dermis. A defect in the dermoepidermal junction results in separation of these layers and bullous formation. Inherited autoimmune diseases of the skin resulting from abnormalities of the dermis include bullous pemphigoid and epidermolysis bullosa.

Gram-positive bacterial infections such as *Staphylococcus aureus*—the causative agent of toxic shock syndrome—present with systemic symptoms such as fever, malaise, and an erythematous rash. Drug reactions can also present with a rash (e.g., erythema multiforme, urticaria). Autoimmune disorders that can cause a rash include SLE (butterfly rash), erythema nodosum, and Kawasaki disease (seen in children).

Viruses are responsible for many cases of rash and are usually self-limiting in patients with intact immune systems. Viral infections that manifest with rash and systemic symptoms such as fever and malaise include

measles, rubella (German measles), hand-foot-mouth disease, erythema infectiosum, herpes simplex infection, herpes zoster, varicella-zoster (chickenpox), and roseola infantum (also known as exanthema subitum) in children.

Rashes are more difficult to see in patients with darker skins because the red to dark pink color that is associated with rash becomes less visible. Instead of the pink to red color, a rash in a person of African descent might appear as a dark brown color. Rashes on patients with darker skin can sometimes go unnoticed unless the patient complains of the problem to the clinician. The clinician must learn to use other dermatological clues besides skin color to differentiate rashes in this population. These include the history of the rash and associated symptoms, the type of lesions present (macule, papule, pustule), the texture of the lesions (flat, raised, rough), and the pattern of distribution (central versus on the extremities). See Focus on History 7.2 and Table 7.1.

Differential Diagnosis

Because the differential diagnoses of rash are so numerous, this section focuses on rashes that are associated

Focus on History 7.2 Rash

Onset of Skin Lesions

- When did the skin lesion(s) first appear?
- How did the skin lesion appear at onset?
- Where did the skin lesion first appear?

Spread of Skin Lesions

- Have the skin lesions spread? Where?

Change in Skin Lesions

- Has the appearance of the skin lesions changed over time?
- Have the skin lesions gotten better or worse?

Symptoms Associated with the Skin Lesions

- Are there any associated symptoms, such as itching, burning, or pain?
- Are there any systemic symptoms such as fever, anorexia, malaise, pharyngitis, or myalgia?

Treatment

- What type of self-treatment has the patient attempted?
- Has the patient seen another health-care provider for the skin lesions? What type of treatment was given? Was it effective?

Foods

- Does the patient have any food allergies or sensitivities, such as dairy, seafood, peanuts, other nuts, strawberries, tomatoes, alcoholic drinks (such as red or white wine, beer, or mixed drinks)?

Medications

- Is the patient taking any prescription medications (e.g., antibiotics such as penicillin or sulfa drugs or pain medications such as codeine) and/or OTC medications such as aspirin, NSAIDs, cold medicines, or vitamins?
- Do any of these medications contain artificial color or preservatives?

Alternative Medicines

- Is the patient taking any herbal medicines or teas, homeopathic remedies, aromatherapy, juices, or other alternative medicines?

Atopic History

- Does the patient have a history of the same rash before? What was the diagnosis? How was it treated?
- Does the patient have a family history of skin conditions or rash?
- Has the patient or family member ever been diagnosed with eczema, psoriasis, skin allergies, asthma or allergies?

Infectious Disease Exposure (any exposure up to 2 weeks before onset of rash)

- Does the patient have any exposure to other people with the same symptoms?
- Does the patient have any exposure to small children, day care, or schools?
- Has the patient had any sexual activity with a new partner (known for less than 3 months)?

Systemic Symptoms (infectious, autoimmune, malignancies, metabolic)

- Does the patient have any systemic symptoms, such as sore throat and rhinitis (viral etiology), fever, fatigue, myalgia, joint pain, nausea, night sweats, weight loss (malignancy) or weight gain (diabetes mellitus)?

Table 7.1 Skin Lesions

Primary skin lesions: 1 cm or less in diameter	*Macules* Nonpalpable; caused by changes in skin pigmentation. Example: Freckles *Papules* Elevated and palpable lesions on top of the skin. Example: Nevi (moles) *Nodules* Elevated and palpable lesions that are deeper than papules and feel harder. Example: Acne nodule
Primary skin lesions: Larger than 1 cm in diameter	*Patches* Nonpalpable; caused by changes in skin pigmentation on a larger area than macules. Example: Cafe-au-lait stain *Plaques* A superficial lesion—flat-topped, firm, and elevated; palpable, with a firm to rough surface. Example: Psoriasis *Tumor* An elevated solid mass with a hard texture; shape and borders can be regular or irregular. Can be benign or cancerous. Example: Neoplasms *Wheal* Transient elevated wheal (hive-like); pink to red color from local edema and inflammation. Borders can be regular or irregular. Example: Mosquito bite, urticaria
Primary skin lesions: Fluid-filled lesions	*Vesicle* Superficial elevated lesion with distinct borders; filled with serous fluid. Example: Herpes simplex *Bulla* A vesicle larger than 1 cm in diameter. Example: Blister *Pustule* Sizes vary. Superficial elevated lesion filled with purulent fluid. Example: Acne pustule *Cyst* Sizes vary. An elevated encapsulated lesion that is deeper than a pustule, with distinct borders. Skin on top of a cyst can be moved. Filled with fluid or semisolid material. Example: Sebaceous cyst
Secondary skin lesions	*Atrophy* A thinning of skin (epidermis and dermis); appears white or translucent. Example: Striae *Lichenification* An increase in skin markings; feels rough and thickened. Frequently caused by chronic scratching or rubbing. Example: Atopic dermatitis *Scale* Shed epithelial cells in variable sizes. Can be flat or flaky in texture; color ranges from white to yellow. Example: Seborrheic dermatitis *Excoriation* A loss of epidermis. Shapes and sizes vary and depend on the cause. Example: Abrasion *Crust* Dried exudate from blood, serum, or pus. Elevated and rough with colors ranging from gold, red or brown. Example: Scab from an abrasion *Fissure* A linear crack extending from the epidermis to the dermis. Example: cheilosis *Erosion* A loss of parts on all the epidermis; appears moist and thick, but more shallow than an ulcer. Example: Rupture of a blister caused by a burn *Ulcer* Depressed lesion due to loss of the epidermis and dermis; appears as a moist pink to red lesion with exudate. Example: Decubitus ulcer

Table 7.1 Skin Lesions—cont'd

	Scar Fibrous tissue that forms as skin trauma heals, extending beyond the epidermis. Color can be red, pink, or white; scars can be hypertrophic (thickened) or keloidal (more common in darker skins). *Keloids* Sharply elevated bulky scar tissue that appears shiny and smooth. Formation of keloids may have a genetic component.
Vascular lesions	*Ecchymosis* Bleeding into the skin layers and surrounding tissue as a result of trauma or coagulation defects. Example: Bruise *Hematoma* A large collection of blood as a result of trauma or coagulation defects. It is frequently tender and discolored; colors change from dark blue (when new) to green, then yellow. A hematoma usually resolves in a few weeks but may take several months. If it occurs in a vital area (brain), causing increased pressure, it is drained surgically or locally. Example: Hematoma on the thigh after a car accident *Purpura* Skin discoloration, ranging from dark pink to purple to blue. Does not blanch with pressure. Purpura can be punctate (capillaries) to larger-sized lesions. Almost all causes of palpable purpura are serious and vasculitis must be ruled out. Example: Large bruise

with serious health consequences. Primary-care clinicians should become familiar with these rashes because of the potential for serious sequelae, including death, if the diagnosis is missed.

Cancers such as mammary Paget's disease present with a rash that looks like eczematous dermatitis of the nipple and areola. Although it is an uncommon intraepithelial adenocarcinoma, the clinician should be careful not to overlook this diagnosis. The onset is very gradual, ranging from several months to years. Early in its course, the disease is asymptomatic except for a rash. During the later stages, it is accompanied by symptoms such as pruritus, discharge, bleeding, and ulceration. The sizes of lesions can range from less than 1 cm in diameter to several centimeters. Sometimes an underlying breast mass is palpable during the later stages of the disease—a worse prognosis is associated with this ominous finding. Patients with suspected mammary Paget's disease should be referred to a breast specialist.

The usual location of the classic rash of mammary Paget's disease is on one nipple (or areola); rarely is it seen on both breasts. The skin lesion appears as an oval-shaped, erythematous scaling plaque with sharp margins. Because of the similarity in the appearance, this lesion can be misdiagnosed as eczema, psoriasis, contact dermatitis, or impetigo. Usually, the lesions of eczematous dermatitis involve both breasts and last from 2 to 3 weeks; the lesions respond to treatment with topical steroids. Contact dermatitis usually involves only one breast (sometimes both); again, the rash usually resolves in 2 weeks and responds to topical steroids. If a rash on the nipple or areolar region lasts longer than 2 weeks and does not resolve with topical steroids, a high index of suspicion is imperative and the patient should be referred to a breast specialist for further evaluation.

Toxic shock syndrome (TSS) is an acute illness caused by toxin-producing *S aureus.* In the United States, though TSS is seen in both male and female patients, its incidence among childbearing women represents 90% of the cases of TSS. Risk factors for menstrual TSS include use of superabsorbent tampons. In these cases, symptoms begin in nearly all patients within days of the onset of a menstrual period in women who have used tampons. Risk factors for nonmenstrual TSS include surgical wounds, nasal packs, burns, catheters, postpartum period, and use of birth control methods such as the sponge and the diaphragm. The mortality rate for nonmenstrual cases is 18%, 5% for menstrual-related TSS. Severe group A beta-hemolytic *Streptococcus* (GABHS) infection can mimic TSS (except that GABHS is associated with necrotizing fasciitis) and has a higher mortality rate (30%).

TSS presents with a sudden onset of high fever (fever higher than 102°F [38.8°C]) and vomiting. It is associated with a tingling sensation of the hands and feet, myalgia, weakness, headache, and diarrhea. In severe cases, it is associated with confusion, hypotension, and shock. It is accompanied by a bright red, fine maculopapular (scarlatiniform) rash and is sometimes accompanied by petechiae and bullae. The skin on the palms of the hands and the soles of the feet is very erythematous, and in 1 to 2 weeks the palms and soles start to desquamate. Abnormal laboratory results include leukocytosis, thrombocytopenia, abnormal liver function

tests, elevated levels of creatinine, and abnormally low levels of platelets (thrombocytopenia).

Complications of TSS include multisystem failure, including adult respiratory distress syndrome, acute renal failure, metabolic acidosis, disseminated intravascular coagulation, septic shock, and death. A high index of suspicion and early recognition of serious causes of rash are important to avoid potential sequelae. Patients with suspected TSS should be referred immediately to a physician or to an emergency department. Treatment consists of hospitalization in the intensive care unit for aggressive systemic antibiotic therapy and systemic supportive therapy.

URTICARIA

Urticaria (hives or wheals) is a common problem seen in primary care. It affects from 10% to 20% of the population at least once in a lifetime. *Urticaria* is defined as a sudden generalized eruption of pale, evanescent wheals or papules that is associated with severe itching. *Angioedema* is urticaria that involves not only edema of the dermis, as in plain urticaria, but the subcutaneous tissues as well. Angioedema and urticaria can be part of a life-threatening immunoglobulin E (IgE)–dependent anaphylactic reaction, which involves bronchospasm, laryngeal edema, and shock. If anaphylaxis is not treated and reversed immediately with subcutaneous epinephrine, it can be fatal. Angioedema associated with chronic urticaria is rarely life-threatening. In these cases, the patient will report a history of angioedema without any compromise of the throat or airway.

Urticarial wheals (hives) and angioedema are produced by the degranulation of mast cells when an offending allergen to which the patient has been sensitized is encountered. Degranulated mast cells release inflammatory factors, including histamines that increase vascular permeability and cause pruritus. On microscopic exam, the edema on the dermis is manifested by the wide separation of dermal fibers in cells from urticarial lesions, along with dilation of the venules and lymphatics. Urticaria is also associated with non–IgE-dependent reactions involving the complement cascade of the immune system. Chronic urticaria may be a symptom of an autoimmune condition.

Differential Diagnosis

The typical patient with urticaria will present with a complaint of numerous intensely pruritic hives or wheals that appear regularly at certain times of the day, then spontaneously resolve within a few hours, only to reappear again the next day. The wheals typically enlarge and coalesce, forming round to irregular shapes. Most cases of acute urticaria spontaneously resolve in 1 to 2 weeks. Because most cases of acute urticaria resolve spontaneously in 2 weeks, some authorities recommend waiting at least 2 weeks before initiating an extensive (and expensive) laboratory work-up. Laboratory results are usually normal when testing is done.

Urticaria that lasts longer than 6 weeks is classified as *chronic idiopathic urticaria.* Studies of patients with chronic urticaria have found changes in the quality of life, including sleep deprivation, social isolation, and mood changes that are on the same level as in patients with ischemic heart disease.

Urticaria is classified into several categories. *Cholinergic urticaria* accounts for one-third (34%) of all cases of physical urticarias. Factors that trigger cholinergic urticaria include exercise, anxiety, elevated body temperature (e.g., fever, exercise, sweating), or hot baths or showers. The lesions usually resolve within 30 minutes after the offending activity is stopped. The hives are small (2–4 mm), are very pruritic, are surrounded with erythema, and appear on the upper trunk and arms. *Physical urticaria* accounts for 17% to 20% of all urticarias; it occurs immediately or shortly after exposure to physical stimuli such as pressure, cold, heat, exercise, sunlight (solar urticaria), water (aquagenic urticaria), vibration, or in response to increased body temperature. Urticarial episodes resulting from exposure to these stimuli are usually of short duration; most last only 2 hours. Dermatographism occurs in 2% to 5% of the normal population and can occur with other forms of urticaria. A dermatographic reaction can be elicited by applying friction with a dull object to the skin and watching for wheal formation. The wheal (hive) lasts for a few hours, then resolves.

Some pregnant women develop an extremely pruritic eruption known as pruritic urticarial papules and plaques of pregnancy (PUPPP). These lesions appear as erythematous urticarial papules and plaques (striae distensae) that usually start on the striae of the abdomen and spread to the thighs, buttocks, and, occasionally, arms. The lesions can start at any time during the third trimester, but they are frequently seen during the last 2 to 3 weeks of pregnancy. The cause is unknown—PUPPP is not associated with increased maternal or fetal morbidity and usually resolves after delivery of the fetus. Treatment during the last trimester of pregnancy involves the use of a moderate-potency topical steroid such as triamcinolone acetonide cream 0.1% (Aristocort, Kenalog) applied two to three times daily on the skin lesions. With topical treatment, improvement of the lesions should be seen in a few days. Topical steroids should not be applied to rashes that are suspected to be of viral etiology (such as herpes simplex or varicella-zoster) because steroids can worsen them. Severe cases are best referred to an obstetrician for possible treatment with systemic steroids. There are no antihistamines that are considered absolutely safe in pregnancy, and their use should be avoided.

Treatment

The treatment for urticaria is to find the cause and to stop exposure to the sensitizing allergen. Certain drugs, such

as aspirin, angiotensin-converting enzyme inhibitors, and NSAIDs should be avoided in patients with urticaria. Tight clothing should be avoided, because wheals tend to occur in areas with increased pressure or friction. Showering or bathing with hot water should be avoided because this worsens itching. Cool environmental temperatures in the home are helpful and aid in inducing sleep.

Allergens that can cause both acute and chronic urticaria include drugs; foods; food preservatives; insect bites; and bacterial, fungal, viral, or parasitic infections. If the patient is taking vitamins, herbs, and supplements that are not necessary, they should all be stopped: Even natural vitamins and herbs are not exempt. The patient can start a trial of eliminating certain highly allergenic foods such as eggs, strawberries, tomatoes, chocolate, citrus fruits, peanuts and other nuts, all vinegars and wines (sulfites), alcoholic beverages, and shellfish, although this is cumbersome and bothersome for most patients. Chronic urticaria can be caused by food dyes or food additives, such as sulfites (found in dried fruit, wines, and vinegar). Food allergens can be occasionally confirmed by the radioallergosorbent test or by skin-prick tests done by allergists. Viral infections that have been implicated in causing urticaria include herpes, hepatitis, acute mononucleosis, and rubella. Bacterial infections such as sinusitis and fungal infections have also been implicated.

In chronic urticaria, the clinical evaluation should look for underlying disease, although the etiology in most cases of chronic urticaria is never found. A careful history (including history of travel abroad) and a thorough physical exam should search for signs of chronic disease such as chronic sinusitis, a tooth abscess, a low-grade fungal infection (candidiasis), intestinal parasites, chronic hepatitis, and so on. Some screening tests that are helpful (depending on the history) include stool sample for ova and parasites, sinus x-ray films or CT scan, ESR or a C-reactive protein, CBC, liver function test, a hepatitis profile, urinalysis, and urine sample for culture and sensitivity. In most cases of chronic urticaria (which is more common in adult women in their 30s to 50s), the cause is never uncovered. Up to half of the cases of chronic urticaria and angioedema may resolve spontaneously after a period of 5 years.

The main drugs used to treat urticaria are the H_1 antihistamines, which are available both OTC (diphenhydramine, loratadine) or by prescription (hydroxyzine, fexofenadine, desloratadine, cetirizine, and cyproheptadine). The timing of administration of the antihistamine is very important—it should be tailored individually so that the bloodstream levels of the drug will peak during the times when the urticarial lesions do occur, which will differ among individuals. All antihistamines, even the so-called nonsedating prescription antihistamines, have the potential for sedation. Susceptible patients, especially elderly patients, are at higher risk for sedation and somnolence. Patients should be educated regarding drowsiness as a potential adverse effect of antihistamine use and should be warned against driving or operating heavy machinery until the effects of the medication on the patient are known. The combination of antihistamines with other central nervous system (CNS) depressants such as alcohol, tranquilizers, and certain antidepressants will increase the risk of sedation.

Different classes of H_1 antihistamines should be tried on patients with chronic urticaria: Some patients will respond better to one type of antihistamine than to another. A combination of H_1 and H_2 antihistamines is used by some clinicians, but studies have shown only a very small increase in effectiveness. Some antihistamines (such as diphenhydramine) tend to cause more sedation than others; diphenhydramine is the main ingredient in OTC sleep aids. For patients who can tolerate its sedating effects (or avoid a problem by taking it at bedtime), diphenhydramine can be taken at 25 to 50 mg every 4 hours (maximum 300 mg daily). The classic prescription antihistamine used for pruritus and urticaria is hydroxyzine. Hydroxyzine can be given as a bedtime dose of 50 mg to reduce risks associated with daytime sedation. Cetirizine is 13% less sedating than hydroxyzine and has a rapid onset of action. The dose of cetirizine is 10 mg once daily given at bedtime. Cetirizine has been found to be especially useful for delayed pressure urticaria. Cetirizine does not cause cardiac toxicity when it is combined with other drugs such as erythromycin, imidazole antifungals, or other hepatically metabolized drugs. Fexofenadine, a nonsedating antihistamine, is given as 60 mg every 12 hours. For treatment of cold urticaria, cyproheptadine (Periactin) is given as 4 mg three times daily. The use of cyproheptadine is contraindicated in angle-closure glaucoma, concurrent use of monoamine oxidase inhibitors, prostatic hypertrophy, and elderly or debilitated patients. Because of its atropine-like actions, caution should be taken in patients with asthma, increased intraocular pressure, heart disease, hypertension, or hyperthyroidism.

Types of urticaria that should be referred to a specialist include urticaria associated with angioedema of the tongue or throat, peanut allergy, latex allergy, and urticaria that persists beyond 6 weeks (chronic urticaria). The anti-IgE monoclonal antibody therapy omalizumab (Xolair) has been proposed for the treatment of chronic urticaria, although it has not been approved by the Food and Drug Administration for this indication.

Teledermatology is the practice of dermatology from a distance and can be used in several ways. Studies evaluating teledermatology have measured the diagnostic concordance rate (DCR) and diagnostic accuracy of remote diagnoses. The DCR refers to the interrater reliability between those assessing the skin pathology. Diagnostic accuracy refers to the correct diagnosis made by the provider and the actual pathology determined via biopsy. Nursing Research–Based Practice 7.1 summarizes a recent reference that describes this emerging trend.

Nursing Research–Based Practice 7.1

Lowie, AM. Teledermatology: A tool for nurse practitioner practice? *J Nurse Pract* 8(8):617–620, 2012.

The emerging teledermatology technology has the potential to affect the current health-care delivery system and provide dermatology care to a greater number of patients in underserved areas. Although current research shows that the diagnostic concordance rates (DCRs) and accuracy rates are high, consultation results inherently depend on the skills and thoroughness of the provider and staff initiating the consultation, in conjunction with a thorough history and total body skin exam. Nurse practitioners have the potential to become active participants in the practice of teledermatology and ensure the provision of dermatology services to underserved populations.

COMMON PROBLEMS: PARASITIC INFESTATIONS

SCABIES

Human *scabies* is a highly contagious infestation that occurs mainly in children, young adults, health-care workers, and institutionalized persons of all ages. It is characterized by generalized intractable pruritus, often with minimal cutaneous manifestations. The diagnosis of scabies infection is easily missed and should be considered in patients of any age with persistent and severe pruritus. Scabies can develop into a chronic condition.

Epidemiology and Causes

Human scabies is caused by the itch mite *Sarcoptes scabiei* var. *hominis,* which infects human skin. The adult female measures 0.3 to 0.5 mm long and has a rounded body with four pairs of short legs. Scabies infestations occur worldwide and are endemic in most parts of the world. Epidemics are historically associated with war, conditions of poverty, overcrowding, poor hygiene, malnutrition, and sexual promiscuity. The World Health Organization estimates that there are about 300 million cases of scabies in the world each year. Some studies suggest 6% to 27% of the general population has scabies, but other surveys find a lower prevalence. Close personal contact is the major mode of transmission for scabies, although casual contact such as nursing care may be sufficient for transmission to occur. Institutional epidemics have been reported in which caregivers were infested. Live mites have been discovered in dust samples from the homes of infested persons, suggesting fomite transmission as a possibility.

Pathophysiology

The scabies itch mite is an aerobic organism and thus requires exposure to surface air to survive. The male mite dies shortly after mating, but the female mite may live 4 to 6 weeks. As an obligate parasite, the scabies mite burrows into the skin shortly after contact. It both resides and reproduces in human skin. The female mite can lay 2 to 3 eggs per day (up to 10–25 total) in burrows created at the base of the stratum corneum of the epidermis, traveling up to 2 mm per day. Burrows average 5 mm in length, allowing for continued exposure to surface air, but soon after egg-laying is completed, the female mite dies. Eggs hatch, and larvae emerge in 72 to 84 hours, molting at least three times before reaching adulthood. Mating of these new mites thus occurs after approximately 17 days.

Interestingly, sensitivity to *Sarcoptes scabiei* must take place for pruritus to occur. Initial sensitivity takes several weeks to develop after primary infection and is caused by a foreign body inflammatory reaction to either the mite itself or its feces. In persons who are experiencing reinfestation, pruritus may occur within 24 hours, because the immune system has been previously sensitized. Individuals who are immunocompromised or have been diagnosed with a neurological disorder such as Down syndrome, stroke, dementia, neuropathy, or spinal cord injury may be predisposed to a variant of scabies known as crusted scabies (*scabies crustosa;* previously known as "Norwegian scabies"). Scabies crustosa is characterized by scaly lesions at the sites of invasion that soon become warty and encrusted, creating a protective barrier for these mites. The number of mites infesting a patient with scabies crustosa can exceed more than a million, whereas infestation with classic scabies is usually limited to 10 mites or fewer. Half of patients with crusted scabies do not experience pruritus, reflecting the absence of key inflammatory mediators seen in classic scabies. A nodular form of scabies also exists in which firm, erythematous, dome-shaped lesions roughly 0.5 cm in size develop over the groin, buttock, and axillary areas. Histamine-mediated urticarial lesions may accompany this rash, which is intensely pruritic. In all forms of scabies, if rashes go untreated, bacterial superinfection by *Staphylococcus* species may result, worsening acute inflammation.

Clinical Presentation

Subjective

The typical patient usually presents with complaints of intense itching that is usually described as being more severe at night. Mothers may report changes in feeding patterns of children and that they are more tired and irritable than usual. Itching may be widespread but is commonly located in the interdigital web spaces, wrists, anterior axillary folds, periumbilical skin, pelvic girdle, penis, and ankles. The palms, soles, face, neck, and scalp are more

frequently involved in small children. The pruritus is usually described as not responding to treatment. Many patients will complain of a rash, whereas others experience itching for months with no apparent rash. Patients are often aware of similar symptoms in family members and/or in sexual contacts. Patients presenting with the symptoms described above should be screened for possible scabies infestation. (See Focus on History 7.3.)

Objective

The earliest physical signs of scabies are small, 1- to 2-mm, red papules located in areas of the body that are most attractive to mites. Because of the intense itching, excoriations from repeated scratching, with crusting and scaling, may also be present. It may be difficult to visualize scabies mites on the skin, and the patient may complain only of incessant itchiness. Skin lesions occur at the sites of mite infestation or result from a hypersensitivity reaction to the scabies mite. Secondary skin lesions including lichenification and excoriations are the result of chronic rubbing or scratching of lesions. Secondary bacterial infections present with increased symptoms, pruritus, and crusting of lesions (secondary impetigo).

The classic scabies skin lesion is the intraepidermal burrow. Each female mite produces one burrow. In light-skinned people, burrows have a whitish color with black specks caused by fecal particles. The female mite resides at the blind end of the tunnel. She can burrow 2 to 3 mm per day. Burrows are usually distributed in areas where there are few or no hair follicles and where the stratum corneum is thin and soft.

Burrows are sometimes seen on the top of early scabetic nodules that occur in 7% to 10% of patients with scabies. Nodules vary in color from pink to brown and are 5 to 20 cm in diameter. They may become more visible after treatment.

Focus on History 7.3 Scabies

If Scabies Is Suspected

- Do you work in a nursing home or group home, in a school, or in a prison?
- Do you have any family members or sexual partners that have similar symptoms?
- Are young children displaying increased signs of fatigue or irritability?
- Have the eating patterns of children changed?

If Patient Is Complaining of Pruritus

- Where is the itching worse?
- What part of your body is itching?
- Is the itching worse at night?
- Does itching interfere with your ability to sleep?
- How long have you been itching?
- Is the itching relieved by anything? If so, what?

Diagnostic Reasoning

Clinical diagnosis of scabies is almost never made until hypersensitivity has occurred. The diagnosis is based on epidemiological history, occurrence of intractable itching, and assessment of the distribution of lesions and pruritus.

Diagnostic Tests

The practitioner should search for the presence of mites. The highest yield of mites is in burrows located on the finger webs, penis, or wrists. The Burrow Ink Test can be easily performed. To do so, rub a felt-tip pen over the suspected burrow. (Blue and green markers work best because they do not interfere with microscopic results.) Remove the excess ink with an alcohol wipe. The remaining ink concentrates in the tunnel and indicates the location of the burrow.

Once a burrow has been located, the clinician should place a drop of mineral oil over it, then scrape off the burrow using a number 15 scalpel blade. The scrapings should be placed on a slide with a drop of oil, then sealed with a cover slip. The identification of the *S scabiei* mite, its eggs, or fecal pellets is diagnostic of scabies. There are no serological tests currently available for scabies.

Failure to identify mites or their eggs or burrows does not rule out scabies infestation. If scabies infestation is suspected because of clinical symptoms, empiric treatment should be tried. Resolution of symptoms within a few days is indicative of previous scabies infection.

Differential Diagnosis

The diagnosis of scabies can be easily missed. Although there are common skin findings (e.g., burrows), the clinical picture of scabies can be extremely variable, depending on the duration of the infection and the severity of the sensitivity reaction. Variants of scabies in immunocompromised persons and persons with neurological disorders further cloud the diagnosis. Accurate diagnosis is essential for effective treatment. See Differential Diagnosis 7.2 for some differential diagnoses for scabies. It should be noted that it is possible for patients to have preexisting skin problems in addition to scabies. A thorough history can help minimize diagnostic pitfalls.

Management

With proper adherence to treatment regimens, cure rates for scabies approach 100%. However, application of medicated creams or lotions is insufficient for an affected person if the entire household is not treated and if all environmental reservoirs of the scabies mite (such as bedding, clothing, or towels) are not sufficiently cleaned with hot water and detergents. Therefore, effective care of patients with scabies involves treating the patient, his or her close personal contacts, and environment. Treating the source of the infestation and any secondary complications such as bacterial

infection (secondary impetigo) or dermatitis should also be included in the management plan.

Initial management of the patient diagnosed with scabies is directed at killing all live mites. Lotions containing scabicides (such as permethrin, lindane, crotamiton, or sulfur) are commonly used. Permethrin is the first-line treatment. Antihistamines and topical steroids are helpful for pruritus. Of the products containing scabicides, lindane is the most toxic. It is rapidly absorbed through the skin and has been associated with CNS symptoms such as irritability, seizures, and, in cases of ingestion or overdose, death. Older patients, young children, and pregnant and lactating women have the greatest risk of toxicity. Therefore, the choice of scabicide should be based on the age of the patient, pregnancy status, resistance patterns, degree of toxicity, and severity of infestation. High mite populations, presence of crusts, and decreased immune status of the host make treating crusted scabies more difficult. It may be necessary to remove crusts that would protect mites from scabicides before treating.

The majority of patients require only medical treatment with a topical scabicide. A number of patients experience hypersensitivity to the mite and mite products, however, and may require the use of systemic corticosteroids to provide relief from severe pruritus. When ivermectin 200 mcg/kg is used as a single dose, it is followed by another dose 1 to 2 weeks later. This should be used in conjunction with a topical cream/lotion. Some patients may delay treatment until a secondary bacterial infection has occurred, necessitating the additional use of an antistaphylococcal antibiotic. Cephalexin or dicloxacillin for 7 to 10 days may be prescribed.

In addition, patients with extensive dermatitis lesions may obtain relief with topical corticosteroids, such as triamcinolone 0.1% cream twice daily for 7 days. Fluorinated steroids must not be used on the face or on skinfolds (intertriginous areas) because of the increased risk of skin atrophy. (See Drugs Commonly Prescribed 7.1.) Management must include a strict isolation protocol for scabies crustosa.

Follow-up and Referral

Uncomplicated scabies infestations should be followed up 1 week after the initial treatment. If generalized itching persists, hypersensitivity to remaining dead mites

Drugs Commonly Prescribed 7.1 Scabies

Drug	Indication	Adverse Reactions and Prescribing Considerations
Topical		
permethrin cream 5% (Elimite)	Presence of live mites (scabicide)	Mite resistance has been reported. Safe for use in children 2 months and older. May also need to treat head and neck. Apply to all areas of body from the neck down. Leave on for 8–12 hours. Repeat application in 1 week. May repeat a third time 1 week later.
lindane 19% (gamma-benzone hexachloride)	Presence of live mites (scabicide)	Potential CNS toxicity. Rapidly absorbed through skin. Do not use on infants or young children, pregnant or lactating women, or if history of seizures. Should not be used after a bath or shower or by persons with extensive dermatitis. Mite resistance has been reported. May also need to treat head and neck. *Adults:* Apply thinly to all areas of body from neck down. Wash off thoroughly after 8 hours.
crotamiton cream 10% (Eurax)	Presence of live mites (scabicide)	Reported failure rates up to 50%. Long- and short-term toxicity has not been studied. Shake well before using. Apply to all areas of body from the chin down for 2 consecutive nights. Change clothing and bed linen after 24 hours. Wash 48 hours after second application.
sulfur ointment 8%–10%	Presence of live mites (scabicide)	Extensive use suggests it is safe to use on pregnant and lactating women and young children. Malodorous and stains clothing. *Adults:* Apply to all parts of the body from neck down 3 successive days. *Children:* May need to treat head and neck also.

Drugs Commonly Prescribed 7.1 Scabies—cont'd

Drug	Indication	Adverse Reactions and Prescribing Considerations
Systemic		
ivermectin (Stromectol)	Presence of live mites (scabicide)	Reported to be effective for common scabies refractory to topical treatment and crusted scabies in conjunction with topical cream/lotion. "Off-label" use 200 mcg/kg by mouth single dose followed by another dose in 1–2 weeks.
Others		
antihistamines	Eczematous dermatitis	Helps patient to sleep at night. Hydroxyzine, diphenhydramine: 25–50 mg at bedtime
topical corticosteroid ointment	Extensive dermatitis	For mild to moderate pruritus. Apply to areas of extensive dermatitis.
systemic corticosteroid	Severe hypersensitivity reaction	For severe pruritus. Prednisone: Tapered course 1–2 weeks
systemic and topical antibiotics	Secondary bacterial infection	Staph and strep are common pathogens. Risk of acute poststreptococcal glomerulonephritis in severe cases. Systemic: 7- to 10-day course

and mite products should be considered. It may be necessary to repeat the scabicide treatment, however. Patients who experience persistent scabetic nodules or crusted scabies may require advanced management and should be referred to a dermatologist.

Patient Education

Patient education is an integral part of successfully treating scabies. Patients should be instructed to trim their fingernails, to reduce the possibility of harboring mites and reinfesting themselves and others. Safety information regarding the use of scabicides should be stressed, such as not exceeding recommended exposure times, toxicity symptoms that should be reported, and the safe storage of treatment products, to prevent accidental ingestion in children. Patients should be informed that itching may continue for up to a week after successful treatment due to local irritation.

Patients should also receive instruction about treating their home environment to avoid reinfestation; they should be reminded that the scabies mite lives on humans, so environmental spraying of pesticides is not effective and therefore not recommended. Bedclothes and clothing should be washed in hot soapy water. Except in cases of crusted scabies, extensive decontamination of the environment is not necessary. Children in day care or school can return after treatment.

PEDICULOSIS

Pediculosis (infestation by lice) in humans has been documented for thousands of years. It is difficult to document the number of lice cases occurring annually in the United States because most states are not required to report it. It is estimated that 6 to 12 million American children are infested with head lice alone each year.

Epidemiology and Causes

Pediculosis infestations occur worldwide and are endemic in most parts of the world. Only three species of lice are known to infest humans: *Pthirus pubis* (the crab louse), *Pediculus humanus capitis* (the head louse), and *Pediculus humanus corporis* (the body or clothing louse). Lice infestations occur in people of all ages. Head lice are commonly seen in school-age children, whereas pubic lice are most often seen in sexually active young adults. Children aged 3 to 11 years are most commonly affected by head lice, with occurrence being more frequent in girls. Lice are blood-obligate parasites that obtain all their nutritional requirements from the host. Both the *Pediculus capitis* and *Pthirus pubis* lice reside and reproduce on the human host. The *Pediculus humanus corporis* louse feeds on the human host but resides and lays its eggs in clothing fibers. Body lice are increasingly rare in the United States but can be seen in communities of persons who are homeless or among persons who live in crowded conditions without the ability to wash and change clothing. Body lice are the only lice associated with disease transmission. Infected feces of the body louse can transmit typhus, trench fever, and relapsing fever. However, lice-borne outbreaks of these diseases have not been seen for many decades in the United States.

Though epidemics of pediculosis in the United States are relatively rare, outbreaks of head lice are common in elementary school settings. Outbreaks usually occur at the start of the school year and after winter and spring breaks. One explanation for the timing of these outbreaks is that they occur after children have spent extended time in the community. Close personal contact is the major mode of transmission for all types of pediculosis.

Treatments, lost wages, and school expenses total an estimated $1 billion annually, making pediculosis a major public health concern and an economic burden on families.

Pathophysiology

Pediculosis infestation can be asymptomatic or can cause few symptoms in the first 2 weeks following exposure. Sensitivity to lice must take place before pruritus can occur. Therefore, in individuals who have never been exposed to lice infestation before, it can take several weeks before clinical symptoms (e.g., pruritus) develop during the initial infestation. A foreign body inflammatory reaction ensues from the lice saliva that is injected into the skin during the insect's bite. In individuals who are experiencing reinfestation, pruritus occurs rapidly, within 24 to 48 hours, due to key inflammatory mediators including histamine.

Head lice infestation averages about 10 lice per patient. However, in severe cases they can number in the hundreds. Head lice are transmitted through close contact rather than by fomites and can survive just over 2 days off a human host, at which time they die from dehydration. Both males and females are equipped with specialized mouth parts adapted for sucking blood, as well as legs capable of adhering to human hairs. Each female head louse may lay from 7 to 10 eggs per day for a month. Pubic lice ("crab lice") lay relatively fewer eggs (up to three per day) that incubate for 1 week before hatching. Severe lice infestations may be complicated by bacterial superinfection from *Staphylococcus* species that normally colonize the skin.

Clinical Presentation

Subjective

Patients may present with complaints of intense itching in areas of the body preferred by the particular type of infesting louse. The itching is usually described as being more severe at night. Mothers may report changes in feeding patterns and that children are tired and irritable. School-age children may become inattentive and restless in class, with frequent scratching of the scalp. Some cases of pediculosis are asymptomatic or present with few symptoms.

Objective

The earliest physical signs of lice infestation are small (2–3 mm), red erythematous macules or papules that may be pruritic. Skin lesions may appear within minutes or several days after initial infestation. Some patients develop an allergic, hive-like reaction, with typical wheal and flare formation after lice infestation.

Pruritus is the hallmark of all types of pediculosis. Because of the intense itching, excoriations on the scalp, body, or pubic area (depending on the type of lice) with crusting and scaling may also be present. Fresh nits (lice eggs) on hair shafts are thought to be deposited closer to the scalp. As the hair grows (0.5 mm daily on the scalp), the nit moves further away from the scalp. Therefore, if nits are found at varying distances on the hair shafts, the infestation has been present for several weeks to months. Individual lice are difficult to see on the scalp and hair strands. They appear as six-legged, wingless insects from 1 to 4 mm in length that move extremely fast. When engorged with blood, the insect's abdomen appears dark red.

Nits (eggs) are much easier to see than live lice: The teardrop-shaped eggs are attached securely to the hair shaft by the female louse. Newly laid eggs may be tan to coffee-colored and are difficult to see. Hatched lice eggs are whitish in color and appear shiny. The cap (operculum) of the egg faces away from the scalp. Distribution of lice, itching, and lesions provides clues to the type of louse present on the host. Head lice *(P h capitis)* prefer the scalp, and crab lice *(P pubis)* infest the pubic and perianal region. However, head lice can be found in facial hairs such as eyebrows, beards, and mustaches. Crab lice and their nits can also be found in such areas as the eyelids, mustache area, axillae, or on the scalp.

Diagnostic Reasoning

Clinical diagnosis of pediculosis, body lice, or pubic lice is based on both the history of pruritus (because of a hypersensitivity reaction to the lice) and the finding of white nits or lice on the hair shaft. Sometimes, lice infestation may be picked up during a routine physical exam.

Diagnostic Tests

The practitioner should search for lice and/or nits on the area of the body where the patient is complaining of pruritus. Lice and their nits can be seen with the naked eye or with a magnifying hand lens. Gloves should be worn during this procedure. Microscopic examination is generally not required. A Wood's light exam can be done for mass screening (or individual screening), but it requires a darkened room and protective eyewear for both the clinician and the child. When the light is directed at the scalp, live nits appear with a pearl-like fluorescence, whereas empty nits do not fluoresce. The Wood's light exam is impractical in school settings and not recommended for use with young children who might be afraid of the dark. If secondary bacterial infection (impetigo) is suspected, bacterial cultures should be done with a standard culturette.

Failure to identify the presence of lice or nits does not rule out lice infestation. When suspicion is strong, based on the history and clinical presentation, the patient should be treated empirically; the relief of signs and symptoms is indicative of lice infestation. Treatment for head lice should be limited to persons who are experiencing an active infestation, which is defined as the presence of live lice. Because pubic lice are considered a sexually transmitted disease (STD), patients with this type of infestation should be screened for other STDs by rapid plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL) tests for syphilis, as well as laboratory tests for HIV infection.

Differential Diagnosis

The diagnosis of pediculosis is easily made. However, "pseudonits" (hair casts, dandruff, or sebaceous plugs) can be mistaken for nits, resulting in inappropriate treatment. A hallmark of nits is that they are firmly cemented in place and therefore do not slide easily on the hair shaft, compared with dandruff scales. Sebaceous plugs result from plugged oil glands on the scalp and (unlike nits) do not originate on the hair shaft. Secondary bacterial infection can also complicate the diagnosis. Secondarily infected skin lesions resemble impetigo lesions, with crusting and erythema. Differential Diagnosis 7.2 lists some differential diagnoses for pediculosis.

Management

Effective care of patients with pediculosis involves treating not only the patient, but also his or her close personal contacts who have been diagnosed with an active infestation. Treatment involves both medication and environmental control measures. It is important to screen all close contacts for head lice, keeping in mind that the contacts may be asymptomatic and have a small number of live lice. Treating the source of the infestation (if identified) and any secondary complications such as secondary bacterial infection (impetigo) or dermatitis should also be included in the management plan. Patients need to be reevaluated after 1 week. If live lice are present or if fresh eggs (nits) are seen close to the scalp, retreatment is necessary.

Initial management of patients who are diagnosed with pediculosis is directed at killing and/or removing lice and their nits. Shampoos and cream rinses containing permethrin, lindane, pyrethrin, and malathion are commonly used to kill lice. (See Drugs Commonly Prescribed 7.2.) Treatment history should be explored with the patient or caregiver. It is common for persons with head lice to delay seeking professional help until three to five treatment failures have occurred. Products resulting in treatment failure should not be tried again.

Of these products, lindane is the most toxic. As noted previously in the section on scabies, lindane is rapidly absorbed through the skin and has been associated with CNS symptoms such as irritability, seizures, and—in cases of ingestion or overdose—death. Lindane should not be used on older patients, any patient with a history of seizure, infants and children younger than 2 years old, or pregnant or lactating women because of an increased risk for toxicity. The pediculicide of choice should be based on the age of the patient, resistance patterns, degree of toxicity, treatment history, and, in reproductive-aged females, pregnancy status.

Manual delousing and nit removal using a fine-toothed comb is gaining popularity in the face of increasing reports of resistance to available pediculicides. In children with respiratory allergies, asthma, or compromised immune status, manual delousing methods should be considered as an initial form of treatment.

Numerous nonpesticidal treatment options have recently become available. There is limited empiric evidence, however, to support their efficacy and safety. Practitioners should caution patients against the use of home remedies that include kerosene and agricultural-grade or veterinary pesticides—such remedies are unsafe and potentially fatal.

The majority of patients with pediculosis require only pediculicide treatment or manual delousing. Some patients may delay treatment until secondary bacterial infection has occurred, necessitating the use of a topical or systemic antibiotic. Complicating staphylococcal bacterial superinfection may be treated by cephalexin or dicloxacillin for 7 to 10 days.

Children who present with pediculosis pubis (infestation by *Phthirus pubis*) in their eyelashes or hair should alert the practitioner to the possibility of sexual abuse, although intimate contact is not the only mode of transmission. Eyelash infestation can be treated by applying petroleum jelly to the eyelid margins twice daily for 10 days. Pediculosis ciliaris (eyelash infestation) may also be treated with physostigmine ophthalmic ointment 0.25% to 1% twice daily for 8 to 10 days, but this treatment may cause eye spasms in younger adults. Lice and nits should also be manually removed from the eyelashes by gently holding and sliding them off the hairs.

Follow-up and Referral

Uncomplicated pediculosis infestations do not require a follow-up. In some areas, however, the American head louse has demonstrated resistance to pyrethrin and permethrin, as well as to lindane, resulting in increased treatment failures. Follow-up in 1 week is recommended if symptoms persist; the patient or the parent can call the office to report any further symptoms. The National Pediculosis Association recommends manual delousing methods at the first sign of medical treatment failure. Because of toxicity concerns and known resistance patterns, lindane should be used only as a last resort, and prescriptions should not be

Drugs Commonly Prescribed 7.2 Pediculosis

Drug	Indication	Adverse Reactions and Prescribing Considerations
Topical		
permethrin 1% lotion OTC (Nix)	Presence of lice/nits; may use for children older than 2 months.	May need to reapply in 7–14 days. Use nit-remover products before application of permethrin. Apply to towel-dried, affected area; leave on 10 minutes, wash off.
pyrethrin 0.3% with piperonyl butoxide shampoo or gel OTC (RID, R&C shampoo)	Presence of lice/nits	May need to reapply in 7–14 days. Use shampoo for head or pubic lice, gel for body lice. Contraindicated in persons sensitive to ragweed. Apply to dry hair until wet; leave on 10 minutes, wash off.
lindane 1% shampoo	Presence of lice/nits	Possible CNS toxicity. Not recommended for children under 12 years of age or pregnant or lactating women. Apply to dry hair; leave on 4 minutes, wash off thoroughly.
malathion 0.5% (Ovide), lotion or gel	Presence of live head lice; not approved for other lice species Lotion for use on children older than 6 years; gel safe to use on children older than 2 years	No reported resistance. Product contains 78% isopropyl alcohol and is flammable. Apply to dry hair. Use sufficient amount to thoroughly wet hair and scalp. Allow to air dry. Shampoo hair after 8–12 hours. Cover all lice on the hair and scalp. Rinse off after 10 minutes, repeat in 1 week.
benzyl alcohol 5% (Ulesfia) lotion	Use in patients older than 6 months and pregnant women	Leave on hair and scalp for 10 minutes. May repeat in 7 days if live lice are still present.
Systemic		
ivermectin (Stromectol)	Resistant pediculosis (Not FDA Approved)	For cases resistant to permethrin and malathion. 200–400 mcg/kg by mouth as a single dose followed by another dose in 1–2 weeks.

written with refills. Referrals for pediculosis infestations are usually not required.

Patient Education

Patient education is an integral part of successfully treating pediculosis. Patients and parents should be instructed not to share hats, combs, scarves, headsets, towels, and bedding. Following removal of hair and debris, combs and brushes should be washed in hot, soapy water, rinsed in hot water, and allowed to air dry.

Safety information regarding the proper use of pediculicides should be stressed, including information on not exceeding recommended exposure times, possible toxicity symptoms that should be reported, and the safe storage of treatment products in order to prevent accidental ingestion by young children. When using head lice products, patients should be instructed to cover the eyes and rinse products out over a sink (not in the shower or bathtub) to reduce unnecessary pesticide exposure. Patients should be informed that itching may continue after successful treatment for up to a week because of the slow resolution of the inflammatory reaction caused by the lice infestation.

Patients should also receive instruction on cleaning the environment. With the exception of the body louse, lice live only on humans. Excessive decontamination of the environment is not necessary. Environmental spraying of pesticides is not effective and may be dangerous and therefore is not recommended. Bedclothes and clothing should be washed in hot soapy water and dried in a hot dryer. Normal vacuuming of carpets, rugs, upholstery, mattresses, cars, and car seats should be sufficient. Parents should devote their energy to removing lice and nits. Children in day care or school can return

after treatment. Some schools have initiated a "no-nit" policy that requires parents to remove all lice and nits before a child may reenter the classroom. Parents should be instructed to screen children once a week for head lice as part of their regular hygiene routine. Early detection results in fewer transmissions and easier treatment regimens.

FUNGAL INFECTIONS

CANDIDIASIS

Candida, an opportunistic pathogen, causes not only superficial mucocutaneous infections but also serious disease that can be fatal, especially to the immunocompromised host. *Candida* belongs to the yeast family of fungi. There are over 20 species of *Candida* yeasts that can cause infection on humans, the most common of which is *Candida albicans. Candida* is part of the normal flora of both the oropharynx and gastrointestinal tract. In addition, up to 20% of women who are asymptomatic yield a positive culture for vaginal *Candida.* Favorable environmental factors and a weakened immune system are the two most important factors contributing to candidal infections. Certain areas of the body are also more prone to infection. Areas where there is increased heat and moisture are more likely to become infected with candidal organisms. Other synonyms for candidiasis include moniliasis and candidosis.

Risk factors for serious disease include conditions that alter cellular immunity, such as AIDS, diabetes mellitus, corticosteroid treatment, bone marrow transplant, chemotherapy, and invasive parenteral catheterization (parenteral feeding catheters are considered high risk). Broad-spectrum antibiotic therapy, including antibiotics following major surgery in normal hosts, can increase the risk of candidal infection. Only superficial cutaneous infections are discussed in this chapter.

Cutaneous infections caused by *Candida* include the following:

- Thrush, diaper dermatitis (infants)
- Oral infections: candidiasis (thrush), angular cheilitis
- Genital infections: vulvovaginitis, balanitis
- Intertriginous (skinfold) infections: inframammary area, groin, axillae, web spaces of the fingers or toes, perianal area
- Other infections: folliculitis, candidal paronychia, subungual candidiasis (beneath the nail)

Epidemiology and Causes

Although *C albicans* is the most common (60%–90%) of all yeast isolates found on the oropharynx and the genitalia, other types of *Candida* coexist in the body, including *C tropicalis, C glabrata, C krusei, C rugosa,* and other yeast strains. Unfortunately, some candidal species *(C krusei, C glabrata)* are less responsive to imidazoles and have developed resistance. *Candida* infection can occur at any age and in either gender. A higher incidence of thrush is seen among patients with AIDS and in infants. No ethnic predisposition to *Candida* has been noted. Areas in the body where there is skin-to-skin contact are more prone to candidal infection. These include areas under the breast (inframammary candidiasis), between the fingers (interdigital candidiasis), between the toes, the groin, the axillae, and the genital area. Infections in these areas are collectively called *intertrigo* or intertriginous infections.

Cellular immunodeficiency states increase the risk of mucocutaneous disease. Conditions such as AIDS, diabetes mellitus, corticosteroid therapy, and immunosuppressive therapy increase an individual's susceptibility to infection to *C albicans.* Infants, who have immature immune systems, can easily become infected with *Candida* through the birth canal or through oral contact with an infected caregiver. In infants (as opposed to adults), oral candidiasis (thrush) and diaper candidiasis are considered benign findings. In adults, however, mucocutaneous candidiasis is the most common AIDS-defining condition seen. In women with AIDS, one of the earliest and most frequent opportunistic infections seen is vaginal candidiasis. Frequent episodes of vaginal candidiasis that are not accompanied by an underlying condition (e.g., diabetes, use of antibiotics, pregnancy, or oral contraceptive use) should prompt the clinician to consider HIV infection in the differential diagnosis, although most cases of candidal vaginal infections occur in normal hosts.

Vaginal infection with *C albicans* is very common; it occurs in up to 75% of women at some point in their lifetime (pregnant women and patients with diabetes are at increased risk). If left untreated, candidal vaginitis will either resolve spontaneously or will become a chronic low-grade infection. Men with diabetes, especially if uncircumcised, are at higher risk for candidal infections of the glans penis (balanitis). The uncircumcised foreskin holds heat and moisture and increases the risk of candidal overgrowth. Males become infected with *Candida* organisms from their female partners through sexual intercourse or through oral sex. In candidal paronychia, the patient will report a history of a hangnail or of minor trauma on the cuticle area before the infection. Dishwashing or frequent water exposure is sometimes the culprit.

Pathophysiology

Candida organisms cause an intense inflammatory response on the skin, which accounts for the intense erythema and pruritus commonly seen with this infection. Once *Candida* has taken hold in the skin, microscopic lesions reveal a pseudomembrane composed of masses of yeast organisms that invade the superficial layer of the epithelium. Satellite lesions are small colonies of *Candida* that have spread beyond the main lesion,

which eventually enlarge and become confluent, resulting in large erythematous patches. Normal commensal flora and intact cellular immunity mediated primarily by cytotoxic T cells are the body's primary defenses against fungal overgrowth and invasive candidal infection. The use of systemic antibiotics has the potential for clearing normal microbial skin flora, and both oral and inhaled steroids, HIV infection and AIDS, malignancy, chemotherapy and other immunosuppressive drugs, diabetes mellitus, and senescence all contribute to decreased helper and cytotoxic T-cell function, increasing the likelihood of candidal skin infection.

Clinical Presentation

Subjective

Oral Candidiasis (Thrush) The patient will complain of a severe sore throat. Pain or difficulty is noted during swallowing (dysphagia), especially with acidic foods such as citrus. (See Chapter 8 for more information.)

Vaginal Candidiasis The patient, ranging in age from adolescence to middle age, typically complains of burning, itching, and irritation, either on the vulva or in both the vulva and vagina (vulvovaginitis). Sometimes, burning is noted during intercourse (dyspareunia) and during urination (dysuria). The vaginal discharge is reported as white in color, with a "cottage-cheese" or thick texture. (See Chapter 14 for more information.)

Balanitis The typical patient is a sexually active adult man who complains of a reddish rash and itching on the glans penis. It is sometimes accompanied by penile burning after intercourse. No burning is associated with urination (dysuria). Some patients will report having a female partner who is being treated for a yeast infection or who has irritative vaginal symptoms. (See Chapter 13 for more information.)

Intertriginous Candidiasis The typical patient is an obese adult who complains of a red, itchy rash that is occasionally "weepy" and moist. It is sometimes accompanied by burning. The location of the rash is the inframammary area, the groin, the perianal area, or the interdigital spaces of both the hands and feet.

Candidal Paronychia The typical patient is an adult who complains of an extremely painful fingertip that is red, hot, and swollen. A history of frequent water immersion of the hands is common.

Subungual Candida No pain or itching is associated with this infection. The typical patient is an adult who reports one or several discolored yellow fingernails for several weeks to months. Some of the nails are deformed or separate from the nailbed. A history of excessive contact with water from dishwashing, bartending, or other occupations is frequently present.

Objective

A cardinal sign of cutaneous candidal infections is a bright red rash with macules or satellite lesions seen on the borders. A cardinal symptom is pruritus and sometimes burning.

Oral Candidiasis (Thrush) The anterior and posterior pharynx (including the tongue) is frequently involved. White creamy patches are seen and can be easily scraped off with a tongue blade, leaving behind erythematous patches. The affected areas are tender to palpation and may bleed with minor trauma. In adults, the buccal mucosa, tongue, and lips may also be involved and may extend to the angles of the mouth (perlèche).

Vaginal Candidiasis The vulvar area and, in some patients, the surrounding area appear erythematous and irritated. During speculum exam, the vaginal tissue appears erythematous, with white, curd-like patches pasted on the vaginal walls. The posterior fornix of the vagina may be full of thick white discharge.

Balanitis The glans penis has small, erythematous eroded patches that are tender to touch. A different presentation is small, white round lesions on a red base on the glans.

Intertriginous Candidiasis Any area of skin on the body where there is maceration (or skin rubbing against skin) or increased heat and moisture can become easily colonized by *Candida.* These areas include the inframammary area, the axilla, the groin, the perianal area, and the interdigital areas between the fingers and toes. In some extremely obese patients, macerated skin may occur in other areas as well. The lesions appear as bright red patches with satellite lesions. The skin will appear eroded and moist and is tender to touch.

Candidal Paronychia The area around the nail (the paronychium) is bright red, swollen, and extremely tender. A purulent pocket of discharge is sometimes present; when fluctuant, this abscess will rupture and drain purulent pus.

Subungual Candida The nail is discolored and a yellow color. It can be partially or totally separated from the nailbed. No pain is associated with this condition, in contrast to candidal paronychia.

Diagnostic Reasoning

Diagnostic Tests

Skin infections caused by *Candida* yeast are generally diagnosed by their classic appearance. *Candida* yeasts are normally present in the mouth, vagina, sputum, or the stool. Candidal cultures can be obtained from skin or mucous membranes with a culturette. Because *Candida* is part of the normal flora, a positive culture from the mouth or vagina is of limited value unless confirming signs and symptoms accompany it. For vaginal candidal infections, a saline wet mount, pH paper, and KOH test are helpful in the diagnosis. (See Advanced Assessment 7.1.) The whiff test will be negative, and the vaginal pH is acidic at 4.5 or less.

Of note, although systemic *Candida* infection is not covered in this chapter, there is a rapid diagnostic test for *Candida* infections of the bloodstream that may cut patient

Advanced Assessment 7.1 Intravaginal Infections

When assessing for candidiasis, a saline wet mount (vaginal discharge) or potassium hydroxide (KOH) exam may be performed. The KOH slide exam is necessary to see candida and tinea fungus; KOH is not necessary to see yeast forms in vaginal infections. The saline wet mount works well and is faster to prepare.

The KOH examination is employed to determine the presence of mycelial fragments or budding yeast cells in a skin lesion. The test involves adding KOH solution on a glass slide, covering the slide, and applying gentle heat. The slide is examined microscopically for the fungal elements.

Performing a Saline Wet Mount Exam

1. Take a small amount of vaginal discharge from the posterior fornix of the vagina with either a long, cotton-tipped applicator or from the end of the speculum.
2. Place a small amount of the vaginal discharge in the middle of a clean, dry glass slide.
3. Add 1–2 drops of normal saline solution to the vaginal discharge and stir/mix to produce a thin, milky mixture.
4. Add a cover slip.
5. View the specimen first under low power, then at 40× magnification. Look for pseudohyphae, spores, and leukocytes.

Performing a Potassium Hydroxide (KOH) Microscopic Exam

1. Scrape an area of the rash with the edge of a clean glass slide or a no. 15 sterile scalpel blade moistened with tap water to contain scales. Transfer the scraped tissue onto a slide and add a small droplet of plain water.
2. Add 1 or 2 drops of KOH 10% solution onto the specimen slide, put on a cover slide, and warm the slide carefully for 15–30 seconds using a match, small candle, or Bunsen burner.
3. Examine the specimen under low power with minimal illumination.
4. Look for pseudohyphae and/or spores. Identify hyphae—thin tubular structures, often branching strands of uniform diameter.
5. Switch to high dry (40×–43×) magnification to confirm findings.

NOTE: Although a positive exam establishes the diagnosis, a negative test does not rule out the disease.

Microscopy Tips: Saline Wet Mount and KOH Exams

- Do not confuse a piece of hair or thread on the slide with pseudohyphae. Hairs or threads will appear as black opaque lines, whereas hyphae are translucent and colorless.
- Pseudohyphae or hyphae (the stems) have thin translucent walls that have septa dividing each segment (like a bamboo stem).
- Spores are small and oval to round in shape, seen either alone or in clusters.
- Leukocytes are round to oval and are the size of nuclei in epithelial cells.
- A large number of leukocytes are seen in candidal and trichomonal infections because of inflammation.
- Few leukocytes are seen in bacterial vaginosis (does not cause inflammation) unless there is concurrent infection with *Candida* or *Trichomonas*.
- Epithelial cells are the largest cells found on the slide. Superficial epithelial cells are the most numerous (about 90%) and appear like rounded squares.
- The presence of immature epithelial cells (from the basal and parabasal layer) indicates severe inflammation. The immature cells are smaller and have larger nuclei than superficial (mature) epithelial cells.
- Bacteria are too small to be seen on a regular microscope. They will appear as extremely small dark "specks" on the slide, under both low and high power.

mortality from 40% to 11% by diagnosing candidemia 25 times faster than a blood culture and quickly identifying the *Candida* species that is causing the infection. The test, T2 Candida, uses a polymerase chain reaction (PCR) assay to amplify *Candida* DNA in the blood.

Differential Diagnosis

The location of the skin lesions determines the differential diagnoses to be considered. Contact dermatitis lesions can appear similar to candidal lesions. Fungal infections caused by dermatophytes in other sites include nails (tinea unguium causing onychomycosis), groin (tinea cruris), scalp (tinea capitis), foot (tinea pedis), and body (tinea corporis, causing "ringworm"). For a review of the differential diagnosis of cutaneous candidiasis, see Differential Diagnosis 7.3.

Management

Most cases of mucocutaneous and vaginal candidal infections (and tinea infections) respond well to topical

Differential Diagnosis 7.3 Cutaneous Candidiasis

Type of Candidiasis	Differential Diagnosis
Thrush (oral candidiasis)	Milk curd (infants) Pharyngeal exudate (bacteria/viral)
Intertrigo (skinfolds)	Contact dermatitis Bacterial intertrigo (erythrasma)
Vaginal candidiasis	Trichomoniasis Bacterial vaginosis Contact dermatitis
Balanitis (glans of penis)	Flat genital warts Erythroplasia of Queyrat (Bowen's disease of the penis) Contact dermatitis Balanitis plasma cellularis (Zoon's balanitis)
Candidal paronychia (tissue surrounding the nail)	Bacterial paronychia (*Pseudomonas, Proteus*) Herpetic whitlow
Subungual *Candida* (under nail)	Tinea unguium (onychomycosis)

treatment with antifungal creams that are available OTC or by prescription. The formulation of the topical antifungal used will depend on the site of the infection and whether the rash is moist or dry. Powders work well with moist, macerated lesions. Creams work well in drier lesions. Solutions and sprays are alcohol based and cause burning on inflamed or macerated skin; therefore, they should be avoided on these areas. Preparations in ointment form are far more adherent than liquid, lotion, or cream forms and tend to work best for intertriginous areas. Oral formulations include suspensions and troches.

Pharmacological Therapy

Topical antifungals such as nystatin (effective for *Candida* only), clotrimazole (Lotrimin), miconazole, Monistat-Derm, naftifine (Naftin), and ciclopirox (Loprox) are effective. Most topical antifungal creams are applied twice per day for at least 2 weeks (and up to 4 weeks). The patient should be instructed to apply creams sparingly because too much cream will cause skin maceration, especially in intertriginous areas. The cream is massaged gently into the rash and the surrounding area. The patient is advised that some mild improvement in the rash is sometimes seen in a week, but frequently it takes 2 to 4 weeks until the rash is cleared. Adverse reactions are usually mild; they include erythema, local irritation, itching, burning, and dryness. In some patients, sensitization occurs, and a true contact dermatitis results. (If so, medication should be discontinued.)

For topical treatment of severe cases of candidal vulvovaginitis, cream formulations often will yield better results than vaginal suppositories. Vaginal suppositories can become dislodged from the vagina when the patient is voiding or during defecation. For mild to moderate cases, suppositories work well and are now available for 3-day treatment. In recurrent candidal vaginitis, both partners may need treatment. Partners should abstain from sexual intercourse until both have finished treatment. If the patient does not have symptoms, treatment is not necessary. Treatment recommendations for vaginal candidiasis are listed in Table 7.2.

Some experts discourage the use of systemic therapies for cutaneous candidiasis because of the potential for adverse effects and an increase in resistance. Studies have found that the increased use of imidazoles for systemic therapy has been associated with an increase in the strains of the *Candida* species resistant to fluconazole (Diflucan). Less common candidal species such as *C glabrata* and *C tropicalis* are also more likely to be resistant to treatment with topical imidazoles. If the patient is immunocompromised, has severe vaginal or perianal candidiasis, or is unresponsive to topical medications, systemic antifungal therapy may be justified. Drug interactions may occur with many oral systemic antifungals that are available by

Table 7.2 Treatment of Vaginal Candidiasis

1-Day Treatment	Butoconazole 2% prefilled applicator in one dose Oral fluconazole 150 mg in one single dose
3-Day Treatment	Clotrimazole 2% applicator daily for 3 days Miconazole 200 mg vaginal suppository for 3 days Terconazole 0.8% cream one applicator full intravaginally for 3 days Terconazole 80 mg suppository intravaginally for 3 days
7-Day Treatment	Miconazole 2% vaginal cream intravaginally for 7 days Miconazole 100 mg vaginal suppository for 7 days Clotrimazole 1% vaginal cream, 1 applicator full daily for 7 days Clotrimazole 100 mg vaginal suppository for 7 days Terconazole 0.4% cream one applicatorful intravaginally for 7 days

prescription when given with Coumadin, phenytoin (Dilantin), and rifampin. Serious adverse events that occur with oral systemic antifungals include hepatotoxicity, angioedema, and anaphylaxis. For significant skin infections resistant to extended topical therapy, systemic antifungal treatment includes fluconazole for 10 to 14 days or itraconazole for 2 to 3 weeks. Skin infections resistant to this treatment should be reevaluated for a nonfungal or noncandidal etiology or infection by a fluconazole-resistant candidal strain in need of alternative oral or even IV antifungal treatment such as voriconazole, amphotericin B, or caspofungin. These treatments would never be prescribed in the primary-care setting because they require highly specialized care and observation.

Oral candidiasis (thrush) is treated with nystatin, which is available in suspension, pastilles, or troches. Nystatin is available in 100,000 units/mL suspension, and 4 to 6 mL (or 1 teaspoon) is given (½ dose at each side of the mouth) 4 to 5 times daily. The patient should be advised to retain the suspension inside the mouth as long as possible before swallowing. Nystatin is available in pastille form (200,000 units); the patient should be told to allow one or two pastilles to dissolve slowly inside the mouth 5 times a day for 14 consecutive days. An alternative is clotrimazole (Mycelex) 10 mg troches; the patient should be told to dissolve one troche inside the mouth 5 times daily for 14 consecutive days. Mycelex troches are also indicated for prophylaxis of thrush; the dose is 1 troche 3 times daily. Itraconazole solution (10 mg/mL) is indicated for oral candidiasis that is unresponsive to fluconazole; it is available in cherry or caramel flavor. The patient is instructed to swish 10 mL (100 mg) at a time twice daily in the mouth for several seconds before swallowing; treatment should continue for 2 to 4 weeks. Itraconazole oral antifungal medications are rated as Pregnancy Category C. Relapse frequently occurs after treatment of thrush in immunocompromised patients.

In candidal paronychia, a warm compress on the affected fingertip will enhance drainage of purulent discharge and help relieve the pain. Incision and drainage of purulent material may speed resolution and provide relief. Candidal infections of the nail (subungual candida) are best treated with systemic antifungals.

Follow-up and Referral

The patient should be seen in 2 weeks to monitor response to treatment. If there is no response to treatment, the initial diagnosis should be reconsidered or the patient should be referred to a dermatologist. If partial response is seen, treatment can be continued for another 1 to 2 weeks and the patient reevaluated. If there is poor response at that time, the patient needs a referral to a dermatologist.

Patient Education

Patients must be taught to decrease favorable environmental conditions for *Candida* such as moisture, warmth, and poor air circulation. To prevent diaper rash, the infant should be kept dry as much as possible, and the use of rubber or plastic pants should be discouraged. Baby powder with cornstarch should not be used because it will worsen the infection (*Candida* can use the cornstarch as food).

For obese patients, one method of keeping deep folds of skin apart is by using clean, dry, white tissues between the folds of skin. Educate the patient on the importance of keeping the affected area dry to assist in healing and to prevent future candidal infections. Patients may be instructed to use a hair dryer but stress that it must be kept on the "low" setting. Patients with candidal paronychia should be advised to minimize exposure of hands to water and the prolonged use of rubber gloves. If a fluctuant abscess is present, the patient should apply a warm compress to the involved finger two to three times per day to assist in drainage.

DERMATOPHYTOSES

Dermatophytoses, or *tinea,* are superficial skin infections caused predominantly by three fungal species: *Trichophyton, Epidermophyton,* and *Microsporum.* Transmission occurs primarily through direct contact with an infected person or animal (dogs, cats). Other modes of transmission include contact with asymptomatic carriers, who can infect family and intimate friends, or contact with soil (which is full of fungal spores). Although this route of transmission is controversial, fomites (shared objects such as combs or hats) have been implicated in spreading tinea infections. It is not uncommon to find two (or more) tinea infections in one patient. Tinea manuum often occurs in the "one hand, two feet" distribution. Tinea pedis ("athlete's foot") can occur simultaneously with both tinea unguium (onychomycosis) and tinea corporis (ringworm), as well as with other combinations. Multiple tinea infections are caused by spreading infection from one area of the body to another through scratching.

Environmental and host factors play an important role in the development of tinea infections. Favorable environmental factors that increase the chances of tinea infection include heat, moisture, and poor air circulation. Host factors include age, broken skin, broken hair shafts, and excessive moisture on the skin or nails. Tinea infections are classified by their location on the body; different types include the following:

- Tinea capitis, or ringworm of the scalp
- Tinea corporis, or ringworm of the body—also known as tinea circinata
- Tinea cruris, or "jock itch"—ringworm of the groin
- Tinea pedis, or "athlete's foot"
- Tinea manuum, or tinea of the hands
- Tinea versicolor—also known as pityriasis versicolor
- Tinea unguium (onychomycosis—covered in a separate section)

Although tinea versicolor is caused by the yeast *Pityrosporum orbiculare (Malassezia furfur)* and is not considered a classic dermatophytosis; it is also discussed in this section.

Epidemiology and Causes

The estimated lifetime incidence of tinea infections is between 10% and 20%. Tinea infections are more common in warmer climates. Individuals with diabetes are at higher risk for tinea and yeast infections. Tinea pedis, or "athlete's foot," is the most common fungal infection in the United States. Acute tinea pedis is caused by *Trichophyton mentagrophytes* var. *interdigitale,* and chronic tinea pedis is caused by *Trichophyton rubrum,* which is more common. Tinea cruris (jock itch) is more common in men and *T rubrum* is the common agent. Tinea capitis (ringworm of the scalp) is more common in children until puberty when, for unknown reasons, the incidence markedly decreases. Tinea unguium (onychomycosis) is seen more frequently in adults and elderly patients.

The most contagious of all dermatophytoses is tinea capitis (scalp ringworm). It has been known to cause epidemics in crowded conditions such as schools and group homes, as well as outbreaks among family members. Tinea capitis infections are more common in toddlers and school-age children from urban areas. The reason why tinea capitis is very contagious is because of the propensity of *Trichophyton tonsurans* to produce large numbers of infectious spores called arthroconidia. *T tonsurans* causes up to 90% of all cases of tinea capitis in the United States and Western Europe. Minor causes of tinea capitis in this country include *Microsporum canis,* a zoophilic fungi from dogs. Less common causes are *Microsporum andounii* and *T rubrum.*

Tinea barbae, an infection of the beard area, is more common in men who work with animals. Tinea manuum (tinea manus), or tinea of the hands, is relatively rare compared with all other tinea infections. Tinea manuum infection frequently occurs with tinea pedis infection. The patient infects the hand by touching or scratching an infected foot. Unlike tinea pedis, in which both feet usually become infected, in tinea manuum infection, only one hand is usually involved. Tinea versicolor (pityriasis versicolor) infection is caused by the yeast *P orbiculare* (which causes round lesions) or *Pityrosporum ovale* (which produces oval lesions); it is more common in the summertime. Tinea versicolor becomes more obvious during the summer, when tanning exposes hypopigmented macules that do not tan.

Pathophysiology

Three types of parasitic fungi are implicated in causing dermatophytic or tinea infections. *Microsporum* and *Epidermophyton* species both cause infections of the skin and nails. *Trichophyton* species cause infections not only of skin and nails but also of the hair. These fungal infections are superficial because all three types have the ability to metabolize keratin, the protein that comprises the topmost layer of body surface epithelium that normally serves as a protective barrier against microbial infection. The clinical presentation of tinea infections depends on the anatomical location and the species of fungi. Asymptomatic carriers do not show symptoms of disease but infect susceptible hosts through direct contact or by depositing spores onto fomites such as combs, brushes, or hats. Acute tinea pedis is usually caused by *T mentagrophytes* var. *interdigitale* whereas chronic tinea pedis is caused by *T rubrum* and is more common. For tinea cruris (jock itch), *T rubrum* is the most common agent.

Microscopic exam of tinea lesions reveals either acute or chronic inflammation and a sponge-like texture in the infected tissue, appropriately termed *spongiosis.* Fungal hyphae are seen on the superficial keratin layer of the epidermis. In tinea capitis, infection occurs either inside (endothrix) or outside (ectothrix) of the hair shaft. In ectothrix infections, fungal hyphae and spores invade the hair shaft, leading to destruction of the hair cuticle. Ectothrix infections are caused by *Microsporum* species (*M canis* and *M andounii*). In contrast, endothrix infections are caused by the *Trichophyton* species (*T tonsurans* in North America) and occur inside the hair shaft, leaving the hair cuticle intact. Spores (also called arthroconidia) are found inside the hair shaft, rather than on skin scrapings of surface scale in endothrix infection, also known as "black dot" tinea capitis. Because this type of infection is most common in African American children, coiling of the hair shaft may play some role in infection susceptibility.

Kerion formation sometimes results from an endothrix infection and is associated with severe inflammatory changes of the scalp consisting of nodules and boggy, exudative tissue. Secondary staphylococcal infection may complicate kerion, causing purulent drainage, with infection possibly spreading to draining lymph nodes, causing painful lymphadenitis. When it heals, it results in scarring and alopecia. A variant of endothrix infection that is uncommon in North America but more common in South Africa and the Middle East is favus infection, a severe form of tinea capitis that results in extensive hair loss and scarring.

Clinical Presentation

Subjective

Tinea Capitis The typical patient with tinea capitis is a toddler or school-age child. The parent often reports a painless bald spot. If kerion formation accompanies the infection, the child will show signs of discomfort or will complain of pain. No systemic symptoms such as fever or malaise are associated with kerion formation.

Tinea Corporis The typical patient will report a history of an erythematous round and elevated pruritic lesion that grows in size and starts to clear in the center—the classic shape of "ringworm." Sometimes,

there is a history of another family member with the same infection. Some patients report a history of prior infection. The clinician should inquire about possible exposure through close contact with domesticated animals such as cats or dogs.

Tinea Cruris The typical patient is an obese adult male who complains of a pruritic rash on the groin that is spreading to the medial inner aspect of the upper thigh. Sometimes, the rash is not associated with pruritus.

Tinea Pedis The typical patient with tinea pedis is usually a male teenage athlete or an adult who comes to the clinic complaining of "athlete's foot" and strong foot odor. Most patients do not have pain with this infection unless it gets secondarily infected with bacteria, causing cellulitis. The patient reports areas of macerated soft, whitened skin between the toes. Some patients will complain of concurrent infections on the hand (tinea manuum), on the body (tinea corporis), and the toenails (tinea unguium).

Tinea Versicolor Most cases of tinea versicolor are seen in the summer because the hypopigmented spots become more visible at that time of year; they do not tan. Tinea versicolor is asymptomatic and has a very gradual onset. Rarely, a patient will complain of some mild pruritus. The typical patient is a teen or young adult, although tinea can occur at any age. People of African descent with tinea will complain of either light-colored (hypopigmentation) or dark-colored spots (hyperpigmentation). In adults, the usual sites are on the back, upper chest, arms, and sometimes the neck and face. In children, the rash is more likely to be on the face or forehead.

Objective

Tinea Capitis Three clinical presentations are seen with tinea capitis infections. One presentation is the "black dot" tinea capitis caused by *T tonsurans.* The child with "black dot" tinea capitis presents with painless patchy alopecia (either single or multiple patches). The skin on the scalp does not have erythema; the "black dot" appearance results from broken hair stubbles that remain on the scalp.

Another presentation is called "gray patch" tinea capitis. The child with this condition also presents with patchy alopecia, but the bald patches are covered with fine gray-white scales. The patch is made up of thick, keratinized skin that is grayish white in color. Broken hair shafts of different lengths are present on the surface. Because the inflammatory response is so minimal in both "gray patch" and "black dot" tinea capitis, pain, erythema, nodules, and kerion are not present.

An extremely painful and inflammatory presentation of tinea capitis is known as the kerion. The kerion looks like a bright red, boggy large "bump" on the scalp with alopecia. Purulent drainage can be expressed out of the kerion by gentle pressure, and pus can be seen oozing out of its tiny follicular openings. Kerion formation can result in scarring alopecia. The affected hair follicles atrophy and become permanently damaged; hair does not grow back, even when the scalp is healed. A permanent bald patch can result from this tinea infection if it is not treated aggressively or if the patient does not present early enough during the course of the disease.

Tinea Corporis This infection presents as the classic "ringworm" infection—it is easy to recognize in the clinical setting. The patient will present with ringlike lesions with a bright red elevated border (collarette) that is covered with scales. Tinea corporis can occur in any age-group from child to adult, and the size of the lesions can range from small to large. The patient or parent will report that the lesion has been getting bigger. Some patients have only one lesion, whereas others have numerous lesions. The lesions are usually very pruritic, but sometimes they are asymptomatic.

Tinea Cruris Tinea cruris ("jock itch") is more common in men in the summer or during warm weather. It is usually extremely pruritic, and most lesions will show some lichenification from chronic scratching. The typical lesion is round to a half-circle; lesions will spread to the inner medial upper thigh but spare the scrotum. In contrast, candidal intertrigo can infect not only the groin and thigh but also the penis and the scrotum. The color of the lesion, depending on whether it is chronic or acute, can vary from a bright red to a dull discoloration. The lesions can become macerated from infection and scratching; they may become secondarily infected with bacteria or with *C albicans.*

Tinea Pedis This infection can be seen in the clinical area in up to five different presentations. Tinea pedis is usually asymptomatic, although sometimes the patient will complain of pain from a secondary bacterial infection. The most common cause of tinea pedis is *T mentagrophytes.* The infection usually starts in the third or fourth interdigital web space and sometimes spreads to all toe webs and the soles. Other fungi that cause tinea pedis (but are less common) include *T rubrum, C albicans,* and *Epidermophyton floccosum.*

The most common presentation of tinea pedis is macerated white skin between the web spaces of the toes; the infection is pruritic with occasional painful fissures and can be accompanied by a concurrent unpleasant foot odor. If it becomes infected with bacteria (usually *Staphylococcus aureus*), a tender cellulitis with redness and ulceration can develop on the web space. This condition is called ulcerative tinea pedis. Moccasin-type tinea pedis is seen more often with *T rubrum* infection. Scaling and thickening of the skin is seen in a moccasin distribution on both feet.

Another presentation of tinea pedis is with an "id" eruption—a dermatophytid. Acute "id" eruptions are caused by a hypersensitivity reaction to the fungus. The "id" eruption presents as vesicles on the sides of the fingers and/or the palms of the hands. The vesicles do not

contain fungus but are sterile. The patient may or may not be aware of a concurrent tinea pedis infection.

Another vesicular type of tinea pedis *(T mentagrophytes)* is associated with burning pruritus and sometimes pain. It is more likely to flare up during warm weather, forming multiple vesicles and bullae. It can become secondarily infected with bacteria, resulting in cellulitis or even lymphangitis.

Tinea Versicolor Tinea versicolor is usually asymptomatic; it is not associated with any pruritus. The patient will present with oval to round, pink or hypopigmented or hyperpigmented macules, located mainly on the back, the chest, the arms, and sometimes the neck and face. Tinea in children is more likely to present on the face, especially on the forehead. Sometimes very fine scales are visible, especially if the patient has not showered or bathed for several days; otherwise, daily bathing usually eradicates the scales.

Diagnostic Reasoning

Diagnostic Tests

Tinea infections are usually diagnosed by their clinical presentation. The classic "ringworm" lesions are fairly easy to recognize. The diagnosis can be confirmed via microscopy in the clinical area (or a specimen [skin scraping] can be sent to the laboratory in a sterile plastic cup). Fungal culture is usually not necessary except in cases where the diagnosis is in doubt or in resistant cases. The exception to this rule is for the treatment of onychomycosis (tinea unguium). Because of the length of treatment and the potential for adverse reaction from systemic antifungals, positive proof by fungal culture is necessary. Fungal cultures can take up to 2 weeks for results to become available, although if done on Sabouraud's agar or with dermatophyte test medium, results may be obtained in 3 days.

A fungal culture is recommended for onychomycosis (tinea unguium) and for tinea capitis. Because these two tinea infections are treated by long-term therapy with systemic antifungals (with a high potential for serious side effects), physician consultation is recommended. Proof of the causative agent must be provided by a positive fungal culture. Fungal cultures are also useful if the clinician is unsure of the diagnosis or if the infection does not respond to treatment. Hair bulbs and broken hair, along with scales from the active lesion, should be cultured. Specimens from the affected site should include scales and hair roots. It is important to look for spores and hyphae on the hair shaft, inside the hair shaft (endothrix), and outside the hair shaft (ectothrix) using microscopy.

To obtain a fungal culture for suspected tinea capitis, the clinician should use a dry toothbrush to brush the areas of alopecia and then impregnate the culture media with the bristles. Another method is to use a wet cotton swab, wipe it over the areas of alopecia, and then implant it on the media. Growth is usually seen in 10 to 14 days of culture.

Microscopy is the most useful diagnostic tool to use for tinea in the primary-care setting. A small piece of skin is scraped from the active edge of the lesion and placed on a glass slide. A drop of 10% KOH is placed on the sample, which is then heated gently with a lighter or match. The slide should not be placed too close to the flame or the KOH will get too hot and boil off. The heating accelerates the effect of the KOH on the keratinized cells' walls. When the sample is ready, the hyphae will be easier to see because the cell walls have already been lysed by the KOH. If KOH is not used in this test, the examiner will not be able to see the hyphae because the keratinized cells are too thick. A Wood's light exam should be used on any area of alopecia and hypopigmentation. Some fungi fluoresce when examined under Wood's light, which emits ultraviolet (UV) light (black light). The examining room should be darkened for this exam. A characteristic color that is associated with two minor causes of tinea capitis is a blue-green or bright green color from *Microsporum canis* or *Microsporum andounii. Trichophyton tonsurans,* the most common cause of tinea capitis, does not fluoresce under a Wood's light exam.

If the tinea infection is resistant to treatment, a fungal culture is mandatory. If a secondary bacterial infection is suspected, a sample of the exudates must be taken for culture and sensitivity using a sterile culture tube.

Differential Diagnosis

Almost all tinea infections tend to have a slow and gradual onset, producing low levels of inflammation. Low levels of inflammation do not produce bothersome symptoms such as pruritus and pain. Some tinea infections have been present for months to years before the patient reports them to a health-care provider. Sometimes, tinea infections are an incidental finding during a routine physical exam.

Some tinea infections, such as tinea manuum and tinea unguium (onychomycosis), are usually asymptomatic and are tolerated by the patient for many years. Tinea infections such as tinea cruris and tinea corporis tend to be more symptomatic—the severe pruritus associated with this infection usually drives the patient to seek medical care. The differential diagnosis of various tinea infections is presented in Differential Diagnosis 7.4. Because onychomycosis is so prevalent, it is discussed separately in a subsequent section.

Management

Most cases of tinea infections (except tinea infections of the scalp and nails) respond very well to a 2- to 4- week course of topical treatment with azole-class drugs such as those listed in Drugs Commonly Prescribed 7.3. These agents should be continued for at least 1 week after the lesions have cleared. They should be applied a

Differential Diagnosis 7.4 Tinea Infections

Location	Differential Diagnosis
Scalp (tinea capitis, tinea of the scalp)	Psoriasis, seborrheic dermatitis Alopecia areata
Body (tinea corporis, "ringworm")	Atopic or contact dermatitis Psoriasis
Hands (tinea manuum)	Atopic dermatitis Dyshidrotic eczema
Groin (tinea of the groin, "jock itch")	Erythrasma Contact dermatitis Candidal or bacterial intertrigo Psoriasis
Feet (tinea pedis, "athlete's foot")	Candidal intertrigo Contact dermatitis Dyshidrotic eczema Impetigo
Nails (tinea unguium, onychomycosis)	Candidal nail infection Psoriasis of the nail Pseudomonal nail infection
Tinea versicolor (Pityriasis versicolor)	Vitiligo Pityriasis alba Pityriasis rosea

few centimeters beyond the edges of the skin lesions. Other drugs, including systemic formulations, are included in Drugs Commonly Prescribed 7.3 as well.

As noted previously, for all patients who are on systemic antifungals, physician consultation is recommended because systemically absorbed antifungal drugs can cause hepatotoxicity. A baseline liver function profile and complete blood count (CBC) should be done initially and repeated again in 4 weeks and periodically thereafter during the course of treatment. Griseofulvin can cause leukopenia and granulocytopenia. A baseline CBC and another repeated in 4 weeks are recommended. Thereafter, a follow-up CBC can be done at 4- to 6-week intervals.

The patient should be told to report symptoms such as anorexia, nausea, vomiting, malaise, dark urine, jaundice, and rash to the clinician. If the clinician suspects hepatoxicity, the offending drug should be stopped and consultation with the supervising physician is recommended.

Tinea Capitis

In tinea capitis, a kerion that looks like a honeycomb may be observed. It is an inflammatory boggy mass containing broken hairs and oozing purulent material from follicular orifices. It is a rare, delayed-hypersensitivity reaction to fungal antigens and may result in permanent hair loss. Kerion rarely needs to be treated with

Drugs Commonly Prescribed 7.3 Tinea Infections

Drug	Indication	Dosage	Comments
Topical Agents			
miconazole 2% cream	Tinea: pedis, cruris, and corporis Cutaneous candidiasis	Twice daily for 2 weeks	Tinea pedis needs longer treatment—for 4 weeks.
clotrimazole 1% cream and solution	Tinea: pedis, cruris, and corporis Tinea versicolor	Twice daily for up to 4 weeks	Tinea pedis—treat for 4 weeks.
betamethasone 0.05% and clotrimazole 1% cream and lotion (Lotrisone)	Fungal skin infections	Apply sparingly twice daily for 2 weeks Maximum: 2 weeks	Contraindications: varicella, herpes, vaccinia, other viral infections. Do not use on face. Can cause steroid atrophic changes if used too long.
terbinafine 1% cream (Lamisil AT)	Tinea: cruris, corporis, pedis Moccasin-type tinea pedis (or plantar tinea pedis)	Tinea cruris/corporis: 2 times daily for 1–2 weeks Plantar tinea pedis: 2 times daily for 2 weeks	Improvement may continue to be seen for up to 2–6 weeks after therapy.

Continued

Drugs Commonly Prescribed 7.3 Tinea Infections—cont'd

Drug	Indication	Dosage	Comments
terbinafine 1% solution (Lamisil solution)	Tinea: versicolor (pityriasis), pedis, cruris, corporis	Versicolor/pedis: Twice daily for 1 week Tinea cruris/corporis: Once a day for 1 week	Alcohol-based solution. Use only for 1 week. Apply on dry skin. Do not use spray on face, mucous membranes; avoid broken or irritated skin.
ciclopirox (Loprox) 0.77% cream, lotion	Cutaneous candidiasis and fungal skin infections (tinea pedis, corporis, cruris, versicolor)	Twice daily for 2–4 weeks	Do not use on children younger than age 10 years. Avoid occlusion.
0.77% gel	Seborrheic scalp dermatitis	Apply and massage into affected areas twice daily up to 4 weeks.	
loprox shampoo 1%	Seborrheic scalp dermatitis	Shampoo and leave on for 3 minutes, then rinse. Repeat twice weekly at least 3 days apart.	Not recommended for those younger than 16 years of age. Avoid eyes and mucous membranes.
ciclopirox 8% topical solution (Penlac nail lacquer)	Onychomycosis of fingernails and toenails	Apply thin coat once daily at bedtime.	Remove with alcohol once per week. Repeat for up to 1 year. Do not use nail polish.
ketonazole 2% (Nizoral) cream, shampoo	Tinea pedis, cruris, corporis, versicolor Cutaneous candidiasis Seborrheic dermatitis	Once daily to twice daily for 2–4 weeks or until clinical clearing.	Contains sulfites. Treat tinea pedis for 6 weeks. Seborrheic dermatitis: Use shampoo or cream for 2 weeks or till clear. Tinea versicolor: Use shampoo (1 application). Apply to damp scalp, leave for 5 minutes, rinse.
econazole 1% cream (Spectazole)	Tinea: pedis, cruris, corporis, versicolor	Tinea: once a day; others: 2 times daily	Treat tinea pedis for 4 weeks, others for 2 weeks.
sulconazole (Exelderm) 1% cream, solution	Tinea: cruris, corporis, versicolor, cream only: tinea pedis	Tinea pedis: twice daily for 4 weeks; others: once or twice daily for 3 weeks	Reevaluate if no improvement within 4–6 weeks.
naftifine 1% cream, gel (Naftin)	Tinea: pedis, cruris, corporis	Cream: once per day Gel: twice daily for up to 4 weeks	If no improvement is seen in 4 weeks, reevaluate. Wash hands after application. Not recommended for children.
nystatin cream	Cutaneous candidiasis (intertrigo)	Twice daily for 2–4 weeks	Apply liberally to affected area.
nystatin powder	Candidiasis, especially moist lesions (under breast, groin, shoes, feet, body folds)	Two to three times a day for 2–4 weeks	Good for weeping lesions under breast, in groin, body folds Irritation rare.
nystatin suspension	Thrush (oral candidiasis)	4–6 mL (1 tsp.) 4 times daily for at least 2 weeks	Retain in mouth as long as possible before swallowing.

Drugs Commonly Prescribed 7.3 Tinea Infections—cont'd

Drug	Indication	Dosage	Comments
Systemic Agents			
itraconazole (Sporanox PulsePak) (Sporanox)	Onychomycosis of toenail or fingernail, histoplasmosis, blastomycosis Tinea: capitis, corporis; recalcitrant tinea pedis infections	Toenail: 200 mg daily for 12 consecutive weeks Fingernail: total of 2 "pulses"; 200 mg twice daily for 1 week, then 3 weeks off; repeat pulse Repeat 200 mg 2 times daily again for 1 week Recalcitrant tinea pedis: 200 mg daily for 2 weeks, or 400 mg daily for 1 week Tinea corporis/severe cruris: 200 mg once daily for 1–2 weeks	Take with food; suspension form is better absorbed. Hypoglycemia with oral hypoglycemics. Numerous drug interactions; check before prescribing. Check liver function before, during, and after treatment.
terbinafine (Lamisil)	Onychomycosis of toenail or fingernail due to tinea unguium	Toenail: 250 mg once daily for 12 weeks Fingernail: 250 mg once daily for 6 weeks	Check liver function/renal function. Use with caution in patients with liver/renal disease. Clinical cure not apparent for months.
fluconazole (Diflucan)	Oropharyngeal, esophageal, systemic candidiasis	All doses once daily: Thrush: 200 mg on day 1, then 100 mg/day for at least 2 weeks Esophageal: 200 mg on day 1, then 100 mg/day for at least 3 weeks	Check liver function test. Contraindicated in patients with liver disease.
griseofulvin (ultramicrosized) Grifulvin V	Tinea capitis, onychomycosis, severe/recalcitrant tinea cruris, pedis, corporis	Tinea capitis: 500 mg once daily for 2–4 weeks Tinea corporis: 500 mg daily for 2–4 weeks Severe: 250–500 mg twice daily for 1–2 weeks Onychomycosis: 750 mg daily for 6 months Maximum: 1 g/day	Ultramicrosize formulation better absorbed. High rate of resistant strains of tinea capitis. Use with caution in patients with liver and renal disease. Monitor renal, hepatic, and hematopoietic function. Decreases effectiveness of oral contraceptives, oral anticoagulants, barbiturates.

concurrent antibiotics because a noninfected kerion can itself look exudative. It needs to be treated only if a secondary staphylococcal infection is obvious. Tinea infections of the hair and nails do not respond to topical treatment at all, unlike the other tinea infections. Tinea capitis should be treated with oral systemic antifungals, along with a topical antifungal for the local scalp lesions. A Wood's light exam should be done on all cases of alopecia on the scalp. Although some infections will fluoresce, others *(T tonsurans, T violaceum)* do not. *Microsporum canis* and *Microsporum andounii* are fluorescent. A fungal culture is necessary not only to help in the diagnosis but also to classify the species of fungi. It is important to examine the patient's close contacts, including family members (especially other children) and schoolmates. Fungal cultures on close contacts are recommended, if possible. Asymptomatic cases of tinea capitis can be treated with selenium sulfide shampoo

(e.g., Selsun Blue). There is no need to wait for results of the fungal culture (which takes 2 weeks) before initiating treatment, especially if there is kerion formation.

The treatment of choice for tinea capitis is griseofulvin (Grifulvin V) 250 to 500 mg by mouth twice per day for severe cases in adults or once per day for children over 50 pounds. For children 30 to 50 pounds, 125 to 250 mg daily is recommended. Treatment duration is from 2 to 4 months or at least 2 weeks after negative cultures are obtained. Some authorities recommend against griseofulvin as the first-line drug because of its potential adverse effects. Other effective alternatives used to treat tinea capitis are oral terbinafine or itraconazole. Male patients on griseofulvin should be advised that this drug affects sperm (it is teratogenic) and to avoid fathering a child for at least 6 months after stopping the drug. Concurrent treatment with selenium sulfide shampoo 3 times per week is used as adjunctive therapy to systemic antifungals.

Tinea Corporis

Topical therapy generally works well with tinea corporis. The patient must be reminded to apply the topical agent for at least 1 week after the resolution of the lesions and to apply the cream a few centimeters beyond the edges. Concomitant short-term treatment with a mild corticosteroid such as hydrocortisone 1% (available OTC) is effective in helping to relieve itch and inflammation. In severe cases, systemic antifungals such as itraconazole or terbinafine daily are effective.

Tinea Cruris

Topical antifungal therapy is very effective for treatment of jock itch. Concomitant short-term treatment with a mild corticosteroid such as hydrocortisone 1% (OTC) is effective in helping to relieve itch and inflammation. If weeping areas are present, compresses made from Burow's solution are helpful. Use of OTC antifungal powders is helpful for prevention of future recurrences. For severe cases, a short course of a systemic antifungal such as itraconazole (Sporanox) or terbinafine (Lamisil) is effective.

Tinea Pedis and Tinea Manuum

Tinea pedis and tinea manuum are both treated with topical antifungals. Treatment of tinea pedis should emphasize moisture control: Use of drying foot powders (miconazole, tolnaftate) is very helpful. If weeping areas are present, compresses made from Burow's solution are helpful. The feet should be exposed to air as much as possible—during warm weather, the use of airy sandals or going barefoot is helpful. If socks are worn, cotton or a synthetic "wicking" blend is the best material. Socks should be changed once a day; changing socks twice a day is indicated if the patient's feet become wet in 4 hours or less. An antiperspirant spray on the soles of the feet (to be applied on normal skin only) can help patients who are afflicted with excessively sweaty feet. Severe tinea pedis can be treated with oral agents such as itraconazole or terbinafine daily. After a short course of systemic therapy, the patient should be placed on maintenance topical therapy with a powder or a spray (miconazole, tolnaftate) to prevent recurrences.

Tinea Versicolor

Tinea versicolor is treated with topical selenium sulfide lotion (Selsun) applied daily for 7 days from neck to waist daily and then lathered for 10 minutes before rinsing thoroughly. Treatment is then done once a week for 1 month, and then once a month for maintenance. Ketoconazole (Nizoral) shampoo can also be used weekly for maintenance. The clinician must not forget to advise patients that treatment will get rid of the infection but not of the hypopigmented spots, which take longer to resolve. Patients should also be warned of the high rate of recurrence, because *Malassezia furfur* is a normal inhabitant of the skin. Exposing the hypopigmented lesions to sunlight can speed up the process in some patients. For patients who want more aggressive treatment, oral ketoconazole 200 mg daily for 1 week or 400 mg in a single dose or at weekly or monthly intervals is effective but does not prevent recurrence. Patients on oral ketoconazole should be advised not to shower for at least 12 to 18 hours because the drug is delivered to the skin by the sweat after it has been absorbed into the bloodstream. The patient should be advised that there is a risk of hepatotoxicity from oral ketoconazole. Because tinea versicolor is a superficial benign disease, this fact should be given serious consideration.

Follow-up and Referral

The patient should be seen for initial follow-up 2 weeks after initiation of therapy. For resistant cases, the clinician should make sure a fungal culture is done, or the diagnosis should be reevaluated. Resistant cases should be referred to a dermatologist for reevaluation or for more aggressive treatment with systemic antifungals. If the patient is on topical therapy only, systemic therapy can be considered. Severe tinea corporis and tinea pedis respond well to oral terbinafine or to itraconazole.

Some tinea infections have higher recurrence rates than others. Tinea versicolor (pityriasis versicolor)—although not a true tinea (because it is caused by a yeast)—has a very high recurrence rate because *P orbiculare* and *P ovale* are normal colonizers of the skin. Tinea pedis also tends to reoccur, so meticulous attention should be given to eradicating favorable environmental conditions by the patient (see discussion of tinea pedis for preventive measures). Maintenance therapy in tinea pedis with topical OTC agents in powder or spray form (miconazole, tolnaftate) is very effective in helping prevent recurrences.

If the clinician suspects that a secondary infection (cellulitis) is complicating tinea infection, a culture

should be done on the purulent discharge. Empiric therapy for mild cellulitis, which is usually caused by gram-positive bacteria such as staphylococci or group A beta-hemolytic *Streptococcus,* includes oral antibiotics such as cephalexin or dicloxacillin for 7 to 14 days. For patients with penicillin allergy, either erythromycin or clarithromycin is a good alternative. Toe web infection (ulcerative type) can be due to gram-negative bacterial infection (*Pseudomonas aeruginosa, Escherichia coli,* and *Proteus*) and must be treated with systemic fluoroquinolones (i.e., ciprofloxacin). Moderate or severe cellulitis should be referred to a physician for more aggressive treatment, including IV antibiotics.

Patient Education

Patients who are on systemic antifungals must be informed of the risk of hepatotoxicity and educated on the signs and symptoms of acute hepatitis, such as anorexia, nausea, vomiting, malaise, dark urine, jaundice, and rash.

For all patients on systemic antifungals, consultation with a physician is recommended. A baseline liver function profile and CBC should be done before treatment is initiated and repeated again in 4 weeks and periodically thereafter. The patient should be told to report symptoms such as anorexia, nausea, vomiting, malaise, dark urine, jaundice, and rash. Griseofulvin decreases the effectiveness of certain drugs, such as oral contraceptives, oral anticoagulants, and barbiturates. Any woman of reproductive age who is on oral contraceptives and is prescribed griseofulvin should be warned that the contraceptive will become less effective and therefore her risk of pregnancy will be increased. The patient should be advised to see her gynecologist about using another effective method of birth control. If a patient who is on a barbiturate or an oral anticoagulant feels strongly about starting antifungal treatment, the patient should consult the physician who prescribed the original medication before starting treatment with systemic antifungals. Terbinafine is potentiated by cimetidine and is antagonized by rifampin. Itraconazole (Sporanox) is contraindicated if the patient is taking any drug that is metabolized in the liver by the CYP3A system. Itraconazole increases the blood levels of triazolam (Halcion), diazepam (Valium), digoxin, dihydropyridine class of calcium channel blockers (Norvasc, Procardia), and several other drugs. Adverse reactions to these agents include gastrointestinal (GI) upset, abdominal pain, dizziness, headache, hepatotoxicity, rash, and taste disturbance (associated with terbinafine). Blood dyscrasias including granulocytopenia and leukopenia, a lupus-like syndrome, and proteinuria are also possible adverse effects of griseofulvin. The following measures should be recommended to help prevent spread or recurrence of tinea infections:

- Tinea capitis: The parent and the child should be advised not to share combs, hats, or any headgear.
- Tinea corporis: The patient should be advised to control excessive sweat and body moisture by wearing looser clothing and to change clothing when it becomes wet or damp. After bathing, a hair dryer on the low setting may be used to dry intertriginous skinfolds.
- Tinea cruris: Cotton boxer shorts are better than tight briefs. The patient should avoid wearing tight jeans, pantyhose, or tight biker shorts.
- Tinea corporis: Some patients (especially children) may think that an actual worm is the cause of "ringworm" infections. Reassuring these patients that the infection is a fungus goes a long way in allaying anxiety.
- Tinea pedis: The patient should be advised to avoid scratching the feet because the infection can spread to the hands and to the body (tinea corporis). The patient should also avoid tight shoes and moist socks, especially socks made out of synthetic material, unless they are designed to wick away moisture. Patients who are prone to "athlete's foot" should change socks two or three times a day and expose their feet to air—they should use sandals if possible in warm weather. Absorbent nonsynthetic socks are preferred. Feet should be washed daily and dried thoroughly (a hair dryer on a low setting is helpful). Use antiperspirant spray on the soles to decrease sweating. Patients should also be advised to clean their showers with bleach and wash all white sheets with bleach. When showering away from home, shower shoes should be worn.
- Tinea versicolor: Advise the patient that exposure to sunlight will help in repigmentation of hypopigmented areas.

ONYCHOMYCOSIS

Onychomycosis (tinea unguium) is a benign superficial and cosmetic infection of the toenails and fingernails. Most patients tolerate tinea infections for many years. Patients who seek treatment are usually younger adults who are disturbed about the cosmetic effects of the infection. The most common etiology for onychomycosis is infection with dermatophytic fungi, but molds, yeast, and nondermatophytic fungi may be causative agents as well. Risk factors that place one at risk for onychomycosis include wearing occlusive shoes, diabetes mellitus, participation in sports, increasing age, and poor circulation of the lower extremities.

Epidemiology and Causes

Onychomycosis, or tinea unguium, is more common in adults and in elderly patients than in children. The combination of poor circulation in the lower extremities as a result of peripheral vascular disease and increasing age makes this a common problem in older adults. Toenails are more likely to become infected than fingernails. Onychomycosis is a common infection worldwide; the

incidence of disease is variable and is dependent on many factors. In the United States, 20% of all adults have onychomycosis. Onychomycosis is sometimes caused by the yeast *Candida albicans.* Dermatophytic species of fungi commonly implicated in this tinea infection are *Trichophyton* species: *T rubrum, T mentagrophytes, T shoenleinii,* and several others. A zoophilic fungi that is normally found in animal species that cause onychomycosis is *T verrucosum.*

Like many infections, onychomycosis frequently has a multifactorial etiology. *C albicans* can be part of the normal flora of the mouth, the GI tract, and sometimes the vagina. The cause cannot be attributed solely to the presence of the offending organism, because most of the yeasts and fungi are ubiquitous to our environment. Molds, for example, are plentiful in soil. The soil mold *Scopulariopsis brevicaulis* is the most common nondermatophytic cause of onychomycosis. Other molds implicated in onychomycosis include the *Aspergillus* and *Alternaria* species.

Pathophysiology

Onychomycosis is classified as either primary or secondary. *Primary onychomycosis* involves invasion of the healthy nail plate. In *secondary onychomycosis,* diseased nails (e.g., from psoriasis or trauma) are involved. Factors that increase the risk of onychomycosis include a decrease in circulation, resulting from either a chronic process such as peripheral vascular disease or from an acute traumatic process, such as a fracture of the lower extremity. Abnormal enervation during spinal trauma has also been implicated. Tinea unguium can result from an extension of an infection with tinea pedis, tinea manuum, or tinea corporis.

Nail invasion can proceed in several ways. In proximal subungual onychomycosis, the pathogen enters the nailbed through the posterior nail and cuticle area, then migrates to the proximal nailbed. This form of onychomycosis is most commonly seen in immunocompromised individuals who exhibit suboptimal T-cell function. In distal and lateral subungual onychomycosis, infection starts on the distal or the lateral margins of the nail. The infection then moves toward the center of the nail until the entire nail is affected. Distal subungual onychomycosis is almost always caused by *Trichophyton rubrum.* Superficial white onychomycosis involves infection of the nail surface only and is caused mainly by *Trichophyton mentagrophytes.* Total dystrophic onychomycosis is associated mostly with chronic candidiasis, which is seen in immunodeficiency states such as AIDS.

Clinical Presentation

Subjective

The typical patient who seeks treatment for onychomycosis is either a young or middle-aged adult who is bothered greatly by the cosmetic effects of the infection. The duration of the infection can range from a few weeks to many years. Onychomycosis is an asymptomatic infection, and there should be no pain involved. Some patients will report having tried several OTC remedies with no result. The patient will complain of thickened nails or nails with cloudy, white-colored patches. Some will report nail discoloration, ranging from yellow to green or brown to black. Some patients will complain of nails that are partially detached from the nailbed (onycholysis).

Objective

Onychomycosis has several presentations. In some patients, two types can occur simultaneously. Superficial infections are more responsive to treatment with prescription topical antifungals (naftifine gel) than subungual types. (Onychomycosis infections with "subungual" as part of their name denote infection beneath the nail.) Superficial white onychomycosis involves only the nail surface but can occur with either distal or lateral subungual onychomycosis. Subungual onychomycosis can include distal, lateral, and proximal sites of infection. The first or fifth toenail is more likely to become infected than the other toes. The infected nail appears dry and has an opaque white patch with sharp borders that start on the distal, lateral, or proximal subungual portion, or occurs only on the surface (superficial white onychomycosis). As the infection persists, the nail becomes brittle and thick. The area underneath the nail accumulates chalky material made up of hyperkeratotic debris that can be scraped off easily for fungal cultures. In some patients, the white opaque areas become discolored—either yellow or brown. A green-black color indicates a bacterial *Pseudomonas* infection.

Diagnostic Reasoning

Diagnostic Tests

All cases of presumed onychomycosis must be confirmed by laboratory findings. A positive result on the fungal culture, which includes proper identification of the fungus species involved, is necessary to start treatment with systemic antifungals. Findings on the classic potassium hydroxide (KOH) exam indicating fungal infection are hyphae and spores or the classic "spaghetti and meatballs" appearance. Under the microscope, hyphae appear like translucent long tubes with septae (separate sections), and spores are small round to ovoid shapes.

Fungal Culture Fungal cultures done on Sabouraud's agar or with Dermatophyte test medium produce results in up to 3 days. The area where the samples are to be taken should be cleansed with 70% alcohol before specimen collection. Skin should be taken from the active border of the lesion. Nail samples should be taken from the subsurface of the infected nail. To obtain samples from underneath the nail, a scalpel can be used to scrape the underside of the infected nail. In proximal subungual onychomycosis, the affected part of the nail is on the proximal fold and cannot be sampled without nail

removal. Nail removal is done with a bilateral digital nerve block and is contraindicated in any bleeding disorder. The patient should be referred to a podiatrist for nail removal and treatment.

KOH Exam A laboratory exam using KOH is necessary for diagnosis, because only 50% of dystrophic nails are due to dermatophytosis. A drop of 10% KOH is placed on the sample of nail clippings and is heated gently with a lighter or match. The slide should not be placed too close to the flame, or the KOH will get too hot and boil off. The heating accelerates the effect of the KOH on the keratinized cell walls. When the sample is ready, the hyphae will be easier to see because the cell walls have already been lysed by the KOH.

Differential Diagnosis

Differential diagnosis of onychomycosis includes psoriasis of the nail, Reiter's syndrome, trauma to the nail, and congenital nail abnormalities. Onychomycosis accounts for only 50% to 60% of abnormal appearing, or dystrophic, nails. Lichen planus, eczematous conditions, and senile nailbed ischemia all may result in similarly appearing nails; however, fungal infection does not underlie such conditions, and antifungal medications would be inappropriate.

Management

Traditionally, onychomycosis of the toenail required long-term treatment with systemic antifungals and had a high recurrence rate. With the advent of newer antifungals (fluconazole, itraconazole, terbinafine), the cure rates for onychomycosis have greatly improved. Fluconazole (Diflucan) has consistently been shown to be less effective than either itraconazole or terbinafine and is not typically recommended. Removal of the affected nail is often curative.

Fingernail infection is easier to cure and has a lower rate of recurrence. The decision to treat onychomycosis aggressively must be considered carefully because it is a benign cosmetic infection. The patient's desires for treatment and his or her health history are probably the strongest determinants in deciding whether or not to treat with systemic antifungals. Other important factors include the presence of any preexisting medical problems and the past medical history. Patients who have liver disease should never be on any systemic antifungal drugs because of the high risk of hepatoxicity and liver failure. A history of infection with viral hepatitis can result in chronic infection with hepatitis B and C. A history of excessive alcohol use can result in cirrhosis of the liver or elevations in liver function tests.

Medication interactions are also problematic. Drugs metabolized by the cytochrome P450 3A enzyme system (CYP450) interact with systemic antifungals. Itraconazole potentiates the effects of many common prescription drugs, including diazepam (Valium), digoxin (Lanoxin), triazolam (Halcion), anticoagulants (Coumadin), HIV protease inhibitors (e.g., indinavir, ritonavir), methylprednisone, and verapamil. Patients who are taking vinca alkaloids (used in cancer chemotherapy) should not take itraconazole.

In addition, itraconazole requires a low gastric pH (acidic) to be absorbed. Therefore, H_2 blockers and antacids must be avoided within 2 hours of taking the drug.

Topical Therapy

Topical treatment of onychomycosis is generally not very effective (10% or less), but it is worth a try because it is not associated with any serious side effects. Good candidates for topical treatment are motivated patients with only mild involvement or with surface involvement (superficial white onychomycosis). A topical solution such as ciclopirox nail lacquer 8% (Penlac) or naftifine gel 1% (Naftin) applied twice daily may be effective when it is applied religiously to toenails for at least 6 to 18 months and to the fingernails for 4 to 6 months. Ciclopirox 8% (Penlac) is indicated for mild to moderate onychomycosis of the fingernails and toenails (without lunula involvement). Initial improvement may take up to 6 months; treatment can continue up to 48 weeks. Penlac should be applied evenly on the affected nail and surrounding 5 mm of skin once daily, preferably at bedtime. It should be applied over previous coats, then removed with alcohol once a week. Nail polish should not be used during treatment.

Systemic Therapy

For patients who desire treatment for onychomycosis, most authorities recommend systemic therapy. If concurrent tinea pedis, tinea manuum, or tinea corporis is present, it should be treated with topical antifungals, so that the source of infection is eradicated. Fingernails are easier to treat than toenails and have a higher cure rate from 50% to 70%. See Drugs Commonly Prescribed 7.3 for recommended systemic medications.

Itraconazole and terbinafine are better choices for toenail infections, which are more difficult to treat. Patients who are on H_2 blockers can also take these drugs. There is no role for griseofulvin in the treatment of toenail onychomycosis because up to 80% to 90% of patients will relapse with this drug.

Follow-up and Referral

After initiation of therapy, liver function tests should be rechecked every 4 weeks. The first follow-up visit is scheduled during the fourth week to monitor for symptoms of hepatoxicity, adverse reactions, and compliance with treatment and to obtain a liver function panel. Thereafter, the patient should be seen for follow-up every 4 to 6 weeks and liver function tests done. Resistant cases of onychomycosis should be referred to a dermatologist. Nail growth should be monitored until the nails become clinically normal.

Patient Education

The patient should avoid tight, ill-fitting shoes because they traumatize nails, especially the first toenail. Cotton socks that become moist should be changed. Patients should be encouraged to air dry their feet and wear open-toed slippers or sandals.

Patients on itraconazole and terbinafine should be advised that although mycological cure has been achieved, normal nails might not be clinically apparent until regrowth in 3 to 12 months.

BACTERIAL INFECTIONS

IMPETIGO

Impetigo is a highly contagious, superficial vesiculopustular infection of the skin that is commonly seen in infants and children. Impetigo spreads easily through direct contact among family members and from one child to another in the classroom or in play groups. Impetigo infection in adults is not as contagious as impetigo infection in infants and younger children. Impetigo infection typically demonstrates a mixed flora of gram-positive bacteria that includes *Staphylococcus aureus* and group A or group B beta-hemolytic *Streptococcus.* Two forms of impetigo are seen in the clinical area—bullous and nonbullous (vesiculopustular) forms. Nonbullous impetigo is the more common form, constituting approximately 70% of impetigo cases.

Epidemiology and Causes

Impetigo affects primarily infants in hospital nurseries and young children 2 to 5 years old, especially those with poor hygiene and who are in day-care groups; however, patients of all ages are susceptible. Impetigo accounts for approximately 10% of skin problems observed in pediatric practices. It is the most common bacterial skin infection and the third most common skin disease among children. Impetigo is more prevalent in hot, humid weather, when biting insects and mosquitoes are most pervasive. The trauma caused by their bites favors bacterial growth on moist skin. There is an increased incidence of impetigo in lower socioeconomic groups because of several factors, including overcrowding, lack of good personal hygiene, and a higher incidence of anemia and malnutrition. In addition, any preexisting skin disease that goes untreated (e.g., atopic dermatitis) may also predispose individuals to secondary infection. Staphylococcal impetigo may be associated with immunodeficiency disease.

Pathophysiology

The infectious process in impetigo is limited to the stratum corneum. The presence of numerous neutrophils within the blister (subcorneal blister) and the presence of gram-positive cocci are characteristic of impetigo infections. The etiological agents may be found alone or in combination. If a combination of gram-positive bacteria is causing the impetigo infection, symbiosis promotes the growth of both bacteria and produces more rapid spread.

Staphylococcus bacteria are usually noted during the very early stage of the lesions, whereas S*treptococcus* bacteria tend to predominate in the later stages. In recent years, epidemiologists have noted an etiological shift in which *Staphylococcus aureus* either alone or in combination with group A *Streptococcus* has replaced the latter as the most common causative organism Thus, chronic skin colonization with either *S aureus* or group A *Streptococcus* predisposes an individual to impetigo. Infected lesions typically result from sites of previous injury, such as insect bites. The blisters are the result of local separation (acantholysis) of the keratinocytes in the underlying epidermal layer forming the floor of the blister. Blister formation is caused by the action of epidermolytic (exfoliative) exotoxins produced by the bacteria. Group A *Streptococcus* is the primary etiological agent for a particularly severe, albeit rare, ulcerative form of impetigo known as ecthyma. Ulcer formation is also aided by coagulase-positive *Staphylococci.*

Finally, bullous impetigo is caused by *Staphylococcus aureus* infection in newborns and young children. In this condition, exfoliative toxin A causes loss of cellular adhesion in the superficial epidermis normally mediated by the protein desmoglein. This results in large blistering lesions known as bullae, which eventually drain, leaving thin, nonpurulent crusts over the entire affected skin area.

Methicillin-resistant *S aureus* (MRSA) is an increasingly common cause of impetigo. This pathogen is observed more frequently with the nonbullous form of impetigo. Over the last decade, an increasing number of community-acquired MRSA and gentamicin-resistant *S aureus* strains have been reported as causes of impetigo.

Clinical Presentation

Subjective

The most common symptom of both types of impetigo is pruritus from the lesions. The parent of a young or school-age child will complain of a red, crusty rash that is spreading or getting larger in size. The rash is usually located on the face or on the extremities. Parents or the child may report that a close friend or classmate of the patient has the same rash.

The provider should ask about the location, onset, and duration of the lesions and any associated symptoms. The clinician should also inquire if any other family member has been affected and if treatment has been effective. Fever is unusual in impetigo; but if present, it should prompt investigation for a deeper infection.

Objective

The plaques of impetigo begin as vesicles whose roofs break down, leaving shallow erosions with yellowish

crusts. The lesions may be discrete or confluent in their distribution and are usually seen on the face. Early impetigo may resemble many vesicular skin conditions, such as herpes simplex. Two forms of impetigo commonly seen in the clinical area are bullous impetigo and nonbullous impetigo.

The bullous type of impetigo may present with bullae that begin as small (1–2 mm) superficial vesicles with a fragile roof that ruptures easily. Sometimes the parent or patient will deny seeing bullae because they rupture so quickly that they are not recalled by the patient or the parent. The serous fluid inside the ruptured vesicles develops into a thin, transparent, and varnish-like crust. Hence the vesicles become pustular in a matter of hours. The bullous type of impetigo is usually caused by *Staphylococcus* bacteria; it commonly occurs on the face, elbows, and knees.

In the nonbullous or vesiculopustular type, the lesions are characterized by thick, adherent, dirty yellow–colored crusts that have erythematous margins. This type of impetigo occurs more often in older children. Both bullous and nonbullous types produce symptoms such as burning and pruritus. In addition, regional lymphadenopathy is seen. When the face is involved, the cervical nodes (and sometimes the preauricular and submandibular nodes) are enlarged; when the lesions are on the upper extremities, the axillary nodes become enlarged.

A variant of bullous impetigo that is caused exclusively by *S aureus* is known as *staphylococcal scalded skin syndrome.* Exotoxins produced by the bacteria lead to bullous, sheet-like necrosis of the epidermis and cause the epithelium layer of the skin to peel off in large pieces. The "scalded skin" thus mimics a thermal burn. This serious infection is more commonly seen in children and usually begins in the intertriginous areas.

A less common form of impetigo that is ulcerative in nature is known as *ecthyma.* This form of impetigo is seen predominantly on the feet, ankles, legs, and thighs. It afflicts mostly homeless people, sewage and garbage workers, alcoholics, and neglected elderly individuals. It is a deeper version of impetigo and often results from a neglected or poorly treated superficial abrasion, or from infected insect bites. Itching is common, and autoinoculation from scratching may cause satellite lesions that are annular in form. Ecthyma presents as pruritic and tender red vesicles or pustules that are surrounded by erythema and that eventually ulcerate. Because this process is very superficial, healing often occurs spontaneously in the center of the lesion and results in scarring. The inflammatory process involves both dermal and epidermal layers. (See Table 7.3.)

During physical assessment, a thorough examination of the skin should search for erosions that are covered with moist, honey-colored crusts. Any firm and dry or dark crusts with surrounding erythema characterize a deeper form of impetigo called *ecthyma.* The physical assessment should include an examination of the head, ears, pharynx, the neck, and the regional lymph nodes should be noted for lymphadenopathy.

Diagnostic Reasoning

Diagnostic Tests

Diagnosis may be based solely on medical history and clinical presentation. Initial testing for impetigo may also include a bacterial culture and sensitivity analysis from the moist crusts of the lesions. The results of the culture

Table 7.3 Types of Impetigo

Types of Impetigo	Causative Agent	Clinical Presentation
Bullous impetigo	*Staphylococcus aureus*	Lesion starts as about 1–2 mm superficial vesicle with fragile roof, easily ruptured; ruptured vesicle forms thin, transparent, varnishlike or classic "honey-colored" crust. Becomes pustular in matter of hours; pruritic; burning sensation.
Staphylococcal scalded skin syndrome	*Staphylococcus aureus*	Variant of bullous impetigo: Epidermal necrosis caused by bacterial exotoxins, resulting in the epithelial layer peeling off in large, sheetlike pieces; mimics scalded-skin thermal burn.
Nonbullous impetigo	*Streptococcus, Staphylococcus aureus*	Lesions are thick, adherent; recurrent with dirty yellow–colored crusts with erythematous margins; pruritic and burning sensation.
Ecthyma	*Staphylococcus aureus, Streptococcus;* other infective organisms may be observed.	Pruritic tender, red vesicles or pustules surrounded by erythema; rash eventually ulcerates. Deeper impetigo resulting from inadequately treated or neglected skin infections; also seen in infected insect bites or abrasions.

and sensitivity help to assess for antibiotic resistance of the responsible pathogen. Resistance can vary from community to community. In addition, a Gram stain can be obtained; if the lesions are caused by impetigo, the stain will reveal gram-positive cocci. If herpes simplex is suspected, a viral culture can be obtained. If the patient is febrile or has systemic symptoms, a CBC with differential should be obtained.

Differential Diagnosis

The typical dirty-looking, honey-colored crust is almost pathognomonic of bullous impetigo, so much so that cultures are not necessary before treatment is started. Bullous impetigo should be differentiated from other vesicular and pustular skin conditions. Many skin diseases with weepy lesions may resemble impetigo, such as varicella-zoster virus, herpes simplex virus, eczematous dermatitis (atopic dermatitis), bullous pemphigus/pemphigoid, and contact dermatitis. The history, distribution, and morphological features of the primary skin lesions provide the best information to help in the differential diagnosis of other skin conditions.

Varicella-zoster infection (herpes zoster or chickenpox) produces a rash with widely distributed papules and vesicular lesions. The onset of the rash typically starts on the head and neck area. The lesions of herpes zoster follow a dermatomal pattern that consists of a group of uniform 2- to 3-mm vesicles on an erythematous base.

A localized group of vesicles located on a single anatomical site, with a clear to cloudy fluid on an erythematous and edematous base, helps to characterize herpes simplex lesions. These lesions are usually preceded by a prodrome of burning and tingling before the lesions erupt.

Bullous pemphigus and bullous pemphigoid are autoimmune diseases affecting the skin and causing bulla that can become eroded and infected. They should be included in the differential diagnosis for any vesicular or bullous skin disease.

Acute nummular eczema manifests as pruritic, coin-shaped plaques or papulovesicles on an erythematous base; the lesions may become exudative and crusted. Candidiasis lesions are bright red; this rash forms satellite lesions along with macerated moist patches. Candidiasis is often accompanied by pruritus and burning in the macerated areas.

Management

There are two principles of therapy in the management of impetigo: (1) Nonpharmacological measures are employed to enhance resolution and to reduce bacterial colonization on the skin surface, and (2) antibiotics are prescribed to help eradicate the responsible pathogen and to prevent recolonization and complications. Even without treatment, impetigo usually heals within 2 to 3 weeks. With appropriate treatment, lesions usually resolve after 7 to 10 days. The key to treating and preventing impetigo is practicing good personal hygiene and maintaining a clean environment.

Nonpharmacological Management

Nonpharmacological management of impetigo involves the use of solutions or substances to debride the impetiginized lesions and to expose the skin surfaces where the bacteria are present. Exudative impetigo lesions may benefit from drying compresses to remove thick crusts and desiccate (dry out) the lesions. Normal saline, plain tap water, or Burow's solution may be applied for 10 to 20 minutes, 3 to 4 times daily. Although the dehydrating effect of the compresses may help to improve the appearance of the skin lesions, disinfectant solutions are not particularly effective in treating the underlying condition.

Pharmacological Management

Pharmacological treatment of impetigo includes the use of both topical and oral antibiotics. Mild cases of nonbullous impetigo can be treated effectively with a topical antibiotic, combined with cleansing and debridement. One topical agent is mupirocin 2% cream or ointment (Bactroban) applied three times per day for 7 days. This is equivalent in efficacy to oral cephalexin. Washing with chlorhexidine (Hibiclens) is a valuable adjunct because of its bactericidal properties. The patient should be instructed to wash the affected skin areas with the bactericidal soap two to three times a day before the mupirocin cream is applied. Antibiotic creams and ointments containing neomycin may be used although neomycin can produce contact dermatitis in sensitive individuals. Sensitization usually develops after long-term use on denuded skin and is not recommended. In addition, OTC antibacterial ointments are typically too weak to kill streptococcal and staphylococcal infections, and using the ointment carelessly may actually spread the impetigo.

Another topical ointment belonging to the pleuromutilins antibiotic class is retapamulin (Altabax). It is specifically for impetigo caused by MRSA. Patients may be more willing to comply with this treatment because it only involves applying the ointment twice daily for 5 days. However, it is not intended for mucosal use.

Systemic antibiotics are indicated for impetigo when there are systemic symptoms such as fever or toxicity, if a large area of the skin is involved, or within the context of athletic teams or child-care or family clusters. Antibiotic therapy should cover *Staphylococcus aureus* and *Streptococcus pyogenes.* The prevalence of MRSA and macrolide-resistant *Streptococcus* are recent challenges. MRSA has been cited as being responsible for nearly 80% of all community-acquired staphylococcal skin and soft tissue infections. Penicillin therapy used to be the standard of care therapy for impetigo, but with the increasing challenge of drug resistance, this is no longer the treatment of choice. Rather, beta-lactamase–resistant

antibiotics (cephalosporins, amoxicillin-clavulanate, cloxacillin, and dicloxacillin) are recommended. The drug of choice for oral antimicrobial therapy in children is cephalexin. If MRSA is suspected, the choice of antibiotic should be clindamycin, trimethoprim-sulfamethoxazole, or vancomycin. Empiric treatment depends on the prevalence and sensitivities of MRSA in the patient's geographical area. Patients with penicillin hypersensitivity should take erythromycin or clindamycin. Erythromycin, however, has not been shown to be superior to topical mupirocin cream. Because oral antibiotics have far more GI and systemic side effects than topical therapy, topical therapy is often preferred for mild to moderate infections.

Follow-up and Referral

The patient with an uncomplicated case of impetigo should be followed up in 10 days to 2 weeks after initiation of therapy. Patients who are toxic or have fever should be followed closely; consultation with or referral to a physician is recommended. Development of acute glomerulonephritis (acute nephritic syndrome) requires referral to a kidney specialist. Symptoms of this disease include the abrupt onset of proteinuria, hypertension, edema, azotemia, and red blood cells in the urine.

The majority of cases of both types of impetigo will resolve uneventfully after 10 days of treatment. Patients with recurrent impetigo should be tested for nasal carriage of *Staphylococcus aureus* bacteria with a culture of the anterior nares. If the culture is positive, treatment of the nares with topical mupirocin (Bactroban) is effective. Repeat culture should be done to confirm the patient's status. In the event of treatment failure, an infectious medicine consultation should be considered. Bullous impetigo typically resolves even without antibiotic treatment. Nonbullous impetigo generally has a good prognosis, although poststreptococcal glomerulonephritis is a possible complication of this infection.

Patient Education

The clinician plays a pivotal role in the treatment and prevention of this highly contagious skin infection through patient education and counseling. Good hand washing and personal hygiene are strongly recommended to reduce the likelihood of spread. The fingernails should be kept short so that there is less likelihood of spread to other areas of the body through self-inoculation.

Children and family members should be educated about the contagious nature of impetigo. They should be told to refrain from participation in any contact sport or activity that might spread the infection. Family members should not share personal effects such as towels, robes, razors, shavers, and so on. Bed linens should be washed with soap and hot water.

The patient should be instructed to gently clean the crusts from the lesions with antibacterial soap before applying mupirocin 2% cream or retapamulin. Nighttime application is also advised. If occlusive dressings are used, they should be discarded carefully to prevent spread of infection. If the patient is on oral antibiotics, the side effects and potential adverse reactions of the drug should be explained, as well as the importance of completing the course of antibiotic therapy to prevent the possible complication of streptococcal glomerulonephritis. Patients should be informed that good personal hygiene and cleanliness, along with prompt attention to skin trauma, will help to prevent future breakouts of impetigo. Patients should not visit hospitals or nursing homes until the infection is resolved. If MRSA is involved, patients should stay at home and not handle food until they have been on antibiotics for 24 hours.

FOLLICULITIS

Folliculitis is a superficial to deep skin infection of the hair follicles. Lesions can range from minute white-topped pustules in newborns to large, yellow-white tender pustules in adults. Bacteria infect the hair follicle at a superficial level, leading to erythematous papules and pustules. Although the main pathogens are gram-positive bacteria, occasional cases are caused by a fungus or by gram-negative bacilli. Folliculitis represents the start of a continuum of skin infections. Deeper infections (as complications of folliculitis) can include the furuncle (boil) or carbuncle (multiple boils), which are covered in depth elsewhere in this chapter.

Epidemiology and Causes

Folliculitis is often caused by bacteria; in particular, it is frequently caused by coagulase-negative *Staphylococcus* bacteria. Predisposing factors include diabetes, obesity, a chronic carrier state of *Staphylococci* (present in the nares, axillae, or perineum), poor hygiene, hyperimmunoglobulin E (Job's syndrome—a primary immunodeficiency disorder), exposure to chemicals and solvents (cutting oils), and chronic skin friction. However, folliculitis may have other etiologies as well. Gram-positive resident flora of the nasal mucosa and adjacent facial skin become suppressed by long-term oral antibiotic therapy and are replaced by gram-negative rods, namely *Klebsiella* and *Escherichia coli.* Thus, gram-negative folliculitis may develop in patients who are on long-term tetracycline therapy for acne or rosacea, as well as in older men who are suffering from seborrhea. Patients who have become colonized by gram-negative bacteria in the sebaceous follicles of the perioral and perinasal areas can become infected due to trauma (e.g., from shaving), resulting in a suppurative process within the hair follicle. This type of folliculitis is usually seen on the upper lip in men. In addition, antibiotic use also increases the risk of candidal folliculitis, due to clearance of the normal bacterial skin flora. Exposure to wet environments such as whirlpools or inadequately chlorinated pools, which contributes to *Pseudomonas aeruginosa* infection, also

predisposes to folliculitis. In addition, chronic steroid use that compromises T-cell immunity contributes to folliculitis by *Candida albicans.*

Folliculitis most commonly occurs among middle-aged individuals (aged 40–60 years) and children, especially if they are immunocompromised or spend an extended amount of time in a prone position due to impaired mobility. Studies have found that folliculitis may be spread by fomite transmission. Intensive care units (ICUs) are the frequent origin of nosocomial outbreaks in the hospital setting. The higher incidence of folliculitis in the ICU is the result of trauma from invasive procedures performed on immunocompromised or severely ill patients. Impairment of host resistance increases a patient's risk of contracting folliculitis in the presence of virulent pathogens such as gram-negative coliform bacilli. In addition, the presence of *Malassezia furfur* (a yeast that is part of the normal skin flora in animals) has been seen among infected ICU patients. One study found the same fungus on the stethoscopes and patient care instruments of the ICU staff who had touched their pets from home.

Folliculitis may occur anywhere on the skin as a result of trauma or damage to the hair follicle from chronic irritation due to friction from clothing or blockage of the hair follicle. Occlusion of the skin with tight-fitting nylon clothing promotes infection, and symptoms may occur abruptly within 1 to 3 days. Occlusive therapy (plastic wrap) used for other diseases such as severe psoriasis allows for significant bacterial multiplication in a moist environment, which can also lead to folliculitis. Spread of bacterial infection to the surrounding skin may develop from exudative or transudative discharge from wounds, abscesses, or any type of draining lesion.

A form of sterile folliculitis called *eosinophilic folliculitis* (EF) was originally identified in an 8-month-old HIV-positive Japanese infant. On histological exam, the hair follicle in EF is invaded by eosinophils and lymphocytes. Clinically, it presents in patients with HIV as intensely pruritic papules and pustules that appear over the entire body. Successful treatment of EF with interferon-alpha 2b has been reported, but the management of this form of folliculitis requires hospitalization and patient isolation. The presence of HIV with EF lesions is a marker for advanced HIV disease, and death from opportunistic infection usually occurs within 6 months of the onset of cutaneous lesions.

Pathophysiology

Infection of the hair follicle with *Staphylococcus* or *Streptococcus* is marked by suppuration and liquefaction necrosis of the follicular base, thus termed a *pyodermal* infection. It is usually localized and results in abscess formation. Liquefaction necrosis develops when lytic enzymes released by polymorphonuclear leukocytes (PMNs) digest bacteria and cellular material. Thus, a competent immune system is required for such a response, as large numbers of PMNs are found in the central area of the abscess, along with necrotic debris. Because this inflammatory response is localized, however, folliculitis rarely causes systemic manifestations in the immunocompetent individual. Interestingly, HIV-positive patients do not display this neutrophilic response because they typically experience an eosinophilic perifollicular pustular folliculitis, as described previously.

Clinical Presentation

Subjective

Generally, the patient will present with a "bumpy rash," which can appear on any area of the body. The rash can be located on the hair follicles of the face, forehead, back of the earlobes, the neck, the shoulder, the buttocks, the torso, or the extremities. Usually, the rash is not accompanied by itching. Often there is no history of previous skin eruptions or of pertinent medical history such as diabetes. The patient is usually concerned about the cosmetic effect of the lesions. The patient may report a history of hot tub use or of borrowing a shaver or razor from a friend. The clinician should inquire about the onset, duration, and location(s) of the rash, its appearance, and whether purulent drainage was present. The patient should also be asked about any associated systemic symptoms of fever and chills.

Objective

The primary lesions in folliculitis are small pustules surrounded by 1 to 2 mm of erythema located over the pilosebaceous orifice or the ostium of the hair follicle. There is no involvement of the surrounding skin. The eyelids, face, scalp, and extremities are the most typical sites. A hair in the center of the pustule sometimes perforates the lesion. This presentation is a hallmark for diagnosis. The pustules resolve into red macules, which fade to leave postinflammatory hyperpigmented scars in susceptible persons. Folliculitis is usually asymptomatic, but it can be very pruritic and is sometimes accompanied by burning. During the physical exam, checking the vital signs, including the temperature, is important to help rule out systemic involvement. The practitioner should inspect the lesion for signs of inflammation and suppuration (erythema, swelling, pustules) and palpate the surface of the pustule for fluctuance. It is also important to palpate the adjacent lymph nodes.

Folliculitis is divided into two main types—*superficial folliculitis* and *deep folliculitis.* Follicular impetigo (Bockhart's impetigo) is a superficial form of folliculitis that presents as small, dome-shaped pustules that occur over the opening of the hair follicle. It is more common on the scalps of children. When follicular impetigo becomes chronic, it may lead to follicle destruction and consequent permanent patchy alopecia.

The distinctive forms of deep folliculitis include barber's itch, pseudofolliculitis barbae, and *Pseudomonas*

folliculitis. In addition, newer diagnoses have been established based on the histological characteristic of the skin eruption, such as eosinophilic folliculitis (HIV-EF) and nosocomial folliculitis.

Barber's itch (sycosis barbae) is a chronic and recurrent staphylococcal infection of the hair follicles on the bearded area of the face in men (usually the upper lip). It is aggravated by shaving and is most commonly seen in black men. It is usually propagated by the autoinoculation of bacteria caused by shaving. A differential diagnosis of tinea barbae is similar to barber's itch, but the tinea infection is caused by a fungus. Pseudofolliculitis barbae, another differential diagnosis for sycosis barbae, is caused by hair in the beard area and posterior scalp and neck that curls toward the skin, causing an inflammatory reaction that can mimic folliculitis. It is more common in men of African American origin due to the curliness of their hair. This can become a chronic problem; the hair follicles involved can become infected with any variety of bacteria.

Pseudomonas folliculitis presents as follicular erythematous papules, pustules, or vesicles over the back, buttocks, and upper arms. Associated features include pruritus, malaise, low-grade fever, sore throat and eyes, and axillary lymphadenopathy. This type of folliculitis resolves spontaneously within 10 days.

Folliculitis decalvans is a rare disease that tends to occur in individuals who have coarse, bristly hair. The predisposing factors of this disease are still unknown. The infection begins as a localized area of follicular pustules or papules. Exudation or suppuration soon follows; as the crust accumulates, the hairs are shed. New follicles become involved at the periphery, while at the center the process eventually subsides, with scarring and permanent hair loss.

Hot tub folliculitis is caused by *Pseudomonas aeruginosa. P aeruginosa* is able to withstand temperatures of up to 107°F (41.6°C) and chlorine levels of up to 3 mg/L. The lesions of this variant of folliculitis are found on the trunk and lower extremities of patients who have a recent history of hot tub use. Superhydration of the stratum corneum softens this protective layer and allows the bacteria to cause infection.

There are documented cases of superficial actinic folliculitis characterized by recurrent skin eruptions occurring within 6 to 24 hours after sun exposure. Histologically, there is perivascular lymphocytic infiltration and intrafollicular accumulation of neutrophils in the upper infundibulum of the follicle; these findings indicate the presence of inflammatory response and a suppurative process.

Diagnostic Reasoning

Diagnostic Tests

A Gram stain and culture of purulent discharge is obtained by rupturing a pustule and getting samples of the exudate. The culture is useful to distinguish *staphylococcal* infections from other bacterial or fungal infections, as well as from epidermal and pilar cysts that are sterile lesions. The Gram stain is usually positive for clusters of gram-positive cocci *(S aureus)* along with a large number of PMNs. With deeper forms of folliculitis, the presence of systemic symptoms and positive blood culture require referral to a physician for hospitalization and IV antibiotics.

If fungal infection is suspected, a fungal culture or KOH microscopic exam is helpful; if results are positive, treatment should change to an antifungal agent.

Differential Diagnosis

Superficial folliculitis is differentiated from tinea barbae by using the KOH exam (see Advanced Assessment 7.1) of the affected hair or by a fungal culture. Acne vulgaris and bullous impetigo may occasionally mimic folliculitis, but the patient's age (i.e., nonadolescent) and the absence of comedones (blackheads or whiteheads) suggests a diagnosis of folliculitis. The lesions of bullous impetigo are usually larger and rupture easily, and the exudate is serous, not purulent. About 50% of HIV-infected persons with scabies have coexistent *S aureus* folliculitis.

Occasionally, follicular lesions extend more deeply, forming abscesses. Rarely, follicles covering an area several centimeters across become infected, forming large violaceous plaques. The plaque may be studded with pustules and have deep sinus tracts connecting infected follicles. Rarely, an abscess of the muscles (pyomyositis) may occur due to extension of the infectious process.

Management

Patients rarely consult a health-care provider for this minor problem except for infections that become recurrent and persistent. The goal of treatment of superficial and deep folliculitis is to make the skin inhospitable to pathogens. This includes both nonpharmacological and pharmacological approaches.

Gentle cleansing by the simple method of washing the skin twice a day with antibacterial soap (e.g., Lever 2000, Safeguard, Dial) is as important as prescription antibacterial medicines. Large pustular lesions with necrotic areas should first be cleansed with a weak soap solution, followed by soaking of (or the use of compresses on) the affected skin with saline or aluminum subacetate twice daily. When the skin is softened, the clinician can gently open the large pustules and trim away necrotic tissue. A triple antibiotic ointment (containing polymyxin B, bacitracin, and neomycin) or simply mupirocin (Bactroban) 2% can be effective when applied 2 to 4 times per day for 10 days. Clearance of nasal colonization of *S aureus* by mupirocin treatment twice daily for 5 days has been shown to reduce significantly the incidence of recurrent folliculitis. Systemic

antistaphylococcal antibiotics may be ordered if the infection is resistant to local treatment or if the scalp is involved. Usually, however, systemic antibiotics are not helpful or advantageous over topical treatments. See Drugs Commonly Prescribed 7.4 for common drugs to use for folliculitis.

Follow-up and Referral

A patient who does not respond to therapy should be evaluated for possible diabetes mellitus or for chronic carriage (in the nares, axillae, or perineum) of *S aureus*. Cultures of the anterior nares, axillae, and perineum are recommended. Topical mupirocin 2% (Bactroban) should be applied twice daily for 5 to 7 days to the sites that yielded a positive culture. Because most strains of MRSA are resistant to topical mupirocin, in cases of MRSA colonization, Altabax should be applied twice daily for 2 weeks.

More severe forms of folliculitis and rare skin eruptions such as HIV-EF should be referred to the physician.

Drugs Commonly Prescribed 7.4 Folliculitis, Acne, and Rosacea

Drug	Indication	Adverse Reactions and Prescribing Considerations
Topical		
mupirocin (Bactroban) 2% ointment or cream	Folliculitis	Consider for secondarily infected skin lesions.
azelaic acid (Azelex) cream 20%	Acne vulgaris and inflammatory Rosacea	Both bacteriostatic and bactericidal. Watch for hypopigmentation on darker-skinned patients. Wash hands after use.
sulfacetamide (Rosula) gel, wash, and cream	Acne vulgaris, rosacea, and seborrheic dermatitis	Avoid mucous membranes.
benzoyl peroxide Benzac-W 2.5%, 5%, 10% Benzac-W Wash 5%, 10%	First-line therapy for acne	2.5% as effective as 10% and less irritating. Use water-based rather than alcohol-based.
metronidazole (MetroGel 1%)	Rosacea	Will not cure rosacea but reduces inflammatory lesions.
Topical Antibiotics		
clindamycin 1% solution, lotion, gel, pledget	Acne vulgaris, rosacea	Not used alone due to antibiotic resistance. Lotion less irritating. May cause diarrhea. Avoid in patients with colitis.
Combination Topical Therapy		
clindamycin + benzoyl peroxide (BenzaClin) erythromycin + benzoyl peroxide (Benzamycin)	Acne vulgaris, rosacea Acne vulgaris, rosacea	Adults only; may bleach fabrics, avoid eyes, mucous membranes. Discontinue use if significant diarrhea occurs. Transient skin discoloration with PABA sunscreens. Caution in pregnant or breastfeeding women.
Topical Retinoids		All Pregnancy Category C unless otherwise stated.
tretinoin 0.05% cream (Renova)	Acne vulgaris	Not recommended for children younger than 10 years. Do not use on sunburned skin.
tretinoin (Retin-A) cream, gel, liquid	Acne vulgaris	Allow effects of other topical agents to subside before using.
tazarotene (Tazorac)	First-line therapy for all acne variants	0.1% strength. Women of childbearing potential, begin therapy during menses.
adapalene (Differin)	First-line therapy for all acne variants	Less sun sensitivity than Retin-A.
isotretinoin (Amnesteem)	Severe recalcitrant nodular acne or rosacea unresponsive to conventional therapy (even antibiotics)	Pregnancy Category X, must register patients in iPLEDGE program, avoid sun, monitor lipids, glucose, CBC, liver enzymes. Take with meals.

Drugs Commonly Prescribed 7.4 Folliculitis, Acne, and Rosacea—cont'd

Drug	Indication	Adverse Reactions and Prescribing Considerations
Combination Retinoid + Antibacterial		
adapalene plus benzoyl peroxide (Epiduo gel)	Acne vulgaris	Good for teenage boys because they may be more likely to use just one topical. Apply a thin film once daily after washing.
Systemic Therapies Antibiotics		
minocycline (Minocin)	Severe acne, rosacea	Take on an empty stomach with fluids.
doxycycline (Vibramycin)	Severe acne, rosacea	Monitor blood, renal, and hepatic function in long-term use. Sub-antibacterial dose doxycycline (Oracea 40 mg) is a good choice in inflammatory acne.
Hormonal Therapy		
norgestimate/ethinyl estradiol (Ortho Tri-Cyclen)	Birth control pills (BCP) for moderate acne vulgaris in females older than 15 years of age.	See Chapter 14 for all the precautions that accompany someone taking BCP.
norethindrone acetate/ethinyl estradiol (Estrostep)	BCP as above	As above
drospirenone + ethinyl estradiol (Yaz)	BCP as above	As above
Other		
ketoconazole (Nizoral) tablets	Fungal forms of folliculitis	Monitor hepatic function before and during therapy. Check the numerous drug interaction warnings.

Systemic IV antibiotics may be necessary. Referral is in order for patients with recurrent or persistent infections that do not respond to the treatment regimen.

Patient Education

The clinician should emphasize to the patient that good hygiene is essential in treating this condition. Good hand washing technique is the best approach in preventing the spread of folliculitis. Patients who are prone to folliculitis can be advised to use an antibacterial soap and to wash the affected areas twice a day with antibacterial soaps before applying topical agents. Patients should also be informed that any source of friction can predispose them to a recurrence of folliculitis.

In hospitals (especially the ICU), an emphasis on proper hand washing and proper disposal of cleaning supplies can help prevent the spread of bacteria on fomites.

Men who are prone to recurrent sycosis barbae should be advised to grow a beard (if possible) during treatment to allow complete healing. A preventive approach is the best treatment for this condition. When shaving is resumed, an electric shaver may cause fewer breaks in the skin than a razor. Patients should be cautioned to avoid borrowing or using old razor blades when shaving infected areas.

FURUNCLES AND CARBUNCLES

A *furuncle (boil)* is a deep bacterial infection of a hair follicle with abscess formation. Furuncles are caused almost exclusively by gram-positive *Staphylococcus aureus.* Furuncles are extremely tender to touch and appear a bright red color. The most common locations for furuncles are the scalp, neck, axilla, buttocks, groin, and thighs. Furuncles frequently become fluctuant. With the application of warm compresses, most furuncles drain pus and resolve spontaneously.

A *carbuncle* is a large, multiloculated abscess that is made up of multiple furuncles in a contiguous area. Carbuncles, which are less common than furuncles, appear as large, red, painful lumps on the skin, with multiple follicular openings. Some carbuncles can be quite large—up to 10 cm in size. Eventually, a carbuncle will spontaneously drain pus.

Epidemiology and Causes

Furuncles and carbuncles are usually caused by *S aureus* and rarely by other pathogens. In some patients, especially

the immunocompromised, infection can be due to MRSA. Conditions predisposing patients to formation of furuncles and carbuncles include diabetes mellitus, poor hygiene, incarceration, obesity, and immune system defects. Chronic staphylococcal carriage in the anterior nares, axilla, and perineum also increase the risk of infection and should be explored in cases of recurrent infections. Favorable environmental conditions that predispose the individual to furuncle and carbuncle formation include areas of moisture, friction, or occluded skin. Any area of skin that is subject to friction, such as the axilla, buttocks, groin, or thighs, is at increased risk of infection.

Pathophysiology

Both furuncles and carbuncles evolve from superficially infected hair follicles (folliculitis), mediated primarily by *S aureus.* Thus, all factors that contribute to folliculitis also predispose to furunculosis and carbuncle formation. As this superficial infection extends along the hair shaft, a small, painful inflammatory nodule is formed at the follicular base that is termed a *furuncle.* Eventually, a series of abscesses form along the hair shaft involving dermal and subcutaneous layers, ultimately coalescing into a fluctuant, subcutaneous mass that develops a soft, pointed necrotic center. When the furuncle ruptures, it results in the extrusion of pus and a necrotic plug at the entrance to the follicle. A small opening or cavitation remains that eventually heals with scarring. Thus, the affected hair follicle is destroyed and does not regenerate, resulting in destruction of the hair itself.

Carbuncles ("boils") undergo a similar process, except on a larger scale. Carbuncles are made up of several furuncles that form into a large, multiloculated abscess with multiple follicular openings that eventually drain pus. Carbuncles are significantly larger than furuncles, typically involving deeper skin layers. They are more likely to occur on thicker skin, in areas such as the nape of the neck and upper back. A systemic response including fever resulting from the production of pyogenic cytokines is more common with carbuncle formation than furunculosis.

Certain risk factors are particularly associated with furunculosis and carbuncle formation. Obesity results in thick skinfolds that are closely approximated. This creates a moist environment in which bacteria are prone to reproduce. Impaired immune function from chronic steroid use, underlying systemic disease such as HIV or diabetes mellitus, or impaired neutrophil function also predispose to this condition. In particular, the presence of a bacterial virulence factor known as the Panton-Valentine leukocidin in certain strains of *S aureus* has been associated with particularly aggressive skin infections.

Clinical Presentation

Subjective

The typical patient will complain of a hot and tender, bright red bump or "boil" of several days' duration that is getting larger. Some furuncles will "come to a head" or become fluctuant and will drain spontaneously on their own. Some patients will report a history of manipulation of the furuncle or carbuncle, either by squeezing it or by puncturing it with a heated needle. Some patients will report a past history of boils and other skin infections.

Objective

Both furuncles and carbuncles are extremely tender to touch and are a bright red color. A furuncle initially appears as a small (0.5–1 cm), red, indurated nodule. As the nodule grows in size, it starts to develop a yellow-colored central plug. It begins to appear conical, with a central "nipple" that is covered by thinning skin. The pus, which is a yellow to green color, gives the "nipple" its characteristic color. Most furuncles eventually spontaneously rupture and drain pus, which hastens their resolution. As the necrotic material and pus are discharged, a small cavitation is left that heals with minimal scarring. Carbuncles initially appear as multiple furuncles that develop into a large, erythematous lump that eventually starts to drain pus from multiple follicular openings. Patients with darker skin can have permanent hyperpigmentation changes as a result of severe inflammation.

Diagnostic Reasoning

Diagnostic Tests

Although most cases of furuncles and carbuncles are caused by *S aureus,* a culture of the fluctuant lesion is still recommended. Occasional cases of MRSA are sometimes found. A CBC with differential is not necessary unless the patient has a severe case with an underlying disease such as diabetes or shows systemic symptoms such as fever.

No subsequent testing is necessary unless a patient is a staphylococcal carrier. The nares and anogenital region should be recultured after treatment with topical mupirocin (Bactroban) is finished. In resistant cases where no response is seen after 1 week of therapy, a repeat culture should be done.

Differential Diagnosis

Some skin conditions to consider in the differential diagnosis of furuncles include an epidermal inclusion cyst that is acutely inflamed. Epidermal inclusion cysts are usually located in areas of the body where there is thicker skin and a large amount of sebaceous glands, such as on the back and upper shoulders. The patient with an epidermal inclusion cyst will report a history of the cyst on the same site for months to years. In contrast, furuncles are an acute process, taking only several days to form. Another characteristic of an epidermal inclusion cyst is a cheesy white discharge with a strong odor that is present when it is expressed. A furuncle or carbuncle will have a purulent yellow to green-colored discharge when it ruptures.

Another differential diagnosis for a furuncle is a deep fungal infection of the soft tissue called *sporotrichosis.* It is more common in gardeners and other agricultural workers and is usually seen on the hands or arms. It is caused by injury from a thorn or wood splinter that has been contaminated with the common soil fungus *Sporothrix schenckii.* Because it is usually asymptomatic, patients tend to ignore it.

If the furuncle or carbuncle is located on the axilla, a differential diagnosis to consider is hidradenitis suppurativa. The lesions of hidradenitis suppurativa are also extremely tender and inflamed. Patients with this condition report a chronic history of recurrent infection in the axilla, groin, or anal region. It is a chronic disease of the apocrine glands of the axilla and groin and is associated with severe hypertrophic scarring and sinus tracts, which are not seen in furuncles or carbuncles. The classic finding in hidradenitis suppurativa that would tend to differentiate it from a furuncle or carbuncle are the numerous hypertrophic scars and sinus tracts that are found on the affected skin.

Management

Carbuncles usually must drain before healing will take place, and this usually occurs spontaneously within 2 weeks. Application of warm compresses will promote the localization and spontaneous rupture and drainage of a furuncle. No treatment with systemic antibiotics is necessary for a healthy host if no surrounding cellulitis is present. Treatment with topical antibiotics with good gram-positive coverage (e.g., mupirocin [Bactroban] or neomycin–polymyxin B [Neosporin]), applied twice per day until resolution, is satisfactory in those cases.

For furuncles or carbuncles on an immunocompromised patient (or one who is at risk for bacteremia because of a preexisting condition), systemic antibiotics are always mandatory and physician referral is recommended. In addition, incision and drainage will speed up resolution of the infection. Preexisting conditions such as diabetes or chronic steroid use (or any condition affecting the immune system) predispose a patient to more complications. These patients should be monitored very closely or referred to a physician. A furuncle (especially if it is located on the upper lip or the central area of the face) or a carbuncle located on the neck, face, or scalp should be treated with physician consultation or referred to a physician for management. Because of its proximity to the cavernous sinus, a furuncle located on the central face can spread via the venous drainage to the cavernous sinus and result in cavernous sinus thrombosis or meningitis. An occasional patient with furuncles or carbuncles will have bacteremia as a complication, with possible hematogenous spread to the heart valves (endocarditis), kidneys (perinephric abscess), joints, spine, and long bones (osteomyelitis).

If a furuncle has not come to a head by the time the patient is seen, the patient should be instructed to apply warm compresses two to three times per day until it becomes fluctuant. Systemic antibiotics are often used to treat and hasten the resolution of furunculosis. However, randomized controlled trials have failed to consistently show the benefit of such treatment. In theory, however, systemic antibiotics should lessen the risk of bacteremia. Fluctuant furuncles are ideally treated with incision and drainage. A sterile 18-gauge needle can be used to puncture the thin skin on top of a small furuncle to allow for adequate drainage of pus. For larger furuncles that are fluctuant, incision and drainage is indicated. The cavity formed by the furuncle should be packed with iodoform or petroleum jelly (Vaseline)–impregnated gauze. After a furuncle has been incised, the patient should be instructed to use warm compresses twice daily to hasten the drainage of pus.

Carbuncles frequently need incision and drainage as well to aid in recovery. Systemic antibiotics and physician referral are always indicated for the treatment of carbuncles. Systemic antibiotics with adequate gram-positive bacterial coverage (except for MRSA) include dicloxacillin, cephalexin, or amoxicillin-clavulanate. For patients with penicillin allergies, erythromycin, clindamycin, clarithromycin, or azithromycin may be used. Many strains of community-acquired MRSA are susceptible to trimethoprim-sulfamethoxazole (Bactrim) plus rifampin, clindamycin, doxycycline, or minocycline. However, particularly aggressive or extensive infections with MRSA or Panton-Valentine leukocidin–expressing strains of *Staphylococcus* may require inpatient IV antibiotic therapy (e.g., vancomycin) to ensure adequate treatment. Linezolid is also used for the treatment of MRSA. However, this antibiotic is typically used only under close physician supervision, given its potential for inducing thrombocytopenia, anemia, and neutropenia. Thus, antibiotic susceptibility testing is critical in these cases to most appropriately direct therapy.

If a patient has a history of frequent infections, a search for staphylococcal carriage is recommended. Cultures should be taken from the patient's nares, the perineum, and the anogenital region. If a patient is found to be a *Staphylococcus aureus* carrier, a daily shower with an antibacterial or benzoyl peroxide soap is recommended. Mupirocin ointment (Bactroban) should be applied three times per day to the anatomical sites where *S aureus* was cultured (nares, body folds, perineum, anogenital region) for 1 week. A repeat culture should be done to document clearance of the bacteria. This program will eliminate the staphylococcal carrier state and reduce the incidence of recurrence. There is some evidence that vitamin C supplementation (1 g per day for 4–6 weeks) may also help prevent recurrent skin infection in persons with impaired neutrophil function.

Follow-up and Referral

The patient should be seen for initial follow-up within a few days to 1 week to monitor response to therapy,

compliance with treatment, and any adverse reactions. Subsequent visits can be scheduled in 7 to 10 days to monitor for continuing progress and resolution of the lesions. For carbuncles or multiple furuncles on immunocompromised patients (or patients at risk for bacteremia because of preexisting disease), a physician referral is recommended.

In addition, if a patient has systemic signs such as fever or appears toxic, physician consultation or referral is recommended. These patients frequently need multiple laboratory tests, including blood cultures, which can be done in a hospital setting, in addition to treatment with parenteral antibiotics.

Patient Education

The patient should be warned not to pop, squeeze, or to manipulate furuncles in any way, especially those that are located on the mid to upper lip or near the border of the nasolabial folds because of the risk of cavernous sinus thrombosis, which is sometimes fatal.

CELLULITIS

Cellulitis is a bacterial infection of the skin involving both the dermis and subcutaneous tissue, which in certain cases may result in death. Most cases of cellulitis are caused by group A beta-hemolytic *Streptococcus* or by *Staphylococcus aureus* (gram-positive bacteria). Less common bacteria that can cause cellulitis include *Haemophilus influenzae* (more common in children), *Eikenella corrodens* (human bites), *Pasteurella multocida* (cat bites), *Capnocytophaga canimorsus* (dog bites), and the *Vibrio* species (seawater-exposed injuries).

The typical lesion of cellulitis is a wide, diffuse area of erythematous skin that is warm and tender to palpation. Infection is occasionally accompanied by severe edema. Systemic symptoms such as fever, chills, and malaise may accompany some cases as well. A cellulitic infection can occasionally result in the loss of a limb.

Cellulitis may become a life-threatening event that is heralded by shock, hypotension, and toxicity. Toxic shock syndrome (TSS) and multiple organ failure resulting from both streptococcal and staphylococcal infections have been reported. The clinician must learn to differentiate between a severe case of cellulitis that is potentially life-threatening and an uncomplicated case that can be treated on an outpatient basis. Special types of cellulitis that have potentially serious consequences discussed in this chapter include erysipelas, necrotizing fasciitis, and periorbital cellulitis (see Table 7.4). Severe cases of cellulitis, such as necrotizing fasciitis, must be treated with surgical debridement in addition to parenteral antibiotics to stop the spread of rapid tissue destruction; these patients require hospitalization. Periorbital cellulitis, an emergent condition, should also be treated aggressively with parenteral antibiotics and hospitalization to prevent permanent vision loss and extension of infection into deep cranial structures.

Epidemiology and Causes

There is usually an obvious portal of entry into the skin or mucous membranes, such as an insect bite or a wound, although in some cases there is no obvious point of entry (this is more common with recurrent cellulitis). Cellulitis may occur at any age, but some organisms are more common in certain age-groups. *Haemophilus influenzae* type B (Hib) infections are more common in children. In adults and elderly patients, *S aureus* and *Streptococcus pyogenes* are more common. In patients with diabetes mellitus or who are otherwise immunocompromised, unusual bacterial pathogens may include *Escherichia coli* and other enteric species *(Enterobacter),* as well as *Proteus mirabilis, Pseudomonas aeruginosa, Acinetobacter, Mycobacterium fortuitum,* and *Cryptococcus neoformans.*

Any break on the skin or mucous membranes is a potential portal of entry for bacterial pathogens. Skin breaks can be caused by surgical incisions, skin tears and wounds, trauma, insect bites or stings, and animal or human bites. Preexisting skin conditions such as stasis ulcers, dermatitides (eczema, psoriasis, contact dermatitis), viral skin infections (herpes simplex, herpes zoster, or varicella-zoster), superficial bacterial infections (acne, folliculitis), and bullous diseases (bullous pemphigoid, pemphigus vulgaris, burns) all have the potential for secondary bacterial infection. The likelihood and severity of cellulitis infection is affected by three important factors: (1) virulence of the pathogen, (2) host immune status, and (3) depth of infection.

Risk factors that predispose an individual to cellulitis include conditions that affect cellular immunity and lymphatic drainage:

- Diabetes mellitus
- Lymphatic blockage
- History of recurrent cellulitis
- Postmastectomy and postsaphenous vein grafting
- HIV infection and AIDS
- Chronic steroid use
- Cancer chemotherapy
- Drug or alcohol abuse
- Peripheral vascular disease

Pathophysiology

The skin and subcutaneous tissue respond to bacterial invasion with an acute inflammatory process. An increase in vascular permeability of the microcirculation of the skin allows protein-rich fluids to leak into the interstitial tissue. This results in tissue edema, which may become chronic in recurrent cellulitis. Agents that are released into the tissue increasing vascular permeability include histamine, cytokines, platelet-activating factor, bradykinin, complement proteins, and arachidonic acid

Table 7.4 Types of Cellulitis

Erysipelas	Erysipelas is a streptococcal infection of the superficial layers of skin that does not involve the subcutaneous layers, unlike more typical cellulitis. An older name for erysipelas is "St. Anthony's fire." Despite the superficial nature of this infection, erysipelas should not be taken lightly, because it can be fatal if it is not treated promptly (especially in the very young and the elderly). Before the advent of antibiotics, a high rate of fatality was associated with this infection. Most cases of erysipelas are caused by group A beta-hemolytic *Streptococcus pyogenes.* Erysipelas is sometimes seen after an episode of strep throat. The most common sites of involvement are the face (especially the cheeks) and the lower legs. Patients usually have systemic symptoms such as high fever, chills, and malaise. Erysipelas on the face first appears as a bright red lesion by the nares that can spread rapidly within a few hours to days. An enlarging shiny, bright red, indurated plaque develops that is very warm to touch and has very sharp and distinct borders, as opposed to cellulitis, which has more diffused, flat borders. The affected skin appears shiny because of the edema from the infection.
Necrotizing Fasciitis	The hallmark of this infection is its rapid progression and the severity of the symptoms. The progress of the infection is measured in terms of hours instead of days, and the border can be seen to literally spread in just a few hours. This infection is caused by "flesh-eating bacteria," and loss of life or limb is a potential complication. Most cases of necrotizing fasciitis are caused by group A *Streptococcus* pyogenes, although several different kinds of bacteria have been implicated in these rapidly progressive infections, including *Staphylococcus aureus, Clostridium perfringens, Bacteroides fragilis,* and *Aeromonas hydrophila.* During the early phase of the infection, the lesion appears as a bright red color with edema that progresses to purpuric changes (indicated by purple color), including gangrene (indicated by black color). The patient will usually complain of severe pain at the affected site, which seems to be out of proportion to the appearance of the skin lesion. This pain is due to involvement of the fascia around the muscle and sometimes of the muscle itself (myositis). Pressure on the skin sometimes reveals crepitus due to gas production by the anaerobic bacteria *Clostridium perfringens.* Gangrene can present in a few hours, with hypotension and mental status changes regarded as particularly ominous signs.
Periorbital Cellulitis	Periorbital cellulitis is a potentially life-threatening form of cellulitis that should be treated as an emergent condition. The typical patient is a young child with erythema and edema over the affected periorbital area. The edema can be severe enough so that the entire affected side of the face is puffy. Symptoms include pain with certain eye movements because of inflamed extraocular muscles. Other symptoms include high fever, tachycardia, lethargy or mental status changes, and other systemic symptoms. On physical exam, the involved eye will lose the ability to move into certain quadrants (i.e., lateral or downward gaze) and will have an abnormal exam of cranial nerves III, IV, and VI (EOMs).

metabolites, including leukotrienes and prostaglandins. Vasodilation also occurs, giving cellulitis its characteristic bright red color and indistinct borders. In addition, during the cellular phase of inflammation, leukocytes accumulate at the site of injury and engulf particulate material such as bacteria, cellular debris, and antigen–antibody complexes. Engulfed bacteria and other cellular debris are digested inside phagolysosomes by potent hydrolytic enzymes. Interestingly, the bacterial burden in cellulitis may be low, except in cases where abscesses or skin ulcers are present.

The most predominant leukocyte during the cellular inflammatory phase is the polymorphonuclear leukocyte (neutrophil or PMN) and, to a lesser extent, basophils, mast cells, and platelets. PMNs express at least three types of granules containing proteolytic enzymes. Necrosis of normal tissue may occur during the inflammatory process due to these proteolytic enzymes, as well as reactive oxygen metabolites. Some aggressive cases of cellulitis may progress to TSS in which certain strains of *Staphylococcus* and *Streptococcus* release toxins that stimulate a massive release of inflammatory cytokines. This in turn can result in shock, multiple organ failure, and ultimately death if untreated. In addition, bacterial exotoxins have been shown to potentiate hypersensitivity responses to fungal antigens such as *Trichophyton,* the primary agent involved in tinea pedis or "athlete's foot" infection. Such responses have been shown to contribute to the pathogenesis of cellulitis in certain individuals.

Clinical Presentation

Subjective

The typical adult patient with cellulitis will complain of a tender, warm, and erythematous area of skin that is usually located on the face, neck, or extremities. The patient will usually report a history of a precipitating condition such as an insect bite or a small cut that "got infected." The patient might already have a preexisting skin condition such as acne, tinea pedis, or chronic eczema with breaks in the skin that can become the portal of entry for bacteria, although at times this is not apparent to the patient. In cases of recurrent cellulitis of the lower leg, the patient will frequently deny any trauma or injury but will report a history of repeated infections on the same leg. The size of involvement can vary from a few centimeters to a larger area, such as an entire limb. The patient will report a history of the lesion or plaque getting progressively larger over several days, but in the case of necrotizing fasciitis, the border will literally be seen to spread in just a few hours. Some patients will complain of tender and enlarged lymph nodes near the affected area. Patients with more severe cases of cellulitis or with special types such as necrotizing fasciitis, erysipelas, and periorbital cellulitis are more likely to complain of systemic symptoms such as fever and chills, lethargy, and malaise.

Objective

In adults, the lower leg is usually the most common site of infection. In cases of lower extremity cellulitis, the clinician should search for signs of tinea pedis. The clinician should look for areas of macerated or peeling skin on the interdigital area of the toes. A chronic tinea pedis ("athlete's foot") infection can become the point of entry for bacteria. In children, and occasionally in adults, the cheeks and the periorbital area are more common sites of involvement. In lighter-skinned patients, the area of skin that is infected will have a bright red color that is warm and tender to touch. In darker-skinned patients, the color will be a darker red. Sometimes extensive edema will be present, especially if an arm or leg is involved.

The red borders seen in cellulitis are flat and diffused, compared with the distinct raised border seen on an erysipelas infection. Serious signs of systemic toxicity to look for include high fever, hypotension, tachycardia, marked leukocytosis, and associated lymphangitis. If these signs are present, the patient must be treated aggressively with hospitalization and parenteral antibiotics. Referral to a physician is recommended for severe or special cases of cellulitis.

Diagnostic Reasoning

Diagnostic Tests

Most cases of mild to moderate cellulitis are diagnosed by clinical presentation and history. In the majority of cases of acute cellulitis, there is usually no discharge or obvious wound present; therefore, obtaining cultures is very difficult. If an open wound or purulent discharge is present, a culture and Gram stain should be obtained. For patients who appear ill or have systemic symptoms such as fever, a CBC and consultation with a physician is necessary. If periorbital cellulitis is suspected (swelling and redness of eyelids, limited extraocular movements [EOMs], fever), testing for EOMs should be done, along with other tests for cranial nerve function. Leukocytosis is seen in periorbital cellulitis, as well as in necrotizing fasciitis and erysipelas.

Differential Diagnosis

The site of the infection helps to guide the clinician in searching for a differential diagnosis. If a lower limb is affected, deep vein thrombosis (DVT) should be considered. It may be difficult to make the distinction between DVT and cellulitis. DVT presents as a swollen and warm limb with erythema that is tender to touch and can be very similar in presentation to acute cellulitis. A history of recent surgery, bedrest, or prolonged immobility points more toward DVT; however, DVT can occur after cellulitis, although rarely. There are usually no systemic symptoms such as fever associated with DVT. If fever is present, it points more toward the presence of cellulitis. If crepitus is noted on palpation or if violaceous bullae and intense pain are present, the clinician should rule out necrotizing fasciitis. Serious systemic symptoms that point to severe infection include hypotension, lethargy (or any change in mental status), nausea and vomiting, severe pain (points to possible fascial involvement), and a toxic appearance. If these signs are present, immediate consultation with a physician or referral to the emergency department is necessary.

Management

Treatment of cellulitis should take into consideration several factors: the severity of the infection, the site of the infection, the presence of underlying disease, and the virulence of the pathogen. Patients with diabetes are known to have a higher incidence of complications from skin infections because of chronic high levels of glucose that adversely affect the immune system and the microcirculation. Patients who are under long-term treatment with steroids or chemotherapy are also at increased risk because of immune system depression. Previous surgical procedures, such as a mastectomy or saphenous vein grafts, predispose the affected limb to cellulitis because of defective lymphatic drainage. Some sites of the body, such as the hands, feet, and the face, must be treated more aggressively to prevent any potential loss of future function. Particular care must be taken with soft tissue infections of the hand because a compartment-like syndrome can ensue in addition to destruction of complex structures.

Human bite wounds are known to have a higher rate of infection because of the large amount of anaerobic

bacteria present in the mouth. Because of increased vascularity, the face and neck areas are less likely to become infected than the hands and feet. Closed-fist injuries are more likely to become infected, probably because exposed tendons and tissue that become contaminated with oral flora retract back into the skin under anaerobic conditions and allow bacteria to proliferate. Cat bites (30%–50%) are more likely to become infected (with *Pasteurella multocida*) than human bites. To a lesser extent, some dog bites (only 5%) become infected with *P multocida* or *Capnocytophaga canimorsus.* The clinician must remember that any injury that occurs in salty or brackish water has potential for infection with *Vibrio* species of bacteria. Periorbital cellulitis is potentially life-threatening and should be regarded as an emergent condition. It is seen more commonly in children than in adults.

Although *Streptococcus* and *Staphylococcus* cause the majority of skin infections, it is still important to establish the specific etiology of any infection. If purulent discharge or an open wound is present, culture and Gram stain should be obtained. Because it is difficult to culture most cases of cellulitis, diagnosis is based mostly on clinical presentation. Empiric treatment for cellulitis must provide good coverage for both staphylococci and streptococci. Good choices for uncomplicated cases of cellulitis that are not associated with human or animal bites include dicloxacillin or cephalexin for 10 to 14 days.

Patients with severe penicillin allergy are prescribed erythromycin. Infected human and animal (cat or dog) bites are best treated with amoxicillin–clavulanic acid (Augmentin) for at least 2 weeks. Physician consultation or referral is recommended in complicated cases of cellulitis. Prophylaxis (not treatment) for fresh, uncomplicated human and animal bites (less than 6 hours old) is amoxicillin–clavulanic acid for 3 to 5 days.

Management of cellulitis infection of the lower extremities requires bedrest (with bathroom privileges) and elevation of the infected leg. Patients who are at increased risk of thrombus formation should be referred to the physician for possible anticoagulation therapy.

Erysipelas is treated in the hospital with parenteral antibiotics. Necrotizing fasciitis must be treated aggressively in the hospital with parenteral antibiotics, surgical debridement, and fluid replacement.

Patients with underlying disease such as diabetes, neuropathy, arterial insufficiency, lymphatic drainage abnormalities, intermittent claudication, and a history of recent trauma on the same leg are more prone to complications and infection with unusual bacterial pathogens (gram-negative bacteria, anaerobes) and must be treated more aggressively. These cases frequently require referral and consideration for hospitalization. Unusual pathogens that may cause cellulitis include *E coli, Klebsiella, Enterobacter,* and *Pseudomonas,* which are more common in patients with impaired immune systems.

Cellulitis of vital structures such as the hand, foot, or face requires close follow-up to monitor for possible complications. Patients who are at higher risk for complications, including those with severe cellulitis and associated crush injuries, should be referred to a physician. Other patients who have a higher risk of complications include patients with preexisting diseases or conditions that affect the immune system such as diabetes, AIDS, immunosuppression, chronic steroid or IV drug use, alcoholism, a history of arterial insufficiency, and chemotherapy.

Patients who are suspected of having a complicated case of cellulitis such as possible bacteremia (fever, chills) or urgent cases such as periorbital cellulitis, necrotizing fasciitis, or erysipelas need immediate consultation with a physician or referral to the emergency department. The clinician should not rely solely on certain laboratory results such as leukocytosis before considering the seriousness of cellulitis infection. Clinical presentation and symptoms are more helpful in guiding the management of cellulitis than any laboratory test result.

For oral therapy, cefuroxime (Ceftin) can be used when *Haemophilus influenzae* is suspected. Azithromycin or clarithromycin is preferred as a macrolide over erythromycin for penicillin-allergic patients if *Haemophilus* flu is suspected. If gram-negative microorganisms are suspected, fluoroquinolones such as levofloxacin, for complicated skin infections, are typically chosen for adult patients. Clindamycin may be added to extend the spectrum of gram-positive coverage. Importantly, however, *Clostridium difficile* (C diff) colitis is particularly associated with clindamycin usage. *Vibrio* infections from seawater-associated injuries are best treated with tetracyclines, whereas cellulitis related to freshwater injuries must cover *Aeromonas* infection and include a fluoroquinolone such as ciprofloxacin combined with cefazolin. Diabetics are typically treated with Augmentin, although this may produce significant GI effects such as loose stools. Other broad-based regimens for hospitalized patients include clindamycin plus ceftriaxone, along with a fluoroquinolone. If tinea pedis infection is concurrent with cellulitis, treatment for this must be initiated using terbinafine or itraconazole (see previous section on dermatophytoses). For information on community-acquired MRSA infection, refer back to the discussion under Furuncles and Carbuncles regarding selected oral agents such as Bactrim. For significant MRSA infection, vancomycin can be used.

Follow-up and Referral

Most cases of uncomplicated cellulitis resolve with adequate antibiotic treatment. Improvement is usually obvious within 48 hours, although some cases might take 72 hours before some improvement is seen. If the patient is responding to treatment, follow-up can be done on an outpatient basis. Recurrent infections of cellulitis on a lower extremity can result in a chronic

nonpitting edema. (The patient should be advised of this potential complication.) Diabetic patients should be advised to adhere to dietary and lifestyle changes (in addition to medication) to control levels of blood glucose. Good diabetic control is associated with fewer and less serious complications, including potential vascular, kidney, and eye damage.

Initial follow-up for cellulitis should be done within 48 hours or earlier for sicker patients. Improvement in signs and symptoms should be seen, including a decrease in swelling, erythema, and pain of the affected area. The borders of erythema should be receding and getting smaller. The clinician can use a marking pen (with the patient's permission) to mark some of the borders during the initial visit: This will make any changes in size easier to notice. If the patient's response is satisfactory, the next follow-up visit is usually done in 1 week (or sooner, if closer follow-up is necessary). Thereafter, the patient can be seen on a weekly basis until the cellulitis is resolved.

If the patient does not respond to treatment with oral antibiotics after 48 to 72 hours or starts to look toxic, a CBC and consultation with a physician (or referral to the emergency department) is necessary.

Patient Education

The clinician should instruct the patient to call his or her health-care provider if the infection worsens or if fever persists despite antibiotic treatment for at least 48 hours. The patient should also call the office in 3 days to report progress of simple cellulitis infection. The patient should be advised to elevate the affected limb as much as possible to decrease swelling. If the patient has chronic tinea pedis ("athlete's foot"), an OTC antifungal powder or spray should be used daily to prevent a recurrence of secondary infection with bacteria.

VIRAL INFECTIONS

WARTS

Warts (verruca vulgaris, plantar warts, flat warts) are skin tumors formed by infected keratinocytes, usually initiated by the human papillomavirus (HPV). Warts are identified based on their morphology (flat, mosaic, digitate, or filiform) and location on the body (e.g., the plantar, anogenital, and palmar areas).

Epidemiology and Causes

HPV is a small, double-stranded DNA virus that infects epithelial cells and causes hyperproliferation of these cells. HPV is species specific and affects only humans, with a particular tropism for epithelial cells and the mucous membranes. There are at least 150 genetically distinct human papillomaviruses (including HPV subunits). HPV type 1 typically causes plantar warts, whereas types 6 and 11 cause anogenital warts. Certain HPV serotypes are also associated with anogenital malignancies, including cervical intraepithelial neoplasia and invasive cervical cancers. Oncogenicity of HPV appears to be determined by the viral gene products E6 and E7 proteins, which are necessary for host cell immortalization. HPV types 6 and 11 are considered either inactive or weakly capable of transformation, whereas E6 and E7 proteins in HPV types 16 and 18 are capable of producing progressive squamous epithelial neoplasia in experimental studies with mice.

In general, HPV and resultant warts can be transmitted by touch or by trauma to skin tissue such as from nail biting or shaving. Plantar warts occur at points of maximum pressure (e.g., at the heads of metatarsal bones and heels), as a thick painful callus forms in response to the pressure. In contrast, anogenital warts are usually sexually transmitted, but the route of transmission does not necessarily have to include penetrative intercourse (e.g., heavy petting, genital-to-genital contact). HPV enters through breaks in the skin or mucosa. Viral particles contained within skin cells serve as the vehicle for person-to-person transmission.

Pathophysiology

Warts (verruca vulgaris, plantar warts, flat warts) are skin tumors formed by infected keratinocytes, usually initiated by HPV infection. Infected keratinocytes form a mass that remains confined to the epidermis. A common misconception is that warts have roots. In reality, the underside of a wart is usually smooth and round. Although the wart appears to infiltrate the dermis and the subcutaneous layers, it is actually limited to the epidermis. Several types of warts form tightly fused cylindrical projections resulting in a uniform mosaic pattern that is unique to warts. This pattern is a useful diagnostic sign. The black dots seen on the surface of common warts are thrombosed capillaries that become trapped in the cylindrical, finger-like projections.

Clinical Presentation

Subjective

Patients typically complain of a wart or small "bump" (or group of bumps) that has been present for the past several weeks to many months, sometimes for years. Some patients report the same wart being treated before and then recurring on the same area. Most adult patients with common warts attempt self-treatment with OTC wart remedies, with limited to no success. Warts are usually asymptomatic. Occasional plantar warts can cause pain on weight-bearing.

Objective

Warts are small or large, fleshy or firm growths or lumps, which can be raised, fairly flat, single, or multiple, isolated, or clustered together to form a cauliflower-like shape. There are no skin lines crossing the surface, and

examination with a hand lens reveals centrally located capillaries (black dots) that bleed with paring.

Common warts initially begin as smooth, flesh-colored papules. As they evolve, they become dome-shaped, gray-brown hyperkeratotic masses with black dots on the surface. Although common warts can be found on any part of the body, the hands are the most frequent site of involvement.

Filiform and digitae warts are finger-like, flesh-colored projections that protrude from a narrow or broad base.

Flat warts (verruca plana) are small (0.1–0.3 cm), slightly elevated, flat-topped papules. They are usually numerous and involve the forehead, mouth, beard, eyes, back of hands, and shaved areas. Scratching may produce a line of flat warts in the shaved areas. Flat warts range in color from pink or light brown to light yellow.

Cutaneous HPV infections (types 1, 2, 4, and 7) are more likely to be seen in children and young adults and have an incubation period of 2 to 6 months. As an individual reaches adulthood, the prevalence of cutaneous warts decreases, probably because of improved host immunity. Because these infections are usually benign, they are rarely brought to the attention of health-care providers. HPV types 5 and 8 are closely linked with a rare form of hereditary skin cancer (epidermodysplasia verruciformis).

Plantar warts occur at the heads of metatarsal bones and heels (points of maximal pressure) and appear as thick, painful calluses. This may lead to repositioning the foot while walking, causing distortion in posture, as well as producing pain in other parts of the foot, leg, or back.

Diagnostic Reasoning

Diagnostic Tests

If the clinician is unable to distinguish the lesion as a wart, a small specimen can be sent to the laboratory for identification.

Differential Diagnosis

Corns may be mistaken for warts and can be differentiated from warts by paring them with a number 15 scalpel blade. Skin lines are absent, and the black dots that are interspersed in the center of the wart will bleed with additional paring. Its mosaic pattern can be easily identified under a hand-held lens. Whereas corns have a painful, hard, translucent core, warts do not. The pain in corns is relieved when the hard central kernel is freed from the corn.

It is important to differentiate between the surface of the foot that is healing from a recent trauma and warts (black warts) that are undergoing spontaneous resolution. The black dots (thrombosed capillaries) seen on the plantar surface of a foot that has sustained a shearing injury may be confused with the black color of warts that are healing. It is hypothesized that the black color of the warts that are spontaneously healing may be part of the process of regression and may represent a specific cell-mediated immune response to HPV-infected keratinocytes.

Management

It is important to remember that most HPV lesions resolve without treatment. Therefore, initial management should be geared toward relieving pain and pressure and minimizing skin trauma and scarring caused by available therapies. Although filiform and digitate warts are relatively easy to treat, flat warts present a unique therapeutic challenge. Their duration is prolonged and they may be resistant to treatment. Because flat warts may be located in areas that are cosmetically important, treatment modalities that produce scarring should be avoided. It is important to note that therapies for HPV are usually contraindicated in pregnant women.

Therapy must be individualized because available therapies may produce unwanted effects such as pain, hyperpigmentation, scarring, damage to normal tissue, sun sensitivity, chemical sensitization, toxicity, and potential harm to pregnant women. In addition, it is important to identify previous treatment failures and successes, as well as the patient's risk factors (such as immunosuppression or lapses in therapy compliance) that may account for the failure of first-line therapy. Treatment intervals usually range from 1 to 2 weeks, but other patients may require prolonged therapy in order to eradicate more resistant lesions.

Simply covering warts with silver duct tape for 6 days at a time, then uncovering the wart, debriding it with an emery board or pumice stone, and covering it back up again a day later for repeated cycles lasting up to a month has been shown to be just as effective as pharmacotherapy. In other words, applying salicylic acid is not critical. This is an effective and inexpensive alternative therapy and might be suggested as first-line treatment.

Pharmacological Treatments

Keratolytic therapy in the form of salicylic acid plasters (Mediplast) or solution (e.g., DuoPlant, Occlusal) is a safe, nonscarring, moderately effective and low-cost OTC treatment of common warts, specifically for plantar and palmar surfaces. Once the wart is pared with a number 15 scalpel blade, pumice stone, or emery board, the area is soaked in warm water to soften the surface and to facilitate penetration of the solution. In the case of salicylic acid solution, one drop or more is applied with an applicator to cover the surface of the wart. The surface is allowed to dry and covered with a piece of adhesive tape or bandage. This will enhance the penetration of the solution.

Tape occlusion may precipitate inflammation and soreness and may necessitate periodic interruption of treatment. The patient may prefer to apply the solution at bedtime. Within a few days, a soft white keratin layer

will form; this layer should be pared or abraded until pink skin is exposed. This procedure may be better accomplished by an occasional office visit. When applying keratolytic plasters (40% salicylic acid), the patient may use the same procedure outlined in the preceding text. The plaster is more useful when treating mosaic warts (a large cluster of warts). Once the plaster is cut to the size of the wart, the backing is removed and the adhesive surface is attached to the wart and secured with adhesive tape. The plaster should be removed in 24 to 48 hours, and the surface should be pared or abraded as outlined earlier; a new plaster should then be applied to the area. Although this treatment may take a few weeks, it is less irritating than the salicylic acid solution.

Chemicals such as bichloracetic acid (BCA) or trichloroacetic acid (TCA) are caustic agents that destroy warts by chemical coagulation of the proteins. These chemicals are frequently used for recurrent warts or at times as initial therapy. The clinician should pare the excess calloused skin and apply petrolatum to the surrounding area before applying the acid with a cotton-tipped applicator. BCA or TCA should be applied sparingly because both are caustic agents that can damage adjacent normal tissue. These acids are self-neutralizing, but any excess amount can be wiped away with a gauze. Repeat applications may be necessary every 7 to 10 days. A change of therapy should be considered if the patient has not improved substantially after three provider visits or if the warts have not cleared after six treatments.

Verruca plana (flat warts) are especially difficult to treat. Treatment includes applying tretinoin cream 0.025%, 0.05%, or 1% (Retin-A) at bedtime, over the entire area. Frequency of application should be adjusted to elicit a fine scaling and mild erythema. If other treatment options fail, 5-fluorouracil (Efudex 5%) can be applied one or two times a day for 3 to 5 weeks. Hyperpigmentation and recurrent warts at the site of inflammation are the limitations of this therapy.

Podophyllin resin 10% to 25% in a compound tincture of benzoin can be used for external warts. Because of the potential complications associated with systemic absorption and toxicity, it is recommended that the area of therapy be limited to 0.5 mL or less of the solution, or to no more than 10 cm of warts per session. To minimize irritation, the area should be allowed to dry and then washed off 1 to 4 hours after therapy. Podophyllin is not used for cervical warts or dysplasia and is primarily reserved for exophytic lesions. Its safety during pregnancy has not been established, and it is contraindicated for use by pregnant women.

Surgical Treatments

Although cryosurgery is very effective for common and genital warts, it may produce severe pain around the palms, feet, and nail areas. Thermal injury to nerve tissue, epithelial cells, and melanocytes can occur and cause changes in pigmentation. Therefore, light applications of liquid nitrogen are preferable. Liquid nitrogen can be stored in 1- to 2-gallon tanks for approximately 10 days. Applications can be repeated every 1 to 2 weeks. OTC home-based cryotherapy kits are now available without a prescription for use on small, isolated warts in easily accessible areas, such as the hands and fingers. Directions for these kits must be followed closely to avoid damage to surrounding normal skin and tissue. These kits should not be used for warts located in highly sensitive areas, such as the face or genitalia; consultation with a healthcare provider is warranted for such cases.

Surgical techniques such as blunt dissection or electrosurgery usually render patients wart-free with a single visit. Additional clinical training, equipment, and longer patient visits are necessary for these procedures. Blunt dissection is relatively painless if performed on areas other than the plantar or palmar surface. After preparation with local anesthesia, a plane of dissection is established by inserting the tip of a blunt-tipped scissors between the wart and normal skin. The wart is cut circumferentially and the lesion is separated from the normal tissue with short, firm strokes. After the lesion is removed, the blunt dissector is moved firmly back and forth over the area of excision, to ensure that no tissue fragments remain. Liquid nitrogen should be applied to the base using a cotton-tipped applicator. Liquid nitrogen will destroy any remaining virus.

Table 7.5 summarizes various treatment strategies for warts.

Follow-up and Referral

For the majority of common wart cases, a satisfactory response occurs after several treatments. For warts that are unresponsive or are recalcitrant to treatment, other, more aggressive treatment options are available—these are best administered by a dermatologist.

Interlesional administration of interferon (natural or recombinant) is more effective than systemic treatment. The Centers for Disease Control and Prevention does not recommend this treatment as first-line therapy because of the need for frequent office visits and the high frequency of systemic side effects. The cure rate (efficacy) is similar to that of the other therapies available. When all other treatments fail, intralesional bleomycin sulfate may be considered. Bleomycin is mixed (with 5 mL of sterile water and 10 mL of lidocaine) to form a solution, and then this solution is reconstituted with normal saline. Using a 30-gauge needle, the solution is injected into lesion to achieve blanching. The size of the wart will determine the amount of solution injected. Larger warts may require repeat injections. Leakage of the solution is unavoidable during the procedure. The cure rate is 48% (for plantar warts) to 71% (for periungual warts). A multiple-puncture method can result in a 92% cure rate. Responsive warts produce hemorrhagic eschars that heal without scarring.

Table 7.5 Warts and Their Treatment

Type of Wart	Description	Treatment
Common warts	Small, hardened growths of keratinized tissue. Warts usually grow around nails, on fingers, and backs of hands; can appear anywhere on the body.	• Silver duct tape therapy for 6 days, then repeat (see text) • Salicylic acid solution/plasters • Freezing with liquid nitrogen • Surgical excision
Flat warts (Verruca plana)	Pink, light brown or yellow; slightly elevated papules: 0.1–0.3 cm. Numerous sites: mouth, forehead, backs of hands, shaved areas (e.g., legs or beard area); may recur despite treatment. Frequently can undergo spontaneous remission. Avoid potentially scarring therapies.	• May resolve without treatment • Tretinoin cream, 0.025%, 0.05%, or 0.1%. Apply to involved areas daily; adjust treatment to produce fine scaling and mild erythema; may require weeks to months • Freezing with liquid nitrogen • Use of 5-fluorouracil (Efudex 5%) once or twice daily for 3–5 weeks produces dramatic results; may produce persistent hyperpigmentation (use ointment to minimize this adverse effect)
Filiform/digitate warts	Fingerlike, flesh-colored projections emanating from a narrow or broad base; sites: mouth, eyes, and ala nasi.	• Easiest to treat, but recurs • Shaving spreads the lesions • Retract skin and use curette drawn across base to remove wart • May use light electrocautery • Cryotherapy
Plantar warts	Lesions appear at maximum point of pressure (e.g., heads of metatarsal bones or heels) or anywhere on plantar surface; thick, painful callus forms around lesion; pain elicited on indirect pressure.	• More refractory to treatment • Remove surrounding callus with pumice stone or paring after soaking feet in warm water to soften skin • Daily application of salicylic acid liquid, film, or plaster after soaking
Black warts	Warts become black when spontaneously healing; black heel caused by sheared capillaries usually associated with trauma.	• Differential diagnosis for black heel: normal skin lines present; when area is pared with #15 blade, skin underneath is soft, and bleeds
Condyloma acuminata	Cauliflower-like wart. Usually found in anogenital region and usually sexually transmitted.	• 10%–25% podophyllin solution • Bichloracetic acid • Imiquimod cream • Cryotherapy • Intralesional injections • Laser vaporization • Refer to specialist for management of warts on anal mucosa or large collections of warts, which may be prone to profuse bleeding
Oral warts	Can be located in hard/soft palate, oral mucosa. Usually transmitted through oral–genital contact.	• Cryotherapy with liquid nitrogen • Surgical excision
Dysplastic cervical lesions	Lesions are usually subclinical. Colposcopy and biopsy for diagnosis; HPV DNA probes; PCR assays.	• CIN stages II & III: cryotherapy—lesions are frozen with liquid nitrogen every 2 weeks • Loop electrical excision • Laser vaporization • Suspicion of invasive disease: cone biopsy
HPV/koilocytosis	Pap smear indicates HPV or koilocytosis.	Refer for colposcopy and possible biopsy
Atypical squamous cells of undetermined significance (ASCUS)		Treat any underlying infections. Follow up with Pap smears every 4–6 months; if ASCUS recurs on repeat Pap smear, consider referral for colposcopy and biopsy

Need for referral to a specialist (dermatologist) is determined by several factors, including lack of response to treatment, possible cosmetic consequences (especially with warts on the face and eyelids), and the clinician's knowledge, experience, and comfort in identifying and treating specific types of warts. If the clinician is unsure of the diagnosis or if the wart is resistant to multiple treatments, the patient should be referred to a dermatologist.

Patient Education

The clinician should educate the patient on means of prevention of self-inoculation and the routes of transmission of the common warts. These measures include limiting shaving in the affected area until warts are eradicated, strategies to control nail biting, and avoidance of scratching and rubbing on the wart (see Table 7.6).

HERPES SIMPLEX INFECTIONS

Herpes simplex viruses are part of the Herpesviridae family and the Alphaherpesvirinae subfamily. *Herpes simplex virus* (HSV) infections are caused by two different types of viruses: HSV-1 and HSV-2. HSV-1 is associated primarily with oral infections, whereas HSV-2 is associated mainly with genital infections. Interestingly, HSV-1 genital infections are becoming more common, as are HSV-2 oral infections, probably due to oral–genital sexual contact (see Table 7.7).

Epidemiology and Causes

Both types of HSV produce identical patterns of infection. More than 85% of people worldwide are HSV-1 seropositive; however, only 20% to 40% of these individuals have a history of lesions. The National Institutes of Health (NIH) estimates that one out of four (or 45 million) Americans has genital herpes. The NIH estimates that 500,000 new cases may occur each year.

Pathophysiology

The majority of HSV-1 and HSV-2 infections are asymptomatic so that only elevated immunoglobulin G (IgG)

Table 7.6 Patient Education: Warts

About the Disease

- Warts are small growths or tumors produced by infection of normal skin tissue by the human papillomavirus (HPV). The most common areas where warts can be found include the plantar and palmar surfaces, nailbeds, hands, face, mouth, penis, vulva, cervix, and anus.
- One in four people are infected with HPV. Despite treatment, most warts will recur. Broken or abraded skin may facilitate the transport of the virus. These lesions can be spread by skin-to-skin contact, including touch, vigorous rubbing, shaving, nail biting, and sexual intercourse.
- Contrary to popular belief, warts do not have roots. The underside of a wart is smooth and round. The black dots found in the center of a wart represent broken small blood vessels (capillaries).
- Immunosuppression caused by diseases such as HIV or cancer and by organ transplants and some medications may reduce the efficacy of treatment. Cigarette smoking affects the immune system and enhances the expression of the viruses. Therefore, smoking should be discontinued.

About Treatments

- See text for information on "silver duct tape therapy."
- Treatment often involves more than one session, at 1- to 2-week intervals, and therapy may be prolonged.
- To minimize inflammation, do not apply medicated solutions, ointments, gels, creams, or plasters beyond the recommended time.
- Cryotherapy may be available in a doctor's office or as a home wart freezing and removal kit. Directions must be followed closely with home-based kits to avoid excessive damage to normal surrounding tissue.
- To improve efficacy, plasters should be cut to the size of the wart and kept in place with an adhesive for 24–48 hours. Pare or use a pumice stone to abrade the area and then reapply the plaster. The process may take a few weeks before you see results.
- Podophyllin is applied only to external warts and the area of application should be limited to 10 cm per session. To minimize irritation, the area should be allowed to dry and washed off 1–4 hours after therapy.
- Caustic acids such as bichloracetic acids or trichloracetic acid are very effective but may damage normal tissue if not allowed to dry properly. Repeat applications may be necessary every 7–10 days.
- Wash the treated area after the recommended waiting period. Always check for any signs and symptoms of infection, such as pus, severe pain, heat, redness, and swelling.
- For mild to moderate pain, take OTC analgesics.
- Pursue stress reduction activities, such as exercise, imagery, biofeedback, meditation, and yoga, and maintain a healthy diet. Decreasing stress will boost the immune system and improve healing, as well as reduce the desire to smoke, overeat, or nail bite.

Table 7.7 Herpes Simplex Infections

Infection	Location	Commonly Affected Age-group
Oral–labial herpes simplex	Lips, oral cavity	Children age 2–5 years, adults
Herpetic keratoconjunctivitis	Eyelids, periorbital area, cornea	Newborns, adults
Herpetic tracheobronchitis	Pharynx, trachea, bronchi	Older adults
Herpes simplex encephalitis	Temporal lobe of the brain	Any age, primarily adults who are immunocompromised
Herpes gladiatorum	Shoulder, neck, knuckles, areas of contact	Age 14 years and older (commonly seen in wrestlers)
Herpetic whitlow	Fingertip	Age 1 year and older
Lumbosacral herpes	Trunk or back	Adult
Herpes simplex of the buttocks	Buttocks	Adult women
Genital herpes	Labia minora, labia majora, vagina, cervix, urethra, penis, rectal area	Young and older adults, 1% of pregnant women
Eczema herpeticum	Face or any area of active or recently healed atopic dermatitis	Infants and older, commonly with a history of atopic dermatitis
Erythema multiforme	Extremities, palms, soles of feet	Age 20–30; more commonly seen in men than women

antibody titer shows evidence of previous infection. Herpes infections can occur anywhere on the skin. HSV infection has two phases: primary infection and secondary or recurrent infection. During the primary infection, the virus enters keratinocytes in the epidermis, eventually migrating to nerve endings. The virus then ascends via peripheral nerves to the dorsal root ganglion, where it enters a latent stage without active viral replication, which can last for days to years. The trigeminal ganglia are the targets of oral viral strains, whereas the sacral ganglia are the targets of genital herpes strains. Infection of the ganglia may occur within 24 hours of initial viral exposure and is essentially lifelong.

The majority of primary infections are subclinical and asymptomatic and can be detected only via an elevated IgG antibody titer. In the past several years, it has been recognized that although HSV infection is largely asymptomatic, most transmission occurs during periods of asymptomatic viral shedding. The severity of the viral infection increases with age. Herpes infection may markedly compromise nutritional intake in the elderly. HSV is spread by direct contact with active lesions, saliva, semen, or cervical secretions. In addition, HSV can be spread by patients without active disease, in whom subclinical or asymptomatic viral shedding occurs. Viral replication in the gingival epithelia facilitates oral shedding of the virus.

Symptoms may occur from 2 to 21 days after exposure. Tenderness, pain, mild paresthesias, or burning can occur before the onset of lesions at the site of inoculation. Headache, fever, muscle aches, localized pain, and tender lymphadenopathy may occur as part of the prodrome. Some patients have no prodromal symptoms. After several days, grouped vesicles on an erythematous base appear, followed by ulcers or erosions that crust over. Eventually there is a loss of crusts and reepithelialization occurs. In the moist genital region, crusts may not form; however, exudate may accumulate. Lesions typically heal in 7 to 10 days without scarring but may last up to 6 weeks or longer if they become secondarily infected with bacteria. Vesicles in primary HSV infection are more numerous and scattered than in recurrent infection.

Tissue destruction in HSV infection is mediated directly by viral replication within keratinocytes and other epithelial cells. A mononuclear cell and lymphocytic infiltrate occurs at sites of infection, consisting primarily of CD4+ T cells early on, but eventually involving equal numbers of CD8+ T cells, as well as macrophages and cytotoxic natural killer cells that attempt to clear infected host cells. The cytokines interferon-gamma and interleukin-6 are primary mediators of cytotoxic killing mechanisms. Interestingly, in animal models, nonclassic T cells endogenous to the skin and mucosal surfaces that express gamma-delta rather than alpha-beta antigen receptors have been shown to protect against severe mucocutaneous and encephalitic HSV infection.

Recurrent disease typically occurs at or near the same site of primary infection. Physical and emotional stress, fever, exposure to ultraviolet light, chapping or abrasion of the skin, immune suppression, menses, or fatigue may cause reactivation of the virus, which descends spontaneously along sensory nerve axons to the skin surface.

The anatomical site of infection and virus type affect the frequency of recurrence. Genital herpes recurs six times more frequently than oral–labial herpes. Genital HSV-2 infections recur more frequently than genital HSV-1 infections. Interestingly, oral–labial HSV-1 infections recur more often than oral HSV-2 infections.

Clinical Presentation

Subjective

The most common manifestation of HSV infection is oral–labial herpes. Primary infection with HSV may present as herpetic gingivostomatitis in children and young adults, though most commonly children aged 2 to 5 years are affected. The patient may present with fever, sore throat, hypersalivation, and painful vesicles and ulcers on the tongue, palate, gingiva, buccal mucosa, and lips. In genital herpes, early symptoms may include pain in the legs, buttocks, or genital area; genital burning or itching; vaginal discharge; and lower abdominal pressure. Within a few days, lesions appear at the site of infection. With the first episode of genital herpes, fever, headache, muscle aches, painful or difficult urination, and inguinal lymphadenopathy may also occur. HSV infections are usually oral or genital; however, any area of the body can be infected.

In elderly patients, primary infection or reactivation of oral–facial HSV-1 can be extensive. Painful oral lesions make eating difficult and can compromise nutritional status. Sometimes, superinfection with bacteria or *Candida* can further complicate HSV infection in the elderly. Of major concern in older adults is autoinoculation of the eye, causing keratoconjunctivitis, which is the most frequent cause of corneal blindness. Signs and symptoms include unilateral excessive lacrimation, edema, chemosis, photophobia, and purulent exudate. Decreased visual acuity is a bad prognostic sign.

Herpetic whitlow is an HSV infection of the fingertip. This disorder was common among health-care practitioners before the use of universal precautions. Now, herpetic whitlow is commonly found in children with a recent history of gingivostomatitis and women with genital herpes. Transmission apparently results from autoinoculation. Vesicles with a red halo may erupt on the finger. Besides generalized symptoms, a red streak may appear up the arm.

A patient with a history of atopic dermatitis who presents with vesicles on the face or areas that have recently healed is likely to have eczema herpeticum. A patient who recently had an HSV infection but now presents with iris-shaped lesions on the palms and soles of the feet most likely has erythema multiforme. HSV lesions on the back are often misdiagnosed as varicella-zoster virus (VZV), and often the correct diagnosis is not made until there is a recurrence. The primary difference on clinical evaluation is that HSV vesicles are uniform in size, whereas varicella-zoster lesions vary in size.

Both types of HSV infection can cause encephalitis. The patient presents with altered level of consciousness, personality changes, fever, and seizures. The patient may also experience smell and taste hallucinations and aphasia. Herpetic encephalitis requires immediate hospitalization and treatment with IV acyclovir (Zovirax). Herpes infections in immunocompromised patients are more severe—frequent HSV recurrences often result in chronic and nearly continuous ulcerations. Focus on History 7.4 lists some questions for eliciting information on HSV infection.

Objective

The lesions must be examined for characteristic location, appearance, and distribution. Depending on the site of lesions, the anterior and posterior cervical chains submental or the inguinal nodes should be checked for lymphadenopathy. Grouped vesicles on an erythematous base occurring in the mouth or on the face or the genitals are most likely the result of HSV infection. Vesicles on the eyelid, chemosis, or the presence of corneal dendrites require prompt referral to an ophthalmologist.

Diagnostic Reasoning

Diagnostic Tests

Viral culture is the standard method of diagnosis. HSV can be cultured from vesicle fluid or from scrapings from the base of erosion. Sampling must be done early (during the first 72 hours) in the course of the outbreak. The

Focus on History 7.4 Herpes Simplex Virus Infections

General

- When did the sores first appear?
- Have you ever had sores on the same area before?
- Before appearance of the sores, did you experience burning, tingling, pain or numbness?
- Do you have muscle aches, fever, and/or weakness?
- Are you able to swallow?
- Have you ever had this happen to you before? If so, when and how was it treated?
- Have you been around any person who may have had these symptoms?
- Do you have a history of any skin problem?

Specific Questions for Genital Herpes

- How old were you at first sexual intercourse?
- How many total sex partners have you had?
- How long have you been with your present partner?
- Have you ever had a sexually transmitted disease?
- Do you use latex condoms? If so, do you use them consistently?
- Do you engage in oral sex? Vaginal sex? Anal sex?
- Have you ever had an abnormal Pap smear?

initial viral culture may be negative, but clinical evaluation and subsequent recurrence with early culture can verify HSV infection. Viral culture differentiates between HSV-1 and HSV-2 with high sensitivity. The Tzanck smear is rapid and easily performed and can be used to identify multinucleated giant cells in vesicular fluid. The Tzanck smear does not, however, differentiate among HSV-1, HSV-2, or VZV. HSV antibodies can be detected in blood, but the serum analysis does not differentiate between HSV-1 or HSV-2. Enzyme-linked immunosorbent assay and complement fixation are available serological techniques that detect circulating antibodies with 90% sensitivity but only 50% specificity. The Western blot (currently not available in doctors' offices) is another serological technique that distinguishes between HSV-1 and HSV-2 with high sensitivity and specificity (greater than 99%). Viral culture remains the gold standard for diagnosis of HSV infection.

Differential Diagnosis

History and clinical presentation are the best guide to diagnosis. Aphthous stomatitis differs from HSV infection in that ulcerations of nonkeratinized mucosa occur. Therefore, lesions rarely appear on gingiva or hard palate, as do herpetic ulcers. Also, no fever or lymphadenopathy occurs. In addition, an aphthous stomatitis ulcer is usually solitary and larger than a herpetic ulcer. Herpangina can also mimic HSV infection. Herpangina is seen predominantly in children and infrequently seen in adults. Treatment is symptomatic for both infections. Hand-foot-and-mouth disease presents with red macules that progress to vesicles on an erythematous base. However, the extremities, in particular the hands and feet, as well as the mouth, develop lesions. Erythema multiforme can result from HSV or *Mycoplasma* infection or a drug reaction. Treatment is based on the underlying cause. Pemphigus is an autoimmune disorder that usually occurs in middle-aged patients (aged 40–60). Erosions of the oral mucosa are followed by bullae over the body.

Management

No cure for herpes exists; however, recurrences tend to be milder and of shorter duration than the primary infection. Therapy is primarily symptomatic and supportive. Nutritional intake is important, especially in elderly patients, who may benefit from using anesthetic mouth rinses. The goals for management include reduction or elimination of pain, decreased viral shedding, and healing of tissue. In cases of frequent recurrence of herpetic lesions, suppressive therapy may be needed.

Initial therapy is palliative and promotes healing. Herpetic keratoconjunctivitis requires immediate referral to an ophthalmologist to prevent blindness. For other forms of HSV infection, the practitioner can initiate management with pharmacotherapy and self-help techniques based on the location and extent of HSV infection. Acetaminophen can be used to control fever and pain. Lesions on the lip (if small) may require nothing more than applications of ice and lip ointments such as Blistex. OTC docosanol 10% (Abreva) applied 5 times daily may improve lesions. If lesions are more extensive, penciclovir 1% cream (Denavir) applied to the affected area every 2 hours while awake for 4 days promotes healing, shortens the course of the illness by several days, and substantially decreases viral shedding. Extensive oral lesions may require the use of oral anesthetics such as viscous xylocaine 2% (Lidocaine) or dyclonine hydrochloride 0.5% to 1% to control pain. In addition, acyclovir suspension 200 mg/5 mL can be used to treat the lesions directly by rinsing the mouth with 1 teaspoon and swallowing five times a day for 7 days.

Initial treatment of genital herpes requires the use of oral antiviral drugs. Valacyclovir and famciclovir have greater bioavailability and require less frequent daily dosing than acyclovir. This type of regimen makes these drugs preferable to acyclovir. Comfort measures such as warm compresses or an oatmeal sitz bath several times a day can relieve pain and promote healing. A patient with genital or urethral herpes may find it easier to urinate into the warm bath water. Every patient with HSV infection benefits from increased fluid intake and rest.

Any necessary subsequent management is based on the recurrence of symptoms. A patient with an initial negative viral culture can be told to return to the practitioner for another viral culture within the first 72 hours if symptoms recur. This procedure is important with an initial negative culture of genital herpes. A patient with genital herpes, after the first occurrence, can be given a prescription for an antiviral drug and instructed to take the medication should he or she experience the beginning of symptoms such as tingling or burning at the site. A patient with genital herpes who experiences six or more recurrent episodes per year should be placed on suppressive therapy. (See Drugs Commonly Prescribed 7.5.) Suppressive therapy will reduce outbreaks by 85%. Ultimately, there will be about a 50% reduced risk of transmission. Long-term suppressive therapy is very safe, and after a period of 5 to 7 years, many patients discontinue such therapy with no relapses.

Follow-up and Referral

Follow-up should be early and repeated depending on the extent of disease. Lesions confined to the lip area may not need to be seen unless they do not resolve. Extensive oral lesions and genital lesions should be seen on a weekly basis until resolution. As previously mentioned, herpetic lesions of the eye must be referred to an ophthalmologist immediately. Patients with herpes zoster ophthalmicus should be instructed to return to the practitioner if they experience a recurrence, until they feel comfortable in handling subsequent episodes

Drugs Commonly Prescribed 7.5 Herpes Simplex Infection

Drug	Indication	Adverse Reactions and Prescribing Considerations
Topical		
docosanol 10% cream (Abreva)	Recurrent oral–facial herpes simplex OTC	Begin at earliest sign or symptom 5 times/day
penciclovir 1% (Denavir)	Recurrent herpes labialis on the lips and face	Every 2 hours while awake for 4 days
Systemic Therapy		
amciclovir (Famvir)	Acute herpes zoster, treatment or suppression of recurrent genital herpes and treatment of recurrent herpes labialis in immunocompetent patients	Pregnancy Category B Check prescribing reference for dosage and precautions
valacyclovir (Valtrex)	Treatment of herpes zoster or herpes labialis Treatment or suppression of genital herpes in immunocompetent patients	As above
acyclovir (Zovirax)	Genital herpes, herpes zoster, varicella, herpes labialis, herpetic whitlow	As above

on their own. A patient with genital herpes may benefit from referral to a local herpes organization for information and emotional support.

Patient Education

Patient education is an integral component of the management of HSV infection. Most patients achieve relief of symptoms within 4 to 7 days of beginning therapy. Self-care techniques and instructions on the proper use of pharmacotherapy are vital. Table 7.8 provides guidelines for patient education on herpes infection.

ACNE VULGARIS

Acne vulgaris (commonly called "acne") is one of the most common skin conditions that the clinician will see in primary care. Acne is derived from the Greek word *acme* meaning "prime of life" because it is a disease primarily of adolescence, although it may continue into adulthood. Acne is an inflammatory disorder of the sebaceous gland and its accompanying hair follicle (or a pilosebaceous unit), with the highest incidence seen in teens and younger adults. There are approximately 5,000 pilosebaceous units on the human body. Most of them are located on the face, back, chest, and upper arms, the most common sites for acne. Acne lesions include comedones, papules, nodules, and cysts. Painful nodules and cysts are found in severe forms of acne.

Although acne is not a life-threatening illness, it has the potential for resulting not only in physical scars but in emotional trauma as well. The primary-care provider should not ignore the impact of acne on self-esteem and identity, which are closely tied to physical appearance during the adolescent period. Many adolescents are reticent to discuss this health-care issue, and the primary care provider should be proactive about treatment in order to prevent disfiguring scarring. Most cases of acne can be treated safely in the primary-care arena. Treatment options should be offered to both the parent and the teen during routine wellness visits, as well as during episodic visits.

Common misconceptions regarding acne abound in the community. Many patients and their parents think that antibiotic treatment can result in a "quick cure." In reality, antibiotic treatment can take up to 4 to 6 weeks before visible results may begin to be seen. No connection has been found between ingestion of certain foods (fried foods, chocolate) and acne. The response rate from acne treatment tends to be slow compared with most infections treated with antibiotics. Good education regarding acne can help prevent disappointment in angry and discouraged patients who might become noncompliant because of a loss of trust in both the treatment and provider.

Epidemiology and Causes

Acne vulgaris has the highest incidence among 12- to 25-year-olds; up to 85% of this age-group is affected at one time or another. Twenty percent of all adults have some degree of acne. Sixty million Americans have active acne, with 20 million having severe acne that may cause scarring. Only 11% of acne sufferers seek advice or treatment from a professional. The incidence of acne

Table 7.8 Patient Education: Herpes Simplex Infection

- Fever, stress, sunlight, and menses can trigger recurrence of lesions.
- Burning and tingling at the site may signal recurrence of the infection. If antiviral therapy was prescribed, begin it at the first sign of infection.
- If symptoms persist beyond 10 days, see your health-care provider.

Treatment

General:
- Apply penciclovir (Denavir) 1% cream to affected area while awake every 2 hours for 4 days, or until symptoms resolve.
- Frequent hand washing, rest, and increased fluid intake are needed during any herpetic outbreak.

Lip lesions:
- Apply ice to lip lesions for 10–15 minutes as needed to relieve pain and decrease swelling.
- Lip balms (such as Blistex) may be used on the lips to prevent drying of sores and reduce pain.
- Apply lip balm sunscreen (such as Chapstick) with an SPF of 15 to lips before sun exposure.

Oral lesions:
- Apply a dental protective paste (such as Orabase) 4 times a day to prevent irritation of the lesions by the teeth.
- An equal mixture of diphenhydramine (Benadryl) syrup (12.5 mg/5 mL) and unflavored Maalox can be used as an oral rinse every 2 hours, then expectorated. Viscous xylocaine 2% (Lidocaine) 5 mL can be added to the mixture or used alone as an oral rinse before meals to decrease pain and facilitate eating.
- For those with orolabial lesions, there should be no sharing of towels, silverware, or glasses, or kissing until lesions are healed.

Genital, anal, and/or buttocks lesions:
- To soothe lesions, apply warm compresses or take a warm oatmeal sitz bath for 20–30 minutes as needed.
- A blowdryer placed on the cool setting can be used to thoroughly dry genital lesions.
- No sexual intercourse until lesions are healed. A latex condom must be used consistently to decrease viral spread.

markedly decreases as people get older. Acne occurs equally in both males and females, although it can be more severe in males. The average age at onset for Caucasians is 11 years for girls and 12 years for boys. There are some racial differences. The average age of onset is 16 years for Hispanics, 19 years for Asians, and 20 years for African Americans. Hispanic teenagers have the highest incidence of both acne and resultant scarring. Acne can recur again during adulthood and is called *adult-onset acne*. Adult-onset acne is more commonly seen in women who are in their mid-20s to 40s. Fifty percent of adult women have premenstrual flares of acne, and many women have their first flare, or worsening of existing acne, during pregnancy. The etiology of acne is interdependent on several factors, which include the following:

- An increase in production of sex hormones (androgens) in puberty and adolescence
- An increase in sebum production resulting from activation of the sebaceous glands (during puberty and adolescence) and genetic factors
- A disorder of epithelial cell "stickiness" (keratinization) and shedding (desquamation), leading to plug formation
- Proliferation of *Propionibacterium acnes* bacteria inside the hair follicles
- The host's inflammatory response

Pathophysiology

Comedones are the basic lesions of acne and are caused by a defect in desquamation at the opening of the pilosebaceous follicle. Instead of regular cellular shedding, desquamation is reduced, and shed epithelial cells become "sticky," forming plugs that block follicular openings in a process known as retention hyperkeratosis. It takes about 2 months for the accumulated shed epithelial cells, sebum, and keratin to finally produce a comedone. *Comedones* are noninflammatory lesions and are classified into two types: *closed* comedones ("whiteheads") and *open* comedones ("blackheads"). Open comedones get their black color from melanin and not from dirt, as the black color results from the oxidation of tyrosine to melanin. Tyrosine, an amino acid precursor of melanin, is a substance that is normally present in the plug material.

Enlargement of the sebaceous glands and increased sebum production triggered by adrenarche during adolescence provides a rich growth medium for the overgrowth of *Propionibacterium acnes* bacteria within the pilosebaceous follicles. *P acnes* is an anaerobic diphtheroid that is part of the normal skin flora in humans and is responsible in large part for the inflammatory response observed in acne vulgaris. *P acnes* bacteria utilize triglycerides as their primary source of nutrients by breaking down the sebum inside the affected hair

follicle into its basic units—fatty acids and glycerol. Free fatty acids act as irritants and produce a sterile inflammatory response inside the sebaceous follicles. *P acnes* itself also causes a direct inflammatory response by releasing proteolytic enzymes such as hyaluronidase, as well as chemotactic factors that attract neutrophils to the site of infection.

These neutrophils extrude lysozyme, which further degrades surface epithelia, leading to rupture of the previously closed comedone. When a comedone ruptures, its contents, which include sebum, bacteria, keratin, and free fatty acids, enter the dermis and elicit a severe inflammatory response. This results in the formation of deep abscesses, which present on the skin surface as nodules and cysts. Although androgen excess may lead to acne formation, most acne sufferers do not overproduce androgens. However, their pilosebaceous glands are likely hypersensitive to these hormones and more prone to retention hyperkeratosis. Some studies have shown that the production of sebum is increased in patients with acne compared with controls of similar age, thus suggesting a possible genetic predisposition for acne vulgaris.

Clinical Presentation

Subjective

The typical patient is an adolescent male or female who has already tried self-treatment for several months with OTC products without much success. The patient might present to the clinician's office not only with numerous acne lesions but also with dry, irritated skin, a common side effect of many topical acne medications. Female patients are more likely to verbalize emotional distress over their appearance. Male patients are more likely to wait until their acne is severe before they will seek treatment from the clinician. Some patients with severe acne complain of pain and tenderness from multiple deep pustules, nodules, and cysts. Mild to moderate acne normally does not cause pain.

Objective

Mild Acne Mild acne is composed mainly of noninflammatory comedones with occasional small papules. Commonly, there is a mixture of both types of comedones. The location of the comedones and papules will vary, from a predominantly facial involvement to other locations, such as the chest, back, and the upper outer arms. Closed comedones are small papules from 1 to 3 mm in size that are the same color as the surrounding skin, sometimes with a visible white plug. Occasionally, a closed comedone can get irritated from trauma (e.g., scratching) and become inflamed. Open comedones have a black-colored central plug. The hard plug on some comedones can be removed easily by putting firm pressure on the sides of the lesion. See the figure of the Iceberg of Acne to appreciate all the issues involved.

Moderate Acne Moderate acne is composed mainly of inflammatory lesions such as papules and pustules. The papules range in size from a few millimeters to half a centimeter. The color of the acne papules in light-skinned patients ranges from light pink to bright red. Papules in darker-skinned patients can be red to shades of brown. Pustules are easier to recognize: They appear like pointed papules, with yellow to green-colored tops. When pustules become fluctuant, they rupture spontaneously, providing relief from pain. Resolution of a pustule is usually rapid after rupture. Scarring is more likely with larger and deeper pustules. Hyperpigmentation can be problematic, especially in patients with darker skin. (Patients with olive-toned complexions and darker tones are more likely to have this problem.) Patients who are prone to hyperpigmentation should be advised to avoid sun exposure to the face and to use oil-free sunblock on the face.

Severe (Nodulocystic) Acne Severe acne, or nodulocystic acne (consisting mostly of nodules and cysts), always results in scar formation. The severity of acne scars is variable, from numerous atrophic pits ("pockmarks") to large, depressed scars. In patients with darker skin, keloids and hypertrophic scars can result. Severe acne is more common in males. Occasionally, fistula formation is seen in some patients. Nodules are inflammatory lesions that appear bright to dark red (or brown), depending on the patient's shade of skin. Nodules are smaller and feel harder than acne cysts. In addition, some darker-skinned patients end up with permanent hyperpigmentation changes secondary to severe inflammation, brown to black-colored macules on skin.

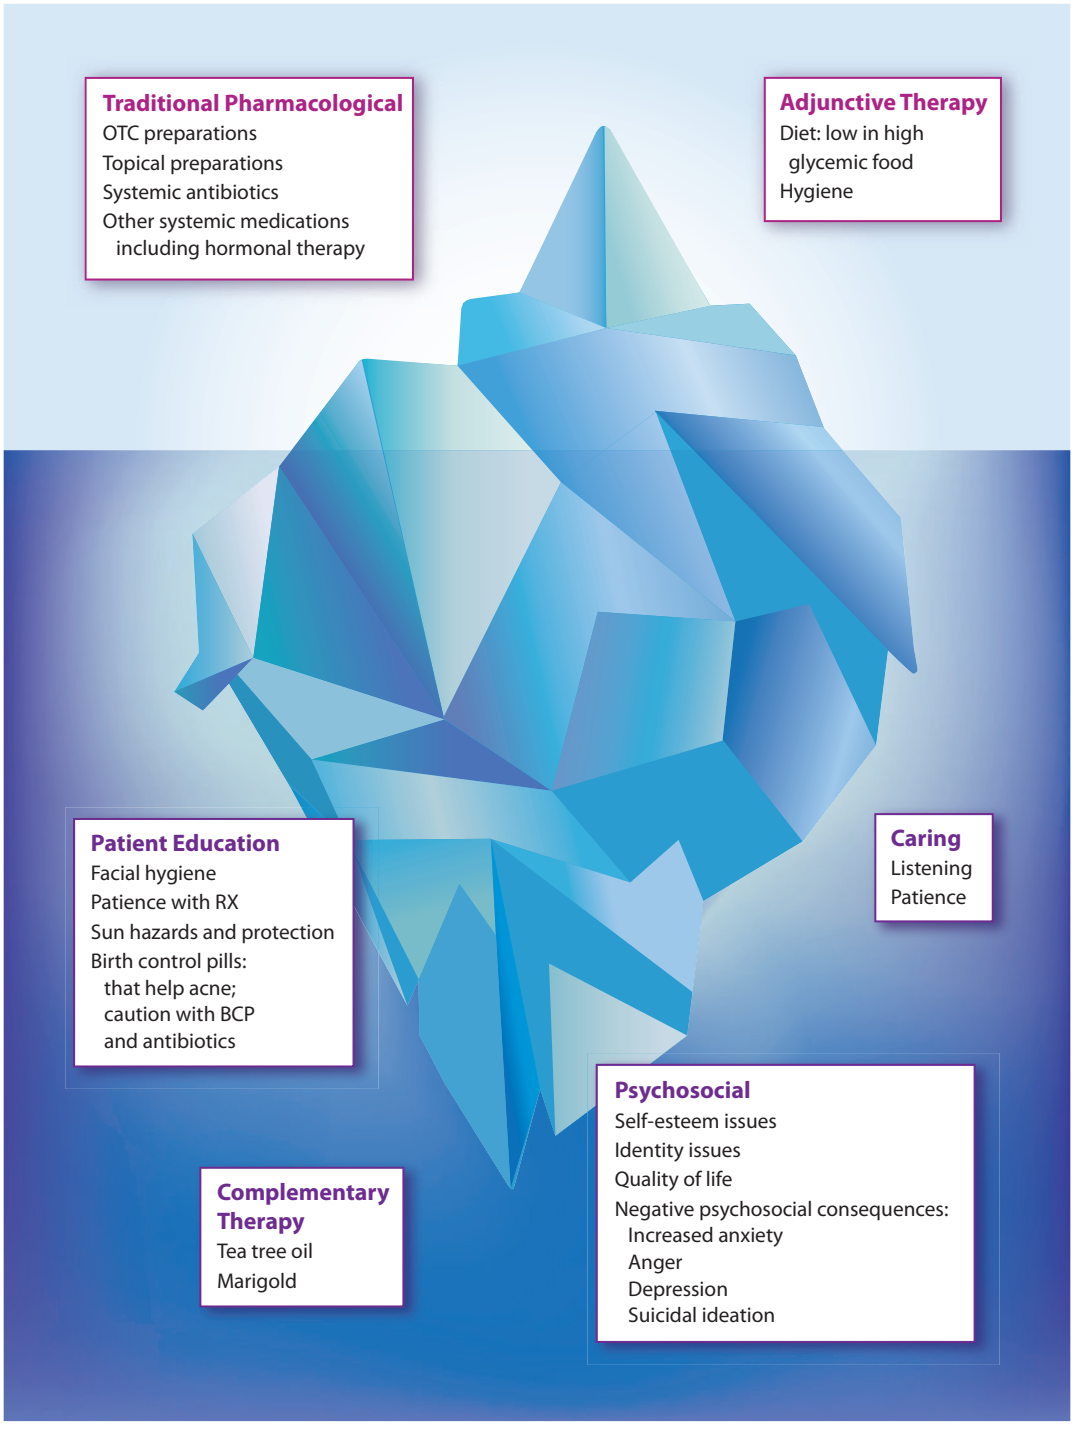
Acne conglobata is severe cystic acne in which nodules, cysts, and abscesses develop; lesions are predominantly located on the trunk area instead of the face. Females with acne conglobata should be evaluated for polycystic ovary syndrome. Acne fulminans is rare and is seen in young adolescent males. An acute onset of multiple painful, ulcerated acne lesions is seen, along with systemic symptoms such as fever, chills, malaise, and generalized joint and muscle aches.

Diagnostic Reasoning

Diagnostic Tests

Acne is diagnosed by its classic location and characteristic lesions. A complete history is crucial to the diagnosis and supplants the importance of most diagnostic tests, which are really only needed when an underlying condition is suspected or for cases refractory to standard treatments. For acne fulminans, a CBC, blood chemistry panel, urinalysis, and ESR can be helpful. Abnormal lab results, however, seen in cases of acne fulminans include an increase in white blood cell count (leukocytosis), an elevated ESR, anemia, and hematuria.

The Iceberg of Acne



If an endocrine disorder such as polycystic ovaries is suspected (e.g., in a hirsute overweight female with moderate to severe acne and amenorrhea or irregular menses), an evaluation for excessive androgen production should be done. A complete physical exam, along with laboratory tests that include serum total and free testosterone and dehydroepiandrosterone sulfate, is recommended. A pelvic ultrasound should be ordered to look for enlarged ovaries.

Differential Diagnosis

Rosacea used to be called "acne rosacea" and needs to be ruled out. Rosacea is more common in adults and older patients and is located more centrally on the face, cheeks,

chin, and nose. Comedones are never found in rosacea. There is a tendency for easy flushing in response to alcohol or heat. Telangiectasia, a dilation of a small group of blood vessels, may be present. It can be accompanied by eye complaints such as excessive dryness and irritation. It is more common in patients from an Irish, Scottish, or English ethnic background. Chronic rosacea can result in rhinophyma (hyperplasia of nasal tissue) and is seen more often in older men.

"Hot-tub" folliculitis (folliculitis lesions caused by staphylococci) appears within 1 to 4 days after hot tub use (because of inadequate temperature and chlorination). Patients will complain of small red pustules that can be occasionally pruritic. Folliculitis is located on the areas of the body that have been immersed in the water, such as the lower torso, buttocks, and legs. Perioral dermatitis appears as small, erythematous papules that occur around the mouth area and the nasolabial folds. The main diagnostic clue is the location: It is seen only on the perioral area and is more common in adult females (usually 20–30 years old). Treatment is similar to that for acne rosacea. Topical steroids are contraindicated.

Management

The primary goal of acne treatment is to prevent and/or to minimize scarring and permanent pigmentation changes. Patient education is very important in acne management and should not be neglected. Mild acne is treated with topical medications only (see discussion that follows). Systemic antibiotics may be used in moderate cases of acne that are unresponsive to topical agents and are used in severe cases.

A combination of several types of acne lesions is not uncommon, but the most predominant lesions present will help in the determination of treatment choices. Other factors that help determine treatment include a higher risk of pigmentation changes (more common in patients with darker skin), a patient's refusal of systemic antibiotic treatment, and severity of the acne. Parental permission is necessary to treat patients younger than age 18 years. The popular media have suggested that tretinoin has been associated with psychotic or suicidal behavior in teens, but this has never been substantiated by rigorous epidemiological data.

Topical Treatment of Comedonal Acne

Comedones respond well to topical retinoids (Level I; Strauss et al, 2007). Synthetic retinoids such as tretinoin (Retin-A) and adapalene gel (Differin) decrease comedone formation by increasing cell turnover and decreasing epithelial cell cohesiveness. Adapalene gel seems better tolerated on sensitive skin than tretinoin, but patients with extremely sensitive skin can still develop skin irritation. Mild adverse effects include dryness, erythema, scaling, and burning. Azelaic acid (Azelex) is the least likely to irritate sensitive skin (compared with retinoids) and does not cause photosensitivity, but practical results in the clinical area have been disappointing. Patients who are unable to tolerate topical retinoids may be good candidates for this drug.

Tretinoin has been shown to thin out the top epidermis during the first 4 weeks of treatment, and thus can be very drying and irritating. At this time, patients might notice more skin sensitivity to the elements (cold air, wind, sun) and an increase in skin photosensitivity. Sunscreen or sunblock should be used during the entire treatment period, especially during this time. The thickness of the epidermis returns to normal after 4 to 6 weeks. Topical retinoids are derivatives of vitamin A and are available in multiple vehicles in a wide variety of concentrations. They are rated as Pregnancy Category C and should not be used in pregnant women or on children.

It is important to warn patients and parents that tretinoin and, to a lesser extent, adapalene gel will cause a worsening of acne lesions during the first 4 to 6 weeks of treatment, because preexisting comedones will continue to surface during this time. Improvement should become visible by 6 to 8 weeks, however. A trial period of 2 months is generally recommended for topical retinoids, unless the patient develops contact dermatitis or other problems with the medicine. To avoid excessive skin irritation, the patient should wait for at least 10 to 15 minutes after washing and should allow the skin time to dry before applying topical acne agents. Patients with a history of eczema or with sunburned skin should not use this medicine. The patient should avoid the eyes, mouth, angles of the nose, and mucous membranes when applying this medicine. Adverse reactions include excessive skin irritation, an apparent exacerbation of symptoms, transient pigmentation changes, stinging on application to the skin, and dry skin. The effects of other topical acne agents, such as benzoyl peroxide, sulfur, resorcinol, and salicylic acid, should be allowed to subside before the application of topical retinoids. (See Advanced Practice Nursing Interventions 7.1.)

Topical Treatment of Inflammatory Acne

Patients with predominantly inflammatory lesions may respond well to topical antibiotics such as erythromycin or clindamycin, benzoyl peroxide, or a combination of benzoyl peroxide and erythromycin. Other good candidates for nonretinoid topical acne therapy include patients who cannot tolerate tretinoin or adapalene gel or patients who have concurrent eczema. All topical antibiotics are applied once or twice daily. The most common side effects include mild erythema or burning. Because topical antibiotic solutions use an alcohol base, they can cause excessive skin dryness. To avoid this problem, the clinician should tell the patient to start gradually on a once-a-day basis for 2 weeks. Monotherapy with topical antibiotics may lead to bacterial resistance with a resultant slower therapeutic effect, so switching the patient to a combination of antibiotics

Advanced Practice Nursing Interventions 7.1
Initiating Tretinoin Therapy

Start with tretinoin 0.025% (Retin-A) cream (the least irritating). Apply three to four times per week at bedtime for the first 2 weeks until the patient can tolerate a daily dose. Give this dose a trial of 6–8 weeks.

- Gradually increase to a 0.05% cream or 0.025% gel if patient can tolerate the above regimen and needs a stronger dose (if no reduction in acne lesions seen after 8 weeks).
- If there is still breakthrough of acne lesions, increase to the 0.1% cream.

NOTE: The most potent and irritating dose of tretinoin is the 0.05% liquid formulation. Remind the patient that acne breakout is expected at weeks 4–6 of treatment, then skin will start to clear up. Tretinoin 0.05% (Renova) has been shown to decrease the effects of solar damage and is approved by the FDA for the treatment of fine wrinkles, mottled hyperpigmentation, and tactile roughness of the skin.

and benzoyl peroxide has shown an increased efficacy and reduction of the antibiotic resistance of *P acnes*. The antibiotics must be stored in the refrigerator. The combination products, available in gel form, include 1% clindamycin–5% benzoyl peroxide (BenzaClin) and 3% erythromycin–5% benzoyl peroxide (Benzamycin). Azelaic acid (Azelex), a dicarboxylic acid with bacteriostatic and keratolytic properties, is approved for acne in the 20% cream formulation. It is particularly effective in treating patients with postinflammatory hyperpigmentation or concomitant melasma.

Systemic Antibiotic and Hormone Treatment of Moderate to Severe Acne

Topical acne medicines are a much safer alternative than oral antibiotics and have less potential for adverse effects. Topical therapy has its limitations, however. Oral antibiotic treatment should generally be continued for 4 to 6 months, and maximal clinical results may not be evident before 3 to 4 months.

Good candidates for oral antibiotic treatment include patients who:

- Have a lack of response to topical medications after a trial of at least 2 to 3 months.
- Have the inability to tolerate topical acne treatment.
- Have large numbers of inflammatory lesions after several months on topical treatment.
- Have severe nodulocystic acne.
- Have large numbers of inflammatory lesions located on the back or upper outer arms (hard-to-reach areas).
- Want quick relief from inflammatory acne.
- Are at increased risk of pigmentation changes or scarring.

Oral antibiotics are the standard of care in the management of moderate and severe acne and treatment-resistant forms of inflammatory acne (Level I; Strauss et al, 2007). *P acnes* is a biofilm-forming organism, and topical treatment is recommended along with oral antibiotics. Oral antibiotics used in the treatment of inflammatory acne include doxycycline and minocycline, which are more effective than tetracycline. There is evidence that minocycline is superior to doxycycline in exerting not only an antibacterial effect against *P acnes* but a direct anti-inflammatory effect as well. Trimethoprim-sulfamethoxazole and trimethoprim are also effective in instances where other antibiotics cannot be used (Level I; Strauss et al, 2007).

One study found that treatment with minocycline resulted in faster resolution of inflammatory acne lesions than tetracycline. The starting dose of minocycline (for tetracycline-resistant acne) is 50 mg at bedtime for 1 week; then the dose is gradually increased to 100 mg at bedtime. Once improvement is seen at 4 to 6 weeks, the dose can be decreased gradually every 6 to 8 weeks. The maintenance dose of minocycline is 50 mg once a day. Adverse effects include vertigo, dizziness, and ataxia (this antibiotic affects the vestibular apparatus of the inner ear). This effect can be avoided or decreased by starting the patient on a lower dose. Rare cases of blue-gray discoloration of the skin are sometimes seen in minocycline use. Other adverse effects associated with tetracyclines include serum sickness, hepatitis, and a lupus-like syndrome.

Doxycycline and minocycline are more lipophilic and can be taken with food without affecting most of the drug's activity. Doxycycline is a good choice for patients who develop erythromycin-resistant *P acnes* infection. Doxycycline should be taken with a full glass of water (if it becomes lodged in the esophagus it can cause ulceration). Adverse reactions to doxycycline include photosensitivity, GI upset, enterocolitis, rash, blood dyscrasias, and hepatotoxicity. If the patient's occupation or hobbies include plenty of sun exposure, another drug besides doxycycline should be considered. The patient must use strong sunscreen or sunblock while on this drug in addition to avoiding excessive sun exposure.

Tetracyclines should not be used on pregnant women and patients younger than 9 years of age because of the risk of tooth discoloration and inhibited skeletal growth. Another important factor to consider is that tetracyclines are labeled by the Food and Drug Administration (FDA) as potentially reducing the effectiveness of oral contraceptives (a potential medico-legal risk). Patients on oral contraceptives should use a reliable second method of birth control, such as condoms. Adverse reactions to tetracyclines include nausea, dizziness, rash, blood

dyscrasias, pseudotumor cerebri, photosensitivity, and hepatotoxicity. Antacids, dairy products, and iron- or magnesium-containing vitamins will inactivate tetracyclines because of their propensity for binding with those substances. Erythromycin is a macrolide antibiotic that prevents the production of bacterial proteins. Although erythromycin is effective, use should be limited to patients who cannot use the tetracyclines (pregnant women or children younger than age 8 years because of the potential for damage to the skeleton or teeth). The development of bacterial resistance is more common during erythromycin therapy (Level I; Strauss et al, 2007). Adverse reactions to erythromycin include nausea, GI upset, abdominal pain, anorexia, candidal vaginitis, hepatic dysfunction, rash, superinfection, and pseudomembranous colitis (rare). Because *P acnes* is quickly becoming resistant to erythromycin, this is usually considered a second-line agent.

The FDA has approved three types of birth control for acne. Norgestimate/ethinyl estradiol (Ortho Tri-Cyclen) uses estrogen combined with a progestin (norgestimate). It is available with different doses of progestin. Estrostep uses estrogen combined with a progestin (norethindrone). It is available with different doses of estrogen. Drospirenone/ethinyl estradiol (YAZ) uses estrogen combined with an artificial form of progestin (drospirenone). Although thromboembolism is an established risk for all forms of hormonal birth control, the FDA has concluded that birth control pills containing drospirenone may have an increased risk for thrombus formation compared with pills containing other progestins. Oral contraceptives are indicated for moderate acne in females who are 15 years of age or older and have acne that is unresponsive to topical medications. The female patient should have no known contraindications to hormonal therapy such as a history of thrombophlebitis or thromboembolic disorders, cerebrovascular or cardiovascular disease, breast or other estrogen-dependent neoplasms, hepatic tumor, or undiagnosed genital bleeding.

Severe

Severe acne should be referred to the dermatologist for aggressive treatment with isotretinoin, a vitamin A derivative that is indicated for severe recalcitrant nodular acne that has not responded to conventional therapy (including oral antibiotics). Isotretinoin induces sebaceous gland atrophy, normalizes follicular keratinocytes, reduces *P acnes* colonization, and has direct anti-inflammatory effects. It is one of the most potent teratogens known today (Category X) and carries huge medico-legal implications for the clinician when it is prescribed to females of reproductive age. The manufacturers of isotretinoin require all prescribers to join a program called iPLEDGE to minimize fetal exposure. The clinician should refer any female of potential reproductive age who is a candidate for isotretinoin therapy to the dermatologist for management. If the clinician decides to prescribe this drug to a reliable female of childbearing potential (physician consultation is highly recommended), the criteria for the iPLEDGE program must be adhered to. The risk and the benefits of therapy should be discussed with the female patient, including the possibility of pregnancy and contingency plans if she gets pregnant (including termination of the pregnancy).

Two negative pregnancy tests must be obtained within 1 week of prescribing the medication, and two forms of reliable contraception must be used (unless abstinence is the chosen method). Monthly pregnancy tests must be ordered thereafter. The patient must have maintained effective contraception for at least 1 month before, during, and after therapy. The most frequent adverse effect is cheilitis, which occurs in up to 90% of patients. Other adverse effects commonly seen during therapy (in up to 80% of patients) include dry skin, dry nose, dry mouth, pruritus, epistaxis, and an increase in skin fragility. The link between isotretinoin and depression remains controversial. Some state that it has been known to cause depression, psychosis, and, rarely, suicide. Because of this, the clinician may not want to prescribe this medication in patients with a history of these conditions. Patients who complain of headache should be evaluated for pseudotumor cerebri or benign intracranial hypertension. Corneal opacities and decreased night vision have also been reported while patients are on this medication. The incidence of hypertriglyceridemia is very high (one patient in four). Some patients develop elevated liver transaminases, and elevated blood sugar levels have been seen in patients with diabetes. Baseline laboratory testing, such as fasting lipids and liver function tests, should be done before treatment and follow-up testing should be done weekly (or biweekly) thereafter until the patient's response to therapy is known; then it can be done monthly.

The dose of isotretinoin is gradually increased to a maintenance dose. Only a 1-month supply of the drug should be prescribed for each visit. Isotretinoin should be taken with food. The medicine can be discontinued early if the acne nodule count is decreased by 70% or more. If the patient complains of moderate to severe myalgias, the medication must be discontinued immediately and follow-up laboratory tests must be done. After a period of 2 months or more off therapy, if persistent or recurrent severe nodular acne recurs, referral to a dermatologist is recommended. Isotretinoin will induce long-term remissions of acne in up to 40% of patients. Patients with acne fulminans should be referred and treated with prednisone, the drug of choice for this condition. For other drugs listed above, see Drugs Commonly Prescribed 7.4.

Other Medical Therapies

There are therapies other than or in conjunction with medications that may assist in the overall treatment of

the patient with acne. The surgical procedure of comedone extraction is common for the treatment of comedomal acne and may be used with topical retinoids. This extraction may be done manually using a comedone extractor. Beta-hydroxy acid peels may also be effective against comedonal acne. To reduce acne scarring, fraxel, laser resurfacing, dermabrasion, and subcision or punch grafting may help. In addition, dermal augmentation with autologous or nonautologous tissue may improve the appearance of atrophic scars.

Photodynamic therapy with the use of a blue light or intense pulsed light and aminolevulinic acid may be given every other week. Results are usually apparent after the second treatment.

Follow-up and Referral

Patients should be reevaluated in 4 to 6 weeks to monitor response and potential adverse effects of acne medication. Noncompliance issues should be addressed. Topical retinoids frequently cause skin dryness and irritation if not started gradually or if used incorrectly. The role of patient education is very important in the use of topical retinoids. Most patients are not willing to try it again after they experience skin irritation and the temporary flare-up of acne seen within 4 weeks of starting therapy. Female patients on oral antibiotics or isotretinoin should be monitored for continued use of reliable methods of birth control. There is no need to wait until the acne becomes severe enough before considering referral to a dermatologist. Severe acne or moderate acne that is unresponsive to conventional treatment should be referred to a dermatologist for more aggressive treatment to minimize scarring.

By the third month of treatment, clinical improvement of acne lesions should be visible. If no improvement is seen or if the acne worsens, topical treatment with two agents or systemic therapy should be considered. The chances of skin irritation are increased when two topical agents are combined; therapy should be started slowly to minimize these effects. Systemic oral antibiotic treatment should generally be continued for a period of 4 to 6 months. Without treatment, acne lesions can last months to years.

Patient Education

Patient education is a vital and important component in acne treatment because of the long duration of treatment and potential for adverse effects (some serious). Patients and parents (if the patient is younger than 18 years) should be warned of potential adverse effects of oral acne medication (as discussed under Management). Table 7.9 presents patient education information. Patients should be encouraged to read product labels and to only use noncomedogenic (non–acne-causing) products, makeup, moisturizers, sunscreens, and so forth.

Patients on oral contraceptives for acne therapy should be aware of potential drug interactions, which include decrease in their efficacy when used in conjunction with certain antimicrobials, including the tetracyclines. Oral contraceptives should not be used in breastfeeding patients.

Table 7.9 Patient Education: Acne

- Wash the face gently at least twice a day with an antibacterial soap (Dial, Lever 2000) or with a very mild soap (Dove soap).
- Wait at least 30 minutes after washing the face before applying topical acne medications in order to minimize the chance of skin irritation.
- Topical acne medications should not be used on sunburned or irritated skin, abrasions, cuts, or on eczematous skin. If these conditions are present, the medication can be temporarily stopped for a few days.
- Avoid contact with eyes, lips, angles of the nose, and the mucous membranes when applying topical acne medicines.
- Sunscreen should be used with all acne medications, especially in sunny climates and during the summer.
- Avoid oily makeup or oily hair conditioners or scalp products.
- Avoid excessive handling of the face and cradling phones on the chin.
- Avoid excessive scrubbing of the face.

ROSACEA

Rosacea is a chronic and progressive skin disorder in middle-aged and older adults that resembles acne. It is characterized by flare-ups that include three cutaneous components that may occur individually or concurrently. The first component is vascular in nature with persistent erythema primarily involving the central face. This may be followed after a period of time by the development of telangiectasia or clusters of small, superficial blood vessels. Flushing episodes may occur spontaneously. The second cutaneous component involves recurrent acneiform erythematous papules and pustules around the central face. The third component consists of connective tissue hyperplasia around the central face with discrete sebaceous gland hyperplasia (rhinophyma), consisting of persistent yellow papules particularly around the nose. Blepharoconjunctivitis may result if there is ocular involvement.

Rosacea is a lifelong condition that is usually exacerbated by sun exposure. Other environmental triggers include the following: hot or cold weather and wind; overheating during exercise; excessive alcohol ingestion or hot beverages; spicy or aged food products such as cheese; emotional stress; irritating cosmetics; hot baths, saunas, or hot tubs; smoking; caffeine; and excessive washing of the face. Rosacea and acne often look similar, may respond to the same treatments, and may coexist in the same patient.

Epidemiology and Causes

Although rosacea affects nearly 14 million Americans, fewer than 10% are diagnosed because patients confuse the symptoms with acne, sunburn, flushing, or a temporary rash. Rosacea is most common in persons aged 30 to 60 years who are of Irish, English, Scottish, Welsh, or eastern European ancestry. Women are three times more likely to develop rosacea than men, particularly the first cutaneous component. Patients sometimes have one or more close relative with the condition. Rosacea is idiopathic with no recognizable causes other than certain triggers that exacerbate the condition. Several researchers have suggested that *Helicobacter pylori,* an organism found in the stomach, may possibly be a cause, as well as the *Demodex* species of mite, which has been found in the hair follicles of patients with rosacea.

Pathophysiology

At present, the underlying pathogenesis of the vascular dilation characteristic of rosacea is not fully characterized. Inflammation, rather than infection, appears to be the primary mechanism, as shown through several lines of indirect evidence. For example, studies have failed to show consistent differences in *H pylori* seropositivity between patients with rosacea and unaffected controls. Moreover, the ability of amoxicillin-metronidazole-bismuth treatments to clear *Helicobacter* infection and improve rosacea symptoms has been attributed to the anti-inflammatory effects of metronidazole. This was similarly shown with tetracycline treatment of rosacea associated with *Demodex* mite infestations. Mite counts were not decreased with this treatment, although symptomatic improvement was evident. Moreover, the anti-inflammatory effects of tetracycline antibiotics have been well documented in the treatment of acne vulgaris.

Clinical Presentation

Subjective

Patients with rosacea usually do not seek out care because they think they have acne, sunburn, or a temporary rash. They usually present because they become intolerant of the persistent burning, itching, or stinging sensations. Patients with ocular rosacea complain of watery, irritated, or bloodshot eyes.

Objective

Initially the patient's forehead, cheek, nose, or chin may have a rosy hue without comedones. This is the central third of the face and is referred to as the "flush/blush" area. There may be inflammatory papules, pustules, and telangiectasias. Scarring is usually inapparent unless the patient also has concomitant acne. Although the lesions tend to be symmetrical bilaterally, they may also appear on only one side. Seborrhea may also be seen. If there has been ocular involvement resulting in blepharoconjunctivitis, there will be redness of the eyelids and conjunctiva.

With prerosacea, the clinician will note a rosy-cheeked ruddy complexion on a patient who never develops the full clinical spectrum of the disease. There is no effective treatment for prerosacea, nor is any needed. Patients should just be observed for signs of developing rosacea and encouraged to use sunscreen.

There are four subtypes of rosacea classified by the pattern or grouping of symptoms:

Subtype 1: Erythematotelangiectatic rosacea—flushing and persistent redness, which may include visible blood vessels

Subtype 2: Papulopustular rosacea—persistent redness with transient bumps and pimples

Subtype 3: Phymatous rosacea—skin thickening usually with hyperplasia of the nose resulting in a large, bumpy, and bulbous appearance

Subtype 4: Ocular rosacea—ocular manifestations with dry eye, tearing and burning, erythematous eyelids, recurrent styes, and the possibility of vision loss from corneal damage

Diagnostic Reasoning

Diagnostic Tests

There is no diagnostic test for rosacea; physical assessment is the key to diagnosis. Although there is no cure for rosacea, if treatment is started early, some of the cutaneous manifestations may be prevented.

Differential Diagnosis

Differential diagnoses include adult acne, perioral dermatitis, seborrheic dermatitis, the "butterfly" rash of systemic lupus erythematosus, and steroid-dependent facial dermatoses. Acne may be a concomitant condition along with rosacea, but acne is characterized by the presence of comedones, a lack of facial flushing and telangiectasias, and a broader distribution around the face than the limited central distribution of rosacea. Perioral dermatitis is typically seen in young women, although it may occur in women aged 15 to 40 years. Multiple acneiform papules are seen around the mouth with a clear area spared directly around the lips. The small erythematous papules or pustules of perioral dermatitis lack telangiectasias. Seborrheic dermatitis usually has a scaly appearance not seen in rosacea. The erythema is without acneiform lesions and may be distributed throughout the nasolabial area, eyebrows, and scalp. The "butterfly" or malar rash of systemic lupus erythematosus lacks papules and pustules, and laboratory evaluation typically verifies the presence of antinuclear antibodies. Long-term topical steroid use on the face can result in burning erythema, sometimes associated with erythematous papules and/or scaling. When topical steroids are abruptly discontinued, a rebound flare-up of this condition typically occurs.

Management

The key to management is early diagnosis and avoidance of triggers because rosacea is a chronic condition with no known cure. Topical treatments should be the mainstay of therapy, with oral antibiotics used only for breakthrough flare-ups. Potent topical steroids should be avoided, because they may worsen the condition.

Topical Therapy

Metronidazole cream is the mainstay of therapy but may take up to 6 to 8 weeks for a therapeutic response. If metronidazole (0.75% or 1%) is not effective, topical clindamycin or erythromycin may be tried. (See Drugs Commonly Prescribed 7.4.) The same therapy is used for perioral dermatitis and topical steroid–induced rosacea.

Systemic Therapy

Antibiotics should be reserved for flare-ups or when initiating therapy with topical medications, and then antibiotics should be discontinued. Clinicians should taper the dose as soon as possible; typically patients readily learn how to taper the dosage at home. Treatment with tetracycline, minocycline, or doxycycline usually delivers a rapid therapeutic response. Antibiotic therapy is usually effective in reducing acneiform lesions, and this helps confirm the diagnosis of rosacea. These antibiotics typically work more as anti-inflammatory agents rather than antibiotics. The flushing of rosacea and the flat telangiectasias tend to persist and do not respond well to antibiotic therapy. In refractory cases, metronidazole, amoxicillin, or rifaximin may be used. Isotretinoin may succeed when other measures fail.

Other Therapies

Electrocautery with a small needle may be used to destroy small telangiectasias. Larger telangiectatic vessels may require lasers (intense pulsed light therapy). For men with rhinophyma, surgical reduction may be used to reduce the bulbous appearance of the nose.

Follow-up and Referral

Patients should be referred to a dermatologist if rosacea results in telangiectasias for electrodesiccation or laser treatment for cosmetic purposes. A dermatologist may also help patients with diffuse facial erythema due to rosacea with pulsed light therapy.

Patient Education

Patients should be taught about the events or circumstances that can trigger a rosacea flare-up and learn how to avoid them. Sunscreen with a sun protection factor of at least 15 should be used on all exposed skin surfaces when outdoors. Patients should stay cool on hot days and protect their face from cold air and wind by using a scarf. Caution should be used when exercising, and patients should be encouraged to exercise for shorter, more frequent intervals, using a cool towel around the neck and taking frequent water breaks. Gentle cleansing with fragrance-free facial cleansers should be encouraged. Proper use of topical creams and lotions should be stressed, along with the use of minimal antibiotics.

DERMATITIS

ATOPIC DERMATITIS

Atopic dermatitis (eczema) is not considered a distinct disease entity but is a descriptive term for a group of skin disorders characterized by pruritus and inflammation, whose distinct cause is unknown. *Eczema* is a more general term that is often used collectively to describe skin of an erythematous and inflamed appearance, reflective of a superficial pathological process. Currently, the terms *eczema* and *dermatitis* are often used synonymously in the clinical arena in a nonspecific sense. The use of the term *eczematous rash,* although also indistinct, may be helpful both diagnostically and therapeutically, because eczematous dermatitis may be classified into two major etiological categories—contact dermatitis and atopic dermatitis. Early in its presentation, atopic dermatitis is erythematous in appearance, with papulovesicular lesions that ooze and crust. At its later stages, the rash becomes a red-purple color, dries, and develops scaling and lichenification, which is exacerbated by itching resulting from its highly pruritic nature.

Epidemiology and Causes

Atopic dermatitis is a constitutional and inherited reaction, which usually begins in infancy. Interestingly, children born to older women are more likely to develop eczema than children born to younger women. For unknown reasons, the prevalence of atopic disease has risen steadily over the past 30 years, and the prevalence is now estimated at 1 in 18 or 5.5%, which amounts to 15 million people in the United States. About 10% of the U.S. population will have atopic dermatitis at some point in their lifetime. Atopic dermatitis presents more severely in childhood. Onset during the first year of life occurs in up to 50% of all patients; in 85%, onset is before age 5 years. Up to 5% of all children are affected by atopic dermatitis. Most cases (40%) resolve by adulthood, however. The remainder of patients with atopic dermatitis are affected with a chronic course of the disease that is characterized by acute exacerbation (often during times of stress) and intermittent remissions.

No ethnic predisposition has been found for atopic dermatitis, and it occurs equally in both sexes. The cause of atopic dermatitis is unknown. Family history is positive for atopy in two-thirds of all cases. Genetic predisposition may be the most important etiological factor in all-atopic conditions. A personal or family history of all

or part of the "atopic triad"—asthma, allergic rhinitis, and eczema—is often present. It has been proposed that individuals with any of these three conditions have preferential production of allergen-specific immunoglobulin E (IgE) and that the presence of such antibodies should be a mandatory criterion for the diagnosis of atopic dermatitis. Such a diagnostic test, however, only establishes the diagnosis of *atopic syndrome,* not atopic dermatitis. Any patient with a history of hives (urticaria), hay fever, or rashes should be considered to have an atopic history.

All atopic individuals seem to have itchier skin, yet what seems to be unique about the atopic patient's skin is its hypersensitivity. Many factors that do not make non-atopic individuals itch will make the atopic person feel itchy. Atopic patients are known to itch seconds after experiencing a stressful event. This type of reaction is thought to be caused by neuropeptide-induced vasodilation, which produces a rise in skin temperature and erythema. Symptoms are triggered or exacerbated through the interaction between genetic predisposition and environmental factors. Environmental factors that trigger atopic dermatitis include dust mites, animal dander, pollen, microbes, pollutants, climate, and emotional stress.

Excessively hot or cold climates or excessively dry or moist environments are particularly suitable for setting the stage for the atopic process. Anything that dries the skin can aggravate symptoms: Common triggers include excessive bathing, hand washing, lip licking, sweating, or swimming. Contact with irritants such as solvents, detergents, deodorants, tobacco, cosmetics, soap, and woolen and synthetic fabrics can precipitate an exacerbation of atopic dermatitis. Heat and sweat may also be aggravating factors for atopic dermatitis. Factors that generate an increase in body temperature include hot showers or baths, overdressing, use of heating pads, and electric blankets. Patients with atopy are intolerant of heat, have difficulty with thermal sweating, and are more likely to develop heat exhaustion. It is thought that perspiration retention might be a complicating factor in atopic patients. Excessive humidity is, therefore, a problem, because it interferes with normal evaporation of sweat from the body. Improperly fitting clothes can create friction and irritate the skin, and contact with certain fabrics, most notably wool, can precipitate a flare-up. Other skin conditions or infections can also lead to an exacerbation of atopic dermatitis (eczema).

Pathophysiology

The inflammatory process in eczema causes erythema of the skin as a result of dilated blood vessels that are surrounded by inflammatory cells that migrate into the epidermis, resulting in edema both inside and in between the epidermal cells (spongiosis). The epidermal cells malfunction as a consequence, resulting in thickening of the epidermis (acanthosis), excess production of keratin, and scaling. The outer epidermal layer of the skin, the stratum corneum, normally forms an impermeable barrier that protects the living cells beneath from environmental irritants and toxins. In atopic dermatitis, this outer barrier is impaired. There is an increase in the water loss and a decrease in water binding, which leads to a brittle outer barrier. This condition is made worse by environmental factors such as physical trauma from scratching, cycles of wetting and drying, and the chemical erosion that is caused by detergents and solvents. In addition, superinfection of eczematous skin by bacterial (e.g., *Staphylococcus aureus*) or fungal (e.g., *Malassezia furfur*) species and irritation from dust mites and their dung is an important factor that worsens atopic dermatitis by potentiating the immune response. Superinfection is also much more likely in atopic dermatitis than in other forms of dermatitis such as psoriasis. Thus, infection may be thought of as both a trigger and a complication of atopic dermatitis.

Immunological abnormalities are key to the pathophysiology of the atopic response. These abnormalities can include elevated serum IgE levels, which are seen in 85% of affected individuals; hypereosinophilia; reduced cell-mediated immunity and antibody-dependent cellular cytotoxicity; slowed chemotaxis of neutrophils and monocytes; relative increase in the number of CD4-positive (CD4+) Th2 helper T cells that secrete interleukin-4 (IL-4); and a decrease in CD4+ T helper cells that secrete interleukin-2 (IL-2). Interestingly, however, in later stages of the immune reaction, Th1 helper T-cell activity, which enhances cell-mediated immunity, appears to play an increasing role. Th17 cells and their associated cytokines have also been implicated in this disease process, including in the protection against infection/colonization with superficial skin fungi and bacteria (e.g., *Staphylococcus*) containing superantigens that are thought to trigger dysregulated immune responses, resulting in eczematous lesions. However, reports in the literature are conflicting and have implicated Th17 cells in both pro-inflammatory and anti-inflammatory roles. Impairment of essential fatty acid metabolism has also been implicated as a causative factor of atopy.

Clinical Presentation

Subjective

Atopic dermatitis is characterized by an extremely low threshold for pruritus and has been referred to as "the itch that rashes." Almost always, the itch occurs before the rash appears, and scratching the rash only worsens it clinically. In fact, the cardinal sign of atopic dermatitis is severe pruritus, which is often extremely distressing in both the acute and chronic stages. In turn, the diagnosis of atopic dermatitis cannot be made without a history of pruritus, and if pruritus is absent, alternate diagnoses should be sought. The patient may report a personal or family history of other atopic conditions (asthma, allergic rhinitis). The patient usually reports a history of

episodic exacerbation of similar symptoms or of a childhood rash or eczema. The clinician should inquire about any exposure to known or unknown common antigens and irritants, regardless of the history. Individuals with atopic dermatitis are not immune to contact dermatitis; in fact, they are more susceptible to irritant reactions because of their impaired epidermal barrier layer. Often, the rash is reported as better in the warmer months and worse in the fall and winter.

Objective

Atopic dermatitis usually begins as infantile eczema, with lesions affecting the cheeks, face, and upper extremities. Erythema is often seen before pruritus. The acute lesions are often excoriated, maculopapular, and inflamed. In infancy and early childhood, oozing and crusting usually characterize the erythema. As the child becomes older, the disease can go into remission or change to a flexural distribution (antecubital fossae and neck area). Flexural eczema usually lasts until about age 4 to 10 years but may continue into adulthood.

In adults, eczema presents with symmetrical lesions that are crusting and excoriated. In the early stages, lesions may be erythematous, papulovesicular, edematous, and weeping. Later the rash becomes crusted, scaly, thickened, and lichenified. Intergluteal involvement is uncommon and should raise suspicion of another diagnosis. The classic locations for lesions are noted to correspond to areas that are most accessible to rubbing and scratching. In addition, the typical flexural sites are more susceptible because they are areas that are more likely to be hot and moist. (See Advanced Assessment 7.2.)

Diagnostic Reasoning

Diagnostic Tests

Laboratory tests are usually not useful in the diagnosis of atopic dermatitis, but they can be helpful in ruling out other disorders or to confirm that a patient is prone to atopy (allergic reactions). If a viral etiology (e.g., HSV) is suspected, a viral culture should be done on the exudate and moist parts of the rash. If atopy (allergy) is suspected, a radioallergosorbent test (RAST) may be done on serum to quantify levels of allergen-specific IgE. The RAST test is usually available to primary-care clinicians, whereas the scratch (skin prick) tests are typically done only by trained allergists. However, interpretation of RAST test results requires specialized knowledge of the specificity and sensitivity of the assay, because false-positive results are not uncommon. Thus, RAST tests should not be ordered arbitrarily or as a general atopic screening tool; instead, they should be directed by a detailed patient history. RAST panels often include not only antigen-specific IgE levels but also antigen-specific IgG and IgM levels, which are not helpful in the diagnosis of atopic disease (hypersensitivity) and are, therefore, prone to misinterpretation.

Advanced Assessment 7.2 Atopic Dermatitis

Distribution

Infants: Trunk, face, extensor surfaces, scalp
Children: Antecubital fossae, popliteal fossae
Adults: Face, neck, upper chest, genital area, hands

Stages

Acute
Erosions with serous exudate
Intense pruritus
Papules and vesicles on an erythematous base
Pain, heat, tenderness

Subacute
Scaly, excoriated
Pruritus (may be intense)
Papules or plaques over an erythematous base
Secondary infection possible

Chronic
Lichenification, pigmentary changes (increased or decreased)
Pruritus
Excoriated papules and nodules
Dryness, fissuring

Other Clinical Manifestations

Keratosis pilaris ("chicken skin"): Asymptomatic follicular papules, particularly on the posterolateral aspects of the upper arms and lateral thighs
Lichenification of the skin: predilection for flexural creases
Ichthyosis vulgaris: Hyperlinear palms and soles and fishlike scales, especially on the lower legs
Dennie's sign/Morgan line: Infraorbital fold
Excessive fissuring under the earlobes, palms, soles, and fingers
Pityriasis alba: Hypopigmented asymptomatic areas on the face and shoulders
Allergic "shiners": Facial pallor and infraorbital darkening
Anterior capsular cataracts
Keratoconus: A cone-shaped cornea may develop in the second or third decade of life (in severe cases)
Facial erythema, dry skin, history of wool intolerance, nonspecific hand dermatitis, and a tendency for skin infection (commonly impetiginization of excoriated skin)

A RAST test panel may include testing for allergy to dust mites, mold, ragweed, animal dander, tree pollen, and many other allergens. RAST testing also exists for food allergens, which are often highly relevant in pediatric patients; however, true IgE-mediated food allergies are far less common in adults. Thus, RAST tests are useful for patients who are suspected of having an atopic

history if ordered in a directed fashion by the patients presenting signs, symptoms, and environmental exposures (Level I; Leung et al, 2004). An atopic or allergic tendency is manifested by chronic or recurrent symptoms (in addition to dermatitis), which might include a history of allergic rhinitis (nasal congestion, chronic postnasal drip, sneezing, itchy nose) and asthma during childhood. Some patients will deny any allergic tendency but will report a history of frequent "sinus problems." The RAST test is usually positive in patients with a history of symptoms of atopic dermatitis, but it often does not correlate well with clinical symptoms. Results appear to vary with the type of allergen being tested. Another potentially helpful marker for atopy is serum IgE levels. Serum IgE levels are usually elevated during acute periods of dermatitis but may decrease during periods of remission. Higher levels of total serum IgE, however, also increase the tendency toward false-positive allergen-specific RAST test results.

Patients should be advised to stop all antihistamines for at least 2 weeks before undergoing allergen skin testing, because these medications will interfere with skin test outcomes and may lead to false-negative results. In addition, delayed-type hypersensitivity responses to epicutaneously applied antigens (as used in scratch and skin-prick tests) may be blunted in atopic skin during periods of disease activity, so scratch tests should be avoided during flare periods to avoid uninterpretable results. Alterations in cell-mediated immune responses may help explain the increased susceptibility of atopic patients to cutaneous viral infections, such as HSV, vaccinia, and molluscum contagiosum. Thus, atopic patients should be warned of their increased risk of these infections and encouraged to take measures to avoid future exposure.

If the diagnosis is confusing or if serious pathology (mycosis fungoides) is suspected, a skin biopsy can provide important information. The skin biopsy of atopic skin will reveal a thickened and hyperkeratoid epidermis, along with perivascular inflammation of the dermis. Patients with pustular superinfection should have their lesions cultured for antibiotic sensitivities if they do not heal in response to empiric therapy.

Differential Diagnosis

Both common and rare skin disorders can mimic atopic dermatitis. Common disorders include contact dermatitis, tinea infections (dermatophytosis), seborrheic dermatitis, and the early stages of mycosis fungoides (cutaneous T-cell lymphoma). In contact dermatitis, the characteristic linear or asymmetrical distribution of the skin lesions helps to distinguish this condition from atopic dermatitis. The location and characteristic ringlike, erythematous lesions with central clearing distinguish tinea corpora infections (ringworm) from atopic dermatitis. Mycosis fungoides skin lesions do not respond to topical steroids; therefore, lesions that do not respond to topical steroids after a minimum of 2 weeks of treatment should be referred for skin biopsy.

If none of the common skin disorders apply, rare systemic diseases and skin disorders that can mimic atopic dermatitis include gluten-sensitive enteropathy, acrodermatitis enteropathica, phenylketonuria, hyper-IgE syndrome, Wiskott-Aldrich syndrome, X-linked agammaglobulinemia, selective IgA deficiency, and Letterer-Siwe disease (see Differential Diagnosis 7.5).

Management

The primary aim in the management of atopic dermatitis is to control signs and symptoms because no cure exists at present. Management of dermatitis embodies the fundamental principles of dermatology: Precipitants should be eliminated, wet lesions should be dried, dried lesions should be hydrated, and inflammation should be treated with corticosteroids. The goals of management are to decrease pruritus, prevent secondary infection, and educate patients so that they can control the disease themselves. Crucial to management is a careful and systematic assessment of trigger factors. In addition, the critical importance of skin hydration cannot be overestimated, because chronic use and overuse of corticosteroids carry significant iatrogenic risks, including both local adverse effects (e.g., skin atrophy, local irritation, telangiectasias) and the potential adverse effects of systemic absorption (e.g., cataract formation, growth impairment, bone demineralization, adrenal suppression). The benefits of barrier-restoring therapies are highlighted in Nursing Research–Based Practice 7.2.

Nonpharmacological Management

Errors in bathing and moisturizing are by far the most common causes of persistent atopic dermatitis. To avoid excessive irritation and skin dryness, the patient should

Differential Diagnosis 7.5 Atopic Dermatitis

- Scabies
- Seborrheic dermatitis
- Allergic contact
- Tinea
- Psoriasis
- Ichthyosis
- Dermatitis herpetiformis
- Mycosis fungoides (cutaneous T-cell lymphoma)
- Netherton's syndrome
- Wiskott-Aldrich syndrome
- Acrodermatitis enteropathica
- Neurodermatitis
- HIV infection (especially in children)
- Phenylketonuria (if symptoms appear during the first year of life)
- Hyper-IgE syndrome
- Dermatomyositis

Valdman-Grinshpoun, Y, et al. Barrier-restoring therapies in atopic dermatitis: Current approaches and future perspectives. *Dermatol Res Pract,* Sept-Oct. 2012. Retrieved from http://dx.doi.org.ezproxy.fau.edu/10.1155/2012/923134

Atopic dermatitis is a multifactorial, chronic relapsing, inflammatory disease characterized by xerosis, eczematous lesions, and pruritus. The latter usually leads to an "itch-scratch" cycle that may compromise the epidermal barrier. Skin barrier abnormalities in atopic dermatitis may result from mutations in the gene encoding for the protein filaggrin, which plays an important role in the formation of cornified cytosol. Barrier abnormalities render the skin more permeable to irritants, allergens, and microorganisms. Treatment of atopic dermatitis must be directed to control itching, suppress inflammation, and restore the skin barrier. Emollients, both creams and ointments, improve the barrier function of the stratum corneum by providing it with water and lipids. Studies on atopic dermatitis and barrier repair treatment show that adequate lipid replacement therapy reduces inflammation and restores epidermal function. Efforts directed at developing immunomodulators that interfere with cytokine-induced skin barrier dysfunction provide a promising strategy for treatment of atopic dermatitis. Moreover, an impressive proliferation of more than 80 clinical studies focusing on topical treatments in atopic dermatitis has led to growing expectations for better therapies.

use mild emollients that are soap substitutes (e.g., Cetaphil) instead of soap. Some patients may insist that soap is necessary for cleanliness; they can be informed of studies showing that Dove soap was the least irritating among 18 soaps and detergent bars that were tested. Reducing exposure to water will minimize the drying effects to the skin; if soap is used, it should be limited only to the axilla, groin, and feet. No other national population bathes as much as Americans, and this practice has become more ritualistic than purposeful.

Personal habits such as excessive bathing can be detrimental because bathing is an effective way to remove the skin's protective oils. Older patients should take short, lukewarm showers and avoid long, hot baths, which are extremely desiccating. The use of bubble baths and fragrance-containing oils should be discouraged. Bath oils are of minimal benefit because whatever oil remains on the skin is wiped off with toweling. Minimizing contact with cosmetics, deodorants, detergents, and solvents should be stressed. Moisturizers are useful in helping to prevent water loss and are most effective when applied immediately after patting the skin partially dry after a short shower. Atopic dermatitis patients should be cautioned against using lotions and gels, because they contain alcohol, preservatives, and fragrance. Patients with atopic dermatitis should not use agents that contain lactic acid or other alpha-hydroxy/glycolic acids that can aggravate the condition.

Ointments (which contain petroleum jelly) form an occlusive layer and are more effective in preventing water loss than lotions. For less severe conditions or in hot, humid areas, creams that do not contain fragrance and have few preservatives are acceptable (e.g., Cetaphil cream, Eucerin, Dermabase, Unibase). Humidifiers are most helpful in cold and dry climates, but they can provide an environment that is conducive to increased dust mite and mold populations. Acaricide is an insecticide that is effective against dust mites; it can be used on all fomites (pillows, beds, sofas, etc.). After application, a thorough vacuuming, preferably with a high-efficiency particulate air–filtered apparatus, must be done to remove the insecticide. Antifungal cleaners for wet and damp areas are recommended for patients who are sensitive to mold. Acaricide and other pesticides/chemical treatments have not been shown to be consistently helpful and are *not* first-line preventive treatments.

Pharmacological Management

If the skin lesions are wet, are inflamed, or have exudate, wet soaks or compresses with cool tap water, Burow's solution (1:40 dilution), saline (1 teaspoon per pint of water), or silver nitrate solution (25.5%) can be used to dry out the lesions and provide comfort. Aluminum acetate solution (Burow's solution) can be applied as a compress for 20 to 30 minutes four to six times throughout the day. OTC topical corticosteroids should be immediately applied to inflamed areas after the soak. Prescription corticosteroid cream may be needed for more severe cases.

Given that dry skin lesions are most characteristic of atopic dermatitis, petrolatum or other emollients (e.g., Aquaphor healing ointment, Eucerin cream, Keralac lotion) should be applied not only to dry eczematous lesions, but also to all noninflamed areas of the skin, in order to maintain hydration. Colloidal oatmeal baths (Aveeno) are soothing and may also be helpful with more generalized lesions.

Although antihistamines are often used to relieve pruritus, they are usually ineffective in atopic dermatitis because histamine is not the only factor responsible for the mediation of pruritus in atopic dermatitis. The sedative effect of antihistamines may be more beneficial than its antipruritic properties if used at night. Individuals with atopic dermatitis have a tendency to scratch in their sleep, so sedation at bedtime may decrease the amount of scratching during sleep. If the patient does not obtain

relief from antihistamines, first generation H_1 blockers, such as ethanolamines (diphenhydramine) and phenothiazines (promethazine), are very sedating. Some tricyclic antidepressants, such as doxepin (Sinequan), have potent antihistaminic activity as well and are useful in urticaria and other forms of pruritus. An added benefit to using an antidepressant agent is the relief of depression that is not uncommonly seen to accompany atopic dermatitis. First generation sedating antihistamines are *not* generally recommended in children, however, because they have been shown to lead to daytime drowsiness and impair school performance in many cases, as well as have a paradoxical effect of inducing hyperactivity in some children. Thus, sedating patients at night for severe atopic dermatitis, urticaria, or other forms of pruritus only applies to adults.

Montelukast sodium (Singulair) at 5 to 10 mg/day may contribute to the treatment of atopic dermatitis in a patient with other forms of concurrent atopy. Montelukast is a leukotriene-receptor antagonist and inhibits eosinophil infiltration in the skin, a major histological characteristic in atopic dermatitis. Of note, however, montelukast is not FDA approved for the treatment of atopic dermatitis.

Corticosteroids are effective anti-inflammatory agents and usually are considered first-line pharmacotherapy for atopic dermatitis, although their use must always be preceded by optimal moisturizing, because restoring skin hydration is the most important step in breaking the itch-scratch cycle of atopic dermatitis. In addition, the use of emollients (e.g., petroleum jelly, Eucerin, Lubriderm) will enhance the absorption and effectiveness of topical corticosteroids. Applying topical corticosteroids after hydrating the skin (after a shower or bath) may increase their absorption up to 10-fold. A weak coal tar preparation applied over a corticosteroid ointment can also reduce itching at night.

Acute exacerbations can be treated with a potent to midstrength topical corticosteroid for a few days to quickly control acutely inflamed skin lesions, but the patient should switch to a weaker-strength agent when the lesion is under control. Medium- to high-potency topical steroids should not be used on the face or neck area because of potential adverse effects such as local irritation, atrophy of the skin, and telangiectasia. Skin atrophy is more likely to occur when potent topical corticosteroids are applied repeatedly to thin and highly absorptive inflamed skin. In some instances, hypopigmentation has been associated with the use of topical corticosteroids, especially in darker-skinned individuals, such as African Americans. Most cases of pigmentation changes are related to the underlying dermatitis, however, rather than the use of topical corticosteroids. Topical corticosteroids may also complicate treatment by masking underlying bacterial or fungal infections or impairing healing processes. Topical corticosteroids should never be used on ulcerated skin.

Systemic corticosteroids are rarely necessary for the treatment of chronic atopic dermatitis, but they may be useful for an incapacitating acute exacerbation or when large numbers of weeping lesions are present. In these rare instances, the patient may benefit from a short course of oral prednisone (40–60 mg per day for adults and 1 mg/kg per day for children). Short-term therapy with prednisone does not require tapering if it is limited to 5 to 7 days and the patient does not have a history of recent oral prednisone use. As the lesions dry, topical corticosteroids may be started. Of note, given the significant adverse effects associated with systemic corticosteroid use, such regimens should be considered a last resort and not used regularly. In some instances, the decision to use systemic corticosteroids to treat atopic dermatitis may signify the need for inpatient care to gain control of a debilitating exacerbation, particularly in pediatric patients.

When the acute inflammation subsides after 2 to 3 weeks, the patient should decrease the frequency of the topical corticosteroids and focus primarily on emollients such as petroleum jelly or Eucerin cream. The chronic use of topical corticosteroids (mid to low strength) should be limited to twice-weekly applications to any given area and should not be continued indefinitely.

Topical tacrolimus (Protopic) and the related agent pimecrolimus (Elidel), applied twice per day, have been shown to be effective and safe for use as second-line agents in atopic dermatitis (Level I; Leung et al, 2004). These are immunomodulating calcineurin inhibitors. Most patients experience a dramatic reduction of pruritus within 3 days of initiating treatment and significant improvement in quality of life. When used as long-term maintenance therapy, topical preparations reduce the number of flares of atopic dermatitis and the requirement for corticosteroid treatment (Level I; Leung et al, 2004). Of note, given limitations in the long-term safety data for these agents, including rare reports of malignancy, the FDA has issued a "black box" warning for tacrolimus and pimecrolimus, warning clinicians against continuous long-term use of these agents in any age-group and highlighting the lack of approval of these agents in children less than 2 years of age.

Aggressive treatment of atopic dermatitis may also include cyclosporine A (CyA), an immunomodulatory drug, which may be as effective as corticosteroids, with fewer adverse effects. It is indicated for patients who have failed to respond to at least one systemic therapy or in patients for whom other systemic therapies are contraindicated or are intolerable. Its use can be highly beneficial in severe cases, but renal function must be closely monitored, and treatment courses must be restricted to 8 to 12 weeks. Azathioprine (Imuran) may also be used for maintenance therapy, but hematological and hepatic function must be followed. As with systemic corticosteroids, the use of a systemic immunosuppressant, such

as CyA or azathioprine, for atopic dermatitis would strongly suggest the need for inpatient care to adequately control such an exacerbation.

Omalizumab (Xolair), an anti-IgE antibody that has been developed as an immunotherapeutic biological agent, has shown benefit in reducing atopy in highly allergic individuals, although it is not FDA approved to treat atopic dermatitis. In severe cases of atopic dermatitis, phototherapy with ultraviolet B radiation or PUVA photochemotherapy (psoralens with ultraviolet A radiation) may be used as an adjunct therapy. Lesions of patients with pustular superinfection should be cultured for antibiotic sensitivities if they do not heal in response to empiric therapy. Bacterial or fungal superinfections must be treated appropriately.

Complementary Therapy

Studies indicate that certain herbs may be of value in the treatment of dermatological conditions. These include chamomile, arnica, calendula, hamamelis (witch hazel), aloe vera, cardiospermum, *Mahonia aquifolium,* oak bark, bittersweet stalk, and capsaicin. Use of these herbs should be reserved for experienced practitioners in alternative health medicine because of the potential for allergic reactions.

Follow-up and Referral

If basic management of atopic dermatitis fails, referral to a dermatologist should be prompt. More aggressive treatment by a dermatologist is necessary for patients who have severe and extensive lesions or who do not respond to usual treatment with topical and/or systemic corticosteroids. Atopic skin is very susceptible to bacterial and viral infections. These patients may develop widespread herpes infections of the skin (eczema herpeticum, which may be life-threatening in children), and they should be protected from people with active herpetic lesions. During an exacerbation, patients may contract secondary bacterial infections, and empiric therapy with erythromycin or penicillinase-resistant penicillins is sometimes necessary.

Patient Education

Patients with atopic dermatitis should be educated to be vigilant in watching for the signs of secondary bacterial infection. The patients should be told to report it immediately so that an oral antibiotic can be prescribed. Education about the importance of environmental measures in the prevention of disease exacerbation should be emphasized. House dust mites, animal dander, and pollen are all identified as potential triggers based on IgE antibodies in the bloodstream of some patients and should be addressed when educating patients. Patients can be assisted in discovering ways to reduce sweating, such as reducing the amount of bedclothes at night; avoiding occlusive, hot garments; and keeping the living areas cool. Patients should be encouraged to recognize their stress "triggers" and to find measures to reduce their stress level, such as exercise.

Because *Staphylococcus aureus* colonizes the skin of more than 90% of patients with atopic dermatitis (compared with only 5% of persons without the disease), fingernails should be kept short, smooth, and clean. This may prevent the scratching, which exacerbates the inflammation that may allow microbes to be introduced into the skin. Patients should be informed that a change in seasons will cause exacerbations of their disease, especially during the fall. Patients can be reminded to use extra care in taking care of their skin at this time by upgrading to stronger moisturizers (from lotions to petroleum jelly). Refills of their medication should be ordered before recurrence of symptoms. The provider can assist the patient in developing a simple regimen of topical steroid therapy for acute exacerbations. Patients with frequent exacerbations of skin lesions on their hands should avoid occupations that require repeated hand washing, immersion in water, or other wet conditions.

Food allergies are a common aggravating factor in up to 20% of patients with atopic dermatitis and are more common in children. A dietitian should be consulted when patients are eliminating foods from their diet, because unsupervised food restriction may lead to malnutrition.

CONTACT DERMATITIS

Contact dermatitis is a common condition categorized as either *irritant dermatitis* or *allergic dermatitis.* Although both of these conditions can have similar presentations, the etiology of each disease is what differentiates the two dermatitides. *Allergic contact dermatitis* is immunologically mediated, whereas *irritant contact dermatitis* is the result of repeated "insults" to atopic skin from caustic, irritant, or detergent-type substances.

Epidemiology and Causes

Almost any substance may induce a cutaneous reaction depending on its concentration, the duration of contact, and the condition of the contacted skin. The etiology of allergic contact dermatitis may be from antimicrobials such as neomycin, antihistamines, anesthetics such as benzocaine, hair dyes, preservatives, latex, or adhesive tape. The etiology of irritant contact dermatitis may be from soaps, detergents, or organic solvents. Irritant contact dermatitis accounts for about 80% of all cases of contact dermatitis.

Delayed-type hypersensitivity reactions are immunological responses to contact allergens that occur in sensitized individuals. One of the most frequent causes of allergic contact dermatitis is from plants in the *Rhus* genus, which includes poison ivy, poison oak, and poison sumac. Other common topical sensitizers include ragweed pollen, dust mites, ethylenediamine (a stabilizer in many topical creams), potassium dichromate,

paraphenylenediamine (dyes), nickel (10% of females are allergic to nickel found in jewelry), rubber compounds, and benzocaine (an OTC topical anesthetic for itching or pain). It is estimated that there are more than 6 million chemicals in the environment and that approximately 3,000 of them are potential sensitizers.

Contact dermatitis accounts for 4% to 7% of all dermatology consults. Hand dermatitis affects 2% of the population at any given time, and 20% of female patients will be affected at least once in their lifetime. Contact dermatitis is more common in adults than in children, and effects are more extreme in elderly patients. Women are twice as likely as men to develop dermatitis and are at highest risk after childbirth. White Americans are affected more frequently, and fair-skinned redheads are the most vulnerable population.

Pathophysiology

Contact dermatitis is considered either allergic or irritant induced. A delayed-type hypersensitivity response (type IV immune reaction) elicits a non–IgE-mediated allergic response to specific antigens when applied to the skin, producing a local reaction characterized histologically by epidermal changes including intracellular edema, spongiosis, and vesiculation. On initial contact with the offending agent, the antigen is taken up and processed by epidermal antigen-presenting cells known as Langerhans cells. These cells present antigens to naïve, antigen-specific CD4+ and CD8+ T lymphocytes, located in regional lymph nodes that drain the affected areas of skin. Over approximately 10 to 14 days, sensitized T cells migrate from the lymph nodes to sites of antigenic exposure, where subsequent reexposure to the same antigen results in an allergic reaction mediated by cytokine release. This response with notable skin surface changes typically occurs within 12 to 48 hours of reexposure to the antigen.

Irritant contact dermatitis is the result of a direct cytotoxic effect of an irritant to the cells of the epidermis, with a subsequent inflammatory response in the dermis. The main pathological feature of contact dermatitis is intracellular edema of the epidermis, which may result in intraepidermal vesicles and bullae formation in the acute phase. In chronic cases, papules, scaling, and lichenification occur. Irritants penetrate and disrupt the stratum corneum and injure the underlying epidermis and dermis as various immune cells congregate around dilated capillaries, contributing to the inflammatory process.

Rubber-glove dermatitis demonstrates the spectrum of pathophysiological mechanisms involved in contact dermatitis. Chemical irritants used in the glove manufacturing process (e.g., thiram, mercapto derivatives) may cause an allergic dermatitis via a delayed-type T-cell–mediated hypersensitivity reaction. In addition, rubber glove components may result in a direct irritant effect on the moist skin of glove-wearers. Finally, the natural rubber protein *latex,* once widely used in medical products, may elicit a profound IgE-mediated immediate hypersensitivity response, leading to systemic anaphylaxis and even death.

Interestingly, people with venous stasis (i.e., impaired venous return with pooling of blood in distended veins, particularly in the lower extremities) are more susceptible to irritant contact dermatitis, particularly from wood alcohols such as lanolin, fragrances, topical antibiotics such as neomycin, and methylparaben preservatives. Correctly diagnosing this condition is often difficult because contact dermatitis is often indistinguishable from stasis dermatitis.

Clinical Presentation

Subjective

The cardinal symptom of contact dermatitis is a pruritic erythematous rash. Often, the patient is not aware of a previous history, but there may have been periodic episodes of pruritic rash that resolved spontaneously. The patient may or may not be able to describe the conditions or substances contributing to the dermatitis, but exposure history to known or unknown common antigens and irritants should be sought by the clinician. In allergic contact dermatitis (in contrast to atopic dermatitis), the inflammatory reaction on the skin occurs much faster, typically within 6 to 12 hours of reexposure. In contrast to allergic contact dermatitis, irritant reactions do not always occur immediately after contact with the offending substance. The response time between the initial contact with the irritant and the symptoms is variable, and the severity of the reaction depends on the concentration, amount, and length of exposure to the irritating substance.

Objective

Contact dermatitis presents with inflammation of the epidermis and is manifested by erythema (as in all types of dermatitis), but it does not present with the smooth, intact epidermal surface that characterizes hives (urticaria). The epidermal inflammation seen in acute contact dermatitis results in rough, reddened patches but without the thickening and discrete demarcation of psoriasis. The acute lesions of contact dermatitis are characterized by weeping lesions with numerous tiny vesicles on an erythematous base that is pruritic or has a burning or stinging sensation. The surrounding area in severe cases is also erythematous, with edema and increased heat in the area, making it difficult to rule out secondary bacterial infection in some cases.

Lesions in nonallergic and delayed-type hypersensitivity contact dermatitis present in similar fashion, but the typical distribution and the lack of an atopic history are the most helpful factors in the diagnosis. A clothing- or detergent-related cause should be suspected if the lesions are generalized and primarily affect the borders

of the axillae, waist, and upper thighs. Reactions to toxic plants (e.g., *Rhus* or *Toxicodendron* species) follow a history of exposure. The characteristic rash is vesicular and linear (or asymmetrical) and is frequently found on the hands and ankles. *Rhus* dermatitis lesions are sometimes found on the facial area if the patient has inadvertently scratched the face with contaminated fingers. Lesions in an area where jewelry has been worn recently (e.g., neck, wrist, earlobes) may indicate a hypersensitivity to nickel. Usually, the area of skin that has been the most heavily contaminated will break out first, followed by areas of lesser exposure. The location of the rash gives the clinician the best clues to the possible etiological agent. For example, a patient with a rash on the scalp and the back of the neck might report a history of the use of a new shampoo, a new hair dye, or other scalp or hair treatments. (See Advanced Assessment 7.3.)

Diagnostic Reasoning

Diagnostic Tests

Diagnosis of contact dermatitis is based on the history of exposure to an irritant or allergen and the subsequent appearance of a rash on the exposed skin, either immediately or later on (delayed hypersensitivity). If scabies is suspected, skin scrapings can be examined under a microscope to rule out that condition. If tinea (corporis, cruris, pedis, manuum) infection is suspected, skin scrapings should be treated with potassium hydroxide (KOH) and gently heated. A microscopic exam for tinea infection should search for hyphae and spores. If bacterial infection (impetigo) is suspected, cultures should be taken from the moist areas of the rash or from the discharge. Viral cultures can be done to rule out suspected viral etiology (herpes simplex, herpes zoster).

Advanced Assessment 7.3 Contact Dermatitis

Stages
Acute
Erythema and edema
Clear, fluid-filled vesicles or bullae
Exudate, clear fluid
Distinct margins
Subacute
Lessening edema
Formation of papules
Less distinct margins
Chronic
Minimal edema
Scaling skin
Lichenification
Minimal erythema

Laboratory tests that are done by specialists (allergist) include the scratch and intradermal tests. Scratch (skin-prick) tests should not be done during an acute episode of contact dermatitis because of an increased rate of false-positive reactions. The patch test performed by a dermatologist is useful to identify specific irritants in patients with histories that are suggestive of acute contact dermatitis. Allergens that are commonly responsible for such reactions are fixed in dehydrated gel layers and taped against the skin of the patient's back for 48 hours and then removed. A final reading done at 72 to 96 hours after initial application will usually reveal any evidence of contact dermatitis. In some patients, a CBC with differential will show eosinophilia, but this blood test is neither sensitive nor necessary for the diagnosis. Skin biopsy is rarely necessary for diagnosis, particularly in the setting of a convincing contact exposure history.

Differential Diagnosis

The differential diagnosis of contact dermatitis is similar to that for atopic dermatitis and includes both common and rare disorders. Common disorders that have a similar presentation to contact dermatitis include seborrheic dermatitis, impetigo, and herpes zoster. Seborrheic dermatitis rashes, although erythematous, have a greasy and scaly appearance and appear only in certain areas of the body such as the hairline, the ears, the scalp, and the face. Impetigo, which is caused by gram-positive *Staphylococcus* or *Streptococcus* bacteria, is more common in children. A honey-colored crust is seen on top of the erythematous lesions; impetigo also does not have a linear appearance like contact dermatitis. Herpes zoster is more common in older patients, and the lesions appear as multiple small vesicles on an erythematous base. Although herpes zoster has a linear distribution, it is more likely to occur on the trunk area (contact dermatitis occurs more often on the hands or face) and will follow the path of a dermatome.

Management

The clinical challenge in the treatment of contact dermatitis is to provide symptomatic relief to the patient while attempting to identify the underlying allergic precipitant. Identifying the antigen or irritant in contact dermatitis is critical, both to eliminate or minimize the current contact and to avoid future exposure (Level I; Beltrani et al, 2006). The responsible irritant should be identified and eliminated to prevent the cycle of itching, scratching, and skin disruption, which can lead to chronic changes in the skin. A careful history of exposures is key in addition to a thorough skin examination. The effects of *Rhus* dermatitis (from poison ivy, poison oak, or poison sumac) may be lessened if the exposed skin is thoroughly rinsed in soap and water or with isopropyl alcohol, as soon as possible after exposure. Exposed clothing should be discarded.

For localized contact dermatitis with weeping lesions, treatment with moist compresses and simple drying agents or antipruritic lotions (e.g., Burow's aluminum acetate solution, Calamine lotion) applied several times a day is usually effective. For more extensive and severe cases, potent topical steroids in cream form (avoid the use of ointments on wet lesions because they can cause skin maceration) can be applied twice daily for the first few days to help decrease pruritus and inflammation. If treatment is necessary beyond 2 weeks, a less potent (mild or moderate) topical steroid may be used twice daily until the rash resolves. High-potency steroids should not be used on the face or in bodily folds (intertriginous areas) because of their ability to thin the skin and cause hypopigmentation.

Oral systemic steroids may be indicated in acute and particularly severe cases of contact dermatitis offering relief within 12 to 24 hours (Level I; Leung et al, 2004). Relatively high doses of oral prednisone can be given for 10 to 14 days (or up to 21 days in the most severe cases). Abrupt cessation of high-dose systemic corticosteroids that are given for more than 5 days' duration should be avoided. Potential adverse effects of oral prednisone therapy are more likely with long-term use and may include any of the following: suppression of the hypothalamic-pituitary-adrenal axis, hypokalemia, hypocalcemia, masking or worsening of infection, increased likelihood of secondary infection, carbohydrate intolerance and worsening of diabetes, glaucoma, cataracts, osteoporosis, dermal atrophy, skin hypopigmentation, and psychiatric disorders including depression, euphoria, or even acute psychosis. It should also be noted that even systemic steroids will likely prove ineffective if exposure to the offending allergen or irritant is not limited.

Follow-up and Referral

Follow-up and referral are determined by the patient's condition and response to therapy. Severe cases should be referred to a dermatologist or an allergist.

Patient Education

The provider should teach the patient and family about the disease and the appropriate use of medications, as well as adverse effects or exacerbations that should prompt the patient to contact the health-care provider. The mainstay of prevention is helping patients identify the agents causing the dermatitis and teaching them to avoid exposure or to use protective clothing and gloves.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is one of the most common skin conditions seen in primary care among adults and the elderly. It is a chronic condition that is marked by remissions and exacerbations. Seborrheic dermatitis commonly manifests in patients with HIV infection. A severe or resistant case on a patient should prompt investigation for risk factors of HIV infection. The rashes of seborrheic dermatitis are seen on skin that is rich in sebaceous glands. (It is associated with an increased production of sebum.) The affected skin is pink, edematous, and covered with yellow to brown scales and crusts. These rashes are most easily seen on the scalp, the forehead, the eyebrows, and the area surrounding the nose and the ears.

Epidemiology and Causes

Seborrheic dermatitis affects approximately 2% to 5% of the adult population. It runs in families and has a known genetic component. It may be an inflammatory reaction to *Malassezia furfur* yeasts. The occurrence of seborrheic dermatitis is most common during early infancy on the scalp ("cradle cap"), after the second decade of life, and in the elderly or immunocompromised patients. A strong association with HIV infection and AIDS is well established.

Pathophysiology

This type of dermatitis was originally defined by excess oil secretion from the sebaceous glands and is thus found on areas of the body where such glands are most concentrated, that is, in decreasing order, the scalp, face, chest, upper back, pubic area, and axillae. Interestingly, however, overproduction of sebum is not seen in all cases of seborrheic dermatitis, nor is the composition of the sebum the main factor in this condition. Skin biopsies typically reveal parakeratotic scale heaped around hair follicles and an inflammatory lymphocytic infiltrate. Thus, mild epidermal hyperproliferation has been cited as a contributing factor. However, it is not known whether this occurs in response to infection by saprophytic skin fungi or vice versa.

Malassezia furfur commonly colonizes affected individuals. Recurrence of symptoms has been linked to an increase in the number of *M furfur* organisms found on the skin surface. Fungal-specific stains of affected skin reveal large numbers of *M furfur* spores within the stratum corneum, the uppermost skin layer.

Clinical Presentation

Subjective

The typical patient is an adult male who complains of a pink, scaling rash located on the face and scalp. Seborrheic dermatitis can also be an incidental finding; some patients, especially elderly patients, are not bothered by the cosmetic effect of the rashes. The lesions are usually asymptomatic in most patients, but pruritus may be present (and is aggravated by perspiration), especially in scalp lesions.

Objective

Seborrheic dermatitis presents as scaly patches that may be slightly papular; each patch is surrounded by erythema. The lesion borders are poorly defined, and the

scales may be greasy and appear yellow. The most frequently involved area is the scalp, and the condition is differentiated from common dandruff (pityriasis sicca) by the appearance of erythema, which may be minimal or moderate. The affected areas may include the forehead at the hairline, eyebrows, nasal folds, and the retroauricular and presternal areas. In more severe cases, intertriginous areas, as well as the external ear canal and umbilicus, are involved. The rashes may be more difficult to recognize in fastidious patients because daily bathing removes some of the scale.

Diagnostic Reasoning

Diagnostic Tests

Diagnosis of seborrheic dermatitis is based on clinical findings and the history. Dermatologists and allergists can test for *Malassezia furfur* using antigen-specific skin-prick or serum RAST testing. Fifteen percent to 65% of patients with seborrheic dermatitis have positive responses to skin-prick tests with *Malassezia* extracts. *Malassezia* antibodies have also been found in young adults with head and neck dermatitis. Fungal-specific periodic acid Schiff and Gamori Methenamine Silver stains identify hyphae and spores in skin scraping or biopsy samples; however, these specialized stains typically require specialist referral and are not commonly used in the primary-care setting. Rather, the diagnosis of seborrheic dermatitis is most commonly based on the characteristic appearance and distribution of the rash, as well as its response to empiric therapy.

Differential Diagnosis

Skin conditions that mimic seborrheic dermatitis include impetigo, atopic dermatitis, psoriasis, scabies, tinea capitis, and Langerhans cell histiocytosis. A history of the same rash recurring at characteristic locations on the body (e.g., the scalp and hairline, sides of the nose and upper lip, eyebrows and eyelashes, cheeks, or ears) will give the clinician the best clues to identify seborrheic dermatitis correctly. Impetigo, a bacterial infection of the skin caused by *Staphylococcus* or *Streptococcus* bacteria, has an acute onset and tends to occur on the extremities (a location not seen in seborrheic dermatitis) or on the face. The most useful distinguishing feature between atopic dermatitis and seborrheic dermatitis is the increased number of lesions on the forearms in the former, compared with the increased number of lesions in the axillae in the latter. The erythema of seborrheic dermatitis typically has a pinkish hue, rather than the bright-red appearance of psoriasis.

Seborrheic dermatitis is also associated with several chronic conditions, including Parkinson's disease, HIV infection and AIDS, phenylketonuria, cardiac failure, zinc deficiency, and epilepsy. Other dermatological disorders, such as acne vulgaris, rosacea, and psoriasis, may also be associated with these diseases, however. Importantly, florid manifestations of seborrheic dermatitis may be an early cutaneous indicator of HIV infection, and these patients may demonstrate extensive symptoms that are often resistant to therapy.

Management

The high incidence and chronic benign nature of seborrheic dermatitis present a therapeutic challenge. Mild to moderate cases do not seem to bother some patients, especially elderly patients who frequently refuse treatment or are noncompliant. Younger patients who are bothered by the cosmetic effects of the rashes on the face frequently request treatment. The therapeutic approach is aimed at managing symptoms and reducing the yeast count on the skin.

The regular use of an OTC dandruff shampoo is sufficient to control most scalp symptoms. The preparations must remain on the scalp for at least 5 to 7 minutes to be effective. Commonly used ingredients in these products include selenium sulfide, zinc pyrithione, tar, salicylic acid, sulfur, or ketoconazole. Zinc pyrithione and selenium sulfide are classified as keratolytic agents. They appear to be both fungicidal and cytostatic. The combination of sulfur and salicylic acid has keratolytic, antifungal, and antiseptic actions. Coal tar agents must be used with caution in fair-haired persons because they may cause an undesirable change in color.

Resistant seborrheic dermatitis may require a prescription shampoo. A 2.5% selenium sulfide shampoo, a ketoconazole shampoo (Nizoral shampoo), and a detoconazole shampoo are available. Keratolytic or oil-based lotions are recommended to soften heavy crusts.

A topical corticosteroid may be necessary when significant erythema is present. Hydrocortisone cream 0.5% to 1.0% (OTC) for the face or betamethasone valerate 0.1% for the scalp should be applied after cleansing. Facial application and long-term use of topical corticosteroids should be avoided because of the risk of telangiectasia and dermal atrophy. These risks are not present with the topical use of ketoconazole. Exudative lesions may require compresses of Burow's solution applied for 30 minutes three times daily. Ketoconazole shampoo every other day is recommended for resistant cases. Ketoconazole 2% cream may be applied to the affected areas twice daily when there is facial or chest involvement.

Calcineurin inhibitors that lower the activity of the immune system may be effective for recalcitrant cases although these drugs are not FDA approved for seborrheic dermatitis. Such agents include tacrolimus (Protopic) and pimecrolimus (Elidel), which are available in topical formulations. As indicated for second-line therapy in atopic dermatitis, the FDA cautions against the chronic, long-term use of these medications in any age group, given concerns over their long-term safety, including rare reports of malignancies.

Once symptoms resolve, maintenance therapy may be required with a once to twice a week application. The prophylactic use of a ketoconazole shampoo (Nizoral) once a week is safe, easy, and at times very rewarding. For a superinfection of gram-positive skin bacteria, cephalexin 7 to 10 days is required.

Because a strong association with HIV infection and AIDS is well established, treating the underlying HIV infection with effective antiretroviral therapy is often the key to resolution of the patient's skin findings.

Follow-up and Referral

Repeated secondary infections or resistance to standard management require a prompt referral to a dermatologist.

Patient Education

Patients should be reassured that seborrheic dermatitis is not contagious or progressive. They must, however, understand the chronic nature of the condition and the need for continued management. The role of emotional stress in acute flare-ups should be explained. If topical steroids are used, the patient needs to be instructed in the proper application and the potential adverse effects. A list of effective OTC preparations should be provided, so each patient can select one that meets his or her personal preferences. Daily shampooing of oily hair is recommended for the first week, decreasing to two or three times a week as maintenance therapy.

PSORIASIS

Psoriasis is a chronic relapsing disorder of keratin synthesis that is characterized by well-circumscribed, raised, erythematous papules and plaques, covered with silvery-white scales, usually involving extensor areas in adults such as the elbows and knees, the scalp, and, in some forms, the flexural surfaces of the body. The phrase "heartbreak of psoriasis" was coined because of the physically and emotionally disabling effects of the disease. The more commonly seen variants of psoriasis are plaque, guttate, inverse, pustular, and erythrodermic psoriasis. Inflammatory arthritis may complicate this condition in 10% to 20% of cases. Plaque psoriasis is the most common form in young adults, which presents as erythematous lesions with well-demarcated margins, topped with a thick, silvery scale. Plaque psoriasis accounts for approximately 80% of all cases of psoriasis. Guttate psoriasis is more common in children, presenting as an acute eruption of multiple, smaller plaques (less than 1 cm). Inverse psoriasis is characterized by localization of psoriatic plaques to flexural (intertriginous) surfaces. Pustular psoriasis is the most serious form characterized by widespread scaling with a sheet of superficial pustules. Erythrodermic psoriasis may be considered a separate entity or as the most severe form of pustular psoriasis, which may be life threatening and is associated with chronic immunosuppression (e.g., HIV disease). Bright-red erythema affecting a large portion of the skin surface is the most prominent feature of erythrodermic psoriasis, which may present with variable keratotic scale and the presence of pustules.

Epidemiology and Causes

Psoriasis affects almost 3 million Americans annually and 2% to 4% of the population worldwide. Psoriasis is universal in occurrence, but the prevalence varies according to geography, race, and ethnicity. Geographical variations in prevalence (e.g., almost no cases in South Americans living in the Andes, nearly 3% of the population in Denmark) reflect the influence of both genetic and environmental factors. Psoriasis is less frequent among Asians and among North and South American native peoples compared with people of European ancestry. It is also less frequent among West Africans, which may help explain the low prevalence of psoriasis among African Americans. Prevalence is highest among Scandinavians, with rates being slightly higher in northern rather than southern Sweden, further supporting the role of climate and sunlight exposure in the expression of the disease. Prevalence of the disease in the United States is about 2% to 3% overall.

Adult men and women are affected with equal frequency. The two peak ages at onset are during the late teens to early 20s and in the late 50s to early 60s. Women and adolescent girls tend to have earlier onset than males. Earlier onset is associated with a more severe disease. There is little to no epidemiological evidence that psoriasis is mediated by infectious agents.

Psoriasis has a strong genetic influence, with one-third of patients with psoriasis reporting having a relative with the disease. In family studies, when one parent is affected, 8% of offspring develop psoriasis and tend to have earlier onset. When both parents have psoriasis, the percentage increases to 41%. The mode of genetic transmission is not yet defined, however.

Environmental factors are known to precipitate the disease among genetically predisposed patients and include trauma to normal skin that results in psoriasis in areas of repeated friction (Köbner's phenomenon), infections (upper respiratory infections, *Streptococcus pyogenes,* HIV), stress, fatigue, warm humid climate, sunlight, and certain drugs (systemic corticosteroids, lithium, beta-adrenergic blockers, NSAIDs, and antimalarials). Risk factors for psoriasis are listed in Risk Factors 7.1.

Despite intensive investigation, the cause of psoriasis remains unknown, but it is deemed to be a multifactorial disease, with genetic, environmental, biochemical, and immunological origins. Psoriasis, formerly theorized as an idiopathic skin disease, is now known to be a genetically controlled, immune-mediated chronic disease. Because cutaneous lesions of psoriasis were thought to result from unregulated hyperproliferative activity in the epidermis, for decades, treatment for psoriasis was

Risk Factors 7.1 Psoriasis

Trauma to Normal Skin (in patients with preexisting psoriasis) That Develops Into New Psoriatic Lesions (Köbner's phenomenon)
Physical, chemical, electrical, surgical, infective, or inflammatory insults
Infections
HIV, *Streptococcus*
Endocrine and Metabolic Factors
Postpartum period Hypocalcemia (e.g., after dialysis and parathyroidectomy)
Weather-related Factors
Extreme cold weather Prolonged exposure to sunlight* or hot, humid weather (more exacerbations occur in summer)
Medications
Systemic corticosteroids Lithium Beta-adrenergic blockers Antimalarial drugs NSAIDs
Psychogenic Factors
Psychological factors, e.g., stress, depression
Other Factors
Fatigue Alcoholism Smoking

*NOTE: Controlled exposure to sun/ultraviolet light can be therapeutic—see discussion in text.

primarily suppressive and was directed toward normalizing the hyperkeratinocytic activity.

Currently, the speculation is that genetically predisposed persons may experience clonal T-cell activation in response to antigenic stimulation. Proponents of this theory advance this view based on evidence that affected persons have an increase of various human leukocyte antigens (HLAs), particularly certain class I HLAs such as HLA-B27, which is also seen in patients with psoriatic arthritis, a form of inflammatory arthritis with redness and painful swelling of joints that may co-occur with psoriasis (although not all patients with psoriatic arthritis will have active skin manifestations). In addition, psoriatic plaques are rich in activated T lymphocytes that are capable of both cellular proliferation and inflammation.

Current research is focused on the role of T cells and the ability of cytokines to influence the dermal immune response to an as yet unidentified antigen. This focus is based on the finding that the immune-modulating agent cyclosporin is capable of improving psoriatic symptoms, which led to a rethinking of disease pathogenesis. The genetic components of the disease have been the subject of extensive research. One genetic region linking susceptibility to psoriasis in some individuals has been isolated to chromosome 6, and the first non–chromosome 6 gene marker for psoriasis has been identified on chromosome 17q. Others have identified possible DNA loci on chromosomes 4, 8, and 16. Thus, a primary goal of current psoriasis research is to elucidate fully the interplay of genetic and environmental influences on the errant cellular effects seen in the disease.

Pathophysiology

Microscopic examination of psoriatic plaques typically reveals thickened stratum corneum with hyperplasia of the epidermis and little inflammation. The basic pathology of psoriasis is the uncontrolled hyperkeratinization of the stratum corneum layer of the skin. Hyperproliferation of keratins 6 and 16 (common to reactive and healing skin) predominates, whereas expression of keratins 1 and 10 (typically found in normal skin) is reduced. The psoriatic process occurs in varying degrees and results in a wide range of clinical symptoms. If increased mitosis or hyperkeratinization predominates, the result is a thick, silvery scale because of the separation of corneocytes and the presence of air in between. Despite this epidermal hyperplasia and parakeratosis, however, the granular layer of the epidermis is significantly thinned or absent. In contrast, if vasodilation predominates, the result is a diffused red and hot, slightly scaling skin. Of note, these two processes may coexist.

There are three stages to the psoriatic process: (1) an increased mitotic rate that results in rapid cellular turnover and shortened transit time for the basal layer to the stratum corneum or epidermis (3–4 days, versus a normal 28 days); (2) dilation of upper dermal capillaries with intermittent extravasation of T cells and polymorphonuclear neutrophils into both the dermis and epidermis, leading to (3) the faulty keratinization and accumulation of the stratum corneum, which clinically presents as raised papules and plaques covered with white, silvery scales. Multiple growth factors (e.g., epidermal growth factor, transforming growth factor–alpha) and cytokines (e.g., interferon-gamma, IL-2, IL-6, IL-8, and IL-17) are overexpressed in psoriatic skin. Moreover, in plaque-type psoriasis, the T cells localized to the epidermis appear to express specific clonalities with regard to their antigenic receptors, implicating unrestrained T-cell replication in the pathogenesis of the disease. Interestingly, however, psoriasis is also associated with many causes of chronic immunosuppression and may be the presenting finding in newly diagnosed HIV infection—particularly the severe erythrodermic form.

Most recently, the importance of a novel subset of CD4 T helper T cells, known as Th17 cells, has been

highlighted in the autoimmune pathogenesis of psoriasis. Activated Th17 cells produce multiple cytokines, including IL-17, IL-21, and IL-22, and proliferate in response to IL-23. Several studies have demonstrated the importance of Th17 cells in fighting infection by extracellular bacteria and fungi. Thus, one theory is that dysregulated Th17 function leads to an exuberant immunoresponse to skin flora and ultimately the hyperkeratinization characteristic of psoriasis. In turn, Th17 cells have been isolated from psoriatic skin plaques. Work in this field is ongoing.

Drug-exacerbated psoriasis offers some insights into disease mechanisms. Lithium is believed to act by enhancing the release of inflammatory mediators from neutrophils. Beta blockers lead to psoriasis by decreasing cyclic adenosine monophosphate (AMP)—dependent protein kinase—an inhibitor of cellular proliferation. NSAIDs cause a buildup of the pro-inflammatory mediator arachidonic acid by inhibiting the enzyme cyclooxygenase. Antimalarials, the antifungal terbinafine, and angiotensin-converting enzyme inhibitors are also associated with exacerbation of psoriasis, although these mechanisms are unclear. Drug-induced exacerbations can be unpredictable and severe. Importantly, they are often delayed and may occur months after the start of drug use.

Clinical Presentation

Subjective

Patients with psoriasis usually present to the practitioner with concern over "itchy, red, inflamed and dry, scaly plaques that have gotten worse." Statements about the onset and course of the disease are highly variable for each individual. Symptoms usually begin gradually and are confined to only a few areas (one or both elbows, knees, buttocks, or scalp), but psoriasis can also be explosive in onset. One cause of an explosive onset is a preceding streptococcal throat infection, which can lead in 2 to 3 weeks to multiple, small, guttate lesions with a generalized distribution over the body. Once the disease appears, it follows an irregular, chronic, unpredictable course. It may remain localized to a few areas, or it may cause intermittent or continuous generalized lesions. Itching is usually not a problem in psoriasis, but it may be severe in some patients. These patients often notice blood stains on the bed linens from traumatic, inadvertent scratching of the plaques during sleep. Lesions often occur at sites of trauma (Köbner's phenomenon). A family history of psoriasis is elicited in one-third of patients, and 50% of these patients have an affected parent.

There are three tools commonly used to assess the severity of psoriasis:

- The Psoriasis Area and Severity Index (PASI) combines the assessment of plaque severity (erythema, induration/thickness, and scaling) and the skin surface area affected.
- The Dermatology Life Quality Index (DLQI) has the patient self-rate the impact of the condition on important aspects of the patient's life.
- Affected Body Surface Area (BSA) is an assessment of the overall skin area involved by percentage.

A Web site for accessing and automatically calculating disease severity scores using these tools is listed under Resources at the end of the chapter. The PASI is the most widely used tool in clinical research and practice settings.

Objective

Physical exam reveals lesions that are erythematous plaques surrounded by a thick, silvery scale (which is not easily removed), resembling mica. When these micaceous scales are traumatically removed, multiple small bleeding sites appear (Auspitz's sign). In intertriginous areas, maceration and moisture prevent dry scales from accumulating, but the lesions remain red and sharply defined.

Lesions usually are distributed symmetrically over areas of bony prominences such as the elbows and knees. Scaly plaques also occur frequently on the trunk, scalp, intergluteal cleft, and umbilicus. The latter three areas are frequently overlooked by the patient and clinician, but are important in making the diagnosis, especially in patients with associated psoriatic arthritis and limited skin lesions. The nature of such inflammatory arthritis may become apparent only after typical skin lesions are recognized.

A thorough examination of the entire skin surface is crucial, therefore, to the diagnosis and treatment of a patient with suspected psoriasis. Another helpful diagnostic feature is the Köbner's phenomenon, in which intense trauma induces formation of new skin lesions. Such isomorphic lesions can also be induced on the palms of patients whose hands are exposed to friction.

Nail involvement may include stippling or pitting of the nail plate or a yellow to red-brown coloring ("oil-staining") of the nails (nail psoriasis). An accumulation of yellow debris under the nails, simulating a tinea infection (tinea unguium), is seen in some patients. Swelling, redness, and scaling of the paronychial margins occur often and are associated with arthritis of the distal interphalangeal joints. The clinical course of this disease is characterized by chronicity and seasonal fluctuations, with improvement in the summer (due to sun exposure) and worsening in the winter as dry skin leads to epidermal injury.

Some patients with psoriasis (10%–20%) may suffer from inflammatory arthritis, although the most common form of arthritis seen in psoriasis patients is osteoarthritis. The inflammatory joint manifestations of psoriatic arthritis may occur when psoriatic skin lesions are present, or they may precede initial skin manifestations, with psoriatic arthritis being suspected in a patient

with inflammatory joint disease due to a family history of psoriasis. Associated inflammatory arthritis seen in psoriasis patients typically involves the distal interphalangeal joints of the hands and feet but may also involve the vertebrae of the spine, as seen with another form of seronegative (i.e., rheumatoid factor–negative) arthritis known as ankylosing spondylitis.

The recognized clinical variants of psoriasis (plaque, pustular, guttate, inverse, and erythrodermic) are discussed in greater detail in Differential Diagnosis 7.6.

Diagnostic Reasoning

Diagnostic Tests

Initial laboratory studies include routine laboratory testing (CBC with differential and serum chemistry profile) plus serum uric acid level, antinuclear antibody titer, and rheumatoid factor. Throat culture is appropriate if *Streptococcus pyogenes* infection is suspected as the precipitating factor (such as in guttate psoriasis). Often, the laboratory values are generally within normal limits except for the serum uric acid level, which may show elevation (hyperuricemia). In more severe variants of psoriasis, other specific tests may be ordered. An elevated erythrocyte sedimentation rate and decreased albumin levels, along with anemia, can be observed in chronic disease. Immunoglobulins are generally normal, but selective IgA and IgG deficiencies are observed in some patients. In pustular psoriasis, leukocytosis and hypocalcemia are seen.

X-ray studies of the hands are sometimes helpful to search for associated psoriatic arthritis in patients who complain of joint pains in their hands. X-ray films of patients with psoriatic arthritis will show extensive erosion and luxation of distal interphalangeal or metatarsophalangeal joints bilaterally.

Only in unusual circumstances (severe or unusual forms of the disease) are histological studies necessary to

Differential Diagnosis 7.6 Psoriasis

Type of Psoriasis	Clinical Presentation	Differential Diagnosis	Key to Diagnosis
Plaque Psoriasis	• Plaques with white silvery scales • Seen on knees, elbows, neck, scalp, between buttocks, or on back	Seborrheic dermatitis	Sharply marginated yellowish red patches with sharp borders and greasy scales. Seen on scalp, central face, eyebrows, eyelids, nasolabial folds, and external ear. Can be pruritic.
	• Usually bilateral involvement • Intertriginous areas may be involved, but scales are absent	Nummular eczema	Pruritic, coin-shaped plaques or papulovesicles on an erythematous base and uniform scaling; may become exudative and crusted. Typically seen on legs, upper extremities, and trunk.
	• Positive Auspitz's sign and Köbner's phenomenon • Gradual onset, chronic course	Lichen planus	Pruritic, flat, irregular purple papules with fine white lines and scales. Commonly seen on flexor surfaces, nails, and scalp.
		Pityriasis rubra pilaris	Generalized erythematous, red-orange lesions with diffuse thickening interspersed with areas of normal skin; the palms and soles are usually affected.
		Mycosis fungoides	Sharply demarcated, scaly, raised plaques to violaceous nodules that may ulcerate. Also known as cutaneous T-cell lymphoma.
		Atopic dermatitis	Severe pruritus; palmar markings; increased infraorbital folds, red cheeks in infancy; sides of neck, hands, and flexural surfaces most commonly affected after age 12 years.

Differential Diagnosis 7.6 Psoriasis—cont'd

Type of Psoriasis	Clinical Presentation	Differential Diagnosis	Key to Diagnosis
Pustular Psoriasis	• Lesions may be localized, appearing on the hands and feet (Barber's disease), or involve the entire skin surface (Von Zumbusch's disease) • Accompanying systemic symptoms • Onset is sudden. Pustules appear on the edges of existing psoriatic plaques and on the palms. Pruritus and intense burning sensation are present. Patient may have a fever and systemic symptoms. Systemic complications include pneumonia, congestive heart failure, and hepatitis.	Pustular dermatitis	Persistent or recurrent dry red and scaly rash; first appearance in infancy; history of dry skin since birth.
Guttate Psoriasis	• Characterized by small, red papules (<1 cm in diameter)	Secondary syphilis	Base of lesion (ulcer) is clean and smooth; edges are raised and well circumscribed. Usually occurs in genital region or on lips.
	• Discrete lesions, seen in a raindrop- or showerlike distribution, usually on the trunk and extremities • Triggered by streptococcal infection • May see Köbner's phenomenon	Pityriasis rosea	Peripheral scaling, well-demarcated, salmon-colored patch, forming a fine collarette (herald patch); followed by other lesions on trunk and proximal extremities. Christmas-tree distribution on exposed areas.
Inverse Psoriasis	• Involves the flexural area (e.g., armpit, groin)	Candidiasis	Erythematous; macerated patches with sharp, scaling border. Satellite papules and pustules that are tender and pruritic are common.
Erythrodermic Psoriasis	• Severe form of pustular psoriasis • Generalized distribution • Erythema with variable scale with fluid and electrolyte loss; chills	Drug eruption	Massive superficial dermal edema lifts the epidermis, forming necrosis, appearing as violaceous plaques or bullae; then heal with postinflammatory hyperpigmentation, e.g., Stevens-Johnson syndrome, toxic epidermal necrosis.
		Pityriasis rubra pilaris	Fine to thick scales on palms or soles; orange-red with diffuse thickening.
		Eczematous dermatitis, mycosis fungoides	See descriptions above for nummular eczema and atopic dermatitis.

diagnose psoriasis. Biopsy is seldom necessary because the clinical features of psoriasis are so distinctive. At times, an invasive biopsy may be necessary for questionable diagnoses. Biopsies should be planned to yield maximal information. When performing a biopsy, intact, nonexcoriated lesions should be sampled. If there are lesions at different stages of eruption, more than one sample is necessary. Biopsies can include partial dermal thickness procedures such as shave or curettage biopsy, or full-thickness sampling with punch or excisional biopsy.

A skin biopsy is done with the use of a local anesthetic to obtain sufficient tissue for accurate diagnosis. Skin biopsy is a "clean" procedure and should be done very simply and quickly. The standard 4 mm punch biopsy is often used and is recommended. Minimal scarring is the desired end result. A biopsy should not be performed on infected skin, on any patient with a bleeding disorder, or on any individual who is allergic to local anesthetics. The key to a good biopsy is good selection of the sample. It is often useful to take two to six samples at the first examination of complex cases. Experience is invaluable in performing good biopsies. Clinicians who are not experienced in this procedure should refer the patient to a dermatologist. (See Therapeutic Procedure 7.1.)

Of note, the sudden onset of psoriasis, in particular erythrodermic forms, may be associated with HIV; thus, the presence of underlying HIV infection should be ruled out in such patients, if unknown.

Therapeutic Procedure 7.1 The Skin "Punch" Biopsy

- Prep the area around the lesion that has been carefully selected.
- Inject 1% lidocaine slowly and superficially at several sites around the lesion, for rapid effect and minimal injury. Epinephrine may be used to control bleeding except at certain sites, given the risk of tip necrosis (nose, ears, fingertips, toes, penis).
- Punch into the skin around the lesion at a 90-degree angle to the plane of the skin, with a quick back-and-forth twisting motion, reaching in fast.
- Carefully lift out the plug and snip it at the base with sharp tissue scissors.
- Place the tissue plug in a formalin solution.
- Apply pressure with sterile gauze for hemostasis.
- Close with two sutures (4.0 or 5.0 size). (Suture removal will be determined according to the location—sutures on the face should be removed sooner than those on the extremities.)

NOTE: Nerve damage can occur in areas where nerves are very superficial, such as the lateral aspects of fingers and the ulnar groove of elbows. Any lesions in these areas (including the face for cosmetic reasons) should be referred to a dermatologist.

Differential Diagnosis

Often, psoriasis is mistaken for other dermatological conditions. It is not uncommon to see a patient with more than one variant of psoriasis at the same time, and the pattern may also change over time. Other skin diseases should be ruled out, especially in atypical cases that are complicated by other systemic disorders. (See Differential Diagnosis 7.6.)

The differential diagnosis for psoriasis includes the following: atopic dermatitis, nummular eczema, cutaneous T-cell lymphoma (CTCL), tinea corporis, lichen planus, seborrheic dermatitis, drug eruptions, and secondary syphilis. Hyperkeratotic eczema of the palms is a common cause of misdiagnosis.

Atopic dermatitis frequently has its first presentation in infancy or childhood. The patient has a persistent or recurrent dry, red, scaly rash and a history of dry skin since birth. Atopic dermatitis at times develops a psoriasiform appearance, especially on the legs. Nummular eczema has a characteristic morphology that helps to distinguish it from other eczematous eruptions. Initially, nummular eczema presents with tiny papules and vesicles and then assumes its characteristic clinical appearance of coin-shaped plaques. It is typically seen on the legs, but it can also appear on the upper extremities and trunk; the lesions are pruritic, erythematous, and surrounded with uniform scaling.

CTCL can be difficult to diagnose in its early stages. Early on, the rash may appear as single or multiple erythematous, scaly macules. In its subsequent stage, which may occur anywhere from 6 months to 6 years later, the development of sharply demarcated, scaly, elevated, red to violaceous plaques, known as mycosis fungoides, occurs. These plaques may coalesce to form larger plaques with annular, circinate, or serpiginous borders, or they may completely regress. The disease may further progress to brown or purplish red dermal nodules (tumors). The nodules often occur in the face, the body folds, and the inframammary area in women. The tumors can progress further to exfoliative erythroderma. Through much of the process, CTCL may resemble atopic dermatitis with diffuse erythema and scaling; a definitive diagnosis can be made by skin biopsy.

Tinea corporis (ringworm) presents as erythematous patches and plaques with central clearing and peripheral scales, crusts, vesicles, and pustules. It may spontaneously resolve or worsen with topical corticosteroid treatment. In seborrheic dermatitis, the lesions are lighter in color, less well defined, and covered with a dull yellow scale. Lesions commonly occur in a similar psoriatic distribution, including face, scalp, and central chest. Lichen planus gives rise to diagnostic difficulty if it presents as hypertrophic lesions on the legs, as penile lesions, or on the hands. It results from excessive

scratching. In pityriasis rosea, a single herald patch occurs first; subsequent smaller eruptions follow skin lines in a Christmas-tree pattern. Pityriasis rubra pilaris presents as generalized erythematous lesions with areas of normal skin; the palms and soles are usually affected.

Drug eruptions resulting from beta blockers, methyldopa, and gold can produce psoriatic-type lesions. Intertriginous psoriasis may appear similar to candidiasis but in most cases would be distinguishable through Wood's light and KOH testing. Mycosis fungoides lesions progress to violaceous, indurated plaques and nodules, which typically begin on the thighs, buttocks, and trunk.

Management

The goal of therapy for psoriasis is to control the disease so that the patient no longer feels physically or psychologically hindered by the skin lesions. For sparse or mild lesions that do not bother the patient, no treatment may be needed. When treatment is indicated, however, the disease is controlled by decreasing epidermal proliferation and underlying dermal inflammation with topical corticosteroids and other immunomodulatory agents, along with phototherapy in some patients. Systemic agents are reserved for moderate to severe or recalcitrant cases. The chronic course of psoriasis and the lack of cure can be both discouraging and challenging for the patient and the clinician. Patients should be reassured that the therapeutic options today are much broader than in the recent past, and several new therapeutic approaches and medications, including highly effective biological therapies, are now available, as well as improvements in phototherapy and photochemotherapy.

Some patients find the presence of even a few small plaques highly objectionable because the location of the plaques in highly visible areas of the body is disfiguring or may hinder physical activity. Other patients are willing to accept the condition as bothersome but not overly impairing, particularly when they realize there is no cure. A long-term individualized plan of disease management is therefore helpful for patients with psoriasis in order to help deal with exacerbations, which frequently cause frustration or discouragement.

Topical Therapy

Topical agents are the first-line pharmacotherapeutics for psoriasis and are usually effective. If less than 20% of the body (e.g., no more than the elbows, knees, ears, and scalp) is involved, topical agents are very effective. But if more than 20% of the body is affected, systemic therapy may be required, and referral to a dermatologist is recommended. For stubborn, persistent, and widespread lesions, ultraviolet (UV) light treatment should be strongly considered. Systemic therapy in psoriasis is usually used as a last resort, because the significant effectiveness of biological agents must be weighed against their significant cost and side-effect profile.

Widely used topical agents are available both as OTC and prescription formulations. OTC emollient creams or ointments applied on the skin at least twice a day are helpful in preventing cracking and fissuring of lesions, especially those on palms and soles. Keratolytic agents, such as 1% to 5% salicylic acid preparations, may be combined with emollients to enhance absorption of other drugs, such as topical corticosteroids, through thick psoriatic lesions. Keratolytic agents may be applied twice daily.

Topical corticosteroids are widely used because they are relatively easy to apply. Those with intermediate and strong potency should be applied no more than once or twice a day. Topical corticosteroids are an appropriate treatment in cases involving 10% or less of the body surface (e.g., the face, neck, flexures, and genitalia). The plaques usually blanch and thin in response to the treatment. More potent corticosteroids may be applied to achieve complete clearing of psoriasis and are helpful in treating exposed areas of the body. However, caution is needed in corticosteroid usage, because they can cause skin atrophy and suppression of the hypothalamic-pituitary-adrenal (HPA) axis, resulting in a Cushingoid syndrome.

The effective treatment approach for exacerbations of psoriasis is to initially use "superpotent" topical corticosteroid preparations (e.g., Diprolene, Psorcon, Temovate, Ultravate) for 2 weeks and then decrease to a lesser potency agent for maintenance therapy. Superpotent corticosteroids should not be used for more than 2 weeks. Once symptoms are under control, other topical agents or a weaker corticosteroid may be substituted after gradually tapering the dose (Table 7.10).

The penetration and absorption of topical steroids will increase with occlusive dressing, but some superpotent corticosteroids should not be applied with occlusion because of increased risk of HPA suppression from systemic absorption. Ointment preparations are preferred over creams or lotions if the psoriatic scale is thick. When heavy scaling is present, gentle brushing of the psoriatic scales after warm soaks or during warm baths before applying the topical agents will increase absorption. Hard scrubbing should be avoided, however, because skin trauma can exacerbate the psoriasis.

Topical corticosteroid therapy has its shortcomings. Remission periods are often relatively short. Prolonged use produces striae and thinning of skin (atrophy), and the rebound effect is much worse, possibly converting a "stable" disease to an "unstable" one if the dose of corticosteroid is suddenly discontinued. Prolonged use of corticosteroids has been associated with suppression of the HPA axis and a Cushingoid syndrome, as noted previously.

Topical tar and anthralin are agents that can be used once a day in combination with topical steroids. Scalp involvement may benefit from use of a tar shampoo (Zetar, Sebutone, Pentrax) before the application of a topical corticosteroid. The tar shampoo is gently massaged

Table 7.10 Potency of Topical Corticosteroids for Atopic Dermatitis

Super High
betamethasone dipropionate, augmented 0.05%
clobetasol propionate 0.05%
fluocinonide 0.1%
flurandrenolide 4 mcg/sq. cm (tape)

on the scalp and left on for a few hours and then rinsed off. Softened scales are gently removed. The scalp should be gently dried before application of the steroid lotion. Wearing a shower cap after corticosteroid application enhances absorption and improves results. Excessive combing after washing the hair should be avoided, in order to prevent trauma.

Anthralin (0.1% and 3.0% ointment) belongs to the class of trihydroxyanthracene compounds; it is used topically for psoriasis. Anthralin is an antimitotic agent capable of inhibiting DNA synthesis. Anthralin is applied once or twice a day and should be washed off after 10 to 30 minutes. It produces quick remission of plaques after several weeks of use but has a tendency to irritate and stain adjacent skin and clothing, making it less preferable than other treatment options. Paradoxically, if topical corticosteroids are added to an anthralin regimen, there may be an increased risk of early relapse.

Another topical treatment includes calcipotriene (Dovonex), a vitamin D ointment derivative. Calcipotriene produces keratinocyte differentiation and controls proliferation. It is superior to a superpotent corticosteroid and is the best treatment for mild to moderate disease. It is a major alternative to topical corticosteroid therapy for plaque-type psoriasis. Studies have found it to be effective in nearly three-quarters of patients with plaque psoriasis, with relatively minor side effects. Pulse therapy utilizes calcipotriene for 5 days and then a moderate- to high-potency topical corticosteroid for 2 days.

A topical agent with similar action to calcipotriene is tazarotene (Tazorac). It interferes with excessive differentiation and proliferation of epidermal cells and also limits the migration of inflammatory mediators to the areas of hyperkeratinization. It achieves a 60% to 70% rate and long remissions (up to 12 weeks). It is available as an ointment, cream, or lotion preparation. Like other receptor-selective retinoids, tazarotene is considered teratogenic and should not be used by pregnant women.

The topical calcineurin inhibitors tacrolimus (Protopic) and pimecrolimus (Elidel), applied twice per day, may be effective. These treatments have been particularly helpful for psoriasis in the facial and intertriginous areas where topical corticosteroid treatments (other than low-potency agents) should be avoided, given the risk of dermal atrophy. Exposure to natural sunlight improves psoriasis and permits a more enduring remission than does the use of topical corticosteroids. In some patients, topical corticosteroids may even be suspended during the summer. Although sun exposure to the point of mild erythema is helpful, sunburn exacerbates psoriasis and should be avoided.

In 1925, W. H. Goeckerman, a physician at the Mayo Clinic, achieved encouraging results with experimental use of midrange ultraviolet B (UVB) light and coal tar ointment for patients whose psoriasis did not respond to topical therapy. With some modifications of the sunbeam spectrum and combined with topicals, the traditional Goeckerman program is still being used. Crude coal tar of 1% to 2% in gel or ointment form is applied at night to the psoriatic plaques and is followed by UVB treatments. UVB treatment is continued for 4 to 6 weeks and causes remission (for up to 4 months) in 60% to 90% of patients without evidence of increased risk of skin cancer. Guttate psoriasis, in particular, responds well to UVB therapy.

A more aggressive treatment approach is photochemotherapy, or psoralen plus ultraviolet A (PUVA). It has been reported to achieve an 80% to 90% rate of remission on otherwise recalcitrant severe forms of psoriasis, such as the pustular form. The treatment inhibits mitosis by stopping DNA replication and is administered two to three times per week. PUVA involves ingestion of an oral psoralen compound (methoxsalen) before light exposure. Psoralen may be taken orally or it can be added to a bath, but "bath PUVA therapy" is

not widely used in the United States. Psoralen is inactive in the body, but on the skin it is activated by UVA (long-wavelength ultraviolet A light). The eyes must be protected during exposure to UVA light because of the potential for cataract formation. Because of the significant occurrence of nausea, body malaise, phototoxic erythema, premature aging of the skin, and pruritus following administration of psoralens, the attrition rate of this treatment is high. Although it can clear chronic plaque psoriasis in 6 to 8 weeks, overexposure to UVA light can cause acute sunburn in the short term; in the long term, it can cause nonmelanoma cancer. Since the mid-1980s, the use of phototherapy has been shown to be associated with squamous cell carcinoma. In 1991, some cases of melanoma began to surface among patients who had received more than 250 courses of treatment. Therefore, careful follow-up of patients who have had PUVA therapy is crucial. Patients considered to be at increased risk for skin cancer (those with fair skin who are easily sunburned or individuals who have had previous x-ray therapy to skin) should not receive PUVA. PUVA in combination with topical agents has been found to be extremely effective (Level 1; Menter et al, 2010).

Systemic Therapy

Systemic therapy is reserved for patients with severe incapacitating disease—pustular, guttate, and/or arthritic psoriasis. It is administered only by expert specialists such as rheumatologists or dermatologists who regularly use systemic antimitotic agents, including methotrexate, etretinate, and cyclosporine.

Methotrexate is a folic acid antagonist and a cytotoxic agent that inhibits cellular proliferation. It is used in chemotherapy for cancer but is also useful in patients with severe psoriatic arthritis. Oral regimens include every other day and once-weekly dosing. If nausea is significant, intramuscular administration can be used. A therapeutic response is usually seen within 2 to 3 weeks, at which time the dose or interval should be reduced. With prolonged use, accumulative doses of methotrexate could result in hepatotoxicity, nephrotoxicity, and bone marrow depression. Coadministration of folic acid 1 mg by mouth daily effectively protects against many of the minor side effects associated with this treatment, such as stomatitis. Methotrexate is contraindicated in patients with cirrhosis of the liver or diabetes or with a history of alcohol or IV drug use.

Monitoring of blood counts, including platelets, should be done weekly, followed by monthly testing. Renal and liver function tests (baseline and follow-up) should be done. Intermittent liver biopsies are recommended because hepatic fibrosis may occur with prolonged use. Methotrexate is teratogenic and should not be given to those who are pregnant or who want to become pregnant.

Cyclosporine is an immunosuppressant that was originally used for prevention of organ rejection in organ transplant patients. Its efficacy in severe erythrodermic and psoriatic arthritis was discovered serendipitously while the drug was being tested for rheumatoid arthritis. Significant improvement and even total clearing of psoriasis becomes evident within days in some patients. Withdrawal of cyclosporine is associated with relapse within weeks. Hypertension and nephrotoxicity can develop during cyclosporine treatment, although in the vast majority of patients renal function subsequently returns to normal. Treatment with cyclosporine for more than 1 year is not recommended because it may cause prolonged immunosuppression and myalgias. Serum creatinine levels should be monitored throughout the duration of treatment because cyclosporine can cause interstitial fibrosis and tubular atrophy. Other systemic immunosuppressants such as hydroxyurea (Hydrea), azathioprine (Imuran), and tacrolimus have also been used, although these systemic agents all carry significant safety risks and their use is reserved only for cases of sufficient severity.

The most significant development in the psoriasis treatment armamentarium in recent years has been the array of immunomodulatory biological agents used for moderate to severe plaque psoriasis, psoriatic arthritis, and refractory disease. These initially included alefacept (Amevive), a recombinant CD2 antagonist fusion protein that inhibits T-cell activation, and efalizumab (Raptiva), a humanized monoclonal antibody against CD11a. However, efalizumab was withdrawn from the market by the FDA in 2009 due to its association with fatal cases of progressive multifocal leukoencephalopathy, and alefacept was voluntarily withdrawn from the market by its manufacturer in 2011. Currently, the most widely used class of biological agents for psoriasis are the tumor necrosis factor–alpha antagonists, which include the tumor necrosis factor receptor fusion protein etanercept (Enbrel), the human monoclonal antibody adalimumab (Humira), the human monoclonal antibody golimumab (Simponi), and the human-murine chimeric monoclonal antibody infliximab (Remicade). Most recently, the anti–IL-12/IL-23 human monoclonal antibody ustekinumab (Stelara), which is specific for the shared cytokine subunit p40, has proven highly effective in the treatment of psoriasis. These biological agents have been revolutionary in the treatment of moderate to severe and refractory psoriasis. However, they require laboratory monitoring and carry the risk of significant side effects, including infection and a theoretical risk of malignancy. In addition, given their significant cost, these agents are typically considered second-line therapeutics when UV light therapy fails.

An oral systemic agent, acitretin (Soriatane), is a retinoid that can be beneficial for patients with moderate to severe pustular and erythrodermic variants of psoriasis. In severe cases, etretinate can be used in combination with PUVA. About 50% of patients who are refractory to PUVA alone improve when a retinoid is added. Female patients who are treated with etretinate should

be advised not to become pregnant for 3 years after ceasing treatment, because retinoids are teratogenic. Careful monitoring of blood counts, plasma triglycerides, and liver function tests is required.

Follow-up and Referral

Newly diagnosed patients and patients who have moderate to extensive skin involvement or severe disease (e.g., pustular psoriasis) should be referred to a dermatologist or psoriasis specialty treatment center. Patient support groups may be of great psychological help. Patients with recalcitrant or frequent flare-ups should be referred to a dermatologist for UV light therapy and/or systemic treatment. An ophthalmology consultation is necessary before UV therapy to rule out the presence of cataracts.

Patients with severe psoriasis are usually followed up every 2 months by a specialist or more often as required by their particular treatment regimen. Patients who exhibit symptoms of depression or poor coping skills will benefit from referral to a psychiatrist for psychological evaluation and therapy.

Patient Education

Psoriasis presents many challenges to both the patient and the health-care provider. For patients with disfiguring and uncontrollable psoriasis, education and support are central to the treatment process. The patient should be informed of available community resources and support groups. Explanation of the disease process and treatment, including potential adverse effects of medications, is very helpful. The new patient and his or her family should be reassured that the disease is not contagious or infectious.

Although the genetic aspects of psoriasis are complex and incompletely characterized, it may be explained to family members of a patient that if neither parent has psoriasis, the chances are less than 10% that another child will develop the disease. If one parent is affected, the chance of developing psoriasis increases to 15%. If both parents are affected, the chance increases to 59% that one or more children will have the disease.

The clinician should educate the patient that there are several ways of remaining in remission: Patients with psoriasis should avoid skin trauma and should keep the skin relatively dry to decrease pruritus, scratching, and scaling. They should avoid photosensitizing medications such as tetracyclines, sulfa drugs, or phenothiazines. If drugs of these types are necessary, patients should be advised to inform the prescribing physician of their psoriasis and to ask for a possible alternative. Although photosensitizing drugs should be avoided, controlled sun exposure during the summer is beneficial. The patient should be advised to use a high-SPF sunscreen to prevent sunburn. Patients should be informed to seek treatment for streptococcal infections (e.g., skin infections, sore throats) immediately. Aggravating factors for psoriasis include increased stress and alcohol.

The clinician should explain to the patient that dietary manipulations do not appear to play a role in treating psoriasis. However, healthy eating habits support a strong immune system, and nutritionists recommend a low-fat, high-fiber diet for patients. Naturopaths recommend many herbal medicines to improve psoriasis and to control or provide relief from the disturbing effects of the flare-ups. (See Complementary Therapies 7.1.) Although many persons subscribe to these therapies, there is a lack of data from randomized clinical trials to confirm their effectiveness.

An active support group for psoriasis is the National Psoriasis Foundation, 6600 SW 92nd Avenue, Suite 300, Portland, OR 97223-7195, 1-800-723-9166, www.psoriasis.org.

SKIN LESIONS: BENIGN

SEBORRHEIC KERATOSIS

Seborrheic keratoses are benign, warty-appearing growths that are commonly seen in older adults. These growths are usually found on the trunk, but they may also be seen on the hands and face. They develop in both sun-exposed and protected areas. See Table 7.11 for information about other skin lesions, including nevi, skin tags (acrochordons), and lipomas.

Epidemiology and Causes

The tendency to develop seborrheic keratosis is an autosomal dominant trait. Seborrheic keratosis is extremely common; it has been found in 88% of persons older than age 65 years. Of this group, approximately 50% often develop 10 or more lesions. In fact, for some individuals, lesions may number into the hundreds. The

Complementary Therapies 7.1

Acne

Herb	*Comments*
Marigold (*Calendula officinalis*)	Topical application Available as a soap Has anti-inflammatory properties
Tea tree oil *(Melaleuca alternifolia)*	Topical application twice daily

Complementary Therapies 7.1—cont'd

Eczema

Herb	*Comments*
Chamomile (*Matricaria recutita*)	Topical application Anti-inflammatory Contraindicated in patients with ragweed allergy
Evening primrose (*Oenothera biennis*)	Should not be taken with phenothiazines
Marigold (*Calendula officinalis*)	Topical application—ointment or cream Has anti-inflammatory properties
Goldenseal (*Hydrastis canadensis*)	Used topically by Native Americans Powdered root mixed with water to make a paste and applied to rash
Licorice (*Glycyrrhiza glabra*)	Topical application Anti-inflammatory properties
Turmeric (*Curcuma longa*)	Topical application; anti-inflammatory

Fungal Infections

Herb	*Comments*
Tea tree oil (*Melaleuca alternifolia*)	Topical application; antifungal properties Apply twice daily

Psoriasis

Herb	*Comments*
Angelica (*Angelica archangelica*)	After ingestion, expose affected area to mild sunlight Contains photosensitizers (*furocoumarin*) Possible interaction with anticoagulants and aspirin
Avena (*Avena sativa*) "Oatmeal"	Applied as an oatmeal paste
Avocado (*Persea americana*)	Cooling, soothing effect Mashed avocados are rubbed into scaling patches
Bishop's weed (*Ammi visnagae*)	Topical application Inhibits cell division Treatment may irritate the skin
Brazil nut (*Bertholletia excelsa*)	Soothing; relieves itching Contains an oil rich in thiamin and selenium
Chamomile (*Matricaria recutita*)	Topical application Anti-inflammatory Contraindicated in patients with ragweed allergy
Flax (*Linum usitatissimum*)	Need to ingest about 10–12 grams (5–6 tsp) May add flaxseeds to salads; caution as to laxative effect
Licorice (*Glycyrrhiza glabra*)	Topical application; may be more effective than hydrocortisone
Milk thistle (*Silybum marianum*)	Anti-inflammatory Taken as a tea, tincture, or in capsules
Oregon grape (*Mahonia aquifolium*)	Antioxidant
Red pepper (*Capsicum*)	Contains capsaicin Reduces scaling and redness, but can cause burning and stinging Wash hands thoroughly after applying, avoid getting in the eyes or on mucous membranes
Omega-3 fish oil	Decreases symptoms and severity of chronic plaque psoriasis and acute guttate psoriasis

Table 7.11 Other Skin Lesions

Lesion	Description	Clinical Presentation	Management
Lipoma	A lipoma is a benign subcutaneous tumor that consists of adipose tissue. Lipomas are most commonly found in older adults; usually asymptomatic. Cause is unknown.	• Rubbery smooth and round mass of adipose tissue that is compressible and has a soft to very firm texture. • May have symptoms of irritation, such as redness and tenderness. • Commonly occurs on back of the neck, trunk, and forearms.	• Observe for changes, rapid growth • Excision or liposuction • Referral to dermatologist if indicated
Nevi	Nevi (moles) are circumscribed areas of pigmentation. Types include congenital, acquired, or atypical or dysplastic (>5 mm, in diameter, with color variation and irregular borders).	• Flat or raised circumscribed area of pigmentation. • Assess for suspected melanoma (check ABCDEs: asymmetry, irregular borders, variations in color, diameter >6 mm, elevation above the surface of the skin).	• Excision • Referral to dermatologist if melanoma is suspected
Skin tags	Skin tags (acrochordons) are benign overgrowths of skin, commonly seen after middle age. Cause is unknown.	• Overgrowths of normal skin that have formed soft, polyp-like lesions that have a stalk. • Usually found on the neck, axilla, groin, upper trunk, and eyelid.	• Usually none unless patient is bothered by the cosmetic effect or irritation • If treatment is required, may include snip excision, electrocautery, or cryosurgery • Referral to dermatologist if skin tag is located on the eyelids or face or if patient has a history of keloids, diabetes, or infection, or is on high-dose steroid therapy, or if there is the possibility of a malignant lesion

lesions found on sun-exposed areas rarely increase in size, whereas seborrheic keratotic lesions in protected areas tend to be darker, have a more crumbly appearance, and may enlarge in size.

Seborrheic keratosis is more prevalent in persons with white skin. The lesions are raised, brownish gray, and appear "stuck on."

Pathophysiology

Seborrheic keratosis lesions originate from the horny layer of the epidermis and are the result of a benign proliferation of immature keratinocytes. Inspection of the lesions may reveal dark keratin plugs or firm, horny cysts on their surface. A predisposition for seborrheic keratosis appears to be inherited in an autosomal dominant pattern. These are epidermal tumors, but they are not considered malignant or premalignant because they do not undergo transformation into cancerous lesions. However, a phenomenon known as the sign of Leser-Trélat exists, which is characterized by the sudden development of multiple seborrheic keratotic lesions, along with skin tags, and acanthosis nigricans (a darkening and mild thickening of the skin in characteristic intertriginous areas). Although the skin lesions in this condition are not considered malignant, the sign of Leser-Trélat is associated with various types of underlying malignancies, including lung and gastrointestinal cancers and, thus, is considered a neoplastic syndrome. Moreover, seborrheic keratosis has also been observed in association with certain skin malignancies such as basal cell carcinomas, occurring at different skin sites.

Clinical Presentation

Subjective

The typical patient is an older white woman who complains of the cosmetic effects of the lesion. The patient typically complains of the unsightliness of the lesion, itching, and constant irritation from friction or clothing.

Objective

Seborrheic keratotic lesions are benign, superficial epithelial growths that appear as well-defined scaly,

hyperpigmented lesions with a warty or "stuck-on" appearance. They are most often found on the trunk, face, and arms. Lesions look as if they could literally be "picked off" the skin surface. Seborrheic keratotic lesions tend to grow slowly and are round to oval in shape. The lesions occasionally appear as smooth papules. The color of the lesions can range from flesh tone to dark brown in white patients. In black women, the lesions also appear as smooth, round to oval black papules on the upper part of the face (dermatosis papulosa nigra).

Diagnostic Reasoning

Diagnostic Tests

No laboratory testing is necessary to diagnose seborrheic keratosis. However, if the patient presents with an atypical lesion, diagnosis should be confirmed with a biopsy.

Differential Diagnosis

The diagnosis of seborrheic keratosis is based on the appearance of the lesion and on patient demographics (especially age). Skin lesions that can mimic seborrheic keratosis include any pigmented papule or nodule. The differential diagnoses for seborrheic keratosis include benign pigmented nevi, pigmented basal cell carcinoma, and malignant melanoma.

Pigmented nevi appear as smooth round macules or papules that do not have a warty appearance. Nevi (moles) are also seen in younger patients as well as in adults, unlike seborrheic keratosis, which appears mostly in patients aged 30 years and older. Pigmented basal cell carcinomas usually have a waxy surface with dilated blood vessels. They may be ulcerated during later stages—a feature not seen in seborrheic keratosis. Malignant melanomas can appear in younger patients; melanomas may be nodular but usually do not have a warty, stuck-on appearance. A malignant melanoma's borders can be irregular, and it can have a variegation (inconsistency) of color. Most patients with melanoma will also report a history of a changing mole.

Management

If the diagnosis is uncertain, especially if melanoma cannot be ruled out, the patient should be referred to a dermatologist for further evaluation. A skin biopsy can be done for a more definitive diagnosis.

Treatment is warranted for those lesions that are symptomatic or are unsightly to the patient. Seborrheic keratosis may be removed using liquid nitrogen therapy or mechanical methods. Results obtained with cryosurgery (liquid nitrogen) are slightly superior to those obtained using electrodesiccation with curettage; however, the choice is generally the practitioner's preference. Liquid nitrogen may produce transient hyperpigmentation or hypopigmentation. Mechanical methods of removal include curettage and snip or shave excision. (See Therapeutic Procedure 7.2.)

Therapeutic Procedure 7.2 Removal of Seborrheic Keratoses

Liquid Nitrogen

- Spray the area with liquid nitrogen or apply the liquid nitrogen with rayon–wool tipped applicators. Special care must be taken not to contaminate the reservoir of liquid nitrogen. If using applicators, dip the applicator into the reservoir only once, apply, and discard.

NOTE: It is generally preferable to lightly freeze (underfreeze) the lesion than to freeze too deeply and risk scarring. A second application may be applied at a follow-up visit if necessary. Hyperpigmentation and hypopigmentation are possible sequelae of liquid nitrogen treatment (cryotherapy). Reactive hyperpigmentation is more common in Asians.

NOTE: Care must be taken in treating areas where nerves are relatively superficial and can be damaged, such as the lateral aspects of the fingers and the ulnar groove of the elbows.

Curettage

- Anesthetize the area with 1% lidocaine and cleanse the area.
- Stretch the skin surrounding the lesion with the fingers of one hand.
- Using a 5-mm or 6-mm curette, scrape off the base of the keratosis with short, clean strokes.

NOTE: If the lesion is in a critical area such as the face, lateral aspects of the fingers, ulnar groove in elbow (superficial nerve present), or if diagnosis is uncertain, referral to a dermatologist is recommended. If the lesion is in the hairline or groin, styptics or aluminum chloride may be used to control bleeding.

Snip or Shave Excision

- Anesthetize the area with 1% lidocaine and cleanse the area.
- Using iris scissors, snip off the lesion, or, using a number 11 or number 15 scalpel, shave off the lesion.

NOTE: Control bleeding using pressure, gel foam, styptic, or aluminum chloride, if needed.

NOTE: Treatment is for patient comfort or for cosmetic reasons only.

Follow-up and Referral

A follow-up visit is generally not necessary unless the liquid nitrogen does not completely remove the lesion. A biopsy should be performed on any keratosis that fails to respond to liquid nitrogen. Should the removal of a lesion by cryotherapy from the dorsa of the hands result in blistering, the patient should return to have the blister drained. This is accomplished by puncturing one edge of the blister with a sterile needle or with a number 11 scalpel. The top of the blister should not be removed. Infection following the application of liquid nitrogen is rare.

A biopsy or referral to a dermatologist should be done if the diagnosis is unclear and the clinician wants to rule out a pigmented basal cell carcinoma or malignant melanoma. A high index of suspicion is necessary in the diagnosis of melanoma because of its aggressive and malignant nature. Any pigmented lesion for which a clinician suspects melanoma should be evaluated by a dermatologist.

Patient Education

The clinician should inform the patient that seborrheic keratoses are a harmless and common occurrence as people age. Some people develop many lesions, whereas others will have only a few. These lesions are not caused by chronic exposure to sunlight and may develop on any exposed or protected area of the body. Color changes in these lesions are harmless, but if the clinician is unsure about the exact nature of the lesion, referral to a dermatologist is recommended.

SKIN LESIONS: PREMALIGNANT

ACTINIC KERATOSIS

Actinic keratosis is the most common precancerous skin lesion found in light-skinned (white) patients. *Actinic keratoses* are premalignant lesions that are also known as senile or solar keratoses. They are found on sun-exposed areas of skin that have been damaged from cumulative sun exposure. Left untreated, actinic keratosis can progress to squamous cell carcinoma with a latency period of 10 years. Estimates of progression to squamous cell carcinoma vary widely from 0.25% to 20%. Another estimate is that only 1 in 1,000 actinic keratotic lesions may progress to squamous cell carcinoma. However, up to 25% of actinic keratoses spontaneously regress without treatment. Therefore, aggressive treatment of these premalignant lesions remains controversial.

Epidemiology and Causes

Actinic keratosis is caused by the accumulation of damage to epithelial skin cells caused by chronic sun exposure. These keratoses are more common in men, probably as a result of occupational exposure (working outdoors). The most susceptible individuals are fair skinned, with a history of frequent sun exposure and evidence of other signs of sun damage, such as freckles, senile lentigines (liver spots), wrinkles, and uneven pigmentation. Actinic keratoses are found predominantly in older adults (older than age 50 years); however, occasionally they are seen in young adults with fair skin. Renal transplant patients have also been found to have an increased tendency to develop actinic keratoses. The typical patient with actinic keratoses is an elderly, fair-skinned, sun-sensitive person.

Pathophysiology

Cumulative damage from ultraviolet radiation in sunlight causes damage to the DNA in epithelial cells. The primary lesions of actinic keratosis consist of macules or plaques that are poorly circumscribed. Secondary lesions appear erythematous and scaly. Areas of skin that have actinic keratosis feel rough to the touch due to hyperkeratosis and have been likened to feeling like sandpaper. With further ultraviolet light exposure, continued cumulative DNA damage may lead to malignant transformation of epidermal cellular clones. Actinic keratoses that progress to squamous cell carcinoma tend not to be very aggressive unless they occur on the lip.

Clinical Presentation

Subjective

The typical patient is a middle-aged or older adult who complains of an irritated rough or scaly rash. Some patients also complain of pruritus, tenderness, or a stinging sensation in one or several lesions. Some patients are asymptomatic and will only complain of cosmetic concerns or uneasiness about a potential malignancy. The lesion is also typically found on a fair-skinned patient. These patients usually have some Celtic background (Irish, Scottish, English) and are light haired (blond or red haired) and blue eyed. They also tend to freckle easily and sunburn.

Objective

The lesions of actinic keratosis appear reddened, scaly, rough, or have an uneven surface. The hyperkeratosis of these lesions is characteristically hard or spiny. Actinic keratoses are found in areas of skin that have been chronically exposed to the sun, such as the face, ears, back of the neck, neckline, dorsum of the arms, and (in women) the dorsum of the legs. Palpation is generally the best diagnostic tool to use because of the typical sandpaper-like texture of the lesions. Actinic keratoses are small (0.2- to 5-mm) papules that can be flesh colored or slightly hyperpigmented. Actinic keratoses are predominantly found on the cheeks, forehead, forearms, and dorsal surface of the hands. In older men, they are also predominant on the ears and balding scalp.

Diagnostic Reasoning

Diagnostic Tests

The diagnosis can usually be made by history and physical examination. Palpating the lesion is key to the diagnosis by feeling for the scaly, rough, and uneven texture, because lesions may be better recognized by palpation rather than by visual inspection. Fluorescence with the use of a photosensitizing drug such as methyl ester of 5-aminolevulinic acid can be used as a diagnostic tool for actinic keratosis, because areas of involvement emit a pink fluorescence with a Wood's lamp or photodynamic therapy lamp.

Differential Diagnosis

Skin lesions that can mimic actinic keratosis include squamous cell carcinoma, seborrheic keratosis, and verruca plana (flat warts). Squamous cell carcinoma is characterized by an indurated plaque or nodule that is eroded or ulcerated and has a thickened scale. The lesion is found on sun-exposed skin, as is actinic keratosis. What differentiates squamous cell carcinoma from actinic keratosis is the induration and ulceration. Seborrheic keratosis lesions are highly pigmented (brown to black) and have a warty, stuck-on appearance. They can appear on both sun-exposed and protected skin. Verruca plana are caused by the human papillomavirus and appear as multiple flesh-colored to light brown warts that are from 1 to 5 mm in size. Their color and smaller size distinguish them from actinic keratoses.

Management

There is no solid evidence that removal of all actinic keratosis lesions on a patient is effective in the prevention of skin cancer. Indeed, only 1 in 1,000 actinic keratoses will progress to squamous cell carcinoma. However, it is standard dermatological practice to remove most actinic keratosis lesions. Because the lesions reside in the epithelium, therapies that separate the epidermis from the dermis are most effective and do not leave scars.

Two methods are currently available to the primary-care provider—topical therapy and surgical destruction of the lesion. Treatment may also include a combination of both methods.

Topical Therapy

Topical application of 5-fluorouracil (5-FU) cream (Efudex, Carac) may eradicate actinic keratosis, because 5-FU is selective for affecting only sun-damaged cells. The cream is applied to the lesion twice per day for an average of 3 weeks. The eyelids, folds of the nose, and lips should be avoided. Healing takes from 2 to 4 weeks and is accomplished by the replication of epidermal and adnexal cells. Patients treated with 5-FU frequently become noncompliant because the inflammatory effect (destruction of the lesion) leaves raw, tender, reddened skin in its place. If the lesion or lesions do not respond to one treatment with 5-FU, these lesions must be evaluated for potential carcinoma via skin biopsy. Some evidence shows that tretinoin (Retin-A) when used in combination with 5-FU may increase effectiveness and shorten the length of therapy. The safety and efficacy of 5-FU during pregnancy have not been established.

Imiquimod 5% cream may be used on face and scalp lesions and is applied three times weekly for 8 weeks. Other topical treatments that have been used include topical chemotherapies such as diclofenac 3% in 2.5% hyaluronan gel (Solaraze) applied twice per day for 60 to 90 days and topical retinoids such as adapalene 0.1% to 0.3% gel (applied to lesions daily for 4 weeks, and then increased to twice per day). Side effects may include erythema, pruritus, rash, and xerosis (dry skin). Some topical chemotherapeutic treatments have even been used in conjunction with phototherapy, such as aminolevulinic acid (Levulan Kerastick) in conjunction with either blue or red wavelength light. These specialized treatments typically give improved cosmesis over the more commonly used method of cryosurgery and may be preferred for facial lesions. In addition, they only require a 2-day course of therapy. A cytotoxic agent, ingenol mebutate, may also be used, which works by killing rapidly growing cells such as the abnormal cells associated with actinic keratoses. For the scalp, ingenol mebutate 0.015% gel is usually applied once a day for 3 days in a row. On the torso or extremities, 0.05% gel is applied once a day for 2 consecutive days.

Another treatment for actinic keratosis is photodynamic therapy, which uses a light-sensitizing compound that uniquely accumulates in actinic keratosis cells, where it is activated by the appropriate wavelength of light. Delta-aminolevulinic acid is a component of the heme biosynthetic pathway that accumulates in dysplastic cells. Once inside the cells, it is enzymatically converted to a potent photosensitizer. With exposure to light of an appropriate wavelength, oxygen free radicals are generated and cell death results.

Cryosurgery

Before cryosurgery is performed, informed consent must be obtained from the patient. Cryosurgery with liquid nitrogen is used most frequently for patients with solitary or few lesions. (See Therapeutic Procedure 7.3.)

With cryosurgery, the clinician must rely entirely on a clinical diagnosis because tissue is destroyed by freezing; therefore, there is no specimen available for pathological analysis. Liquid nitrogen is a rapid and effective treatment for eradicating actinic keratoses, especially in patients with one to few lesions. The liquid nitrogen probe should be applied firmly to the lesion for 10 to 15 seconds and repeated twice in one visit. The lesions will crust over and generally disappear in 10 to 14 days. A possible drawback to this procedure is the potential for hypopigmentation because a white spot may appear at the treated site.

Therapeutic Procedure 7.3 Performing Cryosurgery for Actinic Keratoses

- Liquid nitrogen applied with a cotton-tipped applicator is preferred because it causes minimal damage to the dermis.
- Using liquid nitrogen, freeze each lesion for 10–15 seconds. It may be necessary to repeat the freezing cycle a second time. The more pressure is applied to the cotton swab, the deeper the point of freeze contact or "freeze ball."
- The "freeze balls" should be approximately 1.5 times as wide as they are deep.
- If in doubt, it is better to underfreeze and to retreat lesions than to overfreeze them and leave a scar or hypopigmentation (if damage to the dermis is avoided, scarring will not occur).
- Any lesion that does not respond to liquid nitrogen must be biopsied.

NOTE: If diagnosis of any skin lesion is in doubt, refer to a dermatologist for possible skin biopsy. The treated area will become red and swollen a few hours after treatment. A serous or blood-filled blister forms and will subsequently crust and disappear in 10–14 days. The patient should be advised not to cover the blister with any bandages and to leave the blister alone. The blister will protect the treated area until it is healed.

Other Surgical Techniques

Lesions that are isolated and thick may be amenable to surgical curettage, shave excision, or conventional excision, particularly when located on the dorsal surfaces of the upper extremities. However, there are few data that speak to the efficacy of this approach, and these techniques are typically not considered first-line interventions. Importantly, however, surgical resection is the only method of actinic keratosis removal that produces an intact biopsy sample available for histological examination and diagnostic confirmation. In addition, this method may be more appropriate for immunocompromised patients or for lesions suggestive of invasive cancer.

Follow-up and Referral

Patients on 5-FU should be followed up in 2 to 3 weeks or during completion of treatment. Adverse effects of the medication, compliance issues, and effectiveness of treatment should be noted at this time. Any skin lesions that remain after treatment with 5-FU cream for 2 to 3 weeks must be biopsied for pathological examination. Patients treated with cryosurgery are reevaluated in 2 weeks. Patients who have had excision biopsy by a dermatologist are usually seen again in 2 weeks.

Any actinic keratosis lesion that does not respond to treatment should be referred to a dermatologist for further evaluation, including the need for a skin biopsy, even for superficial lesions. A dermatologist may remove multiple superficial lesions with an acid followed by pulsed light laser therapy or photodynamic therapy. This is effective on the face and does not result in the hypopigmentation that may result from cryotherapy. An added benefit is one of esthetic skin rejuvenation.

Patient Education

Regardless of the method of treatment, the patient should be educated regarding the need for using sunscreen and wearing of protective clothing such as a hat and a shirt with long sleeves. The hallmark of actinic keratosis management must actually center on prevention—avoidance of excessive sun exposure is key to avoiding development of these premalignant lesions and their cancerous sequelae. In addition, the patient can also be taught the signs and symptoms of melanoma screening by using the ABCDE mnemonic: A = asymmetry, B = border irregularity, C = color change, D = diameter larger than a pencil eraser (greater than 6 mm), E = elevation from a flat lesion to a raised or evolving lesion.

Patients treated with 5-FU should be warned that exposure to sunlight during treatment can exacerbate the inflammatory effect of the medicine. The clinician should instruct the patient that if erosions develop while using 5-FU cream, petroleum jelly can be applied to provide comfort, but the treatment must be continued for a total of 10 to 14 days. Patients should be warned to avoid prolonged sunlight exposure during and after treatment. A good-quality sun block should be worn after treatment to prevent future damage to the skin.

Patients treated with cryosurgery should be informed that bandages are not necessary after treatment and actually impede healing. If blister formation results, the patient should be instructed to return to the office so that the blister can be drained. The patient should be advised to avoid irritation of the treated lesion with clothing or jewelry. Showering and the use of makeup are permissible. The patient should be taught to monitor for the signs and symptoms of infection (e.g., redness, purulent discharge, heat). Infection is a rare occurrence after cryosurgery.

SKIN LESIONS: MALIGNANT

MALIGNANT MELANOMA

Malignant melanoma is the most deadly of all skin cancers. *Melanoma* is malignancy of the skin that arises from epidermal melanocytes. Melanocytes produce *melanin,*

a brown-black pigment that is responsible for skin, hair, and eye color. Almost all melanomas arise from the skin (more than 90%), but a few melanomas originate from the eye (uveal melanoma), and very few (less than 4%) do not have a primary site.

Types of melanoma are *superficial spreading* (70%–85%—characterized by extensive lateral or radial growth before vertical invasion), *nodular* (15–30%—characterized by vertical growth only), *lentigo maligna* (5%—an in situ form that may persist for years before vertical extension), and *acral lentiginous* (2%–8%—a particularly aggressive form most common in darker-skinned patients, especially when appearing on the hands or feet).

Although the majority of skin cancers in the United States are basal cell carcinoma (the most numerous type) and squamous cell carcinoma, melanoma is responsible for 75% of all skin cancer deaths. Melanoma, if discovered early enough, is a highly curable malignancy, but if the melanoma extends beyond 4 mm in depth, the prognosis is extremely poor. A 75% mortality rate is associated with this stage. Therefore, the role of primary-care clinicians in screening for this skin cancer is important and cannot be overemphasized. Screening programs that result in early diagnosis are important weapons in the armamentarium against this disease. The American Cancer Society's ABCDE mnemonic, explained in the premalignant section, is an easy tool for the clinician to remember and use to teach patients how to recognize potential melanomas and dysplastic nevi, the precursor lesion of melanoma, at an early stage.

Epidemiology and Causes

The incidence of melanoma in the United States has been rising for both men and women over the past decade, with rates of melanoma increasing annually for both white men and women, although rates have remained stead for African Americans, Hispanics, Asians, and Native Americans, in whom melanoma is much less frequent. In 2009, the Centers for Disease Control and Prevention estimated that there were 61,646 cases of melanoma and 9,199 deaths from it in the United States. Of the seven most common cancers in the United States, melanoma is the only type of cancer whose incidence is consistently increasing. In adults aged 25 to 29 years, melanoma is the most common form of cancer and the second most common among 15- to 19-year-olds. One contributing factor is the use of tanning beds among young people, because just one indoor tanning session has been estimated to increase a person's chances of developing melanoma by 20% and each additional session during the same year increases that rate by another 2%.

Several factors have been identified that increase an individual's risks of melanoma (see Risk Factors 7.2). Exposure and sensitivity to sunlight remain two of the most widely recognized risk factors. A disproportionate number of melanoma deaths occur among whites, particularly fair-skinned individuals who sunburn easily. Whites (Caucasians) who are at highest risk come from Celtic (Irish, Scottish, English) backgrounds and have light hair (especially red hair), light eyes, and freckles. The ability of the skin to freckle in response to sun exposure is thought to be a marker of susceptibility to melanoma, although stronger risk factors for melanoma exist. Teaching patients about the proper use of sunscreen cannot be overemphasized. One study found that the risk of developing any melanoma was reduced by 50% and invasive melanoma by 73% with daily rather than discretionary use of sunscreen.

Risk Factors 7.2 Malignant Melanoma

Age
Risk increases with age
Skin, Eye, Hair Color
Fair, blue or green eyes, red or blond hair
Personal History
History of skin cancer History of dysplastic nevi; congenital nevi >20 mm History of blistering sunburn before age 20 years History of immunosuppression
Family History
History of melanoma
Environmental History
Excessive exposure to ultraviolet radiation/indoor tanning

Research into the genetic component of melanoma and the presence of dysplastic nevi has found a relationship between dysplastic nevi, family history, and the development of melanoma. The finding of dysplastic nevus (one or more atypical moles) or any other type of skin cancer (such as basal cell carcinoma or squamous cell carcinoma) is thought to increase one's risks of melanoma. The number of nevi (moles) normally peaks during young adulthood (ages 20–25 years), then gradually decreases after age 50 years. Large numbers of nevi on an individual who is older than 50 years is considered to be a strong marker for increased risk of melanoma. It is estimated that 7% of the white population has at least one atypical nevus; many individuals have numerous nevi that should be monitored closely.

All melanomas should be tested for mutations in *BRAF,* a gene involved in cell growth signaling, because they appear in about half of all metastatic melanomas. Although *BRAF* is the official symbol designation, the gene is also known as *B-Raf* or *v-Raf murine sarcoma viral oncogene homolog B1.* As with other proto-oncogenes, when mutated this gene has the potential to cause normal

cells to become cancerous. The benefit of identifying this mutation is in the personalization of melanoma therapy, because at least two small molecule inhibitor drugs, vemurafenib (Zelboraf) and dabrafenib (Tafinlar), have been developed to treat *BRAF* mutation–positive melanomas. This drug and others are mentioned in the treatment section.

The combination of a history of a first-degree relative with melanoma combined with the presence of one or more dysplastic nevi increases the chances of developing melanoma by up to 50% compared with the general public. Individuals in this population tend to develop multiple primary lesions at a younger age than individuals with other melanomas. In addition, large-sized nevi (more than 20 mm) are believed to be associated with increased melanoma risk. Currently, lifetime risk among all populations is estimated at 1 in 75, with fully one-third of all cases occurring in persons younger than age 45 years.

Pediatric overexposure to UV rays, especially a history of one or more blistering sunburns before age 20 years, has been linked to a dramatic increase in lifetime risk of developing melanoma. The effect of accumulated sunburn in addition to genetic predisposition may not be seen until years later, because the incidence of malignant melanoma in children is low. Intermittent intense exposures (e.g., those that may occur in occupational groups such as farmers) that result in blistering sunburn appear to be associated more with increased melanoma risk than chronic exposure.

Pathophysiology

A combination of UV exposure and genetic susceptibility is believed to be the most common mechanism for developing melanoma. Studies have linked UV radiation, particularly UVB rays, to genetic mutations in DNA in susceptible individuals, resulting in the development of abnormal pigmented lesions (dysplastic nevi). Genetic predisposition to melanoma appears to be the result of the presence of a mutated or absent tumor suppressor gene. Abnormalities have been mapped to chromosomes 1 and 9. In particular, mutations in chromosomal region 9p21, which encodes the tumor suppressor gene *CDKN2A* that produces the protein p16, have been observed in a large proportion of both familial and spontaneous melanomas, as well as the previously discussed mutations in the *BRAF* gene, which are seen in over half of all melanomas. Germline mutations in the gene *CDK4* have also been observed. Individuals in these susceptible groups tend to develop melanoma at multiple primary sites at an earlier age. Another strong genetic association is observed in the autosomal recessive condition xeroderma pigmentosum. Persons affected with this inherited disorder lack a critical DNA repair mechanism that corrects UV light–associated cross-linked DNA nucleotides. This results in multiple DNA breaks in response to cumulative UV light exposure and a resultant high level of sun-associated skin cancers.

Atypical nevi are precursors to malignant melanoma. They differ histologically from benign nevi in that they are disorganized and carry higher potential for transformation into malignant tissue. Initially, the tumor remains confined to the epidermis. If left untreated, it spreads into the subcutaneous fat. Metastasis occurs in the regional lymph nodes and occasionally into distant sites such as the lungs, liver, bone, brain, and other viscera. Microscopic lesions of superficial spreading-type melanoma have large, atypical pigmented cells of variable colors in the epidermis and the papillary dermis and lymphocytes. Nodular melanoma lesions have multiple tumor cells that form a nodule in the dermis, with invasion to the deeper dermal layers. Metastases to distant sites result when tumors invade through dermal lymphatics or blood vessels. The most commonly affected target organs are the lung, liver, and brain.

In the absence of metastasis, the four primary prognostic factors for melanoma are patient age and gender, tumor thickness, and tumor location. Worse prognoses are seen in older men with thicker tumors located in an axial distribution, as opposed to on the extremities. In addition, the relative importance of certain prognostic factors also depends on tumor stage. In earlier disease limited to the skin, tumor thickness and the presence of ulceration are key. However, in more advanced disease, along with the presence of ulceration, the degree of nodal involvement is the most important factor.

Clinical Presentation

Subjective

The typical patient is an adult who is concerned about a large mole that has changed in appearance. A change in characteristics of a mole is a frequent observation made by melanoma patients. Some patients who come in do so in response to a concerned family member, typically a spouse, who has advised them to have the mole checked. The patient typically will report having had the same mole for many years. A family history of melanoma or skin cancer may be reported by some patients. There are usually no symptoms associated with the majority of cases of melanoma; however, some patients present with a pruritic, ulcerated, or bleeding mole.

Objective

Most melanomas appear on sun-exposed areas of skin. The back and the neck are the most common sites in men, and the legs are more common in women. In blacks and Asians, the feet, fingers, nailbed, eyes (uveal tract), and mucous membranes are more common sites.

Melanoma often presents as an asymmetrical lesion with an irregular border, notching, and a diameter greater than 6 mm. The tumor often exhibits variegation in color, with admixtures of blue, red, tan, brown, black, and white. Rarely, tumors appear as amelanotic. Early nodular tumors, for example, are typically flat and may

lack most of the typical characteristics of melanoma. As the tumor advances, an increase in thickness causes elevation into a firm nodule (in nodular melanoma). Atypical nevi bear many of the same characteristics of a true melanoma, including irregular, ill-defined borders; color variegation; and large size (more than 6 mm). The emphasis on larger lesion size as an increased risk factor for melanoma is not always accurate because early melanomas can be smaller than 6 mm in diameter. Distinguishing between malignant melanoma and benign nevi can be difficult and often requires a skin biopsy.

Nailbed or subungual melanoma may be observed in older patients and is most commonly found on the thumb or great toe. This variant of acral lentiginous melanoma may present similarly to an ungual fungal infection, because discoloration of the nailbed known as longitudinal melanonychia may distort the nail itself. Posterior nailbed involvement called Hutchinson's sign is an ominous physical finding associated with advanced disease.

Diagnostic Reasoning

Diagnostic Tests

Following a thorough physical exam including full-body skin inspection, suspicious lesions should be biopsied under local anesthesia by a dermatologist. Excisional biopsy is the preferred method if melanoma is suspected because measurement of thickness can be made along with staging, as a predictor of prognosis and guide for treatment. Thickness or depth of the melanoma is one of the critical factors in determining both prognosis and choice of therapy. Traditionally, the Breslow depth classification system has been used as a prognostic factor, complemented by the Clark staging system of tumor invasiveness, as described in Table 7.12. In addition, the American Joint Committee on Cancer classification system has been developed to take into account tumor thickness, mitotic rate, ulceration, and invasiveness (localized tumor versus nodal or distant metastases) as key prognostic factors.

If biopsy pathology reveals only atypical nevi, removal of the lesion by excisional biopsy is sufficient treatment. A patient who has dysplastic nevi should receive regular skin surveillance. Skin exams are usually done at 6-month intervals by the dermatologist. A patient diagnosed with melanoma should be referred to a dermatologist or an oncologist for excision of the melanoma and its margins.

Subsequent testing may include a lymph-node biopsy via computed tomography (CT)–guided needle aspiration. Sentinel node biopsy and lymphatic drainage mapping have been shown to identify more occult metastases, employing a technique that identifies the lymph node that specifically drains the area of skin that contains the melanoma. This node, called the *sentinel node,* is excised and examined for melanoma cells. If any cancer cells are present, the remaining nodes in the area are dissected. If biopsy of the sentinel node is negative, metastasis is unlikely and recurrence rates are low. If metastatic disease is suspected, however, a thorough physical exam, laboratory tests, x-ray films, and CT scans are done to identify distant sites of metastases.

Table 7.12 Skin Cancer Classification Systems

Malignant Melanoma

The American Joint Committee on Cancer (AJCC) has an ongoing collaborative staging system in process. (See www.cancerstaging.net)

The TNM (tumor, node, metastasis) system adopted by the AJCC uses both Clark and Breslow's methods to clinically stage malignant melanomas (MMs). The extent of the tumor is determined only after excision.

The presence or absence of lymph node involvement is the most important predictor of survival.

- Clark's Levels—describes the lesion based on the invading depth into the dermis and subcutaneous fat and is related to the metastatic potential of the lesion.

Level I (in situ)	Confined to epidermis
Level II	Extends through the basement membrane and into the papillary dermis (upper)
Level III	Extends into the papillary dermis (lower)
Level IV	Extends into the reticular dermis
Level V	Invades the subcutaneous tissue

- Breslow's method—describes tumor thickness by measuring the distance from the dermis to the deepest level of involvement. The thicker the lesion, the higher the incidence for metastasis. Measured in millimeters (mm).

Non-Melanoma Staging System

Stage	Criteria
0	Squamous cell carcinoma in situ, or Bowen's disease Involves only the epidermis
I	Less than 2 cm deep No spread to lymph nodes or organs
II	More than 2 cm deep No spread to lymph nodes or organs
III	Spread to muscle, bone, or cartilage and/or regional lymph nodes No spread to organs
IV	Spread to organs, e.g., lungs or brain

Differential Diagnosis

Differentiating between melanoma and benign or premalignant lesions can prove challenging, even for dermatologists. Although the majority of atypical nevi and melanomas fit the ABCDEs of melanoma, an occasional lesion will escape early detection. The differential diagnosis for melanoma includes pigmented skin lesions such as benign nevi, solar lentigines, and seborrheic keratoses.

Seborrheic keratoses are benign lesions that are common in elderly and older adult patients. The lesions are light to dark brown and appear as soft, wart-like growths, located mainly on the trunk. In contrast, melanoma is usually located on sun-exposed areas such as the neck, the back, or the legs. Solar lentigines (liver spots) are pigmented (light to dark brown) macules that appear on sun-exposed areas such as the dorsum of the hands and arms. Benign nevi (moles) are round to oval, with regular borders; most are less than 5 mm in diameter. The color is evenly distributed in a benign nevus; it is asymptomatic.

Management

A high index of suspicion is necessary because it is often hard to distinguish atypical nevi from melanoma or from normal nevi. If a clinician suspects possible melanoma or dysplastic nevi, referral to a dermatologist is necessary. There are four treatments available for melanoma: biological therapy, chemotherapy, radiation, and surgery.

If the melanoma lesion is discovered early enough (at less than 4 mm in diameter and with superficial involvement only), the chance of a complete cure with excision is good. Management will depend on the staging of the lesion (see Table 7.12). In situ melanomas require excisional margins of at least 0.5 cm. Melanomas measuring less than 2 mm in thickness require at least a 1-cm circumferential surgical margin, whereas thicker tumors need at least 2-cm margins. Lymph node dissection is required when there is evidence of draining lymph node involvement on clinical exam, but its ability to improve outcomes is unclear when performed empirically.

Nonmetastatic melanomas that have not spread beyond their site of origin are often curable. Melanomas with a Breslow thickness of 2 mm or more are curable in a significant proportion of patients, but the risk of lymph node and/or systemic metastasis increases with increasing thickness of the primary lesion. Some melanomas that have spread to regional lymph nodes may be curable with wide local excision of the primary tumor and removal of the involved regional lymph nodes.

In addition to excision of the lesion with its margins, patients with metastatic disease are treated with several modalities. One of the main treatments is chemotherapy with dacarbazine, cisplatin, and vincristine or a combination of these agents. Only 15% to 30% of patients respond to chemotherapy with a reduction in tumor size. Unfortunately, the response to chemotherapy is typically short term. Fewer than 5% of patients will experience a remission of their disease. If the melanoma is located on a limb, high-dose chemotherapy via isolated limb perfusion is available. In this technique, the circulation of the affected limb is isolated by tourniquet at the root of the limb. High-dose chemotherapy is infused and is limited to the affected limb only, minimizing adverse systemic effects from the chemotherapy.

External beam radiation to treat melanoma is usually reserved for palliative treatment. For metastatic lesions of the lung, brain, or viscera that cause pressure on tissue, radiation therapy is used to reduce the tumor's size and provide relief from pain.

Administration of biological therapy such as high-dose interferon and interleukin-2 in high-risk patients (to prevent recurrence) has shown some promise. In addition, therapies directed at specific gene mutations as mentioned above have also shown promise. Although melanomas that have spread to distant sites are rarely curable, the small molecule serine/threonine protein kinase inhibitors vemurafenib (Zelboraf) and dabrafenib (Tafinlar), as well as the fully human monoclonal antibody biological therapy ipilimumab (Yervoy), which is an antagonist of the cytotoxic T-cell inhibitory factor CTLA-4, have demonstrated improvements in progression-free survival of metastatic melanoma patients in large studies. Combination therapy with both biological therapy and chemotherapy continues to be studied.

In addition, vaccines that stimulate immune function against tumors are being developed and tested. Despite chemotherapy, the melanoma patient with extensive metastasis has a life expectancy of about 6 to 8 months.

Follow-up and Referral

The patient identified as being at increased risk for developing melanoma should be referred to a dermatologist for increased surveillance, including regular physical exams and full skin and mucosal surface inspection. Ophthalmological exam may also be indicated in the metastatic patient without a readily identifiable primary tumor (e.g., a patient with melanomatous liver metastases but no primary skin tumor), given the propensity for melanoma to develop in the pigmented uveal cells of the eye. The patient who wishes to participate in clinical trials for melanoma can obtain information on current studies from the oncologist. Hospice and palliative care should be offered for consideration to the patient and his or her family.

Patient Education

Prevention of all skin cancers should start early during infancy, especially in individuals with Celtic backgrounds or with a positive family history for skin cancer. Prevention remains the most important intervention, and early diagnosis significantly improves treatment outcomes. Thus, early detection is made easier to remember with the ABCDE mnemonic. The patient should avoid staying out in the sun during the hottest part of the day, high-SPF sunscreens should be applied on a daily basis, and hats or headgear are useful in helping to protect the scalp and the back of the neck. The hazards of tanning beds need to be discussed with all patients. Wearing loose-fitting long-sleeved shirts and pants provides some protection from the sun and is equivalent to wearing a

sunscreen if the skin is entirely covered. Unfortunately, although the level of evidence regarding preventive teaching is at Level III, most clinicians think it is crucial and will continue to aggressively teach about self-examination and give preventive advice (Early detection of cancer, 2012).

Survivors of melanoma need to be informed of their increased risk of a second primary tumor or of recurrence of the previous lesion. Any change in an existing lesion or any new pigmented skin lesion should be reported to the patient's primary-care clinician and dermatologist. Likewise, patients should be urged to report any swelling in the lymph nodes of the neck, axilla, or groin area.

NONMELANOMA SKIN CANCERS

The two most common forms of nonmelanomatous skin cancer in humans are basal cell carcinoma and squamous cell carcinoma. *Basal cell carcinoma* is a malignant tumor of the skin that originates from the basal cells of the epidermis. It is a slow-growing and locally invasive tumor that rarely metastasizes. It represents the beginning of a continuum of skin cancers in both severity and mortality. *Squamous cell carcinoma,* a malignant tumor originating from keratinocytes, can invade the dermis and occasionally metastasize to distant sites. Avoidance of excessive sun exposure is an important factor in preventing these skin cancers. In addition, screening programs are important in the early recognition and diagnosis of these skin cancers, because they are highly curable when discovered in their early stages.

Epidemiology and Causes

The incidence of basal and squamous cell carcinoma is expected to rise in the United States during the next decade because of the increase in the older adult population and a longer overall life expectancy. The exact incidence of basal cell and squamous cell carcinoma is not known, because physicians are not required to report cases of nonmelanoma skin cancers. However, more than one out of every three cancers are skin cancers, and the vast majority are basal cell carcinomas. There are an estimated 2,500 deaths annually from basal and squamous cell carcinomas.

Basal cell carcinoma is the most common malignancy seen in humans, accounting for approximately 75% of all skin cancers. Rarely, basal cell carcinoma results from basal cell nevus syndrome, an inherited autosomal dominant disorder. Patients with this disorder tend to have multiple sites of basal cell carcinoma at a younger age; it is associated with bone cysts, palmar skin pits, and frontal bossing (a protuberance of bones of the skull—particularly those under the skin of the forehead).

Squamous cell carcinoma is the second most common skin cancer, accounting for an estimated 20% of all skin cancers. Bowen's disease is an intraepidermal squamous cell carcinoma that can be induced by exposure to inorganic trivalent arsenic or inhaled mustard gas, in addition to chronic sun exposure. It affects mostly older white men.

The most important risk factor for both basal cell and squamous carcinoma is chronic accumulated sun exposure. Therefore, these skin cancers are typically seen in older adults and elderly patients. In particular, midrange ultraviolet light in the UVB part of the spectrum is believed to be more cancer inducing than UVA rays. Individuals most at risk are those patients of Celtic background (Irish, Scottish, English) who are fair haired (red haired or blond), blue eyed, and freckled and who sunburn easily. In addition, men are twice as likely to develop basal cell carcinoma and three times as likely to develop squamous skin cancers compared with women. Other conditions that increase the risk of squamous skin carcinoma include immunosuppression, a history of exposure to ionizing radiation, exposure to arsenic and polycyclic aromatic hydrocarbons (paint thinners, organic solvents), treatment with psoralens and UV light (PUVA therapy, used for psoriasis), and infection with oncogenic human papillomavirus (HPV). Squamous cell carcinomas are also seen with increased frequency in areas of damaged skin resulting from chronic inflammation, burns, old scars, or chronic ulcers. (See Risk Factors 7.3.)

Pathophysiology

The majority of basal and squamous cell carcinomas are the result of DNA damage in skin cells that have been

Risk Factors 7.3 Nonmelanoma Skin Cancer

Age
Risk increases with age
Gender
Male
Skin, Eye, Hair Color
Fair; tendency to tan poorly and burn quickly Blue eyes, red or blond hair
Personal History
History of skin cancer History of basal cell nevus syndrome History of precancerous lesions, including actinic keratosis History of burn scars or areas of skin damaged by chronic inflammation or ulcers History of immunosuppression
Environmental History
Excessive exposure to ultraviolet radiation Exposure to arsenic, polycyclic aromatic hydrocarbons, or radiation

exposed to many years of UV radiation from sunlight. The damage is cumulative and is mediated primarily by defects in DNA repair mechanisms in response to mutational cross-linking by UV light. Such cumulative damage is particularly important in the development of basal cell carcinoma, particularly within skin containing a high concentration of sebaceous glands. Several forms of basal cell carcinoma are seen clinically, including nodular, sclerosing, and superficial forms. The nodulo-ulcerative type is the most common, with well-differentiated tumor cells that may extend from the dermal–epidermal interface into the dermis and subcutaneous fat. Superficial basal cell carcinoma appears similar to dermatitis with erythema and scaling bordered by a fine rim. The origins of these tumors appear to be multifocal, with multiple small nodules arising from different epidermal foci. The sclerosing, or morpheaform, type of basal cell carcinoma is highly aggressive with a high rate of recurrence, presenting as a white plaque with palpable fibrosis and poorly circumscribed margins. Histologically, these tumors consist of spindle cells invading the dermal skin layer. If left untreated, basal cell carcinomas continue to grow and invade surrounding cartilage, bone, and soft tissues. Basal cell carcinomas rarely metastasize to distant sites, however.

In contrast, squamous cell carcinoma is considered more dangerous than basal cell carcinoma because of its faster rate of growth and its more aggressive tendency to metastasize. The precursor lesion of most squamous cell carcinomas is a skin lesion called actinic keratosis, a relatively common finding in older white patients. Actinic keratosis results from accumulated chronic sun exposure and is found only on sun-exposed skin. Actinic keratoses are premalignant lesions involving the uppermost layer of the epidermis and have a very low potential for malignancy (estimated at 1%–5% chance). In situ squamous cell carcinoma (Bowen's disease) involves the full thickness of the epidermis and is the earliest form of squamous cell carcinoma. Interestingly, in contrast to basal cell carcinoma, more recent excessive UV light exposure, rather than cumulative lifetime exposure, correlates best with the development of squamous cell skin cancer, particularly in areas with few sebaceous glands. Invasive squamous cell carcinoma is characterized by penetration through the epidermis and into the dermis, with a rate of metastasis of approximately 5%, primarily to the regional lymph nodes. Lesions that metastasize at a higher rate include those located on the lips, the ear, or at sites of trauma such as old scars and chronic wounds (ulcers). Larger lesions (more than 2 cm in diameter or more than 4 mm in depth) and patients on immunosuppressive therapy also have a higher rate of metastasis.

As observed in melanoma, any underlying condition affecting the capacity for DNA repair increases the risk of developing basal cell and squamous cell carcinoma, for example, the rare autosomal recessive condition xeroderma pigmentosum in which individuals lose the ability to repair UV light–induced DNA cross-linking damage, resulting in multiple DNA breaks and malignant transformation of skin cells. UV light exposure has also been correlated with mutations of specific oncogenes and tumor suppressor genes, including *p53* (seen in more than half of all basal cell carcinomas and up to 90% of squamous cell carcinomas) and the human patched gene. Such mutations result in dysregulated programmed cell death (apoptosis) and uncontrolled proliferation of epidermal cellular clones.

Several other mechanisms also contribute to the development of keratinocyte and basal cell skin cancers. Epidermal antigen-presenting Langerhans cells suffer direct damage from UV radiation, compromising the ability of the immune system to recognize and clear tumor antigen-expressing cancer cells. Systemic glucocorticoids also contribute to immunosuppression and have been shown in some studies to more than double the risk of nonmelanoma skin cancer. In fact, intact immunosurveillance is key to the prevention of cutaneous carcinomas, because basal cell carcinoma is 10 times more likely to develop in chronically immunosuppressed organ transplant recipients, whereas squamous cell carcinoma is up to 250 times more likely to occur. Although these tumors tend to develop at least 2 years after the transplant, they are more aggressive, more likely to occur at multiple sites, and begin to develop at a younger age than in nontransplanted, immunocompetent individuals.

Several types of pro-inflammatory cytokines have been identified in affected skin including tumor necrosis factor–alpha and IL-10. Prostaglandin synthesis also appears critical to this process, and selective cyclooxygenase-2 (COX-2) inhibitors have been shown to confer a protective effect against basal cell and squamous cell carcinoma in mouse models. HPV infection is well associated with the development of anogenital squamous cell carcinoma—particularly by serotypes 16 and 18. In immunosuppressed individuals, the development of cutaneous warts and nonmelanoma skin cancers appears to be correlated. In addition, keratoacanthoma (a fast-growing hyperkeratotic nodular lesion indistinguishable from well-differentiated squamous cell carcinoma) has also been associated with HPV infection. However, the specific role of HPV in additional forms of keratinocyte skin cancers remains controversial, and further research to explore this relationship is ongoing.

Clinical Presentation

Subjective

A typical patient with nonmelanoma skin carcinoma is an adult or elderly patient who presents with complaints of a spot or a bump that is getting larger or a sore that is not healing. The skin lesion may be pruritic or asymptomatic.

Objective

Basal cell carcinomas typically appear in areas of skin that are chronically exposed to the sun, such as the face, ears, cheeks, nose, and the neck. Nodulo-ulcerative basal cell carcinomas are characterized by elevated papules that have a pearly appearance, with some crusting. When the crusts are removed, a small amount of bleeding ensues. On close examination, telangiectatic blood vessels are seen on the border of the lesion. A central ulceration is seen during the later stages of basal cell carcinoma lesions. Basal cell carcinoma lesions may be the same color as the patient's skin or have areas of variegated color such as blue, black, or brown.

Squamous cell carcinomas are typically found on sun-exposed areas, such as the lips, the tips of ears, nose, the upper cheeks, the scalp (in bald men), the dorsa of the hands and forearms, and the shins in women. Smokers are prone to cancerous lesions on the lips and tongue. The most common presentation of squamous cell carcinoma is a firm papule with a scaly (keratotic) rough surface with irregular borders. These lesions may even present as cutaneous horns, with columnar hyperkeratosis atop an erythematous base. Later on, the surfaces of squamous cell carcinoma lesions tend to bleed easily (become friable) with minor trauma and appear eroded with ulcerations. The typical lesion of Bowen's disease appears as a solitary, slowly enlarging erythematous, red-brown hyperkeratotic plaque that has a slight scaling and minimal crusting. Similar lesions in the anogenital region known as Bowenoid papulosis have been associated with oncogenic HPV strains.

The presence of actinic keratosis lesions on patients is considered a marker for excessive sun exposure. Recognition of actinic keratosis, a precancerous skin lesion, is important because treatment during this stage is very simple. Typical actinic keratosis lesions appear on sun-exposed surfaces and are pink to red or sometimes brown. In contrast to basal cell carcinomas, where only one or a few lesions are present at a time in most patients, actinic keratosis lesions typically are present in greater numbers. Lesions vary in size from 2 mm to 1 cm in diameter. These numerous lesions are also located on chronically sun-exposed areas such as the face and the head, the back of the neck, the dorsum of the hands and arms, and the upper shoulders.

Diagnostic Reasoning

Diagnostic Tests

Suspicious lesions (if not located on the face) can be biopsied by an experienced primary-care clinician or referred to a dermatologist. Because basal cell carcinomas rarely metastasize, staging of the lesions is not necessary. Squamous cell carcinomas, however, have a higher rate of metastasis and may require staging based on the pathologist's report. Other important factors that determine staging include tumor characteristics, spread to regional lymph nodes, and metastasis to other organs (see Table 7.12).

Differential Diagnosis

The differential diagnosis of nonmelanoma skin cancer includes seborrheic keratosis, eczema, solar lentigo, and actinic keratosis. In contrast to squamous and basal cell carcinoma, seborrheic keratosis lesions predominantly appear on nonexposed areas such as the trunk in older adult patients and do not appear erythematous or scaly. A patient with eczema will report an atopic history and recurrence of lesions on the same location that resolve with treatment on steroid creams in 2 weeks. Solar lentigo lesions are found in older adults on sun-exposed areas of skin; these "liver spots" appear as multiple smooth, flat brown macules (like enlarged freckles) that are from 1 to 3 cm in size.

Management

Management of nonmelanoma skin cancers is dependent on several factors: size and depth of the invasion, location, cosmetic concerns, and metastasis to other sites. Squamous cell carcinoma has an overall rate of remission of up to 90% after therapy.

Almost all cases of basal cell carcinoma and most cases of squamous cell carcinoma require only simple excision under local anesthesia. Some primary-care practitioners and dermatologists elect excisional biopsy at the time of initial diagnosis; this procedure is both diagnostic and curative. Alternative methods for removal of small basal and squamous cell carcinomas include electrodesiccation and curettage, cryosurgery (liquid nitrogen), and laser surgery.

Mohs microsurgery has the highest cure rate for both basal and squamous cell carcinomas. This precise technique involves the surgical removal and simultaneous microscopic examination of small layers of skin, with removal of only the smallest amount of tissue necessary to eradicate the tumor (until disease-free margins are confirmed). This technique involves less scarring and is particularly suited for treatment of tumors in places of cosmetic importance, such as the face. Skin grafting may be necessary in addition to tumor removal.

In addition to surgical excision, lymph node dissection and systemic chemotherapy are used to treat large and invasive squamous cell carcinomas that have metastasized. External beam radiation is used as the primary treatment on tumors that are large or located in areas of skin that make surgery difficult, or in elderly or debilitated patients who are poor surgical candidates. External beam therapy is also used as adjuvant therapy in lesions with high risk of recurrence or in cancers that have metastasized.

Topical therapies are also used for superficial forms of basal cell carcinoma, including imiquimod cream (used five times weekly), topical 5-fluorouracil (5-FU), and photodynamic treatment (used for both nodular and superficial forms) utilizing a photosensitizer with blue wavelength phototherapy to create reactive oxygen species. Similar approaches are being used for squamous cell carcinoma, for example, imiquimod for in situ Bowen's disease. Premalignant actinic keratosis is also typically treated with topical chemotherapy (e.g., 5-FU cream) or cryotherapy with liquid nitrogen. Other treatment options include dermabrasion, shave excision, electrodesiccation and curettage, and laser therapy.

Recurrence rates for both basal cell and squamous cell carcinomas after treatment range from 5% to 50%. Rates vary with tumor characteristics and treatment modality, and most recurrences occur within 3 years after treatment. Mohs microsurgery is an option for recurrent lesions; it has a particularly high curative rate in lesions that have recurred after other types of treatment.

Follow-up and Referral

Referral to a dermatologist or oncologist is necessary for all suspicious skin lesions, including nonmelanoma skin cancers. The majority of patients require only simple excision of the skin lesion, with follow-up to monitor skin healing by the dermatologist or practitioner who performed the procedure. Subsequent follow-up includes complete physical exams with skin exams every 6 to 12 months or more often if there is any sign of new or changing skin lesions or recurrence at the primary site. The patient who has been diagnosed with any type of skin cancer is at increased risk of developing more skin lesions in the future or of recurrences of the primary lesion.

Patient Education

The American Cancer Society recommends annual skin exams for all adults aged 40 years and older. The importance of careful examination of the skin on an annual basis in certain patients cannot be overemphasized. This includes patients with a family history of melanoma, multiple nevi, a history of sunburns and frequent sun exposure, and persons who work in certain occupations or avocations, such as farmers, gardeners, and sailors. Unfortunately, research has shown that a large proportion of primary-care practitioners do not routinely document findings related to the skin on physical exams. Patients of all ages should be taught the importance of monthly skin self-exams and to report any changes in preexisting skin lesions (see Table 7.13).

The patient should be instructed to report any changes in existing moles or the development of new or rapidly growing lesions. Survivors of nonmelanoma skin cancer should be informed of increased risk of developing a second lesion or of recurrence of the original lesion. Approximately 80% of lifetime exposure to UV radiation occurs before age 20 years in the majority of patients. Strategies to avoid sun exposure should be discussed with all patients at every physical exam, particularly with parents of infants, young children, and

Table 7.13 Patient Education: Skin Self-Exam

• Once a month, perform a skin self-exam. Record your initial exam, then note any changes with each subsequent exam. Use the table below as a guide for your exam.

Head	Looking in a mirror, carefully inspect your head. Using a comb or hair dryer, carefully part your hair and inspect your scalp.
Face and neck	Looking in a mirror, carefully inspect your entire face and neck, including the nose, lips, and ears.
Arms and hands	Holding up each arm, carefully inspect each arm and hand, including the underarms and back of your upper arms (a mirror may be needed). Holding up each hand, carefully inspect the front and back of each hand and wrist, including the areas between each finger and the fingernails.
Chest, torso, and front of the legs	Standing and looking in a full-length mirror, carefully inspect your chest (including breasts), torso, and front of the legs.
Back, buttocks, and back of the legs	Standing and looking in a full-length mirror, turn so that you can carefully inspect your full back, buttocks, and back of the legs (a hand mirror may also be needed).
Ankles and feet	Sitting and propping each foot on a chair or stool at a comfortable height, carefully inspect the tops and bottoms of both ankles and feet, including the areas between the toes and the toenails.
Genitalia	Sitting and using a hand mirror, carefully inspect the genitalia.

adolescents. Patients and their families should be advised of the following preventive strategies:

- Avoid sun exposure from 11 a.m. to 4 p.m.—the time of the most intense UV radiation.
- Wear protective clothing (tight-weave fabric, long-sleeve shirt, and wide-brimmed hat).
- Wear large-framed, wraparound sunglasses with 99% to 100% UV absorption.
- Apply a sunscreen with an SPF of at least 15 as directed, even on hazy days; reapply sunscreen as needed.
- Avoid the use of tanning beds and sun lamps.

Chapter 8

Eyes, Ears, Nose, and Throat Problems

Susan Kelly-Weeder, PhD, FNP-BC • Sharon Thrush, DNP, APRN, FNP-BC • Brian Oscar Porter, MD, PhD, MPH

COMMON COMPLAINTS

This section briefly introduces common complaints involving the eyes, ears, nose, and throat that are frequently encountered in the primary-care setting. Several of these conditions are further expanded in the section on common problems.

DRY EYE

Dry eye is a relatively common syndrome that affects a significant portion of the U.S. population, especially those older than 40 years of age, and may be more prevalent in Asian and Hispanic populations. It is characterized by inadequate tear production. Dry eye occurs as a result of (1) mechanical abnormalities that interfere with the spread or maintenance of tears over the eyeball surface, (2) lacrimal gland malfunction, or (3) mucin deficiency. Mechanical abnormalities include abnormalities of eyelid structure and function and protrusion of the eyeballs; they may also result from the misuse of contact lenses.

Dry eye commonly affects both eyes and is often described as "a feeling of sand in the eyes," especially when blinking. The eyes feel hot, irritated, and gritty and may redden. The patient may present with complaints of blurred vision, lack of tears, or excessive tearing, burning, itching, foreign body sensation, sensitivity to light, and loss of glossy appearance of the cornea. The complaint worsens with smoky or dry environments, such as hot air heating systems, or with excessive computer use.

Differential Diagnosis

Differential diagnosis of dry eye includes, but is not limited to, the following:

- Conjunctivitis
- Blepharitis
- Contact lens complications
- Exophthalmos
- Ectropion
- Bell's palsy
- Medicamentosa
- Sjögren's syndrome
- Age-related changes
- Hormonal changes
- Systemic vitamin A deficiency
- Drug action

EXCESSIVE TEARING (EPIPHORA)

Excessive tearing is often a case of paradoxical tearing, that is, a response to dry eye. It is an especially common complaint in elderly patients and in individuals with allergies. A healthy eye is a wet eye; however, a continuously wet eye with uncontrolled tearing signals a malfunction due to a variety of possible causes. The complaint of excessive tears may be related to dryness of the eye. If there is a malfunction of the lacrimal apparatus or nervous control of the lacrimal apparatus, eyes that were dry may tear inappropriately. The eye may also water secondary to an irritant. Excessive tearing is frequently related to allergy, infection, trauma, pain, or structural abnormalities, as in ectropion. Eyes can also water as a result of eyestrain that may be sustained, for example, with prolonged computer use, which can also lead to pain that spreads to the neck, shoulders, and back. The patient may complain of "excess tears," when in reality the tears are a discharge secondary to some form of red eye. Sensitivity to preservatives in certain eyedrops and contact lens solutions can also cause this relatively common problem. Excessive tearing may also occur secondary to a blockage in the drainage system from the accumulation of discharge from conjunctivitis. Frequently, excess tearing will lead to increased irritation and even more tearing, so it is necessary to break this cycle to treat the symptom effectively.

Differential Diagnosis

Differential diagnosis of epiphora includes, but is not limited to, the following:

- Allergens
- Dry eye syndrome
- Viral or bacterial conjunctivitis

- Blocked lacrimal duct
- Ectropion
- Trauma (e.g., foreign body or corneal abrasion)
- Environmental pollutants
- Glaucoma

This subject is dealt with in detail later in the chapter.

EYE PAIN

The most important thing for the clinician to know in the case of eye pain, and in dealing with eye problems in general, is when to refer the patient to an ophthalmologist. The liability and potential for human suffering related to damage to vision are high.

Table 8.1 presents conditions associated with any eye pathology that require immediate referral to an ophthalmologist.

Because of the subjective nature of the pain experience, the presentation of eye pain might mean a variety of things. In addition, it is important to differentiate whether the pain is coming from the eye itself or from one of the surrounding structures. The most common cause of eye pain is trauma.

Differential Diagnosis

Differential diagnosis of eye pain includes, but is not limited to, the following:

- Referred pain (trauma, headache, sinusitis, temporomandibular disorders [TMDs], herpes zoster ophthalmicus, postherpetic neuralgia, tumors, stroke, trigeminal neuralgia)
- Eyelid disorders (hordeolum, trauma, blepharitis)
- Conjunctivitis, corneal abrasions, ulcerations, foreign body, ultraviolet light overexposure, overuse of contact lenses or computer use
- Pain with swelling (orbital cellulitis)
- Pain with eye movement (scleritis, episcleritis)
- Deep pain (uveitis, glaucoma)

Table 8.1 Conditions Requiring Immediate Referral to an Ophthalmologist

Patient complains of severe and sudden vision loss or sudden severe nontraumatic eye pain.
Physical exam reveals:
- Corneal ulceration
- Suspected herpes zoster ophthalmicus
- Hazy cornea
- Irregular pupil
- Elevation of fundus on funduscopic exam
- Papilledema
- Limbal flush
- Muscle paresis

Management issues:
- Conditions requiring steroid therapy
- Patient not improving with conservative therapy

RED EYE

Red eye, a common ophthalmic problem encountered in the acute and primary-care settings, is a nonuniform redness of the conjunctiva from hyperemia, which can be diffuse, localized, or peripheral, or may encircle a clear cornea. The most common condition is viral conjunctivitis (pink eye), which is benign; other causes of red eye include bacteria, allergies, chemical irritations, or minor eye irritation from inadequate sleep, overuse of contact lenses, environmental irritants, or excessive rubbing. Some conditions are benign; others may threaten vision and require the immediate attention of an ophthalmologist.

Differential Diagnosis

Differential diagnosis of red eye includes, but is not limited to, the following:

- Conjunctivitis
- Hordeolum (stye)
- Glaucoma
- Iritis
- Corneal abrasions
- Dry eyes, keratitis sicca
- Subconjunctival hemorrhage

Differential Diagnosis 8.1 presents a comparison of the selected differential diagnoses for red eye.

VISUAL DISTURBANCES AND IMPAIRED VISION

Patients often come to the primary-care setting with symptoms related to changes in their vision. The list of differential diagnoses of impaired vision is quite lengthy; however, a number of conditions occur commonly and should be well known to the clinician.

Common visual disturbances include “floaters” and flashing lights. These subjective complaints usually have different causes. The visualization of floaters is usually due to contraction of the vitreous humor, which is a common sequela of the aging process (degenerative vitreous changes, or syneresis). This may also result from tear-film debris or from material in the vitreous. Floaters are usually unilateral and are often seen when looking at a bright background. Floaters that appear gradually and become less noticeable over time are usually benign and require no treatment. Floaters that appear suddenly, especially if bilateral, may warrant further evaluation. *Photopsia,* or flashing lights, is the subjective sensation of sparks or flashes of light induced by mechanical or electrical retinal stimulation. Any patient who complains of seeing flashing lights should be evaluated immediately for retinal tear or detachment. Monocular photopsia may occur secondary to cataracts, migraine headaches, epilepsy, vertebral basilar insufficiency, retinitis, retinal hole, detachment of the retina, or retinal microembolization. In addition, a condition seen especially among

Differential Diagnosis 8.1 Red Eye

Assessment	Bacterial Conjunctivitis	Allergic Conjunctivitis	Viral Conjunctivitis	Iritis	Acute Glaucoma
Discharge	Purulent, thick Crusted lids in morning	Stringy mucoid	Watery	Rare	None
Visual acuity	Normal	Normal	Normal	May be decreased if iritis is severe	Decreased
Pain	Sandiness	Itching and burning	Itching	Moderate pain	Severe pain
Conjunctival abnormalities	Moderately heavy, diffuse	Mild, diffuse	Moderate, diffuse	Moderate, around cornea	Anterior chamber may appear narrow with penlight exam
Pupillary abnormalities	None	None	None	Poor light reflex	Middilated nonreactive or sluggish
Photophobia	No	No	No	Yes	Mild
Bilateral involvement	Sometimes	Usually	Often, highly contagious	No	Sometimes
Intraocular pressure	Normal	Normal	Normal	Normal	Increased
Preauricular lymph nodes	Not palpable	Not palpable	Palpable	Not palpable	Not palpable
Other symptoms	Occurs in fall and winter	Rhinorrhea, sneezing, watery eyes, occurs in the fall and spring	Upper respiratory infection	May have connective tissue disease	Nausea, vomiting, and headache

women 55 to 65 years of age is vitreous detachment, causing a fluid-filled, optically empty space between the vitreous and the retina.

Differential Diagnosis

Differential diagnosis of impaired vision includes, but is not limited to, the following:

- Refractive errors
- Cataracts
- Glaucoma
- Diabetic retinopathy
- Macular degeneration
- Retina detachment
- Vitreous hemorrhage
- Central retinal artery or vein occlusion

Differential Diagnosis 8.2 presents a comparison of the selected differential diagnoses for impaired vision.

EAR PAIN (OTALGIA)

Ear pain in general is a common clinical complaint. Ear problems are often caused by an infection. However, in the absence of physical signs in the structures of the ear, other causes of ear pain need to be ruled out, such as dental abscesses, sinus infections, temporomandibular joint (TMJ) disease, or mastoiditis. Otalgia can be bilateral or localized to one ear. Ear pain may also have a seasonal affinity such as in otitis externa, which is more common in the summer months, or sinus infections, which may be more common during peak allergen season. Ear pain associated with acute and chronic otitis media are frequently associated with eustachian tube disorder, especially in the pediatric population.

Differential Diagnosis

Differential diagnosis of ear pain includes, but is not limited to, the following:

- Otitis externa
- Acute otitis media
- Otitis media with effusion
- Eustachian tube dysfunction
- Barotrauma
- Ceruminosis
- Dental disease
- TMJ dysfunction

Differential Diagnosis 8.2 Impaired Vision

Diagnosis	Patient Age	Subjective Assessment	Objective Assessment	Urgent Treatment Required
Refractive Error				
Myopia	Teenager	Painless progressive loss of vision (PPLV)	No change in fundal exam	No
Presbyopia	Older than 40	PPLV; may have blurred vision	No change in fundal exam	No
Cataracts	Older adults	PPLV	Vision decreased Opacity may be apparent, cloudy lens, decreased view of fundus	No
Macular degeneration	Older adults	PPLV Decreased central vision	Decreased central vision Blood, lipid exudates on fundal exam	Usually not
Diabetic retinopathy	Related to length of time patient has had diabetes and any comorbid conditions	PPLV	Vision will usually not improve with pinhole test Varies with stages of retinopathy Dot-blot hemorrhages Microaneurysms, lipid exudates Infarcts in nerve fiber layer	Usually not
Chronic glaucoma	Usually older than 40, but may occur in younger patients	PPLV Halo around lights	Decreased peripheral field of vision, decreased central vision is a later sign Increased intraocular pressure, increased cup-to-disc ratio Normal chamber angle	Usually not
Acute glaucoma	Usually 50–85	Sudden onset Severe eye pain, vomiting, headache	Conjunctiva may be infected Steamy cornea, pupil may be fixed, partially dilated, narrow chamber angle	Yes

- Perforated tympanic membrane
- Sinus disease
- Cervical lymphadenopathy

IMPAIRED HEARING

Hearing loss is the decreased ability or complete inability to hear. It may involve the middle ear, which indicates a mechanical or conductive problem (usually implying a reversible problem), or the inner ear, which indicates a nerve or sensorineural problem. Hearing loss may have both conductive and sensorineural components. Often cerumen (ear wax) impaction is present. Many types of hearing loss can be improved with hearing aids; however, only 10% to 15% of patients who could benefit from a hearing aid actually use one.

The prevalence of hearing loss increases after age 40 years. Hearing loss affects approximately 25% of all adults aged 65 to 74 years and 50% of all adults older than age 85 years. Sensorineural hearing loss increases with age. The degenerative decline starts at age 20 years. Ethnicity and gender are not significant. Hearing loss is a universal phenomenon of aging, with an increased incidence in individuals with a family history of hearing loss.

Differential Diagnosis

Differential diagnosis of hearing loss includes, but is not limited to, the following:

- Presbycusis
- Noise exposure
- Ototoxic drugs
- Eustachian tube dysfunction
- Cerumen impaction

- Chronic middle ear infection, effusion
- Otosclerosis
- Tympanosclerosis
- Cholesteatoma
- Trauma
- Congenital disorders

TINNITUS

Tinnitus is a subjective perception of noise when in reality no environmental noise is present. It may be intermittent, continuous, or pulsatile (synchronous with heartbeat). It has been variously described as the sound of escaping air, the sound of running water, or the sound heard inside a large seashell or as a buzzing, ringing, or humming noise. Tinnitus also has been described as a roaring or musical sound. It may be unilateral or bilateral.

Recent estimates suggest that as many as 40 million Americans are affected by tinnitus. Approximately 90% of patients with hearing loss experience some tinnitus, and approximately 1% of the population suffers from chronic tinnitus.

Differential Diagnosis

Differential diagnosis of tinnitus includes, but is not limited to, the following:

Subjective Tinnitus

- Otologic: Hearing loss, Ménière's disease, acoustic neuroma
- Ototoxic medications or substances
- Neurological: Multiple sclerosis, head injury
- Metabolic: Thyroid disorder, hyperlipidemia, vitamin B_{12} deficiency
- Psychogenic: Depression, anxiety, fibromyalgia

Objective Tinnitus

- Vascular: Arterial bruit, venous hum, arteriovenous malformation, vascular tumors
- Neurological: Palatomyoclonus, idiopathic stapedial muscle spasm
- Patulous eustachian tube

MOUTH SORES

Problems of the oral cavity and throat account for approximately 20% of visits to primary-care providers. Although the mouth may be thought of as merely a receptacle for food and a vehicle for speech, several anatomical structures within the oral cavity may be the foci of disease. The oral cavity is lined by the buccal mucosa, which is rich in mucous glands. The mucous glands of the lips open into the oral cavity. The mouth cavity communicates with the pharynx posteriorly. The floor of the mouth contains the tongue and the openings of submandibular and sublingual salivary glands.

Specific lesions of the oral and buccal mucosa are immunogenic, inflammatory (most commonly aphthous ulcers), or traumatic or may be caused by a localized malignancy. Painful inflammatory lesions may occur in isolation, or they may be associated with a generalized disorder of other mucous membranes or skin. The patient's history is important because it indicates whether the lesions are acute or chronic, single or multiple, and primary or recurrent.

Differential Diagnosis

Differential diagnosis of mouth sores includes, but is not limited to, the following:

- Food or drug allergies
- Chemical irritation
- Dry mouth
- Mechanical or thermal injury
- Infections (bacterial, viral, fungal)
- Host immunosuppression
- Nutritional deficiency

HOARSENESS

Hoarseness is a common complaint; the term describes a voice with harsh quality and low pitch. Use of the term can also include weakness, raspiness, or simply a change from the usual voice quality. Hoarseness suggests an abnormality in voice production at the level of the larynx. It is a common symptom that may occur in both men and women at any age. Changes in the voice are part of the natural process of aging. In elderly men, the voice becomes weaker and higher in pitch as a result of muscle atrophy and increased stiffness of tissues. In women, the same changes occur, but the pitch of the voice becomes lower because during menopause, mucoid edema accumulates in the submucosa of the vocal folds. More severe edema and polyps may occur in women who smoke. Hoarseness is a cardinal sign of laryngeal cancer, which is most commonly seen in men 50 to 70 years of age.

Differential Diagnosis

Differential diagnosis of hoarseness includes, but is not limited to, the following:

- Infection
- Inflammation
- Overuse
- Vocal cord pathology (polyps, nodules, tumors)
- Vocal cord paralysis
- Muscle atrophy (aging)
- Gastroesophageal reflux disease
- Chronic allergies

Differential Diagnosis 8.3 presents a comparison of the differential diagnosis of hoarseness.

SORE THROAT

Sore throat is defined as discomfort or pain in the throat that is most intense when swallowing. It can be associated with sore mouth, especially if there is a viral infection such as herpes simplex virus (HSV) that erupts as

Differential Diagnosis 8.3 Hoarseness

Infectious	Neurological	Traumatic	Neoplastic
Viral laryngitis	Dystonia	Vocal cord nodules or polyps	Vocal cord cancer
Bacterial tracheitis or laryngitis	Neuromuscular disease	Smoke inhalation	Supraglottic cancer with muscle invasion
Papillomatosis	Laryngeal nerve involvement by thyroid, pulmonary, or esophageal causes	Esophageal reflux Chronic cough	

lesions that can cause soreness in both anatomical locations. Sore throat can be part of a generalized upper respiratory infection or a specific infection localized in the pharynx. The most common causes of sore throat are streptococcal and viral infections, such as those of rhinovirus. Each year in the United States, pharyngitis is responsible for 40 million visits to health-care providers, and viral pharyngitis is one of the most common causes of absence from work or school.

Differential Diagnosis

Differential diagnosis for sore throat includes, but is not limited to, the following:

- Streptococcal pharyngitis
- Tonsillitis
- HSV
- *Gonococcus*
- Candidiasis
- Aphthous ulceration
- Influenza virus
- Rhinovirus, adenovirus, Epstein-Barr virus, coxsackievirus
- Mycoplasma

COMMON PROBLEMS

LID PATHOLOGY

BLEPHARITIS

Blepharitis is an inflammation of the eyelids and margins. There are two forms of blepharitis: (1) a nonulcerative form associated with seborrhea of the face and scale and (2) an ulcerative form that may involve the lash follicle and the meibomian glands of the eyelid. Secondary infections may develop with either form, and recurrences are common and frequently persistent. Both types may coexist.

Epidemiology and Causes

Blepharitis is the most common ocular disease, affecting males and females equally. Nonulcerative blepharitis is occasionally seen in those with trisomy 21 and tends to affect people with psoriasis, seborrhea, eczema, allergies, and lice infestations. Poor hygiene is implicated, as well as poor nutritional status, immune suppression, acne rosacea, and yeast infections. Exposure to chemical or environmental irritants, as well as the use of eye makeup and contact lenses, may contribute to the development of this disorder.

Pathophysiology

Although difficult to discern without a full ophthalmological exam, the localization of blepharitis speaks to the differentiation of affected structures. Anterior blepharitis typically affects the eyelash hair follicles along the eyelid's anterior lamella, whereas posterior blepharitis involves inspissation and inflammation of the meibomian gland orifices (meibomianitis) along the tarsal plate. Seborrheic gland dysfunction, along with accelerated shedding of skin cells, appears to be the primary insult resulting in inflammation in the nonulcerative form, in which an oily crust envelops individual eyelash cilia (seborrheic blepharitis). The inflammatory, noninfectious skin disorder known as acne rosacea, which commonly affects the central face, is another common etiology of blepharitis in the younger population. Blepharitis may also be a manifestation of an allergic process such as a contact dermatitis if a foreign irritant comes into contact with facial skin. In contrast, underlying infection by skin flora, most notably *Staphylococcus aureus,* produces an ulcerative form that may become chronic, extending to the conjunctivae and cornea, known as blepharoconjunctivitis—a condition with a strong potential to affect eyesight.

Clinical Presentation

Subjective

Both forms of blepharitis may present with complaints of itching and burning, and foreign body sensation in the eye. Sensitivity to bright lights and tearing may also be present. Presentation may be unilateral or bilateral.

Objective

Lid margins are edematous and erythematous. Inspection with a magnifying glass may reveal scaling, erythema, and ulcers. Nonulcerative blepharitis may present with scales

along the lid margins that are easily removed. With ulcerative blepharitis, there may be pustules at the base of the hair follicles that may crust and bleed. The lashes become thin and break easily. Use gloves to palpate the lid margins and lid for masses and palpate for preauricular lymphadenopathy.

Diagnostic Reasoning

Diagnostic Tests

With any eye problem, it is vital to evaluate visual acuity. Any alteration in visual acuity may indicate a potentially serious underlying problem that warrants further investigation. If there is a discharge, a culture and sensitivity should be considered. Referral for patients with blepharitis should occur in the following situations: visual loss, moderate to severe pain, chronic redness of the eye, corneal involvement, recurrent blepharitis, and when patients fail to respond to therapy. Any lesion in or around the eye that does not respond to conventional therapy within 1 month should be referred to a specialist for possible biopsy. Persistent inflammation and thickening of the eyelid margin may indicate squamous cell, basal cell, or sebaceous cell carcinoma. Sebaceous cell carcinoma has a 23% fatality rate; up to one-half of potentially fatal sebaceous cell carcinomas resemble chronic, benign inflammatory disease, particularly chalazion and blepharoconjunctivitis.

Differential Diagnosis

Persistent inflammation and thickening of the eyelid margin may indicate squamous cell, basal cell, or sebaceous cell carcinoma masquerading as blepharitis. Carcinoma may also mimic styes or chalazion.

Management

Any swelling or inflammation of the eyelid that does not resolve promptly (within 1 month) with treatment should be evaluated further. Therapeutic Procedure 8.1 describes the management of various forms of blepharitis.

Follow-up and Referral

The clinician should reevaluate the patient in 2 weeks; if symptoms are improving, the patient should be reevaluated in 2 months. As noted, if there is no resolution in

Therapeutic Procedure 8.1 Blepharitis

Type	Description	Treatment
Nonulcerative Blepharitis	This type of blepharitis may be persistent and treatment is aimed at improving hygiene.	Eyelid hygiene with dilute 1:1 no-tears shampoo (baby shampoo) and water using a soft washcloth or cotton balls. Warm, moist compresses to provide comfort and serve to open meibomian glands and facilitate drainage. The patient should apply compresses for 20 minutes, then rest for at least an hour. Patients should be advised that eyelid hygiene may be required for life, and that symptoms may recur if treatment is discontinued. Advise the patient to discontinue the use of eye makeup and contact lenses.
Staphylococcal Blepharitis/ Ulcerated Lesions	Infectious blepharitis should be treated with topical antibiotic ointments that adhere to the eyelid margins more effectively than drops.	Bacitracin or erythromycin 0.5% ointment can be prescribed and applied on the eyelids one or more times daily or at bedtime after gentle cleansing and using warm compresses. Treatment may continue for 1 or more weeks. The frequency and duration of treatment should be guided by the severity of the blepharitis. For resistant staphylococcal infections, a quinolone antibacterial ointment is appropriate or a sulfacetamide/ corticosteroid combination that, like erythromycin, has been shown to be effective against staphylococci. The combined corticosteroid is useful in decreasing both inflammation and symptoms. Use of the two agents combined has been shown to increase patient compliance. Blephamide is available in an ophthalmic suspension and in an ointment, both containing the same concentrations of active ingredients (10% sulfacetamide/ 0.2% prednisolone).
Severe Blepharitis	Associated with rosacea.	Oral doxycycline 100 mg PO twice daily or tetracycline 250 mg PO four times daily is appropriate. These are prescribed for several weeks and then tapered. Continued hygienic measures as above.

1 month, the patient should be referred to an ophthalmologist. Vision changes and pain in the eye also warrant referral. Blepharitis may be difficult to resolve, and recurrences are common. Hordeolum, loss of lashes, or misdirection of the eyelashes (trichiasis), scarring, and corneal infection may occur.

Patient Education

Patients should be encouraged to wash their hands often and dry them with clean towels to prevent reinfection or transfer of bacteria or virus to other persons. In addition, patients should be advised to avoid environmental irritants, to use hypoallergenic soap and makeup, and to exercise care in use of contact lenses. The clinician should educate the patient as to the chronic and recurrent nature of this disorder and the need for vigilance in adherence to the treatment plan until the blepharitis is completely resolved. Long-term eyelid hygiene—gently cleansing with diluted baby shampoo daily—is required to control this disorder. Eye makeup should not be used until resolution of the disorder, and then the patient should switch to hypoallergenic makeup. A blepharitis fact sheet is available from www.med.nyu.edu/patientcare/library/article.html?ChunkIID=12013.

HORDEOLUM/CHALAZION

A *hordeolum,* also known as a *stye,* is an acutely presenting, erythematous, tender lump within the eyelid. This condition involves an inflammation/infection of the eyelid margin affecting the hair follicles of the eyelashes (external hordeolum) or the meibomian glands (internal hordeolum) and may evolve into a chalazion. A *chalazion* is a granulomatous infection of a meibomian gland, presenting in the form of painless swelling on the eyelid. Initially, a chalazion may be tender and erythematous before evolving into a nontender lump. Blepharitis is frequently associated with chalazia.

Epidemiology and Causes

These are common eyelid disorders that affect men and women equally. The cause is often a blockage in a duct of the meibomian gland leading to the eyelid surface; secondary infection may be present, again, commonly with *Staphylococcus.* This duct obstruction results in inflammation that may manifest as a hard mass (chalazion), infection of the sebaceous glands of the eyelash (external hordeolum), or infection of posterior margin of the eyelid (internal hordeolum). Previously unresolved blepharitis, poor hygiene, immunosuppression, and underlying chronic diseases all contribute to the development of eyelid disorders. Again, skin conditions such as acne rosacea or seborrheic dermatitis may also predispose the individual toward the development of a hordeolum.

Pathophysiology

Hordeolum and chalazia are various manifestations of the inflammatory response at the eyelids, exhibiting both microscopic (accumulation of fluid and cells at the inflammatory site) and macroscopic (redness, swelling, heat, pain, and loss of function) hallmarks of inflammation. An internal hordeolum is a suppurative infection of the oil-secreting meibomian glands within the tarsal plate of the eyelid that may evolve into a chalazion. An external hordeolum occurs with infection of the more superficial anteriorly located glands of Zeis or Moll found at the eyelid margin. With a stye (hordeolum), the eyelid may manifest a classic inflammatory reaction; however, a chalazion results from an obstruction of the meibomian gland with a granulomatous response and is typically painless. The blockage of the gland's duct at the eyelid margin results in the release of the gland's contents into the surrounding eyelid soft tissue, and a lipogranulomatous reaction ensues, producing a pea-sized nodule within the eyelid. Occasionally, a chalazion may also become secondarily infected with *Staphylococcus aureus.*

Clinical Presentation

Subjective

Hordeolum presents as a localized tender inflammation of the eyelid (external) or redness at the margin of the eyelid, with swelling (internal). In addition, patients may experience itching or scaling of the eyelid, chronic redness, and eye irritation, leading to localized tenderness and pain.

Chalazion commonly presents as a slow-developing, painless hard mass, with inflammation and possible involvement of the surrounding tissue.

Objective

The clinician should evaluate visual acuity. With chalazion, inversion of the eyelid will reveal a red, elevated mass that may become quite large and press against the eye, causing nystagmus and distortion of vision. With a hordeolum, there is erythema and localized tenderness with palpation; there may also be drainage from the lesion on the margin of the lid. The clinician should also palpate for preauricular adenopathy.

Diagnostic Reasoning

Diagnostic Tests

Hordeolum and chalazia are usually diagnosed by their appearance. If drainage is present, culture the drainage. If the conditions persist, referral for biopsy may be indicated.

Differential Diagnosis

As noted previously, any inflammation or swelling that does not resolve within 1 month with treatment should be referred. Squamous cell, basal cell, or sebaceous cell carcinoma may mimic other disorders of the eyelid. As noted previously, sebaceous cell carcinoma, according to some reports, has a 23% fatality rate. Up to one-half of

these potentially fatal carcinomas may resemble benign inflammatory disorders. A concurrent and predisposing blepharitis may be present.

Management

Therapeutic Procedure 8.2 describes the various treatments of hordeolum and chalazion.

Follow-up and Referral

Any patient with visual change or pain should be referred to an ophthalmologist. Recurrence of hordeolum/chalazion is likely without proper lid hygiene. If there is no improvement in 1 month, refer for evaluation.

Patient Education

The clinician should explain the recurrent nature of the disorder and the need for vigilance, and begin treatment at the first sign of recurrence. The practitioner should explain that staph (*S aureus*) infections are contagious and instruct the patient and family members not to share towels or washcloths. The patient should use clean cloths for each warm compress to the eye and be sure to wash his or her hands frequently.

DRY EYE

Lacrimal disorders may be acquired or congenital. Acquired disorders may be systemic, such as Sjögren's syndrome; may reflect a more local infectious process, as in some forms of conjunctivitis; or may be related to trauma, such as in facial nerve (cranial nerve [CN] VII) palsy. It has been shown that patients with chronic dry eye experience increased activation of T cells. These T cells produce cytokines that may result in a neural signal to the lacrimal gland that disrupts production of natural tears; this process leads to a decrease in the patient's own tears, to tissue damage in the lacrimal glands and on the ocular surface, to recruitment of additional T cells, and, therefore, to increased cytokine production.

Certain medications, such as anticholinergic agents, beta-adrenergic blockers, and antihistamines, decrease tear production because the lacrimal gland is stimulated by the parasympathetic system. Mucin deficiency may also be caused by certain medications, such as those listed here, as well as by vitamin A deficiency, by certain forms of chronic conjunctivitis, or as a result of the aging process. Consequently, tear production decreases with aging, especially in women during menopause, so this is a frequently encountered complaint. In addition, patients may have a diminished blink rate due to working at a computer or a microscope, which can cause evaporative loss.

Epidemiology and Causes

Dry eye is a common disorder affecting a significant percentage (approximately 10%–30%) of the population, especially those older than 40 years. In the United States,

Therapeutic Procedure 8.2 Hordeolum/Chalazion

Initial Treatment of Hordeolum	At the first sign of inflammation and pain, warm compresses should be applied to reduce inflammation and increase blood supply and potentiate spontaneous drainage. Gently scrub the eyelids with a 1:1 dilution of baby shampoo and warm water two to four times a day, or directly apply diluted baby shampoo with a cotton-tipped applicator and then rinse with warm water. Follow with gentle massage of the eyelid. Blepharitis, if present, should be treated. Eye makeup should be discontinued until infection resolves. Contact lenses should not be used during treatment. *The hordeolum (stye) should not be squeezed.*
Infection or Inflammation	Erythromycin ophthalmic ointment or sulfacetamide (Sulamyd) ophthalmic ointment can be applied four times a day or ciprofloxacin ointment (Ciloxan, Cipro) can be applied three times a day. Use a thin application to the lid margin with a cotton-tipped applicator.
Resistant or Recurrent Hordeolum *Basal cell carcinoma or sebaceous cell carcinoma of the eyelid can be misdiagnosed clinically as a recurrent hordeolum or chalazion.*	A course of oral antibiotics that is effective for *Staphylococcus* and *Streptococcus* organisms, such as Cephalexin (Keflex, Keftabs), can be prescribed.
Chalazion (Unresolved) *A chalazion that persists for more than 4 weeks needs referral to an ophthalmologist for incision and drainage, biopsy, or injection directly with glucocorticoids.*	Warm compresses and gentle massage of the swelling in the lid with a 1:1 dilution of baby shampoo and warm water may help to open the blocked meibomian duct.

an estimated 3.23 million women and 1.68 million men, a total of 4.91 million people, aged 50 years and older are affected. The frequency of this condition internationally closely parallels that of the United States. However, the frequency and the clinical diagnosis of dry eye are greater in the Hispanic and Asian populations.

Keratoconjunctivitis sicca associated with Sjögren's syndrome is a type of dry eye that affects 1% to 2% of the population, and 90% of those affected are women. Approximately 1% of the U.S. population is affected with Sjögren's syndrome, and it affects 15% of patients with rheumatoid arthritis.

Pathophysiology

A genetic predisposition to Sjögren's syndrome–associated keratoconjunctivitis sicca is evidenced by a high prevalence of human leukocyte antigen B8 in these patients. This is associated with a chronic inflammatory state, producing autoantibodies (antinuclear antibodies [ANAs], rheumatoid factor [RF]) and inflammatory cytokine release and focal lymphocytic infiltration (CD4 T cells and B cells) of the lacrimal and salivary glands, with eventual degeneration and apoptosis of the lacrimal glands and conjunctiva. The result is dysfunction of the lacrimal gland, decreased tear production, loss of response to neural stimulation, and less reflex tearing. Cytokine release inhibits neural function and may also convert androgens into estrogens, resulting in meibomian gland dysfunction. Both androgen and estrogen receptors are located in the lacrimal and meibomian glands. At menopause, there is a decrease in circulating sex hormones, possibly affecting the secreting function of the lacrimal gland. Deficiency of mucin synthesizing genes may be a factor in dry eye syndrome development as well. Vitamin A deficiency, Stevens-Johnson syndrome, and ocular cicatricial pemphigus may contribute to loss of goblet cells and promote dry eye syndrome.

Clinical Presentation

Dry eye commonly affects both eyes and is often described as "a feeling of sand in the eyes," especially when blinking. The eyes feel hot, irritated, and gritty and may become reddened. The patient may present with complaints of blurred vision, lack of tears, burning, itching, foreign body sensation, sensitivity to light, and loss of glossy appearance of the cornea. The triad presentation of burning, itching, and a foreign body sensation in the eye is sometimes referred to as *keratoconjunctivitis sicca* (KCS). This symptom is frequently associated with the diagnosis of Sjögren's syndrome, a systemic disorder affecting all secretory glands that is often associated with rheumatoid arthritis.

Untreated or severe KCS may result in inflammation, erosion, and eventually keratinization of the cornea and/or conjunctiva, and may even cause blindness. A correlation does not always exist, however, between the failure of tear production, leading to dry eye, and inflammatory or degenerative changes to the surface of the eye. Accessory glands in the palpebral conjunctiva may secrete sufficient tears to prevent corneal damage.

Subjective

Careful history taking (Focus on History 8.1) includes inquiries about current medication usage, especially the overuse of artificial tears, in which the ocular surface develops toxicity to active ingredients or preservatives in lubricant formulations. Consider vision-threatening issues such as cataracts, macular degeneration, and glaucoma and attendant medication usage for these conditions. Past medical history about coexisting connective tissue disorders, rheumatoid arthritis, Parkinson's disease, rosacea, and thyroid abnormalities will help the clinician to formulate a diagnosis. A family history of rheumatoid arthritis may contribute to the diagnosis. In the review of systems, dry mouth (xerostomia), muscle or joint pains, and heat or cold intolerance are significant findings.

Objective

The physical exam of the eyes must always include visual acuity, which may be normal. The exam may reveal a mechanical, infectious, and/or traumatic cause for the complaint of dry eyes. If one of these conditions is revealed, once it is treated, the dry eye complaint should resolve. The conjunctiva may be infected and dull, and the lids and surrounding tissues may be erythematous due to frequent rubbing. The lacrimal apparatus will be nontender; and in the case of keratoconjunctivitis sicca or Sjögren's syndrome, the mucous membranes of the mouth will be dry. Examination of the eyes with fluorescein staining and slit lamp may reveal punctuate lesions of the conjunctiva.

Diagnostic Reasoning

Frequently the complaint of dry eye is a subjective finding with few or no cues in the physical exam, and a clinical diagnosis will require referral to a specialist for

Focus on History 8.1 Eye Complaints

- Onset of symptoms (sudden or gradual)
- Change in vision (sudden or gradual)
- Pain
- Photophobia
- Mechanism of injury (if pertinent)
- Discharge characteristics
- Use of contact lenses (type, wearing schedule, and care)
- Current medication(s)
- Past history of eye problems
- Exposure history (new cosmetics, contact with person with an eye infection, travel, work environment, etc.)
- Systemic complaints (fever, genital discharge, rash, joint pains, etc.)

specialty examination and testing. Occasionally the patient will complain of excessive tearing (epiphora) or inappropriate tearing, which may be reflexive due to poor neural control of the lacrimal apparatus from dry eyes.

Diagnostic Tests

In addition to slit-lamp examination, a Schirmer test to quantify lacrimal secretions may be done. Laboratory tests to rule out an autoimmune disease include an erythrocyte sedimentation rate, ANA, and RF. If discharge is associated with the complaint, it should be cultured.

Differential Diagnosis

Differential diagnosis includes conjunctivitis, blepharitis, contact lens complications, exophthalmus, ectropion, Bell's palsy, medicamentosa, Sjögren's syndrome, age-related and hormonal changes, and systemic vitamin A deficiency.

Management

It is not unusual that the patient's contact lens prescription may need to be altered or that the self-care regimen may need to be addressed. Elimination of systemic medications that may have contributed to the condition should be considered. A patient with chronic complaints of dry eye or conjunctivitis may need to be referred to an ophthalmologist. Reports in the literature have associated the relief of dry-eye symptoms with the institution of estrogen replacement therapy in postmenopausal women. Most cases of dry eye are best managed symptomatically. However, when the complaint of dry eye is persistent and unrelieved by self-care measures, referral is necessary.

The principles of treatment for dry eye are based on the severity of the condition and the 2007 Report of the International Dry Eye Workshop (Level I) (Management and therapy of dry eye disease, 2007).

The first level of treatment provides education and suggests environmental and dietary modifications. It includes elimination of offending systemic medications; the introduction of artificial tear substitutes, lubricants, gels, and ointments; and possibly eyelid therapy. Wearing wraparound sunglasses to keep wind from drying the eye surface, using a humidifier in the home, and avoiding rubbing the eyes are methods patients can use to overcome dry eye. Specific pharmacological measures include application of ocular lubricants such as an ophthalmic ointment of petrolatum, lanolin, and mineral oil (Duratears Naturale) as needed, which is especially helpful for use with soft contact lenses, or a 1 to 2 drops of 1% polyvinyl alcohol preservative-free ophthalmic solution (HypoTears) as needed. Sodium chloride 2% or 5% ophthalmic solution (MURO 128) may be used (1–2 drops) every 3 to 4 hours, reducing frequency as inflammation subsides. Transient stinging may occur on instillation.

The second level of care is instituted if the first level is not effective. This includes the use of specific pharmacological measures, including ocular lubricants, nonpreserved artificial tear substitutes, and anti-inflammatory agents such as topical cyclosporine A, topical corticosteroids, or topical/systemic omega-3 fatty acids. Topical cyclosporine ophthalmic emulsion (Restasis) is used to treat chronic dry eye. It contains a very small concentration of cyclosporine, which is believed to inhibit the activation of T cells. T cells disrupt normal tear production in the lacrimal glands. Improving lacrimal gland function is believed to result in increased tear production and resultant relief of inflammation and further damage. Temporary punctal plugs may be warranted after inflammation has resolved. Punctal plugs are painlessly inserted and act as a sort of dam that prevents tears from draining into the puncta and into the nasolacrimal duct. Several studies have demonstrated positive subjective and objective findings as to the efficacy of punctual plugs in the treatment of dry eye syndrome. Moisture chamber spectacles have been in use for many years; however, there is limited evidence in the literature for the efficacy of this treatment.

The third level of treatment is instituted when the previous levels have failed to adequately treat the symptoms. The therapies at this level consist of use of autologous serum, special contact lenses, and permanent punctual occlusion. The final level includes the institution of systemic anti-inflammatory agents and possible surgical intervention to correct abnormalities of the lid. Other surgical procedures may include grafting of mucous membranes or possible transplantation of a salivary gland duct.

Follow-up and Referral

Supportive measures such as listening to the patient's fears associated with vision changes or the possible systemic causes of dry eye are both therapeutic and compassionate. Arranging for prompt referral to an ophthalmologist for accurate diagnosis and specialized treatments promotes a patient's confidence in the primary-care clinician.

Patient Education

In general, the prognosis for visual acuity in patients with dry eye syndrome is good. However, complications of decreased visual acuity and blindness can occur, and patients need to seek medical advice should visual acuity diminish or if the current regimen has lost effectiveness or the symptoms worsen. Table 8.2 summarizes several environmental modifications that patients can make to minimize the symptoms and recurrence of dry eye.

Omega-3 fatty acid deficiency, especially reduced levels of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), have been linked to dry eye syndrome. Dietary intake of these compounds is generally lower than the recommended daily intake; therefore, it is important to encourage patients to increase their dietary intake of DHA- and EPA-rich foods (e.g., salmon, tuna, mackerel, anchovy, halibut, and scallops). Regular use of lubricating drops or ointments and consistent use of prescribed ocular medications should be stressed.

Table 8.2 Ocular Self-Care for Dry Eye

Keep home humidity between 30% and 50%.
Cleanse humidifier frequently with 1:10 bleach solution. Rinse well with fresh water.
Wear wraparound sunglasses, especially on windy days.
Wear goggles when swimming.
Use a preservative-free artificial tears preparation or bathe your eyes in an herbal therapy solution made with Eyebright (*Euphrasia officinalis*) when irritated.
Avoid blowing hot air from hair dryer in the eyes.
Take frequent rest periods away from computer or microscope work.
Stop smoking.

A helpful link for patient information on a variety of ocular disorders is www.emedicinehealth.com/script/main/art.asp?articlekey=60170.

EXCESSIVE TEARING (EPIPHORA)

Excessive tearing is often a case of paradoxical tearing; that is, it is a response to dry eye. It is an especially common complaint in elderly patients and in individuals with allergies. Anatomical abnormalities such as ectropion, entropion, lower lid laxity, and lacrimal pump weakness due to Bell's palsy may lead to structural and functional problems in the distribution and drainage of tears. Lacrimal obstruction that limits normal drainage into the lacrimal ducts is a significant contributor to the problem. Obstruction can be associated with thickened discharge secondary to infection, tumor, trauma, or autoimmune diagnoses. The eye may water excessively secondary to irritation from contact lenses, medications, or irritants in the environment as a protective mechanism; or excessive tearing may be related to allergy, infection, trauma, or pain. The patient may complain of "excess tears," when in reality the tears are a discharge secondary to some form of red eye. Sensitivity to preservatives in certain eyedrops and contact lens solutions can also cause this relatively common problem. Frequently, excess tearing will lead to increased irritation and even more tearing, so it is necessary to break this cycle to treat the symptom effectively. As mentioned previously, a healthy eye is a wet eye; however, a continuously wet eye with uncontrolled tearing signals a malfunction due to a variety of possible causes.

Epidemiology and Causes

Epiphora is a common problem and will become more widespread as the population ages. Because epiphora is frequently associated with "dry eye," the epidemiological statistics are similar.

Pathophysiology

Tears are made up of several layers, and each layer has a role to play in the maintenance of a stable tear film. The outer layer is a lipid layer, which forms a superficial layer of the tear film. The intermediate layer is an aqueous layer derived from the main lacrimal gland. The inner layer is a mucin layer derived from goblet cells. During blinking, a suction effect draws the tear film into the lacrimal apparatus. In the case of facial nerve palsy, the loss of the blink reflex allows tearing to occur without any anatomical obstruction. This is also an issue with prolonged computer use accompanied by decreased blink reflex; the eyes become dry and may reflexively tear excessively. A malfunction of the lacrimal apparatus or neural control of the lacrimal apparatus may also cause eyes to water inappropriately.

Clinical Presentation

Subjective

A complete history, which should include any trauma and infections that could be vision threatening, needs to be elicited. If the patient complains that clear tears run down the cheek, it may signal that there is an obstruction of the lacrimal system. If the complaint is of "watery eyes," with tears collecting or welling up in the lower eyelid pouch, the problem may be associated with poor tear quality or poor tear distribution. The complaint of blurred vision, diplopia, photophobia, or eye pain may herald a serious condition. Allergic causes for excessive tearing are common, and frequently the source of the allergen is identified early during the history. Past medical history of seasonal allergies, asthma, or other atopic diseases, as well as a family history of atopic conditions, contributes to making an accurate diagnosis. The review of systems addresses systemic symptoms such as fever, headache, upper respiratory complaints, sore or itchy throat, cough or wheeze, dizziness, malaise, and skin changes.

Objective

The physical exam will focus on visual acuity and careful examination of the structures in the eye and the surrounding tissues, looking for edema, redness, discharge, rashes, and any structural abnormalities. Careful examination for foreign bodies or corneal irritants is essential. Most practice environments have access to a slit lamp and fluorescein staining or use of the slit lens on the ophthalmoscope, which can demonstrate damage in the anterior structures of the eye. In addition, signs of allergies such as pale, boggy mucous membranes in the nose, dry skin, or eczematous changes may be present.

Diagnostic Reasoning

Diagnostic Tests

Diagnostic testing would rarely be done in primary care with the exception of slit-lamp examination. However, the clinician should be aware that ophthalmologists will

use a variety of tests to determine tear quality, quantity, and flow. The dye disappearance test is one such test. A drop of fluorescein dye is placed in both eyes in the inferior fornix, and the tear meniscus height is measured after 5 to 10 minutes. This is an easy test for assessing whether there is an excretory problem with the tearing or not. There are other dye tests that look at whether fluid drains into the inferior meatus and into the lacrimal sac. Lacrimal irrigation and probing can demonstrate a punctual or canalicular problem. Occasionally, computed tomography scanning of the lacrimal drainage system can be done.

Differential Diagnosis

Presentation of acute unilateral epiphora with red eye and pain suggests foreign body or corneal abrasion. Irritating bilateral epiphora may be due to allergies, dry eye syndrome, environmental pollutants, glaucoma, or viral conjunctivitis. Blocked lacrimal duct and bacterial conjunctivitis is usually unilateral. Ectropion may be unilateral or bilateral, whereas the development of lid laxity associated with aging is usually bilateral.

Management

Treatment of excessive tearing secondary to trauma or infection includes the use of topical antibiotics. Steroid eyedrops and anesthetic drops should not be used, because they may retard healing and increase the risk of infection. If, on physical exam, a foreign body is visualized, it should be removed by saline flushes. If it cannot be removed with flushes, referral is necessary. Eye rest is important, but patching may be too uncomfortable and is not advised. Corneal abrasions should be reevaluated in 24 hours. If corneal erosion is suspected or there has been no relief in the excess tear production and the pain level is unchanged or worsens, the patient needs to be referred immediately for evaluation by an ophthalmologist. It is important to communicate this information to the patient, and again, timely referral to specialists is essential.

Treatment of allergic causes for excessive tearing (allergic conjunctivitis) consists of cold compresses for comfort and relief of itch, topical antihistamines, topical NSAIDs, mast cell stabilizers, and systemic antihistamines. Occasionally it will be necessary for consultation with an allergy specialist for allergy testing and recommendations for treatment. See Drugs Commonly Prescribed 8.1 for approved medications for allergic and other forms of conjunctivitis.

Follow-up and Referral

The patient with chronic epiphora should have an ophthalmological consultation to evaluate and consider treatment with possible surgical correction. Individuals with conjunctivitis should be reevaluated after a course of antibiotic therapy or after 2 weeks of instituting

Drugs Commonly Prescribed 8.1 Conjunctivitis

Allergic Conjunctivitis	Mast Cell Stabilizers	Drugs
	Block a calcium channel essential for mast cell degranulation, stabilizing the cell and thereby preventing the release of histamine and related mediators.	lodaxamide 0.1% (Alomide) nedocromil 2% (Alocril) pemirolast 0.1% (Alamast)
	Antihistamines	
	Combat the histamine released during an allergic reaction by blocking the action of the histamine on the tissue.	emedastine 0.05% (Emadine) levocabastine 0.05% (Livostin)
	Combination Mast-Cell Stabilizers and Antihistamines	olopatadine 0.1% (Patanol) azelastine 0.05% (Optivar) ketotifen fumarate 0.025% (Zaditor) epinastine 0.05% (Elestat)
	Nonsteroidal Anti-Inflammatory Agents	ketorolac 0.5% (Acular)
	The mechanism of their action is thought to be due to the ability to inhibit prostaglandin biosynthesis; thereby, they have an analgesic and anti-inflammatory action.	

Drugs Commonly Prescribed 8.1 Conjunctivitis—cont'd

Bacterial Conjunctivitis	Antibiotics	Drugs
Usual organisms: *Streptococcus pneumoniae, Haemophilus influenzae*, group A *Streptococcus, S aureus*, pseudomonads	First-line therapy: Treat empirically with broad-spectrum topical agents. High levels of the agent are delivered directly to the site of infection. The level of concentration exceeds what is normally achieved in body tissues by oral or parenteral routes. Most agents available as ointments or solutions.	sodium sulfacetamide (Bleph 10, Cetamide, AK-sulf) erythromycin ointment (E-Mycin) azithromycin ophthalmic (AzaSite) bacitracin (AK-Tracin, Baciguent) ciprofloxacin (Ciloxan) trimethoprim and polymixin B (Polytrim) tobramycin (Tobrex) neomycin (Mycifradin) ofloxacin (Ocuflox) levofloxacin (Quixin) gatifloxacin 0.3% (Zymar) besifloxacin (Besivance) gentamicin (Genoptic, Ocumycin)
Chlamydial Conjunctivitis	**Antibiotics**	**Drugs**
Common in developing nations. Leading cause of blindness in these nations.	*Systemic antibiotics in addition to topical agents are necessary*. Sexual partners should be evaluated for infection and treated simultaneously.	azithromycin 1 g as a single dose or doxycycline 100 mg twice daily for 7 days
Viral Conjunctivitis	**Antibiotics**	**Drugs**
	Usually not recommended unless there is a secondary bacterial infection. Lubrication for comfort.	Ocular lubricants: artificial tears (Refresh, Celluvisc, Murine) 1–2 drops 4–8 times a day
	Antiviral Agents	
	Herpes simplex conjunctivitis requires systemic or topical antiviral agents. *Any patient with HSV or herpes zoster ophthalmicus (varicella zoster virus) eye disease needs to be seen by an ophthalmologist.*	pyrimidine (thymidine) ophthalmic sol. *(may have toxic reaction)* Oral antivirals: Acyclovir (Zovirax) PO. *Start therapy within 72 hours to prevent postherpetic neuralgia.*

pharmacological measures for allergic problems. Referral to an allergist may be appropriate.

If symptoms worsen before the next scheduled visit, the patient should be reevaluated as soon as possible. The presentation of acute epiphora suggests a corneal abrasion or a foreign body, and the patient should be followed up in 24 to 48 hours.

Patient Education

Patients need to be attentive to changes in pain or discharge and should understand general expectations as to how quickly symptoms should resolve. In addition, they should be alert as to when to seek medical intervention. Vision loss is a very concerning issue, and problems of red eye with visual changes must be addressed promptly. Hygienic measures, such as washing hands, using separate washcloths, and disposing appropriately of dressings, should be stressed. Washing hands before applying eyedrops or ointment is essential to prevent infection or cross-contamination of a bacterial infection. Patients need to know that there are surgical options to manage changes in eyelid structure that have caused epiphora during the aging process. If the excessive tearing is paradoxically associated with "dry eye," consistent, appropriate use of topical cyclosporine emulsion will eventually bring both symptoms under control. It may take several weeks for the full effect to be realized.

RED EYE/CONJUNCTIVITIS

Conjunctivitis is an inflammation of the conjunctiva (mucous membrane) covering the front of the eye. The conjunctiva protects the eye against foreign materials and microorganisms. "Pink eye" refers to non-*Neisseria* bacterial conjunctivitis. Although most conjunctivitis is

self-limiting, a few types may lead to permanent vision impairment if not promptly diagnosed and treated. It is essential for the clinician to be able to distinguish between types of conjunctivitis. Differential Diagnosis 8.1 presents a comparison of selected differential diagnoses for red eye.

Epidemiology and Causes

Conjunctivitis is the most common of all eye disorders, affecting all ages. Males and females are equally affected; there are no specific ethnic predispositions. Risk factors are numerous, including trauma from wind, heat, smoke, cold, chemicals, and foreign bodies. Common causes of conjunctivitis include infectious agents (which may be bacterial, viral, or fungal), as well as toxicity (from an inciting agent of some sort) and allergy. Sexual transmission and ophthalmia neonatorum (transmission from passage down the birth canal) are associated with *Chlamydia, Neisseria gonorrhoeae,* and herpes simplex virus (HSV) I. Trachoma, the leading cause of blindness in developing nations, is caused by *Chlamydia trachomatis;* it is spread by direct contact with eye, nose, and throat secretions from affected individuals or contact with fomites (inanimate objects), such as towels or washcloths, that have had similar contact with these secretions. Flies can also be a route of mechanical transmission. Untreated, repeated trachoma infections result in entropion—a painful form of permanent blindness in which the eyelids turn inward, causing the eyelashes to scratch the cornea. Children are the most susceptible to infection because of their tendency to frequently get dirty, but the blinding effects or more severe symptoms are often not felt until adulthood.

Most forms of conjunctivitis, depending on the organism, may be transmitted by contaminated towels, washcloths, or the patient's own hands. Noninfectious conjunctivitis may be drug-induced as a result of chronic irritation from use of eye medications over a long period of time. A chronic inflammatory conjunctivitis may develop similarly, secondary to irritation from contact lens use, seen most commonly with soft lenses but occasionally with hard lenses. A family history of atopy is a risk factor for certain types of allergic conjunctivitis.

Pathophysiology

A hallmark of conjunctival inflammation is hyperemia of the ocular and palpebral surfaces, with injection of this cell layer by engorged, superficial capillaries. Contact with viruses, bacteria, or allergens is the most common cause of inflammation of the conjunctiva. There is also an idiopathic form of conjunctivitis associated with certain systemic diseases such as thyroid disorders and infectious monoarthritis (formerly known as Reiter's syndrome). The most common causative bacterial agents include *Staphylococcus aureus, Streptococcus pneumoniae,* and *Haemophilus influenzae. Neisseria gonorrhoeae, Moraxella catarrhalis,* and *Chlamydia* are responsible for a particularly virulent hyperacute bacterial conjunctivitis. Viral agents implicated are adenovirus serotypes 3, 4, 7 (which cause pharyngitis with conjunctivitis), adenovirus serotypes 8 and 19 (which cause epidemic keratoconjunctivitis), adenovirus 11, coxsackievirus A24, enterovirus 70 (which causes acute hemorrhagic conjunctivitis), primary or recurrent HSV (usually type I), and herpes zoster (which spreads down the optic nerve), as well as molluscum contagiosum. *Chlamydia trachomatis* (trachoma) causes adult inclusion conjunctivitis, as well as ophthalmia neonatorum. *Chlamydia oculogenitalis* (which causes inclusion conjunctivitis) and *Chlamydia lymphogranulomatis* (which causes lymphogranuloma venereum) are also sexually transmitted causative agents.

Allergic (atopic) conjunctivitis may be linked to a systemic humoral or local histaminic response to an inciting environmental allergen. Certain autoimmune phenomena such as Sjögren's syndrome or Wegener's granulomatosis may also be involved. The conjunctivitis may be (1) seasonal, also called hay fever conjunctivitis, which is usually caused by grass pollens in May and June and by ragweed pollen in August and September; (2) vernal keratoconjunctivitis, which usually occurs in childhood and youth in individuals with a family history of atopy, is recurrent in warm weather, and is associated with large "cobblestone" papillae lining the posterior pharynx in those with a history of chronic atopy; or (3) an atopic keratoconjunctivitis that usually occurs in the late teen years.

Clinical Presentation

Subjective

Symptoms will vary with the cause, but cardinal symptoms of conjunctivitis are itching, watering, and redness of the eye. There may be a foreign body sensation and/or a sense of fullness around the eyes. Bacterial infections such as *S aureus* may produce significant thick, yellow, sticky exudate of the eyelids. This profuse exudate occurs especially in the morning, and patients may complain that their eyelids "are stuck together" when they wake. Bacterial infections usually begin unilaterally whereas viral infections often appear in both eyes at once. Adenovirus conjunctivitis causes a foreign body sensation and minimal pruritus and exudate but profuse tearing. This type of conjunctivitis is often bilateral; preauricular adenopathy is common, along with systemic symptoms typical of a virus, such as fever, myalgia, and the like. Other family members may be affected. Associated upper respiratory tract infection symptoms may point to a viral cause. Visual loss, photophobia, and severe eye pain may suggest corneal involvement. The clinician should ask the patient about any history of allergens and potential contacts, including mention of symptoms of sexually transmitted diseases. Chlamydial causality tends to present bilaterally, with minimal pruritus and moderate to profuse tearing and exudate. Allergic

conjunctivitis also presents bilaterally, with severe pruritus, moderate tearing, and no exudate.

Objective

Use gloves when examining the eyes of a patient with suspected conjunctivitis. The first step in the examination is testing of visual acuity in both eyes, as well as in each eye when tested separately. On inspection, there will be hyperemia and tearing. The clinician needs to determine the amount of inflammation involved, and it is important to note where the inflammation is in regard to the pupil, whether it is local or diffuse, and whether it is symmetrical or asymmetrical in one or both eyes. If exudate is present and is thick and copious, the cause is probably bacterial or chlamydial. There may be eyelid swelling. The clinician needs to examine the eyelids, lashes, and surrounding skin for abnormalities. Areas of lymphoid tissue hyperplasia that appear as dome-shaped elevations with blood vessels on their surface are called follicles; these are present in many types of conjunctivitis. If follicles are prominent in the upper tarsus, this is usually indicative of a viral etiology such as adenovirus or *Chlamydia.* Minute elevations with vascular cores that may coalesce to form large papillae occasionally form secondary to inflammatory process. These may be present on the superior tarsal plate in cases of vernal keratoconjunctivitis, adenovirus, or HSV.

Preauricular nodes often represent a viral etiology, such as HSV or adenovirus, and in chlamydial infections and in *N gonorrhoeae.* The nodes are less prominent and more tender to palpation in patients with conjunctivitis of bacterial etiology. Subconjunctival hemorrhage may be seen in bacterial conjunctivitis or enterovirus 70 conjunctivitis.

Assess papillary response for equality and reactivity to light and accommodation. Failure to react appropriately is indicative of a more serious problem and should be referred to an ophthalmologist for evaluation.

Corneal involvement, which often manifests as eye pain, decreased visual acuity, and photophobia, may be present; it may manifest as punctate epithelial lesions. The potential for corneal involvement is increased in cases of adenovirus, vernal keratoconjunctivitis, and *N gonorrhoeae.* The presence of a membranous film that covers and adheres to the entire surface of the conjunctival epithelium is usually associated with epidemic keratoconjunctivitis, HSV, *S pneumoniae,* and *N gonorrhoeae.* If the membrane is removed, a bleeding surface is left behind.

Diagnostic Reasoning

Diagnostic Tests

The clinician should always check visual acuity first. Additional testing in routine cases of conjunctivitis is usually not necessary. A dilated pupil exam should be performed in patients with hyperemia accompanied by proptosis, optic nerve dysfunction, decreased visual acuity, diplopia, or anterior chamber inflammation. Fluorescein staining may be indicated to rule out corneal involvement or keratitis. Use blue penlight illumination to observe for corneal scratches, corneal dendrites (which represent HSV), or corneal ulceration. The clinician should use anesthetic drops before staining the eye. If *N gonorrhoeae* is suspected or conjunctivitis has failed to respond to treatment or in cases of ophthalmia neonatorum, membranous conjunctivitis, and prolonged, severe conjunctivitis, Gram stain and culture should be done. In cases of suspected *Chlamydia* or herpes, the clinician should perform specific cultures and/or a fluorescent antibody test.

In persistent cases of conjunctivitis, referral to an ophthalmologist is essential so that scrapings, cultures, and smears can be taken. Conjunctival biopsy is occasionally useful in refractory or atypical conjunctivitis and is always done in cases of suspected neoplasm. When a hypopyon (a layer of white blood cells) or hyphema (a layer of red blood cells) in the anterior chamber is detected on examination, an immediate referral to an ophthalmologist is required, because this may reflect infectious keratitis/endophthalmitis or penetrating eye trauma.

Differential Diagnosis

In *bacterial conjunctivitis,* signs and symptoms include itching and tearing, either bilaterally or unilaterally, with a moderate amount of mucopurulent (yellow-green) discharge. There is a moderate amount of conjunctival hyperemia, with a shiny red appearance to the lower lids. There is no pain, nor are there any visual disturbances. The cornea is clear; there is no preauricular adenopathy. Bacterial conjunctivitis most commonly occurs in the winter and fall.

In *allergic conjunctivitis,* there is bilateral itching, with a watery discharge. The patient may have a history of atopy. The conjunctiva and lids are swollen and reddened. This is a seasonal occurrence, most common in fall and spring, and may be accompanied by sneezing, rhinorrhea, and throat itching.

Viral conjunctivitis should also be ruled out. The patient with this type of conjunctivitis typically complains of itching, burning, and increased tearing. The conjunctiva is brilliant red, diffuse, and peripheral. There is a watery mucoid discharge, with a moderate amount of mucoid debris. The patient may also have conjunctival edema, follicles on the palpebral conjunctiva, and lid edema. Preauricular adenopathy may also be present. There are usually signs of an upper respiratory tract infection or a history of recent contact with another person with red eye.

In *iritis,* the patient presents with marked conjunctival injection, mainly around the cornea; it is unilateral, without discharge. The patient has moderate to severe pain and photophobia. The vision is blurred, pupils are constricted, and pupillary response to light is poor. Iritis requires a prompt referral to an ophthalmologist.

Keratoconjunctivitis, as discussed earlier in this chapter in the section on dry eye—in which the lack of an adequate tear film to cover and protect the cornea and conjunctiva causes a nonspecific irritation, with burning, redness, dryness, the sensation of foreign body, and generalized eye pain—should also be ruled out.

Other conditions that may present as red eye include the following:

Blepharitis, as discussed earlier in this chapter, is an inflammation involving the structures of the lid margin, with redness, scaling, and crusting. It commonly affects older adults, and is usually secondary to either chronic staphylococcal infection or seborrheic dermatitis. Treatment includes warm eyelid compresses and eyelid scrubs with dilute baby shampoo two to four times per day. Chronic cases may require antibiotic ointment.

Pterygium, a conjunctival degeneration that results in an opacity that partially covers the cornea, is most commonly seen at the 3 and 9 o'clock positions. There is conjunctival injection and tear filming; the opacity is usually slow growing and may eventually obstruct the vision. Pterygium is most commonly seen in persons with excessive exposure to ultraviolet light, windy conditions, or dusty surroundings. Treatment includes artificial tears to alleviate irritation, protective eyewear to be worn when outside, and surgical removal of the opacity if visual disturbance occurs.

Subconjunctival hemorrhage—the sudden onset of painless red eye without any other associated symptoms—is usually caused by trauma, excessive straining, coughing, or hypertension. No treatment is needed if the cause can be found. The patient should be reassured that resolution will take place in 2 to 4 weeks.

The signs and symptoms of *herpes zoster ophthalmicus* include eye pain (which may be severe), tearing, photophobia, mucoid discharge, and moderate conjunctival hyperemia. The cornea may be clear or cloudy. Vesicles may or may not be present. Symptoms are usually the result of reactivation of latent zoster infection because of stress or infection. Patients with herpes zoster ophthalmicus should be immediately referred to an ophthalmologist.

Signs and symptoms of *corneal abrasion* include pain, foreign body sensation, photophobia, tearing, and conjunctival hyperemia. The patient will usually have a history of scratching the eye, contact lens irritation, or actual trauma. The clinician should stain the eye with fluorescein and use cobalt blue filter light or slit lamp to inspect the eye for foreign objects or scratches. Treatment includes antibiotic drops or ointment for 5 days. Patching is not usually necessary. The patient should avoid wearing contact lenses until the abrasion heals. The clinician should follow up daily until symptoms are resolved.

With acute closed-angle *glaucoma,* the patient will have a sudden onset of severe pain and blurred vision, with nausea and vomiting. The patient will report seeing rainbow halos around lights. There will be corneal cloudiness, with diffuse conjunctival hyperemia. The pupil of the affected eye will be moderately dilated and completely unresponsive to light. Any patient with glaucoma should be referred to an ophthalmologist immediately. Corneal disease or foreign body may be ruled out with fluorescent staining. The patient who presents with acute glaucoma is usually older; more visual loss is present, pain is more severe, and there may also be headache and nausea. Uveitis (iritis, iridocyclitis, choroiditis) usually presents with more severe eye pain, photophobia, blurred vision, injection in the limbus area, and deposits in the cornea. All of these are ocular emergencies; patients should be referred to an ophthalmologist immediately to avoid permanent vision loss.

The more typical task for the clinician is to decide which type of conjunctivitis is involved, an essential task before treating the patient. See Differential Diagnosis 8.1 for a comparison of the selected differential diagnoses for red eye.

Management

Treatment will depend on etiology. In general, visual acuity should be assessed and recorded. Do not patch the eye. Although steroids sometimes help with irritation, clinicians should not routinely order topical steroids, but rather refer the patient to an ophthalmologist, especially if there is an ulcer, keratitis, or suspected herpes or if the conjunctivitis worsens in 24 hours. Any purulent material or debris should be removed from the conjunctival area. Lubrication of the eye with artificial tears is recommended, or frequent cleansing by lavage. With blepharitis or conditions that are accompanied by discharge, the patient should be instructed to clean the lid margins with a dilute no-tears shampoo and discontinue wearing contact lenses (if any). Compresses are often effective for local relief; they should be warm in cases of infective conjunctivitis and cold in cases of allergic or irritative conjunctivitis. The patient should be cautioned to avoid spreading the conjunctivitis (or persistent reinfection) through autoinoculation. Pharmacological therapy will depend on the identified or suspected causative agent (see Drugs Commonly Prescribed 8.1: Conjunctivitis).

Follow-up and Referral

Given the potential for unresolved conjunctivitis to be vision threatening, patients with red eye that does not resolve as expected with standard therapy should be referred to an ophthalmologist in a timely fashion for further diagnostic studies and therapeutic management.

Patient Education

The clinician should instruct the patient to instill medication in the outer aspect of the lower lid. It may be best to use ophthalmic solution during the daytime and

then to apply a thin film of ointment before sleep. The clinician should explain that secretions may remain infectious for at least 48 hours after the start of treatment. Conjunctivitis is highly contagious; therefore, the patient should take care when coming in contact with other members of the household, especially infants, children, older adults, and pets. Spread of conjunctivitis may be prevented by using effective hand washing, avoiding touching the eyes, and not sharing towels and washcloths. The clinician should instruct the patient to avoid autoinoculation: The patient should not touch the medication applicator to the eye, and should use separate eyecups for each lavage. No contact lens usage is allowed until the infection is resolved.

VISUAL DISTURBANCES AND IMPAIRED VISION

REFRACTIVE ERRORS

Normal vision is dependent on a clear image being projected through the cornea, aqueous humor, lens, and vitreous humor onto the retina. All of these structures must be clear to provide a clear retinal image, and the optic nerve must be healthy to transmit an accurate image to the visual cortex in the occipital lobe of the brain. Refractive errors result in blurred vision due to aberrations in how external light is reflected into the eye.

Epidemiology and Causes

Refractive errors that are incompletely corrected or not corrected are the most common cause of visual impairment. Approximately 45% of the U.S. population has some degree of refractive error.

Pathophysiology

In order to transmit an external image into the eye, parallel rays of light enter the cornea, which are bent by the cornea and lens to converge on the retina. The macula of the retina is responsible for central visual acuity and, thus, is the most important portion of the retina for distinguishing visual details, such as when reading. The patient perceives a blurred image when light rays do not converge on a common point on the retina. Light-ray convergence in front of the retina causes myopia or nearsightedness. If light rays converge posterior to the retina, the patient is hyperopic or farsighted. If light rays focus on two separate lines rather than a single point, the patient has astigmatism.

Clinical Presentation

Refractive errors have a gradual onset and are not usually accompanied by pain or redness. Often, if the refractive error is in only one eye, no problem is perceived unless something happens to the other eye.

Diagnostic Reasoning

A simple "pinhole test" can be administered in the primary-care setting to determine if the diminished visual acuity is the result of a refractive error or the presence of organic disease. A pinhole test is performed by creating pinholes 0.5 to 2 mm in diameter in a stiff paper card. The patient is asked to look through one of the pinholes one eye at a time. If the visual acuity improves without the use of corrective lenses, the diminished acuity is a refractive error. If there is no improvement, the diminished acuity is organic. This is because the pinhole card blocks peripheral light waves, which are most distorted by a refractive error.

Management

Corrective lenses (eyeglasses or contact lenses) must be ordered to correct refractive errors. Accurate prescriptions for such lenses may be obtained from appropriately trained and equipped clinical vision experts, such as optometrists or ophthalmologists.

Follow-up and Referral

Accurate diagnosis and characterization of refractive errors requires referral to an optometrist, ophthalmologist, or other qualified clinician, with the appropriate equipment to measure refractive errors. These referrals are needed to obtain prescriptions for effective corrective lenses, as well as to screen for other common eye problems, which may also be contributing to decreased visual acuity.

Patient Education

Patients should be encouraged to use corrective lenses for all activities that require optimal visual acuity, such as reading, driving, or operating machinery. Proper care of eyeglasses and contact lenses should be discussed with all patients.

CATARACTS

A *cataract* is any opacity of the natural lens of the eye. It may or may not be associated with visual impairment or functional consequences, and may be localized or generalized. More than 90% of cataracts are age related. Other causes of cataracts include congenital, metabolic, and traumatic etiologies, such as excessive exposure to sunlight (ultraviolet B [UVB] rays) without protective lenses over time. In the United States, cataract surgery is the most common surgical procedure performed under Medicare, is most commonly done in an outpatient setting, and is effective in improving vision in 95% of patients treated.

Epidemiology and Causes

Cataracts remain one of the leading causes of blindness worldwide. An estimated 17 million people have become blind from cataracts, mainly in third world countries.

More than 50% of all people aged 65 to 75 have cataracts; 92% of all patients older than age 75 have some opacities, and 46% of this group have significant vision loss, defined as 20/30 or worse. These percentages are equally distributed between males and females, as well as across ethnic groups.

Risk factors for cataract formation include aging and predisposing diseases such as diabetes, uveitis, intraocular tumor, medication usage (such as corticosteroids, inhaled, nasal, or oral) over time, excessive exposure to sunlight (UVB rays) over time, trauma (blunt or penetrating), excessive exposure to heat (e.g., glass blowers, welders), radiation exposure, and electrical injury. Smoking has been identified as a risk factor for cataracts, along with family history, excessive alcohol intake, poor dietary habits (lack of antioxidants), and atopic dermatitis.

Pathophysiology

The transparency of the human lens results from the highly ordered nature of its composite stratified epithelia, which contain a high density of cytoplasmic proteins called crystallins. Normally, the lens is a naturally clear, biconvex structure located behind the cornea and supported by zonules. Over time, the crystalline lens becomes fibrotic, hardened, and dehydrated, in turn progressively opacifying and transforming into a cataract. Contained within the lens capsule is a central nucleus surrounded by a cortex. The lens is avascular, deriving its metabolic needs from the aqueous and vitreous humors. Early in life, the lens is pliable and can change its shape as connecting zonules anchored to ciliary bodies place varying degrees of stress on the lens through involuntary contraction and relaxation. These changes in lens shape result in accommodation, allowing objects to come into focus at varying distances.

Aging alters the biochemical and osmotic balance required for lens clarity, as does the hyperglycemia of uncontrolled diabetes mellitus. Fluctuating visual acuity and rapid-onset nearsightedness known as a "myopic shift" caused by alterations in the glucose, electrolyte, or water balance within the lens are early symptoms of diabetes mellitus. Moreover, unlike the other endothelia in the body, the lens cannot shed nonviable cells. Thus, as the lens ages, it loses both its pliability and its clarity. These changes are thought to occur because of damage from oxidation, a biochemical process set in motion when a highly reactive form of oxygen (an oxygen radical) forms within the cells of the lens itself. In addition to senescence, several other cataract risk factors are thought to increase oxidative damage, including alcohol consumption, sunlight (UVB) exposure, and tobacco smoking, which has been attributed to more than 20% of the cataracts in the United States. Additional well-recognized risk factors include excessive lead exposure and systemic corticosteroid use. Moreover, healing fibrosis from ocular trauma is a primary etiology of acquired cataracts, whereas secondary cataracts may also result from other forms of ocular inflammation that extend to the lens, including uveitis, topical anticholinesterase preparations, and radiation therapy used to treat ocular tumors.

There are three subtypes of cataracts, categorized by anatomical localization: nuclear sclerotic, cortical spoking, and posterior subcapsular. Many patients have a combination of these subtypes. The size, density, and location of the cataract determine its effect on vision and the most appropriate method of surgical intervention/lens replacement. Nuclear cataracts are characterized by significant nearsightedness and a slow, indolent course. In contrast, cortical cataracts do not significantly impair vision. Posterior cataracts, on the other hand, create a subcapsular haze and a severe glare in bright light. They are strongly associated with systemic steroid use and progress much faster than the nuclear form (months rather than years). Regardless of anatomical type, immature cataracts are those that do not obscure the red retinal light reflex on funduscopy. In contrast, mature cataracts obscure the red reflex with significant visual impairment, and hypermature cataracts are characterized by liquefaction of the cortical lens with mobility of the nucleus.

Clinical Presentation

Subjective

The patient with cataracts may or may not present with visual changes and/or functional impairment. Cataracts produce a gradual, painless, progressive loss of vision; many patients are unaware of vision problems. For example, with monocular (asymmetrical) cataracts, reduced vision may only be apparent when the less affected eye is covered. Age-related cataracts tend to be bilateral in nature and may manifest as blurred or distorted vision, with complaints of a glare when driving at night or in bright light, or the patient may present after a fall, injury (e.g., hip fracture), or accident due to decreased visual acuity. Because of the increase of yellow-brown pigment in the lens, color perception is also affected.

The increased density of the lens nucleus results in nearsightedness that may require frequent eyeglass prescription changes. Myopia, or nearsightedness, may result from nuclear cataracts. The term "second sight" refers to older adults who abandon their reading glasses related to this phenomenon; however, as the cataract worsens, so does their vision. Mononuclear diplopia (double vision in one eye) is a cardinal refractive error associated with cataracts. Cataracts in patients younger than age 60 should raise suspicion of an underlying systemic or localized eye disease.

Objective

In some patients, opacity will be apparent on inspection, but this is not always the case. Decreased visual acuity, often manifested as asymmetry, is the most common

objective finding associated with cataracts. Mature or "ripe" cataracts eventually produce a gray or white pupillary reflex known as leukoria, although a dense posterior subcapsular cataract may produce reduction in vision without altering the pupillary reflex. Cataracts are best evaluated by slit-lamp evaluation after pupillary dilation, a procedure that is usually performed by an ophthalmologist.

Diagnostic Reasoning

Diagnostic Tests

A visual acuity of 20/30 or worse that is not corrected with glasses, with concurrent observation of opacity, confirms the diagnosis of cataracts. In family practice, cataracts should be classified according to types based on visual impairment using Snellen far and near visual testing. Cataracts are classified as follows:

- Type I is characterized by visual acuity better than 20/40 in the affected eye/eyes.
- Type II is characterized by visual acuity of 20/40 or worse in the affected eye/eyes.

Cataracts do not produce an afferent pupillary reaction (Marcus Gunn pupil); if abnormal pupillary reactions are present, other ocular pathology must be ruled out. In these cases, biomicroscopic (slit-lamp) exam or careful ophthalmoscopic exam should establish the diagnosis.

Visual quality assessment tests such as the Glare test may assist in the diagnosis or assessment of retinal/macular function. Increased intraocular pressure and/or an increased cup-to-disc ratio with significant cupping should raise the suspicion that glaucoma is contributing to the vision loss.

Differential Diagnosis

Cataracts remain the most common cause of decreased visual acuity in adults. Among patients suspected of having cataracts, the following causes of visual impairment should be ruled out: (1) error of refraction, (2) corneal opacities, (3) glaucoma, (4) retinopathy, and (5) age-related macular degeneration. Any sudden change in vision or sudden vision loss should be treated as an emergency and referred to an ophthalmologist immediately. Cataracts are gradual in onset; they develop over time. Macular degeneration usually presents as a slow, progressive loss of central vision, but may also manifest with symptoms of acute vision loss and distortion (metamorphopsia) resulting from leakage from abnormal subretinal vessels. Open-angle glaucoma produces a slow, painless visual field loss that usually begins peripherally and often (although not always) presents with increased intraocular pressure and/or an increased cup-to-disc ratio and cupping. Diabetic retinopathy may also contribute to vision loss; funduscopic exam will usually reveal dot-and-blot hemorrhages, microaneurysms, exudates, dilated and torturous vessels, and neovascularization of the disc and retina. Cataracts often obscure the fundus, however, making assessment difficult.

Opacities may be a surface opacity of the cornea (scarring), lens opacities, tumor, retinal detachment, or gliotic retinal scars. In elderly patients, visual impairment is usually the result of multiple factors, including cataracts and macular degeneration, to name a few. Cataracts develop sooner in diabetic patients because metabolic imbalances predispose the lens to cataract formation.

Management

The role of the clinician will involve referral to an ophthalmologist. Although surgery is the only definitive treatment for cataracts, the patient may manage at first with monitoring and frequent eyeglass prescription changes. The decision regarding at what point to have surgery should be determined by the patient and the ophthalmologist together. Surgery may be indicated when the cataract interferes with the optic nerve and retina, not allowing visualization in cases of patients with diabetes, macular degeneration, and glaucoma. Surgery should be discussed when changes in eyeglasses no longer help, when quality of life is jeopardized, and when it is thought that the surgery will be effective. Current cataract surgery is a relatively safe outpatient procedure.

Patients who are scheduled for cataract surgery may be referred to their primary health-care provider for a preoperative health assessment. However, among healthy adult patients scheduled for cataract surgery under local anesthesia, no routine preoperative medical testing is necessary. For patients with risk factors or comorbid conditions, a physical exam, electrocardiogram, electrolytes, and urinalysis may be required. Causes for concern are the presence of diabetes mellitus, hypertension, ischemic heart disease, certain pulmonary disorders, and the use of anticoagulants. Any patient with uncontrolled diabetes runs the risk of postoperative vision loss related to diabetic macular edema, which causes the retinal vessels to leak, leading to swelling of the visual center. If possible, anticoagulant therapy should be discontinued before surgery. Systemic hypertension may place the patient at risk for intraocular hemorrhage during or after surgery. All medications, intolerances, and allergies should be reviewed, especially in elderly adults, who make up the bulk of patients that undergo this procedure.

Two surgical techniques are currently used—phacoemulsification and extracapsular cataract extraction. In both surgeries, an incision is made into the eye, and the central anterior lens capsule is removed. In phacoemulsification, the surgeon makes a 2- to 4-mm incision and inserts an ultrasonic vibrating needle that breaks the cataract into small pieces, which are then aspirated through the needle's central bore. The smaller

incision and smaller sutures used in phacoemulsification make it the preferred method for cataract removal. In extracapsular surgery, the surgeon makes a 10- to 14-mm incision, and the entire lens nucleus is loosened from the cortex and removed through the incision. In both cases, the surgery continues with removal of the residual lens cortex and insertion of an intraocular lens. The incision may be self-sealing or closed with sutures. More than 95% of patients achieve visual acuity of 20/40 or better after surgery.

After surgery, the patient should have a protective eye shield in place and topical antibiotic and steroid ophthalmic medications. Lifting and bending should be avoided for several weeks, until cleared by an ophthalmologist. Bilateral cataract surgery is common and often indicated because of better visual acuity outcomes, although optimal timing of the second surgery remains controversial. Cataract surgery has been shown to be highly cost-effective, given the reduction in comorbidities and injury associated with progressive visual impairment.

Follow-up and Referral

As noted, these patients need early referral and monitoring by an ophthalmologist. The most important job for the clinician is to rule out any acute threat to vision and to encourage referral for more gradual cases of deteriorating vision loss. Education about the advances in surgical techniques and reassurance may be important aspects of care before referral. Comprehensive preoperative assessment is important, including psychosocial aspects of care, such as who will drive the patient to and from the surgery and assist him or her during the postoperative period.

Patient Education

Some of the educational and adaptive measures have been mentioned previously. In addition, the patient will need to have his or her vision reevaluated several weeks after the surgery for a new prescription for corrective lenses. Use of wraparound ultraviolet protecting glasses in sunny climates may slow progression of cataracts.

The use of antioxidant vitamins has been suggested as a method to decrease the risk of cataract development; however, inconsistent results have been noted in both observational and intervention studies (Level I) (Wang et al, 2013; Zhao et al, 2014). The American Optometric Association currently supports dietary increases in vitamins C and E because large proportions of the population do not get 100% of the recommended daily intake for these vitamins. It is prudent to discuss dietary sources of these nutrients with patients in an effort to decrease their risks. Vegetables rich in antioxidant nutrients such as beta-carotene, the precursor of vitamin A, and vitamins C and E—any yellow, orange, or dark green, leafy vegetables—may help prevent the oxidation process that can contribute to and worsen cataracts. Carrots contain carotenoids, which have been documented to provide preventive effects against cancers, cardiovascular diseases, and cataracts. Likewise, magnesium and manganese appear to play a role in cataract prevention. Enzymes that contain these minerals assist in the disposal of proteins damaged by oxidation. These proteins are known to contribute to eye clouding. Catnip and other mints contain both these essential trace minerals, as well as flavonoids (see Complementary Therapies 8.1).

Complementary Therapies 8.1

Supplement	Indication	Considerations and Adverse Effects
Bilberry *(Vaccinium myrtillus)*	Cataracts Macular degeneration	80–160 mg (standardized extract) PO 2 or 3 times daily. Boosts oxygen and blood delivery to the eye. Protects the cells in the eye from free-radical damage and boosts oxygen delivery to the retina. *May require adjustment of antidiabetic drugs. May inhibit platelet aggregation and may have additive effects with warfarin (Coumadin). Do not use with bleeding disorders.*
Vitamin C	Cataracts Macular degeneration	500–1500 mg PO daily (may cause diarrhea at higher doses). Antioxidant. Prevents lens damage from cigarette smoke and UV light. Slows the progression of macular degeneration.
Beta-carotene	Cataracts	25,000 IU PO daily. The body converts beta-carotene to vitamin A, which maintains a healthy lens. *High doses have been associated with an increased risk of lung cancer in smokers. May also interfere with the absorption of lutein. Do not exceed the recommended dose on label.*

Complementary Therapies 8.1—cont'd

Supplement	Indication	Considerations and Adverse Effects
Vitamin E	Cataracts Macular degeneration	400 IU PO daily. Research has shown that people taking vitamin E supplements cut their risk of cataracts in half. Protects against free-radical damage and decreases risk of late-stage macular degeneration. Slows progression of macular degeneration. *Patients taking warfarin (Coumadin) or other anticoagulants should check with their clinician before taking vitamin E supplements because there is a risk of internal bleeding.*
Zinc	Cataracts Macular degeneration	25 mg PO daily. Boosts the effectiveness of vitamin A. Critical in the functioning of the retina and macula and slows vision loss in those with macular degeneration. *Many drug interactions with the use of zinc.*
Quercetin	Cataracts	400–500 mg PO 3 times a day. Blocks an enzyme that leads to sorbitol accumulation that contributes to cataract formation in diabetes. *May competitively inhibit quinolone antibiotics by binding to the DNA gyrase site on the bacteria.*
Alpha-lipoic acid	Cataracts	100 mg PO daily. Increases effectiveness of vitamins C and E in protecting the lens from UV damage.
70% (rubbing) alcohol and white vinegar	Otitis externa	Equal parts rubbing alcohol and vinegar are mixed and then one dropper full is instilled in each ear after swimming. May prevent otitis externa. May also be effective in changing the pH in the ear canal making it less hospitable to *Pseudomonas*.
Bilberry	Sore throat	80–160 mg (standardized extract) PO 2–3 times daily. Decreases mild inflammation in mucous membranes. *May need to adjust antidiabetic drugs.*
Slippery elm *(Ulmus rubra)*	Sore throat	Lozenge: 1 every 4 hours (dissolve in mouth). Tea: 1 tsp. slippery elm bark powder in 2 cups of boiling water; let it stand for at least 10 minutes, then drink 1–2 cups daily. (May add sugar.) Mucilage is the major chemical compound that restores the mucous coating of irritated mucous membranes. *Pregnant women and nursing mothers should not use because safety data are lacking.*
Lemon balm *(Melissa officinalis)*	Oral herpes simplex and mouth sores	Tea: 2–3 tsp dried leaves in ⅔ cup of boiling water; steep for 5–10 minutes. Apply to lesions with a cotton ball after cooling. Also available in a cream as Herpilyn or Phyto-Pharmica Cold Sore Relief (formerly Herpalieve). Apply to sores 3 or 4 times daily at first sign of prodrome. Maximum length of use 14 days. Mechanism of action unknown, but may keep herpes virus from attaching to cells. *May potentiate barbiturates. May interfere with thyroid hormone replacement therapy. Do not use in pregnancy. Avoid use with glaucoma.*
Lysine	Oral herpes simplex and mouth sores	1,000 mg PO 3 times daily with meals at the first sign of outbreak for as long as outbreak lasts. For those prone to herpes outbreaks, maintenance dose is 500 mg daily. Lysine competes with arginine needed for herpes replication. *Do not use in pregnancy. May increase supplemental calcium absorption and decrease urinary calcium loss.*

Continued

Complementary Therapies 8.1—cont'd

Supplement	Indication	Considerations and Adverse Effects
Nasal irrigations/ nasal douche/ Neti Pot	Sinusitis/postnasal drip/ allergies/cold prevention	Mix ¼–½ tsp noniodized salt with 8 oz. warm water or use Alkalol nasal douche solution diluted 1:1 with warm water. Fill Neti Pot or nasal douche apparatus with solution. Stand over the bathroom sink and, with head tilted back and to one side, let the solution flow into the nose and out the opposite nostril or down the back of the throat. Repeat on other side. Saline solution can help increase the speed and improve coordination of the cilia that line the nasal mucous membranes so that they may more effectively remove the bacteria, allergens, and other irritants that cause sinus problems. Alkalol is made of natural ingredients and essential oils that include menthol, peppermint, eucalyptol, wintergreen, cinnamon, and a few others. No prescription needed. It is very refreshing and can be used full strength as a gargle to soothe sore throats. *Do not swallow. Safe for use in pregnancy.*

Lutein and zeaxanthin, which are nutrients found in green leafy vegetables and other foods including eggs, have been reported to reduce the risk of age-related macular degeneration (AMD) and cataracts. These compounds are found in large quantities in the retina; they are carotenoids that filter light and act as antioxidants in the eye. Studies have reported that lutein and zeaxanthin improve visual performance. Current recommendations for individuals with intermediate AMD include lutein 10 mg, zeaxanthin 2 mg, zinc 25 mg, vitamin C 500 mg, and vitamin E 400 IU per day.

GLAUCOMA

Glaucoma is defined as a group of diseases characterized by progressive damage to the optic nerve, resulting in optic nerve atrophy and blindness, most typically associated with elevated intraocular pressure. Glaucoma is classified as open-angle glaucoma and angle-closure glaucoma (classically referred to as closed-angle or narrow-angle glaucoma). These classifications are based on the anatomy of the anterior chamber. Both types of glaucoma may be present in the same eye (referred to as combined-mechanism glaucoma). Glaucoma is further differentiated as primary or secondary (associated with an ocular condition or a systemic process). There is also a congenital form of glaucoma seen in infants. Open-angle glaucoma is more commonly seen and is characterized as a chronic form of the disorder that, before loss of peripheral visual fields, is strikingly asymptomatic. It has an excellent prognosis if treated early and appropriately. Angle-closure glaucoma, on the other hand, may have subacute and chronic components, but it is most associated with acute episodes of significant eye pain, redness, and acute visual loss, which, if untreated, may rapidly lead to permanent blindness.

Epidemiology and Causes

Glaucoma affects approximately 4% of all individuals older than age 40. Primary open-angle glaucoma (chronic glaucoma) is the most prevalent form of glaucoma and accounts for 90% to 95% of all cases. Angle-closure glaucoma (acute glaucoma) is not as common; it affects approximately 100 per 100,000 of the population (approximately 0.1%). Glaucoma is the second-leading cause of blindness among white Americans and the most common cause of blindness in African Americans. Chronic open-angle glaucoma usually occurs after age 40 years but can occur at any age. Angle-closure glaucoma tends to occur in people aged 55 to 70 years. African Americans have a higher incidence of chronic open-angle glaucoma. Angle-closure glaucoma is more prevalent in people of Asian descent, as well as in those with Eskimo ancestry, especially among the Inuit. Chronic open-angle glaucoma occurs equally in males and females. Angle-closure glaucoma occurs more frequently in females.

Increased intraocular pressure, positive family history, older age, and being of African American descent place an individual at increased risk for glaucoma. Older African Americans have a higher prevalence of glaucoma and a more rapid progression of the disease. Specifically, myopia (nearsightedness) and diabetes may both contribute to the development of chronic open-angle glaucoma, whereas hyperopic (farsighted) eyes and a small cornea contribute to angle-closure glaucoma.

Glaucoma may also develop secondarily as a result of a number of ocular and systemic diseases or medication

use. The use of steroid therapy (topical, inhaled, or systemic) may lead to increased intraocular pressure. Antidepressant drugs or other anticholinergic drugs and emotional stress may contribute to an acute episode, as may childbirth, sneezing, laser therapy or surgery, and IV overhydration. Increased pressure in the anterior chamber that is uncorrected will, over time, impair peripheral visual fields, destroy central vision, and ultimately destroy the optic nerve. Increased intraocular pressure, optic nerve atrophy, and visual field loss make up the classic triad of glaucoma.

Pathophysiology

The ciliary body of the eye produces aqueous humor, which circulates from the posterior chamber to the anterior chamber and then exits through the trabecular meshwork. In primary open-angle glaucoma (in which no secondary cause is identified), elevated intraocular pressure is almost always caused by obstruction of the outflow channels, especially the trabecular meshwork; however, overproduction of aqueous humor may also occur. The manner in which the trabecular meshwork is obstructed is a matter of debate, but it probably involves changes in the biochemical makeup of the cells lining this meshwork. These changes appear to occur with aging. In addition, secondary glaucoma may result from increased intraocular pressure caused by ocular trauma or inflammation such as uveitis, chronic steroid use, vasoproliferative retinopathy, and recurrent retinal hemorrhages.

The specifics regarding how intraocular pressure leads to optic nerve atrophy are also debated. One theory is that intraocular pressure causes direct mechanical damage and loss of retinal ganglionic cell axons known as "cupping." Others theorize that intraocular pressure impairs the small-vessel circulation that provides nutrients to the optic nerve and extracellular matrix. Glutamate toxicity and processes involved with runaway apoptosis leading to axonal loss are also currently being investigated. It is critical to recognize, however, that optic atrophy may occur in the absence of increased intraocular pressure. Traditionally, elevated intraocular pressure has been defined as greater than 21 mm Hg. Ocular hypertension has also been identified in the absence of optic nerve atrophy. Thus, other pathophysiological processes leading to progressive, irreversible vision loss also function in primary open-angle glaucoma; increased intraocular pressure by itself must be considered only a risk factor, rather than the definitive glaucomatous etiology. Work is also underway to identify the gene products and functions associated with inherited forms of open-angle glaucoma, which typically occur before the age of 40 years, known collectively as juvenile glaucoma.

Angle-closure glaucoma, which may be either acute or chronic, is less common than open-angle glaucoma and is caused by anatomical narrowing of the anterior chamber angle, a factor that is fundamentally determined by genetics and becomes more likely with advanced age. This narrowing is primarily related to the size of the eyeball and lens. Specifically, angle-closure glaucoma results from the forward displacement of the iris toward the cornea, with narrowing of the iridocorneal angle resulting in an obstruction of outflow from the anterior chamber. Acute angle-closure glaucoma occurs when there is an acute closure of the iridocorneal angle with a sudden, severe rise in intraocular pressure, often well above 40 mm Hg, which is highly symptomatic. Permanent vision loss may result if this condition is not treated within 24 hours of onset.

Clinical Presentation

Subjective

Generally, patients are asymptomatic until optic nerve damage is quite advanced. Chronic open-angle glaucoma has a gradual onset, with slow, painless bilateral peripheral vision loss and poor night vision. Frequent changes in refractory prescription may be a common presenting symptom. In later stages, symptoms may include seeing halos around lights and further visual loss. Acute angle-closure glaucoma has a rapid onset, with unilateral pain and pressure, blurred vision, seeing halos around lights, and photophobia, followed by loss of peripheral vision, subsequently followed by central vision loss. A headache may be present and possibly nausea and vomiting as well. Chronic angle-closure glaucoma is as insidious in onset as open-angle glaucoma. Its fundamental mechanism relates to the anatomical narrowness of the anterior chamber angle. Often patients have a history of vague discomfort about the eyes and intermittent blurring of vision.

Objective

The physical exam in most patients with chronic glaucoma will most likely be unremarkable. In later stages, the eyeball may be hardened. Visual acuity may or may not be affected. Visual field abnormalities to confrontation will be present only in very late, profound cases. A Marcus Gunn pupil (afferent pupillary defect) may be present.

In acute angle-closure glaucoma, intraocular pressure rises rapidly to very high levels. The eye becomes red and painful, the cornea may have a "steamy" appearance, and vision is severely blurred. There may be a pupil that is mid-dilated and immobile. Findings on funduscopic exam may show a pale optic disc with excavated cupping and a shallow anterior chamber; there may be an increased cup/disc ratio related to atrophy and asymmetry on comparison with the other eye. Visual acuity is severely affected because visual field defects are common. In many cases, the clinician can detect a shallow anterior chamber and narrow angle with the flashlight test: In this test, a penlight is held at the temporal limbus of the eye and the degree of illumination is noted. A narrow

angle is suggested if the nasal half of the iris is in the shadow. Dilation of the pupil with mydriatic agents tends to narrow the angle further, which can lead to an acute attack, as can dim light or darkness, and physical or emotional stress. The primary-care provider should closely monitor patients with a family history of angle-closure glaucoma or hyperopia accompanied by a history of eye ache, headache, and blurred vision.

Diagnostic Reasoning

One of the most important aspects of glaucoma in the primary-care setting is screening. The U.S. Preventive Services Task Force has found good evidence that early treatment of adults with increased intraocular pressure detected by screening reduces the number of persons who develop small visual field defects, and that early treatment of those with asymptomatic glaucoma decreases the number of persons whose visual field defects progress.

In general, tonometry readings are recommended as part of every eye exam, although the measurement of intraocular pressure by any form of tonometry has been shown to be an imperfect, insensitive screening tool for glaucoma. Nonetheless, tonometry readings are recommended as part of every annual eye exam after age 40 years, either in the primary-care setting or by an ophthalmologist or optometrist, with any visual changes requiring further evaluation by an ophthalmologist.

At the present time, guidelines for glaucoma screening by the primary-care practitioner have not been firmly established. Improvement in the diagnostic skills for the early detection of glaucoma in the primary-care setting, coupled with clear guidelines for referral to an ophthalmologist, will have significant economic and health implications. Multiple testing methods requiring specialized equipment and training are available, including pneumotonometry, which uses a puff of air against the eyeball, or the more accurate method of applanation tonometry, in which the cornea is directly observed while pressure is placed against it. Normal intraocular pressure is typically considered to be 8 to 21 mm Hg. In all chronic forms of glaucoma (open- or closed-angle glaucoma), intraocular pressure may or may not be elevated, whereas in an acute exacerbation of angle-closure glaucoma, symptomatic pressures may be as high as 40 to 80 mm Hg. However, increased intraocular pressure alone is not diagnostic, because many patients with open-angle glaucoma consistently have intraocular pressure within the normal range.

Diagnostic Tests

The diagnosis of glaucoma is not made on the basis of a single test but on the finding of characteristic degenerative changes in the optic disc and defects in visual fields. Tonometry to measure intraocular pressure is essential, though not diagnostic. In chronic, closed-angle glaucoma, there may or may not be elevation of intraocular pressure. Normal intraocular pressure is 12 to 22 mm Hg. In chronic, open-angle glaucoma, there may be normal or elevated intraocular pressure, whereas in an acute exacerbation of angle-closure glaucoma, intraocular pressure may be as high as 40 to 80 mm Hg. However, increased intraocular pressure alone is not required for the diagnosis of glaucoma because many patients with open-angle glaucoma consistently have intraocular pressure within the normal range.

Physical diagnosis relies on gonioscopic evaluation of the angle by an ophthalmologist. Gonioscopy determines the angle of the eye's anterior chamber and thus enables the examiner to differentiate between open-angle and angle-closure glaucoma; the angle is normal in open-angle glaucoma, although this often narrows with aging. Visual inspection of the angle is done using a special lens (goniolens) at the slit-lamp biomicroscopy. The two primary types of disease—open-angle glaucoma and angle-closure glaucoma—are classified according to the anatomy of the anterior chamber angle. Both types of the disease may be present in the same eye.

The appearance (e.g., color and contour) of the optic nerve and findings on visual field examination are the most important clues to diagnosis. Pathognomonic changes indicate glaucoma. Funduscopic examination of the optic nerve reveals changes in the cup and neuroretinal rim relatively early in the disease, indicating the possibility of open-angle glaucoma. Particularly significant are the size of the cup relative to the optic nerve, any thinning or nicking of the disc rim, and the presence of disc hemorrhages. Visual field examination, which requires specialized equipment, detects defects in the field of vision that are characteristic for glaucomatous damage to the optic nerve relatively early in the disease.

Testing of visual fields using confrontational finger motions to test where the patient's fields are compared with the examiner's is unreliable for diagnosing glaucoma. There are specialized tests that can be performed by an ophthalmologist or optometrist for visual field assessment, including automated perimetry, Goldmann perimetry, or tangent screen testing. Pachymetry, which is a method of measuring corneal thickness, may also be done by an ophthalmologist. Thinner corneas are at higher risk for the development of primary open-angle glaucoma.

Differential Diagnosis

Conjunctivitis and uveitis will be ruled out because of other symptomatology the clinician may observe in cases of glaucoma, specifically visual changes. Vascular disease may also produce funduscopic changes; however, these changes will be more hemorrhagic in nature. Medications such as steroids, amphetamines, and chlorpromazine can all increase intraocular pressure. Many ocular and systemic conditions are associated with the development of glaucoma; in addition, the use of topical, systemic, and inhaled corticosteroids may increase

intraocular pressure, depending on dose and duration of treatment.

Management

Once nerve damage has occurred, it is irreversible; thus, the goal of treatment is to prevent progression of damage and to protect the optic nerve from pressure. Glaucoma is a disease of pressure; adequate lowering of intraocular pressure by one means or another almost always stops optic nerve damage.

Traditionally, open-angle glaucoma is managed pharmacologically for as long as possible, with laser or surgical treatment reserved for glaucoma that cannot be controlled by medication alone. The choice of medication regimen is usually made by an ophthalmologist. The goal of pharmacological therapy is to decrease and control intraocular pressure. (See Drugs Commonly Prescribed 8.2: Glaucoma.)

Beta blockers are usually first-line therapy, but sometimes prostaglandin analogs may be used as first-line therapy or added soon after beta blockers are started. Treatment compliance with multiple doses of eyedrops daily is often poor in open-angle glaucoma; however, newer topical agents require less frequent dosing (once daily for prostaglandins). If medications do not control pressure, surgical options include laser or external trabeculectomy. Laser therapy is often effective only in the first several years after surgery and then the pressure begins to build again. The timing of surgery has not been shown to influence visual outcomes, and surgery imparts greater risk for future cataracts; therefore, medications should be tried first. Target intraocular pressure that therapy attempts to achieve must be decided on an individual basis. If one medication is not sufficient to lower the intraocular pressure, a second medication from a different class may be added. It should be noted that occasionally localized or systemic reactions to the medication may occur and the patients should be instructed as to what to look for. Other systemic medications that the patient may be taking must be taken into consideration.

Drugs Commonly Prescribed 8.2 Glaucoma

Classification of Medication	Mechanism of Action	Drugs
Cholinergic	Pupillary constriction to open the angle and allow aqueous humor to escape.	pilocarpine (Isopto, Pilocar, Pilostat) *Contraindicated in conditions in which pupillary constriction is to be avoided.*
Beta blocker	Reduces the production of aqueous humor.	timolol (Timoptic), betaxolol (Betoptic), levobunolol (Betagan), carteolol (Cartrol), metipranolol (Betanol) *Additive effect in patients who are on an oral beta blocker. Contraindicated in asthma, sinus bradycardia, second- or third-degree atrioventricular block, overt CHF.*
Prostaglandin analog	Decreases intraocular pressure by increased ureo-scleral outflow (drainage).	bimatoprost (Lumigan), latanoprost (Xalatan), travoprost (Travatan) *Can cause conjunctival hyperemia, iris pigment color changes, uveitis, and macular edema.*
Carbonic anhydrase inhibitor	Reduces aqueous humor production.	brinzolamide (Azopt), dorzolamide (Trusopt), echothiophate (Phospholine), physiostigmine (Eserone sulfate ophthalmic). *Caution in patients with nephrolithiasis, diabetes, hepatic disease, and a history of sulfonamide sensitivity.*
Alpha-adrenergic agonist	Inhibits aqueous humor production.	epinephrine and dipivefrin (Propine), apraclonidine (Iopidine), brimonidine (Alphagan). *Avoid in patients with grade 2 or 3 heart block, CHF, chronic obstructive pulmonary disease, asthma, or pulmonary edema.*
Systemic medications	Reduces production of aqueous humor.	acetazolamide (Diamox), dichlorphenamide (Sulfonamide), metazolamide (Sulfonamide)

CHF- congestive heart failure.

Angle-closure glaucoma may be either acute or chronic and is less common than open-angle glaucoma. Angle-closure glaucoma is caused by anatomical narrowing of the anterior chamber angle, a factor that is determined by genetics and becomes more likely with advancing age. The narrowing is primarily related to the size of the eyeball and lens. Specifically, angle-closure glaucoma occurs when there is an acute closure of the iridocorneal angle, with a sudden, severe rise in intraocular pressure, often well above 40 mm Hg, which is symptomatic. Acute angle-closure glaucoma requires emergency treatment, or total blindness will follow within 2 to 5 days. Medications are administered during the acute attack to lower intraocular pressure so that surgical intervention can occur. Acetazolamide (Diamox) and intravenous mannitol with a topical miotic, such as pilocarpine, may be administered, followed by laser iridotomy or peripheral iridectomy. Bedrest should be maintained until the attack is broken.

Follow-up and Referral

Patients with glaucoma should be referred to and followed by an ophthalmologist. Nonetheless, as the primary-care provider, the clinician needs to understand what medications the patient is receiving as well as how often the patient should be monitored by an ophthalmologist (every 3–4 months for life). The clinician needs to be alert to possible signs and symptoms of exacerbation. There is always potential for loss of vision and possible blindness if acute glaucoma attacks are not treated promptly and consistently.

Patient Education

Careful and lifelong follow-up is essential for patients with glaucoma, especially periodic checks of intraocular pressure and eye exams. The need to take medications as ordered, to be aware of adverse effects of medications prescribed, and to recognize changes (such as sudden changes in vision) that warrant a call to the health-care provider is essential for all patients with glaucoma. The clinician may need to teach the patient how best to instill the eyedrops. If vision is severely compromised, a caregiver will need to be taught as well. Any sign of eye infection, especially fever, should be reported. In addition, the knowledge that certain medications, such as systemic steroids, may interfere with glaucoma control is essential. Support and counseling may also be necessary. In the case of open-angle glaucoma, patients need to know that they will most likely need bilateral treatment because the second eye is at risk for the same disease process.

DIABETIC RETINOPATHY

Diabetic retinopathy is a noninflammatory disorder of the retina that develops in patients with diabetes mellitus. It is typically divided into three stages: (1) background diabetic retinopathy, (2) preproliferative diabetic retinopathy, and (3) proliferative diabetic retinopathy. The initial evaluation for a patient with diabetes mellitus should include a referral to an ophthalmologist for a comprehensive eye evaluation, with particular attention to the aspects relevant to diabetic retinopathy.

Epidemiology and Causes

Approximately 6.6% of the population aged 20 to 74 have diabetes mellitus; approximately 25% of individuals with diabetes have some form of diabetic retinopathy. Most patients with diabetes will eventually develop some form of retinopathy. Diabetic retinopathy accounts for approximately 10% of new cases of blindness each year and is the leading cause of new cases of legal blindness among Americans aged 20 to 64.

The peak incidence of type 1 diabetes mellitus is between ages 12 and 15; the peak incidence of type 2 diabetes mellitus is between ages 50 and 70. Almost all patients with diabetes will develop background diabetic retinopathy after they have had diabetes for at least 20 years. Two-thirds of patients with type 1 diabetes who have had the disease for at least 35 years will develop proliferative diabetic neuropathy, and one-third will develop macular edema. The proportions are reversed for patients with type 2 diabetes.

Diabetes mellitus type 1 occurs about equally in males and females, whereas type 2 is more common in women. Predilection for type 1 diabetes is higher among Anglo Americans (African Americans have the lowest incidence); however, certain groups, such as the Pima Indians, have a 35% incidence rate of diabetes mellitus type 2.

The longer the patient has had diabetes mellitus, the greater the likelihood that he or she will develop retinopathy. In addition, poor glycemic control translates into end-organ damage, including retinopathies, in patients with either type 1 or type 2 diabetes. Pregnancy, renal disease, systemic hypertension, smoking, and elevated serum lipid levels (associated with an increased risk of retinal lipid deposits) are all risk factors for the development of retinopathy.

Pathophysiology

The key insult driving diabetic retinopathy is uncontrolled hyperglycemia. The precise mechanism by which this causes retinal damage is unclear, but there are several prevailing hypotheses that likely contribute to varying degrees. Hyperglycemia is known to contribute to the dysregulation of retinal blood flow. In the setting of systemic hypertension, increased shear stress on retinal blood vessels drives the release of vasoproliferative factors (e.g., vascular endothelial growth factor, insulin-like growth factor–1, basic fibroblast growth factor, hepatocyte growth factor) that stimulate neovascularization of the retina, optic nerve, and iris. The buildup of sorbitol (a by-product of glucose metabolism by the enzyme aldose reductase) in retinal cells is believed to increase intracellular osmolality, causing fluid shifts (cellular edema) and subsequent retinal damage. In hyperglycemic states,

free amino acids, serum, and tissue proteins may all become irreversibly glycosylated. These end products are thought to cross-link with collagen fibers within the extracellular space, initiating microvascular complications. Retinal microthromboses composed of platelets and fibrin have also been proposed to stimulate neovascularization, as the body attempts to compensate for decreased retinal blood flow. Moreover, several other risk factors have been identified, including certain genetic predispositions and enzymatic allelic variants, serum hypertriglyceridemia, anemia, and hormonal fluctuations associated with pregnancy.

In the case of background diabetic retinopathy, retinal pericytes and the microvascular endothelium are damaged early in the disease process, leading to vascular permeability and basement membrane thickening (similar to the histopathological changes seen in diabetic nephropathy). This predisposes retinal capillaries to microaneurysms and the retinal surface to thickening with deposits of proteinaceous and lipid material (hard exudates). If the macula is affected (i.e., macular edema occurs), vision may gradually blur and progress to profound visual loss if left untreated. In the preproliferative phase, multiple cycles of cellular death and renewal lead to venous beading, tortuous venous dilation, and intraluminal cellular proliferation, along with platelet, erythrocyte, and fibrinogen aggregation, which ultimately results in vascular occlusion. Upstream of such lesions, flame-shaped and blot hemorrhages occur; downstream, microvascular infarcts present as "cotton wool spots" or soft exudates on funduscopy. Finally, the proliferative phase is characterized by neovascularization on the retinal surface, optic nerve, and iris. These fragile vessels may be venous or arterial in origin and may extend into the vitreous chamber, attaching to the posterior pole of the vitreous in a fine fibrous mesh. This network places stress on the retinal surface as the fibers contract. As a result, hemorrhage into the vitreous body and even retinal detachment may occur, requiring both vitrectomy and laser photocoagulation.

Clinical Presentation

Subjective

The patient will complain of visual changes as the disease progresses but is usually asymptomatic in the early stages.

Objective

Changes will be noted on funduscopic exam. In background diabetic retinopathy, microaneurysms, intraretinal hemorrhage, macular edema, and lipid deposits may be apparent. As the disease progresses, nerve fiber layer infarctions ("cotton wool" spots), venous beading and dilation, edema, and, in some cases, extensive retinal hemorrhage will be noted. In the proliferative form of diabetic retinopathy, new blood vessel proliferation (neovascularization) may be seen on the retinal surface, optic nerve, and iris.

Diagnostic Reasoning

Diagnostic Tests

A thorough eye exam should be done, including an assessment of visual acuity and documentation of the status of the iris, lens, vitreous, and fundus. Fluorescein angiography will demonstrate retinal nonperfusion, retinal leakage, and proliferative diabetic retinopathy.

Differential Diagnosis

A history of diabetes, especially if present for more than 10 years, correlated with observable changes on funduscopic exam, establishes the diagnosis. Other causes of retinopathy include hypertensive retinopathy, radiation retinopathy, and retinal venous obstruction.

Management

The first goal for patients at risk for microvascular complications, including diabetic retinopathy, is prevention. Risk is significantly increased for patients with blood sugar levels above 200 mg/dL. The most significant preventive measure is to keep blood sugar under control. The American Diabetes Association sets an acceptable level of glycated hemoglobin or HgbA1C at less than 7%. In patients who have their blood sugar under adequate control, the incidence of diabetic retinopathy is far lower and the onset in those who do develop this disease is later. All patients who carry the diagnosis of diabetes mellitus must be referred to ophthalmology on diagnosis.

Similarly, patients with diabetes and hypertension should strive to maintain as normal a blood pressure as possible to prevent the development of end-organ damage. Because many patients have both disorders, vigilance is especially important in this subset of patients.

The only pharmacological agent that has been found to slow the progression of diabetic retinopathy is lisinopril, an angiotensin-converting enzyme inhibitor.

Laser surgery is recommended for patients with proliferative diabetic retinopathy and for patients with clinically significant macular edema.

Diabetic retinopathy patients should be followed by an ophthalmologist, who can decide when to treat the disorder with laser treatment (focal and panretinal photocoagulation); in certain cases, cryoretinopexy can be used to decrease the neovascular stimulus and to treat proliferative diabetic retinopathy. Vitrectomy may be considered for patients with severe proliferative diabetic retinopathy, traction retinal detachment involving the macula, and nonclearing vitreous hemorrhage (this surgical option should be considered after 1 month for a vitreous hemorrhage that has decreased the vision to the 5/200 level or worse).

Follow-up and Referral

All patients with diabetes mellitus should be monitored annually by an ophthalmologist. The patient with background retinopathy should be followed at least every

6 months, and patients with proliferative retinopathy should be seen at least every 3 to 4 months. Patients with active proliferative retinopathy should be seen approximately every 8 weeks.

Glaucoma, cataracts, retinal detachment, vitreous hemorrhage, and disc edema (papillopathy) are all common in patients with diabetic retinopathy, even in its early stages. Cataracts, especially, are common in patients with diabetes. If the patient has retinopathy, he or she should try to postpone the cataract surgery as long as possible because cataract surgery can sometimes worsen diabetic retinopathy.

Patient Education

Obviously, this is a critical area. Patients with diabetes, as well as those with hypertension, need to be educated regarding the need to keep their disease under maximal control to decrease the incidence of complications. Creating an alliance with the patient and family is essential in encouraging lifestyle changes. Working with the patient over time and being there for the patient are essential. Patients should be educated about the importance of ophthalmological evaluation and follow-up. Patience, advocacy, and commitment are all important qualities in working with these patients. Optimism and emphasis on the possibility for change, even if just to prevent further disease progression, are essential characteristics.

MACULAR DEGENERATION

Macular degeneration, or low vision, as it is sometimes referred to, is a disease of aging and is the leading cause of blindness in patients older than 60 years. Risk factors associated with macular degeneration are shown in Risk Factors 8.1. Macular degeneration is a condition characterized by slow, progressive atrophy and degeneration of the retina. This condition is called "dry" macular degeneration. Occasionally, new blood vessels develop under the retina in the macula, causing a sudden distortion or loss of central vision. This condition is known as "wet" age-related macular degeneration; it presents as a sudden decrease in vision that should be referred immediately to an ophthalmologist. There is often a progression from "dry" to "wet" macular degeneration. The macula is the most sensitive and central portion of the retina, a nerve-rich area essential for sight. For largely unknown reasons, after age 60, the macula begins to break down. As it degenerates, central vision and fine detail perception deteriorate. Patients typically cannot read well (if at all), see facial details, read signs, or carry out ordinary daily visual activities.

Epidemiology and Causes

A recent study reported that 30% of individuals aged 75 and older have some form of age-related macular degeneration (AMD), and 7% of those aged 75 and older have an advanced form. Recent studies estimate that 8 million Americans are considered to be at risk for developing advanced AMD in the next 5 years, and 1.75 million are currently affected with the advanced form of the disease. AMD is the leading cause of blindness in older North Americans.

Risk Factors 8.1 Macular Degeneration

Caucasian race
Female gender
Age older than 60
Cigarette smoking
Family history
Macular degeneration gene (complement factor H)
Other risk factors that are unproved, but documented in some studies, include the following:

- High serum cholesterol/obesity
- Low serum carotenoid levels
- Exposure to ultraviolet light
- Hypertension
- Light-colored eyes
- Farsightedness
- Past cataract surgery

Pathophysiology

Research in mice has provided a few genetic-based clues to the pathogenesis of AMD and has suggested that inflammatory dysfunction may have a role in pathogenesis. Growth factor, choriocapillary endothelial damage, and key inflammatory cytokines are likely involved. Most recently, genetic research has shown that mutations in the gene for complement factor H on chromosome 1 are strongly associated with AMD, supporting a possible inflammatory etiology of AMD.

Clinical Presentation

Subjective

The clinician's main task is to determine if the problem is an acute one, needing referral for immediate treatment, or a more routine one. Determining whether the onset of the visual impairment has been acute or gradual will assist the clinician in making this determination. Likewise, the severity of the visual loss is also important. Severe and sudden visual loss should be referred immediately to an ophthalmologist. Vitreous hemorrhage, retinal detachment, uveitis, retrobulbar optic neuritis, and vascular occlusion generally present in this manner. A gradual progressive change is more indicative of changing refractive error, cataract, glaucoma, diabetic retinopathy, and macular degeneration.

Objective

First, visual acuity must be evaluated, with the patient wearing any assistive lenses. If vision is less than 20/20, it should be checked by the pinhole test. Vision that

Nursing Research–Based Practice 8.1

Moore, LW, and Miller, M. Older men's experience living with severe visual impairment. *J Adv Nurs* 43(1):10–18, 2003.

Mr. Nesbitt is a 78-year-old widower who has been in your practice for 15 years. You have managed his hypertension and mild congestive heart failure for the past 5 years, and he has been following all your advice, including walking 1 mile every day, weather permitting. He was recently diagnosed with age-related macular degeneration (AMD), and his visual loss has been progressive. He has always been very active in community events since the death of his wife and spends several hours each day at the local Senior Center where he entertains the other seniors by playing the piano during lunchtime. He usually drives himself the 2 miles across town to the center and has been doing all of his own grocery shopping, cooking, and tending to his house and yard. He has a large garden and shares his produce with his neighbors. He tearfully admits that his children have been after him to stop driving and to give up his home and move to an assisted living facility. He says he has not had any accidents and that he stays close to the center line when he drives and he knows the route by heart. "I could get there blindfolded," he jokingly remarks. As to moving he says, "Why would I do that? I know where everything is, and I haven't had any problems. My kids can help me. If they put me in a home, I might as well be dead." Mr. Nesbitt has 2 sons aged 50 and 49. Both of these men have jobs that take them out of town a good portion of the week. Both work in the family business started by their father. One son is divorced with two teenage boys, and the other is married with four children and one grandchild.

This past week both sons called asking you to bring Mr. Nesbitt to his senses and to take away his car keys, relating that he has had two near misses in the past 2 weeks. They say that he refuses to listen to reason and that his reason for the near misses is that he "got distracted by a pedestrian jay walking and by a school bus."

Consider the issues in this case based on the findings in this small study.

A phenomenological approach was used to investigate the experience of severe visual impairment in eight older men with macular degeneration. Data were gathered through audiotaped interviews and analyzed using a modified Giorgi method. The aim of the study was to gain an understanding of severe visual impairment from the perspective of older men with macular degeneration. The eight participants were recruited from a local agency for people with vision loss, and they were 68 to 87 years old with macular degeneration in both eyes. The duration of the macular degeneration ranged from 6 months to 2.5 years. Interviews were conducted in participants' homes, and spouses were present in four of the interviews. The six central themes that emerged were as follows: (1) abilities and inabilities, (2) cherishing of independence, (3) creating strategies, (4) acknowledging the progression of visual impairment, (5) confronting uncertainties and fears, and (6) persisting with hope and optimism.

One interesting finding in this study was that the theme of uncertainties encompassed skepticism about their diagnosis and treatment. Acceptance of the fact that there is no successful treatment for AMD is very hard for most individuals, and persisting with hope and optimism is interesting in the face of severe progressive visual loss and mistrust of how their case is managed.

corrects with the pinhole test implies an uncorrected refractive error. The clinician should then evaluate the external structure of the eye. The lids, conjunctivae, pupils, and extraocular movements should be checked. Acute angle-closure glaucoma presents with an unreactive pupil, for example. A Marcus Gunn pupil implies damage to the optic nerve. In addition, conjunctival injection is present with trauma, corneal problems, iritis, acute angle closure, glaucoma, and hyphema.

The funduscopic exam is normal in patients with refractive errors. If dense, cataracts may make it hard to visualize the retina, but otherwise the exam is normal. Patients with glaucoma have increased cupping of the optic disc (a normal cup-to-disc ratio is 0.5 or less). Increased cupping is cause for referral to an ophthalmologist. Retinal hemorrhages, hard exudates, "cotton wool" spots, or neovascularization indicates diabetic retinopathy. If the fundus is difficult or impossible to view, suspect vitreous hemorrhage, especially in diabetic patients with sudden visual loss. Yellow round spots (drusen) may be indicative of early macular degeneration. Clumps of pigment irregularly interspersed with depigmented areas of atrophy in the macula are more typical of a later phase of the disorder.

Diagnostic Reasoning

Diagnostic Tests

Analysis of central vision may be done with an Amsler grid to locate macular blind spots and areas of distortion and wavy lines. Measurement of contrast sensitivity with specially designed tests for low vision may reveal the degree of loss of retinal sensitivity (contrast) and indicate the potential success or failure of optical magnifying devices.

Differential Diagnosis

As previously discussed, visual impairment may be associated with a variety of conditions. The task of the

clinician is to know when to refer for ophthalmology evaluation and treatment and which conditions can be treated in primary care. The characteristics of the associated symptoms and physical findings in the problem of visual loss require focused history and excellent physical exam skills.

Management

There are no proven strategies for preventing AMD, nor are there any treatments for the initial stage of early disease. Some evidence has shown that in the intermediate stage of the disease, oral intake of high-dose antioxidant vitamins and zinc supplements modestly decreased the risk of developing severe vision loss.

Thermal laser photocoagulation may be used to treat certain forms of wet AMD. However, its use is of limited value for lesions in the central macula area. Wet AMD is also treated with injections directly into the eye (intravitreal) by a retinal specialist or ophthalmologist (see Drugs Commonly Prescribed 8.3: Wet Acute Macular Degeneration). The medication used belongs to the class of drugs called anti–vascular endothelial growth factor (anti-VEGF) therapies. These drugs reduce the growth of abnormal blood vessels and may slow leakage from blood vessels. Large-scale clinical trials have demonstrated that these drugs preserved and even improved visual acuity. There are four drugs in this class: the monoclonal antibodies ranibizumab (Lucentis) and bevacizumab (Avastin); the nucleic acid VEGF inhibitor pegaptanib (Macugen); and the receptor fusion protein aflibercept (Eylea). These drugs are expensive and may not readily be covered by medical insurance.

A number of clinical trials are also investigating potential alternative treatments for AMD, such as submacular surgery, photodynamic therapy, and irradiation. Antioxidants and other plant chemicals (phytochemicals) have been shown to protect against the development of macular degeneration.

Follow-up and Referral

Refer the patient to a rehabilitation source where the outcome of the disease can be evaluated, daily living needs can be assessed, and visual aids may be offered. Sources may include ophthalmologists who provide low-vision services in their practices; optometrists who are trained to offer low-vision remediation; agencies for the visually impaired (either private or state supported); institutions that offer services for veterans; and organizations such as the American Academy of Ophthalmology, the American Optometric Association, the National Eye Institute, and Lighthouse International. A team approach is useful in rehabilitation, and the primary-care provider is part of the team. Because the loss of vision can be especially debilitating, quality of life needs to be assessed during routine primary-care visits. Vision loss increases the risk of falls and may limit the patient's ability to live on his or her own. Depression rates are high in cases of vision loss, and screening in primary care for signs of depression is important. A psychosocial assessment with a multidisciplinary team

Drugs Commonly Prescribed 8.3 Wet Acute Macular Degeneration

Drug	Indication	Dosage	Adverse Effects
aflibercept (Eyla) *VEGF-receptor fusion protein*	Wet AMD (FDA approved)	2-mg intravitreal injection once a month for 3 months, then every 2 months	*Severe:* Allergic reaction including hives, difficulty breathing, and facial swelling; retinal detachment; endophthalmitis
bevacizumab (Avastin) *Anti-VEGF monoclonal antibody*	Wet AMD (unapproved)	1.25-mg intravitreal injection once a month (off-label use)	*Moderate:* Eye pain; eye redness; sudden vision changes, including flashes of light; photophobia; severe headache with confusion
pegaptanib (Macugen) *Nucleic acid VEGF inhibitor*	Wet AMD (FDA approved)	0.3-mg intravitreal injection every 6 weeks	*Mild:* Watery eyes; blurred vision; pain at injection site; edema of eyelid
ranibizumab (Lucentis) *Anti-VEGF monoclonal antibody*	Wet AMD (FDA approved)	0.5-mg intravitreal injection every month	

should be arranged to explore resources and monitor quality of life.

Patient Education

Recognition of the signs of advanced AMD is crucial for the success of treatment in preventing visual loss. Self-monitoring of central vision in both eyes using an Amsler grid may be useful in detecting subtle visual changes or distortion, as well as monitoring changes in vision once they have been detected. A hallmark of AMD is visual difficulties in low light.

Smoking cessation and improvement of cardiovascular risk factors are important variables in the progression of AMD. Patients should be instructed as to rehabilitation resources in the community and encouraged to take advantage of programs specifically targeted for AMD.

Optical aids include spectacles with and without prisms, hand magnifiers, stand-mounted magnifiers, and telescopes. As with any type of rehabilitation, time and patience are needed to determine the appropriate remedial lens for the patient. Working with the patient until he or she understands how to use the device is an important part of patient education. In addition, patients may be taught practical skills such as folding money in such a way that the denomination is more apparent, as well as techniques for grooming and for identifying medications. The goal is to use "whatever works" for each patient (see The Patient's Voice 8.1).

The Patient's Voice 8.1

Macular Degeneration

My mother, who is 78, called me in a panic because she could not see out of one eye. The ophthalmologist agreed to see her right away. When we met with the doctor after her exam, he told us that she had been diagnosed with macular degeneration 4 years ago. She had never told a soul! "I couldn't stand the thought of being a burden." That's what she told me. If only I'd known, maybe we could have done more to slow down the disease. Now, if anything happens to her other eye, I don't know what we'll do. This will change everything about how my mother lives and will affect everyone in the family.

EAR PROBLEMS

HEARING LOSS

Exposure to loud noises, either occupationally or recreationally, is a risk factor for hearing loss, as are ototoxic drugs (e.g., aminoglycoside antibiotics, aspirin, and quinine). Allergies and other causes of eustachian-tube obstruction may also contribute to hearing loss. Risk factors for cerumen impaction specifically are ear canal hairs, hearing aids, bony growths secondary to osteophyte or osteoma, and previous episodes of impacted cerumen. Chronic middle ear infections (otitis media) also are a contributing factor in the development of hearing loss.

Epidemiology and Causes

Approximately 17% (36 million) of American adults 45 to 64 years old have a hearing impairment. Among older Americans, hearing impairment is present in 30% of 65- to 74-year-olds, and 47% of adults who are 75 years old or older have some form of hearing impairment. Men are more likely than women to experience hearing loss.

Pathophysiology

Sensorineural hearing loss is defined as a lesion in the organ of Corti or in the central pathways, including the eighth cranial nerve (CN VIII) and auditory cortex. Age-related hearing loss, termed *presbycusis,* is a form of sensorineural hearing loss. After age 50, hair cells in the organ of Corti tend to degenerate. A capillary-fed layer of stratified epithelium known as the *stria vascularis* that secretes endolymph and promotes the sensitization of hair cells in the cochlea may atrophy. This first affects perception of high-frequency sounds and then progresses to affect hearing of lower-frequency tones. Sensorineural loss may also be a result of Ménière's disease (discussed later in this chapter) or be noise induced. Other causes of hearing loss include tumors, genetic predisposition, ototoxicity related to a variety of medications, syphilis, and metabolic disorders, such as hypothyroidism. Hearing loss also may be due to an inner ear fistula, usually secondary to pressure changes or trauma. Viral syndromes, especially mumps, may also affect hearing.

Conductive hearing loss is a lesion involving the outer and middle ear to the level of the oval window that may result from a variety of structural abnormalities. Cerumen impaction, a reversible form of hearing loss, is a common cause in all age groups. Perforation of the tympanic membrane, middle ear fluid, damage to the ossicles from trauma or infection, otosclerosis, tympanosclerosis, cholesteatoma, middle ear tumors, temporal bone fractures and injuries related to trauma, or congenital problems may all cause conductive hearing loss.

Clinical Presentation

The most important task, and frequently a difficult one, is to determine whether the hearing loss is sensorineural (which is usually irreversible) or conductive (which is often reversible). Another important piece of data is whether the loss is unilateral or bilateral. Presbycusis produces a typical high-frequency loss that is bilaterally symmetrical. Ménière's disease causes fluctuating hearing loss, usually unilateral, associated with tinnitus and vertigo. Acoustic neuroma (schwannoma), a rare tumor of cranial nerve VIII, causes unilateral constant or progressive hearing loss, possibly associated with headache. With a tumor of the acoustic nerve, there will most likely be neurological changes, such as facial weakness and tingling and loss of taste and dysphagia, in addition to hearing loss.

Subjective

Hearing loss is not a distinct clinical entity; it is a symptom or sign of multiple medical conditions. Patient complaint terminology is more diversified than for many other medical conditions. A patient may report having "difficulty hearing," which may be associated with pain, pressure, discomfort, vertigo, or loss of balance. Or the patient may complain of tinnitus, dizziness, blockage, popping, pressure, crackling, distant sounds, or stiffness. The clinician should question the patient as to how long he or she has noticed a hearing loss and whether it is partial or complete. Does the patient think both ears are affected? Is there a family history of hearing loss? The clinician should inquire whether the patient has ever had any injury or surgery to the ears and if he or she has had any serious illnesses or tuberculosis (which might have required treatment with ototoxic drugs). The review of systems should focus on the neurological system, including cranial nerve function (e.g., facial weakness or tingling, loss of taste, or dysphagia). The social and occupational history should include specific questions regarding noise or toxin exposure and any blast-related injuries, including a history of hunting and/or target shooting. A complete history of prescription and over-the-counter (OTC) medication use should be obtained.

Objective

The physical exam should include otoscopic examination to inspect the external auditory canal and middle ear. The clinician should note any redness, foreign objects, discharge, scaling, lesions, and cerumen (ear wax). There may be a significant accumulation of cerumen, especially in elderly patients. The tympanic membrane should have no perforations and should be a translucent pearly gray. Changes in the tympanic membrane may be consistent with conductive hearing loss.

The clinician should perform Weber, Rinne, and Schwabach tests to determine whether hearing loss is primarily conductive or sensorineural. Unexpected findings from the three tuning fork tests must be integrated to differentiate clinically what is occurring. Conductive hearing loss occurs when sound transmission is impaired through the external or middle ear. Sensorineural hearing loss occurs because of a defect in the inner ear that leads to distortion of sound and misinterpretation of speech.

For office testing, use the Weber test first. A vibrating 512-Hz (or higher-frequency) tuning fork is placed midline on the patient's skull. Normally, the sound should be equal in both ears. In sensorineural loss, the sound in the unaffected (or less affected ear) is louder. In conductive loss, the sound is louder in the affected ear.

The Rinne test can also be done in the office. A vibrating tuning fork is placed on the mastoid process. When the sound fades away, the fork is promptly placed (without restriking it) over the external auditory meatus. Normally, via air conduction, the sound can be heard for twice as long as in bone conduction. In sensorineural loss, the ratio remains the same, whereas in conductive loss, the ratio is closer to 1:1, or even reversed.

In the Schwabach test, a vibrating tuning fork is placed over the mastoid process of the patient and then the examiner and the results are compared. In sensorineural loss, the patient's bone conduction is present for a shorter time than the examiner's; in conductive loss, the patient's bone conduction persists for a longer time.

Diagnostic Reasoning

Diagnostic Tests

Often, the patient needs to be referred for audiometry. Audiometry includes pure tone and speech testing, as well as impedance (middle ear pressure) testing. Both types of hearing loss may fluctuate, making audiometric results variable from test to test. Marked conductive loss on one ear may be difficult to exclude (mask) when testing the opposite ear. Computed tomography (CT) and magnetic resonance imaging (MRI) scans are used to detect tumors such as acoustic neuromas and glomus tumor, as well as damage from traumatic injuries.

The various mechanical obstructions, be they wax or tumor or fluid associated with infection/inflammation, that lead to conductive hearing loss may be visualized. CT scan and/or MRI may be needed to demonstrate tumors and cholesteatoma. Cholesteatoma may sometimes be identified by perforation that is located near the margin of the eardrum.

Differential Diagnosis

The differential diagnosis for hearing loss includes conditions that cause either sensorineural or conductive loss. Aging is associated with the sensorineural presbycusis. However, other possible conditions need to be ruled out. Sensorineural loss may also have the etiology of otoxicity, exposure to loud noises, an autoimmune issue, an acoustic neuroma, or possibly Ménière's disease. Conductive hearing loss may be explained simply by cerumen accumulation or impaction (cerumenosis) or a foreign body in the external canal, otitis externa, chronic otitis media, middle ear effusion, otosclerosis, a vascular anomaly, or cholesteatoma. To treat hearing loss properly, the etiology must be accurately identified.

Management

Many types of conductive loss are reversible; sensorineural causes tend to be irreversible. In cases of conductive hearing loss caused by cerumen buildup, cerumen disimpaction may be necessary. The recommended procedure is as follows: Use a 1:1 mixture of 3% hydrogen peroxide and warm mineral oil. Place three drops in the external ear and wait 1 hour. Then attempt to lavage the ear with warm saline. Direct the saline toward the canal wall, not toward the drum. An

alternative method is to put three drops of warm olive oil in each ear to soften the wax, then flush with warm 3% hydrogen peroxide. Cerumenolytic agents such as 6.5% carbamide peroxide (Debrox) are effective; docusate sodium liquid may also be used. These agents should not be used in the presence of a perforated tympanic membrane or infection. Press gently but firmly behind the ear, then in front of the ear. Pull the lobe up and down to work the wax out. Dry the ear canal after the irrigation with a hair dryer on low, if one is available. Advise the patient who has cerumen buildup but may not be complaining of hearing loss to use Debrox for 1 week before returning for an ear irrigation as described above.

If not performed properly, cerumen removal may cause damage to the external auditory meatus, perforation of the tympanic membrane, and/or otitis media. Consider steroid/antibiotic otic solution (Cortisporin otic), four drops 3 or 4 times daily for 5 to 7 days after prolonged irrigation and trauma to the canal. Consider cerumenolytic installation 2 times daily for 5 days monthly in recurrent, resistant cases. Do not disimpact the ear if tympanic membrane perforation is present. If hearing loss is caused by infection, treat as appropriate (see section on otitis media/externa under Common Ear Problems). The cause of the hearing loss in cases of sensorineural loss must also be identified correctly to treat it properly. Noise damage is a common cause of hearing loss in the United States. Although this type of hearing loss is not reversible, it is preventable. Hearing loss related to the use of ototoxic medications (especially certain antibiotics) needs greater recognition. This etiology should be suspected when hearing loss, dizziness, and tinnitus occur during the course of treatment with certain medications. In this case, the patient should stop the medications. Salicylate toxicity, for example, is reversible. In cases resulting from metabolic causes, such as hypothyroidism, the underlying disorder should be treated.

Follow-up and Referral

Patients should be referred to an ear, nose, and throat specialist if perforation is present, as well as in cases of damage to the ossicles, tympanosclerosis, otosclerosis, tumor, and temporal bone injury. Referral to an audiologist for further evaluation may be appropriate. Patients who are suspected of having Ménière's disease should be referred to an ear, nose, and throat specialist and an audiologist for appropriate diagnostic testing and treatment. In the case of perilymphatic fistula, diagnosis should be based on evidence or history of injury to the ear (including barotrauma during diving), and referral to a specialist is indicated. Acoustic neuromas should be referred for surgical treatment.

For cases of sudden, sensorineural hearing loss with no apparent cause, high doses of steroids (80 mg per day of prednisone or equivalent) are sometimes used. Any patient who presents with this type of acute hearing loss should be referred to a specialist for treatment.

Patient Education

In cases of presbycusis, although no specific treatment will reverse the process, it is important to educate and support the patient so that no further damage will occur; for example, exposure to excessive noise and ototoxic drugs should be avoided. Severe nerve deafness, particularly when associated with tinnitus, may produce severe depression and isolation and occasionally even lead to suicide. Clinicians should inquire as to daily activities and social interaction. Teach the patient lip-reading if appropriate, and instruct family members to speak clearly, facing the patient. Encourage the purchase of hearing aids. Consult a telephone equipment company about special audio equipment that is available.

Permanent hearing loss is common in cases of sensorineural hearing loss and may also occur with conductive hearing loss. Patients need to be counseled about follow-up with audiometry and the need to use hearing aids. Middle ear problems may progress to chronic ear problems such as perforations and/or cholesteatoma, which will adversely affect hearing.

As a prevention strategy, as well as in cases of occupational or recreational hearing loss, the patient must be counseled to always use protective devices. It is also important to teach the patient to equalize ear pressure when diving and to chew gum while in airplanes. Decongestants might be indicated. If an upper respiratory infection is present, the patient should avoid flying and/or diving.

TINNITUS

Tinnitus is a subjective perception of noise when in reality no environmental noise is present. It may be intermittent, continuous, or pulsatile (synchronous with heartbeat). Risk factors include hearing loss, labyrinthitis, Ménière's disease, otitis media or externa, otosclerosis, ear-canal blockage (from ear wax or a foreign body), a history of high or low blood pressure, head trauma, anemia, hypothyroidism, hyperthyroidism, or allergies. Chronic exposure to noise, especially high-pitched sounds, may damage the cilia and auditory hair cells, causing tinnitus. Certain medications may contribute to tinnitus, some with reversible effects (salicylates, quinine, alcohol, and indomethacin [Indocin]) and others with irreversible effects (kanamycin, streptomycin, gentamicin, and vancomycin).

Epidemiology and Causes

Recent estimates suggest that as many as 40 million Americans are affected by tinnitus. Approximately 90% of patients with hearing loss experience some tinnitus, and approximately 1% of the population suffers from chronic tinnitus. Tinnitus is strongly associated with aging. Experts estimate that 15% of Americans have

experienced tinnitus that lasts longer than 5 minutes and that 155 million have sought medical care for tinnitus. About 6% of that number report being incapacitated by tinnitus. The peak range of patients with tinnitus is 40 to 70 years. Patients in their 70s have a 25% to 30% risk of developing tinnitus. Men have a higher risk of developing tinnitus, and whites experience tinnitus in greater numbers than blacks.

Pathophysiology

Tinnitus is classified in several different ways. In addition to the subjective and objective classes as presented in the common complaints section of this chapter, tinnitus may also be divided between vibratory and nonvibratory tinnitus. Vibratory tinnitus is caused by transmission to the cochlea of vibrations from adjacent tissues or organs. Nonvibratory tinnitus is produced by biochemical changes in the nerve mechanism of hearing. Subjective tinnitus, which is more common, is heard only by the patient. Objective tinnitus can be heard by an examiner through a stethoscope placed over the head and neck structures near the ear.

The causative mechanism is poorly understood. Theories include injured cochlear hair cells discharging repetitively and stimulating auditory nerve fibers in a continuous cycle, spontaneous activity in individual auditory nerve fibers, hyperactivity in the auditory nuclei in the brainstem, or a reduction in the usual suppressive activity of the central auditory cortex on peripheral auditory nerve activity.

Clinical Presentation

Subjective

Most patients are not bothered by tinnitus when they are surrounded by the usual sounds of everyday life. However, when they are in an unusually quiet location, the perception of tinnitus may be profound. In more extreme cases, tinnitus may interfere with their lives, affecting concentration and sleep and causing severe depression in the worst cases. Tinnitus that manifests as a continuous and unbearably loud sound has led a few patients to self-destruction.

Patients have variously described tinnitus as the sound of escaping air or running water or the sound heard inside a large seashell or as a buzzing, ringing, or humming noise. Tinnitus also has been described as a roaring or musical sound. It may be unilateral or bilateral.

Other presentations commonly seen include a stiff neck and pain aggravated by activity that produces the tinnitus, accompanied by vertigo, nystagmus, hearing loss, and pain that radiates down the arms. Weakness, confusion, and feelings of unsteadiness (orthostatic hypotension) may also occur, especially when the patient stands up quickly. These symptoms may be indicative of atherosclerosis as a causative factor.

Complaints of ear fullness, itching, and hearing loss along with the tinnitus may be caused by a foreign body obstruction, such as cerumen (ear wax) impaction; obstruction should always be ruled out. Bilateral, high-pitched tinnitus may occur with severe hypertension (diastolic blood pressure exceeding 120 mm Hg). The patient may have associated symptoms of headache, numbness, nausea, and vomiting.

The patient may describe a sudden onset of vertigo, unilateral or bilateral hearing loss, dizziness, nausea or vomiting, and nystagmus. Labyrinthitis may be considered.

Objective

In addition to usual vital signs, the blood pressure should be evaluated via orthostatic measurements. Physical exam will include gross hearing tests, as well as the Weber and Rinne tuning fork tests to detect conductive or sensorineural hearing loss. A thorough otologic exam should be done. Auscultation of the upper part of the neck near the ear of the affected side may detect a bruit and palpation may reveal a weak pulse. Vascular studies may need to be considered. Cardiovascular evaluation including electrocardiogram may detect changes associated with atherosclerotic disease. Neurological exam should be done to rule out other deficits.

Diagnostic Reasoning

Diagnostic Tests

Laboratory studies are necessary to confirm possible underlying causes of tinnitus. A complete blood count (CBC) should be done to rule out anemia or infection. Metabolic studies need to be done to rule out thyroid disease, hyperlipidemia, vitamin B_{12} deficiency, zinc deficiency, or electrolyte abnormalities. If drainage from the ear canal is evident, a culture should be obtained. MRI may reveal pathology in detail; this is currently the diagnostic procedure of choice. If the patient cannot tolerate MRI, CT scan with dye enhancement is an alternative. Special tests to determine the presence of middle ear fluid may be considered, such as tympanometry, acoustic reflex measurement, or acoustic reflectometry. Because of the association of depressive disorders in severe tinnitus, screening for psychological disorders should be done.

Differential Diagnosis

Tinnitus may arise from cardiovascular and system disorders (hypertension and anemia). Nonpathological causes include acute anxiety and presbycusis. The patient experiencing tinnitus may also present with multiple symptomatology; those symptoms may alert the practitioner to the underlying cause. For example, hearing loss and tinnitus accompanied by vertigo, facial paralysis, headaches, nausea, vomiting, and papilledema may occur with acoustic neuroma. An early symptom of acoustic nerve (CN VIII) tumor is unilateral tinnitus. Occasionally, anemia may produce mild, irreversible

tinnitus. In this case, the patient may complain of dim vision, syncope, and the associated signs of anemia, such as fatigue, weakness, exertional dyspnea, and tachycardia, that accompany the tinnitus.

Bilateral, high-pitched tinnitus may occur with severe hypertension (diastolic blood pressure exceeding 120 mm Hg). The patient may have associated symptoms of headache, numbness, nausea, and vomiting.

In Ménière's disease, low-pitched tinnitus, along with vertigo and fluctuating hearing loss, may occur. Tinnitus accompanied by bleeding from the ear canal can be caused by trauma. Purulent drainage and pain with tinnitus may be caused by infection. Other presenting symptoms of tinnitus may be fever, chills, and dizziness.

Management

Elimination of possible offending medications (such as aspirin-containing products and NSAIDs) is a priority. Tinnitus usually cannot be treated successfully. However, management of symptoms and treatment of the underlying disorder (if one can be identified) may help. Overall, learning to cope with the tinnitus is the best approach. Avoidance of risk factors such as excessive noise whenever possible is advised. Some experts suggest supplementation with vitamin A, vitamin C, cyanocobalamin, and nicotinic acid or with magnesium or copper.

Protective earplugs may need to be worn. Tinnitus-masking devices can match the frequency range and intensity of the tinnitus, producing a level of noise that will help block out the tinnitus without interfering with hearing. The device fits in the ear like a hearing aid and presents a more pleasant sound. Regular relief may be obtained by masking the tinnitus with background noise. Hearing aids are also helpful in tinnitus suppression: they help to amplify environmental sounds, thereby obscuring tinnitus. For patients who find the noise intolerable, biofeedback may be needed to help with psychological problems that can develop from the near-constant feeling of distress.

Although there is no medication to help tinnitus, oral antidepressants have proved to be effective in reducing symptoms. Nortriptyline (Elavil), at an initial dose of 50 mg orally at bedtime, may be considered. Meclizine HCl (Antivert, Bonine) is the most commonly used vestibular suppressant. Diazepam (Valium), usually in low doses such as 2 mg, may be a valuable adjunct therapy to treat an acute attack of vertigo, as well as being effective for those with anxiety. If chronic vertigo and dizziness accompany the tinnitus, vestibular rehabilitation should be considered.

Patients with tinnitus related to otitis media or other infections should be treated with antibiotics for an adequate duration, with careful monitoring of serum peak and trough levels. This will also prevent loss of vestibular function and deafness from antibiotic therapy with aminoglycosides. If medical management does not resolve ear infections, surgical intervention—with myringotomy and possible tube placement—may need to be considered. Referral to an otorhinolaryngologist should be initiated.

Follow-up and Referral

Referral to an audiologist should be initiated for a patient with tinnitus and hearing loss. If vertigo, nausea, and vomiting accompany the tinnitus, the patient should be referred to an otorhinolaryngologist.

Patient Education

General measures might include playing background music during the daytime and before sleep. Patients should be advised to quit smoking and to cut back on caffeine, chocolate, and salt intake. Fatigue may increase tinnitus; therefore, patients need to be encouraged to rest during the course of the day. Chewing gum or swallowing should be encouraged during descent on airplanes to promote eustachian tube opening with deglutition (swallowing).

MÉNIÈRE'S DISEASE

Ménière's disease (Ménière's syndrome, endolymphatic hydrops) is a peripheral sensory disorder of both the labyrinth (semicircular canal system) and cochlea of the inner ear. Endolymphatic volume and, in turn, pressure are increased due to unknown etiology, resulting in both vestibular (proprioceptive, balance-related) and auditory dysfunction, characterized by recurrent attacks of tinnitus (ringing or buzzing in the ears), vertigo (a sense of whirling or spinning in space), and progressive hearing loss. Although Ménière's disease is not life-threatening, if untreated, acute attacks typically recur over the course of many years.

Epidemiology and Causes

Well-documented incidence figures for Ménière's disease are not available, but it is estimated that 46 new cases per 100,000 occur annually in the United States. Prevalence is estimated at 1,150 per 100,000. Age at onset is anywhere from 30 to 60 years, with most cases developing during the fifth decade of life. The disease is rare both in young children and in adults older than age 70. Some studies indicate that white Americans of European descent are at an increased risk of developing the disease. Both sexes are affected nearly equally, but some studies have reported slightly higher rates in women.

Stress, allergies, high salt intake, and exposure to high noise levels for periods of many years have all been cited as risk factors.

Pathophysiology

The precise cause of Ménière's disease is not fully established, but marked edema of the membranous labyrinth is typically observed at autopsy, and endolymphatic hydrops has been established as the defining pathological finding in the disease. Theories have implicated the inflammatory response of the inner ear

to a variety of insults, including blunt trauma; viral infection; allergies; reduced or negative middle ear pressure; and various vascular, endocrine, and lipid disorders. Migraine headache and autoimmune conditions, including systemic lupus erythematosus, rheumatoid arthritis, and certain thyroid disorders, also predispose to Ménière's disease. A genetic predisposition has also been identified in 8% of people affected.

Dilation of the endolymphatic system may lead to rupture of the membranous labyrinth. This engorgement has been associated with excessive endolymph production, decreased resorption of fluid in the endolymphatic sac, and hypoplasia of the vestibular aqueduct. Resultant mixing of the endolymph and perilymph is thought to cause degeneration of both vestibular and cochlear neuroepithelial sensory hair cells, which are particularly sensitive to ionic changes from the potassium-rich endolymph, resulting in vertigo, tinnitus, and hearing loss. Compression of the vestibular portion of CN VIII by an enlarged blood vessel is yet another etiological theory.

Clinical Presentation

Subjective

Acute episodes of Ménière's disease last anywhere from 20 minutes to 3 hours and are characterized by sudden attacks of nausea; emesis; pallor; diaphoresis; dizziness (spatial disorientation); vertigo; roaring tinnitus; and increased pressure, fullness, and hearing loss in the affected ear. Patients typically refer to any vestibular symptomatology as "dizziness." Rapid movement aggravates all proprioceptive symptomatology, and patients often report a history of falls or accidents during acute episodes. The frequency and severity of attacks may decrease over time, and hearing may improve immediately after an acute attack. However, some episodes have been known to last for more than 24 hours. Overall, low-frequency hearing loss is typically progressive, with bilateral involvement in 10% to 50% of cases. Patients may also experience motion-related imbalance without vertigo between acute attacks. Complete hearing loss in advanced cases of Ménière's disease is associated with a cessation of vertiginous episodes.

Objective

On inspection, otoscopic examination typically demonstrates no apparent abnormalities, unless underlying otitis media is present. Dilation of the inner ear endolymphatic system is apparent only at autopsy. Spontaneous nystagmus is often observed after preventing eye fixation by having the patient wear 40-diopter glasses (Frenzel lenses) during the period of observation.

Diagnostic Reasoning

Diagnostic Tests

Diagnosis of Ménière's disease is based on a careful history, neurological assessment, and response to empiric therapy, because no specific diagnostic testing exists. The American Academy of Otolaryngology and Head and Neck Surgery has established diagnostic criteria requiring two distinct episodes of rotational vertigo lasting at least 20 minutes each, along with sensorineural hearing loss and either tinnitus or a perception of aural fullness. Thus, both the Weber and Rinne tests typically elicit findings characteristic of a sensorineural hearing defect. Sound lateralization to the nonaffected ear occurs when a 512-Hz tuning fork is placed midline on the top of the head (Weber test), and air conduction is superior in duration and volume to bone conduction (positive Rinne test). Audiometry also demonstrates low-frequency sensorineural hearing loss, as well as impaired speech discrimination. Both cold and warm caloric responses are typically reduced in the affected ear, as demonstrated by electronystagmography (ENG) or direct patient observation (while wearing 40-diopter Frenzel lenses), and the direction of the fast phase of nystagmus is variable. These findings are not diagnostic for Ménière's disease, however. Vestibular function tests are used to evaluate CN VIII function; however, these findings are questionable in patients taking sedative drugs of any kind.

Differential Diagnosis

Ménière's disease is a diagnosis of exclusion. Thus, numerous disorders that mimic its clinical picture must first be ruled out. Otitis media (OM) is evaluated through otoscopic examination and culture of otic fluid. If middle ear infection is present, the tympanic membrane is typically erythematous and either edematous or retracted, with altered bony landmarks and a diminished cone of light reflex. Bubbles or an air/fluid level may be seen directly behind the membrane, and mobility is reduced or absent on insufflation with a pneumatic otoscope. OM and Ménière's disease are not mutually exclusive conditions, however, because negative middle ear pressure associated with serous otitis media may be a contributing factor to Ménière's disease. OM may also precipitate a viral infection of CN VIII known as vestibular neuritis (benign recurrent vertigo), which presents as recurrent vertiginous episodes lasting several hours, which may be accompanied by severe vomiting and nausea. Vestibular neuritis may also be idiopathic, but in these patients (unlike those with Ménière's disease), auditory impairment is rarely noted. Secondary or tertiary syphilis can also affect CN VIII and is ruled out via a variety of immunological tests specific for its causative agent *Treponema pallidum,* such as the microhemagglutination (MHA), fluorescent treponemal antibody (FTA), and treponema immobilization (TPI) assays. Acute viral or bacterial infection of the labyrinth may also present with similar symptoms; however, pathogenic microorganisms are not associated with Ménière's disease because it is not of infectious etiology. Discrete lesions of the central nervous system (CNS), such as tumors or infarcts of the brain and cerebellum, as well as

degenerative nervous disorders such as Parkinson's disease, multiple sclerosis, and Alzheimer's disease, may be ruled out via CT and MRI. Hypothyroidism may also mimic Ménière's disease and is ruled out through measurement of both free and protein-bound thyroid hormone levels (thyroxine [T_4] and triiodothyronine [T_3]), as well as pituitary thyroid-stimulating hormone (TSH).

Benign positional vertigo (benign paroxysmal vertigo) is a more common diagnosis than Ménière's disease of vestibular dysfunction in elderly patients who complain of dizziness. It is characterized by paroxysmal vertigo accompanied by nystagmus when lying down, turning over in bed, or tilting the head backward. The Nylen-Bárány maneuver is used to make this diagnosis: The patient is reclined rapidly from a sitting to supine position with the head tilted to one side, and the neck is hyperextended 30 degrees below the horizontal for at least 10 seconds, off the end of the examination table. The maneuver is then repeated with the head tilted to the opposite side. In this benign condition, nystagmus lasting between 15 and 45 seconds is observed after each maneuver, following a brief 1- to 5-second latent period. In contrast to Ménière's disease, benign positional vertigo does not present with hearing loss or tinnitus.

Presbycusis, the most common cause of sensorineural hearing loss in the elderly, is distinguished by high-frequency rather than low-frequency hearing loss as revealed by audiometric testing. Serum glucose levels should be evaluated to rule out hypoglycemic disorders, and hemoglobin and hematocrit are measured to assess anemic conditions, if suspected. Lipid disorders affecting cerebral blood flow and, in turn, vestibulocochlear function may be ruled out via serum lipid studies. Other cerebral and cardiovascular disorders, such as transient ischemic attacks, vertebrobasilar ischemia, or subclavian steal syndrome, may lead to CNS ischemia and vertigo, thus mimicking Ménière's disease. However, syncope (fainting) and generalized weakness are also usually observed. Angiography is used to rule out such disorders, if suspected. Another common cause of a vestibular and auditory dysfunction is iatrogenic, drug-induced ototoxicity from many commonly used drugs, including aspirin; potent diuretics; quinine; tetracyclines (especially minocycline); many cancer chemotherapies, such as *cis*-platinum; and aminoglycoside antibiotics, including gentamicin, neomycin, kanamycin, and streptomycin. If use of these medications is not prolonged, ototoxicity may be reversible once drug intake has stopped. Sedative side effects of many medications, as well as undesirable multidrug interactions, are a common cause of dizziness, especially in elderly patients, who are at an increased risk of polypharmacy-related sequelae. In the adult patient, acoustic neuroma, causing compression of the auditory portion of CN VIII, is one of the most important diagnoses of auditory dysfunction to rule out because these tumors may be life-threatening if untreated. MRI and auditory brainstem response audiometry are used to detect such neoplasms. Finally, psychiatric diagnoses should be a major consideration if examination and laboratory findings rule out systemic disease and specific organ involvement as the cause of vestibulocochlear dysfunction. Psychiatric illness is the second most common etiology of dizziness in elderly patients after peripheral nervous system disorders. Common conditions include depression, anxiety, panic attacks, somatization disorders, alcoholism, and other forms of substance abuse. A proper psychiatric evaluation, which may include drug screens of the urine and blood, is necessary to rule out such illnesses.

Management

Acute attacks are best treated by calm bedrest with the eyes closed and protection from falling. Attacks rarely last longer than 4 hours. Pharmacotherapy, if necessary, is directed at symptomatic relief because no medications are known to affect this nonspecific disease process. A low-salt diet (less than 1,000 mg/day) is considered first-line therapy to reduce endolymphatic pressure and volume, along with a mild diuretic such as chlorothiazide (Diuril) 500 mg/day orally (PO) and potassium supplements to counter diuretic-induced hypokalemia. Caffeine avoidance and tobacco cessation are also suggested to avoid vasoconstriction of the labyrinthine system. However, as with salt restriction, the efficacy of these therapies is based primarily on anecdotal evidence.

Acute attacks are managed with a combination of antimuscarinics or anticholinergics and vestibulosuppressive histamine (H_1) blockers from various classes. The muscarinic antagonist atropine 0.2 to 0.4 mg IV or the anticholinergic scopolamine (Transderm Scop 0.33 mg/24 hours—1 transdermal disc or portion thereof applied behind the affected ear for at least 3 days) or glycopyrollate (Robinul) 2 mg PO 2 times daily may be used to relieve vertigo, nausea, and emesis. Other agents with antihistaminic, antimuscarinic, and sedative effects used for acute attacks include betahistine 8 to 16 mg PO 3 times daily (not currently available in the United States), promethazine (Phenergan) 12.5 to 25 mg IV given slowly, diphenhydramine (Benadryl) 50 mg IV given slowly, and droperidol (Inapsine) 1.5 to 2.5 mg IV given slowly. GABA-ergic anxiolytics such as diazepam (Valium) 5 to 10 mg IV given slowly may also be used to sedate patients during severe episodes, but it should be noted that sedatives will affect the outcome of all vestibular function tests. Oral maintenance therapies include meclizine (Antivert, Bonine) 25 to 100 mg at bedtime or in divided doses, promethazine (Phenergan) 12.5 to 25 mg PO every 4 to 6 hours, dimenhydrinate (Dramamine) 50 mg PO 3 or 4 times daily, metoclopramide (Reglan) 10 mg PO 2 times daily, or diphenhydramine (Benadryl) 25 to 50 mg PO every 4 to 6 hours, not to exceed 300 mg/day. Of note, these treatments are most effective for vertiginous symptoms, whereas tinnitus and hearing loss are less affected.

If conventional treatment fails, intratympanic perfusion with dexamethasone may prove effective, especially if an underlying autoimmune disorder is present. As a last resort, if Ménière's disease progresses bilaterally, streptomycin or gentamicin ablation therapy may be appropriate to reduce unbearable vestibular symptoms. An aminoglycoside antibiotic is administered over a course of several days to weeks, to intentionally damage the neuroepithelium of the vestibular centers in the inner ear, thus reducing related symptomatology. However, hearing must be carefully monitored both during and after this treatment to avoid damage to auditory structures. Disabling symptoms of Ménière's disease may require surgical intervention, typically used in 5% to 10% of all cases. For patients with normal hearing ability, decompression of the endolymphatic sac may be accomplished by surgically draining excess endolymph into the mastoid or subarachnoid space. Alternatively, the vestibular nerve may be transected intracranially. For patients whose hearing ability has degenerated and is deemed unsalvageable, the cochlea itself may be decompressed (via cochleocentesis) or directly perfused with streptomycin. A more radical surgery is labyrinthectomy of the affected ear, a procedure that entirely ablates vestibular function.

Follow-up and Referral

If symptoms do not worsen, patients may return for follow-up in 3 to 6 weeks. However, patients should return for reevaluation immediately if disabling symptoms such as tinnitus, vertigo, nausea, or emesis persist. Hearing loss, in particular, must be carefully monitored for progression because this is a telltale sign of an underlying, potentially life-threatening acoustic neuroma. Patients often report that previously consulted clinicians failed to take this condition seriously when they first presented with symptoms. Thus, close follow-up care of the patient with Ménière's disease provides emotionally beneficial validation, as well.

Progressive bilateral hearing loss may result from Ménière's disease, leading to chronic tinnitus, deafness, and disabling vertigo. Accidental injuries related to vestibular dysfunction may occur in the work or home setting, and patients often report an increasing inability to function productively at their present jobs in the face of progressive disease. Failing to diagnose an underlying acoustic neuroma is a potentially life-threatening complication.

Referral to a specialist is necessary if symptoms worsen with treatment. Advanced diagnostic procedures such as ENG or specialized vestibulocochlear function tests require referral to a neurologist. A physician consultation is also needed in cases involving persistent emesis, convulsions or seizures, syncope, or fever. New, unexplained symptoms (which are often due to multidrug interactions or adverse effects of medications) also require referral to a specialist for diagnosis and treatment. Streptomycin ablation therapy and surgical interventions should be directed by a qualified specialist only, because the risk of serious sequelae is significant, including permanent hearing loss.

Patient Education

Patients must be encouraged to stop smoking because this aggravates all otic disorders. Stress levels should be monitored and controlled. Salt intake should be reduced to a maximum of 1 g/day to lessen the severity of future attacks. All ototoxic medications should be avoided, and polypharmacy (multiple prescription drug usage) should be evaluated with the aid of a specialist.

Patients should be instructed to return for further evaluation if symptoms worsen or acute episodes increase in frequency. Patients need to understand that treating Ménière's disease pharmacologically is difficult, and acute attacks are best managed with quiet bedrest and careful protection from falls. To avoid accidental injuries and minimize symptoms, patients should not drive, climb ladders, work near dangerous machinery, walk without assistance, read, or look at glaring lights during these episodes. Food intake should also be reduced during acute attacks to lessen nausea and vomiting.

OTITIS EXTERNA

Otitis externa is an inflammation of the membranous lining of the auditory canal and/or contiguous structures of the outer ear. The term refers to a wide spectrum of both acute and chronic inflammatory processes that may be diffuse, localized, or invasive in nature. This disorder is largely benign and self-limiting, albeit painful. Invasive otitis externa (malignant otitis externa, necrotizing otitis externa) is a potentially life-threatening disease, however, if left untreated.

Epidemiology and Causes

Ear pain, in general, is a common clinical complaint, accounting for 2% to 3% of all family practice office visits. Specifically, otitis externa is 10 to 20 times more likely to occur during the warmer summer months than in cooler seasons. Adults older than 50 years of age are at the greatest risk of developing invasive otitis externa, particularly if they are immunocompromised from medications, such as steroids, or if they have chronic diseases such as cancer or diabetes mellitus. No ethnic predispositions to otitis externa have been documented. Men and women are affected equally.

Immunocompromised persons on steroid therapy or individuals with chronic conditions such as diabetes mellitus are at a greater risk for developing infectious otitis externa and, in particular, invasive disease. Deep tissue invasion may be related to decreased polymorphonuclear neutrophil function and/or microvascular disease associated with diabetes. Steroid use specifically increases the likelihood of otomycosis, which is significantly more prevalent in the tropics and southeastern

United States, but as a whole, environmental changes are the most common risk factors for otitis externa. When the pH of the auditory canal shifts from acidic to alkaline or an increase in temperature and/or humidity occurs, the auditory canal becomes conducive to pathogenic colonization. In fact, excess moisture from any cause may predispose the external ear to infection. *Pseudomonas* infections, in particular, commonly result from the mild ear canal trauma associated with excessive swimming in hot, humid weather, especially in polluted water, hence the common name "swimmer's ear." Highly chlorinated pool water can also contribute to this disorder because it can dry out the ear canal, creating a potential portal of entry for bacteria and fungi. Inadequate cerumen (ear wax) production removes another critical nonspecific barrier to infection. In addition, patients with seborrhea have an increased risk of otitis externa resulting from seborrheic dermatitis caused by their excess sebum production. Manual picking of the ear; foreign bodies in the auditory canal; and the prolonged use of ear plugs, hearing aids, or cotton swabs may all contribute to local irritation of the external ear, as well. Other risk factors include previous ear infections, as well as skin allergies, particularly those to hair sprays and dyes that may enter the ear canal and cause contact dermatitis. In fact, dermatitic processes often precede microbial infection of the auditory canal because they create a potential portal of entry through the skin for pathogens.

Pathophysiology

Inflammation of the external ear is most commonly caused by microbial infection. Pathogenic colonization of the external ear is prevented by a number of immune and anatomical mechanisms. The keratinizing squamous epithelia of the ear canal continually sloughs, and the hair follicles that line the outer third of the canal rhythmically sweep laterally, acting as a natural cleansing mechanism and mechanical barrier to the accumulation of matter in the auditory canal. The production of viscous, hydrophobic cerumen in the auditory canal maintains an acidic pH and repels moisture, both of which antagonize bacterial growth. In addition, the presence of competing, nonpathogenic endogenous microbial flora inhibits the overgrowth of more virulent bacteria along the auditory canal. If any of these protective mechanisms is compromised, pathogenic colonization by bacteria or fungi normally found in the auditory canal may occur, resulting in acute otitis externa.

Bacterial agents of infectious otitis externa include *Pseudomonas aeruginosa,* which is the most common cause of diffuse infection and accounts for nearly all cases of invasive otitis externa, and *Staphylococcus aureus,* which typically causes a localized lesion stemming from an infected hair follicle, although it may cause the diffuse form as well. In addition, group A *Streptococcus pyogenes* is associated with localized disease, presenting as a folliculitis or, more frequently, as outer ear erysipelas. Polymicrobial infection has also been noted in up to one-third of cases of diffuse disease, and the anaerobic bacteria *Bacteroides* and *Peptostreptococcus* have been cited in up to one-fourth of cases. Commonly identified fungal agents include *Aspergillus niger* (which typically causes focal lesions but may occasionally lead to invasive disease with bony involvement in immunocompromised patients), *Pityrosporum,* and *Candida albicans.* Hyperkeratotic processes such as eczema, psoriasis, and contact or seborrheic dermatitis can also lead to outer ear inflammation. Chronic otitis externa may result from inadequately treated otitis media with continuous serous or exudative drainage from the middle ear into the auditory canal.

Additional risk factors, if not direct causes of otitis externa, include local skin maceration and traumatic injury. The anatomy of the outer ear, which includes the tragus and conchal cartilage, serves as a physical barrier to foreign body entry into the outer ear canal. However, excessive cleaning of the ear with cotton swabs or other devices may leave small pieces of foreign matter in the canal, where they eventually disintegrate due to the canal's acidic pH, serving as a nidus of infection. This irritation in turn leads to pruritus, and excessive scratching of the ear canal only aggravates this cycle of epithelial damage and infection by creating physical access through this protective barrier. Excessive moisture in the external canal, particularly associated with swimming or humid environments, acts in a similar manner, leading to maceration and breakdown of the skin with subsequent bacterial infection.

Necrotizing otitis externa (formerly known as malignant otitis externa) is the most severe infectious form of external otitis in which bacterial infection extends from the skin of the auditory canal into the soft tissues, cartilage, and bone in the temporal region or base of the skull (i.e., skull osteomyelitis). Multiple cranial nerves may become involved, increasing morbidity, and death may result from septic thromboemboli to vessels of the brain if inadequately treated. *Pseudomonas aeruginosa* remains the most common infectious agent in such severe disease, although invasive fungal disease in immunocompromised individuals may also extend to multiple tissues.

Clinical Presentation

Subjective

The most common presenting complaint of patients with otitis externa is an acute, often severe otalgia of sudden or gradual onset, which may present bilaterally. Pain may worsen at night and disturb sleep, and it is exacerbated by pulling the pinna or earlobe or by applying pressure to the tragus. In severe cases, chewing may also elicit otic pain. Severe pain is common in invasive disease. In its early stages, the affected ear may feel full or obstructed, and a temporary conductive hearing loss

related to luminal occlusion on the affected side is common if edema is severe. The affected ear may also be pruritic. A purulent discharge may be evident in bacterial disease, and systemic symptomatology such as fever or chills, although rare, may accompany cases of infectious etiology. Chronic otitis externa usually presents with dryness and pruritus of the ear canal. The ear canal may be slightly red and edematous, and there is usually an absence of cerumen.

Objective

A classic sign of acute otitis externa is tenderness on traction of the pinna and/or pain on applying pressure over the tragus. The clinician should instill several drops of benzocaine/antipyrine (Auralgan) otic solution before attempting examination in patients in acute distress. This solution should not be used in cases of suspected ruptured tympanic membrane, however.

On otoscopic examination, the auditory canal typically appears edematous and erythematous, preventing full visualization of the external canal and tympanic membrane; there also may be accumulation of purulent drainage in cases of bacterial infection. Diffuse cases present with nearly complete involvement of the auditory canal, whereas localized processes are recognized as focal lesions (pustules or furuncles) anywhere along the auditory canal or external ear structures. Sebaceous secretions in the ear canal are usually evident in patients with seborrhea, but cerumen production among patients is variable, depending on etiology. Fluid may be apparent in infectious cases. *Pseudomonas* infection produces a copious green exudate, whereas *Staphylococcus* infection presents as a yellow crusting in the midst of a purulent exudate. Fungal infections present as a fluffy white or black malodorous carpet of growth, and allergic reactions are characterized by scaly, cracked, and/or weepy tissue. Granulation tissue spreading out from the primary site of infection and eroding into the temporal bone, outer auricle, or through a perforated tympanic membrane is indicative of frank invasive disease.

Except in invasive disease or cases related to chronic otitis media, head and neck lymphadenopathy typically is not detected. Invasive disease may also be accompanied by tenderness of the temporomandibular joint (TMJ).

Diagnostic Reasoning

Diagnostic Tests

Laboratory tests are rarely needed if symptomatology clearly fits the classic clinical picture of otitis externa. However, any fluid from the ear may be cultured and, if microorganisms are detected, tested for antibiotic sensitivity. This may be particularly important in determining alternative treatment approaches for patients who do not respond promptly to empiric antibiotic therapy or those with chronic otitis externa, particularly with purulent exudates indicative of bacterial infection. Cultures and antibiotic sensitivity testing are also important for immunocompromised patients because their disease may be caused by rare pathogens or even by endogenous, typically nonpathogenic microbial flora. Fungi and mycobacteria should be ruled out, in particular. The erythrocyte sedimentation rate may be elevated, although this finding has not been thoroughly studied. Soft tissue or bony involvement in malignant disease may be assessed by CT and MRI scans. The temporal bone is the first bone to be affected. It is important to remember that at least one-third of bone mineral must be lost before radiological changes become apparent. Plain films and gallium or technetium-99 bone scans may also detect bony involvement, but these imaging techniques are less desirable because they lack specificity and, in the case of x-ray films, sensitivity.

Differential Diagnosis

In the absence of visible changes in the auditory canal and tympanic membrane, otalgia from referred pain associated with other disorders must be ruled out. These disorders include TMJ dysfunction, dental disease, neurological disorders such as trigeminal and glossopharyngeal neuralgia, parotitis (paramyxoviral infection) secondary to mumps, or, rarely, tumors of the middle ear and auditory meatus. Chondrodermatitis chronicus helicis may cause an otalgia similar to otitis externa in elderly patients, manifesting as an extremely tender nodule of the inner ear helix. TMJ dysfunction and dental disease may be specifically ruled out via dental x-ray films to demonstrate alterations in joint morphology or dentition. Mumps may be diagnosed serologically by measuring antibody titers; but in general, a thorough head and neck examination, complete with cranial nerve testing, typically will differentiate among the aforementioned causes of ear pain.

Otitis media may be distinguished from otitis externa by changes in the tympanic membrane that are characteristic of middle ear infection, including erythema, edema, and a significant lack of mobility on insufflation with a pneumatic otoscope. Moreover, movement of the tragus fails to elicit pain in middle ear infection. Otitis media should be suspected if continuous discharge from the middle ear is evident for more than 10 days, and x-ray films may aid in ruling out this diagnosis. Otitis externa and otitis media may occur concurrently. A systemic dermatological condition, such as seborrheic dermatitis, psoriasis, or erythroderma, may manifest as otitis externa.

Alternative pathologies to rule out through otoscopic examination include other dermatological disorders such as impetigo, herpes zoster infection, and even insect bites. Serious cranial infections requiring aggressive therapy must also be considered. Mastoiditis is characterized by fever, spontaneous rupture of the tympanic membrane, tenderness, edema, and erythema posterior to the

auricle, as well as by palpable preauricular and anterior cervical lymph nodes. The mastoid process is exquisitely painful in mastoiditis, unlike otitis externa. Meningitis typically presents with fever, diffuse headache, altered mentation, vomiting, and cervical stiffness. A recent history of upper respiratory tract infection (URI) may be a clue to these and other infectious processes, including sinusitis and otitis media. Blood in the auditory canal may indicate temporal bone fracture or the presence of an invasive tumor. Carcinoma should be ruled out if invasive disease is suspected through the biopsy of apparent granulation tissue, which in otitis externa will demonstrate necrotizing vasculitis with no evidence of malignant cells. Other noninfectious diagnoses that may be ruled out through biopsy include primary skin and cartilage disorders such as sarcoidosis, discoid lupus, and trauma-related perichondritis of the pinna. Perichondritis may also be of infectious origin caused by *P aeruginosa,* as confirmed by culture. Excessive cerumen buildup may also lead to a feeling of fullness or stuffiness in the ear, as well as pain and hearing loss. Otoscopic examination performed before and after irrigation of the auditory canal will rule out cerumen impaction. Gouty tophi may also affect the external ear, but they are usually painless. Rarer infectious conditions that should be ruled out by special stains, cultures, and antigen/antibody tests in refractory cases include tuberculous otitis (diagnosed by acid-fast stain for *Mycobacteria*), leprosy (diagnosed by acid-fast stain for *Mycobacteria*), and syphilitic otitis (diagnosed by rapid plasma reagin [RPR] and Venereal Disease Research Laboratory [VDRL] tests and dark-field microscopy to identify the causative agent *Treponema pallidum*).

Management

Because the predominant symptom of otitis externa is pain, alteration in comfort is a primary focus of care. Medical management of the disease should focus on alleviating pain promptly.

- Local application of heat to the outer ear can offer some relief of pain.
- Some patients get relief with application of an ice pack to the outer ear.
- Nonprescription pain reliever such as aspirin or acetaminophen (325–650 mg PO every 4 hours as needed; maximum daily dose 4000 mg/day) or an NSAID such as ibuprofen (400–600 mg PO every 4–6 hours as needed to a maximum dose of 1.2 g/day).
- In cases of extreme pain, Tylenol with codeine # 3 or acetaminophen/hydrocodone 5 mg PO every 8 hours may be prescribed for the first 24 to 48 hours.
- Keep the ear dry. No swimming or submersion of the ear under water for 4 to 6 weeks.
- Treatment of otitis externa involves three basic steps:
  1. Gentle cleaning of the ear canal to remove all cerumen, exudate, and epidermal debris using a cotton pledget or irrigation with warm tap water. (Irrigation should be done cautiously until tympanic membrane perforation has been ruled out.)
  2. Evaluation of otic discharge and edema of the auditory canal and tympanic membrane.
  3. Selection of an appropriate local medication once the etiology has been identified.

Occasionally, the pustules or furuncles associated with localized otitis externa may require surgical drainage before initiating pharmacotherapy.

Diffuse bacterial otitis externa may be treated empirically. Several preparations are available for use. (See Drugs Commonly Prescribed 8.4: Bacterial Otitis Externa.)

Common topical otic preparations approved by the U.S. Food and Drug Administration (FDA) include acetic acid/aluminum acetate, acetic acid/hydrocortisone, ciprofloxin/hydrocortisone, ciprofloxin/dexamethasone, neomycin/polymixin B/hydrocortisone, and ofloxacin. Liquid ophthalmic preparations of gentamicin and tobramycin may be used otically to cover both *Pseudomonas aeruginosa* and *Staphylococcus aureus.* If the ear is edematous, a small cotton plug soaked in an otic preparation should be inserted. An absorptive 1-inch cotton wick or sponge may be inserted into a highly edematous ear canal by gentle twisting if luminal occlusion prevents the passage of otic preparations. Antibiotic drops may then be placed on the wick for the first 2 to 3 days of treatment, until swelling subsides. After this, drops should be placed directly into the ear canal.

Cases that are refractory to initial therapy or involve auricular cellulitis require systemic antibiotic treatment covering both *Staphylococcus* and *Pseudomonas.* Systemic antibiotics are also indicated in the case of specific host factors such as diabetes or in an immunosuppressed patient. Diffuse and localized otitis externa may need to be treated with multiple systemic antibiotic choices:

- First generation cephalosporins or penicillins with relatively narrow coverage such as cephalexin (Keflex) 250 to 500 mg PO 4 times daily and dicloxacillin 250 to 500 mg PO 4 times daily.
- Second generation cephalosporins such as cefuroxime (Ceftin) 250 to 500 mg PO 2 times daily or Omnicef 300 mg PO 2 times daily, or beta-lactamase–resistant penicillins such as amoxicillin/clavulanate (Augmentin XR) 1000 mg PO 2 times daily based on the amoxicillin component, which have broader-spectrum coverage.
- Fluoroquinolones such as ciprofloxacin (Cipro) 500 mg PO 2 times daily or levofloxacin (Levaquin) 500 mg PO 4 times daily with similarly broad coverage.
- Ceftazidime (Ceftaz, Fortaz) 2 g IV every 8 to 12 hours or a combination of tobramycin (1–1.5 mg/kg IV every 8 hours with dosage adjusted by monitoring serum levels and renal function) and ticarcillin (3 g IV every 4 hours). These regimens, however,

Drugs Commonly Prescribed 8.4 Bacterial Otitis Externa

Drug	Indication	Prescribing Considerations and Adverse Reactions
Drugs Safe to Use With Perforated Tympanic Membrane (TM)		
ciprofloxacin 0.3% and dexamethasone 0.1% (Ciprodex otic)	Antibiotic and steroid	Not recommended <6 months >6 months: 4 drops in affected ear 2 times daily for 7 days
ofloxacin 0.3% (Floxin otic)	Antibiotic	6 months–13 years: 5 drops to affected ear daily for 7 days Adults: 10 drops to affected ear for 7 days
Drugs Not Safe to Use With Perforated TM		
ciprofloxacin 0.2% and hydrocortisone 1% (Cipro HC otic)	Antibiotic and steroid	Not recommended <1 year >1 year: 3 drops in affected ear 2 times daily for 7 days
chloroxylenol 1 mg, pramoxine HCl 10 mg, hydrocortisone 10 mg/mL (Cortane B aqueous)	Antibacterial/antifungal + topical anesthetic + steroid	Children: 3 drops in affected ear 3 times daily for 7 days Adults: 4–5 drops in affected ear 3 times daily for 7 days
colistin 3 mg, neomycin 3.3 mg, hydrocortisone acetate 10 mg, thonzonium bromide 0.5 mg (Cortisporin-TC otic)	Antibiotic + steroid + surfactant	5 drops in affected ear 3–4 times daily for 10 days only

carry a significant risk of nephrotoxicity, ototoxicity, and bleeding diatheses. An alternative to IV therapy is the oral quinolone ciprofloxacin 750 mg 2 times daily, which is generally well tolerated and has a high cure rate in complicated disease.

- Patients who are immunocompromised from steroid therapy or who have chronic disorders such as diabetes, as well as patients with invasive bony involvement, may require surgical debridement of the affected area to drain abscesses and remove sequestered collagen. This therapy is usually followed by 4 to 6 weeks of IV antipseudomonal therapy.
- In the overwhelming majority of patients who present with chronic otitis externa, the condition is caused by persistent fungal infection. The ears are often dry and scaling. The treatment of fungal infections differs mainly in the choice of antimicrobials.
- Careful cleaning of the auditory canal is done. Then a single dusting of sulfanilamide powder is applied, followed by an otic suspension such as hydrocortisone/acetic acid otic (VoSol) solution, or acetic acid/aluminum acetate (Otic Domeboro). Four drops are placed in each affected ear 4 times daily for 7 to 10 days.
- Topical fungicide preparations containing nystatin or clotrimazole are increasingly accepted, although these agents are not available solely as otic preparations. If this treatment is planned, a referral to an ear, nose, and throat (ENT) specialist should be considered. In chronic cases of otitis externa from fungal infection, systemic antifungals such as fluconazole, ketoconazole, or griseofulvin may be considered. Clotrimazole solution is available over the counter and should be used as 4 drops in each ear daily. Ketoconazole cream may be placed into the external canal by a trained specialist using an operating microscope and a syringe with a blunt needle. About 1 inch of cream is needed to fill the canal, and it should be removed a week later.
- Steroidal therapies such as 0.1% triamcinolone solution or cream may be applied 3 or 4 times daily to relieve eczematous or psoriatic lesions.
- When otitis externa has been determined to be secondary to otitis media, therapy should be directed toward the underlying middle ear infection.
- Pharmacotherapy for chronic otitis externa is directed by extensive antibiotic sensitivity testing after the infectious organisms have been cultured and identified in the laboratory.

Follow-up and Referral

Acute otitis externa is commonly cured after 7 to 10 days of treatment. A follow-up appointment to assess the effects of treatment may be scheduled after 1 week of therapy for uncomplicated cases. If an ear wick has been placed, the patient should return in 2 days for removal and canal cleaning. The patient should be instructed to call if symptoms do not begin to subside in 48 hours.

Immunocompromised patients with invasive disease and any patient receiving IV antibiotic therapy require daily follow-up during hospitalization, and periodic appointments are recommended for up to 1 year after the discontinuation of treatment. Otherwise healthy patients with invasive disease who do not respond to treatment promptly should also be monitored closely; these patients should undergo further evaluation and diagnostic procedures as necessary. CT and MRI scans remain abnormal for many months after clinical resolution of invasive disease; thus, serial nuclear medicine scans (gallium scans) may be preferable in evaluating treatment efficacy during follow-up, because recurrence of infection may be as high as 10% within 6 months after treatment.

A common complication in the management of otitis externa is dermatitis medicamentosa. Neomycin, an antibiotic commonly found in otic preparations, is known to cause skin reactions and ototoxicity; however, these complications may be minimized by limiting the duration of pharmacotherapy. The use of neomycin-containing agents in cases in which the tympanic membrane is ruptured is controversial because neomycin may be toxic to middle ear structures if applied directly. Otitis externa may also lead to severe furunculosis (boil formation) or cellulitis (deep-tissue infection) within the ear canal. Invasive otitis externa is a potentially life-threatening complication of poorly treated diffuse and localized disease that must be detected early. Fever, excruciating pain, and the presence of friable granulation tissue are ominous signs of this sequela. Other serious cranial infections may result from inadequately treated otitis externa, including meningitis, mastoiditis, parotitis, and osteomyelitis of either the temporal bone or the base of the skull. Cranial nerve (CN) palsies affect 20% to 30% of patients with invasive disease, most commonly involving CN VII and, if disease progresses unchecked, CNs IX, X, XI, and XII.

Invasive otitis externa, cellulitis, bony involvement, and all complicating cranial infections must be referred to a specialist for immediate treatment. Patients who are immunocompromised from steroid therapy, diabetes, or other chronic illnesses should be referred to an otorhinolaryngologist to fully evaluate the extent of disease.

Patient Education

Patients should avoid getting water in the ears for at least 4 to 6 weeks after symptoms subside because moisture from any source can trigger a recurrent episode of infection. Shower caps or ear plugs should be worn when bathing, and swimming should be prohibited entirely for at least 1 month after an acute episode (cotton balls impregnated with petroleum jelly may be used as temporary ear plugs). For persons who are particularly susceptible to repeated infections, a 2% acetic acid solution may be used prophylactically to acidify the ear canal (2–3 drops in each ear, 2 times daily and after any contact with water in which the ears become wet). (See Complementary Therapies 8.1.)

Patients should be instructed in the proper method of cleaning the ears (with a soft cotton pledget) and warned never to use swabs, sticks, or chemical agents to clean the auditory canal. Patients should understand that a small amount of ear wax is necessary to prevent infection in the auditory canal and that excessive cleaning can be harmful. Clinicians should instruct patients or family members as to how to instill topical drops.

The importance of keeping the ear canals dry for at least 4 to 6 weeks, both during and after an acute episode, should also be stressed. The clinician should also discuss the importance of avoiding strong jets of water from showerheads or dental water-jet systems. Alternative or complementary therapies such as candling have not been shown to be efficacious and may in fact cause harm.

OTITIS MEDIA

Otitis media (OM) is an inflammation of the structures within the middle ear. Otitis media with effusion (OME) involves the transudation of plasma from middle ear blood vessels, leading to chronic effusion in the absence of the signs and symptoms of acute infection. Acute otitis media (AOM), also referred to as suppurative OM or purulent OM, denotes the presence of fluid in the middle ear in association with local or systemic illness, including otalgia, otorrhea, and fever. Recurrent OM is characterized by the clearance of middle ear effusions between acute episodes of otic inflammation. Chronic OM is present when inflammation persists for more than 3 months, typically related to tympanic membrane perforation with either intermittent or persistent otic discharge. Seventy-five percent of children experience at least one episode of OM by their third birthday. Almost half of these children will have three or more episodes of OM during their first 3 years. Measures to prevent AOM in infants and young children should be discussed with parents at well-child visits. Preventive measures include avoidance of tobacco exposure, exclusive breastfeeding for the first 6 months of life or longer, and annual influenza vaccine and pneumococcal conjugate vaccine for all children according to the updated immunization schedules. Although OM is primarily a disease of infants and young children, it can also affect adults.

Epidemiology and Causes

Ear pain, in general, is a common clinical complaint, accounting for 2% to 3% of all family practice office visits. Specifically, the incidence rate of OM increases during

the winter months, when the climate is colder. Although AOM is most common in very young children, elderly adults also have a significant risk of developing disease because of decreases in natural immunity. Native Americans, particularly Navajos, and Native Alaskans have higher prevalence rates than the general population. A smaller increase in rate is also seen in white Americans of European descent. Men and women are affected equally, although OM tends to be rare in adults.

Factors contributing to eustachian tube dysfunction leading to OME include allergies, sinusitis, rhinitis, and pharyngitis, all of which cause swelling of the membranous lining of the eustachian tube. However, the most significant precipitating event is a recent or concurrent URI, attributed most often to influenza type A (*Influenzavirus,* in family Orthomyxoviridae), respiratory syncytial virus (*Pneumovirus,* in family Paramyxoviridae), or adenovirus. URI is thought to contribute to host immunosuppression and the loss of ciliated epithelium in the eustachian tube; in turn, bacterial adherence to the membranous lining is increased. Anatomical abnormalities that can lead to direct blockage of the eustachian tube include hypertrophy or chronic inflammation of the adenoids (pharyngeal tonsils), cleft palate, deviated nasal septum, and nasopharyngeal tumors. Perforation of the eardrum from direct blunt trauma, swimming or diving accidents, or sudden outward pressure or suction (such as from a kiss over the ear), may create a portal of entry for bacteria directly into the middle ear. Certain genetic conditions such as Down syndrome (trisomy 21) also predispose an individual to middle ear infections. Both active and passive smoking have been associated with an increased risk of all forms of OM, and crowded or unsanitary living conditions, along with a family history of OM (particularly in the same household), are also contributing factors.

Pathophysiology

AOM results when bacterial infection by nasopharyngeal microorganisms follows eustachian tube dysfunction in which the narrowest portion of the tube (the isthmus) becomes obstructed. Inflammation results primarily in response to bacterial products, including endotoxins and cell-wall components, creating in effect a middle ear abscess. Pressure from this buildup of pus may impinge on the fine blood vessels supplying the tympanic membrane, weakening its structure, reducing tensile strength, and eventually causing perforation or rupture of the eardrum to facilitate draining of inner ear fluid. Fortunately, in the absence of underlying immunocompromise, this structure typically begins to heal spontaneously within hours and may be fully healed by 1 or 2 weeks with complete restoration of baseline hearing capacity. OME is caused by a transudation of plasma fluid through engorged blood vessels resulting from the loss of eustachian tube patency, caused either by swelling of the membranous lining or direct anatomical blockage of the eustachian tube. Swelling of the mucosa is particularly common in the presence of an antecedent viral URI or acute allergy attack. Effective drainage of middle ear fluid is thus prevented, and negative pressure develops in the middle ear cavity, further drawing in fluid.

Streptococcus pneumoniae (implicated in 40%–50% of AOM cases) is the most frequent pathogen isolated from middle ear effusions in adults, because the currently available polyvalent streptococcal vaccines cover only 60% to 70% of these isolates. In turn, the increasing administration of the childhood pneumococcal vaccine covering 7 serotypes (Prevnar), as well as the separate 23-serotype Pneumovax vaccine used in high-risk and elderly patients, has yet to affect incidence rates of AOM. Other common organisms include nontypable *Haemophilus influenzae* (10%–30% of cases), which are not covered by the *Haemophilus influenzae* type b (Hib) vaccine, and *Moraxella (Branhamella) catarrhalis,* the vast majority of which express the beta-lactamase gene and are resistant to first-line penicillin and cephalosporin antibiotics. These organisms are thought to reach the middle ear from the upper respiratory tract via aspiration or reflux. *Staphylococcus aureus* and *Streptococcus pyogenes* are far less common causative agents, particularly since the introduction of sulfonamide antibiotics such as trimethoprim-sulfamethoxazole (Bactrim).

Up to half of AOM cases are attributed to viral infections originating in the nasopharynx and extending to the middle ear via the eustachian tube, including rhinovirus, adenovirus, coronavirus, influenza, and respiratory syncytial virus. In fact, nearly 40% of documented influenza cases in children younger than 3 years of age are complicated by AOM, adding to the impetus for widespread flu vaccination. *Mycoplasma* and *Chlamydia pneumoniae* are also rare causes of OM. *Chlamydia trachomatis* is typically seen only in infants younger than 6 months; in developing countries, unusual agents such as *Mycobacteria tuberculosis, C. diphtheriae,* parasites (*Ascaris*), or fungi (*Blastomycoses, Candida, Aspergillus*) may be identified.

OME may be viral in origin but is usually attributed to beta-lactamase–producing bacterial strains that are resistant to first-line antibiotic therapies. Importantly, middle ear effusions often last for weeks to months after an AOM clears; thus, OME may simply reflect part of the natural history of a resolved episode of AOM. Recurrent OM typically results from bacterial infection due to anatomical abnormalities that repeatedly compromise eustachian tube patency. Chronic OM may also be caused by any of the bacteria associated with AOM, as well as *Escherichia coli* and *Proteus,* but *P aeruginosa* and *S aureus* are the most commonly isolated pathogens in the chronic suppurative form.

Clinical Presentation

Subjective

The patient with OME will typically complain of stuffiness, fullness, and a loss of auditory acuity in the affected

ear only. Pain is rare, but patients may describe popping, crackling, or gurgling sounds when chewing, yawning, or blowing the nose. Very rarely, patients may experience vertigo (a sense of whirling or spinning in space) or ataxia, if inner ear complications such as labyrinthitis are present. Although patients are typically afebrile, a recent history of viral URI or either allergic or vasomotor rhinitis is common.

In contrast, AOM usually presents with marked "deep" ear pain and fever, as well as unilateral hearing loss, otic discharge, and a recent history of URI. Some patients may also experience dizziness (space disorientation), vertigo, tinnitus (ringing in the ears), vomiting, or nausea. Pain typically subsides if the tympanic membrane ruptures because this relieves middle ear pressure. In these cases, patients also usually complain of otic discharge. Recurrent OM is characterized by the clearance of middle ear effusions between acute episodes of inflammation.

Chronic OM typically presents with a history of repeated bouts of acute otitis media, followed by a period of continuous or intermittent otorrhea lasting for more than 3 months. Pain is seldom a complaint, as hearing loss (related to tympanic membrane perforation) is the primary concern. Risk factors for AOM include enrollment of a child in day care, presence of tobacco smoke in the home, and residing in communities where antibiotic-resistant forms of *S pneumoniae* are endemic.

Objective

Examination of the external ear in patients with OME is typically unremarkable; however, the mucous membranes of the nasal and oral cavities may be infected or edematous, confirming a recent history of URI. The eardrum may be dull but usually is not bulging, and eardrum mobility typically decreases on pneumatic otoscopy. When examining a patient with AOM, the use of Auralgan otic solution (a combination analgesic and anesthetic agent—contraindicated in cases of perforated eardrum) may be needed to facilitate the examination if the patient is experiencing pain. The tympanic membrane may be amber or yellow-orange, or the membrane may be infected and pinkish gray to fiery red in color. The tympanic membrane is typically full or bulging in acute cases, with absent or obscured bony landmarks and cone light reflex.

Although the auditory canal usually shows no abnormalities, a discharge from the middle ear may be present if the tympanic membrane has perforated as a result of the collection of middle ear fluid and subsequent inflammatory response. Otorrhea may be purulent or mucoid, depending on the stage of inflammation; polymorphonuclear neutrophils are prominent in the early stages of bacterial infection. Otoscopic examination in chronic OM usually reveals a perforated, draining tympanic membrane and possibly invasive granulation tissue. Chronic, foul-smelling otorrhea is typical of anaerobic bacterial infection, and a chronic, grayish-yellow suppuration may indicate the development of a cholesteatoma from the degenerative products of invasive epithelialization (involuted squamous epithelia and keratin debris) at the site of infection. In rare cases, bullae formed between layers of the tympanic membrane (bullous myringitis) caused by certain viruses or *Mycoplasma pneumoniae* are seen, and multiple perforations of the tympanic membrane are characteristic of tuberculous otitis.

On palpation, in cases of acute infection, lymphadenopathy of the preauricular and posterior cervical nodes is common. If OM is complicated by an acute mastoiditis, tenderness over the mastoid will be elicited, because the bony architecture of the middle ear is continuous with the mastoid process.

Diagnostic Reasoning

Diagnostic Tests

Laboratory tests are rarely needed if symptomatology clearly fits the classic clinical picture of OM. However, if confirmation is desired, pneumatic otoscopy will demonstrate decreased or absent tympanic membrane mobility in serous, acute, or chronic OM with effusion. Tympanometry may be useful if fluid buildup behind the middle ear is suspected in the absence of other clinical signs; a flat tympanogram is consistent with restrictive disease of the middle ear cavity. A complete blood count is usually not indicated; however, patients with AOM may demonstrate a leukocytosis, particularly if they are febrile. Cultures of tympanocentesis fluid are not indicated in serous OM and are of little practical value in acute disease unless the patient is immunocompromised or infectious complications such as mastoiditis are evident. In subacute, recurrent, or chronic cases of OM, however, cultures and antibiotic sensitivity testing are helpful in guiding alternative treatment approaches. If cultures are obtained, fungi and mycobacteria should be specifically ruled out. Conventional sinus x-ray films and CT scans (which can reveal mucosal thickening in the middle ear space) may be helpful in evaluating patients with effusion and particularly patients with recurrent infection.

Pure-tone audiometry may be helpful both before and after treatment; Weber and Rinne tuning-fork tests typically will reveal conductive, as opposed to sensorineural, hearing loss. Sound lateralization to the affected ear occurs when a 512-Hz tuning fork is placed midline on the top of the head (Weber test), and bone conduction is superior in duration and volume to air conduction (negative Rinne test).

Differential Diagnosis

OM must be distinguished from otitis externa, which is inflammation of the auditory canal and/or external ear, including the pinna and tragus. These structures are usually not affected in OM, and otitis externa typically does not involve the tympanic membrane. Otitis externa

resulting from furunculosis, local skin maceration, or trauma from a foreign body or direct blunt force must be ruled out. Exacerbated pain on manipulation of the tragus, pinna, or earlobe is a telltale sign of external ear inflammation. Barotrauma may also mimic OM, with transient middle ear effusion resulting from air travel or drastic increases in altitude, such as when driving up mountains. TMJ syndrome pain is similar to the pain of AOM. Patients may complain of ear pain when in fact the pain is being referred from the TMJ. Mastoiditis presenting without middle ear infection should be considered when no physical signs of middle ear involvement are evident. Referred otalgia from TMJ dysfunction or dental abscesses may be ruled out by dental x-ray films. Parotitis secondary to mumps (paramyxoviral infection) may be ruled out via serology studies (antibody titers), if suspected. Nasopharyngeal neoplasm must be ruled out through biopsy in cases of unilateral recurrent, chronic, or refractory OM. Rarer infectious conditions, which should be ruled out by special stains, cultures, and antigen/antibody tests, include tuberculous otitis (order an acid-fast stain for *Mycobacteria*), leprosy (order an acid-fast stain for *Mycobacteria*), and syphilitic otitis (order RPR and VDRL tests, and dark-field microscopy to identify the causative agent *Treponema pallidum*). Excessive ear wax buildup (cerumen impaction) with or without infection may also lead to a feeling of fullness or stuffiness in the ear, as well as pain and hearing loss. Otoscopic examination is performed before and after irrigation of the auditory canal to rule out this disorder.

Management

Uncomplicated cases of OM are likely to be self-limited and may require no specific intervention other than pain and symptomatic relief (see Therapeutic Procedure 8.3); however, pharmacological treatment of complicated or recurrent OM is indicated to prevent permanent anatomical changes of the middle ear and subsequent hearing loss. Changes in characteristics of auditory stimuli related to middle ear pathology lead to sensory or perceptual alterations. In the unfortunate instance when middle ear infection leads to permanent comorbidity, loss of auditory perception may affect a patient's lifestyle, communication patterns, socialization, and self-concept. Other identifiable clinical problems include alteration in comfort and an increased potential for injury related to hearing loss. Interventions should focus on moving the patient toward acceptance, identifying effective communication patterns, and recognizing support mechanisms and resources for coping with hearing loss. Fortunately, the vast majority of OM cases never reach this advanced stage.

In cases of OME, watchful waiting is indicated, with monthly exams to monitor for resolution. If the effusion is unresponsive to medical treatment and persists for longer than 12 weeks, a 10-day course of an antibiotic should be considered in addition to a referral to an otolaryngologist. Antibiotic choice needs to be individualized; however, for the patient who is not penicillin allergic and has not recently been exposed to antibiotics, amoxicillin (80–90 mg/kg/day) is a reasonable choice. For patients who have had antibiotics in the last month, a beta-lactamase stable agent (e.g., amoxicillin/clavulanate) or a second or third generation cephalosporin would be a good choice. Studies have indicated that prolonged (more than 10 days) treatment of OME has not shown an advantage over a 10-day course of therapy. Some studies suggest the addition of prednisone; however, the most recent recommendations from the American Academy of Pediatrics suggest that steroid medications are not recommended for treatment of OME in a child of any age (Level I) (Lieberthal et al, 2013; Waseem et al, 2014). Studies have not borne out the effectiveness of decongestants or antihistamines, although these may be of some benefit in patients with comorbid allergic rhinitis.

Although there is an increasing trend to observe uncomplicated AOM in children for the first 48 to 72 hours rather than prescribe early antibacterial treatment in the hopes of self-limited resolution (see Nursing Research–Based Practice Box 8.2), antimicrobial therapy in adults is largely the norm. Selection of an agent to treat AOM requires consideration of several factors, including the patient's age, OM history, drug hypersensitivity, prior antimicrobial response, and associated illnesses. For children aged 6 to 24 months, observation and systemic analgesics without the use of antibacterial agents is an option for selected children with uncomplicated AOM, based on diagnostic certainty, age, illness severity, and assurance of follow-up. In children older than 24 months, many cases of AOM may resolve and do not require antibiotics, as long as the symptoms are manageable with systemic analgesics, the child has access to reevaluation at 48 hours, and symptoms do not persist. If signs and symptoms of AOM persist in spite of using systemic analgesics for 48 to 72 hours, the child should be reassessed and antibiotic treatment should be considered. Given that the majority of AOM cases occur in pediatric patients, pharmacotherapeutic approaches for AOM in both children and adults are summarized in Therapeutic Procedure 8.3.

Follow-up and Referral

Patients with OME should be reevaluated 4 to 6 weeks after treatment because the full clinical course of the disease may last up to several weeks. Monthly otoscopic or tympanometric exams should be done as long as OME persists. Patients with AOM should be seen for follow-up in 48 to 72 hours if symptoms have not resolved. Otherwise, a follow-up appointment may be scheduled several days after the completion of pharmacotherapy. Most patients experience spontaneous closure of a ruptured tympanic membrane and recovery of normal hearing within 4 weeks of treatment. Otoscopic exam should be done 4 weeks after diagnosis. If symptoms persist, consider changing the antibiotic regimen to cover

Therapeutic Procedure 8.3 Initial Pharmacotherapy of AOM in Pediatric Patients

Indication	Drug	Dose	Prescribing Considerations
Otherwise healthy with mild symptoms	Acetaminophen (Tylenol) Ibuprofen (Motrin, Advil)	10–15 mg/kg/dose PO every 4 hours as needed (**max 75 mg/kg/day**) 5–10 mg/kg/dose PO every 6–8 hour as needed (**max 40 mg/kg/day**)	For ages 6–24 months, observation with the use of systemic analgesics *without* the use of antibacterial agents is an option for selected children with uncomplicated AOM, based on diagnostic certainty, age, illness severity, and assurance of follow-up. If older than 24 months, most cases of AOM resolve and do *not* require antibiotics, as long as symptoms are manageable with systemic analgesics, the child has access to reevaluation at 48 hours, and symptoms do not persist. If signs and symptoms of AOM persist in spite of using systemic analgesics for 48–72 hours, reassess and consider treatment with antibiotics.
***No* day-care attendance and *no* antibiotics within 90 days**	Amoxicillin	**Standard Dose:** 40–45 mg/kg/day PO in 3 divided doses • ≥2 years old: treat for 5 days • <2 years old: treat for 10 days	High risk factors increase the risk of resistant *Streptococcus pneumoniae* (*S pneumoniae*)
Day-care attendance and antibiotics within 90 days	Amoxicillin	**High Dose:** 80–90 mg/kg/day PO in 3 divided doses • ≥2 years old: treat for 5 days • <2 years old: treat for 10 days	Amoxicillin retains the best activity of all oral β-lactam agents against *S pneumoniae,* including penicillin intermediate resistant strains
β-lactam allergy	The incidence of cephalosporin cross reactivity with penicillin allergy is less than 2%. Consider allergy testing when infection resolves to confirm penicillin allergy.		
Penicillin allergy (mild, nonanaphylactic)	**Cefuroxime axetil**	30 mg/kg/day PO in 2 divided doses • ≥2 years old: treat for 5 days • <2 years old: treat for 10 days	Due to poor taste of cefuroxime suspension, recommend tablets if possible, can be crushed and put into a palatable fluid
	Cefprozil	30 mg/kg/day PO in 2 divided doses • ≥2 years old: treat for 5 days • <2 years old: treat for 10 days	Compared with cefuroxime, liquid cefprozil has a better taste but inferior coverage of *Haemophilus* and penicillin intermediate resistance–*S pneumoniae*
Penicillin allergy (severe, anaphylactic) or cephalosporin allergy	**Clarithromycin**	15 mg/kg/day in 2 divided doses for 10 days	TMP/SMX and macrolides are inferior options due to high resistance rates and clinical failure rates

Continued

Therapeutic Procedure 8.3 Initial Pharmacotherapy of AOM in Pediatric Patients—cont'd

Indication	Drug	Dose	Prescribing Considerations
	Trimethoprim/sulfamethoxazole (TMP/SMX)	6–12 mg TMP/kg/day PO in 2 divided doses • ≥2 years old: treat for 5 days • <2 years old: treat for 10 days	Consider referral to otolaryngologist for tympanocentesis
	Azithromycin	10 mg/kg/day PO on the first day and 5 mg/kg/day PO for 4 days	

Failure of Initial AOM Treatment in Pediatric Patients

Indication	Drug	Dose	Therapeutic Considerations
Failure of standard dose amoxicillin	**Amoxicillin PLUS**	40–45 mg/kg/day PO in 3 divided doses for 10 days	The combination is recommended to provide a high dose of amoxicillin (for penicillin intermediate resistance–*S pneumoniae*) and regular dose of amoxicillin-clavulanate (for coverage of β-lactamase–producing *H influenzae* and *M catarrhalis*) without excessive clavulanate (>10 mg/kg/day), which may lead to increased incidence of diarrhea
	Amoxicillin-clavulanate (use 7:1 formulation) (2 separate prescriptions should be given)	45 mg/kg/day PO in 3 divided doses for 10 days (based on amoxicillin component)	
Failure of high-dose amoxicillin	**Amoxicillin-clavulanate** (use 4:1 formulation)	40 mg/kg/day PO in 3 divided doses for 10 days (based on amoxicillin component)	Due to poor taste of cefuroxime axetil suspension, recommend tablets if possible, can be crushed and put into a palatable fluid
	Cefuroxime axetil	30 mg/kg/day PO in 2 divided doses for 10 days	
	Cefprozil	30 mg/kg/day PO in 2 divided doses for 10 days	
β-lactam (penicillin) allergy	**Clarithromycin**	15 mg/kg/day PO in 2 divided doses for 10 days	Therapeutic options for these patients are very limited; consider referral to otolaryngologist for tympanostomy Macrolides and TMP/SMX are less efficacious than amoxicillin-clavulanate; there is significant macrolide resistance in *S pneumoniae*
	TMP/SMX	6–12 mg TMP/kg/day PO in 2 divided doses for 10 days	
	Azithromycin	10 mg/kg PO first day then 5 mg/kg/day x 4 days	

Treatment of AOM in Adults

Indication	Drug	Dose
AOM	Amoxicillin	500 mg every 8 hours OR 875 mg 2 times daily for 10 days
β-Lactamase–resistant AOM	Amoxicillin-clavulanate (Augmentin)	875 mg 2 times daily for 10 days
	Cefixime (Suprax)	400 mg daily for 7 days
AOM in penicillin-allergic patients	Macrolides	
	Azithromycin (Zithromax)	500 mg day 1, then 250 mg daily for 4 days
	Clarithromycin (Biaxin)	500 mg every 12 hours for 7 days

Drugs to Avoid in AOM

Cephalexin	No activity against penicillin intermediate resistant–*S pneumoniae* No activity against *Haemophilus influenzae/Moraxella catarrhalis*
Cefaclor	No activity against penicillin intermediate resistant–*S pneumoniae* Marginal activity against *Haemophilus influenzae/Moraxella catarrhalis*

Therapeutic Procedure 8.3 Initial Pharmacotherapy of AOM in Pediatric Patients—cont'd

Cefixime	No activity against penicillin intermediate resistant–*S pneumoniae* Excellent activity against *Haemophilus influenzae*
Ceftriaxone	Routine use of this agent is not recommended due to potential for increased resistance to third generation cephalosporins. May be an option in severe cases who have failed therapy, in immunosuppressed patients, or in neonates. **Note: 3 days of IM/IV therapy recommended** (single dose not as effective in eradicating penicillin-resistant *S pneumoniae*)
Clindamycin	No activity against *Haemophilus/Moraxella* spp. (Clindamycin may be an option for *S pneumoniae* in severe penicillin-allergic patients)
Erythromycin	Poor activity against *H influenzae* Significant macrolide resistance in *S pneumoniae*

Nursing Research–Based Practice 8.2

Siegel, RM, et al. Treatment of otitis media with observation and a safety-net antibiotic prescription. *Pediatrics* 112(3):527–532, 2003.

J. S. is a 2-year-old child who presents to the pediatrician's office with a temperature of 101.8ºF. Her mother reports that for the past 2 days she has been tugging on her right ear, producing a moderate amount of yellow nasal drainage, and has been very irritable. On physical exam you discover that the tympanic membrane is erythematous, is bulging, and has decreased mobility. The mother states that the child's appetite is normal and denies any vomiting or diarrhea. The child's history is negative for previous ear infections, congenital syndromes, and prematurity. Immunizations are up to date, and no one else in the family has experienced these symptoms. The mother states that the child started attending day care 2 weeks ago.

Your diagnosis is acute otitis media (AOM). What treatment plan would you develop for this patient? How would you explain your diagnosis and treatment plan to the mother? What instructions would you give the mother to assist her in caring for her child?

A quasi-experimental study design was conducted to evaluate the treatment options of AOM. The aim of the study was to determine if parents in the United States would wait at least 48 hours before deciding whether to fill a safety-net antibiotic prescription (SNAP) for the treatment of uncomplicated acute otitis media in children aged 1 to 12 years. Pain control was the treatment of choice for all 194 participants in the Cincinnati Pediatric Research Group's study. After criteria had been met and consent forms were signed by the parents, the SNAP was given with instructions to wait 48 hours before filling the prescription and to treat the symptoms with acetaminophen, ibuprofen, and anesthetic otic drops. Patients were contacted on day 10 with a telephone interview and were questioned about the treatments given. Initial data and the 10-day telephone interview information were entered into the researcher's Internet Web site. The findings showed that 175 participants completed the 10-day interview. Of the 175 participants, 31% had filled the SNAP, and 78% of the parents were satisfied with acetaminophen treatment alone. Sixty-three percent of the parents were willing to treat future acute otitis media episodes with pain mediation rather than with immediate antibiotics.

beta-lactamase–producing organisms. Chronic OM requires monthly follow-up to assess the efficacy of treatment and monitor for recurrence of infection.

If medical management does not clear the infection, inner ear effusion persists, or OM episodes recur, referral to an ENT specialist for potential surgical evaluation is indicated. Common surgical procedures include myringotomy (incision of the eardrum to allow draining and relieve fluid buildup in the middle ear) or tympanostomy (insertion of tubes across the eardrum into the inner ear to drain pus or serous fluid). Tonsillectomy and/or adenoidectomy may also be used as secondary prevention measures. All infectious sequelae of contiguous cranial structures, as well as invasive complications requiring excision such as a cholesteatoma, require referral to a specialist.

OME can lead to irreversible conductive hearing loss if middle ear structures are permanently damaged from effusion-related pressure changes. If AOM is poorly treated or is present in an immunocompromised patient, it may lead to OME; chronic OM; otitis interna (labyrinthitis); vertigo; ataxia; or several acute, subacute, and chronic infections of adjacent cranial structures, including mastoiditis, petrositis, meningitis, and epidural, subdural, or brain abscesses. Other complications include perforation of the tympanic membrane, cholesteatoma, facial nerve palsies, lateral sinus thrombophlebitis, and otitic hydrocephalus.

Although the clinical course of OME may last for several weeks, patients should be referred to a specialist for impedance audiometry testing and further evaluation to rule out nasopharyngeal tumors and other anatomical

eustachian tube obstructions if hearing loss persists beyond 6 weeks, extends bilaterally, or reaches more than 20 decibels. Patients with AOM may require referral to a specialist if vertigo or ataxia develops, if a ruptured tympanic membrane fails to close, if symptoms worsen after 3 to 4 days of treatment, or if significant hearing loss is present.

Patient Education

Swimming should be avoided until the infection clears because immersion in water may lead to otitis externa, complicating the middle ear infection. The ear canal should be kept as dry as possible. Tympanic membrane perforation can be avoided by not using cotton swabs or sharp objects of any kind to clean the ears. Traumatic injuries to the middle ear should be avoided as well to prevent perforation. In all cases, especially those in which the tympanic membrane is perforated, blowing of the nose should be avoided. If the nose must be blown, it should be done as gently as possible.

All patients and their families should be encouraged to stop smoking because smoking aggravates all forms of otic inflammation. Folk remedies such as "sweet oil" should also be avoided. Patients should be instructed to return to the clinic for further evaluation after 48 hours if symptoms of AOM have not ameliorated. Explain that OM per se is not contagious but that predisposing URIs may be passed from person to person. Bedrest or reduced activity may be suggested in severe cases until fever and pain subside, and the importance of completing the full regimen of all antibiotic therapies should be emphasized. Instruct patients to keep the ear canal dry during the course of infection, and demonstrate the proper method of cleaning the ear canal without chemical agents, sharp objects, cotton swabs, or a finger.

COMMON NOSE AND THROAT PROBLEMS

EPISTAXIS

Commonly called a "nosebleed," *epistaxis* is a hemorrhage of the nasal mucosa resulting from the traumatic or spontaneous rupture of superficial veins and/or arteries, located most often on the anterosuperior portion of the nasal septum known as Little's area (Kiesselbach's triangle or Kiesselbach's plexus). Epistaxis is a physical sign rather than a disease. Therefore, after the initial management of bleeding, a thorough evaluation is essential to determine its underlying cause.

Epidemiology and Causes

Although actual prevalence statistics for epistaxis are undocumented, it is an extremely common condition. Approximately 10% of the population experiences at least one significant nosebleed over a lifetime. Epistaxis most commonly occurs in children younger than age 10 years and in adults older than 50 years. Minor, self-limited epistaxis is twice as common in children as it is in adults. In contrast, posterior epistaxis is more common in elderly patients. No ethnic predispositions are apparent. Men and women are affected equally by nosebleeds, although some predisposing clotting disorders such as hemophilia may be expressed predominantly in males.

Excessive dryness of the nasal mucosa in poorly humidified environments or at high altitudes weakens nasal vessels, predisposing them to rupture. Septal deviation may thus contribute to epistaxis through the disproportionate exposure of one side of the nose to dry environmental air. Coagulopathies may be associated with chronic disorders such as cirrhosis, renal disease, cancer (especially Hodgkin's disease), and hypertension. As a whole, however, coagulopathies and neoplasms are associated with only 10% of cases of epistaxis. Vascular diseases such as hereditary hemorrhagic telangiectasia and arteriovenous nasal malformations are also risk factors. Medications that prolong bleeding time (e.g., warfarin, aspirin) contribute to all types of bleeding disorders, as does cocaine abuse (snorting), which leads to septal perforation. Prolonged use of nose drops is also a risk factor because it may lead to reflex nasal inflammation, known as rhinitis medicamentosum. In an elderly patient, arteriosclerosis is a contributing factor, specifically for posterior hemorrhage epistaxis. Many nutritional deficiencies and febrile infectious disorders may also predispose an individual to nosebleeds, including scurvy (extreme vitamin C deficiency) and rheumatic, scarlet, or typhoid fever.

Pathophysiology

More than 90% of nosebleeds result from local irritation related to trauma or inflammation, occurring most often in the absence of any anatomical abnormality. Trauma to both nasal polyps and the well-vascularized watershed area of the nasal mucosa known as Kiesselbach's plexus is perhaps the most common direct cause of nosebleed, particularly from picking of the nose (epistaxis digitorum) or forcible injury related to blunt trauma. Kiesselbach's plexus marks the anastomosis of three major blood vessels of the nasal cavity: the septal branch of the anterior ethmoid artery, the septal portion of the superior labial branch of the facial artery, and the lateral nasal branch of the sphenopalatine artery. Similarly, posterior epistaxis most commonly originates from rupture of the posterior wall and choanal branches of the sphenopalatine artery. Vascular disease accounts for up to one-fourth of posterior bleeds, and rupture of an intracranial or cervical vascular aneurysm must also be considered as a potentially life-threatening etiology.

Spontaneous rupture of weakened vessels may also result from acute or chronic sinusitis, upper respiratory infection, and drying or crusting of the nasal mucosa from viral or allergic rhinitis. Foreign bodies lodged in the nasal airways are another common source of vessel injury.

Inhaled drugs of abuse (e.g., cocaine and snorted heroin) chronically dry and aggravate friable nasal mucosa, predisposing to epistaxis. Anticoagulant medications such as warfarin (Coumadin) and heparin may also predispose to nosebleeds by inhibiting natural clotting pathways, and alcohol intake has been implicated as an independent, albeit far from universal, epistaxis risk factor. Malignant growths in the nasal cavity or paranasal sinuses may erode into blood vessels and present with epistaxis as their sole manifestation. An exceedingly rare cause of nasal bleeding is the presence of nasal ectopic endometrium (nasal endometriosis). Familial blood dyscrasias such as hemophilia A (factor VIII deficiency), hemophilia B (factor IX deficiency or Christmas disease), and von Willebrand disease (the most common genetic bleeding disorder), as well as hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease), are examples of inherited conditions that may be complicated by significant epistaxis.

Clinical Presentation

Subjective

The patient with recurrent minor anterior epistaxis typically presents with a history of several episodes over several weeks. If blood loss has been extensive, patients may report light-headedness or shortness of breath. In addition, a rapid heartbeat may be detected, and the patient may report blackened stools (melena) that are discolored from clotted, swallowed blood. Posterior epistaxis may be asymptomatic or may present with hemoptysis (coughed-up blood), nausea, hematemesis (blood-streaked vomitus), or melena.

Objective

Prominent blood vessels are typically seen traversing the anterior septum, and a small amount of clotted blood may be visible. If the patient is actively bleeding from the front of the nose, blood is typically bright red, and localizing the bleeding source may be difficult. The second most common site of hemorrhage (after Little's area) is the anterior end of the inferior nasal turbinate. Epistaxis originating deeper in the nose may produce either bright red or dark blood. Usually only one bleeding site exists, but if multiple sites or a diffuse ooze are evident, an underlying systemic bleeding disorder is likely. If the source of hemorrhage is located in the posterosuperior nasal cavity, the bleeding is termed *posterior epistaxis*. In these cases, blood loss will extend into the pharynx as well, and clotted blood and brown to red throat discoloration may be evident. The most common sites of posterior bleeding are just under the posterior half of the inferior nasal turbinate or the roof of the nasal cavity. Patients with significant blood loss may demonstrate pallor, particularly in the face. Palpation of the paranasal sinuses may reveal tenderness if underlying sinusitis or malignancy is present. Likewise, percussion of the paranasal sinuses may demonstrate tenderness in sinusitis-related or malignancy-related cases.

Diagnostic Reasoning

Diagnostic tests are rarely called for when bleeding can be managed, and most episodes of epistaxis are not recurrent. A variety of diagnostic tests are helpful in determining the underlying cause of nasal hemorrhage. Laboratory tests exist for deficiencies of most clotting factors, but factor VIII and factor IX deficiencies are clearly the most commonly observed and tested for. In the past, bleeding times were monitored to help diagnose platelet-related coagulopathies. Because the test is labor intensive and results vary among laboratory technicians, it is rarely performed. Today a more sophisticated test called platelet function assay detects the ability of the platelets to work, not just the number of platelets. A prolonged bleeding time (more than 7 minutes) may reflect platelet-related coagulopathies (e.g., von Willebrand's syndrome or thrombocytopenia), whereas a prolonged prothrombin time (PT) or partial thromboplastin time (PTT) is characteristic of clotting factor disorders. Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) produce a prolonged PTT, whereas disorders of the extrinsic clotting pathway (factor VII deficiency) result in a prolonged PT. A CBC including hemoglobin, hematocrit, and mean corpuscular volume may offer insight into the chronicity of the condition. Radiological (x-ray) examination of the nasal cavity and paranasal sinuses may identify masses, including neoplasms or foreign bodies, as well as sinusitis if mucosal thickening or air–water levels are apparent. CT scan of the head may also be done with greater sensitivity for detecting structural and soft tissue abnormalities.

Differential Diagnosis

For the patient with recurrent minor epistaxis, bleeding of nasal cavity origin must be distinguished from bleeding due to chronic sinusitis. In addition, nasopharyngeal or paranasal sinus tumors should be ruled out via x-ray films, as previously described. Differentiation among posterior epistaxis, hemoptysis, and hematemesis is critical if signs of anterior nasal bleeding are inapparent. In the absence of respiratory or gastrointestinal findings, a diagnosis of posterior epistaxis can be assumed if visual evidence exists for a posterior source of bleeding, if the majority of bleeding has occurred into the pharynx, or if anterior nasal packing fails to control hemorrhage.

Management

Specific treatment should be based on the underlying cause of epistaxis. If the etiology is undetermined, interventions should be geared toward alleviating anxiety related to symptoms of an unknown etiology, as well as stopping the bleeding. If the cause of epistaxis is found to be traumatic injury from nose picking and/or dry and cracked mucosa, advanced practice nursing

interventions should be focused on educating the patient in self-care.

No pharmacological treatments to control acute nasal bleeding are available; however, any medication regimen that prolongs bleeding time should be reevaluated in the light of recurrent epistaxis. Initial treatment of uncomplicated anterior epistaxis consists of applying firm, continuous pressure for 10 to 15 minutes to both sides of the nose, immediately superior to the nasal alar cartilages. Patients should breathe through the mouth during this treatment period and must not release pressure to "sneak a peek" at the bleeding nares. To reduce vascular pressure, the patient should be seated upright with the head bent forward. Patients with no underlying medical problems may be treated at home, with directions to sit upright, minimize physical activity, and rest with the head elevated 45 to 90 degrees at night. Elderly or debilitated patients with epistaxis may require inpatient care, however, because of the increased risk of immunosuppression and anemia.

Recurrent minor epistaxis can be treated between episodes of active bleeding with vasoconstricting agents and/or chemical cauterization. A small piece of cotton or nasal pledget soaked in a topical vasoconstricting agent (such as 0.25% phenylephrine, 1:1,000 epinephrine, 0.1% xylometazoline, or 4% cocaine solution) should be applied to the nasal vestibule and pressed against the bleeding site for 5 to 10 minutes. Epinephrine should be avoided in hypertensive patients or those with coronary artery disease, and cocaine should be avoided in children. An ice pack may also be placed over the nose. Almost all venous anterior nosebleeds are stopped in this manner, but the treatment may need to be repeated. If this treatment fails, chemical cauterization of the bleeding site may be necessary. The mucosa should first be anesthetized with a cotton ball soaked in 4% cocaine, 4% lidocaine, or 2% lidocaine viscous preparation, held over the bleeding site for several minutes. Alternatively, 2% lidocaine jelly may be used. A bead of chromic acid, 25% to 50% trichloroacetic acid solution, or a silver nitrate stick is then applied directly onto the bleeding vessels with firm pressure for 30 seconds, which will allow for limited, shallow cautery of the bleeding site. Thermal or bipolar electrocautery may be required in cases of deeper lesions involving larger vessels; however, indiscriminate cauterization of a large area should be avoided.

If bleeding does not stop, anterior nasal packing should be placed to fill the entire nasal fossa. Layers of ½-in. × 72-in. gauze impregnated with petroleum jelly should be inserted in folding layers with a nasal speculum and bayonet forceps, extending as far back as possible to the posterior nasal choanae, while retaining the gauze ends at the nares. Each layer should be pressed firmly against the preceding one without disturbing the walls of the nasal cavity, with the folded ends alternating front and back in an accordion pattern. Typically, the entire 72-in. strip will be accommodated, if properly placed. A 2-in. × 2-in. gauze pad is then taped over the nostrils to prevent the anterior packing from dislodging and to catch dripping blood. Anterior packing should be removed within 2 to 3 days. The gauze inserts may be impregnated with an antibiotic cream or ointment to minimize bacterial growth and reduce odor. In addition, oral antibiotics may be administered if infection is suspected; however, the benefit of systemic antibiotics as a prophylactic measure (although common in practice) has not been confirmed by well-designed clinical trials. Recently, user-friendly nasal tampons have entered the market that are simply inserted in the nares in desiccated form and rehydrated by bathing them in 10 to 20 mL of saline or an antibiotic-containing solution (e.g., bacitracin). Posterior sources of bleeding require more complex treatment by a qualified specialist because this type of bleeding is usually more severe and difficult to control. Treatments include posterior nasal packing, sphenopalatine ganglion nerve block, and even surgical ligation of the compromised vessels. Nasal balloon-packing systems are an alternative to nasal packing, but they must not be overinflated and should be removed within 24 to 36 hours. Importantly, any form of nasal packing tends to be particularly painful for the patient once the local anesthetic has worn off, and oral or parenteral opioid analgesics should be considered. OTC analgesics such as acetaminophen may not be potent enough, whereas NSAIDs are best avoided because of their tendency to impair platelet function, which may lead to further bleeding.

All underlying medical conditions that might contribute to epistaxis should also be appropriately treated (e.g., platelet transfusions or clotting factor administration for coagulopathies). Iron supplements may be given if significant blood loss has occurred. If leukemia or another source of bone marrow immunosuppression is suspected as a causative factor of epistaxis, nasal packing should be avoided because of the increased risk of infection. In these cases, topical thrombin or hemostatic substances (Oxycel cotton or Gelfoam) should be first-line treatment.

Follow-up and Referral

Follow-up is not indicated for minor cases of nosebleed from local trauma or inflammation; however, the treatment of recurrent epistaxis should be monitored for effectiveness. Hemodynamics and blood loss should also be monitored in severe cases that require hospitalization. In the event of severe hemorrhage, anemia or even hypovolemia may develop. Various treatment modalities for epistaxis may also have important sequelae: Cocaine and lidocaine always present risks of toxicities when they are used. In addition, prolonged nasal packing may lead to infection of the nasal cavity, sinusitis, or impaired gas exchange, if poorly monitored. Excessive trauma during nasal packing or cauterization can result in septal

hematoma, abscess, or perforation. External nasal deformities may also result from pressure necrosis from the anterior portion of nasal packing. Balloon-packing systems may result in mucosal pressure necrosis if the balloons are overinflated. Likewise, if the anterior portion of a two-balloon system breaks, the posterior balloon may migrate posteriorly down the airway and cause obstruction. Some patients experience vasovagal episodes during nasal packing and may pass out.

All cases of anterior epistaxis that are recurrent, particularly severe in blood loss, or refractory to vasoconstrictive or cauterization therapy should be referred to a specialist or emergency department, as appropriate. Hypovolemic or anemic patients require physician referral to evaluate the need for transfusion. Electrocautery for recurrent epistaxis caused by deep lesions should be performed only by a qualified specialist. Any elderly or debilitated patient who requires hospitalization for epistaxis should also be referred to a specialist. The management of posterior epistaxis requires a specialist because treatment modalities may include ganglionic nerve blocks, posterior nasal packing, and vessel ligation. Coagulopathy-related and malignancy-related epistaxis require specialized treatment related to the underlying disorder. Finally, infections resulting from nasal packing may necessitate referral to a specialist, especially if the patient is febrile.

Patient Education

Patients who have been treated for epistaxis should not blow their nose and should avoid sneezing for at least 12 hours after an acute episode to avoid dislodging the protective blood clot. Increased environmental humidity in the home also helps to prevent acute attacks, especially during the winter months. Petroleum jelly applied liberally to the nares promotes mucosal hydration, which helps prevent drying and cracking of the nasal mucosa. If nasal probing is persistent, the patient's fingernails should be cut to avoid mucosal trauma. Proper nasal pinching techniques should be demonstrated to enable patients to administer self-care at home for minor episodes of epistaxis. The importance of maintaining nasal mucosal hydration should be stressed, as well as the need to avoid nasal probing and vigorous blowing of the nose. The ability of certain medications to contribute to bleeding disorders (e.g., antiplatelet effects of aspirin, anticoagulant therapies such as warfarin) should also be discussed. Patients should be told not to swallow blood because this may upset the stomach, resulting in nausea, vomiting, or "gagging" (inhalation of blood into the trachea and bronchi). Patients should not talk during episodes of active bleeding for the same reason, and alcohol and hot liquids should be avoided after an acute attack.

RHINITIS

Rhinitis (coryza) is an inflammation of the nasal mucosa characterized by nasal congestion, rhinorrhea, sneezing, pruritus, and/or postnasal drainage. Its etiology is varied, but in general, it is categorized as either allergic or nonallergic rhinitis. Allergic rhinitis may be either seasonal or perennial. Nonallergic rhinitis may be (1) infectious, (2) irritant related (often in the workplace), (3) vasomotor, (4) hormone related, (5) associated with medication use or overuse (rhinitis medicamentosum), or (6) atrophic (seen primarily in geriatric patients). It may be acute or chronic, but the most common forms are viral rhinitis and perennial or seasonal ("hay fever") allergic rhinitis.

Although rhinitis is often a benign and self-limited disorder, poorly controlled allergic rhinitis may contribute to sleep loss, absenteeism from work or school, secondary daytime fatigue, learning impairment, decreased overall cognitive functioning, decreased long-term productivity, and decreased quality of life. In addition, poorly controlled rhinitis may lead to the development of other related disease processes, such as sinusitis, nasal polyps, OME, hearing impairment, aggravation of underlying asthma, and sleep apnea.

Epidemiology and Causes

Although the actual prevalence of acute rhinitis is undocumented, it is extremely common, occurring at least as frequently as the common cold. Moreover, an estimated 40 to 50 million U.S. adults suffer from some form of chronic rhinitis; some sources quote cumulative frequencies of 42% of the population of the United States by age 40. Specifically, the incidence of seasonal allergic rhinitis parallels pollen production, increasing in the fall and spring and peaking in the winter. Other forms of rhinitis may last year-round if they are caused by perennial allergens such as dust or house mites. Allergic rhinitis occurs in all age-groups, most commonly in adults aged 30 to 40 years, but it is rare in adults older than age 50. Onset of symptoms typically occurs between ages 10 and 20 years.

Nonallergic infectious rhinitis may be acute or chronic. Acute rhinitis is usually viral and self-limiting, whereas chronic rhinitis may be associated with bacterial sinusitis and may have associated allergic or mucociliary disturbances as predisposing factors. Rhinitis medicamentosum affects primarily young to middle-aged adults (correlating with medication use), and atrophic rhinitis affects primarily older adults, although the onset of symptoms may begin as early as puberty.

Most forms of rhinitis appear to have no ethnic predispositions. Hispanics, Asians, and African Americans seem to be particularly susceptible to atrophic rhinitis, however. In contrast, the incidence of this form is low in natives of equatorial Africa. Viral and atrophic rhinitis affect women more often than men, whereas most other forms affect both sexes equally.

Viral upper respiratory tract infections (URIs) occur more frequently in families with young children, whereas exposure to offending allergens is the primary risk factor for allergic rhinitis. The most common irritants

implicated in the seasonal form are pollen and mold spores. Dust mites; insect debris (cockroaches, locusts, fish food); tobacco smoke; and animal dander, dried saliva, and urine are most common for the perennial form of allergic rhinitis. Immunosuppression secondary to illness or drug/medication use and a family history of allergic disease (e.g., eczema and/or asthma) are also risk factors for allergic rhinitis. Vasomotor rhinitis is aggravated by low humidity, sudden temperature or pressure changes, cold air, strong odors, emotional stress, cigarette smoke, and other nasal irritants. Use of nasal decongestants more frequently than every 3 hours or for periods longer than 3 weeks is the primary risk factor for the development of rhinitis medicamentosum. In some patients, certain drugs may precipitate rhinitis: Antihypertensive agents are the most frequently cited culprits. Angiotensin-converting enzyme inhibitors, beta-adrenergic antagonists, certain anti-inflammatory agents, guanethidine (Ismelin), clonidine (Catapres), hydralazine (Apresoline), prazosin (Minipress), chlordiazepoxide (Librium), amitriptyline (Elavil), or even aspirin can be a contributing factor. Oral contraceptive use and estrogen replacement therapy have also been implicated as risk factors for rhinitis, along with a family history of rhinitis and septal/anatomical obstruction. In addition, ingestion of certain foods may precipitate rhinitis in susceptible individuals. Illicit drug use such as cocaine snorting may precipitate rhinitis.

Pathophysiology

Viral rhinitis stems from an acute catarrhal response caused by viral replication in the nasopharynx, resulting in varying degrees of nasotracheal inflammation. Strongly associated with viral upper respiratory tract infection (URI or the "common cold"), the primary etiological agents of viral rhinitis include rhinovirus, influenza virus, parainfluenza virus, respiratory syncytial virus, coronavirus, adenovirus, echovirus, and coxsackievirus. When viral sinusitis is also present, the condition is collectively referred to as rhinosinusitis. The vast majority of rhinosinusitis is due to viral infection, but bacterial superinfection may complicate a small percentage of these cases. Anatomical defects or obstructions anywhere along the nasopharyngeal tract may predispose to infection by impairing physiological nasal drainage.

In contrast, allergic rhinitis results from immunoglobulin E (IgE)–mediated type I hypersensitivity to airborne irritants affecting the eyes, nose, sinuses, throat, and bronchi. IgE antibodies, elicited by repeated allergen exposure, bind to eosinophils and basophils in the bloodstream and their mucosal counterparts known as mast cells. These leukocytes subsequently degranulate, releasing chemoinflammatory substances, including histamine, leukotrienes, prostaglandins, slow-reacting substance of anaphylaxis, and erythrocyte chemotactic factor, which results in increased vasodilation, capillary permeability, mucus production, smooth muscle contraction, and eosinophilia. On rare occasions, food allergies may be the cause. In addition, chemical or particulate airborne irritants may cause direct mucosal inflammation in the absence of IgE production or immune hypersensitivity.

Vasomotor rhinitis is a chronic, noninfectious process of unknown etiology without accompanying eosinophilia, characterized by periods of abnormal autonomic responsiveness and vascular engorgement unrelated to specific allergens. Fluctuations and reductions in estrogen associated with menses, hormonal birth control preparations, pregnancy, and menopause may all predispose to nonallergic rhinitis. Rhinitis medicamentosum is a rebound condition secondary to medication overuse. In some patients, it is caused by certain antihypertensive medications via undefined mechanisms, but most often mucosal inflammation results from the use of topical nasal decongestants such as phenylephrine (Neo-Synephrine) for greater than 3 to 4 days, which leads to secondary vasodilation, repeated small-vessel coagulation, and eventual fibrosis. Bacterial infection is thought to play a role in the development of atrophic rhinitis, in which the nasal epithelia and bones progressively atrophy, resulting in distinct morphological changes.

Clinical Presentation

Subjective

Viral rhinitis is typically accompanied by malaise, headache, sore throat, and occasionally fever. Patients with allergic rhinitis usually complain of itching in the nasal passages, conjunctivae, and roof of the mouth, as well as epiphora (stringy, watery ocular discharge). Sneezing, coughing, and a sore or burning throat commonly present in both viral and allergic rhinitis.

In contrast, patients with vasomotor rhinitis (noninfectious rhinitis without eosinophilia) rarely display any of the aforementioned symptoms. However, watery rhinorrhea, nasal congestion, "nasal" speech, and forced mouth-breathing are common complaints of patients with viral, allergic, vasomotor, or medication-related rhinitis. The onset of congestion is rapid in vasomotor rhinitis; patients typically complain of a pronounced, watery postnasal drip, as well as persistent nasal obstruction that may switch sides with each attack. Rhinitis medicamentosum patients may present with increased heart rate and elevated blood pressure because of the effects of sympathomimetic decongestants. Patients with atrophic rhinitis may complain of nasal congestion, a thick postnasal drip, frequent clearing of the throat, anosmia (impaired olfaction), a constant foul odor in the nose, and severe epistaxis (nosebleeds).

Objective

On inspection, the nasal mucosa typically appears erythematous in viral rhinitis, and throat inspection may reveal pharyngitis or laryngitis, characterized by erythematous

and edematous pharyngeal mucosa or vocal cords. If the viral rhinitis is complicated by a secondary bacterial infection, the nasal discharge may be greenish yellow, which is indicative of purulence. In allergic rhinitis, the mucosa are pale, are boggy (edematous), and may take on a bluish hue. Yellowish, gray, or erythematous mucosa may also be seen. Gray-blue to yellow-tan nasal polyps may present with chronic perennial rhinitis. The conjunctivae are usually inflamed (allergic conjunctivitis), with the palpebral conjunctiva being particularly edematous (chemosis) and "cobblestoned" in appearance, owing to chronically infected blood vessels. Dark circles under the eyes ("allergic shiners") may be apparent, along with excess wrinkles under the lower eyelid (Dennie lines). In both viral and allergic rhinitis, the external nose may appear erythematous, with a transnasal crease resulting from repeated upward wiping and nose wrinkling (nasal salute). The nasal turbinates and palatine or pharyngeal tonsils (adenoids) may also be enlarged. The nasal mucosa in patients with vasomotor rhinitis will range from bright red to bluish in hue, and again, the nasal turbinates may be swollen. The mucosa in patients with rhinitis medicamentosum is also infected and edematous. In contrast, the mucosa in patients with atrophic rhinitis usually appear crusted with dried mucus or blood from repeated bouts of epistaxis, although the nasal passages typically remain patent.

The nasal mucosa in patients with viral rhinitis appears particularly friable. If present, nasal polyps are typically soft, edematous, and nontender. The external nose may be tender from repeated sneezing in patients with viral and allergic rhinitis. Some patients with rhinitis medicamentosum may present with dry and rubbery mucosa. On auscultation, wheezing breath sounds may reflect concurrent asthma associated with allergic rhinitis.

Diagnostic Reasoning

Diagnostic Tests

Laboratory tests are not typically indicated for uncomplicated cases of viral rhinitis, allergic rhinitis, or rhinitis medicamentosum. However, if an exudate is present in a colored or translucent nasal discharge, a Giemsa- or Wright's-stained smear should be prepared, along with a CBC to characterize the disease process. Leukocytosis or the presence of polymorphonuclear neutrophils in the discharge reflects an infectious disorder other than a typical viral URI. Eosinophilia in the discharge is indicative of allergic rhinitis. Peripheral eosinophil count and serum IgE levels have low predictive values; however, intradermal skin testing of minute amounts of allergens may be helpful if the diagnosis of allergic rhinitis is in doubt. Vasomotor rhinitis tends to be a diagnosis of exclusion because nasal smears and skin tests are typically negative, and no family history of allergic disorders is expected. Hormonally related rhinitis and rhinitis medicamentosum are diagnosed primarily through patient history, once other common forms of rhinitis have been excluded. Atrophic rhinitis may be confirmed by nasal mucosal biopsy. Histopathology will demonstrate transformation of ciliated pseudostratified columnar epithelia into the stratified squamous form. In addition, the lamina propria will be decreased in thickness and vascularity, and bacterial culture of nasal secretions may also be helpful.

Differential Diagnosis

Acute or chronic sinusitis resulting from bacterial infection of the facial sinuses may also inflame the nasal mucosa. Sinus x-ray films demonstrating mucosal thickening, air-fluid levels, or opacification are effective at ruling out this disorder, as are cultures or smears of sinus aspirates to identify the infectious organisms present. Physical exam may rule out nasal foreign bodies, nasal polyps, or a deviated septum as causes of mucosal inflammation or congestion. Cocaine snorting, inhalant abuse (sniffing, huffing), and other forms of substance abuse should also be ruled out through a detailed patient history and, if appropriate, serum drug screens. Chronic inflammatory conditions such as sarcoidosis may be ruled out via biopsy, which would reveal granulomatous (histiocyte/macrophage) inflammation of the nasal mucosa. Hormonal changes associated with pregnancy and hyperthyroidism or hypothyroidism may also lead to nasal vasodilation and inflammation. Such conditions are ruled out through a careful physical exam, detailed patient history, and hematological hormone screens.

Management

With all types of rhinitis, much of the treatment regimen will focus on the relief of symptoms and self-care measures, although environmental issues must also be addressed.

Viral rhinitis is treated symptomatically, because viral URIs are predominantly self-limited. The following list outlines adult dosages:

- Fever and headache may be treated with acetaminophen 325 to 650 mg PO every 4 hours as needed (daily maximum dose 4,000 mg/day). Aspirin is not recommended because it may increase viral shedding. Rhinorrhea may be treated with oral decongestants such as pseudoephedrine (Sudafed) 30 to 60 mg PO every 3 to 4 hours as needed or topical preparations such as phenylephrine (Neo-Synephrine) 0.25% to 0.5% nasal spray one to two sprays in each nostril every 3 to 4 hours as needed for no more than 3 to 4 days.
- Intranasal ipratropium (Atrovent) 0.03% two sprays in each nostril 2 to 4 times daily as needed may also relieve excessive runny nose.
- Persistent coughs may be treated with dextromethorphan 15 to 30 mg PO every 3 to 4 hours as needed, but prescription codeine 10 to 15 mg PO every 3 to 4 hours as needed usually proves to be the only consistently effective cough suppressant.

For allergic rhinitis, avoidance or reduced exposure to offending allergens is the primary method of treatment because acute attacks are typically self-limited if not continually aggravated by allergen. Newer generation oral antihistamines designed to be less sedating are now the first-line short-term treatment of choice for allergic rhinitis. These work best for early symptoms of allergy such as sneezing, watery eyes, and ocular pruritus. However, intranasal corticosteroids have traditionally been considered the best means of controlling the longer-term symptoms of allergic rhinitis, including nasal congestion and discharge. In fact, meta-analyses have suggested that intranasal corticosteroids are the best overall first-line treatment for allergic rhinitis. It should be stressed, however, that intranasal steroid therapy may require 2 or more weeks of continuous daily use before symptomatic relief is apparent. Systemic steroids have significant side effects and tend to be discouraged for such a common condition. A newer class of medication, leukotriene receptor antagonists, has been approved for allergic rhinitis. Randomized controlled studies have shown montelukast (Singulair) to be as effective as loratadine (Claritin) in the symptomatic relief of allergic rhinitis.

Vasomotor rhinitis is also treated symptomatically, albeit at times unsatisfactorily, with environmental humidification using a vaporizer or humidified central heating system. Rhinorrhea may also be treated with systemic oral decongestants such as pseudoephedrine (Sudafed) 30 to 60 mg 3 or 4 times daily as needed. Congestion may also improve with topical saline nasal sprays. Thorough cleaning of the nose and restoration of nasal patency may be achieved using a powered device such as a Grossan nasal irrigator or a Neti pot. Intranasal ipratropium (Atrovent) 0.03% two sprays in each nostril 2 to 4 times daily as needed or azelastine (Astelin) two sprays in each nostril 2 times daily may also relieve symptoms. Rhinitis medicamentosum or "rebound rhinitis" is characterized by nasal congestion without rhinorrhea following the short-term use of topical vasoconstrictive medications. This condition can be remedied by immediately stopping all topical decongestant use. The condition typically resolves after 2 to 3 weeks.

- Oral antihistamine-decongestant preparations or short courses of topical nasal steroids may provide symptomatic relief.
- A short course of systemic steroids such as prednisone 30 mg PO daily for 5 days may be needed if other treatments prove ineffective.

Atrophic rhinitis may be treated with bacitracin ointment applied intranasally 2 or 3 times daily until the nasal crusting and foul odor are eliminated. Expectorants such as guaifenesin 400 mg PO every 4 hours as needed, physiological saline solutions as a nasal spray, regular use of a Neti pot or other means of nasal douching, or electric nasal irrigators (e.g., Grossan) may provide symptomatic relief. (See Complementary Therapies 8.1.) Menopausal women may be helped by systemic estrogens. See Drugs Commonly Prescribed 8.5: Rhinitis for more information.

Drugs Commonly Prescribed 8.5 Rhinitis

Drug	Indication	Dosage	Prescribing Considerations
Antihistamines—First Generation			
diphenhydramine (Benadryl)	Allergic rhinitis	25–50 mg PO every 4–6 hours; maximum 300 mg/day Children: 6–12 years: 12.5–25 mg PO every 4–6 hours; maximum 150 mg/day	Must use 3–5 hours before anticipated exposure or on a regular basis as long-term therapy. **Adverse effects:** CNS sedation, GI upset, anticholinergic effects (dry mouth, blurred vision), additive CNS-depressant effects of alcohol, sedative, hypnotics. Use with caution in older adults.
chlorpheniramine maleate (Chlor-Trimeton)		2–4 mg PO every 4–6 hours Children: <2 years not recommended; 2–5 years—1 mg PO every 4–6 hours; 6–11 years—2 mg PO every 4–6 hours	Must use 3–5 hours before anticipated exposure or on a regular basis as long-term therapy. **Adverse effects:** CNS sedation, GI upset, anticholinergic effects (dry mouth, blurred vision), additive CNS-depressant effects of alcohol, sedative, hypnotics. Use with caution in older adults.

Drugs Commonly Prescribed 8.5 Rhinitis—cont'd

Drug	Indication	Dosage	Prescribing Considerations
azelastine HCl (Astelin)	Seasonal rhinitis	(137 mcg/spray) two sprays per nostril 3 times daily Children: <5 years not recommended; 5–11 years—1 spray/nostril twice daily	Intranasal **Adverse effects:** Bitter taste, somnolence, CNS sedation, GI upset, anticholinergic effects (dry mouth, blurred vision), additive CNS-depressant effects of alcohol, sedative, hypnotics. Use with caution in older adults. Pregnancy Category C.
Antihistamines—Second Generation			
desloratadine (Clarinex) (Clarinex RediTabs)	Seasonal allergic rhinitis	5 mg PO daily dissolved on the tongue Children: <6 years use different formulation; 6–11 years—2.5 mg PO daily	**Adverse effects:** Pharyngitis, dry mouth, somnolence, headache, fatigue. Pregnancy Category C. Not recommended for nursing mothers.
loratadine (Claritin)	Rhinitis	10 mg PO daily Children: <2 years not recommended; 2–5 years—5 mg PO daily; >6 years—10 mg PO daily or 5 mg PO twice daily	**Adverse effects:** Headache, mild drowsiness. Not as effective as first generation; use in patients who cannot tolerate sedation.
cetirizine (Zyrtec)	Rhinitis	10 mg PO daily Children: <2 years not recommended; 2–6 years—2.5 mg PO daily; maximum 5 mg/day >6 years—5–10 mg PO daily	Somewhat more sedation than others, but less than first generation. Not as effective as first generation; use in patients who cannot tolerate sedation. **Adverse effects:** Drowsiness, somnolence, dry mouth, pharyngitis. Not recommended for pregnant women or nursing mothers.
fexofenadine (Allegra)	Rhinitis	60 mg PO 2 times daily or 180 mg PO daily Children: 2–11 years—30 mg PO twice daily	Not as effective as first generation; use in patients who cannot tolerate sedation. **Adverse effects:** Headache, back pain, viral infection, dizziness. Pregnancy Category C.
olopatadine (Patanase)	Seasonal allergic rhinitis	665 mcg/spray Two sprays per nostril 2 times daily Children: <6 years not recommended; 6–11 years—1 spray per nostril 2 times daily	Avoid eyes. Monitor for nasal mucosal changes. **Adverse effects:** Bitter taste, headache, epistaxis, throat pain, nasal ulceration, somnolence. Pregnancy Category C.

Drugs Commonly Prescribed 8.5 Rhinitis—cont'd

Drug	Indication	Dosage	Prescribing Considerations
Decongestants (Monotherapy)			
pseudoephedrine HCl (Sudafed)	Nasal congestion	30–60 mg PO every 4–6 hours; maximum 4 doses/day	Should not be used for longer than 3–4 days. Decongestant only. Can cause CNS excitation, hypertension, and palpitations. *Use with caution in elderly patients and those taking beta blockers.* *Contraindicated in patients with diabetes, benign prostatic hyperplasia (BPH), hypertension, monoamine oxidase (MAO) inhibitors, cardiac disease.*
Decongestants (Combination Therapy)			
NSAID and sympathomimetic (Advil Cold and Sinus)	Rhinorrhea, sinusitis, flu	One to two tablets every 4–6 hours; maximum 6 tablets/day	Should not be used for longer than 3–4 days. Take with food. *Use with caution in patients with hypertension, diabetes, glaucoma, BPH, and those taking beta blockers.*
diphenhydramine HCl (Benadryl) 25 mg and pseudoephedrine HCl (Sudafed) 60 mg	Rhinorrhea, nasal congestion	One tablet every 4–6 hours	Should not be used for longer than 3–4 days. *Do not use with MAO inhibitors or in patients with bronchospasm, hypertension, diabetes, BPH.* *Potentiates the effects of alcohol, sedatives.*
loratadine (Claritin) 10 mg and pseudoephedrine 50 mg (Claritin-D 24 Hour)	Rhinitis, sinusitis with congestion, allergic rhinitis	One tablet daily	Should not be used for longer than 3–4 days. Do not crush or chew. *Contraindicated in patients with glaucoma, BPH, hypertension, coronary artery disease (CAD).* *Use with caution in elderly patients and those taking beta blockers.*
fexofenadine HCl 60 mg and pseudoephedrine 120 mg (Allegra-D)	Seasonal rhinitis with nasal congestion	One tablet 2 times daily	Should not be used for longer than 3–4 days. Extend tab. Avoid giving with food.
Antihistamine and Sympathomimetic			
			Avoid other sympathomimetics. *Contraindicated in patients with glaucoma, BPH, or hypertension, and those taking MAO inhibitors.* **Adverse effects:** Palpitations, hypertension.
clemastine fumarate 1.34 mg and phenyl propanolamine HCl 75 mg (Tavist-D)	Rhinorrhea, nasal congestion, common cold	One tablet every 12 hours	Should not be used for longer than 3–4 days. Sustained release tablets. Do not crush or chew.

Drugs Commonly Prescribed 8.5 Rhinitis—cont'd

Drug	Indication	Dosage	Prescribing Considerations
			Use with caution in patients with hypertension, CAD, diabetes, and those taking MAO inhibitors, beta blockers, and CNS depressants, as well as in older adults.
Intranasal Corticosteroids			
beclomethasone dipropionate (Beconase AQ)	Decrease nasal inflammatory reaction	42 mcg/spray: one or two sprays per nostril 2 times daily	Available in aerosol and metered pump. May eliminate need for antihistamines or decongestants. Must be used regularly; onset of action in 2 or more days; use decongestant before application if necessary. **Adverse effects:** Local irritation, increased rhinorrhea, localized fungal infection.
budesonide (Rhinocort Aqua)	Decrease nasal inflammatory reaction	32 mcg/spray 2 sprays per nostril once daily Maximum dose 4 sprays per nostril once daily	Aerosol. May eliminate need for antihistamines or decongestants. Must be used regularly; onset of action in 2 or more days; use decongestant before application if necessary. **Adverse effects:** Local irritation, increased rhinorrhea, localized fungal infection. Caution with CYP3A4 inhibitors (e.g., ketoconazole). Pregnancy Category B.
ciclesonide (Omnaris)	Decrease nasal inflammatory reaction	50 mcg/spray: 2 sprays per nostril daily	Aerosol. May eliminate need for antihistamines or decongestants. Must be used regularly; onset of action in 2 or more days; use decongestant before application if necessary. **Adverse effects:** Local irritation, increased rhinorrhea, headache, pharyngitis, localized fungal infection. Respiratory TB. Pregnancy Category C.
fluticasone propionate (Flonase)	Allergic rhinitis	50 mcg/spray: 2 sprays per nostril daily or 1 spray per nostril 2 times daily	Available in metered pump. Maintain regular regimen. Monitor for visual changes. **Adverse effects:** Local irritation, increased rhinorrhea, localized fungal infection. Caution with CYP3A4 inhibitors (e.g., ketoconazole). Pregnancy Category C.

Drugs Commonly Prescribed 8.5 Rhinitis—cont'd

Drug	Indication	Dosage	Prescribing Considerations
triamcinolone acetonide (Nasacort)	Allergic rhinitis	55 mcg/spray: 2 sprays per nostril once a day	Available in aerosol or metered pump. Maintain regular regimen. Monitor for visual changes. **Adverse effects:** Headache, viral infections. Pregnancy Category C. It is unknown if drug accumulates in breast milk; however, other corticosteroids are excreted in breast milk. Nursing mothers should use with caution.
mometasone furoate (Nasonex)	Allergic rhinitis	50 mcg/spray: 2 sprays per nostril once daily	Begin 2–4 weeks before start of pollen season. Maintain regular regimen. Monitor for visual changes. **Adverse effects:** Local irritation, increased rhinorrhea, localized fungal infection. Caution with CYP3A4 inhibitors (e.g., ketoconazole). Pregnancy Category C.
Anticholinergic			
ipratropium bromide nasal spray 0.03%, 0.06% (Atrovent)	Prevention of rhinorrhea	21 mcg/spray: 2 sprays per nostril 2–3 times daily 42 mcg/spray: 2 sprays per nostril 2–3 times daily	Does not relieve itching or nasal blockage. **Adverse effects:** Epistaxis, pharyngitis, nasal dryness. Avoid in patients with BPH, glaucoma. Pregnancy Category B.
Mast Cell Stabilizer			
cromolyn sodium (Nasalcrom)	Prevention and relief of nasal allergy symptoms	5.2 mcg/spray: 1 spray per nostril 3 or 4 times daily; maximum 6 sprays/nostril/day	Regular use required. Do not use to treat sinus infection or asthma.
Other Categories			
Leukotriene receptor agonist (Singulair)	Seasonal rhinitis	4 mg or 5 mg chewable tabs PO once daily	Monitor with potent CYP450 inducers and with drugs metabolized by CYP2C8. **Adverse effects:** URI

Desensitizing immunotherapy may be an option for allergic rhinitis that is refractory to pharmacological treatment. Patients receive subcutaneous injections of purified allergen weekly at a dosage that increases with each treatment. The interval between injections is lengthened once a maintenance dose is reached. This treatment regimen may last up to 3 to 5 years, but it should not be continued past 12 months if symptoms are not improving; cure rates may be as low as 20%. In addition, to reduce the risk of anaphylactic reactions, antigen injections must never be given intravenously. Occasionally, surgery is recommended if the etiology of refractory or recurrent rhinitis is anatomical, including nasal polypectomy for obstructing lesions or septoplasty if septal deviation is significant enough to interfere with the benefits of medication.

Follow-up and Referral

A return visit should be scheduled in 2 to 3 weeks to review patient education, adherence to the treatment plan,

and effectiveness of prescribed treatments. After this, quarterly or biannual visits are recommended, depending on the patient's comfort level and general state of health.

Complications of most forms of rhinitis include serous OM (extension of nasal infection into the ear), acute or chronic sinusitis, and repeated or disseminated respiratory infections. Allergic rhinitis may lead to restless sleeping and chronic fatigue, and asthma may complicate allergic attacks. Rhinitis medicamentosum may be complicated by physical addiction to topical nasal decongestants, because relief periods shorten and severity of rebound congestion increases with each use. Thus, stopping the use of these drugs becomes especially difficult for the addicted patient.

Physician referral may be necessary for allergen skin testing, allergen immunotherapy, or nasal irrigation. The diagnosis and treatment of certain sequelae such as chronic sinusitis or high fever may also require physician referral. Surgical referral is necessary if anatomical obstructions of the nasal cavity (e.g., nasal polyps or a deviated septum) are etiological or complicating factors.

Patient Education

Viral rhinitis is best avoided by limiting exposure to persons with an acute URI. Allergic flare-ups are best prevented by avoiding exposure to environmental irritants. Many preventive steps may be taken. Windows and doors should be kept closed to reduce pollen entry into the household, and high-efficiency particle air (HEPA) filters are helpful in removing allergens from ambient air. Pet traffic from outside should be minimized because this may transport pollen indoors, and patients should avoid being outside on excessively sunny or windy days. Allergic attacks to mold spores can be prevented by avoiding piles of leaves during the fall months, by wiping down household surfaces where mold grows with bleach solutions, using HEPA filters, and reducing ambient humidity to 30% to 40%. Allergic attacks caused by perennial antigens such as dust or mites can be minimized by thoroughly cleaning or removing all carpets, drapes, curtains, and fabric-covered or stuffed furniture from the house, as well as by damp mopping, floor waxing, and dusting of all surfaces with a damp cloth. Stuffed animals, feather pillows, rubber mattresses, and box springs should either be covered with plastic or removed and replaced with synthetic materials, such as polyester. Chenille bedspreads, quilts, or comforters should be avoided, and bedding should be washed weekly. The use of air conditioning with frequent filter changes, rather than open windows, to cool automobiles or homes is recommended. Patients who are allergic to animal dander should bathe their pets often and restrict them from the bedroom or from the house altogether. Prophylactic use of 4% cromolyn sodium nasal spray (one spray in each nostril 3–6 times/day at regular intervals) before known antigen exposure may prevent allergic flare-ups but is ineffective once an attack is underway. Ophthalmic cromolyn sodium preparations are also available for the symptom of itchy eyes (1 to 2 drops can be instilled in each eye 4 to 6 times/day). Vasomotor rhinitis is also best avoided by limiting exposure to environmental triggers, and rhinitis medicamentosum can be prevented by diligently monitoring topical nasal decongestant use.

Patients with allergic rhinitis should be taught to avoid allergens and to observe the onset, duration, and progression of symptoms so that they can correlate their flare-ups to environmental conditions and thus better guide self-treatment. Emphasize all preventive and prophylactic measures, particularly the importance of keeping bedrooms allergen-free. Patients with all forms of rhinitis should understand the reasoning behind limiting nasal decongestant use, as well as the appropriate use of prophylactic cromolyn sodium sprays. It is also critical to explain that symptomatic relief from topical nasal steroid preparations may not be evident until 2 weeks into therapy. All patients should be instructed to arrange for further evaluation if clear rhinorrhea becomes purulent.

SINUSITIS

Sinusitis is an inflammation of the mucous membranes of one or more of the paranasal sinuses: frontal, sphenoid, posterior ethmoid, anterior ethmoid, and maxillary, with the latter two sinuses most often affected. This inflammation may be classified as (1) acute, which is characterized by an abrupt onset of infection and post-therapeutic resolution of symptoms lasting no more than 4 weeks; (2) subacute, in which a purulent nasal discharge persists despite therapy and lasts from 4 to 12 weeks; or (3) chronic, which occurs with episodes of prolonged inflammation with repeated or inadequately treated acute infection lasting greater than 12 consecutive weeks.

Epidemiology and Causes

The frequency of upper respiratory tract infections (the "common cold") accounts for the frequent occurrence of sinusitis in the general population. Researchers have estimated that 0.5% of all colds are complicated by bacterial infection of one or more of the paranasal sinuses. Acute bacterial sinusitis accounts for 16 million clinical visits annually, whereas chronic sinusitis is classified by the U.S. Public Health Service as the most common chronic disease in the United States and is estimated to account for more than 2 billion dollars a year in healthcare costs. Sinusitis affects adults of all ages, males and females equally, with no specific ethnic predisposition.

Mucosal inflammation and congestion from a viral URI that lasts more than 7 to 10 days is a primary risk factor for sinusitis (especially for maxillary sinus involvement), particularly during the autumn, winter, and spring seasons. Smoking; exposure to air pollution; persistent coughing; sneezing against a closed mouth; exposure to cold, damp outdoor weather or dry indoor

heat; sudden changes in temperature; injury to the nose or sinuses from foreign bodies (e.g., nasogastric tubes or nasotracheal intubation) or trauma; nasal polyps; and chronic use of OTC or prescription decongestants may all impair mucociliary function, which can lead to mucosal inflammation, blockage of the sinus ostia, hypooxygenation of the sinuses, and transudation of fluid because of negative sinus pressure. Dental abscesses with oroantral fistulae extending into the paranasal sinuses can introduce pathogenic microorganisms; this etiology is associated with 10% to 15% of acute sinusitis cases. In addition, particularly during the summer months, airborne allergens, as well as swimming, diving, and jumping into contaminated water without holding the nose, are also common mechanisms for sinusitis to develop; allergic rhinitis is seen in 25% of sinusitis cases. Traveling in an airplane while suffering from a URI may predispose an individual to develop sinusitis. Recurrent or persistent bacterial infection resulting from blockage of nasociliary sinus drainage via the sinus ostia has been particularly associated with subacute and chronic sinusitis. Mechanical blockage may result from anatomical abnormalities such as a deviated septum, adenoidal hypertrophy, nasal polyps, reduced ostial diameter, and sinus or nasal neoplasms. Half of all asthmatic patients suffer from some form of sinusitis as a result of their inflammation-prone, hypersensitive airways. Furthermore, mucosal immunoglobulin A (IgA) deficiency, immobile cilia syndrome (Kartagener's syndrome), and cystic fibrosis also contribute to decreased mucociliary clearance and persistent sinus infection resulting from stasis. Chronic inflammatory diseases such as sarcoidosis and Wegener's granulomatosis also predispose patients to mucosal inflammation. In particular, diabetic, HIV-infected, malnourished, or other chronically immunocompromised patients may develop severe, invasive sinus disease.

Pathophysiology

Infection by nonendogenous pathogens and bacterial invasion of the sinuses by normal nasal or pharyngeal microbial flora are the primary causes of acute sinusitis. The vast majority (more than 95%) of acute sinusitis cases are caused by the same viruses associated with uncomplicated URIs. However, many of these patients do not seek primary-care interventions. Viral sinusitis (more accurately termed *viral rhinosinusitis*) is most commonly caused by the following five viruses, which collectively account for 80% of all URIs: rhinovirus (30%), coronavirus, adenovirus, echovirus, and coxsackievirus, as well as respiratory syncytial virus, parainfluenza virus, and influenza virus.

Viral rhinosinusitis is the main predisposing factor for acute bacterial sinusitis, which complicates about 2% of all cases. During these episodes, mucosal secretions from sinus goblet cells increase in volume and viscosity. The nasal mucosa also swells in response to viral replication, creating an anatomical barrier to the steady outflow of nasal secretions. Nasal polyps, foreign bodies, allergen-induced mucosal swelling, and altered sensorium affecting nasal clearance and coordinated swallowing reflexes are other potential mechanisms of impaired nasal outflow. Moreover, the act of sneezing creates a tremendous pressure in the nasopharynx up to 60 to 80 mm Hg, capable of forcing fluid not only out the nares, but from the nasal cavity into the sinuses as well, transporting viruses and bacteria into these ideal environments for microbial replication. Here the normally ciliated pseudostratified, columnar epithelium lining the sinuses is eroded as infecting organisms proliferate, resulting in a loss of mucociliary clearance through sinus ostia (bony openings) and the ostiomeatal complex located in the anterior ethmoid region, which serves as a common drainage pathway for the frontal, maxillary, and ethmoid sinuses. Blockage of the ostiomeatal complex and/or impairment of ciliary function is thought to underlie all forms of sinusitis.

The only consistently reliable method of identifying causative organisms in acute sinusitis is direct sinus aspiration, which typically is performed only in controlled research trials or by ENT specialists because of its invasive nature. The most common bacterial pathogens isolated in acute sinusitis are *Streptococcus pneumoniae,* seen in nearly 40% of all cases, particularly during the summer and fall; *Haemophilus influenzae,* implicated in nearly 30% of all cases, especially in winter and spring; and, to a far lesser extent, *Moraxella (Branhamella) catarrhalis,* a far more common pathogen in children. Thus, the infectious agents of sinusitis closely pattern those of AOM. *Streptococcus pyogenes* (especially group A beta-hemolytic *Streptococcus*) and *Staphylococcus aureus* have each been identified in 5% of sinusitis cases studied, with *S aureus* most frequently isolated in intracranial complications. The specific role of bacteria, fungi, and viruses in chronic sinusitis is hotly debated. *S aureus,* gram-negative rods, and, in up to half of cases, anaerobic bacteria (including *Peptostreptococcus* and *Bacteroides*) are most often implicated. Polymicrobial infection is also more common in chronic than acute sinusitis. *S aureus* and *Pseudomonas aeruginosa* are the most common causes of cystic fibrosis–related and nosocomial sinus infection associated with nasal or endotracheal intubation and nasogastric feeding tubes.

In the immunocompromised host, gram-negative aerobic bacteria must be considered, as well as the fungi *Aspergillus fumigatus* and *Mucor* species, both of which may cause severe, rapidly invasive sinusitis in diabetic or otherwise chronically immunocompromised patients. More common than invasive fungal sinusitis, however, is allergic fungal sinusitis occurring in atopic individuals in which the nasal and sinus mucosa undergo an IgE-mediated type I hypersensitivity response to airborne fungal spores or fungal proliferation facilitated by obstructed sinus outflow. Dematiaceous (brown-pigmented) molds

account for more than 75% of these cases, and *Aspergillus* is implicated in 10% to 20% of cases. The sinuses become filled with allergic mucin consisting of necrotic cellular debris, eosinophils, and fungal hyphae. If neither a hypersensitivity response nor an invasive sinusitis ensues, fungal colonization may result in unilateral chronic sinusitis characterized by formation of a dense fungal ball with sclerosis of the surrounding bone.

Clinical Presentation

Subjective

During the early stages of sinusitis, patients typically report a gradual onset of symptoms, including recurrent or chronic dull, constant pain over the affected sinuses (because of expanding purulent inflammation); as sinusitis progresses, pain increases and becomes characteristically throbbing. Typically, pain over the cheeks and upper teeth is correlated with maxillary sinus involvement; pain over the eyebrows indicates frontal sinus involvement; and pain over or behind the eyes indicates ethmoid sinusitis. Pain is exacerbated by coughing and sudden head movements. Specifically, frontal sinus pain may worsen with recumbency, whereas maxillary sinus pain may worsen when the patient is erect. Ethmoidal sinusitis is associated with retro-orbital pain. Notably, however, subacute and chronic sinusitis are often painless, as are some cases of acute sinusitis. These cases typically develop after at least 2 weeks of viral URI symptoms (such as a cough from postnasal drip, purulent nasal discharge, and headache). All types of sinusitis may present with nasal congestion (stuffiness), mucopurulent rhinorrhea (runny nose), a feeling of pressure inside the head, cough (in some cases), sore throat (in some cases), eye pain from ethmoid involvement, malaise, and fatigue. In particular, acute sinusitis is strongly predicted by maxillary toothache, a poor response to nasal decongestants, and a colored nasal discharge. Such patients usually report yellow-green or even blood-stained rhinorrhea, voice nasality, anosmia because of edematous nasal turbinates, early morning periorbital edema, fever and chills (in 25%–50% of cases), and a headache that is worse in the morning or when bending forward. These patients also sometimes report a nonproductive cough and disturbed sleep. Subacute or chronic sinusitis patients typically report a persistent cough or cold-like symptoms that may last from several weeks to several months, as well as a headache or feeling of pressure specifically across the cranial midline. Fever is less common, and most patients have a past history of responding poorly to sinusitis pharmacotherapy. Other symptoms include a thick postnasal discharge (postnasal drip), "popping" ears, excessive tearing, toothache-like cheek pain, difficulty chewing, and halitosis. Immunocompromised patients may present with more subtle signs and symptoms, because leukopenia may limit the inflammatory response to infection.

Objective

On inspection, purulent nasal secretions (recognized by polymorphonuclear neutrophils in a Giemsa-stained nasal smear) and total opacification of affected sinuses on transillumination (e.g., through the supraorbital or maxillary bony ridges) are strongly predictive of acute sinusitis. Although only one in four patients with decreased transillumination typically has a sinus infection, complete light transmission rules out an active sinus infection. A nasal speculum should be used to examine the anterior nasal passages. A red, swollen nasal mucosa indicates infection; a pale mucosa that appears swollen, with watery secretions, points to allergic sinusitis or rhinitis. Purulent secretions seen coming from inside the middle meatus are characteristic of sinusitis. Black or necrotic material may be seen in mucormycosis-related rhinorrhea in immunocompromised patients. Ethmoid sinus involvement may result in chemosis (eyelid mucous membrane edema), proptosis, conjunctival injection, extraocular muscle palsy, or orbital fixation.

On palpation, the affected sinuses may be exquisitely tender to palpation. Sphenoid sinusitis presents as tenderness over the vertex or mastoids, ethmoid sinusitis as retro-orbital or nasal bridge tenderness, maxillary sinusitis as cheek or dental tenderness, and frontal sinusitis as tenderness of the forehead. In the event of maxillary sinusitis related to a dental abscess, percussion over the affected sinus will produce marked tenderness in the teeth and gums.

Diagnostic Reasoning

Diagnostic Tests

It is important for the clinician to put the emphasis on clinical signs and symptoms for initial diagnosis and avoid unnecessary diagnostic tests. Even though laboratory tests and x-ray films are not needed for typical presentations of sinusitis, anteroposterior, lateral, and particularly occipitomental sinus x-ray exams can be done if symptoms show no improvement after 4 to 5 days of pharmacotherapy. Air-fluid levels, mucosal thickening beyond 4 mm, or complete opacification of the sinuses on any of these views is strongly suggestive of sinusitis. However, it should be noted that such mucosal thickening as well as impaired sinus transillumination on physical exam have both been observed in healthy, asymptomatic individuals who do not meet the criteria for acute sinusitis. In turn, the positive and negative predictive value of these diagnostic tests has consistently been questioned in the literature.

A CBC to detect leukocyte elevation may be indicated if an infectious etiology is suspected in acute sinusitis; however, leukocytosis is rarely observed in chronic sinusitis. Stains or cultures of nasal and throat secretions do not correlate with the causative agents of sinusitis because the nasopharyngeal mucosa is widely colonized by a diverse array of endogenous, nonpathogenic microbial

flora. However, the presence of at least 10,000 organisms/mL on Gram stain of sinus aspirates may confirm the presence of local sinus infection. Allergic skin testing may be necessary if the patient history suggests allergic disease (e.g., allergen exposure, seasonal attacks), and these patients often demonstrate peripheral eosinophilia and elevated total or allergen-specific IgE levels. Culture and microscopic examination of sinus aspirates, sinus mucosal biopsy, or flexible fiberoptic rhinoscopy by a well-trained specialist is typically needed only for subacute, chronic, or suspected fungal sinusitis cases that are refractory to several courses of empiric pharmacotherapy or when intracranial extension is suspected. Chronic sinusitis, in particular, is characterized by a morphological change of the ciliated sinus epithelia to a hypertrophied, stratified squamous form that is evident on biopsy.

Although sinus CT scans may demonstrate mucosal thickening and osteomeatal occlusion in a large number of people with uncomplicated viral URI, this type of imaging may be helpful in cases of chronic sinusitis, infection that has spread into orbital or intracranial regions (e.g., orbital cellulitis or brain abscess), or for an immunocompromised host, to fully evaluate the disease process. Sinus MRI is superior for soft tissue discrimination but is poor at visualizing bony structures. Thus, MRI tends to be reserved for suspected sinus neoplasia or extension of sinus disease into intracranial soft tissues.

Differential Diagnosis

Myofascial pain that is unrelated to infectious causes may mimic the pain from acute sinusitis, but pain from other myofascial disorders is typically more diffuse and does not progressively worsen. Uncomplicated dental abscesses may produce a similar pain, but the pain will not extend into the maxillary sinus on physical exam. Patients with migraine, cluster headache, or trigeminal neuralgia also present with fascial and cranial pain, but, again, the sinuses will be nontender to palpation, and the accompanying signs and symptoms of inflammation will not be observed in these patients. Allergic rhinitis, vasomotor rhinitis, rhinitis medicamentosa, mechanical nasal airway obstruction, acute viral URI (persistent viral rhinitis), and chronic inflammatory conditions such as sarcoidosis or Wegener's granulomatosis may all present with nasal congestion or pain. If these cases are uncomplicated by sinusitis, no signs of sinus inflammation will be detected on examination.

If a patient has had an URI for at least 7 days, the presence of two or more of the following signs and symptoms will confirm the diagnosis of sinusitis: colored nasal drainage, poor response to decongestant, facial or sinus pain (particularly if aggravated by postural change or Valsalva maneuver), and headache. In addition, a documented history of prior episodes of sinusitis, a fever higher than 102°F (38.9°C), and tooth pain accompanying these findings all support a diagnosis of sinusitis. Viruses may produce all of the clinical manifestations described; however, patients who meet the 7-day criteria described in the preceding text are more likely to have bacterial sinusitis than a viral URI.

Management

It is important to realize that because the vast majority of acute sinusitis cases are caused by viruses rather than bacteria, antibiotics are largely unhelpful. Their indiscriminate use for symptom complexes failing to meet the aforementioned diagnostic criteria for bacterial sinusitis offers no medical benefit, wastes financial resources, and is potentially harmful in that it encourages widespread antibiotic resistance in common nasopharyngeal flora. With this in mind, antimicrobial therapy usually cures acute uncomplicated bacterial sinusitis, although recurrence is not uncommon. Adjunctive measures may also be used to enhance mucociliary clearance, countering the main risk factor for the development of sinusitis. Saline nasal spray may be helpful in improving sinus drainage, but dedicated sinus irrigation two or more times a day with an adequate volume of saline to fully flush the sinuses has been shown to significantly relieve symptoms even without antimicrobial therapy. Patients are instructed to infuse their sinuses using a warm isotonic or hypertonic saline-filled bulb syringe expressed into each nare, followed by immediate drainage of the liquid over a sink to remove both infectious organisms and excess mucus. A number of commercial saline sinus irrigation systems with balanced salt solutions are currently available. However, homemade preparations may be made by mixing 1 teaspoon of salt with 8 ounces of warm water; noniodized salt should be used, because iodine is a known mucosal irritant. A cool-mist, ultrasonic humidifier (cleaned daily with a 1:10 solution of bleach and water) may also assist in thinning sinus secretions and facilitating drainage. Smoke and other environmental pollutants should be avoided. Fluid intake should be increased, and heated mist from a facial sauna, steam bath, shower, or hot, moist towels wrapped around the face may help relieve sinus and nasal pain by liquefying secretions.

Oral analgesics may also be used for pain (e.g., ibuprofen [Motrin, Advil] 400–600 mg every 6–8 hours as needed, acetaminophen [Tylenol] 650 mg every 4–6 hours as needed, or a stronger combination of acetaminophen 300 mg/codeine 30 mg [Tylenol 3] one to two tablets every 4–6 hours as needed). In general, nonprescription medicated nose drops and sprays should be avoided, and prescription nasal sprays should be taken no longer than 3 to 4 days at a time because long-term use can lead to rebound nasal congestion (rhinitis medicamentosum) and addiction. Phenylephrine (Neo-Synephrine; one to two upright sprays in each nostril 3–4 times daily as needed) or the stronger oxymetazoline (Afrin; one to two upright sprays in each nostril 2–3 times daily as needed) may be helpful in adults. Pseudoephedrine (Sudafed) 30 to 60 mg every 4 to

6 hours as needed is an oral alternative but tends to be less effective than topical preparations. Expectorants such as guaifenesin 200 to 400 mg every 4 hours as needed and iodinated glycerol 30 to 60 mg PO 4 times daily as needed are used to liquefy sinus secretions and facilitate drainage. Anti-inflammatory topical steroids in nasal spray preparations such as fluticasone 0.05% (Flonase), mometasone (Nasonex), or triamcinolone (Nasacort), all at two sprays in each nostril daily, used for 2 to 3 weeks are becoming increasingly popular; however, randomized controlled trials have been inconsistent with regard to their effectiveness. In fact, steroid therapy has actually been shown to increase viral load in acute viral rhinosinusitis. Oral antihistamines should be avoided unless an allergic component is evident because they tend to dry the mucosa, thicken purulent sinus fluids, and slow mucosal drainage, although some studies have suggested their efficacy in symptomatic relief of uncomplicated viral URIs.

Although localized sinus infection may be self-limited, antibiotic and symptomatic therapy may be considered appropriate for suspected bacterial sinusitis to prevent disease progression and complications. Empiric antibiotic therapy for 7 to 10 days covering the most common etiological agents should be instituted before the identification of causative organisms because symptoms may progress while laboratory confirmation is awaited. In adults, common choices include narrow-spectrum antibiotics such as amoxicillin (Amoxil) 500 mg to as high as 1 g PO 3 times daily, trimethoprim/sulfamethoxazole (Bactrim) 160 mg/800 mg, one Double Strength tablet PO 2 times daily, or doxycycline 100 mg PO 2 times daily. In light of increasing resistance of *Streptococcus pneumoniae, Haemophilus influenzae* (up to 50% of strains), *Moraxella catarrhalis,* and virtually all *Staphylococcus aureus,* one of the following beta-lactamase–resistant alternatives may be considered: clarithromycin (Biaxin XL) 1,000 mg PO daily, cefaclor (Ceclor; second generation cephalosporin) 500 mg PO every 6 hours, cefpodoxime (Vantin; third generation cephalosporin) 200 mg PO 2 times daily, cefdinir (Omnicef; third generation cephalosporin) 600 mg PO daily, levofloxacin (Levaquin) 750 mg PO daily, moxifloxacin (Avelox) 400 mg PO daily, gatifloxacin (Tequin) 400 mg PO daily, and amoxicillin/clavulanate (Augmentin XR) 1,000 mg/125 mg PO 2 times daily. Penicillin-allergic or cephalosporin-allergic patients are usually steered toward an oral quinolone or trimethoprim/sulfamethoxazole as first-line therapy. Immunocompromised hosts typically require broad-spectrum coverage for gram-positive and gram-negative organisms and possibly empiric antifungal therapy. Tetracyclines do not cover *Streptococcus pneumoniae,* however; and erythromycin, penicillin, and first generation cephalosporins do not cover *Haemophilus influenzae.* Acute infections that fail to clear after one course of antibiotic therapy are often treated with a second course from a separate antibiotic class for 14 days.

Antibiotics against anaerobic organisms such as *Peptostreptococcus* and *Bacteroides* are typically required for subacute and chronic sinusitis, with regimens lasting up to 3 to 4 weeks or even as long as 6 weeks for refractory chronic cases. Antibiotic regimens include amoxicillin/clavulanate (Augmentin XR) 1,000 mg/125 mg PO every 12 hours or cefuroxime (Ceftin; second generation cephalosporin) 250 to 500 mg PO 2 times daily. For penicillin-allergic patients, antibiotics include clarithromycin (Biaxin XL) 500 mg PO daily or clindamycin (Cleocin) 300 mg PO every 6 hours; for documented gram-negative infection, one of the fluoroquinolones (e.g., levofloxacin, moxifloxacin, or gatifloxacin) should be prescribed at the doses mentioned previously. Patients requiring three or more antibiotic courses will likely benefit from referral to an otorhinolaryngologist for further diagnostic work-up. Similarly, serious invasive fungal sinusitis often requires surgical debridement and inpatient intravenous antifungal therapy with amphotericin B (1 mg/kg IV daily) or, if not tolerated due to rigors, chills, or hypotension, a liposomal amphotericin preparation (Abelcet; 5–7.5 mg/kg IV daily). In contrast, allergic fungal sinusitis calls for sinus drainage and systemic corticosteroids for 2 to 4 weeks followed by topical steroid therapy, because the benefits of antifungal therapy have not been clearly demonstrated. Fungal balls associated with sinus colonization must be removed surgically, because neither steroids nor antifungals have been shown to be effective in relieving obstruction.

Maxillary sinus puncture and aspiration may be needed to relieve pain in any form of sinusitis that fails to subside following pharmacotherapy, and patients with subacute or chronic sinusitis may require surgery to remove damaged mucosal tissue or to correct anatomical obstructions of the sinus ostia such as recurrent nasal polyps. In addition, complementary therapies may be considered in the treatment of patients with chronic sinusitis. Several studies indicate that vigorous exercise, for example, has been shown to improve nasal function (through vasoconstriction and decreased nasal resistance) in healthy patients, as well as those with allergic rhinitis. The same benefits may also result in patients with chronic sinusitis. Some patients with particularly severe chronic disease have reported trying acupuncture, herbal therapies, biofeedback, and self-help groups.

Prompt treatment of all respiratory infections can prevent acute sinusitis complications, and surgery to correct anatomical blockages of the sinus ostia (e.g., deviated septum or nasal polyps) may prevent chronic sinusitis. When sinus inflammation is connected with an allergy, desensitization by a trained allergist should be considered. Recurrent attacks of sinusitis can sometimes be prevented by the routine use of a humidifier and/or air conditioner. Nose drops or sprays should be discarded after use during an acute episode, however,

and should never be shared to avoid person-to-person transmission of infectious organisms.

Follow-up and Referral

Patients should be reevaluated for symptomatic improvement in 48 to 72 hours, and a return visit should be scheduled for 10 to 14 days from the initial assessment. If symptoms fail to improve with pharmacotherapy, the patient should be evaluated for antibiotic resistance, allergic contributions, or immunological abnormalities. Sinus x-ray films may remain abnormal for up to 2 months after the resolution of acute sinusitis, so follow-up films to document improvement are not usually indicated until at least 6 weeks after initial therapy. Immunocompromised patients with sinusitis should be monitored daily in an inpatient setting.

Although complications are relatively uncommon, visual impairments, ophthalmoplegia, orbital or facial cellulitis, severe fever, aphasia, abducens palsy (CN VI deficit), seizures, altered mental status, osteomyelitis of the frontal or maxillary bones, and focal swelling over the frontal bone are all reflective of localized extensions of bacterial infection. Rare but potentially life-threatening complications that require a high index of suspicion include meningitis, subdural empyema, epidural abscess, cavernous sinus thrombosis, and other CNS complications.

Patients should be referred to a specialist if their sinusitis is allergic or immunological, refractory to antibiotic therapy, recurrent, or associated with unusual opportunistic infections, or when the infection is adversely affecting their quality of life. In addition, when sinusitis is associated with chronic OM, bronchial asthma, nasal polyps, recurrent pneumonia, immunodeficiency, allergic fungal disease, granulomas, or multiple antibiotic resistances, the patient should be referred to an allergist or an otolaryngologist.

Patient Education

Patients should be instructed to be wary of worsening symptoms after the institution of pharmacotherapy. Patients should also be informed of potential complications and should be instructed to contact the practitioner at once if telltale signs such as periorbital swelling develop. The clinician should stress the importance of avoiding contact with all contributing factors (e.g., cigarette smoke or airborne allergens), as well as the exacerbating side effects of nonprescription antihistamine use. Patients should make sure that OTC decongestant preparations do not contain antihistamines, and they should drink plenty of fluids to thin nasal secretions.

STOMATITIS AND GLOSSITIS

Stomatitis is a generalized inflammation of the oral mucous membranes characterized by erythema and/or vesicular or ulcerative lesions. *Glossitis* is an acute or chronic inflammation of the tongue that shares many of the same etiologies as stomatitis. Either of the two may present alone, although glossitis often accompanies stomatitis, and clinicians often group the two conditions together under the latter designation. In general, both disorders are classified according to their etiology, which is extremely variable.

Epidemiology and Causes

A variety of types of stomatitis are seen in adults; these include oral candidiasis, aphthous stomatitis (aphthous ulcers, or "canker sores," often reoccur, and may be referred to as recurrent aphthous stomatitis [RAS]), secondary herpetic stomatitis/herpes labialis, Vincent's stomatitis (acute necrotizing ulcerative gingivitis, or "trench mouth"), allergic stomatitis, nicotinic (cigarette-related) stomatitis, denture-related stomatitis, angular stomatitis, pseudomembranous stomatitis, and parasitic glossitis (black hairy tongue, anthracosis linguae). Glossitis is also a common symptom of systemic skin diseases such as erythema multiforme (Stevens-Johnson syndrome) and pemphigus vulgaris. Herpetic stomatitis and RAS occur commonly, as do nicotinic and denture-related stomatitis. Other causes are less commonly seen.

Herpes simplex virus (HSV) infection in the United States is widespread. According to recent estimates, up to 20% of the adult population may be secreting herpes simplex type 1 or 2 viruses at any given time. The prevalence of HSV-specific antibodies indicative of past or dormant HSV infection is up to 30% in higher socioeconomic strata and may approach 100% in lower socioeconomic groups. In general, prevalence of infection is estimated to be between 20,000 and 70,000 per 100,000. Oral candidiasis most commonly occurs in immunocompromised adults, such as patients with HIV infection or in cancer patients after chemotherapy and/or radiation therapy. Nicotinic stomatitis and denture-related stomatitis are common. Most other forms are rare among adults. Mouth sores may affect adults of all ages. Specifically, Vincent's stomatitis is seen among adolescents and adults aged 20 to 40 years, whereas denture-related stomatitis affects primarily elderly patients.

Chronic mouth-breathing dries the tongue and oral mucosa, and hot foods or beverages may lead to thermal injury. Chemical irritation may result from spicy, acidic, or salty foods such as potato chips and pickles, as well as from peroxide-containing mouthwashes, toothpaste, and other dental care products. Viral, bacterial, and fungal infections, prolonged radiation or chemotherapy treatments, long-term corticosteroid or antibiotic use, chronic metabolic diseases such as diabetes, emotional or physical stress, anxiety, depression, premenstrual tension, advanced age, low socioeconomic status, and malnourishment may all contribute to host immunosuppression and in turn to the development of stomatitis/glossitis. Systemic autoimmune or inflammatory diseases also predispose patients to these conditions. Pregnancy has been associated with erythema multiforme. Tobacco

smoking and chewing (dipping snuff) clearly can lead to nicotinic stomatitis, whereas ill-fitting dentures, recent dental work, repeated biting during convulsive seizures, and poor oral/dental hygiene contribute to mechanical injury–related inflammation of the oral cavity and tongue. Occupational or domestic exposure to chemical irritants or allergens are risk factors, as are resective gastrointestinal surgery involving the ileum and malabsorptive disorders of the ileal mucosa such as sprue (villous atrophy), both of which impair vitamin B_{12} absorption, contributing to angular and other vitamin deficiency–related forms of stomatitis. In fact, anemia of any type is a risk factor. Repeated emesis secondary to bulimia may inflame the oral mucosa and erode the posterior (lingual) surfaces of the teeth because of repeated exposure to stomach acid in the vomitus. In addition, anorexia, bulimia, and off-and-on ("yo-yo") dieting may lead to malnourishment, vitamin deficiencies, or immunosuppression.

Prior HSV infection is the primary risk factor for all secondary manifestations of herpes simplex infection. In addition, any factors that lead to immunosuppression may be considered contributing factors. Specifically, fever, physical and/or emotional stress, excess sun exposure, menstruation, common colds, gastrointestinal upset, and dental work that excessively stretches the mouth, as well as other underlying systemic illnesses, may be considered precipitating factors. Intercourse with multiple sexual partners and unprotected sex (failure to use barrier protection, e.g., condoms during intercourse or oral sex or latex dental dams during oral sex) increase the likelihood of HSV transmission from infected sexual partners.

Pathophysiology

In general, excessive dryness of the oral cavity; food and drug allergies; chemical irritation; mechanical or thermal injury; bacterial, fungal, and viral pathogens (e.g., coxsackievirus causing hand-foot-and-mouth disease, varicella-zoster virus causing oral and lingual vesicular lesions, primary HIV infection); host immunosuppression; and nutritional deficiencies of iron, folate, riboflavin (B_2), niacin, pyridoxine (B_6), and cyanocobalamin (B_{12}) are all risk factors that can cause stomatitis and glossitis. Aphthous ulcers are one of the most common types of oral lesions, yet their pathogenesis is poorly defined. Stress, hormonal fluctuations, inflammatory bowel disease, and antimetabolite chemotherapies all predispose a patient to aphthae. Specifically, the spirochete *Borrelia vincentii* and certain fusiform *Bacillus* bacterial species are strongly associated with Vincent's stomatitis, although some cases are of indeterminate etiology. If complicated by HIV infection and left untreated, this condition may progress to necrotizing stomatitis. Nicotinic stomatitis results directly from the chemical irritants in tobacco. Denture-related stomatitis results from the mechanical injury caused by ill-fitting dentures. Angular stomatitis is symptomatic of the vitamin deficiencies discussed in the preceding text, and pseudomembranous stomatitis has been associated with numerous chemical irritants and bacterial pathogens.

Parasitic glossitis is caused by several mycoses of the tongue, including *Cryptococcus linguae-pilosasae* and *Nocardia lingualis* co-infection. The use of systemic antibiotics is well known to clear normal microbial flora from the oral cavity and, in fact, the entire gastrointestinal tract, thus facilitating fungal overgrowth caused by the lack of endogenous microbial competition. In addition, both oral and inhaled steroids are known to compromise cellular immunity within the oral cavity—the main defense mechanism against fungal overgrowth and infection. HIV infection and AIDS, malignancy, chemotherapy, diabetes mellitus, and age-related decreases in natural immunity may all contribute to immune suppression as well, increasing the likelihood of fungal overgrowth and viral reactivation of HSV.

Erythema multiforme is a widespread immune-mediated inflammatory reaction of the skin and in the advanced stages can involve the mucous membranes, including the oral cavity. This condition may be caused by different types of infection (e.g., HSV, *Mycoplasma, Streptococcus pyogenes*), drug allergies (e.g., anticonvulsants, sulfonamides, allopurinol), as well as collagen vascular disorders. However, oral involvement in erythema multiforme, as well as its extreme forms (Stevens-Johnson syndrome, toxic epidermal necrolysis) will never be isolated to stomatitis, because these are systemic, life-threatening conditions. In contrast, the etiology of pemphigus vulgaris is unknown, but flaccid bullae typically begin in the oropharynx as superficial epidermal layers separate from their base. A similar appearing blistering disorder, bullous pemphigoid, only rarely presents with isolated oral lesions; but as this disease progresses, roughly one-third of individuals may demonstrate oral involvement. A number of inherited disorders of the epidermis and dermis known collectively as epidermolysis bullosa may also involve the oral mucosa in their moderate and severe forms. Finally, a wide array of autoimmune disorders such as systemic lupus erythematosus may also present with mucosal ulcerative lesions.

Clinical Manifestations

Subjective

In general, patients with stomatitis may complain of excessive dryness of the mouth; halitosis; difficulty speaking or swallowing; minor to severe oral pain; or bleeding, swollen, or erythematous gums; as well as constitutional symptoms (including fever, malaise, headache, and weight loss) that may be secondary to infection or malnourishment. Additionally, patients with Vincent's stomatitis may complain of excess salivation. Patients with secondary herpetic stomatitis usually report a 24- to 48-hour prodrome consisting of a burning sensation in the

mouth, followed by the appearance of 1- to 2-mm vesicular lesions, initially fluid-filled bullae, which then evolve into ulcerated lesions, which eventually crust over the course of several days. These frequently appear around the lips. Although most patients report only one to two recurrences per year, 5% to 25% of patients suffer more than one attack per month. Patients may also report itching and burning in the mouth, particularly in cases of allergic stomatitis. In contrast, parasitic glossitis is usually painless, whereas anemia and niacin deficiency lead to lingual pain.

Objective

The mouth and the tongue (if also inflamed) often appear bright red and swollen, either at the tip and edges (from vitamin deficiencies or mechanical injury) or over the entire glossal surface. Depending on the cause of inflammation, the tongue may be ulcerated (from niacin deficiency, streptococcal infection, erythema multiforme, or pemphigus) or smooth and pale (from iron, folate, or B_{12} deficiencies). Vincent's stomatitis causes necrotic ulceration of the interdental gingival papillae and oral mucous membranes, characterized by a purulent, gray exudate. Allergic stomatitis causes intense, shiny erythema and slight swelling of the mucosa and tongue. Nicotinic stomatitis presents with centrally erythematous white nodular elevations, and pseudomembranous stomatitis produces a membrane-like exudate coating the oral mucosa. Inflammation and external fissuring of the corners of the mouth are characteristic of angular stomatitis. Parasitic glossitis presents with hypertrophied (1-cm) filiform papillae that color the dorsum of the tongue dark brown or black. In contrast, syphilis and mouth-breathing result in white patches on the tongue. Erythema multiforme presents with polymorphous disseminated macular, papular, nodular, vesicular, bullous, and target (bull's-eye–shaped) lesions of the skin and mucous membranes. Pemphigus is also characterized by disseminated thin-walled bullae throughout the skin and mucosa, which, when ruptured, leave raw patches. The lesions of pseudomembranous stomatitis cannot be scraped off with a tongue blade, whereas the lesions of parasitic glossitis are easily broken. Anterior cervical or jaw lymphadenopathy may be felt in cases that are related to autoimmune or systemic inflammatory disease.

Inspection of the oral mucosa of patients with HSV infection reveals individual or groups of 1- to 2-mm vesicular lesions that evolve into ulcers, apparent after the prodromal period (24–48 hours, characterized by pain, tingling, burning, and itching preceding vesicle formation), particularly on the gingivae, hard palate, buccal mucosa, and tongue. If observed at a later stage of healing (4–10 days after vesicle formation), oral lesions may appear ulcerated but crusted over. Herpes labialis presents as similar clusters of open vesicular lesions in the labial area, particularly at the mucocutaneous border, with erythematous bases and possibly crusting, if the lesions are in an advanced stage of healing. Palpation of the oral mucosa may demonstrate edema or tenderness, aiding in the identification and characterization of oral lesions. Anterior cervical or jaw lymphadenopathy may be felt in both conditions.

Although not directly related to HSV infection, back percussion to the posterior lungs may reveal the dull tones of pulmonary consolidation characteristic of lung infections (e.g., tuberculosis) common to HIV infection, AIDS, or other immunocompromising disorders that often underlie the reactivation of HSV infection. Likewise, chest auscultation may reveal signs such as crackles, crepitus, or wheezing, which may indicate the presence of systemic inflammatory disease or pulmonary infections secondary to an underlying immune disorder.

Oral candidiasis may exhibit diverse clinical patterns, and some patients exhibit more than one form. Factors that affect clinical presentation are the immune status of the host, such as the presence of HIV or a history of organ transplant, as well as the oral mucosal environment, for example, the impaired salivary function seen in Sjögren's syndrome, postradiation xerostomia, or age-related atrophy, and whether the person is dentate or edentulous (more common) and a nonsmoker or smoker (more common). Pseudomembranous candidiasis, also known as "thrush," is recognized by the development of creamy white plaques that resemble cottage cheese or curdled milk. When these plaques are scraped off, an erythematous mucosa is exposed. There is also an erythematous candidiasis, in which the oral mucosa appear fiery red and the mouth feels like it has been "scalded with a hot beverage." This form often follows broad-spectrum antibiotic therapy but is also associated with immunosuppression and xerostomia. Breath mints, cinnamon gum, mouthwash, or toothpaste can cause allergic reactions that mimic this form of candidiasis; so the patient's history is very important in differentiating the clinical picture because treatment will vary accordingly.

Chronic hyperplastic candidiasis, or candidal leukoplakia, is the least common form of oral candidiasis. Patients have a white patch (leukoplakia) that cannot be scraped off. Some researchers believe that this is a candidiasis superimposed on a preexisting leukoplakia lesion. Hairy leukoplakia is associated with Epstein-Barr virus (EBV). These white mucosal lesions do not rub off and may appear as faint vertical streaks or thick, furrowed areas of leukoplakia. *Candida* is present without the tissue's normal inflammatory reaction to the fungus. Hairy leukoplakia has been reported in organ and bone marrow transplant recipients and, on rare occasions, in immunocompetent patients. However, its presence strongly suggests HIV infection in an individual with no other signs of immune suppression. HIV patients with hairy leukoplakia frequently develop AIDS within 2 years of the lesion onset. Other conditions leading to an inflamed appearance of the oral mucosa include

systemic or local vasculitis and oral neoplasia; the latter (oral or glottic cancer) often presents as a single, painless lesion. Biopsy is needed to rule out these conditions if lingual or mucosal lesions are chronic or recurrent. Measles (roseola paramyxovirus infection) also leads to erythematous patches with bluish white centers on the lingual and buccal mucosa, known as Koplick's spots. However, this systemic infection is accompanied by a skin rash, cough, and coryza 24 to 48 hours after the appearance of these distinctive oral lesions.

Diagnostic Reasoning

Diagnostic Tests

Stomatitis or glossitis may result from multicausal phenomena. However, detecting the primary underlying problem is key to effective management. A CBC may reflect bacterial infection if polymorphonuclear neutrophils are elevated or viral infection if lymphocytes and mononuclear leukocytes predominate. Biochemical tests, special cellular stains, and cultures are used to identify most causative microorganisms, along with specific serologies such as the RPR test for the syphilitic agent *Treponema pallidum.* Serum levels of iron, folate, riboflavin, niacin, or cyanocobalamin may reveal nutritional deficiencies that can cause stomatitis and glossitis. Autoimmune disorders are diagnosed through a wide array of serologies (e.g., antinuclear antibody test for systemic lupus erythematosus).

Herpetic stomatitis caused by HSV may be ruled out via serum levels of anti-HSV antibodies, viral culture, or a Tzanck smear of lesional scrapings, which will present as multinucleated giant cells with intranuclear inclusions. Concurrent genital lesions are common in herpetic infection, as is also the case with Behçet's disease, a neutrophilic inflammatory disorder treated with topical and systemic steroids, which does not appear infectious. Non–*Candida*-related pseudomembranous stomatitis may be distinguished from oral candidiasis by negative findings for the fungus on Gram stain or more appropriately 10% potassium hydroxide wet mount of lesional scrapings. Oral candidiasis, as well as lichen planus, may resemble nicotinic stomatitis. Lichen planus may be ruled out by biopsy, which demonstrates hyperkeratosis, irregular acanthosis, and lymphocytic dermal band–like infiltrates. Biopsy is also indicated in the case of suspected neoplasia.

Viral culture and serological tests may rule out measles and other viral infections, including infectious mononucleosis (EBV infection), warts (papillomaviruses), prodromal primary HIV infection, and severe cases of chickenpox (varicella-zoster infection), which may also present with vesicular lesions of the oral cavity, pharynx, and larynx.

Differential Diagnosis

The primary goal of the differential diagnosis for mouth sores is to determine their precise cause because etiology of these lesions is so variable. Although the aforementioned hematological screens (CBC and nutrient levels) and serological tests may be used to detect specific pathogens or nutritional deficiencies, the signs and symptoms elicited from patient history and physical exam provide the most useful information in determining the cause of mouth sores. For example, self-induced vomiting associated with bulimic disorders should be ruled out through a careful patient history. Similarly, physical exam can rule out aphthous stomatitis, which, unlike the other forms listed, produces characteristic shallow, grayish, nonvesicular ulcers surrounded by a ring of hyperemia and covered with a fibrinous yellow membrane. Pregnancy epulis (pregnancy gingivitis) results from hormonal changes and may be confused with other forms of stomatitis. However, hyperplasia is usually limited to the interdental papillae, and pyogenic granulomas may form. "Geographic tongue" (benign migratory glossitis), which may be confused with pathological forms of glossitis, presents as continuously changing areas of loss and regrowth of filiform papillae with thickened white borders surrounded by red patches, creating a map-like appearance of the tongue. Geographic tongue is considered to be a harmless, normal variant requiring no treatment.

Management

Most cases of stomatitis are effectively treated with outpatient care unless severe or resulting from an underlying disease requiring inpatient care (e.g., advanced syphilis). For example, if severe dehydration secondary to oral pain and dysphagia is present, parenteral fluids may be required.

- All behaviors or conditions contributing to lesion formation should be stopped or corrected (e.g., smoking, eating hot or spicy foods, or wearing ill-fitting dentures).
- Underlying causative infections should be treated appropriately, but treatment specific to oral inflammation is primarily symptomatic and pharmacological.
- Baking soda or salt water rinses three or more times a day (½ tsp. salt or sodium bicarbonate in 8 oz. water) may be sufficient to relieve mild discomfort. Alternatively, oral rinses of half strength 3% hydrogen peroxide solution (1:1 with water) may be used.
- Liquid antacids such as attapulgite (Kaopectate), aluminum hydroxide (Amphogel), or magnesium hydroxide (Maalox) may effectively relieve pain when taken 4 times daily.
- Equal amounts of antihistaminic elixirs such as diphenhydramine (Benadryl) may be mixed with liquid antacids (1:1) and used as an oral rinse to reduce inflammation.
- Nonprescription analgesics such as acetaminophen (Tylenol) 650 mg every 4 to 6 hours may be used to relieve mouth pain.

- A viscous solution of 2% lidocaine may be applied to oral lesions every 3 hours as a topical anesthetic or used as a gargle or swish and spit (15 mL) before meals and every 3 hours as needed.
- Severe attacks in adults may require topical gel–based 0.1% triamcinolone (Kenalog) or fluocinonide applied at bedtime and, if needed, 3 times daily after meals.
- Anti-inflammatory oral steroid "bursts" may be appropriate in severe cases of stomatitis and glossitis, but all oral medications should be monitored for toxicity because significantly more absorption than expected may result from open oral ulcers. In addition, steroids would not be indicated in immunosuppressed patients or those with viral infections, although antiviral medications such as amantadine (Symmetrel) may be appropriate. For cases of HSV, ice cubes applied locally for an hour to newly formed lesions may prove helpful; likewise, drinking cool liquids and sucking on frozen juice bars may reduce discomfort.
- Pharmacological preparations for HSV may be helpful such as Valtrex 1 g 2 times daily for 2 days or Famvir 500 mg 2 times daily for 5 days.
- High fluid intake and antiseptic mouthwashes (without alcohol, which may be irritating and painful) may help prevent secondary bacterial infection.

In cases of candidiasis, antifungal agents should be used in conjunction with antibiotics and oral hygiene.

- Nystatin (Mycostatin, Nilstat), a polyene antibiotic, is formulated for use as a pastille (lozenge) or suspension 400,000 to 600,000 units PO (swish and swallow) 4 times daily. Because it is not absorbed across the gastrointestinal tract, the drug must remain in contact with the organism and must be reapplied several times a day.
- Clotrimazole (Lotrimin, Mycelex), an imidazole agent, is not well absorbed and must be administered at least 4 times daily as a 10-mg trouche.
- Ketoconazole (Nizoral) 200 to 400 mg PO daily for 7 to 14 days, another imidazole, is absorbed across the gastrointestinal tract and provides systemic therapy by the oral route. It should not be used routinely for routine oral candidiasis, however, because of possible drug interactions and potential liver toxicities. The triazole agent fluconazole (Diflucan) 200 mg PO on the first day, then 100 mg daily for 7 to 14 days, is well absorbed systemically and only rarely causes liver toxicity, although other drug interactions, as well as drug resistance, have been documented.
- Hydrocortisone-iodoquinol (Vytone) cream can be used to ease the discomfort of angular cheilitis. It combines the anti-inflammatory and antipruritic effects of hydrocortisone with the antifungal and antibacterial properties of iodoquinol.
- In terms of hygiene, toothbrushes should be changed frequently. A patient with candidiasis who wears dentures or partials must also treat the appliances to combat the infection.

Treatment of erythema multiforme requires eliminating exposure to the offending agent in the case of drug hypersensitivity or specific treatment to the underlying infectious agent (e.g., acyclovir for HSV infection). Specialist care by a dermatologist and close inpatient observation are required for severe cases that risk progression to Stevens-Johnson syndrome or toxic epidermal necrolysis. Vincent's stomatitis requires oral penicillin V potassium (Pen-Vee K; 250–500 mg every 4–6 hours) to fight infection, as well as significant fluid intake of at least four to six glasses of nonacidic fruit juice or water per day. Severe gangrenous stomatitis requires IV antibiotic treatment and debridement of wounds. Autoimmune disorders such as systemic lupus erythematosus, bullous pemphigoid, and pemphigus vulgarus are primarily treated with systemic corticosteroids. The mucosal lesions of lupus may be treated with topical or intralesional steroids if located on the lips, whereas lesions of the oral cavity respond to antimalarials, provided no drug hypersensitivity manifests. However, for recalcitrant cases, increasingly potent immunosuppressive medications may be necessary. Treatment of any of these disorders typically requires specialist care and rapid referral.

Dehydration and malnutrition can result from altered eating habits due to oral pain. Secondary bacterial infections may complicate any type of ulcerative oral lesion. Recent scarification of lesions may progress to facial space infection, tonsillar or cervical lymph gland infection, involvement of the vocal cords, bronchial tubes, rectum, vagina, and even sepsis. Thus, oral surgery may be needed to trim away rough, highly inflamed, infected gum tissue. Glossitis may become chronic if inadequately treated, and severe gangrenous or necrotizing stomatitis seen in severe HIV-infected cases may lead to death if untreated.

Follow-up and Referral

As for difficult to treat and refractory cases, stomatitis and glossitis due to underlying systemic disorders, such as autoimmune conditions, require specialist referral to guide further management.

Patient Education

The importance of proper oral hygiene and healthful nutritional habits should be stressed to all patients. Patients should be instructed to brush their teeth with a soft-bristled toothbrush at least twice daily and to floss regularly (once a day, if possible). Patients should also wear protective headgear whenever bicycling, skating, or playing contact sports, to prevent cases of trauma-related tongue injury. Increased fluid intake during treatment

should be encouraged, as should maintaining the recommended medication regimen while avoiding hot, spicy, salty, or acidic foods, and carbonated or alcoholic beverages. Patients may be instructed to drink through a straw if lesions are particularly painful. A liquid diet may be recommended during the first 2 to 3 days if pain is severe. Milk, liquid gelatin, yogurt, ice cream, and custard are usually well tolerated. Severe cases of Vincent's stomatitis may even call for at-home rest during the first few days of treatment.

The contagious nature of pathogen-related forms of stomatitis or glossitis should be emphasized. The most effective means of avoiding secondary manifestations of reactivated HSV infection, for example, is to refrain from behaviors that put the individual at risk of HSV infection or reinfection—most notably, unprotected sex with multiple partners and physical contact with persons who have active herpetic lesions. Kissing and oral sex should be avoided if an individual is actively infected, and frequent hand washing during active flare-ups of herpetic lesions will aid in preventing autoinfection and viral transmission. It is also helpful to inform patients of the high prevalence rate of HSV infection to reduce the stigma commonly associated with herpes. Early treatment of primary or secondary HSV infection may also help to prevent stomatic or labial involvement. Wearing zinc oxide-containing sunscreens on the lips and face helps to prevent herpes labialis flare-ups when exposed to excessive sunlight.

In the long term, the most effective means of avoiding stomatitis is to refrain from risk behaviors such as smoking, eating hot or spicy foods, drinking alcohol, and practicing poor dental hygiene. Avoiding exposure to affected persons, especially in the case of HSV, as well as avoiding exposure to allergens, chemical irritants, or foods that seem to trigger attacks, is also recommended. Care should be taken to fit all dentures and dental prostheses properly to prevent mechanical injury; for cases related to bruxism (tooth grinding), a night-guard prosthesis with removable splints to reduce biting pressure on tooth surfaces may reduce damage to dentition, in turn, preventing related inflammation. Early treatment of viral, bacterial, and fungal infections may prevent stomatic and glossal involvement. Wearing protective headgear during bicycling, skating, and contact sports could prevent trauma-related injury in the mouth.

PHARYNGITIS AND TONSILLITIS

Pharyngitis and *tonsillitis* denote generalized inflammatory processes of both infectious and noninfectious etiology, involving the pharynx and pharyngeal tonsils, respectively. Most virally related cases are self-limited, with spontaneous recovery, although other infectious cases may require antibiotic or antifungal therapy. Pharyngitis and tonsillitis may occur independently of one another; however, they often co-occur, sharing a common etiology, clinical course, and treatment regimen. Many cases of pharyngitis and virtually all cases of tonsillitis are contagious.

Epidemiology and Causes

About 8% of all patient visits in the ambulatory care setting each year are for complaints of sore throat. Viral pharyngitis related to respiratory tract pathogens occurs most often in the colder fall and winter months. Influenza infection typically occurs in epidemics between December and April. The incidence of group A beta-hemolytic streptococcal infection pharyngitis typically increases from 10% of cases reported in the fall to 40% in the winter and spring. Herpangina is known to peak in the summer and fall. Allergic pharyngitis may also peak seasonally during the summer months. Although infectious (bacterial and viral) pharyngitis and tonsillitis tend to occur most frequently in young children aged 5 to 10 years, both conditions may occur at any age. Streptococcal infection most frequently affects patients younger than age 25; however, it may occur sporadically in older adults. Infectious mononucleosis (primarily caused by Epstein-Barr virus [EBV]) is also common in adolescents and young adults and is rarely seen in the elderly. Pharyngitis associated with the postnasal drip of sinusitis most often affects adults. No ethnic predispositions have been reported for either pharyngitis or tonsillitis.

Men and women are affected equally by both conditions. URI is a common predisposing factor for the development of viral pharyngitis. The postnasal drip associated with URI or sinusitis may also contribute to irritant-related pharyngitis. The risk of all forms of infectious pharyngitis (viral, bacterial, and fungal) is increased in immunocompromised persons who are afflicted by chronic illnesses, including diabetes mellitus and white blood cell dyscrasias such as agranulocytosis or acute leukemia. Work-related stress and excessive alcohol consumption have also been implicated as a cause of decreased resistance to throat infection. In general, close living quarters, such as military barracks, schools, and day-care centers, increase the risk of person-to-person transmission of the infectious agents causing both pharyngitis and tonsillitis. EBV transmission typically requires intimate person-to-person contact between susceptible persons and symptomatic viral shedders (hence its nickname of "kissing disease"). Young adults and adolescents from higher socioeconomic backgrounds in developed countries who have not been exposed to EBV in their childhood are most susceptible. Persons with pharyngitis related to *Neisseria gonorrhea, Treponema pallidum* (syphilis), *Chlamydia,* or herpes usually have a history of receptive oral intercourse with an infected sexual partner. Sexual abuse may be a factor in these cases as well. Bisexual and homosexual men and patients with anogenital gonorrhea are the groups most frequently affected by gonorrheal pharyngitis. Adult cases of *Corynebacterium diphtheriae* occur almost exclusively

in nonimmunized individuals. Recent contact with a wild animal (especially through a bite) is the major risk factor for the development of *Francisella tularensis* infection. Excessive antibiotic use has been associated with candidal infection and an overgrowth of *Candida* (thrush) in the oropharynx; tobacco and particularly marijuana smoking have also been implicated.

Pathophysiology

In up to 40% of pharyngitis cases, no causative agent is identified. Definitive diagnosis of an infectious agent is difficult, because the nasopharynx is a nonsterile environment normally colonized by an array of nonpathogenic flora. However, the current literature suggests that in adults, upper respiratory tract viruses are the most common cause of infectious pharyngitis, accounting for 30% to 50% of all cases: rhinovirus, coronavirus, adenovirus, influenza viruses A and B, parainfluenza virus, coxsackievirus (herpangina and hand-foot-and-mouth disease), enterovirus, and respiratory syncytial virus (RSV). Rhinoviruses and influenza viruses inflame the oral and nasopharyngeal mucosa via direct invasion and colonization, but the specific pathogenic mechanisms of other viruses is not well understood. Members of the herpes family of viruses are also common causative agents, including EBV and in immunocompromised hosts, cytomegalovirus (CMV), HSV, and reactivated herpes zoster. EBV, which infects pharyngeal B-lymphocytes and disseminates throughout the entire lymphoreticular system, is the primary causative agent of infectious mononucleosis, accounting for 1% to 2% of all pharyngitis cases. However, CMV causes up to 20% of all infectious mononucleosis cases. Primary infection with HIV may also cause pharyngitis owing to rapid retroviral replication; thus, HIV risk factors should always be assessed.

Bacterial agents typically cause an exudative pharyngitis, which represents roughly 20% of all cases of sore throat. Group A beta-hemolytic *Streptococcus pyogenes,* which accounts for 10% to 20% of adult pharyngitis cases, invades and multiplies within the pharyngeal mucosa, causing an intense inflammatory response known as "strep throat." Collectively, *Streptococcus* bacteria are characterized into groups based on cell-wall antigenicity. Clinically relevant groups include A, B, C, D, and G. Group A is the most important cause of pharyngitis because it may lead to the most serious complications, including heart valve damage that may occur many years after systemic infection known as acute rheumatic fever. More than 80 serotypes of *Streptococcus* have been identified. The most clinically significant strain is based on the M protein, which is the major virulence factor of group A beta-hemolytic *Streptococcus pyogenes.* M protein is antiphagocytic, because it blocks activation of the alternative complement pathway. An immune response to bacterial M protein stimulates long-lasting type-specific anti-M antibodies that adhere to individual bacteria and facilitate their phagocytosis (i.e., opsonization), protecting patients against subsequent exposure to bacteria of the same M-protein serotype. The amount of time needed for patients to mount a protective immune response is unclear. In the past, it had been suggested that treatment of group A *Streptococcus* be delayed so that a protective immune response could be mounted, but this practice has since been refuted, and rapid treatment is now the standard of care. Importantly, *S pyogenes* strains are becoming increasingly virulent, and the incidence of subsequent acute renal insufficiency due to postinfectious glomerulonephritis has increased over the past 15 years. Reports of bacteremia, deep tissue cellulitis, and systemic toxic shock–like syndrome mediated by *Streptococcal* exotoxins are also well characterized, with pharyngitis often recognized as the presenting complaint.

Other bacterial agents of pharyngitis include *N gonorrhoeae* (especially in young, sexually active adults), *Haemophilus influenzae, Streptococcus pneumoniae, T pallidum, Staphylococcus aureus,* and *Corynebacterium diphtheriae* and *C hemolyticum* (both often associated with epiglottitis and a potentially obstructive fibrinous gray membrane adherent to the posterior pharynx). The relative importance of atypical organisms known to cause bronchitis including *Chlamydia pneumoniae, C trachomatis,* and *Mycoplasma pneumoniae* as pharyngitic agents is controversial. Studies have demonstrated markedly varied prevalence rates (0%–20%), and nasopharyngeal colonization by these organisms may be asymptomatic.

Noninfectious etiologies of pharyngitis may include trauma, allergies, collagen vascular diseases such as Kawasaki's syndrome, autoimmune blistering diseases such as pemphigus, chemical or drug-induced damage, and severe dehydration. Tobacco and particularly marijuana smoking are major contributing factors to noninfectious pharyngitis related to chemical irritation, and exposure to allergens such as dust and pollen increases the risk of allergic pharyngitis, typically associated with a past history or family history of atopy. Severe drug reactions mediated by both type I immediate hypersensitivity and type III antibody–antigen immune complex reactions may extend in their most serious form to the oropharynx, as well as other mucosal sites. Both low humidity and mouth-breathing may contribute to dehydration-induced mucosal inflammation.

In contrast, tonsillitis (which may involve the posterior pharyngeal tonsils as well as the more anterior adenoid glands) is foremost a disorder of infectious etiology. It is characterized by inflammation, swelling, and purulent exudation of these lymphoid tissue collections that directly drain the colonized or infected nasopharynx. The spectrum of causative agents in this disorder is similar to that described for pharyngitis, including bacteria and upper respiratory tract viruses. Acutely, it is most often caused by group A *Streptococcus* infection, and a

chronic form may also result from repeated *Streptococcus* infections. Streptococcal tonsillar infection always has the potential for progressing to peritonsillar or tonsillar abscess requiring aggressive management (incision and drainage followed by antibiotic therapy).

Clinical Presentation

Subjective

Most patients with pharyngitis and/or tonsillitis report mild to severe throat pain or the sensation of a "tickle" or pruritus in the throat. Infectious mononucleosis, adenovirus, and especially group A *Streptococcus* pharyngitis ("strep throat") tend to cause the most painful sore throats, with fever. Many patients also describe their throats as feeling swollen, with a "lump" in the back of the throat that persists despite repeated swallowing. A history of dysphagia (difficulty swallowing) is also common with throat inflammation, particularly from *H influenzae* infection, and hoarseness is often associated with *C pneumoniae.* Laryngitis and cough are commonly associated with viral infection, although fever occurs only occasionally. In contrast, chills and fever are common with bacterial infection, although cough and rhinorrhea are rarely present. Group A *Streptococcus* infection usually produces a fever higher than 101°F (38.3°C); the patient may be tachycardic, and there is usually pharyngeal exudate. As with viral infections, streptococcal symptomatology is rapid in onset; in contrast, in viral disease systemic symptoms are few. Allergic pharyngitis, on the other hand, does not present with fever, but is recognized most readily by a persistent postnasal drip, paroxysmal sneezing, itchy, watery eyes, rhinorrhea, and a mild sore throat that typically worsens with recumbency. Malaise, generalized aches and pains, and headache may also be reported in both conditions. Infectious mononucleosis is famous for its gradual onset of low-grade fever and marked fatigue and severe sore throat. Anorexia and nausea may also be present. Influenza infection is characterized by an abrupt onset of fever ranging from 100°F to 104°F (37.8°C to 40°C), myalgias, and headache, which last for about 3 days, followed by 3 to 4 days of cough, rhinorrhea, and pharyngitis, and finally a 1- to 2-week convalescent period with persistent cough and malaise. Geriatric patients with influenza may also present with gastrointestinal symptoms such as nausea, vomiting, and diarrhea. Reactivated herpes zoster infection is characterized by painful prodromes before active flare-ups. In contrast, HSV infection does not usually cause a sore throat. Moreover, primary or secondary syphilitic lesions tend to be painless. Gonococcal pharyngitis may be asymptomatic. Severe cases of tonsillitis may also present with ear pain and sometimes with cough or vomiting.

Objective

On inspection, the inflamed throat typically appears erythematous, although color may vary. Conjunctivitis is often associated with adenovirus and other respiratory viruses, whereas mucosal exudates and enlarged tonsils occur only occasionally. EBV-related infectious mononucleosis, however, may present with an exudative tonsillitis (in about 50% of cases), in addition to palatal petechiae and exanthem. The 1- to 2-mm vesicular lesions of herpes simplex infection may extend from the pharynx to the lips, gingivae, buccal mucosa, and tongue. Reactivated herpes zoster infection typically presents with 2- to 4-mm vesicular lesions unilaterally on the tongue, lip, and buccal mucosa. Herpangina presents as 1- to 2-mm oral vesicles or ulcers on the pharynx, tonsils, soft palate, pillars, uvula, and posterior buccal mucosa. Hand-foot-and-mouth disease presents with oral lesions co-occurring with exanthem on the hands and feet. Maculopapular rashes on the extremities of young adult patients may be indicative of many types of infection, including *C hemolyticum,* HIV, enteroviruses, or *T pallidum* (syphilis).

Exudates and enlarged tonsils are common findings in bacterial infections. Streptococcal infection produces a characteristic white to yellow exudate and may be accompanied by a sandpaper-like, scarletiniform rash. *Mycoplasma*-related cases may be clinically indistinguishable from streptococcal infections. *C diphtheriae* presents with a characteristic grayish pseudomembrane overlying the pharyngeal mucosa, tonsils, epiglottis, uvula, or even the nasal cavity. The nonvesicular lesions of primary syphilis are 5 to 15 mm in size and appear indurated or "healed up," extending to the lips, tonsils, or tongue. Secondary syphilitic nonvesicular lesions (2–10 mm) arise symmetrically on all parts of the oropharynx and mouth. Candidal infections produce thin, white, nonvesicular, diffuse or patchy (3–11 mm) exudative ulcers on all parts of the oropharyngeal mucosa. In most inflammatory conditions of the throat, the pharyngeal mucosa and tonsils are edematous, particularly with group A beta-hemolytic streptococcal infection. This is true of allergic pharyngitis as well, although erythema of the pharynx is minimal. Tonsillitis presents with readily noticeable swollen lymph glands located bilaterally between the fauces of the posterior pharynx.

Bacterial pharyngitis commonly presents with significant tender lymphadenopathy of the draining anterior cervical lymph nodes. This finding also occasionally occurs in viral infections such as infectious mononucleosis or primary HIV infection. However, 90% of infectious mononucleosis cases present with posterior cervical lymphadenopathy. Hepatosplenomegaly is also a common finding. Tonsillitis usually presents with swollen lymph glands on either side of the jaw.

Diagnostic Reasoning

Diagnostic Tests

Inasmuch as most cases of pharyngitis and tonsillitis are self-limited, laboratory work-up and identification of causative organisms through culture is unnecessary if the

patient's clinical picture is consistent with influenza, the common cold, or irritant-induced throat inflammation. However, bacterial and viral cultures of throat swabs may be appropriate for more complicated cases or those requiring pharmacotherapy such as with herpes virus or streptococcal infection. Herpangina and hand-foot-and-mouth disease are diagnosed via coxsackie-positive viral cultures and positive serologies. For exudative cases of pharyngitis, the Rapid (10-minute) Streptococcal Antigen (Rapid Strep) Test is used to detect group A streptococcal antigens and diagnose infection. Increased antistreptolysin O (ASO) titers are also observed, but treatment may blunt this antibody response. Rapid Strep Tests are highly specific (90%) and sensitive (80–90%) when used judiciously. A Rapid Strep Test to guide antibiotic therapy is considered appropriate for any patient with two or three of the following criteria: fever above 100.5°F (38.1°C), tonsillar exudate, tender anterior cervical lymphadenopathy, and the absence of cough. Patients meeting three or four of these criteria may be empirically diagnosed with group A *Streptococcus* and treated immediately. Throat swab cultures of the posterior pharynx and tonsils—the current "gold standard" test for the diagnosis of *Streptococcal* infection—are sent rather than the Rapid Strep Test for patients meeting fewer criteria and considered to have a low pretest likelihood of infection (less than 20%). Patients with an intermediate pretest likelihood of *Streptococcus* infection (20%–50%) who present with sore throat and only two of the associated criteria are given the Rapid Strep Test first and, if positive, may avoid a throat culture. However, if the result is negative, it must be followed up by a throat culture which typically displays greater sensitivity than the Rapid Strep Test. During the summer and fall, the false-positive rates of Rapid Strep Tests may approach 50%. In turn, the recommended diagnostic approach is less aggressive at this time than during the winter or spring. During the summer and fall, no testing is recommended for patients with a sore throat who meet only one of the associated criteria unless the patient is at high risk for *Streptococcus* infection due to immunocompromising illnesses such as diabetes mellitus or HIV, has a history of rheumatic fever, or is presenting during a community outbreak of *Streptococcus* infection. If possible, household members should also be screened because treated patients may be reinfected via contact with asymptomatic carriers in the home.

Immunofluorescence staining or viral throat swab cultures are used to detect herpes virus infection. A special Tzanck smear of any ulcerative exudative lesion is used to diagnose HSV and herpes zoster; multinucleated giant cells with ballooning degeneration represent a positive finding. Infection by the many types of herpes viruses (including HSV, EBV, and CMV) may also be diagnosed by serological tests detecting virus-specific antibodies. Convalescent titers may be necessary for proper interpretation. Pharyngeal, endocervical, and urethral cultures on Thayer-Martin agar can specifically detect gonorrheal growth, if suspected in high-risk patients. Syphilis is diagnosed via serology and, if disease is in its secondary stage, by dark-field microscopy of lesional scrapings that demonstrates *T pallidum* spirochetes. *C pneumoniae* and *C trachomatis* are typically evaluated via serology, although cultures and titers are not recommended initially, because the relative contribution of these pathogens to throat inflammation remains highly controversial. Suspected *Candida* infections are diagnosed via a potassium hydroxide (KOH) wet mount or Gram stain of pharyngeal exudates, which will demonstrate spores and budding hyphal yeast forms, as well as by yeast cultures for speciation if needed. Nonspecific heterophile antibody tests, such as the Monospot test, are used to diagnose infectious mononucleosis related to EBV, although this test decreases in sensitivity when used at the extremes of age. A CBC may be done in any case of infectious pharyngitis. An increase in granulocytes indicates bacterial infection, and a documented lymphocytosis (50% lymphocytes, of which at least 10% show atypical morphology) strongly supports a viral etiology. The presence of eosinophils in a Gram stain of nasal secretions or a nasal mucosal scraping is strongly indicative of allergic pharyngitis. Radiological evaluation of the posterior pharyngeal wall may be appropriate to detect retropharyngeal processes if abscess formation is suspected.

Differential Diagnosis

Although the entire oropharynx may be involved during many infectious processes, certain microorganisms have a greater propensity for affecting the oral cavity, resulting in stomatitis, before pharyngeal involvement. Pharyngitis from postnasal drip secondary to rhinitis or sinusitis may be ruled out via nasal cavity examination and sinus x-ray films. Epiglottitis due to *C diphtheriae* is an important consideration in nonimmunized (or inadequately immunized) individuals; it should be ruled out carefully by history and general presentation, including inability to swallow, with resultant drooling and inability to speak. Examination of the oral pharynx may trigger sudden glottic spasm and risk of occlusion of the airway. Examination of the throat should take place in a facility that could support severe respiratory compromise that may result from dislodging the pseudomembrane from the posterior pharynx. Pharyngeal or tonsillar malignancy requiring surgical removal of the affected tissues must be ruled out via biopsy if malignancy is suspected.

Infection with group A *Streptococcus* causes intense mucosal inflammation because of bacterial extracellular factors such as pyrogenic exotoxin and streptolysin O. A major virulence factor is the streptococcal cell-wall M protein (with 80 serotypes), which has antiphagocytic properties; particular serotypes appear to correlate with the occurrence of rheumatic fever and glomerulonephritis, which can lead to acute renal failure. Patients may be sicker and more febrile with bacterial infection, but this

is not always the case. When challenged with an infectious agent, numerous factors are brought into play, including the host's defense mechanisms, microbial virulence, quantity of infectious inoculum, and the host's susceptibility.

Management

Pharmacological Management

Most cases of pharyngitis and tonsillitis in otherwise healthy patients are entirely manageable with home care and/or antibiotics. For allergy-related forms of throat inflammation, contact with environmental irritants including tobacco smoke should be minimized, and patients may be treated symptomatically with a combination of antihistamines and decongestants as described for allergic rhinitis. In general, for infectious forms, patients should limit their physical activity until symptoms of pharyngitis and tonsillitis have subsided. Daily fluid intake should be increased to 8 to 12 glasses (2–3 quarts) of fluids such as water or nonacidic juices. Bedrest is recommended if fever is present, and regular physical activity should be resumed only after 2 to 3 days of normal temperature readings. Viral pharyngitis requires only symptomatic care, and antibiotics are never indicated (other than selected antiviral therapies). In fact, many cases of bacterial pharyngitis are self-limited as well (such as those caused by atypical organisms). However, cases of group A *Streptococcus* and *N gonorrhoeae* merit rapid antibiotic treatment to prevent significant sequelae in both the short and long term. In addition, cases caused by *C diphtheriae, H influenzae,* or influenza virus may require hospitalization because of the risk of life-threatening complications. Fungal infections also typically require antimycotic therapy.

Throat pain may be significantly relieved by the following measures:

- Voice rest
- Ambient humidification, saline nasal sprays, viscous xylocaine
- Various types of gargles taken as needed, including hot or cold double-strength tea or a warm saltwater solution (1 teaspoon of noniodized salt in 8 ounces of water)
- A regularly cleaned cool-mist, ultrasonic humidifier to increase ambient air moisture, which may be useful in relieving feelings of dryness or tightness in the throat
- Nonprescription throat lozenges or sprays (e.g., Cepastat, Chloraseptic) containing topical anesthetics such as phenol may also alleviate minor pain
- Nonprescription analgesics such as acetaminophen or aspirin (325–650 mg every 4–6 hours as needed) to relieve intermediate pain, and codeine preparations (30–60 mg PO every 4–6 hours as needed) to possibly relieve more severe pain
- Warm, moist compresses applied 4 times daily for at least 30 to 60 minutes at a time to relieve enlarged, tender cervical lymph glands (see Complementary Therapies 8.1)

Viral infections tend to be treated symptomatically, as described previously. Influenza symptoms may be relieved within the first 2 days of symptoms by prescribing amantadine (Symmetrel; 100 mg PO 2 times daily) for documented cases of influenza A, but this drug may also cause insomnia, dizziness, drowsiness, or difficulty concentrating. Thus, the dosage for elderly patients is reduced to once a day. Oseltamivir (Tamiflu; 75 mg PO 2 times daily for 5 days) may be similarly given within the first 48 hours of symptom onset to reduce duration of illness and symptom severity, as well as prophylactically in high-risk individuals during peak flu season at once-daily dosing.

Antibiotic therapy for group A streptococcal pharyngitis has been shown to shorten the clinical course of disease and reduce lymphadenopathy, fever, and pain (after 1–3 days of therapy), prevent suppurative complications and autoimmune sequelae such as rheumatic fever, and decrease person-to-person spread of infection. Empiric antibiotic therapy may be instituted before receiving culture results in certain clinical situations to prevent rheumatic fever, cardiac sequelae, and acute renal insufficiency due to poststreptococcal glomerulonephritis. Studies have demonstrated, however, that delaying treatment for 48 hours in anticipation of culture results does not significantly affect the reduction in autoimmune sequelae provided by antibiotic therapy. In cases of fever under 100.5°F (38.1°C) without an associated tonsillar exudate or anterior cervical lymphadenopathy, neither throat swab culture nor antistreptococcal therapy is recommended because a false-positive culture may lead to unnecessary antibiotic therapy. If fever greater than 100.5°F (38.1°C) accompanies a tonsillar exudate and tender anterior cervical adenitis, antistreptococcal therapy should be instituted immediately because a false-negative culture could delay critical treatment. This is especially important for patients younger than 25 years of age. If a similar fever occurs with only one of the other two physical signs, antibiotic therapy should be instituted only for culture-positive patients. High-risk factors favoring immediate empiric treatment include a past history of acute rheumatic heart fever or related cardiac damage, a scarlatiniform rash, a diabetic or other immunocompromised state, a documented exposure to group A *Streptoccocus* within the past week, or the presence of a known epidemic within the community.

Adults are typically given a 10-day course of penicillin V potassium (Pen-Vee K; 500 mg PO 2 times daily or 250 mg PO 4 times daily) or benzathine penicillin (Bicillin; 1.2 million units IM once) as an alternative to prolonged oral medication. If the patient is allergic to penicillin, erythromycin (250 mg PO daily) is recommended. If the patient fails to respond to antibiotic therapy, tests for infectious mononucleosis and streptococcal antibiotic sensitivity should be performed. A 10-day course of amoxicillin/clavulanate (Augmentin; 40 mg/kg PO daily based on the amoxicillin component, in divided

doses 2 times daily), erythromycin ethyl succinate (50 mg/kg PO daily in divided doses 3 times daily), or erythromycin stearate (1 g PO daily) have all been shown to be effective for penicillin-resistant beta-lactamase–producing organisms, whereas tetracycline or trimethoprim-sulfamethoxazole preparations (Septra, Bactrim) should be avoided.

N gonorrhoeae infection calls for ceftriaxone (Rocephin; 125 mg IM once), along with empiric treatment for *C trachomatis* (azithromycin [Zithromax] 1 g PO once or doxycycline 100 mg PO 2 times daily for 7 days), given its propensity for co-infection. Extensive throat infection with *Candida albicans* (thrush, pharyngitis, esophagitis) requires antifungal treatment such as fluconazole 200 mg PO daily once, followed by 100 mg PO daily for 2 weeks total. *M pneumoniae* and *C pneumoniae* are both treated with erythromycin 250 to 500 mg PO 4 times daily for 10 days, depending on the specific preparation.

Surgical Management

Surgical removal of the pharyngeal tonsils (tonsillectomy) and/or adenoids (adenoidectomy) is absolutely indicated if tonsillar inflammation leads to airway obstruction associated with any of the following: cor pulmonale (right-sided cardiac hypertrophy), dysphagia, or weight loss. Tonsillectomy may also be indicated if active flares recur more than three times a year, if the patient experiences mild dysphagia, if the tonsils remain chronically hypertrophied after a bout of infectious mononucleosis, or if the patient has a history of rheumatic fever with heart damage due to recurrent tonsillitis. However, in these situations, the indication for surgical intervention is relative and must be evaluated further. It should also be noted that lymph glands normally swell during episodes of active inflammation as part of the body's normal immune response. In turn, tonsillectomy is not indicated for colds, asthma, allergic rhinitis, focal infections, fever of unknown origin, cervical lymphadenopathy, or enlarged tonsils without obstructive symptomatology.

Follow-up and Referral

Most cases of pharyngitis and tonsillitis are self-limiting, and symptoms tend to improve in 2 to 3 days. If symptoms fail to improve within this time, patients should return for a follow-up appointment. Throat cultures for *Streptococcus* may be repeated on completion of therapy to confirm resolution of any infectious processes. This is not recommended, however, for asymptomatic patients who have completed a 10-day therapeutic regimen for streptococcal infection or for patients whose symptoms improve within 5 days of antibiotic therapy because clinical resolution is typically the best measure of therapeutic success.

Group A *Streptococcus* pharyngeal or tonsillar infections may lead to scarlet fever or autoimmune rheumatic fever if not treated with antibiotics or if antibiotic therapy is discontinued before a full 10-day course. These patients should be referred to a specialist. In areas where group A streptococcal infection is endemic, the probability of developing rheumatic fever is 0.3%. With epidemic pharyngitis, the risk increases to 3%. Rheumatic heart disease may develop after rheumatic fever in an adult patient with recurrent streptococcal infection or a history of poorly treated streptococcal pharyngitis as a child or young adult. This may lead to severe sequelae such as calcification of the mitral valve and/or other heart valves, as well as to the destruction of cardiac myocytes, which is attributed to cross-reacting antistreptococcal antibodies. Even when acute rheumatic fever is treated appropriately with prophylactic antibiotic therapy, 4% of patients may develop debilitating cardiac sequelae and 1% may develop severe class IV rheumatic heart disease. Chest pain is a key indicator of cardiac complications. Hematuria resulting from poststreptococcal glomerulonephritis may occur 1 to 3 weeks after acute pharyngeal or tonsillar infection because antibiotic therapy has not been shown to protect against this immune complex–mediated complication.

Cases caused by *C diphtheriae,* if left untreated, may lead to epiglottitis, which can obstruct breathing and may prove fatal if the pseudomembrane dislodges and chokes the patient as it is inadvertently swallowed. Spread of infectious organisms from the pharynx to the lungs may lead to pneumonia and severe respiratory complications. Infections of the posterior oropharynx may also ascend to the nasopharynx, leading to sinusitis and rhinitis—inflammation of the mucous membranes of the sinus and nasal cavities. The middle ear is another possible target of disseminated pharyngeal infection because the nasopharyngeal (eustachian) tube acts as a conduit for the spread of microorganisms. OM may occur in more than 20% of adenovirus infections. A less common complication of bacterial pharyngitis is septic jugular vein thrombophlebitis, which may occur several days after the initial sore throat. Patients with this complication are typically teenagers or young adults who experience an increase in neck pain and tenderness, as well as swelling of the jaw angle.

Liver function tests (e.g., serum aspartate aminotransferase [AST], serum alanine aminotransferase [ALT], serum bilirubin, platelet count, and the Coombs' autoantibody test) should be performed for all cases of suspected infectious mononucleosis to diagnose serious sequelae, including hepatitis (ALT or AST levels of more than 1,000 units/L; bilirubin levels of more than 10 mg/dL), hemolytic anemia, granulocytopenia, and thrombocytopenia. Airway obstruction may also occur in patients with infectious mononucleosis as a result of pharyngeal swelling. Such complications may require treatment with a corticosteroid such as prednisone (60–80 mg PO daily in divided doses, tapered over 1–2 weeks). Splenic rupture related to trauma is also a serious risk for all patients with infectious

mononucleosis who have marked hepatosplenomegaly (liver and spleen enlargement).

Tonsillitis that goes untreated or fails to resolve with treatment may lead to grossly swollen, suppurative cervical adenitis, OM, or a peritonsillar abscess of the surrounding throat area, characterized by increasing unilateral ear and throat pain ipsilateral to the affected tonsil, dysphagia, drooling, trismus, erythema, and edema of the soft palate with fluctuance on palpation. Suppurative sequelae such as these may require surgical drainage and/or tonsillectomy. Repeated attacks of acute tonsillitis may lead to a chronic condition with a recurrent sore throat and greatly enlarged tonsils, which may complicate breathing and become potentially life-threatening; these cases also require surgical intervention.

All patients developing suppurative or retropharyngeal sequelae should be referred to an otolaryngologist. The physical exam and treatment of *C diphtheriae* infection is also highly risky and must be supervised by a qualified specialist. Surgical interventions such as tonsillectomy or abscess drainage require surgical referral.

Patient Education

Both pharyngitis and tonsillitis may be prevented by avoiding contact with persons with actively inflamed throats, particularly with URIs. Throat swabs from household members of patients should also be cultured to identify and treat carriers simultaneously in an effort to prevent the development of clinical disease and prevent reinfection. Toothbrushes should be replaced as soon as a sore throat develops because they may harbor causative microorganisms, and all eating and drinking utensils should be cleaned thoroughly and should not be shared. Food and washcloths also must not be shared during a period of active infection. It is critical to keep all immunizations up to date, particularly the diphtheria-pertussis-tetanus (DTaP, Tdap) vaccine that confers immunity against *C diphtheriae.* If a sexual partner is suspected of being infected with a sexually transmitted agent, sexual contact should cease until a proper diagnosis and any applicable treatment have been completed. In general, oral intercourse between persons of either gender should be performed only using a form of latex barrier protection, such as a condom during fellatio or a dental dam during cunnilingus, to avoid orogenital transmission of infectious organisms. Environmental irritants such as tobacco and marijuana smoke, pollution, dust and other allergens, and low-humidity environments should be avoided to prevent noninfectious forms of pharyngitis.

Warm compresses applied to relieve enlarged, tender cervical lymph nodes can be effective; however, patients must be cautioned not to burn the skin inadvertently. Although the use of aspirin during viral infections in adults has not been linked to the development of Reye's syndrome (as is the case in children), NSAIDs should be used cautiously if patients suffer from ulcers or other gastrointestinal disorders. Heavy lifting and contact sports must be prohibited for all patients with infectious mononucleosis because these activities carry a high risk of splenic trauma and rupture. Patients must be instructed to finish their entire course of antibiotics or antifungals to avoid complications from latent infection such as glomerulonephritis or myocarditis. In cases involving dysphagia, patients may be instructed on how to maintain a healthy liquid or soft food diet (e.g., milkshakes, soups, and high-protein diet or instant breakfast drinks) for a few days until the pain subsides. Patients who demand prescriptions for antibiotics in the absence of a throat culture confirming disease of bacterial origin should understand the rationale for using antibacterials versus other types of medication.

HOARSENESS

Hoarseness is a common complaint; the term describes a voice with harsh quality and low pitch. The term can also indicate weakness, raspiness, or simply a change from the usual voice quality. Hoarseness is the symptom, whereas *dysphonia* is the diagnostic term. Hoarseness suggests an abnormality in voice production at the level of the larynx. It is a common symptom that may occur in both men and women at any age. Changes in the voice are part of the natural process of aging. In elderly men, the voice becomes weaker and higher in pitch as a result of muscle atrophy and increased stiffness of tissues. In women, the same changes occur, but the pitch of the voice becomes lower because during menopause mucoid edema accumulates in the submucosa of the vocal folds. More severe edema and polyps may occur in women who smoke. Hoarseness is a cardinal sign of laryngeal cancer, which is most commonly seen in men 50 to 70 years of age. Psychogenic dysphonia may present with a monotonous and bizarre aberration of vocal sounds.

Epidemiology and Causes

Hoarseness affects approximately 20 million people in the United States at any given time, and about one in three people will become hoarse at some point in their lifetimes. Hoarseness is frequently the result of a viral infection of the larynx (laryngitis). Usually, acute laryngitis affects individuals aged 18 to 40 years; however, children aged 3 years and older have been clinically observed with laryngitis. In women, the prevalence of hoarseness not associated with infection is 50% higher than it is in men. Professional teachers, performers, aerobics instructors, telemarketers, and the elderly are at risk.

Pathophysiology

Vocal cord inflammation and edema as a result of an infectious process (usually viral) result in vocal fold movement that is asymmetrical with reduced mucosal waves and incomplete vibratory closure. In the process of phagocystosis, the vocal folds become more edematous and vibration is adversely affected. The phonation

threshold pressure may increase to a degree that generating adequate phonation pressure in a normal fashion becomes difficult, thus eliciting hoarseness. Gastroesophageal reflux disease (GERD) may also contribute to inflammation and edema of the vocal cords. Laryngeal tumor may present as hoarseness.

Clinical Presentation

Subjective

Onset of the problem is an important key to the diagnosis. A 1-day complaint is unlikely to be caused by cancer, whereas hoarseness persisting for 1 year is unlikely to be the result of an acute infection. Hoarseness that persists for greater than 3 weeks requires a workup for chronic laryngitis. Associated conditions should be ascertained. Sore throat and otalgia often accompany hoarseness in malignant tumor of the larynx or pharynx. Chronic pain often suggests more serious underlying disease than acute onset of pain. Dysphagia or odynophagia accompanying hoarseness indicates the presence of disease affecting the pharynx or esophagus. Cough suggests irritation of the endolarynx or pulmonary disease. Hemoptysis is more serious, suggesting a malignant process of the pharyngeal, laryngeal, or pulmonary areas. Fever and oral, nasal, or otalgic discharge suggest an infectious process.

Voice use and lifestyle should be reviewed. A professional singer or weekend football fan can suffer voice overuse and abuse. An individual who smoked two packs of cigarettes per day for 45 years may have irritation or malignancy. A scratchy throat the morning after eating spicy foods suggests a diagnosis of GERD, as does chronic clearing the throat throughout the day. Previous head or neck surgery history may be a factor affecting the laryngeal nerve, as well as recent intubation or radiotherapy to the neck.The use of asthma inhalers may also produce hoarseness, and chronic exposure to pollutants may contribute as well.

Objective

A complete examination of the head and neck is necessary. Nasal drainage and excess mucus may indicate sinusitis. Tonsillar erythema or exudates indicates viral or bacterial infection. Ear canal erythema or exudate suggests infection. A normal ear exam, despite the complaint of otalgia, may be seen in patients with cancer of the pharynx or larynx. The clinician should inspect and palpate the oral cavity including the buccal mucosa, the floor of the mouth, and the tongue with a gloved hand. Palpate the neck and lymph nodes for masses. Infections often feel warm, tender, tense, or fluctuant. Malignancies typically are hard masses that may be fixed to underlying tissue. Inspect and palpate the neck anatomy, including tracheal alignment. A thorough head, eyes, ears, nose, and throat (HEENT) exam looking for evidence of infection may be essentially negative.

Diagnostic Reasoning

Diagnostic Tests

Infections cause elevated white blood cell counts. Culture and sensitivity of oral or otalgic discharge can reveal the organism responsible for the infection and guide antibiotic therapy. If hoarseness persists for more than 4 weeks and is clearly not caused by infection, referral to an otolaryngologist for laryngoscopy is required. An adequate laryngeal exam should visualize the base of the tongue, epiglottis, pyriform sinuses, false vocal cords, subglottic larynx, and true vocal cords. Use of stroboscopy improves detection of small lesions by "freezing" the vocal cords (making them appear immobile) during vibration. Adequate examination of structures may require general anesthesia, which is necessary for palpation and biopsy of any abnormalities. Routine use of CT scanning is neither cost effective nor necessary. If vocal cord paralysis is seen, CT scans from the skull base to the aortic arch are required to assess the recurrent laryngeal nerves. Thyroid tumors are the most common cause of bilateral vocal cord paralysis; esophageal and pulmonary tumors are common causes of left-sided vocal cord paralysis.

Differential Diagnosis

Differential diagnosis of hoarseness includes viral infection, which is the most common etiology, inflammation from overuse, vocal cord pathology (polyps, nodules, tumors) especially in smokers, adverse effects from medicines, vocal cord paralysis, muscle atrophy (aging), GERD, and chronic allergies.

Differential Diagnosis 8.3 presents a comparison of the differential diagnosis of hoarseness.

Management

The causes of nearly all cases of hoarseness are benign or self-limited conditions. Recent guidelines for the management of hoarseness have been developed by the American Academy of Otolaryngology–Head and Neck Surgery Foundation and are reviewed here:

- Review current medications that may be causing the symptom.
- Use common sense to avoid vocal excess and irritants such as inhaled smoke.
- Completely rest the voice. Avoid whispering because this strains the larynx.
- Avoid antihistamines because they serve to dry the mucous membranes.
- There is no benefit in using antibiotics to treat acute laryngitis.
- Imaging studies should not be performed before visualizing the larynx with laryngoscopy.
- Use of humidified air especially at night and during dry seasons may be helpful.
- Encourage increased oral fluids.

- Treatment with antireflux medication should not be undertaken in the absence of signs or symptoms of significant GERD and prior evaluation by laryngoscopy.
- Voice therapy, typically one or two sessions per week for 4 to 8 weeks, is a well-established intervention for patients of all ages who have hoarseness.
- Use of an amplifying device during heavy voice use can reduce hoarseness.
- Oral steroids are not recommended.

In the case where the "show must go on" and voice rest is impossible, if laryngeal examination rules out vocal fold hemorrhage or abrasion, it is usually safe to manage vocal fold edema temporarily with oral or parenteral steroids. A long-acting vasoconstrictor such as oxymetazoline (Afrin) may be applied directly to the laryngeal mucosa to reduce edema further. These measures do not promote healing, nor do they prevent further damage to the vocal cords.

Follow-up and Referral

For repeated and recurrent episodes of hoarseness, vocal hygiene and voice therapy should be considered, especially in professionals who must rely on their voice. Screening for contributing conditions (such as underlying allergies, chronic sinusitis, or GERD) should be pursued. As noted earlier, if hoarseness persists for more than 2 weeks, further evaluation by an ENT specialist is warranted.

Patient Education

Because hoarseness is generally self-limited, instructions to stop smoking and rest the voice are essential to facilitate improvement. Humidification and adequate fluid intake will help healing of inflammed tissues. Avoid cough and cold preparations that have antihistamines in the formulation because they will have a drying effect. Patients should return within 2 weeks to evaluate resolution of hoarseness. Patients should be instructed that persistent or chronic hoarseness requires evaluation by an ENT specialist for laryngoscopic visualization.

TEMPOROMANDIBULAR JOINT DISEASE

Temporomandibular joint (TMJ) *disease* is a collective term that refers to disorders affecting the masticatory musculature, the temporomandibular joint and associated structures, or both. The terms *craniomandibular disorders* (CMDs) and *temporomandibular disorders* (TMDs) are synonymous with the more familiar term *temporomandibular joint (TMJ) disease.* Most current research favors the phrase *temporomandibular disorder* (TMD). Although TMD has been traditionally viewed as one syndrome, it is actually a cluster of related disorders in the masticatory system that has many features in common. The most common presenting symptom is pain in the muscles of mastication, the preauricular area, and/or the TMJ. Chewing, bruxism (clenching, grinding, or gnashing of the teeth during nonfunctional movements of the mandible), or other jaw functions tend to aggravate the pain. TMDs are considered to be a subclassification of musculoskeletal disorders.

Epidemiology and Causes

Symptoms of TMD in individuals are common, yet not every person with symptoms would be considered to have the disorder. Epidemiological studies in specific populations show that about 75% have at least one sign of joint dysfunction (joint noise) and about 33% have at least one symptom (face or joint pain). It is estimated that only 5% of these individuals are in need of treatment for TMD. For many patients, TMD can be mild and self-limiting; for others, it may progress to chronic pain and discomfort, which will require consultation with multiple professionals over many years.

Signs and symptoms of TMD generally increase in frequency and severity from the second through the fourth decade of life. The majority of patients are between ages 15 and 45, with a mean age at onset of 35. The vast majority of patients with TMD (84%) are women, yet some data demonstrate that men have symptomatology but do not present for treatment. Symptoms may be self-limiting or may fluctuate over time, as suggested by the declining incidence with increasing age. The lack of a universally accepted classification scheme with diagnostic criteria makes it difficult to accurately determine the prevalence of TMD.

Because TMDs are diverse and multifactorial, a universal etiology does not exist. It may be more appropriate to differentiate contributing factors into predisposing, initiating, and perpetuating categories. *Predisposing factors* increase the risk of orofacial pain or TMD development. *Initiating factors* cause the onset of the disorder, and *perpetuating factors* interfere with healing and complicate management. Contributing factors are not necessarily etiological; they may be the result of the disorder instead.

Predisposing factors include biomechanical, genetic, or psychological factors that increase the chances of an individual developing TMD. Initiating or precipitating factors generally fall into two main categories—macrotrauma as a result of a single event, or microtrauma in the form of repetitive adverse loading of the masticatory system. Perpetuating factors include personality, social, emotional, and cognitive factors that are often related to the stresses of daily living. The dividing line between categories is not always clear-cut. Some initiating factors (e.g., bruxism) may also act to maintain the disorder after onset. Differential Diagnosis 8.4 and Table 8.3 present contributing factors to TMD.

Pathophysiology

The TMJ is one of the most complex joints in the body. It is a synovial, encapsulated joint that is stress bearing.

Differential Diagnosis 8.4
Temporomandibular Disease

- Sinusitis
- Myofascial pain
- Arthritis (rheumatoid arthritis, osteoarthritis, gout, septic, psoriatic, Lyme)
- Parotid gland pathology
- Otitis media and otitis externa
- Temporal arteritis
- Neuralgia
- Foreign body or cerumen in the ear canal
- Mastoiditis
- Dental abnormalities
- Headaches (cluster, migraine, tension, vascular)
- Psychogenic pain
- Mood disorders (depression, anxiety)
- Tumors of the head, neck, or brain
- Myopathies

The TMJ differs from other joints in the body in that its articular surfaces are covered with fibrocartilaginous tissue rather than with the chondrocartilage found in other joints. The articular disc separates the upper and lower joint spaces. Pain from the TMJ arises from injury to the retrodiscal tissue or the capsular ligament. Locking of the joint may occur secondary to jaw malocclusion and, most commonly, anterior disc dislocation. However, several variations of articular disc displacement have been noted with the condition, as joint laxity from underlying connective tissue disorders and even asymmetrical body alignment from poor posture have been cited as risk factors. Dental manipulation of the jaw and degeneration of the TMJ from rheumatoid arthritis or osteoarthritis often underlie extracapsular joint dysfunction, because misalignment of the TMJ places pressure on nearby ear structures, resulting in otalgia (ear pain), tinnitus, vertigo, hearing loss, and tongue pain.

TMJ pain may also be intracapsular in origin and involve the masticatory musculature, known as TMJ myofascial pain syndome or simply TMJ syndrome. Similar to all skeletal muscles, the TMJ muscles are susceptible to muscle splinting, spasm, or inflammation. Pain that originates in the orofacial area may be referred to other areas, such as the neck, shoulders, and head, and TMJ syndrome often coexists with fibromyalgia. However, pain from the masticatory musculature is usually related to mandibular dysfunction. Abnormal chewing patterns, chronic tension of the jaw musculature, and facial trauma all predispose to muscle dysfunction. Stress-related jaw clenching and psychogenic nocturnal bruxism (unconscious nighttime teeth grinding) have also been strongly associated with TMJ syndrome. The importance of psychological stress in the development of this disorder is further bolstered by the observation that a worse prognosis is associated with a diminished capacity for supportive interpersonal relationships.

Clinical Presentation

Subjective

Patients may present with several complaints that lead to the suspicion of TMD or with only one symptom. The most common presenting symptom is pain (89%), followed by jaw noise (85%) and limited jaw movement (40%). Ear symptoms account for 28% of clinical presentations. Only 4% of patients present with obvious jaw dislocation.

Pain is usually localized in the muscles of mastication, the preauricular area, and/or the TMJ. Chewing or other jaw functions frequently aggravate the pain. Patients may complain of poorly localized pain in the face or head, which is dull, unilateral, centered in the temple, above and behind the eye, or in and around the ear. Other less obvious symptoms may include tinnitus, sinus symptoms, a foreign body sensation in the external

Table 8.3 Factors Contributing to Temporomandibular Disorders

Biomechanical Factors	Macrotrauma	Psychological Factors	Systemic Medical Conditions	Microtrauma	Habits

ear canal, decreased hearing, neck or shoulder pain, visual disturbances, limited jaw opening, and popping or grating joint sounds. Patients may present with a history of trauma to the TMJ or cervical disc area (such as whiplash).

Several questionnaires have been developed to assist the health-care professional in screening for TMD. Any patient who presents with symptomatology (complaints of orofacial pain, headaches, ear pain, or tinnitus) should be screened for TMD by asking questions such as the following: Do your jaw joints make noise? Does using your jaw—such as chewing, talking, and/or yawning—cause you pain or difficulty? Have you had jaw joint problems before, and were you tested? When moving your jaw, does it ever get "stuck," "lock," or "go out"? Is opening your mouth difficult, or does it cause pain? Do you ever have pain in the head and neck area, such as the face, ears, temples, and/or forehead? Has your jaw, neck, or head ever been injured? If so, when? Do you clinch or grind your teeth at night or during the day? If you have tinnitus, does the ringing sound change in any way as you open and close your mouth while applying external pressure to the joint? Do you have frequent headaches, neckaches, or toothaches?

Objective

Because many of the presenting symptoms of TMD may be secondary to underlying medical conditions, a complete examination should be done in order to exclude metabolic, nutritional, neurological, or hormonal etiologies. Visual acuity should be assessed. Special attention should be directed to observation of the patient's balance, gait problems, or unusual habits. The muscles of mastication and the TMJ should be palpated using a bimanual technique. Muscles to be palpated include the masseter, temporalis, medial pterygoid, digastric, and mylohyoid. Tenderness, enlargement, swelling, and unusual texture should be noted. Cervical muscle groups should also be palpated to differentiate craniocervical disorders. The oral exam may reveal ground-down teeth, which would indicate bruxism.

Next, the TMJ should be examined with the mouth in the closed position, which will allow palpation of the lateral aspect. On opening of the jaw, assessment of mandibular range of motion and TMJ sounds can assist with diagnosis. A mandibular opening of less than 40 mm is considered restrictive; the mandible may deviate to one side or the other when opened (asymmetrical opening). Joint sounds may be described as clicking, popping, or crepitus. Pain may also be elicited with mandibular movement and should be noted.

Diagnostic Reasoning

Diagnostic Tests

Initial testing for diagnosing TMD may first include ruling out other underlying medical conditions. Laboratory testing should include CBC with differential, platelets, chemistry panel, erythrocyte sedimentation rate, rheumatoid factor, and thyroid-stimulating hormone. Radiographical imaging (x-ray films) may be helpful in confirming a clinical diagnosis of TMD. The clinician must remember that even if anatomical changes are found, imaging results rarely have any bearing on clinical outcome. Imaging testing is confirmatory at best, but the diagnosis may be made via history and clinical exam alone. Films are best reserved when dental anomalies are suspected or severe symptoms are refractory to conservative treatment. A transcranial view (lateral oblique projection) is the most common film taken of the TMJ. This view is useful for identification of gross osseous pathology and degenerative or traumatic changes of the joint; however, it is subject to distortion and shows only the lateral one-third of the condylar head and may not be sensitive enough to detect condylar displacement.

Subsequent testing should most likely be ordered by the dentist, otolaryngologist, or oral surgeon on referral of the patient. This could include panoramic films, CT, or MRI. CT provides the clearest picture of the osseous structures, and, with contrast, can help visualize the soft tissue of the head and neck; however, it is not useful in the diagnosis of disc displacement of the TMJ. MRI visualizes the soft tissues of the joint without radiation and the injection of contrast dye. MRI can be used to determine disc position and morphology. MRI may also show arthritic changes in the TMJ. Moreover, disc displacement seen on MRI may also be observed in asymptomatic patients, so these findings should never guide therapy alone. Diagnostic injections with anesthesia, synovial fluid analysis, or biopsy of suspicious areas by the specialist may be useful for differentiating diagnosis.

Differential Diagnosis

Because of the extensive list of contributing factors and potential symptoms, it may be difficult to arrive at a diagnosis of TMD. Accurate diagnosis is essential and has traditionally been the weak link in the chain of management of TMD. Disorders of the intracranial structures should be ruled out initially because they may be life-threatening and require immediate attention. New or abrupt onset of pain, progressively more severe pain, interruption of sleep by pain, and systemic symptoms such as weight loss, ataxia, fever, and neurological symptoms (e.g., seizures, paralysis, vertigo) are characteristic of intracranial disorders. Differential Diagnosis Table 8.4 presents common differential diagnoses for TMD.

Management

Effective care of patients with TMD involves understanding and treating the whole patient via an individualized program. A multidisciplinary approach is frequently indicated. Contributing factors must be addressed rather than concentrating on eliminating signs and symptoms.

The goals for management are similar to those of any musculoskeletal condition—reduction or elimination of pain and restoration of acceptable mandibular function. Complete resolution of TMD may not always be possible, however, as in the case of permanent damage to joint structures. In these cases, the term "cure" or "treatment" has been abandoned for the term "management."

Initial therapy should be reversible and is designed to be palliative and to promote healing. Acute disc displacement or active trigger points may require rapid treatment/referral. In general, however, the practitioner can initiate management with conservative therapies such as self-help techniques and pharmacotherapy.

One of the most significant contributions toward management of TMD can be made by adjustment in diet consistency, education and alteration of oral parafunctional habits, and application of ice (for acute symptomatology) or moist heat (for chronic symptomatology). On occasion, self-treatment alone may control signs and symptoms; specific recommendations are listed under Patient Education.

Physical therapy may be employed, primarily as an adjunct to other therapeutic modalities, in an attempt to relieve pain of musculoskeletal origin and restore normal masticatory function. Physical therapy for TMD may include electromodalities and therapeutic exercises as prescribed by a physical therapist. Behavioral therapy is indicated for patients with behavioral and emotional problems and/or noxious habits that accompany TMD. Stress relief and pain control methods such as counseling, hypnosis, biofeedback, and guided imagery are safe and noninvasive.

Pharmacotherapy can be beneficial in controlling pain and inflammation associated with TMD. Careful monitoring of the patient's tolerance to prescribed medications, as well as the effectiveness of the drug, is indicated. To avoid potential abuse of any drug that may produce dependence, dosing at regular intervals for a definite period of time is preferred, as opposed to as-needed dosing. Drugs Commonly Prescribed 8.6 presents the drugs that are commonly used to treat TMJ disease. Injection of trigger points with anesthetic agents

Drugs Commonly Prescribed 8.6 Temporomandibular Joint Disease (TMD)

Drug	Indication	Dosage	Comments
Tricyclic Antidepressants			
amitriptyline (Elavil)	TMD (chronic)	25 mg 3–4 times daily or 75 mg at bedtime Begin with low nightly dose and increase	May result in decreased orofacial pain, improvement in sleep disorders, and promotion of muscle relaxation and decreased bruxism. *Contraindicated within 14 days of use of MAO inhibitors and acute post–myocardial infarction (post-MI). Monitor serum levels with concomitant use of drugs metabolized by CYP450.* **Adverse effects:** Anticholinergic effects, drowsiness, dry mouth, arrhythmias, etc.
Benzodiazepines			
clonazepam (Klonopin)	TMD (acute)	0.5 mg 3 times daily Use as a short course of 1–2 weeks only	For relief of acute pain secondary to masticatory muscle spasm or TMD pain. *Contraindicated with severe liver disease and acute narrow-angle glaucoma. Monitor for suicidal tendencies. Potentiates many CNS effects. Caution with drugs that inhibit CYP3A.* **Adverse effects:** CNS effects, especially depression. Pregnancy Category D. Not recommended for nursing mothers.

Drugs Commonly Prescribed 8.6 Temporomandibular Joint Disease (TMD)—cont'd

Drug	Indication	Dosage	Comments
diazepam (Valium)	TMD acute and chronic	2–10 mg 2–4 times daily	*Contraindicated with acute narrow-angle glaucoma. Potentiates ETOH.* **Adverse effects:** CNS depression, ataxia, memory impairment.
Nonopioid Analgesics			
acetaminophen (Tylenol)	TMD chronic	1,000 mg 3 times daily	May relieve orofacial pain.
ibuprofen (Motrin, Advil)	TMD chronic	400–800 mg 3–4 times daily	May help inflammatory pain.
naproxen (Aleve)	TMD chronic	220 mg every 12 hours	*Contraindicated with aspirin allergy. Do not use in third trimester of pregnancy. Increased risk of GI bleed with concomitant use with ETOH.*
Muscle Relaxants			
cyclobenzaprine HCl (Flexeril)	TMD acute	5–10 mg 3 times daily	May relieve muscle spasm. Use with physical therapy (PT) modalities. *Contraindicated acute post-MI, arrhythmias, heart block, and other conduction disturbances. Not recommended with liver disease, urinary retention, glaucoma. Potentiates anticholinergics. Can precipitate hypertensive crisis with MAO inhibitors.* **Adverse effects:** Drowsiness, blurred vision, dry mouth, dizziness. Nursing mothers and Pregnancy Category B.
Corticosteroids			
methylprednisolone (Medrol, Solu-Medrol)	TMD acute and severe	Start slow Do not use for longer than 2–3 weeks Dose pack	*Used only for short term in severe unrelenting pain in the TMJ related to inflammatory conditions. Potentiated by CYP3A4 inhibitors. May antagonize anticoagulants. Need to monitor International Normalized Ratio (INR).* **Adverse effects:** Susceptiblitiy to infection, glaucoma, cataracts, electrolyte imbalances.

may be beneficial; however, it is most likely that this would be done by the specialist (dentist or oral maxillofacial surgeon) to whom the patient has been referred.

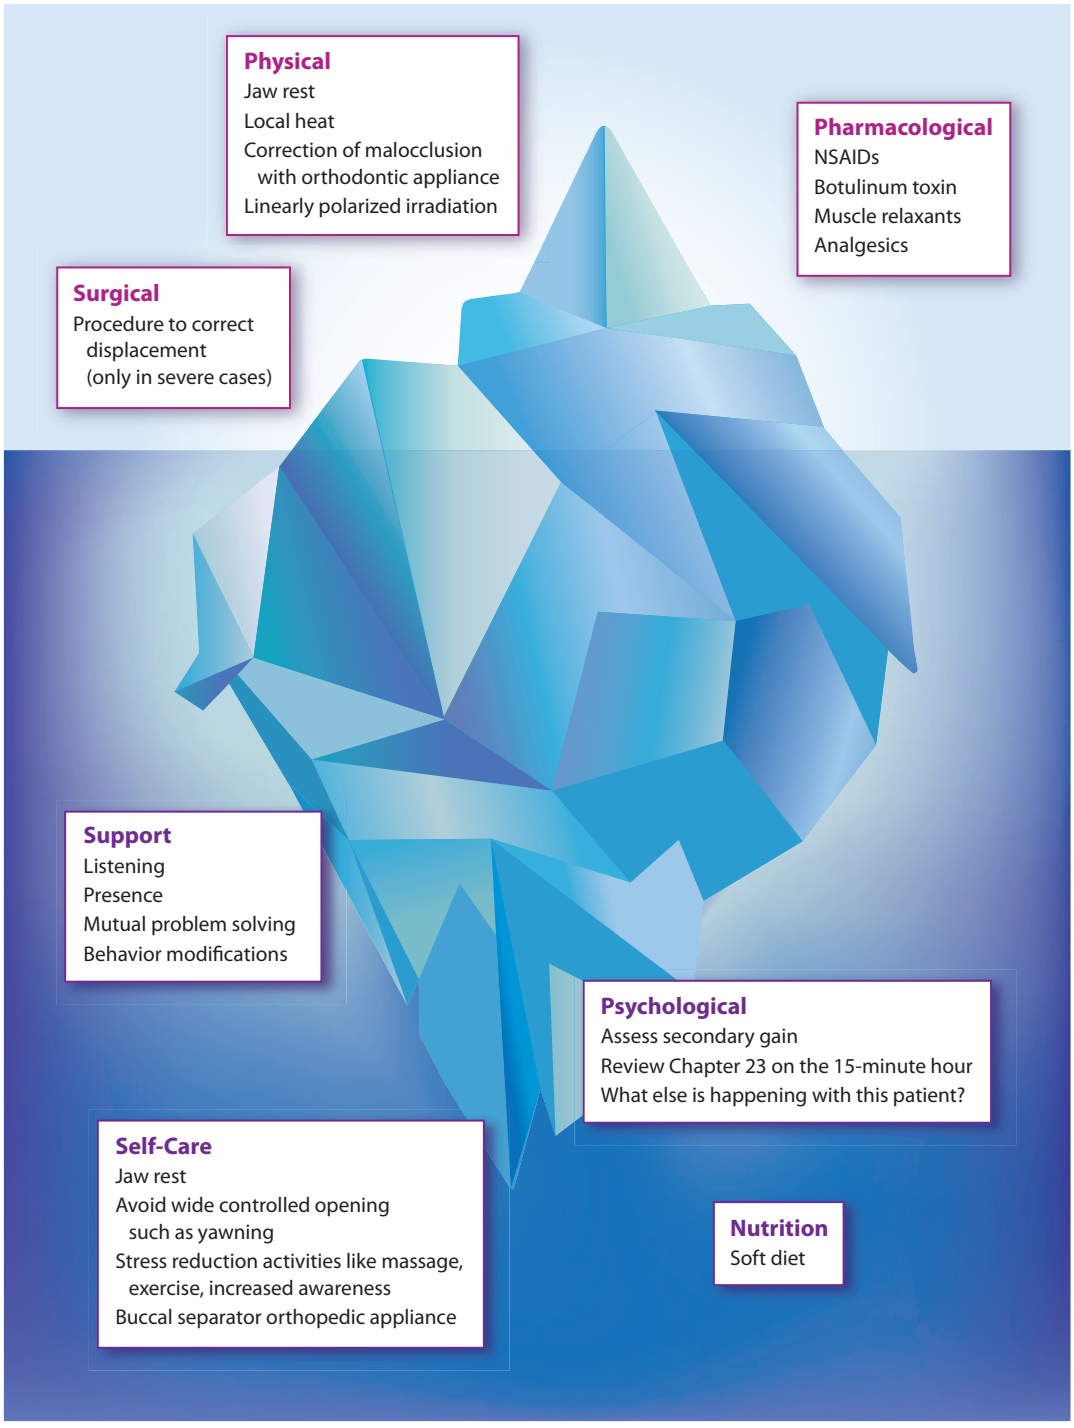
For the majority of cases of TMD, any necessary subsequent management will be initiated and followed by the dentist, otolaryngologist, or oral surgeon to whom the patient has been referred. Most of the therapies employed by these practitioners are not considered part of initial therapy for TMD because they are irreversible procedures. These therapies include orthodontics, prosthodontics, occlusal equilibration, or surgery. Wearing an intraoral appliance with an occlusal appliance or splint may be recommended, generally by a dentist. At the present time, this type of therapy is highly controversial and may not be considered an option by many practitioners although it may be indicated for patients

with gross structural changes in the alignment of the TMJ. Surgery, including arthroscopic surgery or arthrotomy, may be recommended by an oral maxillofacial surgeon. Surgery may be indicated in patients who do not respond to nonsurgical therapy and who have disabling pain or dysfunction related to TMD. (See The Iceberg of TMD.)

Follow-up and Referral

The decision to refer a patient with TMD to a specialist should be made based on the individual practitioner's knowledge level and comfort in treating TMD. Once other systemic conditions have been ruled out, the practitioner may choose to begin initial management of

The Iceberg of TMD



TMD symptoms. Follow-up should be early and repeated (e.g., in 1–2 weeks initially, and then monthly), especially if pharmacotherapy is ordered. If there is any uncertainty about the diagnosis, referral should be made at this time to a dentist or otolaryngologist or to an oral maxillofacial surgeon who is knowledgeable in the treatment of TMD. If initial therapy is unsuccessful or if advanced management is indicated, appropriate referrals should be undertaken.

Patient Education

Home care and patient education is an integral component to the management of TMD. The majority of patients achieve relief of symptoms with conservative therapy, including self-care techniques. Patient information for management of TMD includes the following recommendations:

- Limit jaw function by eating softer foods, taking smaller bites, and not opening wide when eating. Avoid foods such as apples, corn on the cob, hard breads, raw vegetables, steak, and so on.
- To help reduce stress, strive for a nutritionally balanced diet and an active exercise program.
- Ice packs can be used for acute pain and muscle spasm. Place an ice pack over the temple area and side of the face for 10 minutes, three or four times a day. For chronic pain, moist heat should be used following the same guidelines.
- Disengage your teeth—the rule is "lips together, teeth apart."
- Do not chew gum or ice.
- Sleep on your back with a pillow under your knees. Do not use firm, full pillows under your head. Orthopedic pillows can be helpful in reducing head and neck pain. Do not sleep on your stomach.
- When talking on the telephone, do not support the receiver with your shoulder.
- Prevent wide-opening when yawning. Do not sit with your chin resting on your hand.
- Practice good posture. If you must sit for long periods of time, try to stand and move around frequently to stretch your muscles.

Chapter 9

Respiratory Problems

Jill E. Winland-Brown, EdD, APRN, FNP-BC •
Brian Oscar Porter, MD, PhD, MPH

COMMON COMPLAINTS

COUGH

Each year more Americans seek medical treatment for a cough than for any other complaint. In the United States, the treatment costs for these visits exceed $1 billion annually. Cough is the body's natural protective mechanism for clearing the airways of secretions and irritants. Cough may be associated with a number of conditions, disorders, and diseases that alter pulmonary secretions (bronchitis, pulmonary edema), increase sensitivity of the cough receptors and airways (asthma), directly stimulate the receptors (aspiration), indirectly stimulate receptors (reflux), or affect psychological health. Cough may be associated with the following conditions: asthma, chronic obstructive pulmonary disease (COPD), bronchiectasis, cystic fibrosis, pneumonias, tuberculosis (TB), lung cancer, interstitial lung disease (ILD), cardiac tamponade, pharyngitis, and gastroesophageal reflux disease (GERD), to mention the most common.

In extreme cases of debilitation or in certain neuromuscular conditions, the cough mechanism may be impaired. There are times when the cough mechanism should be supported to clear the airways of unwanted irritants and times when it should be suppressed. These issues are discussed in relation to the underlying condition that initiates the cough mechanism.

Differential Diagnosis

The differential diagnosis of cough requires a comprehensive history and assessment to provide appropriate treatment and management. One patient may present with the complaint of a dry, hacking cough of sudden onset *(acute cough);* another may present with a cough of longer duration. A *chronic cough* is defined as one that lasts longer than 3 weeks. Many patients try over-the-counter (OTC) measures for a chronic, nagging cough and delay seeking treatment or seek treatment only when the cough becomes productive or when there is blood in the sputum.

A diagnosis can be made about 80% of the time via a thorough history by exploring with the patient the following details regarding the onset and nature of the cough:

- When did the cough first start? What factors may have prompted the cough (e.g., recent respiratory infection or exposure to noxious agents)? Is there a seasonal pattern? Is it related to work or hobbies?
- When does the cough occur—on arising, at bedtime, during exercise, or throughout the night?
- What factors seem to stimulate the cough or make it worse? Is the cough aggravated by exposure to certain chemicals, body position, exercise, or cold air? Does the person have any reactive airway disease?
- Has the patient identified any factors that seem to provide relief from the cough, such as sitting upright or avoiding exposure to certain agents? What measures have been tried to alleviate the cough?
- What is the quality of the cough—is it dry and hacking, wet, raspy, deep, or throaty?
- Is the cough productive or unproductive? If the patient produces sputum with the cough, ask the patient to describe the amount of sputum produced per day (e.g., 1 tsp, 1 tbsp, etc.), the color (e.g., yellow, gray, green, brown, clear, white, blood-tinged), and consistency (e.g., thick, ropy, frothy, or tenacious). When is the productive cough most productive?
- Does the patient cough more when lying supine? Is the cough 24/7?

In addition, it is essential to find out if the patient has signs and symptoms associated with the cough, such as pedal edema, dizziness, chest pain or tightness as with reactive airway disease, fatigue, dyspnea, hoarseness, fever, tachypnea, chills, heartburn, wheezing, and hemoptysis. In describing dyspnea, it is best for the patient to use a continuum scale similar to the pain scale that can describe today's dyspnea versus previous dyspnea on a scale of 0 to 10. Research indicates a vertical analog scale is best for patients to "plot" this and keep a diary or record of this until their next visit. The patient should be asked to describe in detail the onset of the associated signs and symptoms. Standard data regarding the patient's medical history should be recorded, including hospitalizations, surgeries, and major illnesses, particularly recent illnesses and respiratory allergies. The patient's lifestyle should be explored, such as occupation and work history; hobbies; exposures to noxious agents; and use of alcohol, tobacco, and other substances. Patients should also be asked about the use of marijuana, because it is now legal in several states, as well as the use of electronic cigarettes that contain nicotine. The most common cause of chronic cough

is cigarette smoking, which triggers the cough reflex by direct bronchial irritation.

The patient needs to be asked about the use of prescription and OTC drugs. Certain antihypertensive drugs such as angiotensin-converting enzyme (ACE) inhibitors and beta blockers can cause hypersensitive airways, producing wheezing and a cough. Other drugs such as nitrofurantoin (Macrobid, Macrodantin) may cause interstitial fibrosis and associated cough. All patients taking nitrofurantoin (Macrobid) should be monitored for changes in lung function. Some individuals who are prone to certain autoimmune disorders seem to be more susceptible to lung disease after taking these antibiotics.

For the physical exam, focus on the following:

- Check the ears for cerumen or hairs impinging on the tympanic membrane, which may cause cough (Arnold's reflex).
- Examine the nose for discharge, edema, polyps, and sinus tenderness. In the throat, look for cobblestoning of the oropharynx, which suggests postnasal drip.
- Palpate the neck, including both anterior and posterior cervical node chains, for enlarged lymph nodes or masses.

A complete assessment of the thorax and chest should be done to rule out cardiac or pulmonary problems. If the patient has not coughed during the visit, ask the patient to reproduce the cough and listen to its sound and character. The lungs should be auscultated, especially for crackles (rales) and rhonchi. The patient should be asked to produce a forced expiration while the practitioner checks for wheezes. Generally crackles, which are fluid, do not clear with cough; but rhonchi, which are mucus, do clear after the patient is asked to cough and clear the airways. The presence of heart murmurs, gallops, and carotid bruits should also be assessed. Any of the following conditions may cause cough:

- **Postnasal drip:** This common problem is most often associated with allergic or vasomotor rhinitis and less often with sinusitis. Patients often describe a sensation of tickling or trickling in the back of the throat.
- **Postinfection:** After a bout with the flu or viral illness involving the respiratory tract, patients may have a cough for 8 or more weeks because of bronchial hyperreactivity.
- **COPD:** Chronic bronchitis, the most common type of COPD, is defined as a chronic productive cough that persists for 3 months of the year or longer for 2 or more successive years. Most smokers eventually develop chronic bronchitis.
- **Asthma:** Asthma is a reversible obstructive pulmonary disease, a reactive airway disease, and is often accompanied by cough and wheezing. The cough may be productive or dry.
- **GERD:** In most cases, cough associated with GERD is thought to be caused by stimulation of the distal esophagus, but in a small percentage of cases, it may be due to microaspiration.
- **Drugs:** Cough occurs in about 10% of patients who take ACE inhibitors, such as captopril and enalapril. A complete history of prescribed and OTC drugs, including any herbal preparations, should be taken.
- **Occupational and environmental factors:** Exposure to air pollution, industrial dust and pollutants, secondhand smoke, and other pollutants may cause chronic cough.
- **Other possible causes of cough:** Tumors (bronchogenic or mediastinal), pulmonary embolism, aortic aneurysm, heart failure, aspiration, bronchiectasis, TB, sarcoidosis, foreign body obstruction, diaphragmatic irritation (which may be seen in ascites), lung abscess, *Pneumocystis jirovecii,* and psychogenic factors.

In most cases, the underlying cause can be determined from a history and physical exam, but it may be necessary to consider the judicious use of one or more of the following diagnostic aids in conjunction with the differential diagnosis process. For example, if one suspects TB, a Mantoux purified protein derivative (PPD) (tuberculin intradermal skin test) should be placed in the forearm and read 48 to 72 hours later by a qualified staff member at a second visit. Information on interpreting the PPD results is given later in this chapter. Another blood test that may be used to detect TB is an interferon-gamma release assay such as the QuantiFERON-TB Gold Test, which only requires a single patient visit. A positive result on either screening test should be followed up with a chest x-ray (CXR) film. For patients who are immunocompromised, the TB skin test may have to be repeated because of T-cell anergy against TB antigens.

Spirometry is helpful to determine the presence of obstructive or restrictive lung disease. A CXR film should be taken if there are signs and symptoms of pneumonia, TB, possible tumor, aspiration, foreign body, or ILD or even if the patient is just not recovering as expected. This follow-up CXR may pick up a hidden tumor that would otherwise have been missed. Sinus films may be useful to rule out sinusitis when the patient presents with a history of chronic postnasal drip and chronic sinus infections.

Computed tomography (CT) scanning of the chest can detect small peripheral lung nodules, evaluate coin lesions (solid, cystic, or calcified), and distinguish the chest wall from areas of pleural or parenchymal disease. Chest vessels can be separated from lymph nodes and other solid, nonvascular structures. The CT scan has replaced bronchography in diagnosing bronchiectasis. CT scan may help to better delineate endobronchial, parenchymal, or mediastinal masses. High-resolution chest CT scan, ventilation–perfusion scan, or pulmonary angiography is indicated when pulmonary thromboembolism is suspected.

A complete blood cell count and differential is helpful in diagnosing a bacterial infection. Fungal serology should be done to identify coccidiomycosis, histoplasmosis, and aspergillosis if the history of exposure is positive or if the patient has AIDS or is immunosuppressed.

Treatment

Because a cough is a symptom, treatment should be directed toward resolving the underlying cause(s) and removing any identified triggers. In patients with chronic cough who are weak and debilitated, the goal is to reduce complications from uncontrolled, forceful coughing, such as fractured ribs, pneumothorax, aspiration, exhaustion, sleep deprivation, and post-tussive syncope.

With severe, acute coughing that disrupts sleep and causes pain or extreme fatigue and weakness, it may be necessary to treat with antitussives, but these drugs have a limited role and should only be used on a short-term basis and only at night, because you want the patient to expectorate during the day. Nonnarcotic agents such as dextromethorphan or pseudoephedrine/brompheniramine/dextromethorphan may be used every 3 to 4 hours as needed. In addition, benzonatate (Tessalon) may be effective. When sleep or eating is interrupted by persistent cough, the preferred choice is codeine, 8 to 30 mg every 3 to 4 hours, but only on a short-term basis. (Patients with terminal lung cancer and patients with cystic fibrosis at the end of life should receive codeine in sufficient doses to keep them comfortable.)

Decongestants and antihistamines, alone or in combination, are indicated in cases of allergic rhinitis and postnasal drip. Antihistamines are most useful for those who have allergic upper airway disease but are usually avoided in asthmatic individuals because they may thicken secretions and inhibit expectoration. Intranasal steroid sprays or aerosols such as beclomethasone (Beconase) or fluticasone (Flonase) may also be useful when used on a consistent basis.

Expectorants are intended to decrease sputum viscosity and are used when the patient has a productive cough and needs help in clearing the airways. Suppression of a productive cough, however, may lead to complications such as obstructive pneumonia, because the patient may not be able to clear the airways and lungs of sputum. Although expectorants may work for some cases, increasing the patient's water intake to 3 to 4 L/day is the most cost-effective means of helping to liquefy secretions, as long as the patient can manage the volume and does not have heart failure or some other disorder in which this volume of water could compromise health. Guaifenesin (Mucinex), which is available without a prescription and in inexpensive generic brands, helps to break up mucus. Patients must be reminded to drink plenty of fluids if taking this medicine. Some practitioners prefer to give an expectorant during the day and a cough suppressant at night, so that the patient may sleep.

Two herbal remedies are currently used but have not been thoroughly researched in randomized controlled trials. Horehound has been suggested as a cough suppressant, and licorice has been said to calm coughs and have expectorant qualities. Caution should be taken with licorice, however, because it may increase the blood pressure.

Encouraging the patient to stop smoking should be a priority, given the effects of cigarette smoke on destroying the mucociliary structures of the airway lining and reducing the body's natural ability to clear mucus and respiratory pathogens. A chronic cough may not disappear in ex-smokers for a year or more after smoking cessation. Smoking cessation techniques are listed later in the chapter.

Patients with GERD, whose cough reflex can be triggered by the reflux of acidic stomach contents, usually respond to a course of antireflux therapy, which includes antacids, histamine-2 receptor blockers, or proton pump inhibitors. The benefits may not be noticed for several weeks, however.

Educating the patient and family about potential environmental and occupational factors that precipitate a cough is essential. Explore ways to avoid exposure to irritants. If a family member smokes, the dangers of secondhand smoke should be explained to the patient and family. Adequate hydration (increasing fluids) and adequate room humidification may also help reduce coughing. Breathing in the steam from a hot shower may also be effective.

DYSPNEA

Like pain, *dyspnea* is a perceived sensation that may vary among patients, which is why using a scale from 0 to 10 is recommended. Patients with dyspnea usually describe a sense of difficult breathing or inability to get sufficient air into or out of the lungs. Dyspnea may also be described as a feeling of breathlessness, suffocation or smothering, air hunger, and labored breathing. In many cases of dyspnea, the respiratory rate is rapid; cough may be present, depending on the underlying disease or cause of the dyspnea. Dyspnea may be caused by a number of different health problems. Some individuals may experience exercise-induced dyspnea or exercise-induced bronchospasm. In an older patient, dyspnea is the major atypical presentation for ischemic heart disease and myocardial infarction and is considered a frequent anginal equivalent. Dyspnea in aging patients may be difficult to evaluate when there are associated comorbidities.

Dyspnea is one of the most commonly occurring complaints for which patients seek help from health-care providers. Dyspnea, or shortness of breath, is estimated to be the third most frequent reason for seeking medical attention. Although dyspnea occurs primarily in patients with respiratory and cardiac disorders, it may also occur in other conditions such as lung neoplasms with metastasis, neuromuscular myopathies, neuropathies, spinal cord lesions, diaphragmatic disorders, and panic disorders. In patients receiving hospice care, it is the second most common symptom secondary to pain.

Differential Diagnosis

In the majority of cases, dyspnea is a result of cardiac or pulmonary decompensation. There are several symptoms associated with dyspnea, such as tachypnea (rapid breathing), orthopnea (dyspnea relieved in the sitting or upright position), and paroxysmal nocturnal dyspnea (sudden episodes of acute dyspnea at night). The causes of dyspnea are often complex. The common causes and precipitants of dyspnea follow:

- Pulmonary: COPD, asthma, pulmonary parenchymal disease, ILD, pulmonary hypertension, severe kyphoscoliosis, exogenous mechanical factors (ascites, massive obesity, extensive pleural effusion)
- Cardiac: Congestive heart failure (CHF), pulmonary venous congestion (mitral stenosis, mitral regurgitation)
- Hematological: Severe chronic anemia
- Psychogenic: Anxiety and panic disorders

Dyspnea may be acute or chronic, and patients with COPD may have both acute and chronic dyspnea. It is important to do a complete work-up to determine the underlying cause of the dyspnea so that appropriate treatment can be initiated. Dyspnea caused by acute anxiety may mimic cardiopulmonary decompensation, and patients with pulmonary hypertension may have episodes that resemble anxiety-related dyspnea. Onset of dyspnea at rest, accompanied by a sense of chest tightness, a feeling of suffocation, and an inability to "get air in," is a common presentation of anxiety-related dyspnea. In the absence of heart and lung disease, a history of multiple somatic complaints, emotional difficulties, no activity limitations (exercise intolerance), and dyspnea unrelated to activities provides evidence for psychogenic-related dyspnea.

About 75% of cases of dyspnea are caused by respiratory conditions that may be acute or chronic. The majority of other causes of dyspnea are cardiac in origin. It is important to explore with the patient the details of the onset and character of the dyspnea. The clinician should note whether the patient has dyspnea at rest or on exertion. Standard questions include the following: (1) How many flights of stairs did the patient climb before dyspnea occurred (e.g., one-flight dyspnea)? (2) How many blocks did the patient walk before dyspnea occurred (e.g., one-block dyspnea)? (3) How many feet did the patient walk before dyspnea occurred (e.g., 100-feet dyspnea)? The rate of the patient's speech during exercise can provide good clinical information.

Exploring when the dyspnea first occurred and what the patient was doing at the time is essential. Specific questions should be directed toward precipitating factors and factors that alleviate the dyspnea. Questions should explore potential environmental exposure (e.g., recent travel) or exposure to agents (e.g., through occupation or hobbies) that aggravate the dyspnea. Paying attention to other signs and symptoms that may be associated with the dyspnea, such as cough, peripheral edema, dizziness, wheeze, fever, chest pain, heartburn, leg pain, and paresthesias, is also critical.

A complete physical exam should be done, with particular attention directed to the pulmonary and cardiovascular systems. The examiner should check for tachycardia, tachypnea, fever, mixed venous oxygen saturation (SvO_2), and hypertension. The quality of breath sounds (increased, decreased, or absent) should be noted, along with the presence of crackles, rhonchi, wheezes, egophony, and fremitus. Bronchial lung sounds heard at other than the normal locations (tubular sounds) are common with acute bronchitis. Assessment should include checking for third and fourth heart sounds, murmurs, friction rubs, jugular venous distention, pedal edema, and calf tenderness. A visual analog scale (0 = no dyspnea; 10 = worst dyspnea ever had) or the Borg scale for perceived exertion with a score of 6 to 20 (6 = no exertion; 20 = very, very hard exertion) are useful in assessing the degree of dyspnea, as previously mentioned. The scales can be used again on the patient's next visit to compare outcome effects of treatments. The scales can also be good for patient self-management.

Diagnostic tests are guided by data from the history and physical exam and the suspected causes of the dyspnea. Chest x-ray films are useful in ruling out tumors, TB, pneumonia, and other major pulmonary disorders. A complete blood count (CBC) with differential should be done to rule out anemia and infection. A blood chemistry profile is done if a metabolic acidosis is suspected and to differentiate anion-gap acidosis from nonanion-gap acidosis. Oximetry to measure the saturation level of oxygen may be useful in assessing whether the patient may be dyspneic because of hypoxemia. If the O_2 saturation level is less than 90%, arterial blood gas (ABG) analysis should be done. Levels of dyspnea have not been found to correlate well with physiological measures.

If there is suspicion of carbon monoxide (CO) exposure, a carboxyhemoglobin (COHb%) level should be obtained. COHb% levels of 4% to 15% may be found in heavy smokers. Levels above 20% may cause dyspnea and headache; levels greater than 40% may cause seizures and death.

Peak expiratory flow rate is a simple, inexpensive test that can be done with a handheld flow meter in the office or at the bedside. This test determines the degree of expiratory airflow obstruction in patients with asthma and COPD. Full spirometry is useful in determining whether the patient has obstructive, restrictive, or mixed (obstructive and restrictive) lung disease (see under Cough). Diffusion capacity should be checked if ILD is suspected. If the patient uses a flow meter at home, he or she can determine whether it is necessary to come into the office for further evaluation and possible treatment.

Treatment

Initial treatment is directed at helping the patient find relief from the shortness of breath by removing the

underlying cause and contributing factors. Subsequent management is directed at prevention and assisting the patient with management of chronic dyspnea in conditions such as COPD or ILD. In cases of dyspnea caused by hypoxemia, supplemental oxygen may be indicated. In cases of shunting, the cause of the shunting must be corrected. For subsequent management, see the sections on asthma, chronic bronchitis and emphysema (COPD), and interstitial lung disease.

For treatment of dyspnea related to cardiac disorders such as CHF, refer to Chapter 10. Appropriate diuretics to relieve fluid overload may improve breathing, and supplemental oxygen may be necessary in some cases.

For anxiety-related dyspnea, psychiatric referral may be needed if other simple measures have been tried without good results. Dyspnea caused by rapid overbreathing during anxiety attacks can be corrected through patient education. Until the patient learns a rebreathing technique, it may be helpful to prescribe short-term use of anxiolytics such as buspirone HCl 20 to 30 mg/day.

HEMOPTYSIS

Hemoptysis is defined as expectoration of blood. The patient often reports coughing up blood or sputum that is streaked or tinged with blood. In addition, hemoptysis may be manifested as fresh (bright red) or old (dark red or black) blood or, in the case of bleeding from an infected lung cavity, it may present as slow oozing or frank bleeding. In cases of profuse hemoptysis, blood clots may be expectorated. The patient should note if the blood is from the nasal cavity, which may only be from severe irritation or dehydration.

Differential Diagnosis

About 80% of hemoptysis cases have inflammatory causes such as bronchitis, bronchiectasis, pneumonia, and TB. Less common causes may include neoplasms that damage a pulmonary vessel and rupture a pulmonary artery or persons with cystic fibrosis who have a good amount of damage to lung parenchyma. Use of pulmonary artery balloon catheters has increased the incidence of pulmonary artery rupture. Cardiovascular causes of hemoptysis include left ventricular failure, mitral stenosis, pulmonary embolism or infarct, primary pulmonary hypertension, and aortic aneurysm. Clotting defects may also cause hemoptysis. Bleeding may occur anywhere in the respiratory tract, including the nose, sinuses, and mouth.

About 95% of pulmonary blood circulation is supplied by the pulmonary artery and its branches, which is a low-pressure system. Bronchial circulation, a high-pressure system, originates from the aorta and usually provides about 5% of the blood to the lungs, mostly to the airways and supporting structures. When bleeding occurs, it usually arises from the bronchial circulation, unless trauma or erosion has affected a major pulmonary vessel. Pulmonary venous bleeding is modest and occurs in pulmonary venous hypertension, especially in conjunction with left heart failure.

The patient usually presents with a complaint of "coughing up" blood. To most people, the presence of blood in the sputum or coughing up blood is a frightening experience, and most will seek immediate medical attention. As in differential diagnosis of dyspnea and cough, a similar line of questioning should be pursued regarding onset, amount, aggravating and alleviating factors, and the presence of other associated symptoms such as dyspnea, cough, dizziness, fatigue, and chest pain. Bronchopulmonary bleeding may present as hematemesis (vomiting of blood). The patient may swallow blood during the night and may vomit blood on arising.

The history and physical exam are focused along the same lines as for the complaints of cough and dyspnea. In addition, if the examiner suspects that the hemoptysis is due to a pulmonary neoplasm, the exam should focus on the pulmonary system and lymph node enlargement.

Further diagnostic tests may be indicated, depending on the results of the history and physical examination. The common causes of hemoptysis will direct the laboratory tests. If hemoptysis occurs in patients aged 45 years or younger, it is likely caused by mitral stenosis, TB, bronchiectasis, or lung abscess. For patients older than age 45 years, common causes of hemoptysis include bronchogenic carcinoma, bronchitis, TB, and pulmonary embolus with infarction. In massive hemoptysis (loss of more than 600 mL of blood in 24 hours, which may occur in lung cancer, TB, bronchiectasis, and lung abscess), the condition is life-threatening and constitutes a medical emergency. There may be time to do only chest radiographs and a CBC before emergency surgery or bronchoscopy.

For nonemergency cases, in which the sputum is tinged or streaked with blood, there is time to do the essential tests to identify the cause of hemoptysis. In addition to chest x-ray films and a CBC, sputum should be cultured for acid-fast bacilli if TB is suspected. For suspected pneumonia or lung abscess, sputum for culture and sensitivity should be done. Patients who present with hematemesis may also have hemoptysis caused by aspiration; a chest x-ray film is indicated for these patients.

Patients with a history of thromboembolism may be taking anticoagulants. If so, clotting times should be checked to rule this out as a cause of the hemoptysis.

Because of the exertion (forceful expiratory maneuvers) required by the patient during spirometry, measurement of lung volumes during periods of active hemoptysis is not recommended.

Treatment

Massive hemoptysis requires immediate treatment, surgery, or bronchoscopy. During this time, prevention of aspiration and keeping the airway open are of utmost importance. Endotracheal intubation may be necessary. Supplemental oxygen and replacement of blood loss may

be necessary, depending on the blood pressure, pulse, ABG results, and hemoglobin count.

Treatment of chronic hemoptysis is directed toward the underlying cause. When the cause is inflammation, as in chronic bronchitis, TB, and bronchiectasis, the patient must be educated to stop smoking, comply with use of prescribed medications (e.g., antibiotics, bronchodilators), perform deep breathing and coughing exercises every 2 to 4 hours regularly, and avoid exposure to secondhand smoke and other noxious agents that might precipitate cough.

Education of the patient and family regarding the causes of the hemoptysis is essential. The patient needs to know what factors may precipitate the hemoptysis and how it can be prevented. The patient should be taught to note any change in the color, amount, and consistency of the blood expectorated. Any sudden increase should be reported to the health-care provider immediately for prompt medical attention.

COMMON PROBLEMS

UPPER RESPIRATORY INFECTIONS

Upper respiratory infections (URIs) include some of the most common infectious diseases encountered and account for millions of visits to health-care providers annually. The majority of URIs are caused by viruses. Bacteria cause about 25% of the cases. For the average adult, URIs are a source of discomfort, disability, and loss of time. For young children, the immunocompromised, and older adults, these infections may be a cause of morbidity and serious illnesses. In children and older adults, as well as adults with underlying respiratory diseases, these viral infections are frequently complicated by bacterial superinfections.

Epidemiology and Causes

Influenza (the flu), the common cold (viral rhinitis or acute coryza), and acute laryngitis are some of the more frequently occurring URIs that the practitioner will need to manage. Infections such as acute epiglottitis and respiratory syncytial virus (RSV) infection occur predominantly in infants and younger children but may occur as a life-threatening infection in adults. RSV infection can cause severe cases of pneumonia and lower respiratory tract disease in older, institutionalized adults and adults with suppressed immune status. Acute epiglottitis can result in complete or partial airway obstruction (Table 9.1).

Influenza epidemics occur every year in the United States, with typically 5,000 to 250,000 cases annually. In some years with more severe outbreaks, as many as 40,000 deaths have occurred. Most of these deaths occur in older persons, particularly those with underlying pulmonary or cardiac disease. Infants and very young children also appear to be at greater risk for influenza-associated morbidity and mortality. Although influenza and colds may occur at any time, most cases occur during the winter and spring months. Acute laryngitis is generally associated with a viral URI and often persists for a week or more after other symptoms have cleared. The incubation period for most URIs of a viral nature is 1 to 4 days.

Table 9.1 Acute Epiglottitis

Acute epiglottitis is a life-threatening, rapidly progressing cellulitis of the epiglottis that may cause complete airway obstruction. Epiglottitis begins as a cellulitis between the tongue base and the epiglottis; the epiglottis is then pushed posteriorly. The epiglottis becomes swollen and threatens airway patency. Epiglottitis is more common and more severe in young children, but it may occur in older children and adults.

Clinical Manifestations

Epiglottitis in adults should be suspected when odynophagia (pain on swallowing) seems severe compared with pharyngeal findings. Other findings include dyspnea, drooling, and stridor.

Diagnostic Reasoning

Direct viewing of the epiglottis with a tongue blade and lighting should never be attempted because immediate laryngospasm and airway obstruction may result. It is recommended that children and adults be transported to the operating room (OR) while sitting up for visualization of the epiglottis with a fiberoptic laryngoscope, with preparations made for immediate airway control. The epiglottis will appear swollen and erythematous ("cherry red"), and an uncuffed endotracheal tube should be inserted.

Management

Acute epiglottitis requires emergency care for adequate airway control. No painful or stressful procedures should be performed on these patients unless preparations are in place for a planned intubation, such as in the OR.

The patient with epiglottitis will require hospitalization for IV antibiotics such as cefuroxine (Ceftin), ceftriaxone (Rocephin), or ampicillin/sulbactam (Unasyn). Dexamethasone (Decadron) should also be administered IV and tapered as signs and symptoms resolve. Continuous pulse oximetry and careful monitoring of the patient's airway are critical. Patients who develop hypoxemia and respiratory distress will require intubation.

Community-acquired respiratory tract infections caused by *Streptococcus* account for more than 20 million primary-care provider visits annually and are a major reason for work and school absenteeism.

Pathophysiology

The common cold (coryza) is caused by viruses spread through direct inhalation of airborne droplet sprays aerosolized by the infected person while speaking, coughing, or sneezing, as well as hand-to-face transmission after handling fomites serving as reservoirs of infection. Hand-to-hand transmission, however, is probably the most common mode of transmission in adults, underscoring the importance of frequent hand washing in the prevention of new cases. Numerous serotypes of rhinoviruses, adenoviruses, coronaviruses, coxsackieviruses, and parainfluenza viruses are associated with the common cold. The ability of the majority of these viruses to mutate readily ensures their ability to consistently evade host immune mechanisms. The number of rhinovirus serotypes, for instance, currently stands at more than a hundred. Following infection, individuals develop immunity to a specific viral strain but are susceptible to repeated infection by the same parent virus after only minor changes in surface proteins or polysaccharides.

Symptoms of congestion, rhinorrhea, and sneezing result directly from inflammation and edema of upper airway mucosal surfaces. The cough reflex may be triggered by this same mucosal inflammation in the posterior pharynx. After acute infection, postviral cough may persist for as long as 6 to 8 weeks due to postnasal drip—the persistent drainage of thin mucus down the posterior pharynx resulting in direct pharyngeal irritation.

Classic flu is caused by the orthomyxovirus influenza type A and, to a lesser extent, influenza type B, both being enveloped RNA-based viruses. In addition to the viral rhinitis symptoms of the common cold, influenza infection further leads to generalized muscle aches and pains, fatigue, significant fever, and rigors (chills). Influenza infection may also develop into frank viral pneumonia (lower airway infection), which may be further complicated by bacterial superinfection, particularly with *Staphylococcus aureus.* These additional manifestations and high potential for complicated disease underscore the importance of widespread yearly vaccination against influenza.

Repeated yearly vaccination is required because the influenza virus is capable of mutating its major surface proteins—hemagglutinin (H) and neuraminidase (N)—rendering protein-specific host antibody defenses ineffective and allowing for viral adherence and entry into host epithelial cells. Each year, a vaccine is developed using influenza proteins from the most likely serotype combination to lead to widespread infection for that year, as determined by complex disease modeling algorithms based on extensive Centers for Disease Control and Prevention (CDC) and World Health Organization epidemiological data. However, each vaccine is, in essence, a best guess, which may or may not provide adequate protection against the year's primary strain. In addition, other strains of the virus not covered by the vaccine may also cause numerous infections in any given year.

Given concerns in recent years for the potential spread of other forms of influenza, including H5N1 influenza (avian or bird flu) and H1N1 influenza (swine flu), significant efforts are also being directed toward developing safe and effective vaccines against these forms of the disease. Throughout history, the most widespread and devastating flu-related pandemics have been traced back primarily to these novel forms of the virus (in particular, avian flu). On an annual basis, however, classic influenza results in far greater morbidity and mortality each year than these other forms. For the last 40 years, widespread pandemics of avian flu and H1N1 influenza have largely been avoided through multinational public health measures. Clinical trials are underway with Vaxart, an influenza vaccine tablet. Although patient trials are being performed, the long-term effects of this drug are not known.

Most cases of laryngitis (inflammation of the vocal cords with extreme hoarseness and temporary voice loss) and croup (any combination of laryngotracheobronchitis with edema leading to airway obstruction with characteristic stridorous breathing) are caused by parainfluenza virus, RSV, influenza virus, coxsackievirus, rhinovirus, and adenovirus. Laryngitis may also be caused by group A beta-hemolytic *Streptococcus pyogenes, Haemophilus influenzae,* and *Moraxella catarrhalis.* These same viral and bacterial agents, along with *Neisseria gonorrhoeae* and Epstein-Barr virus (causing infectious mononucleosis), are also common causes of pharyngitis (see full discussion in Chapter 8).

RSV and influenza A (and less so influenza B) are the most common causes of bronchiolitis in children and adolescents, but adults tend to experience infection in the larger airways (i.e., acute bronchitis). Since the advent of widespread vaccination against *H influenzae* type B (Hib vaccine) and *Corynebacterium diphtheriae* (DTaP vaccine), epiglottitis occurs only rarely in the United States (see Table 9.1). Bacterial tracheitis is a serious purulent infection of the subglottic trachea caused primarily by *S aureus,* with a toxic clinical presentation requiring hospitalization and IV antibiotic therapy.

Clinical Presentation

The onset of influenza is usually abrupt, with fever, chills, malaise, myalgia, headache, nasal stuffiness, sore throat, and sometimes nausea. A nonproductive cough is usually present and occurs early in the course of illness. The fever may be as high as 103°F (39.4°C) in adults and typically lasts 3 to 5 days. Subjective findings in the person with the common cold include headache, myalgia, nasal congestion, watery rhinorrhea, sneezing, and a "scratchy throat." Laryngitis results in an inflammation of laryngeal mucosa and the vocal cords. Symptoms include hoarseness, aphonia, and, occasionally, pain when

swallowing. Physical findings in cases of URIs are usually minimal, with normal assessment findings on chest auscultation. Cervical lymphadenopathy may be present.

Diagnostic Reasoning

Diagnostic Tests

Diagnosis of influenza tends to be more accurate during epidemics. A successful presumptive diagnosis requires appropriate symptoms at the right time of the year and a knowledge of patterns of influenzal illnesses around the world. If necessary, the diagnosis can be confirmed via virology studies (e.g., nasal and pharyngeal cultures, cells from nasopharyngeal washings stained with monoclonal antibody fluorescence stains, and complement fixation studies on paired serum samples). Diagnosis of colds and laryngitis typically are based on the subjective presentation of the patient except when the etiological agent in laryngitis is thought to be bacterial. In these situations, the practitioner should perform a throat culture to rule out group A beta-hemolytic streptococcal infection. Leukocytosis found on a CBC with differential may help to diagnose a bacterial infection.

Differential Diagnosis

Other conditions that need to be ruled out include allergic rhinitis; atypical *Mycoplasma* pneumonia, infectious mononucleosis; *Chlamydia;* and possibly mumps, rubeola, and cytomegalovirus. Close attention to epidemiology (e.g., current outbreak in the community) is important. Contact the CDC or the local health department in your community to help determine the type of disease outbreak.

Management

Management of influenza and the common cold is generally symptomatic and is directed toward relief of symptoms and prevention of secondary infections. Antibiotics are not indicated for influenza or colds unless a secondary bacterial infection occurs. Mucopurulent rhinitis frequently accompanies the common cold and is not an indication for antimicrobial treatment. Although antibiotics are often viewed by the layperson as a viable treatment for a cold or the flu, these drugs have no effect on viruses and if taken injudiciously may produce resistant organisms. In the past, clinicians ordered antibiotics in about half of the cases of URI, which is thought to have contributed to the current antimicrobial-resistant crisis (Level I; Demeter et al, 2009). Health-care providers continue to prescribe antibiotics 50% or more of the time to adults and children with viral infections.

Generally, most patients with influenza should rest at home until symptoms decrease in severity. The older patient or the patient with an underlying chronic illness may require hospitalization for influenza. In addition to rest and fluids, antipyretics and analgesics are recommended. Cough suppressants with codeine may be necessary for adequate cough control. If the practitioner is reasonably confident that the virus in question is type A influenza, the patient may benefit from an antiviral drug. Widespread amantadine (Symmetrel) and rimantadine (Flumadine) resistance among influenza A virus strains has made this class of medications less useful clinically. Therefore, amantadine and rimantadine are not recommended for antiviral treatment or chemoprophylaxis of currently circulating influenza A virus strains. The majority of currently circulating influenza viruses are susceptible to the neuraminidase inhibitor antiviral medications oseltamivir (Tamiflu) and zanamivir (Relenza). Antiviral treatment is recommended as early as possible (within 48 hours of symptom presentation) for patients with confirmed or suspected influenza who have severe, complicated, or progressive illness; who require hospitalization; or who pose a risk for influenza-related complications. Oseltamivir, both as a pill and liquid form, is approved for the treatment of influenza in persons aged 2 weeks and older and for chemoprophylaxis to prevent influenza in patients 1 year of age and older. Zanamivir, as a powder that is inhaled, is approved to treat flu in people aged 7 years and older and to prevent influenza in patients aged 5 years and older. Zanamivir is not for persons with respiratory problems, such as asthma or COPD. Both medications are usually prescribed for 5 days for individuals in primary care, although people hospitalized with the flu may need the medication for longer than 5 days. Rest, fluids, and antipyretics are also useful in controlling the discomfort associated with a cold. Decongestants such as pseudoephedrine (e.g., Sudafed) are widely used and may help control rhinorrhea and nasal congestion. These should be used only for 3 days due to rebound effects and should not be used in the presence of hypertension. Nasal sprays such as phenylephrine (Neo-Synephrine) or ocular decongestants such as oxymetazoline (e.g., OcuClear, Visine LR) are rapidly effective. Patients should be cautioned to use them only for a few days, because chronic use leads to rebound congestion. Intranasal ipratropium (Atrovent) has also been approved for significant rhinorrhea associated with URIs. Vitamin C and zinc lozenges with echinacea are currently popular "remedies" that are sold as OTC therapies. Despite numerous randomized trials, the evidence of effectiveness of zinc lozenges in reducing the duration of colds is lacking. The efficacy of vitamin C supplements to decrease the incidence of colds or to shorten the duration has also not been demonstrated. The only exception may be for the patient who has a possible vitamin C deficiency. Several small studies have shown that black elderberry syrup shortens the duration of flu-like illnesses by up to 4 days.

Treatment of laryngitis includes complete voice rest, steam inhalations, codeine or nonnarcotic cough suppressants for cough and pain, and a liquid or soft diet. If throat cultures are positive for group A beta-hemolytic *Streptococcus,* penicillin should be prescribed, if the patient is not allergic to penicillin. Erythromycin should be used for infections associated with *M catarrhalis* or

H influenzae. For particularly toxic bacterial infections such as bacterial tracheitis, blood cultures may be appropriate to rule out bacteremia.

For the management of croup, racemic epinephrine and dexamethasone are indicated and intubation may be needed in extreme cases. Bacterial tracheitis requires IV antibiotic therapy with nafcillin or an appropriate cephalosporin, or, if methicillin-resistant *S aureus* is suspected, vancomycin or linezolid. Because of impaired oral intake, all such infections, other than the common cold, may lead to dehydration requiring oral or IV rehydration therapy. In addition, hypoxemia based on pulse oximetry or blood gas analysis should be addressed with supplemental oxygen therapy. Bronchodilator therapy is often used as well, but randomized clinical trials do not consistently demonstrate its efficacy.

Follow-up and Referral

The duration of an uncomplicated case of influenza is 1 to 7 days; the prognosis is excellent. Frequent complications do occur, however, including acute sinusitis, otitis media, purulent bronchitis, and pneumonia. Influenza causes necrosis of some respiratory epithelium, predisposing the infected person to secondary bacterial infections. The interaction between bacteria and influenza is bidirectional, with bacterial enzymes activating influenza viruses. If a fever persists for more than 4 days, if the white blood cell count rises to 12,000 cells/mcL or higher, or if the cough becomes productive, bacterial infection should be ruled out or verified and treated.

The most common complication of influenza is pneumonia; most fatalities result from bacterial pneumonia. The patient with bacterial pneumonia will experience gradual improvement of symptoms for 2 to 3 days and then develop cough and purulent sputum. Pneumococcal pneumonia is the most common bacterial pneumonia associated with influenza, but staphylococcal pneumonia is the most serious. Primary viral influenza pneumonia is the least common but has a high mortality rate among pregnant women and patients with rheumatic heart disease. The patient develops symptoms of influenza that become increasingly severe. Respiratory distress is often sufficient to require mechanical ventilation.

Most cases of the common cold and laryngitis are self-limiting. Complications of a cold may include pharyngitis, sinusitis, otitis media, tonsillitis, and chest infections. Unless symptoms of these complications are present, antibiotic therapy is not indicated. The patient with laryngitis needs to maintain voice rest until hoarseness and aphonia have resided. Any vigorous use of the voice such as shouting or singing may foster the formation of vocal cord nodules.

Patient Education

There currently is no immunization for the prevention of colds. Research has demonstrated that the best method of preventing transmission of infected droplets is through frequent hand washing, particularly in day-care facilities and congregate adult living facilities. During the cold and influenza seasons, the person with a chronic illness or a compromised immune status should be advised to avoid crowded, close situations and other persons who have obvious symptoms.

Trivalent influenza vaccine provides partial immunity (in approximately 86% of patients vaccinated) for a few months to 1 year. The vaccine's antigenic configuration changes yearly. It is based on the prevalent strains of the previous year, the viruses that are currently being seen in other parts of the world during the current year, and the estimated antibody response in persons previously infected with or vaccinated against these viruses. Vaccination in October or November of each year is recommended for all persons older than 65 years of age; nursing home residents; adults and children with underlying conditions, including heart, pulmonary, malignant, and some metabolic diseases; and health-care workers. High-risk children have a particularly low influenza vaccination rate annually, which is of significant concern. Vaccination is also encouraged for members of any large groups who may be the principal vectors of influenza in their community such as schoolchildren, children in day care, college students, military personnel, and employees of large companies. Low-income minority populations typically have lower vaccination rates than other populations. Medicare covers the cost of influenza and pneumococcal vaccination. Recent research has shown that obtaining yearly influenza vaccination can be influenced by the health-care provider's recommendations and phone calls offering encouragement and reminders. *Healthy People 2020* has set a goal of vaccinating 80% of noninstitutionalized adults aged 18 to 64 years annually; currently 25% receive the annual flu vaccine. HP 2020 has also set the goal of vaccinating 90% of high-risk adults aged 18 to 64 years; currently 39% of this population receives the annual flu vaccine. For adults aged 65 years and older, the 2020 goal of annual vaccination is 90 % (currently 67%). For health-care workers, in 2012 to 2013, the vaccination rate was only 72%, although for health-care workers in occupational settings that require vaccinations, the rate was 96.5%. The practitioner may keep abreast of current epidemiological trends in influenza epidemics and changes in vaccine recommendations by accessing the Web site for the CDC at www.cdc.gov.

ASTHMA

Asthma is a chronic, inflammatory, obstructive disease of the airways. It may occur at any age and may be characterized by wheezing (airway spasms), tightness in the chest, breathlessness (dyspnea), and cough. The signs and symptoms may remit spontaneously or exacerbate in response to intrinsic (stress) or extrinsic (environmental) triggers. The severity of asthma is highly unpredictable, ranging from mild attack to complete airway

obstruction and death. Many pediatricians use the term *reactive airway disease* rather than "asthma," because some parents have a negative connotation of the word "asthma."

Epidemiology and Causes

Asthma affects more than an estimated 100 million people worldwide, and the number is increasing rapidly. In the United States, more than 34 million Americans have been diagnosed with asthma, or reactive airway disease, at some point in their lives. It has been estimated that 8.2% of noninstitutionalized adults and 9.5% of children currently have asthma. African Americans have asthma-related mortality rates that are higher than the rates for Caucasians. Despite newer antiasthmatic drugs, asthma is responsible for more than 134 million days of restricted activity and about half a million hospitalizations annually. In the United States, 5,500 deaths each year are attributable to asthma. Despite current prevention efforts, the incidence of asthma continues to increase every year.

Clinical practice guidelines were last updated in 2007 by the National Asthma Education and Prevention Program, which is part of the National Heart, Lung, and Blood Institute. This document is known as the Expert Panel Report 3 (EPR-3). These evidence-based practice guidelines include ways to help patients control their asthma signs and symptoms and improve their quality of life.

Although the exact cause is unknown, three principal triggers for exacerbations of asthma have been identified:

- Allergens and environmental factors: Allergens may include inhaled substances, such as molds, pollens, dust, animal dander, cosmetics, and tobacco smoke; food additives with sulfite preservative agents; and medications, especially beta blockers and aspirin or aspirin-containing drugs.
- Infections: Upper respiratory infections are common precursors to an asthma attack. Viral infections commonly precede an asthma episode.
- Psychological factors: Stressful events at work or home or a series of crises may precipitate an asthma attack. Many times, stressors may be overlooked or dismissed.

Inflammation of the airways contributes to bronchial hyperreactivity, airflow limitation, and the resultant characteristic signs and symptoms of asthma: wheezing, breathlessness, chest tightness, and cough. The stage is then set for acute bronchoconstriction, airway edema, mucous-plug formation, airway narrowing, and bronchial obstruction.

Pathophysiology

Asthma is a chronic inflammatory disease characterized by reversible hyperreactivity of the bronchi and bronchioles to a variety of stimuli. Genetic predisposition, allergy, environmental factors, stress, and infectious agents are factors that play a role in the etiology of asthma. Immunologically mediated inflammation, the major pathological mechanism of this disease, involves mast cells, eosinophils, lymphocytes, neutrophils, and macrophages, which may directly infiltrate the airway at both smooth muscle and basement membrane layers. These cells release a variety of mediators that stimulate bronchoconstriction, vasodilation, edema formation, and increased mucus production, including histamine, interleukins, leukotrienes, tumor necrosis factor, bradykinin, thromboxanes, fibroblast growth factor, and prostaglandins.

In particular, CD4+ T-helper (Th) cells bearing a Th2 phenotype (predominantly humorally mediated immunity) and resistant to apoptotic killing produce interleukin (IL)–3, IL-4, IL-5, and granulocyte-macrophage colony-stimulating factor after being stimulated by the offending allergen, which, in turn, upregulates the allergic response and airway hypersensitivity. Th1 T cells (predominantly cell-mediated immunity) have been implicated to a lesser extent. Eosinophils are a rich source of leukotrienes that directly cause contraction of bronchial smooth muscle and increase vascular permeability. Activated B lymphocytes transform into plasma cells, synthesizing large amounts of immunoglobulin E (IgE) antibody that binds and activates tissue mast cells and eosinophils. Mast cell-bound IgE molecules then become cross-linked by environmental allergens, which activates histamine release and further IL-4 and IL-5 production, thereby provoking bronchial smooth muscle contraction and vasodilation.

With each acute exacerbation of asthma, inflammatory mediators incite a structural remodeling of the airways. The alveoli remain largely unaffected, because this is not a parenchymal disease. Rather, airway remodeling entails thickening of the bronchial and bronchiolar mucosa, submucosa, and smooth muscle layers, which contributes to the persistence of disease. Increased collagen is deposited below the basement membrane, while the loose areolar connective tissue found between epithelial and smooth muscle layers also hypertrophies. Therefore, prevention of acute episodes, which minimizes the amount of remodeling, is key to the proper treatment of asthma.

Asthma is an obstructive pulmonary disease with hypoxia as the universal finding during acute exacerbations. With acute bronchospasm, residual volume increases in the lungs and peak expiratory flow rate diminishes. Inflammation and constriction of the bronchioles increase airway resistance, decrease inspiratory capacity and expiratory volumes, and lead to ventilation–perfusion mismatching and altered arterial blood gas concentrations. As a result of hyperventilation, respiratory alkalosis and hypocapnia are common findings with each episode. As an acute attack resolves, narrowing in the larger airways tends to reverse first, whereas the peripheral airways remain most constricted. If such an attack progresses, however, and fails to reverse, respiratory acidosis and an elevated arterial carbon dioxide concentration typically

result, signaling impending respiratory failure. Indeed, severe irreversible bronchoconstriction and inflammation, termed *status asthmaticus,* can be fatal.

Clinical Presentation

The clinical presentation varies and depends on whether the patient is currently experiencing an acute attack or is seeking help to manage chronic asthma. It is important to note that not all people with asthma wheeze and that not everyone who wheezes has asthma.

Subjective

During an acute attack, the patient may present with a complaint of breathlessness and may be unable to talk or may be able only to blurt out short sentences. There may be profuse sweating and a complaint of air hunger. In patients who are severely obstructed, there may be no wheezing; only cough may be present.

The patient may present complaining of wheezing, persistent and recurrent cough, difficulty breathing, and/or tightness in the chest, particularly at night or in the early morning. Endurance problems during exercise may occur. Ninety percent of individuals with asthma report that exercise exacerbates their respiratory symptoms.

Any single symptom or combination of symptoms may occur, and symptoms are usually worse at night. The disease spectrum varies from a few mild episodes in a lifetime to daily debilitating symptoms. Food additives, particularly metabisulfite (used as a food preservative), certain dairy products, and, for some individuals, monosodium glutamate, may also cause symptoms. An extreme emotional state such as excessive laughing and/or crying may precipitate or exacerbate an attack.

Objective

Reversible airflow limitation and diurnal variation as measured by peak flow meter are objective signs and symptoms of asthma. Variability between morning and evening peak expiratory flow (PEF) may reflect airway hyperresponsiveness and indicate asthma instability and severity. Nasal discharge, mucosal swelling, frontal tenderness, nasal polyps, and allergic "shiners"—dark discoloration beneath both eyes—should be noted. The clinician should also check for manifestations of allergic skin conditions such as eczema. Wheezing during forced exhalation is no longer considered a reliable indicator. It may be absent between attacks and may be obscured during acute attacks related to diminished breath sounds.

Audible inspiratory and expiratory wheezing may be heard. The patient may be using accessory muscles of breathing (scalene and sternocleidomastoid) and sitting upright. Auscultation of the chest may reveal inspiratory and expiratory wheezes.

Diagnostic Reasoning

Expiratory airflow measurements are essential to the differential diagnosis of asthma. The essential elements to consider in making the diagnosis of asthma are listed in Table 9.2. In addition, asthma should always be considered as a possible etiology in a patient with a chronic cough (Level I; Demeter et al, 2009).

Differentiating asthma from other diseases is usually not difficult, particularly with the aid of pulmonary function tests (PFTs), a complete history, and laboratory test results. Spirometry is recommended for the diagnosis of asthma. A common feature of asthma is nocturnal awakening with one or more of the following symptoms: dyspnea, cough, and wheezing. Persistent wheezing localized to one area of the lung, with paroxysms of cough, is indicative of endobronchial disease such as foreign body aspiration, neoplasm, or bronchial stenosis. Acute left ventricular heart failure may initially present as asthma (wheezing), but the findings of moist, basilar crackles, gallop rhythms, and other signs of heart failure exclude the diagnosis of asthma.

Allergic rhinitis and eczema often accompany a diagnosis of asthma. Concurrent treatment for these conditions is critical. Effective treatment of allergic rhinitis

Table 9.2 Essential Elements to Consider When Diagnosing Asthma

History	• Cough (especially nocturnal) • Recurrent wheeze (absence does not rule out asthma) • Recurrent episodic dyspnea • Recurrent chest tightness
Symptoms worsen in relation to specific factors	• Airborne chemicals or dust • Animals with fur or feathers • Changes in weather • Exercise • Gastroesophageal reflux • Sensitivity to aspirin, other NSAIDs, and sulfites • Dust mites in house (mattresses, furniture, carpets) • Menses • Mold/pollen • Nighttime (patient awakens) • Nonselective beta blockers • Pollen • Smoke (tobacco, wood, etc.) • Strong emotional expression (laughing or crying hard) • Viral infection/rhinitis/sinusitis
Reversible (at least partially) airflow limitations with diurnal variability Exclusion of alternate diagnosis	• Variation in peak expiratory flow rate of at least 20% between first morning measurement (before taking an inhaled, short-acting beta-adrenergic agonist) and early afternoon measurement (after using the inhaler)

(discussed in Chapter 8) is critical as another mode to prevent triggering acute asthma attacks.

Diagnostic Tests

To establish the diagnosis of asthma, episodic symptoms of airflow obstruction must be present, airflow obstruction must be at least partially reversible, and the provider must have ruled out any alternative diagnoses. Spirometry measurements are helpful in diagnosing and then evaluating the management of the disease. Forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV_1) are helpful measurements. Prebronchodilator and postbronchodilator PFTs, including spirometry and diffusing capacity, to determine the response to bronchodilators are essential in the differential diagnosis and subsequent management of asthma. The diagnosis is made by demonstrating the reversibility of the airway obstruction from the pre- and post-PFTs. Reversibility is defined as a 15% or greater increase in the FEV_1 after two puffs of a beta-adrenergic agonist have been inhaled. When spirometry is nondiagnostic, bronchial provocation testing may be useful with histamine, methacholine, or exercise.

A chest x-ray film may show only hyperinflation but may include thickening of the bronchial wall and diminished peripheral lung vascular shadows.

Arterial blood gas (ABG) analysis is included in the initial work-up to establish a baseline and to determine the degree of hypoxemia and the need for supplemental oxygen. The results of the ABG analysis and spirometry, along with the clinical history and findings on exam, are triangulated to classify the severity of the asthma, as shown in Table 9.3.

A CBC with differential, with special attention to the sedimentation rate and eosinophil count, is done.

Table 9.3 Classification of Asthma Severity

Classification	Clinical Features Before Treatment	Daily Medication Required to Maintain Control
Mild intermittent	• Intermittent symptoms less than once a week, brief exacerbations (lasting from a few hours to a few days)* • Nighttime asthma symptoms less than twice a month • Asymptomatic and normal PEF between exacerbations • PEFR or FEV_1: >80% predicted; PFT variability >20%	• Intermittent reliever medication taken as needed only; inhaled short-acting beta-2 agonist or cromolyn before exercise or allergen exposure • Intensity of treatment depends on severity of exacerbation • No daily medication needed
Mild persistent	• Symptoms more than 2× per week but less than 1× per day, may be several times at night/month • Exacerbations may affect activity and sleep • Nighttime asthma symptoms more than twice a month • PEFR or FEV_1: >80% predicted; PFT variability 20%–30%	• One daily controller medication: low-dose inhaled corticosteroids; cromolyn/nedocromil; leukotriene modifiers • Inhaled beta-2 agonists as needed
Moderate persistent	• Symptoms daily, but not continual, nighttime symptoms more than once a week, but not every night • Exacerbations affect activity and sleep • Daily use of inhaled short-acting beta-2 agonist • PEFR or FEV_1: 60%–80% predicted; PFT variability >30%	• Daily controller medications: combination inhaled medium-dose corticosteroid and long-acting bronchodilator (especially for nighttime symptoms); cromolyn-nedocromil; leukotriene modifiers
Severe persistent	• Continuous daily symptoms, frequent nighttime symptoms • Frequent exacerbations • Physical activities limited by asthma • PEFR or FEV_1: ≤60% predicted; PFT variability >30%	• Inhaled beta-2 agonists as needed • Multiple daily controller medications: high-dose inhaled corticosteroid, long-acting bronchodilator, cromolyn/nedocromil; leukotriene modifiers; may need long-term corticosteroids • Inhaled beta-2 agonist as needed

US Department of Health and Human Services, Public Health Service, National Institutes of Health (NIH), National Heart, Lung, and Blood Institute (NHLBI), Bethesda, MD.

*The presence of one of the features of severity is sufficient to place a patient in that category.

Levels of nasal eosinophils, serum eosinophils, and IgE are assessed to determine the allergic status of the patient. Intradermal skin testing may be indicated if the allergic status is significant.

Infections often precede an asthma attack. If infection is suspected (because of a productive cough with colored sputum), a sputum test for culture and sensitivity should be done.

When persistent asthma is present, the EPR-3 recommends that skin testing or in vitro radioallergosorbent tests be done to determine sensitivity to allergens to optimize treatment and prevention.

Differential Diagnosis

Airflow obstruction may result from foreign body aspiration or viral infections, as well as a variety of underlying pulmonary infections, such as aspergillosis, TB, hypersensitivity pneumonitis, or habitual cough. Hyperventilation syndrome, mitral valve prolapse, recurrent pulmonary emboli, congestive heart failure, and chronic obstructive lung disease may mimic asthma. In addition, for some sensitive patients, cough may be secondary to the use of certain drugs, such as ACE inhibitors, beta blockers, aspirin, and NSAIDs. One key feature to making the diagnosis of asthma is the reversibility of the obstructive phenomenon.

Management

If the patient has never been diagnosed with asthma, the clinician may want to make an initial referral to a pulmonologist. An aggressive approach to asthma management is recommended to improve symptoms in the short term, prevent recurrence of symptoms, and/or manage a potentially chronic problem—all with the goal of improving the patient's quality of life by achieving and maintaining control of symptoms. The principles of management include the following:

- Identification of factors that exacerbate the condition
- Daily monitoring of PEF with a symptom record (see Asthma Attack Trigger Diary at http://davisplus.fadavis.com)
- Written instructions on managing an acute asthma attack
- Intensive education and follow-up, emphasizing joint decision making

Initial and subsequent management of asthma is aimed at first removing all identified triggers or precipitants. The step therapy approach is a guide to assist the provider in working with the patient to make the best treatment decisions. As a rule, the highest appropriate step should be used to gain early control. The therapy should be "stepped up" if control is not maintained. The clinician should always review the patient's medication technique, adherence, and control of triggers at each visit. The stepwise approach, according to the severity of the asthma, is shown in Treatment Flowchart 9.1.

Asthma management can require daily pharmacotherapeutics with inhaled corticosteroids, long-acting beta-2 agonists, and/or leukotriene antagonists. In patients with other comorbidities, management may be complicated. Daily medications for those with mildly persistent to severe asthma may significantly reduce and control symptoms, leading to improved quality of life.

In the management of chronic asthma, ABG analysis (in hospital) and PFTs (in primary care) are done periodically to measure how well the patient is responding to treatment. The patient can be taught to use a handheld peak flow meter to measure the peak expiratory flow rate (PEFR) and gauge response to treatment. Several peak flow rate readings should be done when the patient is stable to establish a baseline (or "personal best"). This baseline can be used as a benchmark for guiding therapy. Once the patient's condition is stabilized, the daily PEFR monitoring can be done by the patient. If the PEFR reading is less than 80% of the patient's personal best, adjustments in medications or lifestyle may be necessary.

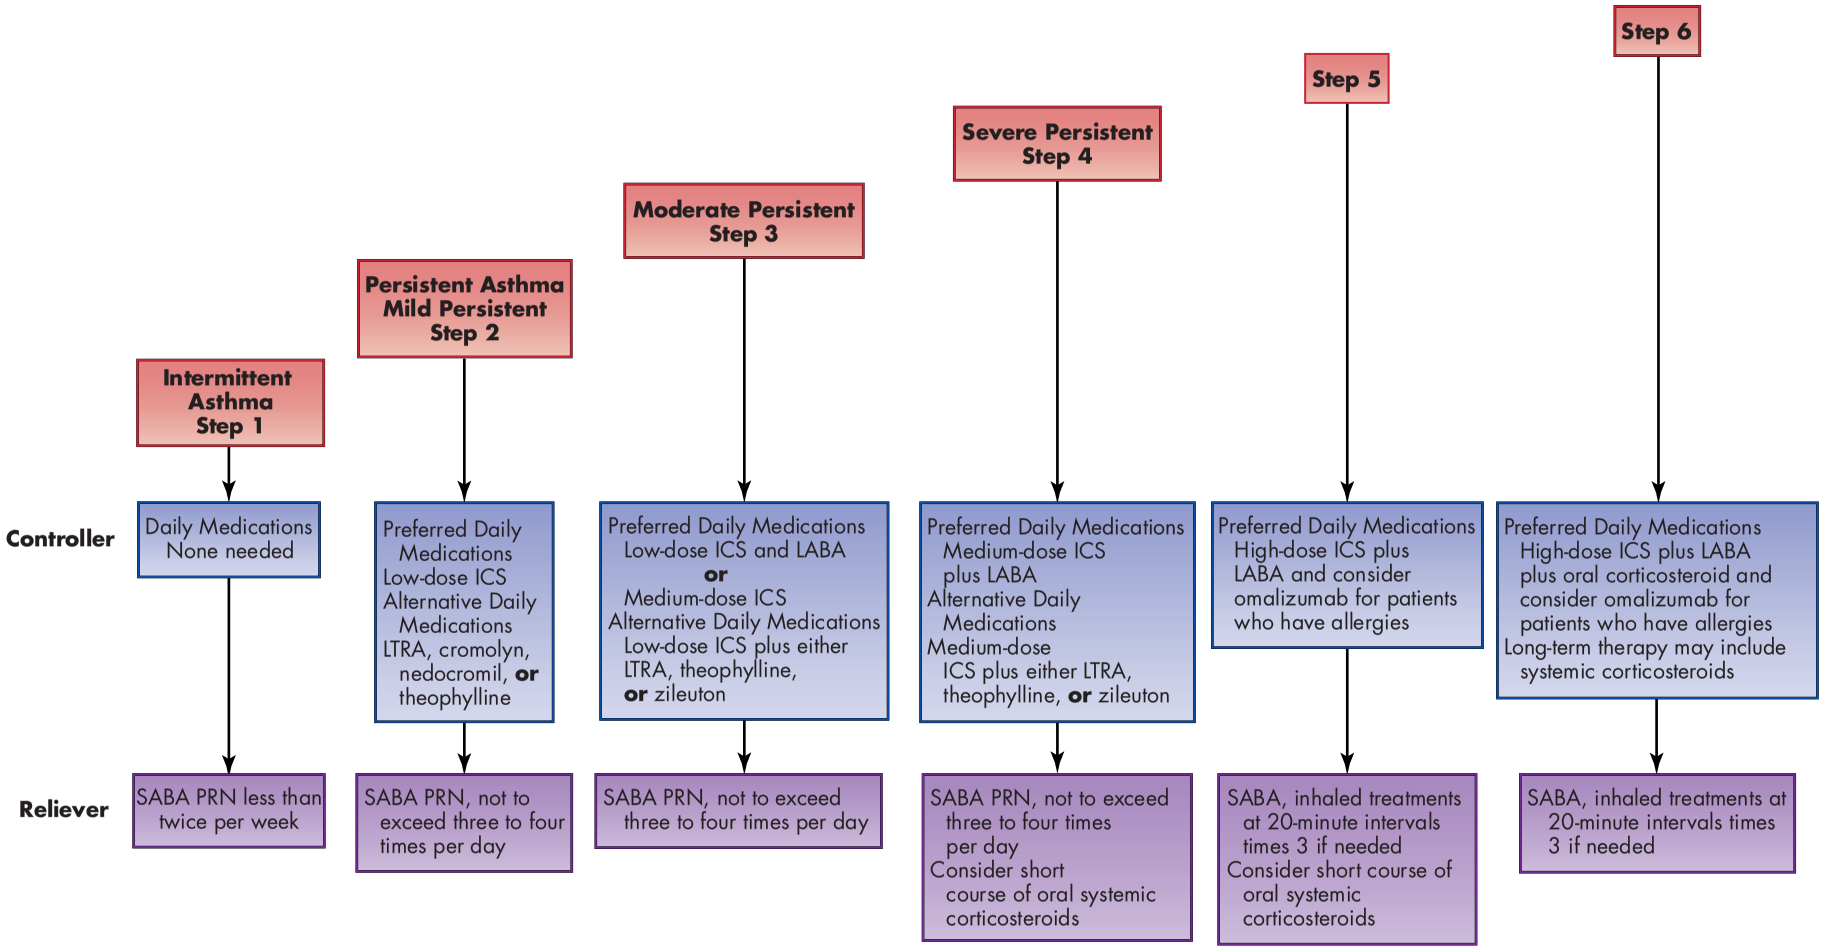
Inhaled corticosteroids are the treatment of choice as anti-inflammatory controller therapies, above other classes of inhaled medications and theophylline. Recent genetic and epidemiological studies appear to imply that certain individuals (especially of African American ethnicity) have a negative reaction to long-term beta-agonist bronchodilators, such as salmeterol. These individuals seem to do worse on long-term beta-agonist therapy. Salmeterol (Serevent) is no longer used as a single agent because of safety concerns regarding increased morbidity and mortality when used without an accompanying corticosteroid. When used in combination with an inhaled corticosteroid (Advair Discus, Symbicort), however, such combinations are extremely effective at improving lung function in patients with moderate to severe asthma.

See Drugs Commonly Prescribed 9.1 for medications for asthma.

Follow-up and Referral

Step down therapy gradually if review of patient's status at 1- to 6-month intervals suggests reduction of treatment is warranted. Smoking cessation for patients with asthma is a must. (For more information on smoking cessation, see Smoking Addiction later in this chapter.) In addition, the patient should avoid exposure to secondhand smoke. Family members also need to be educated about the hazards of secondhand smoke. Regular visits to their primary-care provider can be combined with appropriate referrals to specialists as necessary.

The use of immunotherapy in asthma remains controversial, and its effectiveness has not been well established. For most patients, avoidance of the allergens and triggers, along with the appropriate use of medications, is adequate therapy. If avoidance of certain allergens is impossible and medications fail, referral to an allergist for immunotherapy may be indicated. However, unless the patient's symptoms are exacerbated by exposure to



SABA = short-acting b2-agonist

ICS = inhaled corticosteroid

LTRA = leukotriene receptor agonist

LABA = long-acting b2-agonist

Step up to the next step if control is not achieved. First, however, review patient medication technique, and control (avoid all allergens or other trigger factors).

Step down to the next step when asthma is well controlled for 3 months.

Review RX every 3–6 months.

Treatment Flowchart 9.1 Asthma

Drugs Commonly Prescribed 9.1 Asthma

Drug	Indication and Formulation	Adverse Reactions and Prescribing Considerations
Short-Acting Beta-2 Agonists		
Provide smooth muscle relaxation.	First-line defense for acute attack; may be used prophylactically prn before exercise. Increased need (usage) indicates need to change treatment regimen.	Adverse reactions: Tachycardia, palpitations, tremor, hypokalemia Use with caution in elderly patients.
albuterol (Ventolin, Proventil)	Syrup: 2 mg/5 mL	As above 2–4 mg PO 3–4 times daily. May increase dose gradually to maximum dose of 24 mg/day.
	Metered-dosage inhaler (MDI) 90 mcg/puff Dry powder inhaler (DPI) 200 mcg/puff Nebulizer 5 mg/mL (0.5%)	2 puffs q4–6h prn 2 puffs tid–qid prn, 2 puffs 5 minutes before exercise 1.25–5 mg (0.25–1 mL) in 2–3 mL of NS q4–8h; may be mixed with cromolyn or ipratropium nebulizer solution
pirbuterol (Maxair)	MDI	As above 200 mcg/puff 2 puffs tid–qid prn
Long-Acting Beta Agonists		
	Appropriate for patients with moderate to severe asthma. Use before sleep to prevent nocturnal attacks. May be helpful in preventing exercise-induced asthma.	Should not be used without inhaled corticosteroids. Should not be used as a rescue inhaler. Should not be used in place of anti-inflammatory therapy.
Anticholinergics		
ipratropium bromide (Atrovent)	MDI: 17 mcg/puff Nebulizer: 0.02% (500 mcg in 2.5 mL) for oral inhalation	Do not give to patients with glaucoma or benign prostatic hypertrophy. 2 puffs qid, max. 12 puffs/day May precipitate heart attack, palpitations. Not for primary treatment of acute attack. 500 mcg tid–qid
Combination Beta-2 Agonist and Anticholinergic		
	May use when second aerosol bronchodilator needed.	When used in combination, overall effect is increased.
Combivent	Ipratropium bromide 18 mcg and albuterol (as sulfate) 90 mcg MDI	Use with caution with other anticholinergics and sympathomimetics. 2 puffs qid Maximum: 12 puffs/day
Leukotriene Receptor Antagonists		
	Long-term control. Prophylaxis and treatment of chronic asthma	NOT FOR ACUTE ATTACK

Drugs Commonly Prescribed 9.1 Asthma—cont'd

Drug	Indication and Formulation	Adverse Reactions and Prescribing Considerations
montelukast (Singulair)	Prophylaxis and chronic treatment 4 mg or 5 mg chewable tablets, 10 mg tablet Oral granules 4 mg/packet	Monitor with potent CYP450 indices May take 10 mg/night
zafirlukast (Accolate)	Prophylaxis and chronic treatment of asthma 10 mg and 20 mg tablets	Take at least 1 hour before meals OR 2 hours after meals May take 20 mg twice daily
cromolyn sodium (Intal)	MDI: 0.8 mg/puff Nebulizer: 20 g/2 mL	Adverse reactions: Bronchospasm, throat irritation, bad taste. 2 puffs 10–60 minutes before exposure to precipitants Acts as a mast cell stabilizer. May use qid
nedocromil sodium (Tilade)	MDI: 1.75 mg/puff	As above May use 2–4 puffs qid
Inhaled Corticosteroids		
	Maintenance treatment of asthma and prophylactic treatment in asthma	
beclomethasone (Beclodisk)	Not for acute attack 40 or 80 mcg/puff	Rinse mouth after use. Avoid excessive use. Max. 10 puffs/day
budesonide (Pulmicort)	Dry powder delivery system 90, 180, or 200 mcg inhaler (800 mg max per day)	Monitor infections; susceptible to oral candidiasis. Rinse mouth after use. Avoid excessive use.
fluticasone (Flovent)	MDI: 44, 110, 220 mcg/puff DPI: 50, 100, 250 mg dose	Monitor infections; susceptible to oral candidiasis. Rinse mouth after use. Avoid excessive use.
flunisolide (AeroBid, Bronalide)	MDI: 250 mcg/puff	Has mint flavor. Contains menthol. Initially 2 puffs bid, max: 8 puffs/day
Combination Inhaled Corticosteroid and Long-Acting Beta-2 Agonist		
fluticasone and salmeterol (Advair Diskus)	Moderate to severe persistent asthma	100, 250, or 500 mcg fluticasone per dose plus 50 mcg salmeterol per dose dry powder 1 puff twice daily
budesonide and formoterol (Symbicort)	Moderate to severe persistent asthma	80 or 160 mcg per dose plus 4.5 mcg formoterol per dose inhalation 2 inhalations twice daily
Systemic Corticosteroids		
	For long-term treatment of severe persistent asthma. Short courses or "bursts" effective for establishing control when initiating therapy or during a period of gradual deterioration.	

Continued

Drugs Commonly Prescribed 9.1 Asthma—cont'd

Drug	Indication and Formulation	Adverse Reactions and Prescribing Considerations
methylprednisolone (Medrol) prednisolone prednisone (Deltasone)		Use with caution in patients with TB, hypothyroidism, cirrhosis, ulcerative colitis, etc. May mask infection May cause hypokalemia, hypernatremia; glucose intolerance; bone demineralization Give 7.5–60.0 mg/day in a single dose or qid as needed for control. Short "burst" 40–60 mg/day as a single dose or in two divided doses over 3–10 days; tapering not necessary.
Methylxanthines		
theophylline (Theo-24)	100, 200, 300, 400 extended-release capsules Long-acting bronchodilator for use in moderate and severe persistent asthma. Occasionally used for mild persistent asthma (step 2). Advantage is that bid level can be measured, and theophylline may have some anti-inflammatory properties.	Not for use in acute attack. Many drug interactions; contraindicated in seizure disorders, arrhythmias, active peptic ulcer disease. **Adverse reactions:** Nausea, headaches, irritability, restlessness, convulsions, diuresis To maintain steady state, keep serum concentration levels between 5 and 15 mcg/mL

an allergen and the allergen can be confirmed by skin-prick testing, it is unlikely that immunotherapy will be effective.

Patient Education

A list of reasonable expectations (see Table 9.4) for patients with asthma should be reviewed with the patient and family. If there are problems in certain areas, spend time exploring potential triggers that might be removed or problematic areas such as noncompliance or improper use of inhalants.

The patient and family should be educated about the following areas for self-care management:

- Basic asthma facts.
- When and how to use a short-acting beta-2 agonist inhaler before exercising. (There may only be exercise-induced asthma.)
- How to recognize early symptoms of an exacerbation and how to initiate a predetermined plan of action.
- Role of medications (long-acting and short-term) and the critical role for anti-inflammatory controller medication regimens to reduce the rate of acute attacks.
- Skills for inhaler (spacer) and daily peak flow meter monitoring (for patients with moderate to severe persistent asthma). Although some medications have "built-in" spacers, spacers are universally recommended for metered-dose inhalers to obtain maximum benefit.
- Use of a nebulizer if necessary. Nebulizers may be necessary when patients cannot take in adequate breaths.
- Environmental control.
- Avoidance measures.
- Importance of pneumococcal and annual influenza vaccination.

Patient and family education is essential for control of triggers and recognition of warning signals. An Asthma Attack Trigger Diary may be used (see DavisPlus at http://davisplus.fadavis.com).

Reinforcement of medication use and proper use of the handheld flow meter should be reviewed at each visit. It should be mentioned that rescue courses of systemic glucocorticoids may be needed at times to prevent acute attacks, although recurrent attacks indicate that a greater degree of controller medication is warranted. Once patients have been followed for some time and have learned self-management, most patients with no cognitive impairment can be instructed on the proper use of glucocorticoids to prevent acute attacks.

Patients may ask which inhaled corticosteroid is the best. Research has shown that if equipotent doses are

Table 9.4 Reasonable Expectations for Patients With Asthma

When entering into a treatment plan, the patient with asthma expects to:

- Be able to participate fully in any activity.
- Be able to sleep through the night.
- Be free of severe symptoms day and night.
- Be satisfied with asthma care.
- Have the best possible pulmonary function.
- Need fewer or no emergency visits or hospitalizations due to asthma.
- Not miss work or school because of asthma.
- Use fewer medications with minimal adverse effects.

The provider is responsible for the following:

- Asking patients about their concerns and issues at each visit.
- Continually teaching and reinforcing key educational points.
- Ensuring ongoing and open communication with the patient and family.
- Reviewing short-term goals agreed on at the initial visit.
- Reviewing the asthma action plan for worsening symptoms and exacerbations.
- Reviewing the daily self-management plan and steps the patient needs to take.
- Supplying patients with appropriate educational materials for self-management and prevention.

used, the efficacy is the same. The key difference is in the delivery technique. With the dry powder inhaler, age is a factor. Providers must spend time teaching the proper technique and observing a return demonstration. One of the adverse side effects of inhaled corticosteroids was believed to be their effects on growth rate in children. Research has shown that this is a very small but definable risk. In a study of 943 children who were followed for 25 years, there was only a ½-inch decrease in growth rate, which occurred in the first 2 years of treatment. Nonetheless, it must be cautioned that all individuals should be on the lowest dose of inhaled corticosteroids possible.

Another question commonly asked is which pets are hypoallergenic. There are many Web sites that promote costly specialty pets that are purported to be nonallergenic, but in reality, there are *no* hypoallergenic pets. Using commonsense measures such as keeping pets out of the bedroom and wiping down cats with a wet washcloth every night to help control dander may help; however, in some cases, removing pets from the home completely may be the only recourse.

The patient and family should be educated to the fullest extent possible to permit self-management and prevention of acute fatal attacks. Although asthma is a chronic disease, patients may die from a particularly severe acute asthmatic attack. The risk factors for fatal asthma are shown in Risk Factors 9.1.

Patients with any of these risk factors need additional teaching time so that they can learn self-management techniques to reduce risk factors to the extent possible. An algorithm for self-management that is similar to the one shown in Treatment Flowchart 9.2 should be reviewed with the patient and family. It is extremely important that the patient be trained to use the handheld peak flow meter and learn to determine the predicted (personal best) PEFR. During exacerbations, the patient should compare a current reading to the baseline PEFR as a guide to determine how severe the attack is and to gauge medication use accordingly.

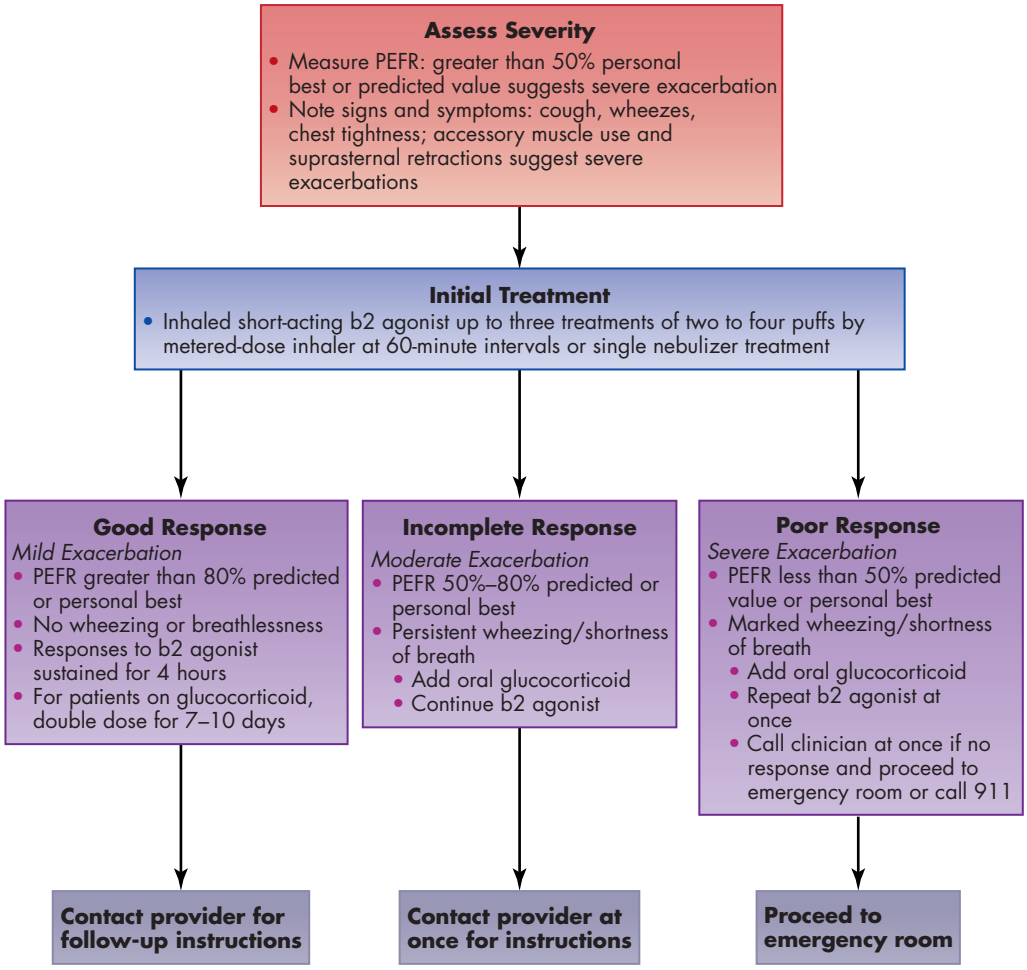
The value of the algorithm as a guide for the patient and family as to when to seek emergency help should be emphasized. A family member should be educated as to how to handle an acute attack, in case the patient becomes severely hypoxic and cognitively impaired.

A caring relationship among the provider, the patient, and family may prove pivotal to effective disease management and improved quality of life. Self-care is an essential component of treatment.

Scant data exist on the prevalence of complementary therapy for asthma. One national survey study estimated that 59% of 4,741 respondents in the United Kingdom had tried some form of complementary therapy. The three adjunct therapies most frequently used in the United Kingdom were breathing techniques, homeopathy, and herbal preparations. Even less research exists on the effectiveness of these therapies, so patients and families should be cautioned about their judicious use. The

Risk Factors 9.1 Risk Factors for Fatal Asthma

- Comorbidity (cardiovascular or pulmonary disease, such as COPD)
- Current use of, or recent withdrawal from, systemic glucocorticoids
- Difficulty perceiving airflow obstruction or its severity
- History of sudden severe exacerbations
- Hospitalization or emergency care for asthma within past month
- Illicit drug use
- Low socioeconomic status and urban residence
- Prior intubation for asthma
- Sensitivity to *Alternaria*
- Serious psychiatric disease or psychosocial problems
- Three or more emergency visits for asthma in the past year
- Two or more hospitalizations for asthma in the past year
- Use of three or more canisters of inhaled, short-acting beta-2-adrenergic agonists per month



Treatment Flowchart 9.2 Self-Management of Asthma Exacerbations

use of breathing exercises and devices such as the inspiratory pressure threshold device has been studied in COPD but less so in asthma. More research is needed in this area.

Nutritional therapies have been used in the treatment of asthma. It is known that certain foods may precipitate an asthma flare. To treat asthma, Moses Maimonides, the noted 13th-century physician, prescribed a spicy, herbal mixture of chicken broth that contained herbs such as fennel, parsley, oregano, mint, and onion. Hydration from such a robust broth is also a helpful component in asthma treatment. Onions and garlic have been known to have some protective effect against allergic reactions.

Strong coffee was a widely used treatment for asthma in 18th-century Europe and continues to be used as an effective bronchodilator today. Although drinking teas has never been particularly favored as an asthma treatment, tea leaves were the original source of theophylline, which means "tea leaf." Some literature cites the use of eucalyptus (as a decongestant/cough suppressant), lycopene (for exercise-induced asthma), vitamin B_{12} and vitamin C, and goldenseal, but evidence-based research lists them only as level C, so caution should be exercised when discussing these with patients.

CHRONIC BRONCHITIS AND EMPHYSEMA (CHRONIC OBSTRUCTIVE PULMONARY DISEASE [COPD])

There are two primary forms of lung disease—obstructive and restrictive. *Obstructive lung diseases* are those in which the expiratory flow rate is impaired. *Restrictive lung diseases* are those in which the lung volumes are reduced due to musculoskeletal disorders, tumors, lung resection, or interstitial lung disease (ILD). Obstructive lung diseases are further classified as reversible (such as asthma) and irreversible (such as chronic bronchitis and emphysema). The American Thoracic Society (ATS) has defined *chronic bronchitis* as a clinical disorder characterized by excessive mucus secretion in the bronchial tree. It is manifested by

chronic or recurrent cough (with or without sputum production), present on most days for a minimum of 3 months of the year, for at least 2 successive years. In addition, dyspnea with or without wheezing is present. Whereas more than 14 million Americans have been diagnosed with COPD, an equal number are probably afflicted but not diagnosed.

Epidemiology and Causes

Chronic bronchitis and emphysema are grouped together as *chronic obstructive pulmonary diseases.* The ATS defines *chronic obstructive pulmonary disease* (COPD) as a disease state characterized by the presence of airflow obstruction due to chronic bronchitis or emphysema. Asthma is not classified as COPD but is sometimes referred to as a reversible obstructive condition, whereas emphysema is irreversible. Chronic bronchitis is usually irreversible, but it may be partially reversible if there is a bronchospastic component and a significant response to bronchodilators. The prevalence and mortality rates for chronic bronchitis and emphysema increase with age. COPD is the third leading cause of death in the United States; there are almost 140,000 deaths due to COPD annually in this country.

Morbidity and mortality are higher in persons with low incomes and less education. It is difficult to estimate the prevalence of chronic bronchitis because there is considerable overlap of conditions: Some patients have all three (asthma, chronic bronchitis, and emphysema), and some have two of the three conditions.

Several studies have established certain predisposing and risk factors for morbidity and mortality from COPD. The established and probable risk factors for COPD are shown in Risk Factors 9.2.

Cigarette smoking is responsible for 80% to 90% of the cases of COPD, and it is also the risk factor most amenable to modification for preventing or delaying the development of COPD. Educational intervention at an early age can help reduce smoking and some other risk factors, such as occupational exposure, exposure to air pollution and allergens, and respiratory infections. If certain genetic risk factors are present, the patient should be educated about periodic baseline testing for pulmonary function and about routine checks to prevent respiratory infections and reduce risks to the extent possible. The probability of a person developing COPD within 10 years can be calculated using the Tecumseh Index, in which points are allotted for the three major risk factors of age, number of cigarettes smoked per day, and FEV_1 as a percentage of the value predicted. Stopping smoking at any age has some beneficial effect for lung function even though there may be permanent damage to lung tissue.

Risk Factors 9.2 Risk Factors for COPD

Established risks:

- Age
- Male gender
- Cigarette smoking
- Reduced lung function
- Occupational exposures
- Air pollution
- Alpha$_1$-antitrypsin phenotypes

Probable or possible risks:

- Infections of the respiratory tract
- Allergic conditions
- Bronchial reactivity
- Climate
- Poor socioeconomic resources
- Alcohol intake
- Poor diet and inadequate nutrition
- ABO, ABH secretor, cell phenotypes
- Impaired immune function
- Familial factors

Pathophysiology

COPD is a progressive disease characterized by airflow limitation that is not fully reversible. The disease process involves a combination of the pathological mechanisms of emphysema and chronic bronchitis. In addition, hyperreactivity of the airways is a common feature. Thus, COPD is a disease of both the lung parenchyma and the small airways (bronchioles).

Emphysema is characterized by destruction of alveolar walls due to an imbalance of proteinase–antiproteinase enzymatic activity. In healthy lung tissue, protective antiproteinases counteract protein-degrading enzymes secreted by white blood cells. In rare cases, a genetic condition called alpha-1 antitrypsin deficiency may play a role in causing COPD. People who have this condition have low levels of alpha-1 antitrypsin, a protein made in the liver. Chronic inflammation, caused by long-term cigarette smoking or chronic exposure to lung irritants, for example, repeatedly recruits white blood cells to the alveoli. In contrast to the atopic processes of asthma, the lymphocytic infiltration of COPD consists predominantly of CD8+ T cells, rather than CD4+ T-helper cells. Neutrophil and monocyte-/macrophage-derived proteinases progressively degrade the alveolar walls, overcoming antiproteinase defenses. Overdistended, hyperinflated, less elastic alveoli are the result of the recurring injury over time. Weak elastic recoil of alveoli leads to air trapping, increased residual lung volume, reduced expiratory flow, and retained carbon dioxide. Individuals experience hypercapnia but can maintain adequate oxygenation early on in the disease process.

Desensitization of the central respiratory receptors to P_{CO_2} occurs with long-term hypercapnia. Under normal circumstances, P_{CO_2} accumulation in the blood stimulates

individuals to breathe independently. However, persons who endure long-term states of hypercapnia lose this normal respiratory stimulus to breathe. Hypoxia becomes the stimulus for breathing instead of P_{CO_2}. Hypoxia is sensed by peripheral chemoreceptors in the arteries, such as the carotid bodies. The individual who has endured hypercapnia for a prolonged period of time begins to rely on low oxygen levels to drive breathing. Consequently, supplemental oxygen must be used judiciously in these individuals because of their hypoxic drive to breathe. High levels of supplemental oxygen, as well as respiratory depressants of any kind (e.g., sedatives, narcotics), can suppress the hypercapnic individual's hypoxic drive to breathe independently.

Cigarette smoking is the major environmental risk factor for development of COPD. Although smoking cessation slows progression of the disease, reversal of pathological changes does not occur. There is a proven causal relationship between cigarette smoking and COPD; however, there is marked variability in the pulmonary function of persons with similar smoking histories. This has led to investigation into genetic risk factors for COPD. As mentioned earlier, one such genetic risk factor is alpha-1 antitrypsin deficiency. Alpha-1 antitrypsin is a major antiproteinase enzyme that can counteract alveolar destruction. Individuals can inherit different genetic mutations that lead to variable degrees of deficiency of this enzyme. Individuals with complete absence of alpha-1 antitrypsin have an increased susceptibility to emphysema and develop the disease early in life.

Compared with emphysema, chronic bronchitis is the more common pathological mechanism involved in COPD. Airflow obstruction in chronic bronchitis is caused by bronchiole edema, hyperplasia of mucus-producing goblet cells, and bronchiole smooth muscle hypertrophy. Clinically, chronic bronchitis presents as a long-term cough or recurrent sputum production, primarily on morning awakening, extending over 3 months for a period of at least 2 years. Individuals with hypoxia and cyanosis have problems with ventilatory obstruction and suboptimal oxygenation of the blood. In chronic bronchitis, long-term hypoxia leads to pulmonary vasoconstriction, which can result in pulmonary hypertension. This increased pulmonary resistance against the right ventricle can lead to right ventricular failure or cor pulmonale. Chronic hypoxia also stimulates renal erythropoietin, which initiates and perpetuates red blood cell synthesis in the bone marrow, thereby increasing hemoglobin concentration and hematocrit, which makes the right ventricle hypertrophic from pumping more viscous blood into a constricted pulmonary artery.

Acute exacerbations of chronic bronchitis are highly characteristic of this disease. Increased purulent sputum production and worsened shortness of breath are the hallmark of such episodes, which may also be accompanied by fever and increased oxygen requirements for patients on supplemental oxygen. Although viral bronchitis requiring only supportive care is the most common etiology of such exacerbations, bacterial involvement must be considered with increased sputum production lasting more than a week or new chest x-ray findings. *Streptococcus pneumoniae* is the most common agent, followed by *Haemophilus influenzae* and *Moraxella catarrhalis,* similar to the causative agents of sinusitis and community-acquired pneumonia. Antibacterial therapy is often instituted empirically, however, without the need for cultures or Gram stain evidence.

The respiratory symptoms of COPD logically follow patterns of pulmonary neuromuscular anatomy, because bronchiole smooth muscle is innervated by beta-2 adrenergic and cholinergic nerve receptors. The bronchiole constriction in COPD is largely cholinergically mediated. For this reason, blockade of cholinergic receptors by anticholinergic drugs enhances the ability of bronchioles to dilate in COPD. Increased mucus production is also counteracted by these agents. In contrast, beta-receptor activation mediates bronchodilation, as reflected in the therapeutic benefits of inhaled beta-agonist drugs. Inhaled and oral steroids, on the other hand, function by decreasing overall airway inflammation mediated largely by T cells.

There is a normal age-related decline in pulmonary function: The forced expiratory volume in 1 second (FEV_1) declines by 0.02 to 0.04 L per year. Cigarette smoking accelerates the decline by twofold to threefold. Though smoking cessation slows the rate of decline, it will not reverse most pathological changes. Pulmonary function patterns and physical findings for various pulmonary conditions are shown in Table 9.5. The PFT results reflect the underlying pathology of the condition.

It is common for patients to have mixed lung disease (both restrictive and obstructive). For example, patients with chronic bronchitis may also present with a restrictive ILD such as sarcoidosis. In cases like this, all lung volumes would be reduced, the diffusing capacity would be reduced, and the arterial blood gases (ABGs) would be abnormal (showing hypoxemia and possibly carbon dioxide retention).

Age and FEV_1 are the strongest predictors of mortality in COPD (Table 9.6). High mortality rates occur when COPD is complicated by respiratory infection (acute bronchitis exacerbations) or cor pulmonale from chronic pulmonary hypertension. These conditions increase risk for ventilation–perfusion mismatch, hypoxemia, hypercapnia, respiratory acidosis, and respiratory failure.

Clinical Presentation

Subjective

The typical smoker who develops COPD may be asymptomatic for 10 to 20 years except for more frequent colds, persistent morning cough, and upper respiratory infections. Men, in particular, may wait until the dyspnea becomes severe before seeking medical help or may seek help only when they need antibiotics for a chronic

Table 9.5 Pulmonary Function and Physical Findings in Obstructive and Restrictive Lung Diseases

Parameters	Asthma	Chronic Bronchitis	Emphysema	Restrictive Disease
Forced Vital Capacity (FVC)	Normal	Normal to increased	Normal to increased	Decreased
Residual Volume (RV)	Normal; increased during attacks	Increased	Increased	Decreased or normal
Total Lung Capacity (TLC)	Normal to increased	Normal	Normal to increased	Decreased
RV/TLC	Normal to increased	Increased	Increased	Normal
Expiratory Flow Rates	Normal to decreased	Normal to decreased	Normal to decreased	Normal to increased
FEV_1/FVC	Normal to decreased	Decreased	Decreased	Normal to increased
Bronchodilator Response (% change)	>15%	0%–15%	None	None
Diffusing Capacity	Normal to increased	Normal to decreased	Decreased	Normal or decreased (depends on type of disease)
Pao_2	Normal; decreased during attack	Decreased	Normal in mild to moderate disease; decreased in severe disease	Normal or decreased
$Paco_2$	First decreased, then increased during acute attack	Increased	Normal until advanced disease, then increased	Normal or decreased; increased in very advanced disease
Breath Sounds	Marked decrease during acute attacks If FEV_1 = 0.5 L or less: absent	If FEV_1 = 1 L: barely audible		Normal or decreased in pneumonia, atelectasis
Crackles (rales)	Coarse crackles during infections	Coarse crackles during infections	Fine crackles may be present	Varies with type of restrictive disease
Wheezes (rhonchi)	High-pitched; continuous	Forced expiratory wheezes	No	No

productive cough. They may ignore symptoms of fatigue, shortness of breath, and cough because of embarrassment. Older persons may attribute the shortness of breath and fatigue to functional decline related to aging. The onset of COPD is typically in the fifth decade or later with a 20-pack-year smoking history (number of packs of cigarettes per day times number of years).

With advanced disease in which chronic bronchitis predominates, pulmonary hypertension may result from chronic alveolar hypoxia, and cor pulmonale develops. Patients with these signs and symptoms are often called "blue bloaters" because of the edema and cyanosis that accompany their condition. A complete blood count (CBC) with differential may reveal polycythemia secondary to the increased erythropoietin stimulation of increased red blood cells to compensate for the chronic hypoxemia.

Patients who primarily have emphysema ("pink puffers") have severe dyspnea but usually present with relatively normal ABGs that are maintained because of high minute ventilation. As the disease progresses, dyspnea increases because the diffusing capacity is severely reduced. These patients often appear very thin and may have the typical "barrel chest" resulting from hyperinflation.

A patient with an acute exacerbation of chronic bronchitis may present with cough and increased sputum that is thick and colored (yellow, brown, gray, or green); fever may also be present. Sudden onset of cough with minimal sputum, chills, fever, and myalgia is more indicative of a viral infection. Remember that older adults

Table 9.6 Severity of COPD Based on the Pulmonary Function Measures: Forced Expiratory Volume in 1 Second (FEV_1)

Stage 1:	
Mild COPD	FEV_1/FVC <0.7 FEV_1 ≥80% predicted
Stage 2:	
Moderate COPD	FEV_1/FVC <0.7 FEV_1 50%–79% predicted
Stage 3:	
Severe COPD	FEV_1/FVC <0.7 FEV_1 30%–49% predicted
Stage 4:	
Very severe COPD	FEV_1/FVC <0.7 FEV_1 <30% predicted or <50% predicted with chronic respiratory failure

Source: Adapted from Global Initiative for Chronic Obstructive Lung Disease (GOLD). COPD diagnosis and management at-a-glance desk reference. Updated February 2013. Retrieved July 1, 2013, from www.goldcopd.org/guidelines-copd-diagnosis-and-management.html

often have blunted responses to infection due to a decreased immune response.

Patients with COPD usually present with a complaint of chronic productive cough (chronic bronchitis) and increasing shortness of breath or dyspnea on exertion (emphysema). Associated symptoms may include fatigue, weakness, hemoptysis, loss of appetite, nausea, and dizziness. By the time there is dyspnea on exertion, the disease is usually well advanced. Patients may report having to sleep sitting up or with three or more pillows to relieve dyspnea. They may report awakening during the night with severe dyspnea (paroxysmal nocturnal dyspnea), which is relieved by sitting upright.

Objective

The physical findings will vary depending on the severity of the COPD. Physical findings are often not significant in mild to moderate COPD. In emphysema or mixed disease, the chest exam may indicate hyperinflation. There may be flattening of the diaphragm, tachypnea, and use of the accessory muscles of respiration (scalene, sternocleidomastoids). In hyperinflation, the predominant palpable or auscultatory cardiac contraction may be noted in the epigastrium rather than in the left intercostal space. On auscultation, breath sounds are distant and are not augmented much with deep breathing. End expiratory wheezes may be heard on forced expiration. Patients with a bronchospastic component may have inspiratory and expiratory wheezes. Measurement of forced expiratory time is useful to determine if airway obstruction is present. When auscultating the lungs, have the patient take a full inspiration, then listen while the patient exhales through the mouth until airflow stops. Normal duration is 3 seconds, but in COPD the time is prolonged because of airway obstruction.

Coarse crackles may be present during an acute exacerbation. Neck vein distention, especially during expiration, may occur as a result of increased intrathoracic pressure. The patient's feet and ankles should be examined for edema that may occur as the disease progresses and cor pulmonale develops. The nailbeds should be examined for clubbing (hypertrophic osteoarthropathy), which often occurs in patients with pulmonary pathology. Other causes of clubbing are atrioventricular shunt, subacute bacterial endocarditis, inflammatory bowel disease, and biliary cirrhosis.

During the physical exam, the patient's ability to follow commands and respond to questions should be documented. Changes in mental status may be caused by hypoxemia or hypercapnia rather than dementia. Fatigue is a common finding.

Diagnostic Reasoning

The diagnostic approach to the patient is directed at assessment of the type of obstructive disease (primarily bronchitis, emphysema, or mixed) and whether it is reversible or irreversible. The possibility of underlying restrictive disease must be eliminated. Patients who have chronic bronchitis and have smoked for 20 years or longer should be evaluated for lung cancer.

Diagnostic Tests

Initial Testing The initial diagnostic evaluation should include PFTs (spirometry, diffusing capacity, and ABGs). The standard PFTs should include prebronchodilator and postbronchodilator testing to determine if there is a significant response to bronchodilators. The diagnostic criterion for COPD is an FEV_1/FVC ratio that is less than 70%. The FEV_1 (percent of predicted value) is the most useful parameter to assess severity of obstruction (see Table 9.6). The American College of Physicians' Guidelines recommend spirometry in the diagnosis of patients exhibiting symptoms but not in those who are asymptomatic.

Even though bronchitis and emphysema usually occur together in most patients, it is important to distinguish the severity of the bronchitis and the emphysema and to identify how much of a bronchospastic component is present in order to direct treatment appropriately. In chronic bronchitis and emphysema, narrowing of the airways is present that usually results in an increase in airway resistance and a decrease in maximal expiratory flow rates. In emphysema, the loss of elastic recoil accounts for a decrease in the caliber of the airways (from loss of radial traction on the airways). The elastic recoil properties of the lung serve as a major determinant of the expiratory flow rates. Maximal expiratory flow

rates represent a complex and dynamic interplay among airway caliber, elastic recoil pressures, and airway collapsibility. As a result of the altered pressure-airflow relations in COPD, the work of breathing is increased in bronchitis and emphysema. The maldistribution of inspired gas (through ventilation) and blood flow (through perfusion) is always present to a degree in COPD. When the mismatching is severe, it is reflected in the ABGs as hypoxemia or hypercarbia.

Chest radiography will appear normal in patients with early COPD. In patients with chronic bronchitis, chest x-ray films may reveal increased lung markings in the lower lobes and peribronchial thickening. In patients with emphysema, the radiograph may show hyperinflation (low flat diaphragm, enlarged retrosternal space), hypovascularity, areas of hyperlucency and bullae formation, and a small cardiac silhouette. Chest computed tomography (CT) scans are used to evaluate the extent and distribution of emphysematous cysts for possible surgery. In recurrent bronchitis, CT scans may be used to rule out bronchiectasis.

Laboratory tests should include a CBC and differential. The hemoglobin, hematocrit (Hct), and red blood cell count should be evaluated to rule out anemia or polycythemia. Serum alpha$_1$-antitrypsin levels should be checked in patients who develop COPD at an early age (younger than 45), those with clinical emphysema who have not smoked, and those with a family history of young onset of COPD. A blood chemistry profile is done to assess the electrolyte (K, Na, Cl) and nutritional status (total protein, albumin) and to rule out renal or liver problems.

For an exacerbation of chronic bronchitis, sputum should be tested via Gram stain. Sputum culture and sensitivity is done to confirm the findings of the Gram stain. The Gram stain is the best clinical method for diagnosing an acute exacerbation because the bacteria can be seen and quantified. Patients with COPD often are colonized by low numbers of bacteria, including *S pneumoniae, H influenzae,* and *M catarrhalis,* which will grow in culture even though they are not present in sufficient numbers to be seen with Gram stain. If the Gram stain shows neutrophils but no bacteria in a patient with chronic bronchitis, the acute exacerbation is probably viral or chlamydial, even when the sputum culture yields *Haemophilus* or *Pneumococcus.* A negative Gram stain indicates that such culture results represent bacterial colonization rather than a true infection.

An electrocardiogram (ECG) should be done if the patient has not had a baseline test and especially if there are signs of cardiac disease or in advanced COPD. Atrial arrhythmias are common in older adults and in pulmonary patients of any age. ECG changes in pulmonary disease include peaked P waves in leads II, III, and aV$_F$ and changes associated with right ventricular hypertrophy. Cardiac abnormalities may have implications for the drugs selected to treat the COPD.

Assessing degree of functional status and quality of life of patients with COPD should be done initially to determine the potential for rehabilitation and to direct appropriate therapy. The SF-36 Health Survey is a valid, reliable tool used worldwide to assess physical and emotional health and is recommended for patients with chronic illnesses such as COPD. The tool is widely available.

Subsequent Testing Annual spirometry, CBC with differential, chemistry profile, and chest radiographs should be done to measure the patient's decline in pulmonary function and to screen for other lung diseases that may be related to smoking. Gram stain, culture and sensitivity test of sputum, and ABG analysis are done as needed during acute exacerbations. Pulse oximetry is a noninvasive test that can be done in the office to screen for hypoxemia. An oxygen saturation of 90% or less at rest warrants monitoring ABGs. The ATS recommends ABG monitoring for hypoxemia and hypercapnia in patients with advanced disease—those with an FEV$_1$ less than 50% of the predicted value.

Differential Diagnosis

Acute bronchitis, asthma, bronchiectasis, bronchogenic carcinoma, acute viral infection, normal aging of lungs, occupational asthma, sleep apnea, and chronic sinusitis are all conditions that need to be ruled out to make a diagnosis of COPD and emphysema. In young adults, cystic fibrosis needs to be ruled out. Patient history and PFT results (including decreased FEV$_1$ with concomitant reduction in FEV$_1$/FVC ratio), as well as poor or absent reversibility, will assist in making the diagnosis of COPD.

Management

It is essential to diagnose COPD early in patients, because the estimated direct medical costs of COPD annually are more than $18 billion. This fact highlights the economic importance of prevention and of interventions aimed at early diagnosis and delaying disease progression. After the initial diagnosis is made, education of the patient and family is critical for therapy to be effective. The patient and family need to understand that although COPD is not a curable disease, with proper management and smoking cessation, the symptoms can be controlled and quality of life improved. A nursing research study (Nursing Research–Based Practice Box 9.1) is provided that shares the importance of collaborative partnerships in caring for patients with COPD due to the myriad of problems experienced with these patients.

Smoking cessation improves declining lung function and is the single most important intervention to slow the rate of lung function decline regardless of disease severity (Level I; University of Michigan Health System, 2010). After 5 years without cigarettes, the lung function returns to almost that of a nonsmoker. Patients should be urged at each clinic visit to stop smoking; family

Nursing Research–Based Practice 9.1

Kirkpatrick, P, et al. Research to support evidence-based practice in COPD community nursing. *Br J Community Nurs* 17(10):486, 488–492, 2012.

Evidence-based practice (EBP) is a requirement of nurses through the generation of evidence to implementing it, in a bid to improve clinical practice. However, EBP is difficult to achieve. This paper highlights an approach to generating evidence for enhancing community nursing services for patients with chronic obstructive pulmonary disease (COPD) through a collaborative partnership. A district nurse and two nursing lecturers formed a partnership to devise a systematic review protocol and perform a systematic review to enhance COPD practice. This paper illustrates the Joanna Briggs Institute (JBI) systematic review process, the review outcomes, and the practitioner learning. Collaborative partnerships among academics, researchers, and clinicians are a potentially useful model to facilitate enhanced outcomes in EBP and evidence application.

members should also be encouraged to do the same if they smoke. For more information on smoking cessation, see Smoking Addiction later in this chapter.

Pharmacological Therapy

Although only supplemental oxygen has been shown to improve the mortality associated with COPD, pharmacotherapy has a significant role in reducing its associated morbidities and improving quality of life. A stepwise approach to therapy, similar to that for asthma and hypertension, is used. Drugs most commonly used for management of COPD symptoms are beta-2 agonists, anticholinergics, combination short-acting beta-2 agonists plus anticholinergics in one inhaler, xanthines, inhaled glucocorticosteroids, and systemic glucocorticosteroids. Antibiotics are warranted in the presence of a prolonged illness, especially with purulent sputum.

Inhaled Beta-2 Agonist Bronchodilators Inhaled short-acting beta-2 agonists (beta-adrenergic agonists) are the first line of therapy in the Global Initiative for Chronic Obstructive Lung Disease (GOLD) Stage I. The major goals of therapy are to prevent bronchospasm with long-acting bronchodilators and to use "rescue" medication to alleviate acute episodes of bronchospasm. Each episode of acute bronchospasm causes permanent remodeling of the bronchioles; therefore, prevention of these episodes is critical. Inhaled short-acting beta-2 agonists (albuterol [Proventil, Ventolin], pirbuterol [Maxair Autohaler]) are prescribed as "rescue" medication for intermittent symptoms of acute shortness of breath. Patients may experience adverse reactions from beta-2 agonists that include tremors, nervousness, and dysrhythmias. Long-acting beta agonists are not first-line therapy but may be used for maintenance therapy to prevent acute bronchospastic episodes. They should not be used without inhaled steroids.

Inhaled Anticholinergic Bronchodilators Inhaled anticholinergic bronchodilators such as ipratropium bromide (Atrovent) are recommended for maintenance therapy in COPD. Bronchospasm in COPD has been found to be mainly cholinergically mediated; therefore anticholinergic inhalers are effective. These drugs are well tolerated by older adults and are not systemically absorbed. Ipratropium is taken routinely, usually two puffs four times a day. A long-acting anticholinergic agent in a dry powder form such as tiotropium (Spiriva) may be effective and is inhaled only once daily. As a scheduled bronchodilator, tiotropium offers significant advantages to patients whose symptoms are not controlled by albuterol. Tiotropium is the recommended therapy for GOLD Stage II along with albuterol as a rescue medication. Many tiotropium studies have shown a reduction in the use of rescue medication, as well as a reduction of COPD exacerbations (Level I; Freeman et al, 2007). Some inhaler medications for COPD contain a combination of an anticholinergic and a beta-2 agonist bronchodilator that act synergistically. Formoterol plus ipratropium, albuterol, or a combination may also be used in Stage II. These are also recommended in Stages III and IV, along with the addition of an inhaled corticosteroid. A combination of inhaled corticosteroid and long-acting beta-2 agonist is fluticasone and salmeterol (Advair Diskus). Patients seem to do better with one inhaler rather than two.

Corticosteroids The primary role of inhaled glucocorticoids in COPD is as an anti-inflammatory agent. The dosing of inhaled corticosteroids such as beclomethasone, budesonide (Pulmicort), and fluticasone (Flovent), among others, should be individualized. Good inhaler technique with a spacing device and frequent mouth rinsing are advised to avoid oral candidiasis. Combination corticosteroid and beta-2 adrenergic agonist inhalers are effective to counteract bronchoconstriction and inflammation.

In rare cases, systemic corticosteroids may be used in the management of an acute exacerbation for no more than 10 to 14 days. However, the potential risks associated with this treatment, including immunosuppression, hypertension, and hyperglycemia, necessitate that it be used with caution. Some studies have shown that for acute COPD exacerbations, systemic corticosteroids are effective in reducing treatment failures (Level I; Quon

et al, 2008). Some clinicians report that 15% to 20% of patients respond both subjectively (perceived dyspnea) and objectively (FEV_1 and improved exercise performance) with low-dose long-term systemic steroids, although this is not a widely accepted treatment. Rather, systemic steroids should be used only when the other drugs have failed and when there is an acute exacerbation with a bronchospastic component to the COPD. Patients who are likely to respond to steroids are those who have blood and sputum eosinophilia, positive allergy skin test results, elevated levels of serum IgE, and a history of allergy and bronchodilator response. Before starting oral steroids, baseline spirometry should be done; then the patient may take oral prednisone 40 mg daily for 1 to 2 weeks. Spirometry is repeated, and an improvement in FEV_1 of 15% indicates a positive response. The dose should then be tapered to a low daily or alternate-day maintenance dose of 7.5 to 15 mg. The adverse effects of systemic steroids are well known (e.g., gastric ulcer, osteoporosis, masked infections, secondary infections), and the patient should be monitored carefully for adverse reactions.

Beta-2 adrenergic agonists and anticholinergic and corticosteroid medications are available in metered-dose inhalers and dry powder inhalers. Use of these inhaler devices requires patient education. The clinician should observe a patient demonstration of proper inhaler technique because there are differences in the technique used with each type of dispenser. Many patients have difficulty mastering the proper inhaler technique to gain optimal pulmonary delivery of medication. Spacers can be used with some inhalers to enable better delivery of the drug. Nebulizers can also be used to facilitate delivery of some inhaler medications. Regardless of the method used, ongoing patient education is essential to ensure proper inhalation of the medication.

Xanthines Aminophylline or theophylline may be used as a fourth-line drug if the beta-2 agonists, the anticholinergic drugs, and the inhaled corticosteroids are not effective. These preparations have a very narrow therapeutic index, and blood levels should be monitored closely for toxicity. The therapeutic levels are 5 to 15 mcg/mL. The therapeutic benefit may be the result of improved muscle contractility and decreased muscle fatigue. Therapy should be initiated with low doses, then increased gradually because of the narrow therapeutic range. Xanthines interact with other drugs commonly taken by patients with COPD, including cimetidine (Tagamet), erythromycin, ciprofloxacin (Cipro), and beta blockers, among others. If the patient is taking a xanthine, it is safer not to use these drugs to avoid drug toxicity.

Antibiotics Antibiotics are often needed for acute exacerbations of chronic bronchitis when purulent sputum is present. There is little to no evidence for the use of chronic suppressive antibiotic therapy, and this practice has fallen out of favor. Most pulmonologists recommend the empiric use of antibiotics to treat acute episodes when the cough increases and the character and the amount of the sputum change (increase in amount, color, and consistency), even in the absence of fever, pulmonary infiltrates, and leukocytosis. For empiric therapy, the antibiotic should be effective against the three most common pathogens (*S pneumoniae, H influenzae,* and *M catarrhalis*), stable against the effects of beta-lactamase, and convenient to take with few adverse reactions. The choice of antibiotic should also depend on local bacterial resistance patterns and individual risk of *Pseudomonas aeruginosa* infection. Patients with COPD who have had a fairly stable course (few hospitalizations) and have not been exposed to many antibiotics typically respond well to therapy. Oral antibiotic options include doxycycline (100 mg every 12 hours), trimethoprim-sulfamethoxazole (160/800 mg every 12 hours), a cephalosporin such as cefpodoxime (200 mg every 12 hours), a macrolide such as azithromycin (500 mg the first day followed by 250 mg for 5 days), a fluoroquinolone such as ciprofloxacin (500 mg every 12 hours), and amoxicillin-clavulanate (875/125 mg every 12 hours). Some practitioners prescribe antibiotics for a period of 3 to 7 days. Some studies have shown that 5 days are as effective as 7 days with fewer side effects. Immunocompromised patients with a turbulent course should be treated carefully with the right antibiotic, even if it is the most expensive, to prevent respiratory failure and admission to an intensive care unit. Persistent gram-negative infection may require prolonged IV antibiotic administration.

Diuretics Diuretics may be necessary when there is evidence of cor pulmonale (right heart failure). Often the triad of prerenal azotemia, hypernatremia, and low cardiac output develops in cor pulmonale, and loop diuretics may be used. Small doses of furosemide (Lasix) and potassium chloride supplements are used in conjunction with a sodium-restricted diet.

Mucolytics and Expectorants Inhaled aerosols of water, saline, steam, or other agents do not improve mucociliary clearance or expectoration. Oral expectorants such as guaifenesin (Humibid, Robitussin) are usually ineffective. Chest physiotherapy and keeping the patient well hydrated is the most cost-effective way to clear the lungs.

Home Oxygen Because hypoxia leads to pulmonary hypertension and increases the work of the right ventricle, low-flow oxygen may help prevent or deter development of cor pulmonale. In addition, of all the therapies mentioned, only supplemental oxygen has been shown to reduce the mortality rate associated with COPD. Requirements for home oxygen include (1) a PaO_2 of 55 mm Hg or less or an oxygen saturation (SaO_2) below 85% and (2) a PaO_2 of 55 to 59 mm Hg if any of the following is present: erythrocytosis (Hct of 56% or more), cor pulmonale (P wave more than 3 mm in leads II, III, and aV_F), edema, or congestive heart failure. The goal

of therapy is a PaO_2 of 60 mm Hg or SaO_2 of 90%, which usually can be accomplished with 1 to 2 L of oxygen per minute for 15 hours per day. The patient should be reevaluated with ABGs or oximetry at 1, 3, and 6 months, then annually. In advanced disease, supplemental oxygen has been shown to reduce the number of hospitalizations and increase the quality of life in individuals.

Surgery

Although surgery will not cure COPD, some patients have benefited from one of three surgical procedures with an improved quality of life. Because of the typically poor pulmonary state of the patient, any surgery is extremely risky and should be performed using an epidural or spinal anesthesia rather than general anesthesia. A bullectomy involves resection of a bulla, which may be effective in reducing the patient's dyspnea. Lung volume reduction surgery involves resecting 20% to 30% of the lung to reduce hyperinflation. Exercise capacity may be improved, but it is highly unlikely that life expectancy would be improved because of the advanced nature of the disease. A lung transplant has been shown to improve the quality of life, functional capacity, and exercise performance. The 2-year survival rate for lung transplantation is 75%. The decision for surgery should be made with the specialist and involve the entire family.

Follow-up and Referral

Patients who are unstable and those with severe disease should be seen monthly. If the patient is stable, an annual visit would be the minimum. If the patient is on theophylline, the blood levels should be monitored every 6 to 12 months once the patient is on the desired dose. If the patient is on home O_2, ABGs should be checked whenever there is any condition change or, at a minimum, semiannually. It is important to monitor oxygen saturation (pulse oximetry) more frequently.

Follow-up for the patient with COPD includes the development of a close and supportive relationship with the health-care provider. Because smoking cessation is the single most effective way to reduce the progression of COPD, the patient should be asked about this at every visit.

Patient Education

Patients with COPD should avoid extremes in temperature and humidity when possible and limit their exposure to areas that have high levels of air pollution. Smoking should not be allowed in the home, car, or other confined places. Occupational exposure to fumes, vapors, dusts, and irritants may aggravate symptoms of dyspnea and bronchospasm. High altitude and air travel can pose problems for hypoxemic patients. Arrangements can be made with the airlines in advance for patients requiring oxygen.

Most lung infections are viral, so avoiding contact with crowds during flu season and limiting exposure to people with colds may help. In the fall, patients with COPD should receive influenza immunizations with polyvalent vaccine from early October through mid-November. Obviously patients with comorbid conditions such as COPD should be treated for a viral infection as soon as possible. Oseltamivir (Tamiflu) is an abortive antiviral that helps shorten the duration and decrease the severity of influenza symptoms if used within the first 48 hours of symptom onset. Polyvalent pneumococcal vaccine should also be given. For people older than age 65, reimmunization every 5 years is appropriate. Respiratory therapy and oxygen equipment used in the home should be routinely cleaned to prevent bacterial colonization and subsequent infection.

Pulmonary rehabilitation should be considered for all patients with functional impairment (Level I; University of Michigan Health System, 2010). Physical rehabilitation is also recommended because it can not only deter functional decline but also help the patient and family to maintain a positive outlook. Often, the best exercise for patients with mild to moderate obstructive disease is an individualized walking program. Physical therapy may also be beneficial; the therapist should prescribe specific breathing exercises, arm exercises, and others that will promote general physical reconditioning. Walking aids have been shown to support the diaphragm and ease the difficulty of breathing while walking. During attacks, use of slow, pursed-lip breathing may help to decrease respiratory rate, reduce bronchospasm, and relieve dyspnea. Effective cough techniques and chest physiotherapy are also recommended.

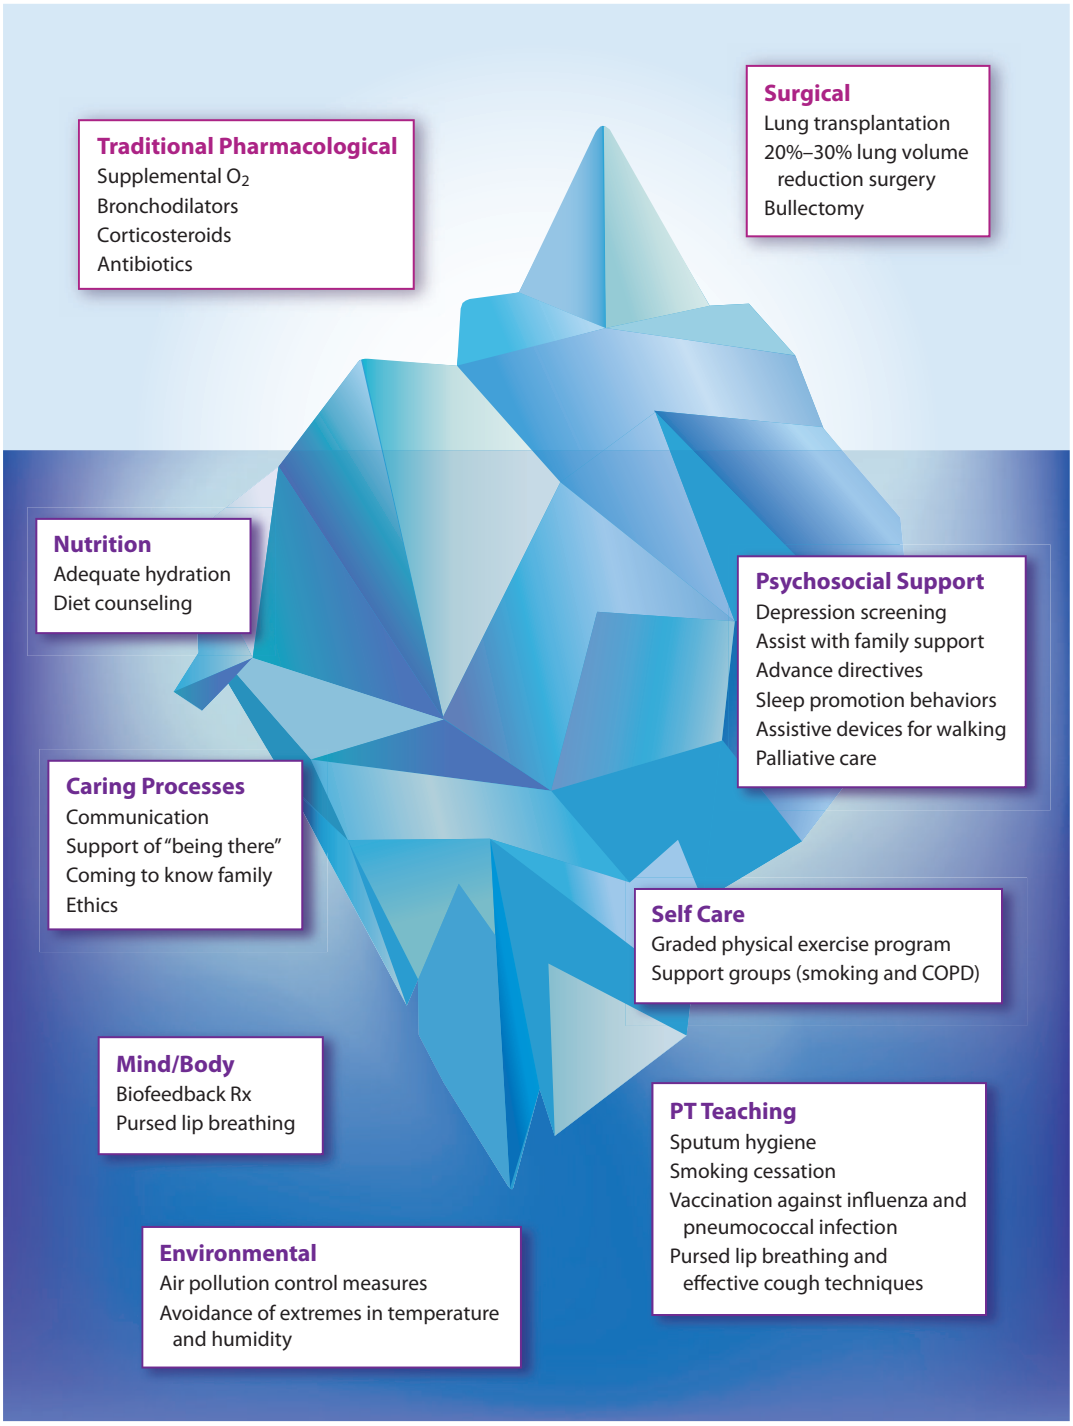
Many patients with COPD find support groups helpful for them and their spouses or caregivers. These support groups are usually sponsored by local chapters of the American Lung Association, and they are usually listed in the phone book. Other patients have used forms of meditation or guided imagery to help relieve dyspnea and anxiety.

Patients with chronic illness such as COPD often are depressed. The Beck depression scale can be used to screen for depression. Use of the selective serotonin reuptake inhibitor antidepressants in patients with lung disease is considered safe and may improve sleep, quality of life, and functional status.

Health-care providers should have a frank discussion with patients and their families regarding end-of-life care, such as advance directives and health-care surrogates. Copies of all documents should be kept in the chart, as well as with patients' families and attorneys. See the Iceberg of COPD figure for additional patient education.

Nursing Research–Based Practice Box 9.2 is an example of how patient teaching by the provider can make a difference in improving patient outcomes.

The Iceberg of COPD



PNEUMONIA

Pneumonia is typically an acute inflammation of the lung parenchyma, usually infectious in origin. The lung tissue typically becomes consolidated as alveoli fill with exudate. Gas exchange may be impaired as blood is shunted around nonfunctional alveoli. The timely diagnosis and appropriate management of pneumonia in patients is critical because of the morbidity associated with bacterial etiologies, as well as the increased mortality among older patients and those with underlying pulmonary disease. Community-acquired pneumonia (CAP) occurs outside the hospital or is diagnosed within 2 days after

Nursing Research–Based Practice 9.2

Stanley, T, et al. Patient and provider attributes associated with chronic obstructive pulmonary disease exacerbations. *J Nurse Pract* 9(1):34–39, 2013.

The purpose of this quality improvement project was to identify key patient and provider attributes associated with chronic obstructive pulmonary disease (COPD) exacerbations in primary care. The study demonstrates clinical quality scholarship undertaken at the point of service to patients. Both the quality improvement processes applied and the outcomes measured have led to new ways of thinking about clinical problems routinely encountered in medical homes. Evidence-based practice, such as that generated through this study, is a means for improving care for patients, providers, and communities. Addition of these skills to the nurse practitioner's existing skill set of providing patient-centered care, patient advocacy, and service coordination will ensure an even more competent nurse practitioner and improve patient outcomes.

hospitalization in a patient who has not resided in a long-term care facility for 2 weeks or more before the onset of the symptoms.

Epidemiology and Causes

It is estimated that in the United States almost 5 million people develop pneumonia annually. Of these, about 1.3 million persons with pneumonia are admitted to hospitals, and more than 90,000 die each year. Approximately 70% to 80% of patients who develop CAP are aged 60 years or older or have a coexisting medical condition. CAP remains one of the 10 leading causes of mortality among elderly people in the United States today and is frequently the terminal event in older adults and those debilitated by chronic diseases, particularly chronic respiratory disease. This population is increasing, thus making adequate treatment of pneumonia a health-care priority. Nosocomial (hospital-acquired) pneumonias account for approximately 15% of all hospital-associated infections; pneumonia is second only to urinary tract infections in terms of frequency among hospitalized patients. The most common pathogens associated with CAP and nosocomial pneumonia are shown in Table 9.7.

Pneumocystis jirovecii (formerly *carinii*) pneumonia (PCP) remains one of the leading causes of death in patients with AIDS. However, widespread use of highly active antiretroviral therapy and antibiotic prophylaxis based on CD4 T-cell counts has led to a dramatic decline in PCP incidence over the last 10 years. For pneumonia in general, however, other vulnerable populations include infants younger than 6 months old, children younger than age 5 years, smokers, alcoholics, residents of nursing homes, young adults living in close quarters (e.g., college students and military recruits), and any patient with impaired swallowing capacity or cough reflex who is at risk for aspiration. Geographical location, the winter season, occupation, travel history, and pet or animal exposure are other factors associated with the development of pneumonia.

Table 9.7 Common Causes of Pneumonia

Community-Acquired Pneumonia (CAP)	Nosocomial Pneumonia
Streptococcus pneumoniae (70% of all cases of bacterial pneumonia)	Most are caused by gram-negative bacteria.
Pneumococcal pneumonia (25%–35% of all CAP)	Enteric aerobic gram-negative bacilli
Staphylococcus aureus	*Klebsiella pneumoniae*
Klebsiella pneumoniae	*Pseudomonas aeruginosa*
Moraxella catarrhalis (less common)	*Staphylococcus aureus* (gram-positive)
Atypical pneumonias:	Oral anaerobes
Mycoplasma pneumoniae (second most common cause of CAP)	*Legionella pneumoniae* (which travel in cooling systems, condensers, and shower heads)
Legionella pneumoniae	
Chlamydia pneumoniae	
Fungi	
Oral anaerobes	
Viruses	

Pathophysiology

Pneumonia is an infection of the alveoli, distal airways, and interstitium of the lungs and, thus, predominantly a parenchymal disease. A pathogen, such as a bacterium, virus, fungus, or parasite, reaches the lower respiratory tract in sufficient number or with sufficient virulence to overwhelm the innate defenses of the respiratory tract. The inflammatory response is set in motion, which increases capillary permeability and attracts neutrophils, lymphocytes, platelets, and fibrinogen to the site of infection. Tissue fluid extravasates into the interstitial space from the pulmonary capillary bed, forming an exudate with a higher protein content than typical transudative fluid. As this exudate develops, an increasing amount of cellular debris accumulates, impeding optimal oxygen diffusion from the alveoli to capillaries with resultant hypoxemia. Vital capacity, lung compliance, residual capacity, and total lung capacity are diminished, and ventilation–perfusion mismatch occurs.

The spongy consistency of the lung tissue becomes fluid filled and infiltrated by several lineages of white blood cells depending on the infective agent involved, including neutrophils, lymphocytes, and macrophages, as well as red blood cells and fibrin. Because of these changes, the area of pneumonia is often referred to as a consolidative focus, which is typically dull to percussion on physical exam. Pneumonia may be classified as lobar pneumonia, interstitial pneumonia, miliary pneumonia, or bronchopneumonia. Figure 9.1 shows some parenchymal changes in pneumonia. Lobar pneumonia involves an entire lobe of the lung, whereas interstitial pneumonia is a patchy or diffuse inflammatory process throughout regions of the interstitium. Miliary pneumonia consists of numerous discrete lesions resulting from hematogenous spread of infection, and bronchopneumonia is a patchy consolidation involving one or several lobes. Moreover, inflammation can also extend into the pleural space, causing a parapneumonic effusion or inflammation of the pleural membranes, known as pleuritis or pleurisy.

Possible routes of infection include aspiration, aerosolization, hematogenous spread from a distant infected site, and direct spread from a contiguous infected site. Aspiration pneumonia occurs most often in postoperative, stroke, comatose, or otherwise mentally altered patients with an impaired swallowing reflex. Although *Streptococcus pneumoniae* remains the most common causative agent in aspiration pneumonia, anaerobic bacteria and gram-negative bacilli (i.e., gastrointestinal flora) must also be considered. Hematogenous spread to the lungs can take place in endocarditis, from IV central catheter line infection, or from infection at other sites such as the urinary tract. Aerosolization, the most common means of infection, is the route by which most bacteria, *Mycobacterium tuberculosis,* fungi, and viruses reach the lungs.

In adults, the most common organisms involved in CAP include viruses, *S pneumoniae, Moraxella catarrhalis, Haemophilus influenzae, Legionella pneumophila,* and methicillin-sensitive *Staphylococcus aureus,* whereas nosocomial (hospital-acquired) pneumonia raises concerns for *Pseudomonas aeruginosa* and methicillin-resistant *S aureus* (MRSA). Of note, increasing numbers of community-acquired MRSA infections are being reported, particularly among elderly nursing home residents, resulting in severe cases of necrotizing pneumonia. Extremely virulent strains of *S aureus* expressing the Panton-Valentine leukocidin toxin, which induces necrotizing pneumonia, are also surfacing in young adults with the same condition.

Streptococcus pneumoniae

The most common cause of CAP is the gram-positive bacteria *S pneumoniae,* also referred to as pneumococcal pneumonia. *S pneumoniae* is one of the leading causes of illness and death worldwide for young children, older adults, and persons with chronic, debilitating pathology. The pathogenesis of pneumococcal pneumonia has been extensively studied and serves as a prototype for the management of other bacterial pneumonia.

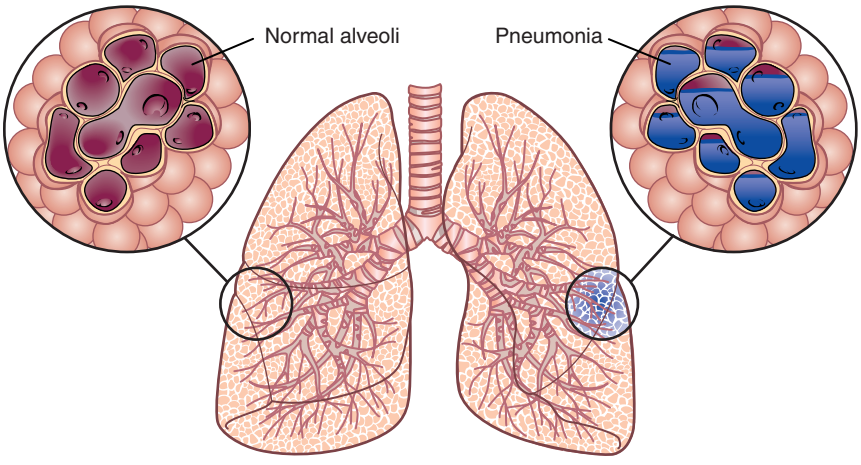


Figure 9.1 Parenchymal changes in pneumonia.

Pneumococcal pneumonia occurs as a result of infected mucus or inhalation of organisms that have colonized in the nasopharynx. *S pneumoniae* can be recovered from the nasopharynx of approximately 40% of healthy adults. In the normal host, the bacteria are inactivated by opsonization with immunoglobulins and complement. Persons with defects in host-defense mechanisms (e.g., inadequate immunoglobulin production or deficiency, impaired phagocytic function, autoimmune disease, immunosuppression, or impaired mucociliary clearance) have a far greater susceptibility.

The lower lobes are most commonly infected because of the effects of gravity. On inhalation, the pneumococcus establishes itself in the alveoli, spreading rapidly through the pores of Kohn. Pneumococcal pneumonia typically includes four responsive stages of infection: engorgement, red hepatization, gray hepatization, and resolution. During engorgement, alveolar capillaries become congested, bacteria and exudate pour into alveoli from alveolar capillaries, and the bacteria multiply without inhibition. There is continued engorgement of the capillaries, with diapedesis of erythrocytes giving the lungs the gross appearance of liver (red hepatization). As the leukocyte count increases in the exudate, it compresses the capillaries and causes the lung tissue to assume a gray color (gray hepatization). At this point, phagocytosis is achieved by polymorphonuclear leukocytes. The presence of opsonizing antibody enhances the ingestion of the bacteria. The stage of resolution is reached when the pneumococci have been destroyed and macrophages are seen within the alveolar spaces, where they lyse and absorb exudate. There often may be pleural involvement from contiguity to parenchymal lesions or by way of the lymphatics. As in the alveoli, there is an outpouring of fluid, followed by polymorphonuclear leukocytes and fibrin. The structure of the pleural space has fewer surfaces suitable for phagocytosis than do the alveoli. Control of the infection in the pleural area is more dependent on heat-stable (specific antibody) than heat-labile (complement opsins) antibodies.

Haemophilus influenzae

H influenzae, a gram-negative bacterium, is the cause of the second most common CAP. It may occur in healthy individuals, as well as in patients with chronic, debilitating diseases and chronic alcohol abuse. Development of *H influenzae* pneumonia follows colonization of the upper respiratory tract. During viral infection epidemics, there is often an increase in the incidence of *H influenzae* pneumonia.

Legionella pneumophila

L pneumophila, a gram-negative bacteria, was identified in 1976 as a causative agent of pneumonia (Legionnaires' disease) during an American Legion convention in Philadelphia. The bacteria thrive in aquatic environments. The source of human infection has been associated with contaminated air-conditioning systems and showerheads. Within the hospital setting, contaminated respiratory tubing and equipment may serve as a source of *L pneumophila.* The bacilli enter the lungs by aspiration, direct inhalation, and hematogenous dissemination. In the normal host, it is thought that the bacilli are cleared by the mucociliary process. This would explain the high incidence of the disease in patients with impaired mucociliary clearance (e.g., smokers, alcoholics, and older adults). Legionnaires' disease may occur in explosive outbreaks if large numbers of susceptible people are exposed to an infectious aerosol. Because of the low communicability of the disease, secondary cases should not occur.

Staphylococcus aureus

S aureus rarely causes pneumonia in healthy, young adults. Local pulmonary or systemic defense must be compromised before the organism can produce pneumonia. *S aureus* accounts for 2% to 9% of CAP in older adults or in patients with concomitant conditions, such as diabetes, chronic renal failure, bronchiectasis, or lung cancer, or with risk factors such as residence in a chronic-care facility or IV substance abuse. Infections may also occur in previously healthy adults following a viral influenza with residual impaired bronchopulmonary mechanism.

Viral Pneumonia

Viral infections account for 5% to 15% of cases of adult CAP. Most viral infections are restricted to the upper respiratory system and tend to cause self-limiting symptoms. Some patients, particularly those with influenza infections, may develop pneumonia. Influenza may result in a primary viral pneumonia or, more commonly, a secondary bacterial pneumonia. Secondary pneumonia is most frequently caused by *S pneumoniae* and *S aureus.* Viral infections are transmitted by hand-to-hand contact or by aerosols (sneezing, coughing). The frequency of influenza as a cause of both CAP and nosocomial pneumonia increases in the winter months.

Mycoplasma Pneumonia

Mycoplasma pneumonia is also known as primary atypical pneumonia or "walking pneumonia" because of the predominance of constitutional symptoms. *Mycoplasma pneumoniae* is a class of bacterial L-forms, which are the smallest known free-living organisms. Children older than age 5 years and young adults are at greatest risk for developing mycoplasmal pneumonia. Outbreaks can occur in populations living in close proximity, such as colleges, military bases, and prisons. Because of the long incubation phase of 2 to 3 weeks and the relatively low communicability, *Mycoplasma* pneumonia tends to move through the community slowly.

Chlamydia pneumoniae

C pneumoniae has only recently been recognized as a pulmonary pathogen. *C pneumoniae* is a gram-negative

bacterium. Little is known about the mode of transmission and pathogenesis. The clinical features are similar to those caused by *M pneumoniae.* Adult-onset asthma subsequent to infection with *Chlamydia* pneumonia has been documented. Recurrent infection is common.

Anaerobic Pneumonia

Anaerobic pneumonia may occur in both the community and the hospital setting. *Prevotella melaninogenica,* anaerobic streptococci, and *Fusobacterium nucleatum* are commonly isolated anaerobic bacteria. Aspiration of oropharyngeal secretions normally occurs during sleep in healthy individuals but rarely causes disease. Individuals who are predisposed to aspiration of larger amounts of oropharyngeal secretions are at risk for anaerobic pneumonia. Alcoholism is the most frequent predisposing factor; others include dysphagia, cerebrovascular accidents, seizures, and general anesthesia. Periodontal disease, which increases the number of anaerobic bacteria, is also associated with anaerobic infection. Pneumonia typically develops in dependent zones. Although body position at the time of aspiration determines which lung zones are dependent, anaerobic pneumonia most often develops in the posterior segments of the upper lobes and the superior and basilar segments of the lower lobes. The onset of symptoms is usually insidious. Empyema, lung abscess, or necrotizing pneumonia may be present by the time the patient seeks medical attention.

Nosocomial Bacterial Pneumonias

Nosocomial bacterial pneumonias are most frequently caused by gram-negative organisms such as *Pseudomonas aeruginosa, Klebsiella pneumoniae, Escherichia coli, Serratia, Proteus,* and *Enterobacter.* However, *S aureus* (especially MRSA), *S pneumoniae,* and *H influenzae* are frequently being reported among elderly nursing home residents. As in CAPs, bacteria invade the lower respiratory tract by aspiration of oropharyngeal organisms, inhalation of aerosols containing bacteria, or by hematogenous spread from a distant body site. Patients at high risk for developing nosocomial bacterial pneumonia include postoperative patients, particularly those undergoing thoracoabdominal procedures, patients with endotracheal incubation and/or mechanically assisted ventilation, depressed level of consciousness, an episode of large-volume aspiration, underlying chronic lung disease, and patients aged 70 and older. Nosocomial pneumonia has a mortality rate of about 30%. Hospital-acquired pneumonia in patients on mechanical ventilation has mortality rates of about 48%. Patients who develop acute respiratory distress syndrome have a mortality rate greater than 68%.

Pneumocystis jirovecii Pneumonia

P jirovecii pneumonia (PCP) is an AIDS-defining opportunistic infection that was once seen in as many as 65% of HIV-infected individuals and remains a major identifiable cause of death in AIDS patients. Disease in adults represents reactivation of latent infection, because almost all people are infected with the fungus *P jirovecii* (originally characterized as a protozoan and named *P carinii,* followed by *P jirovecii*), during the first decade of life. Most cases of PCP occur when the CD4-positive T-lymphocyte count has fallen below 200 to 250 cells/mcL. Pathologically, alveolar membranes become thickened, and mononuclear cell interstitial inflammation occurs as the disease progresses.

Cytomegalic Inclusion Virus Cytomegalic inclusion virus (cytomegalovirus [CMV]) is a causative agent of pneumonia in immunocompromised patients. CMV is a type of herpes virus that results in latent infections and reactivation with shedding of the infected viruses. Pathologically, CMV produces an interstitial pneumonia that ranges from a mild disease to a fulminant course resulting in pulmonary insufficiency and death.

Clinical Presentation

Although pneumonias may be classified as two different syndromes, typical and atypical, according to the clinical presentation, they are very similar. The characteristics of the clinical manifestations do have some diagnostic value.

Subjective

The "typical" pneumonia syndrome is that which is seen in pneumococcal pneumonia, as well as in pneumonia caused by *H influenzae* and *S aureus* (Table 9.8). The syndrome is characterized by a sudden onset of fever, cough, and chest pain. Generally, patients with a productive cough are more likely to have a bacterial infection. Patients with pneumococcal pneumonia produce sputum that has a characteristic rusty coloration; purulent sputum may also be evident. Fevers may run as high as 106°F (41.1°C), with peaks observed in the afternoon or evening. The chest pain tends to be pleuritic in nature and increases in intensity during coughing or

Table 9.8 Typical Pneumonia Syndrome Associated With Pneumococcal Pneumonia

Subjective Findings	Objective Findings
Sudden onset of fever (may be blunted in older adults)	Crackles
Productive cough	Dullness on percussion
Rust-colored or purulent sputum	Bronchophony, egophony, whispered pectoriloquy
Pleuritic-type pain	Pleural friction rub (severe consolidation)
Splinting	Decreased or absent breath sounds
Chills	Dense, homogenous shadows in one or more lobes on x-ray
Myalgia	

on inspiration. Patients often feel cold; about half experience teeth-chattering, shaking, and chills. Myalgia is a common complaint and may extend to tenderness in the calves and thighs. Severe myalgia, particularly when accompanied by vomiting, should strongly suggest the possibility of bacteremia. Respiratory and nonrespiratory symptoms are less commonly reported by older patients with pneumonia. The reduced prevalence of symptoms in older patients is most pronounced for the febrile response (chills and sweats) and for pain (myalgia, headache, and chest pain). Although the older adult may present with attenuated symptoms, this should not be misconstrued as an indication that such patients are less ill.

"Atypical" pneumonia is typically produced by *M pneumoniae* but can also be caused by *L pneumophila, C pneumoniae, P jirovecii,* and viruses. The atypical pneumonia syndrome is characterized by a more gradual onset, dry "hacking" cough, fever, and prominence of constitutional symptoms (e.g., pounding headaches, coryza, sore throat, shaking chills, and myalgia).

Pneumonias caused by anaerobic infections usually present with subacute or chronic constitutional and pulmonary symptoms. A chronic cough that produces purulent sputum is reported by the majority of patients. From 30% to 60% of patients report putrid sputum. This finding is considered to be virtually diagnostic of an aerobic infection and is associated with the development of tissue necrosis and cavitary lesions. Patients also present with chest pain that is dull or pleuritic in nature, hemoptysis, anemia, leukocytosis, and weight loss.

Patients with PCP present with fever, sweats, weight loss, nonproductive cough, decreasing exercise tolerance, and dyspnea on exertion. The median duration of symptoms is 1 month. Tachypnea is universal and is worsened by activity.

Objective

Physical examination of a person with typical pneumonia syndrome usually reveals an acutely ill patient who complains of chest pain and often splints on one side of the thorax. In some patients, crackles and dullness to percussion may be the only abnormality, particularly early in the disease. This finding may correlate with the period of outpouring of fluid into the alveoli. A second group of patients shows the classic signs of consolidation: egophony, bronchophony, whispered pectoriloquy, bronchial breath sounds, and dullness on percussion. In patients with severe consolidation, crackles may be absent or minimal; a leathery pleural friction rub may be heard over the area of chest tenderness. Finally, a third group of patients has one or more areas of dullness, inspiratory crackles, and diminished breath sounds, a sign of mucous plugs in the smaller bronchioles. Objective findings in atypical pneumonia tend to be less pronounced. Fine to medium crackles may be heard early or at the very end of the inspiratory cycle. Dullness on percussion and crackles or wheezing are more likely to be observed later in the disease. Frank consolidation, pleural friction rubs, and pleural effusions are less common than in a typical pneumonia.

Although there is no "typical" syndrome of nosocomial pneumonia, one or more of the following clinical findings are present in most patients: fever, leukocytosis, purulent sputum, and a new pulmonary infiltrate on chest x-ray film. These findings must occur more than 48 hours after admission to the hospital to be considered suggestive of nosocomial pneumonia.

Auscultation of the lungs is generally negative in patients with PCP, although fine crackles may occasionally be heard. Mucocutaneous lesions such as oral thrush, hairy leukoplakia, and Kaposi's sarcoma are common and suggest the presence of underlying HIV-related immunodeficiency in previously undiagnosed individuals. Physiologically, patients manifest arterial hypoxemia.

Diagnostic Reasoning

Diagnostic Tests

Initial Testing Although a specific etiological diagnosis is optimal in the management of CAP, limitations in diagnostic testing make this difficult. The responsible microbe is not identified in approximately 50% of patients, even when extensive diagnostic tests are performed. The three most helpful tests used in the initial establishment of a diagnosis of pneumonia include the chest radiograph, leukocyte count, and Gram stain of sputum specimens.

The chest x-ray study is important for three reasons. First, it may help distinguish whether the pneumonia is bacterial or viral in nature. Lobar infiltrates strongly suggest a bacterial infection. A bacterial pneumonia will show dense homogeneous shadows involving one or more lobes. Diffuse interstitial infiltrates are suggestive of a viral, *Mycoplasma,* or *Chlamydia* infection. Lateral and anterior-posterior views are necessary to evaluate lesions lying directly behind the heart.

A second reason for a chest x-ray study is to rule out a pleural effusion, a complication occurring in approximately one-third of pneumococcal pneumonia patients. It is important to note that chest x-ray films may be normal in patients who are unable to mount an inflammatory response or early in an infiltrative process. Follow-up chest x-ray films are needed to see if the infiltrate clears completely. Younger patients and those with only single-lobe involvement tend to have earlier resolutions.

Finally, cavities may be seen on chest x-ray films in patients with pneumonia caused by anaerobes, *S aureus, S pneumoniae* serotype III, *Mycobacterium tuberculosis,* aerobic gram-negative bacilli, and fungi. Cavities occur when necrotic material is discharged into airways, resulting in a necrotizing pneumonia (multiple small cavities, each less than 2 cm) or lung abscess (one or more cavities greater than 2 cm). Anaerobic abscesses are located in

dependent segments, are most frequently seen in the right lung, and have air–fluid levels. Typical and atypical tuberculosis produce unilateral, well-drained, upper-lobe fibrocavitary disease. Cavities are rarely produced by *H influenzae, M pneumoniae,* viruses, and other serotypes of *S pneumoniae.*

Although pulmonary infiltrates on x-ray films are considered suggestive of a nosocomial pneumonia, findings tend to be very nonspecific. Conditions such as an atelectasis, pleural effusion, pulmonary thromboembolism, and pulmonary edema may mimic nosocomial pneumonia on x-ray evaluation.

It may not always be practical or feasible to obtain a chest x-ray study, so good clinical judgment is essential. Factors that have been found to be predictive of pneumonia infiltrates on chest films include fever above 100°F (37.8°C), tachycardia, locally decreased breath sounds, and sputum production. Chest x-ray films may be normal when the patient is unable to mount an inflammatory response (e.g., in agranulocytosis), is in the early stages of an infiltrative process, or in PCP associated with AIDS.

To help identify the patients who need hospitalization, a complete blood count (CBC) with differential should be done. The count may aid in differentiating between bacterial and viral pneumonia. Although there is no clear distinction, total white blood cell counts of more than 15,000 suggest a bacterial infection. A differential cell count is not a reliable indicator of causation. Leukopenia may be seen in severe infections, as well as in alcoholics, older adults, and malnutrition. Blood cultures are indicated only for patients who require hospitalization or for cases of suspected nosocomial pneumonia.

A Gram stain of sputum remains the only diagnostic tool available to all practitioners at the onset of therapy. Caution needs to be exercised in the evaluation of a sputum specimen because expectorated material is frequently contaminated by pathogenic bacteria that colonize the upper and lower respiratory tracts without causing disease. Large numbers of epithelial cells (more than 25 per low-power field) reflect contamination of the specimen with oral contents and mandate that another specimen be collected. If the sputum has been properly collected, polymorphonuclear leukocytes can be readily seen with a Gram stain and the characteristic lancet-shaped, gram-positive diplococci associated with pneumococcal pneumonia are generally seen in abundance.

Gram stains are seldom useful in patients with atypical pneumonia because sputum is scant and most organisms that cause this syndrome cannot be detected by a Gram stain.

Acid-fast staining of sputum should be done when mycobacterial infection is suspected. (See Advanced Assessment 9.1.)

A sputum culture is less valuable than a Gram stain for providing a causal diagnosis in bacterial pneumonia. Approximately 50% of patients with pneumococcal pneumonia have negative sputum cultures, even when large numbers of organisms are present on Gram stain. Sputum cultures are also negative in 35% to 50% of cases of proven *H influenzae* pneumonia. Isolation of the causative agent in atypical pneumonia is rare.

Sputum cultures may be valuable in the diagnosis of subacute and cavitary pneumonia. Mycobacteria grow well on culture media, and it has been estimated that sputum cultures can detect as few as 10 acid-fast bacilli per milliliter of concentrated sputum. For a more in-depth discussion of the use of sputum cultures for the isolation of mycobacteria, refer to the section on tuberculosis.

The usefulness of fungal cultures varies with the organism and the stage of the disease. Chronic forms of coccidiomycosis and blastomycosis may yield positive cultures in 70% to 100% of cases if multiple specimens

Advanced Assessment 9.1 Sputum Stains

Sputum Stain	Organism
Gram stain	*S pneumoniae* (gram-positive, lancet-shaped diplococci) *H influenzae* (gram-positive coccobacilli) *S aureus* (gram-positive tetrads and grape-like clusters)
Acid-fast stain	Mycobacterial infection
Direct fluorescent antibody (DFA) stain	Viral respiratory culture
Fluorescent antibody: sensitivity diminished with concurrent use of inhaled pentamidine	*Legionella* infection
Wright-Giemsa stain: frequent false-positive and false-negative results	PCP
Gomori's methamine silver	Fungal growth
Periodic acid-Schiff stain	

are collected. Accurate positive cultures are not found in patients with histoplasmosis until the disease is in the chronic, cavitary stage. Fewer than 50% of patients with cryptococcosis have positive sputum cultures.

Expectorated sputum is usually collected in patients with a productive, vigorous cough, but may be scant in those with atypical pneumonia syndrome, in older adults, and in patients with altered mental status. If the patient is not producing sputum and can cooperate, respiratory secretions can be induced with ultrasonic nebulization of 3% saline solution. The use of more invasive procedures to induce sputum in the patient who is unable to produce a sputum specimen carries risks that must be weighed against the potential benefits. In patients who do not require hospitalization or in hospitalized patients who are not severely ill, the need to establish an accurate microbial diagnosis may not be crucial, and empiric therapy can be started on the basis of clinical and epidemiological evidence alone. Patients who are hospitalized with CAP and are seriously ill or those who acquire a nosocomial pneumonia clearly need to have a specific causal diagnosis established. In these patients, it may be necessary to obtain specimens from the lower respiratory tract by fiberoptic bronchoscopy, transtracheal puncture, or percutaneous transthoracic lung puncture. Of these invasive procedures, fiberoptic bronchoscopy is currently the preferred technique for obtaining lower respiratory secretions. Specimens obtained by bronchoscopy should be tested with Gram and acid-fast stains, *Legionella* direct fluorescent antibody, and Gomori's methenamine silver stains and should be cultured for aerobic and anaerobic bacteria, *Legionella,* mycobacteria, and fungi.

Diagnostic testing for CAP with *S pneumoniae* may include a pneumococcal urinary antigen test that can detect a protein common to all pneumococcal serotypes. Within 15 minutes, this test can demonstrate the presence of pneumococcus in unconcentrated urine. This can facilitate more immediate decisions about antibiotic therapy. However, the sensitivity of this test varies, and it is a complement to sputum and/or blood culture. Urinary antigen testing is also available for the gram-negative bacteria *L pneumophila* (but only for serogroup 1, which may not capture all forms of the disease), as well as the fungus *Histoplasma.*

Subsequent Testing If the pneumonia is severe enough to require hospitalization, at least two blood samples should be obtained for culture, as well as CBC and serological analysis of sodium, urea, nitrogen, creatinine, and glucose. Liver and enzyme tests should be included if hepatic disease or malnutrition is suspected. Serological studies are sometimes helpful in defining the etiology of certain types of pneumonia. An immunoglobulin M or immunoglobulin G titer obtained by indirect immunofluorescence may be diagnostic of *M pneumoniae* or *C pneumoniae.* A *Legionella* titer or a urinary antigen test may help confirm Legionnaires' disease.

Pulse oximetry is indicated if the patient presents with respiratory distress, dyspnea at rest, or tachypnea or if the chest x-ray film shows multilobar pulmonary infiltrates. A blood gas analysis should be performed if the patient has known carbon dioxide (CO_2) retention, exacerbations of asthma, or COPD. Typically, an Sa_{O_2} of less than 90% or a Pa_{O_2} of less than 60 mm Hg indicates a need for supplemental oxygen. These threshold values must be modified if the patient is chronically hypoxemic.

Differential Diagnosis

Acute bacterial pneumonia should be differentiated from acute bacterial bronchitis. Both of these respiratory infections will cause fever and a productive cough. On auscultation, however, a patient with bronchitis will have clear lung sounds except for a few scattered rhonchi and possibly tubular sounds. In comparison, the patient with bacterial pneumonia will likely have crackles, dullness to percussion, and abnormal breath sounds. Cavitary forms of pneumonia need to be differentiated from pulmonary tuberculosis and systemic mycoses, particularly coccidiomycosis and histoplasmosis. Likewise, the patient who presents with symptoms of PCP and a history of fever, weight loss, and pulmonary symptoms should be concurrently evaluated for tuberculosis, lymphomas, and brucellosis. Signs and symptoms secondary to central or endobronchial growth of a primary lung cancer will mimic those of a bacterial pneumonia (e.g., productive cough, fever, cough, dyspnea, hemoptysis). The practitioner needs to be aware of any occupational or environmental hazards to which the patient is exposed. For example, workers who develop berylliosis through exposure to beryllium (found in ceramics, high-technology electronics, and alloy manufacturing) may present with an acute pneumonia or, more commonly, with a chronic interstitial pneumonia. Exposure to moldy hay can result in symptoms of pneumonia (e.g., coughing, fever, chills, malaise, and dyspnea) within 4 to 8 hours after exposure. This disease (known as "farmer's lung") may become chronic.

Severe acute respiratory syndrome (SARS) should also be ruled out. Patients should be questioned about travel to an area with known transmission of SARS, as well as close contact with a person who has SARS. The causative agent is a coronavirus. Symptoms include a fever greater than 100.5°F (38°C), cough, or respiratory distress. The diagnosis is via enzyme-linked immunosorbent assay or reverse transcriptase–polymerase chain reaction assays. Treatment is supportive care. The identification is critical from a public health standpoint rather than from the need of initiating SARS-specific care, which remains supportive.

Management

The initial task in the management of patients with CAP is to determine whether the person can be treated on an outpatient basis or whether hospitalization is required.

The use of hospital services is costly and may further impair the patient's health because of the risk of nosocomial infections. The majority of patients with CAP with no comorbidity can be treated successfully as outpatients. Most patients, even those treated initially in a hospital, prefer outpatient treatment.

The decision to hospitalize a patient with CAP may be the single most important decision during the entire course of the illness (Level I; Burman & Wright, 2007). Scoring systems are helpful in determining the site-of-care decision. The Pneumonia Outcomes Research Team's Pneumonia Severity Index (PSI) is a risk-assessment tool used to determine the need for hospitalization of patients with pneumonia. The PSI uses calculations to categorize patients into five severity classes based on age, comorbidities, physical examination, and laboratory findings. Outpatient care can usually be recommended for patients in classes I, II, or III. However, patients suffering from substance abuse or severe psychosocial problems or those lacking social support may require hospitalization despite their PSI classification. The PSI calculator may be found at http://pda.ahrq.gov/clinic/psi/psicalc.asp, and the Community-Acquired Pneumonia Prognostic calculator may be found at www.ursa.kcom.edu/CAPcalc/default.htm.

The CURB-65 criteria to determine the severity of CAP is an objective, easy tool to remember. This severity-of-illness scale (shown in Table 9.9) will help determine where treatment will take place. In addition, known risk factors for CAP-associated mortality and complications are summarized in Risk Factors 9.3.

Antimicrobial therapy represents the mainstay of treatment for patients with suspected or confirmed pneumonia. Additional management is supportive in nature and includes the use of analgesics for relief of chest pain and myalgia, antipyretics to control fever, increased fluid intake (typically at least 3 liters over 24 hours), restricted activity or bedrest, a position of comfort (usually upright) to facilitate breathing, and humidified air to relieve irritated nares and pharynx. Expectorants may be indicated to decrease sputum viscosity and clear airways if a productive cough is present. Although many promote the use of expectorants, it bears repeating that the best and most cost-effective way to liquify secretions for ease of coughing and eliminating the secretions is hydration with water. Patients experiencing a dry, nonproductive cough may benefit from a cough suppressant with codeine.

Patients requiring hospitalization need to have ongoing assessment for any indications of impaired respiratory status. Patients who manifest arterial hypoxemia will require supplemental oxygen therapy to attempt to maintain Po_2 above 80 mm Hg. In the past, chest

Table 9.9 CURB-65 Criteria for Community-Acquired Pneumonia (CAP)

Clinical Factor	Points
Confusion (new disorientation)	1
B**U**N >19 mg per dL	1
Respiratory rate (≥30 breaths/min)	1
BP (systolic <90 mm Hg or diastolic ≤60 mm Hg)	1
Age ≥65 years	1

Scoring:
- 0–1: Low risk—consider home treatment
- 2: Short, in-patient hospitalization or closely monitored outpatient treatment
- ≥3: Severe pneumonia, hospitalize and consider ICU

Adapted from Ebell, MH. Outpatient vs. inpatient treatment of community-acquired pneumonia. *Am Fam Physician* 73:1425–1428, 2006. Retrieved July 1, 2013, from www.aafp.org/afp/2006/0400/p41.html

Risk Factors 9.3 Risk Factors for Mortality or Complications From Community-Acquired Pneumonia

Age: Older than 65 years
Presence of coexisting illness:

- Chronic pulmonary disease
- Diabetes mellitus
- Chronic renal failure
- Congestive heart failure
- Chronic liver disease of any etiology
- Previous hospitalization within 1 year of the onset of pneumonia
- Suspicion of aspiration
- Altered mental status
- Postsplenectomy state
- Chronic alcohol abuse or malnutrition

Abnormal physical findings:

- Respiratory rate above 30 breaths/min
- Diastolic BP 60 mm Hg or below and/or systolic BP 90 mm Hg or below
- Temperature above 101ºF
- Evidence of extrapulmonary sites of disease (e.g., septic arthritis, meningitis)
- Decreased level of consciousness or confusion

Abnormal laboratory findings:

- WBC count <4 × 106/L or >30 × 106/L
- Pao2 <60 mm Hg or Paco2 >50 mm Hg on room air
- Hemoglobin <9 g/dL
- X-ray showing more than one lobe involvement, pleural effusion, evidence of rapid spreading
- Severe electrolyte or renal abnormality not known to be chronic (e.g., BUN >50 mg/dL, creatinine >1.2 mg/dL, sodium <130 mEq/L)

physiotherapy had been widely used to mobilize secretions. However, percussion and postural drainage probably offer no added benefit to the patient who has an uncomplicated pneumonia without underlying pulmonary disease.

Community-Acquired Pneumonia

The Infectious Diseases Society of America has recommended specific therapy for CAP. The clinician must note whether the patient had recent antibiotic therapy or not and determine what coexisting diseases are present, such as COPD or congestive heart failure. Treatment Standards/Guidelines 9.1 summarizes the empiric treatment of the patient with CAP (Level I; Mandell et al, 2007). In addition, treatment guidelines from 2011 are cited. In the past, macrolides were used for monotherapy, but these are now avoided because approximately 25% of *S pneumoniae* strains are naturally resistant to all macrolides. Preferred monotherapy for CAP includes doxycycline or a respiratory quinolone. These are the most cost-effective way to optimally treat CAP. No increased resistance is noted with extensive use. These are well tolerated in oral and IV forms and are ideal for IV-to-oral switch monotherapy in terms of patient compliance, safety, and cost. Highly penicillin-resistant *S pneumoniae* strains are a rare cause of CAP because most *S pneumoniae* strains remain susceptible to ceftriaxone. Avoid using proton-pump inhibitors (PPIs) for gastric protection when using respiratory quinolones for CAP drug therapy because they may alter drug levels. Either stop the PPI or use a histamine-$_2$ receptor (H_2) blocker for the duration of therapy. However, there is conflicting evidence as to the relative safety of using PPIs and H_2 blockers.

Treatment regimens for community-acquired MRSA pneumonia should typically start with vancomycin, until sensitivities are back, which may indicate susceptibility to Bactrim. Most recently, guidelines have established

Treatment Standards/Guidelines 9.1 Empiric Antimicrobial Choices for Community-Acquired Pneumonia (CAP)

Patient Profile	Antimicrobial Agent
Uncomplicated CAP	
Without recent antibiotic therapy (ATBX)*	macrolide azithromycin (Zithromax) clarithromycin (Biaxin) erythromycin OR doxycycline (Vibramycin)
With recent ATBX†	Respiratory fluoroquinolone moxifloxacin (Avelox) levofloxacin (Levaquin) OR azithromycin or clarithromycin PLUS High-dose amoxicillin (Amoxil) OR azithromycin or clarithromycin PLUS High-dose amoxicillin–clavulanate (Augmentin)
Patient with CAP plus influenza	A respiratory fluoroquinolone OR A beta-lactam IV ceftriaxone (Rocephin) IV cefotaxime (Claforan)
Patient with community-acquired methicillin-resistant *S aureus* (MRSA) pneumonia	vancomycin (Vancocin) OR Linezolid (Zyvox)

*ATBX antibiotic therapy within the last 3 months.

†Use a different class of antibiotic not chosen previously.

Sources: Adapted from Mandell, L, et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. *Clin Infect Dis* 44(Suppl 2):S27–72, 2007; and Struble, K. Community-acquired pneumonia empiric therapy. Medscape, 2011. Retrieved July 1, 2013, from http://emedicine.medscape.com/article/2011819-overview

linezolid (Zyvox) as an effective alternative therapy for susceptible vancomycin-resistant infections and CAP.

NOSOCOMIAL PNEUMONIA

Antimicrobial therapy is the mainstay of therapy for nosocomial pneumonia, as well as for anaerobic/cavitary pneumonia and PCP, but recommendations are less specific. Treatment for nosocomial pneumonia, like treatment of CAP, is usually empiric. Because of the high mortality rate associated with nosocomial pneumonia, treatment must be started as soon as pneumonia is suspected. Empiric therapy for nosocomial pneumonia in patients who are not in an intensive care unit (ICU) may consist of a beta-lactam antimicrobial agent against *Pseudomonas aeruginosa* such as ceftazidime (Fortaz), piperacillin-tazobactam (Zosyn), ticarcillin-clavulanate (Timentin), or imipenem-cilastin (Primaxin). *Staphylococcus aureus* has become increasingly methicillin resistant. Such strains are resistant to all beta-lactam antibiotics and can be resistant to erythromycin, clindamycin, and the fluoroquinolones. Vancomycin should be prescribed when methicillin-resistant organisms are the possible cause of pneumonia.

Empiric therapy for patients with ICU-associated or ventilator-associated pneumonia should be a combination of antibiotics directed against the most virulent organisms, such as *P aeruginosa, Acinetobacter,* and *Enterobacter.* The most common regimen is a broad-spectrum beta-lactam (an antipseudomonal penicillin, a third generation antipseudomonal cephalosporin, or imipenem/cilastin) plus an aminoglycoside. If the causative pathogen is isolated, it may be possible to switch to a regimen with a narrower spectrum.

The therapy for anaerobic/cavitary pneumonia depends on the pace of the illness and the degree of clinical toxicity. Clindamycin (Cleocin) is effective for most patients with anaerobic pulmonary infections and is the drug of choice. Antituberculosis therapy should also be initiated if the clinical suspicion is high. Treatment of other causes of chronic cavitary pneumonia may be postponed until a diagnosis is established.

Nursing home residents should get a respiratory fluoroquinolone alone or Augmentin plus a macrolide. MRSA CAP has been seen in nursing home patients, as well as particularly sick young adults. In these patients, vancomycin is the IV treatment of choice, with Linezolid as the alternative for MRSA treatment. Sensitivities may reveal additional susceptibilities, though, allowing for narrowing of therapy.

Refer to Chapter 17 for the therapy of *Pneumocystis jiroveci* pneumonia (PCP).

Subsequent Management The advent of antimicrobial therapy has greatly decreased complications that were commonly seen before the use of antibiotics. Pneumonia that is associated with bacteremia, leukopenia, or multiple lobe involvement increases the likelihood of complications and of death. The mortality rate for patients older than age 65 years with bacteremia and involvement of more than three lobes is approximately 60%. Complications that do occur are more frequently found in patients with underlying chronic diseases.

The radiographic resolution of CAP is complete in half of patients after 2 weeks and in two-thirds of patients after 4 weeks. Follow-up x-ray studies should be done within 3 to 6 months for all patients who smoke or who are older than age 40 years. If an abnormality has not cleared on follow-up films, the patient should be evaluated for a possible cancer.

Pleural effusion represents the most common complication seen in patients with pneumonia. Fluid can be detected radiographically in the pleural space of more than 40% of patients hospitalized with pneumonia. In most cases, the amount is so small that needle aspiration is unsuccessful. If fluid is removed it typically is not purulent, nor can microbes be seen on a Gram stain.

Fluid that is purulent and has a gram-positive stain or has a pH less than 7.1 is indicative of an empyema. *Streptococcus pneumoniae, Streptococcus pyogenes,* and anaerobic pneumonias are associated with most cases of empyema. It is critical that the infected material be removed from the pleural space by means of a thoracentesis, needle aspiration, or thoracotomy. If this treatment is delayed, the patient is likely to require a prolonged hospital stay. Lung abscesses develop infrequently in *S pneumoniae* but often occur as complications of pneumonias caused by gram-negative bacteria (e.g., *Klebsiella*), anaerobic bacteria, and *S aureus.* Drainage of the abscess is essential to prevent further necrosis of the lung tissue. Prolonged antimicrobial therapy is critical for the successful treatment of this complication.

Delayed resolution results from persistent infection and is seen on x-ray studies as residual consolidation. Delayed resolution occurs most often in the patient who is older, malnourished, or alcoholic or who has COPD. Progression of infiltrates in spite of antimicrobial therapy is a poor prognostic sign.

Metastatic infections that do occur tend to develop in the meninges, pericardium, heart valves, and skeletal system. Although these complications occur less frequently with antimicrobial therapy, persons with compromised health status remain at risk for the development of these infections. Possible metastatic infections include arthritis, pericarditis, endocarditis, and meningitis. Patients who develop arthritis will experience swollen, red, and painful joints. Purulent exudate may be aspirated from the joints. Meningitis caused by *S pneumoniae* produces purulent cerebrospinal fluid. Patients with pneumococcal pneumonia who become disoriented, confused, or somnolent should have a lumbar puncture.

Criteria for hospital discharge include the resolution of fever, an ability to take medications orally, no need for supplemental oxygen, no progression of an infiltrate seen on chest x-ray films, a decrease in the leukocyte count, and the presence of social and family support.

Follow-up and Referral

Patients considered well enough for outpatient treatment do not need to be closely monitored unless symptoms worsen in spite of antibiotics. The patient should be contacted within 24 to 48 hours of starting therapy and should be scheduled for an office visit at 1 week and 4 to 6 weeks after the initial evaluation.

X-ray resolution of CAP is complete in 50% of patients after 2 weeks and in two-thirds of patients after 4 weeks. Examination at the second follow-up should include a chest x-ray film if clinical symptoms have not resolved. X-ray evaluations should be done for all patients who smoke. If an abnormality has not cleared on follow-up films, the patient should be evaluated for a possible cancer.

Smoking cessation is essential if respiratory health is to be maintained. Patients may be most receptive to antismoking counseling while they are still ill or recovering from pneumonia. The follow-up examination provides an opportune time for patient education. Pneumococcal and influenza vaccines should also be given at this time if indicated.

Patient Education

Influenza vaccine is strongly recommended for those older than age 65 years and persons of any age who are at risk for adverse complication from influenza. A vaccine against the 23 most common serotypes of *S pneumoniae* has been available since the early 1980s. The Advisory Committee on Immunization Practices recommends that it be administered to persons older than age 2 years who have any of several underlying conditions (e.g., COPD, splenectomy, organ transplants) and to all persons aged 65 or older. *Healthy People 2020* objectives target the vaccination of 90% of persons over 65 years old at risk for pneumococcal pneumonia by 2020. Currently, the percentage of adults over 65 years old who receive this vaccination has been estimated at approximately 60%. Despite the availability of the vaccine, it is underutilized. The increasing prevalence of multiantibiotic resistance of pneumococci makes immunization of high-risk individuals of utmost importance. For the very elderly patients and those who are institutionalized, revaccination every 5 years is indicated. Vaccine use tends to increase when efforts are made to raise awareness and promote the benefits of vaccination. The practitioner may obtain current and relevant data on pneumococcal vaccines, incidence rates of CAP and hospital-acquired pneumonia, drug therapy, and other pertinent information by contacting the CDC, the National Institute on Aging, and the National Foundation for Infectious Diseases.

TUBERCULOSIS

Tuberculosis (TB) is one of the oldest human diseases. It is an infectious disease, most frequently caused by *Mycobacterium tuberculosis* in humans. In early writings, TB was called "consumption" because of its tendency to produce great wasting in its victims. During the 18th and 19th centuries, it was known as the "white plague." TB is the leading cause of death worldwide from any single infectious agent. The pandemic of HIV infection and the emergence of drug-resistant TB have worsened the global problem of TB.

Epidemiology and Causes

TB had once been considered to be under such good control that a possibility of eradication of the disease in the developing countries was considered to be an obtainable goal. However, it is estimated that 15 million persons in the United States alone are infected with *M tuberculosis.* Worldwide, the majority of infected persons are living in developing countries; about 75% of these infected people are younger than age 50 years. Each year, 3 million people worldwide die from the disease. TB is the most common HIV-associated opportunistic infection in many developing countries. Currently the highest estimated case rates occur in Africa.

According to the CDC, in the United States the number of reported TB cases in 2011 was the lowest recorded since national reporting began in 1953. In addition, since the 1992 TB resurgence peak in the United States, the number of TB cases reported annually has decreased. TB disproportionately affects patients belonging to racial and ethnic minorities. The prevalence is three times higher in urban than in rural populations. Case rates are approximately 10 times higher in African American populations and about five times higher among Native Americans and Hispanics. TB among foreign-born residents of the United States accounts for approximately 60% of the national total. A factor in the increase of TB among foreign-born persons is the changing trends in countries of origin. Immigration has been increasing from Asia and Latin America, where TB rates are 5 to 20 times higher than those in the United States. Currently, the foreign-born population is concentrated largely in California, New York, Florida, Texas, and New Jersey.

Overall, approximately 10% of persons infected with *M tuberculosis* will develop clinical TB sometime during their lifetimes. About 5% of infected persons will manifest the disease within 1 year of infection. The remaining persons who develop the disease will have a delayed onset of TB, typically at a point of declined protective immunity, such as occurs in silicosis, diabetes mellitus, and diseases associated with immunosuppression, for example, HIV infection and immunosuppressive drugs. Susceptibility to TB is also greater during the first 2 years of life, at puberty, and during adolescence.

Geographically, the largest increases in reported TB cases have been in areas such as New York and Florida, which, in addition to having large foreign-born populations, also have a large number of AIDS cases. Outbreaks

of drug-resistant TB (resistant to at least one anti-TB drug) and multidrug-resistant TB (resistant to isoniazid and rifampin) have occurred in hospitals, prisons, shelters for the homeless, nursing homes, and AIDS residential facilities.

The genus *Mycobacterium* includes the causative agents of TB and leprosy. Mycobacteria are aerobic, asporogenous, nonmotile, acid-fast rods. Of the 58 species of the genus *Mycobacterium,* the members of the TB complex (*M tuberculosis, M bovis, M africanum,* and *M microti*) are closely related, based on DNA homology studies. The TB complex does not occur in nature and depends on host transmission for its survival. *M tuberculosis* is the major cause of human disease. Disease due to *M bovis* is rare in the United States. *M africanum* is a common cause of TB in Africa, and *M microti* is a pathogen for rodents.

Pathophysiology

Mycobacteria tuberculosis (TB) strains vary in virulence due to differences in the bacteria's genetic makeup. Similarly, persons display varying susceptibility to TB infection due to genetically conferred resistance, age, and comorbid conditions (e.g., chronic illness, immunosuppression). *M tuberculosis* is most commonly transmitted from person to person by droplet nuclei that are aerosolized by coughing, sneezing, or speaking. Transmission from an infected individual to another is influenced by the intimacy and duration of contact, the degree of infectivity of the patient, and the shared contact environment. Patients with acid-fast staining organisms in their sputum are most infectious to others.

After *M tuberculosis* organisms are inhaled, some are expelled by the ciliated epithelium, and only a small fraction reaches the alveoli, leading to primary infection. There, alveolar macrophages attempt to phagocytose and contain the bacteria; however, virulent strains can multiply rapidly and overcome these macrophages, countering their oxidative bactericidal mechanisms. Nonetheless, activated macrophages react by releasing inflammatory mediators such as interleukin-12 and tumor necrosis factor–alpha, which contribute to fever, anorexia, and weight loss. Macrophages also stimulate the recruitment of T lymphocytes to the area of infection. Helper T (CD4+) and cytotoxic killer T (CD8+) lymphocytes are also integral in the effort to kill bacteria, as activated macrophages and T lymphocytes form granulomas, or tubercles, in an effort to confine bacterial growth by walling off the mycobacteria.

Within these tubercles, multiplication of the organisms is inhibited by low oxygen content and low pH. T lymphocytes release inflammatory mediators that neutralize the bacteria contained in the tubercle's central necrotic area known as the caseum because of its cheese-like appearance on gross inspection. In a minority of cases, highly virulent strains of *M tuberculosis* may cause rapid infection, invading lung parenchyma, bronchioles, and blood vessels. Hemoptysis, a frequent clinical sign of active infection, may reflect the erosion of a granuloma into a pulmonary blood vessel. Old granulomas eventually calcify, identifiable as one or more Ghon complexes on chest x-ray film. Known as latent TB infection (LTBI), viable bacteria may remain dormant in these lesions for decades, only to be reactivated when the fine balance between host immunity and bacterial pathogenesis is tipped in favor of the mycobacteria. This results in secondary infection known as reactivation TB, seen typically in chronically ill or otherwise immunosuppressed individuals.

Mycobacteria can also spread via lymphatics or hematogenously, resulting in disseminated infection. Extrapulmonary sites of tuberculous infection include the lymph nodes, pleura, bones, meninges, peritoneum, pericardium, and genitourinary tract. Solid organs may be seeded at multiple tiny foci, taking on a millet-seed–like appearance on gross inspection termed *miliary tuberculosis.* Such pathological findings have been noted as far back as the 1700s. Today, the term *miliary TB* has been extended to encompass all forms of progressive, disseminated TB infection but is still seen most often in children younger than 1 year of age.

When testing for TB, persons with previous exposure or infection develop a positive cell-mediated (type IV) delayed-type hypersensitivity skin reaction as a result of previously sensitized helper T lymphocytes (CD4+) that are attracted to the testing site when a small amount of mycobacterial antigen (purified protein derivative [PPD]) is injected intradermally (also known as a tuberculin skin test [TST]). Reactions of this type typically require 48 to 72 hours to develop and are classified based on the degree of skin induration (rather than erythema) at the site of injection in relation to specific population norms.

In addition to the PPD skin test, two interferon-gamma release assays (IGRAs) may be used. The QuantiFERON®-TB Gold In-Tube test (QFT-GIT) and the T-SPOT® (T-Spot) are whole-blood tests that can aid in the diagnosis of TB but do not help differentiate LTBI from tuberculosis disease.

M tuberculosis organisms are aerobic and therefore particularly attracted to the apical segments of the upper lung lobes where high oxygen concentration favors their proliferation. Although the upper lung zone is the most common site of accelerated growth of the bacilli, there may be a later progression at distant sites in the body. The kidneys, brain, and bones are the most common sites of distant progression.

Individuals may continue to discharge mycobacteria into the environment from pulmonary tubercles until multiple-drug therapy is instituted to drive bacteria into a dormant state or eradicate infection completely. Although mycobacteria are almost always found in the bone marrow, liver, and spleen when disease occurs, uncontrolled multiplication of the bacilli in these organs is

rare. Immunosuppressed individuals, particularly those with T-lymphocyte deficiencies and compromised cell-mediated immunity (e.g., persons living with HIV), are highly susceptible to TB.

Clinical Presentation

Subjective

TB may mimic or occur concurrently with pneumoconiosis, pneumonia, bronchiectasis, sarcoidosis, lung abscess, neoplasm, or fungal infections. It is common for the onset to be insidious, with symptoms of anorexia, fatigue, digestive disturbances, a slow weight loss, irregular menses, and a lack of stamina. Persons may complain of being unable to complete a day's work. This pattern of onset will continue for several weeks or even months, when a low-grade elevation of temperature appears characteristically in the afternoon.

Pulmonary TB is characterized principally by a productive cough, purulent sputum, and repeated occurrences of coryza-like symptoms with rhinorrhea and nasal congestion. The cough progresses slowly over weeks or months to become more frequent and associated with the production of mucoid or mucopurulent sputum. The cough is usually due to sloughing of small caseous lesions within the presence of exudate in the bronchi. Sputum is characteristically yellow but is not tenacious or foul smelling. Hemoptysis is a common symptom in patients with necrotizing or cavitary lesions. Blood usually appears as small streaks in the sputum. Dyspnea is uncommon in pulmonary TB and usually indicates extensive parenchymal involvement, massive pleural effusion, or other underlying cardiopulmonary disease.

A less frequently seen pattern of onset may be that of an acute febrile illness with an abrupt onset of high fever, chills, tachycardia, and weakness. A productive cough is seen, along with myalgia and sweating. Erythema nodosum may occur with the acute onset of symptoms. These patients may have paid no attention to milder symptoms that have preceded the acute episode. This is a common finding in the uneducated, in alcoholics, or in older adults.

Less frequent modes of onset include pleuritic pain and hoarseness. Pleuritic pain, usually unilateral, tends to be accentuated by coughing or deep inspiration. Hoarseness is usually a result of involvement of the larynx and may be accompanied by severe pain. Constitutional symptoms tend to be general in nature and consist of night sweats, fatigue on exertion, weight loss, and malaise.

In obtaining the health history, the clinician must keep in mind the chronicity of TB and the insidious nature of the onset of symptoms. Patients should be questioned about exposure to anyone with an open case of TB. Potential sources of exposure include the family and coworkers. Other significant disclosures obtained from a health history include a past diagnosis of pneumonia with recurrence, pleurisy, uncontrolled diabetes, alcoholism, malnutrition, and occupational exposures to quartz dust or silica. Other risk factors that should be taken into account are drug abuse, country of origin, corticosteroid use, and gastrectomy.

Objective

A complete examination of any patient suspected of having TB should always be performed. Although pulmonary TB is the most common form of TB, the clinician needs to be cognizant of any indications of extrapulmonary TB. Examination of the chest will usually provide the primary indications of pulmonary TB. Rhonchi, crackles, wheezing, and bronchial breath sounds may be heard on auscultation but may have no radiographic counterparts. Dullness on percussion is commonly associated with pneumonic lesions. Persons with long-standing disease may manifest asymmetrical lung expansion, displacement of the trachea, and muscular atrophy. Although there are no specific changes related to pulmonary function, in patients with extensive parenchymal involvement, the vital capacity and other lung volumes may become decreased.

The patient should be examined for any evidence of present or past extrapulmonary TB in such structures as the genitourinary tract, lymph nodes, bones and joints, peritoneum, larynx, eye, abdominal organs, and neurological system (Table 9.10). Physical findings may include hepatomegaly, splenomegaly, and generalized lymphadenopathy. Abnormal behavior, headaches, and seizures may herald TB meningitis. Meningitis occurs frequently in infants and small children as a complication of early infection, but it may be seen in any age-group. Bone and joint involvement, most often seen in older adults, may result in arthritis, osteomyelitis, fever, and localized pain. The lower spine and weight-bearing joints are most often affected by skeletal TB. Genitourinary TB may present as recurrent urinary tract infections with no growth of common pathogens, pyuria without bacteriuria, pelvic inflammatory disease, amenorrhea, infertility, and perianal fistulas.

Diagnostic Reasoning

Diagnostic Tests

Initial Testing The tuberculin skin test (TST) remains the standard test for determining infection with *M tuberculosis* but does not distinguish between active and latent infection. The TST tends to have a strong positive predictive value, but poorer negative predictive value. Skin testing on a patient suspected of being infected may easily be done in an office or clinic setting. It is useful as an epidemiological tool to identify infected and especially recently infected people for preventive therapy and contact tracing. The American Thoracic Society (ATS) has developed criteria for tuberculin testing.

Table 9.10 Clinical Indicators of Extrapulmonary Tuberculosis

Extrapulmonary Sites	Clinical Manifestations
Genitourinary tract	Recurrent urinary tract infections with no growth of common pathogens Pyuria without bacteriuria Unexplained hematuria Irregular menses, amenorrhea, pelvic inflammatory disease, infertility Epididymitis Induration of the prostate
Bone and joints (lower spine and weight-bearing joints most common site)	Arthritis, osteomyelitis Fever and localized pain
Meninges	Headaches, convulsions Abnormal behavior
Peritoneum	Ascites, fever
Pericardium	Pericarditis
Lymph nodes	Hilar or mediastinal lymphadenitis Cervical and supraclavicular lymphadenopathy

Screening Recommendations/Guidelines 9.1
Guidelines for Tuberculin Screening

- A person with signs and/or symptoms of current TB
- Close contact with known TB cases
- Persons with HIV infection
- Persons who inject illicit drugs
- A person from a medically underserved or high-risk minority population
- A resident or employee in a prison or long-term care facility
- An employee in a health-care facility
- Infants, children, and adolescents exposed to adults in high-risk categories (use of IGRAs for children less than 5 years of age is not established)
- Foreign-born persons arriving within 5 years from countries that have high TB incidence or prevalence (use IGRAs for persons with recent BCG vaccination)
- Persons on long-term high dose corticosteroid therapy (use TST rather than IGRA)
- Persons on immunosuppressive therapy (use TST rather than IGRA)
- Persons with medical conditions that increase the risk of TB: chronic renal failure, diabetes, hematological disorders, cancer of the head or neck, body weight less than 10% of the ideal body weight, silicosis, gastrectomy, jejunal bypass

Adapted from Catanzaro, A. The diagnosis of TB in an era of diminishing incidence of TB. Retrieved July 1, 2013, from www.thoracic.org/sections/chapters/thoracic-society-chapters/ca/current-news/resources/2DXTB.pdf and cdc.gov/tb/publications/factsheets/testing/IGRA.htm

Table 9.11 Factors Contributing to a Decreased Response to Tuberculin Skin Testing

Infections:
- Viral: measles, mumps, chickenpox, HIV infection
- Bacterial: typhoid fever, brucellosis, typhus, leprosy, pertussis, recent or overwhelming *M tuberculosis* infection
- Fungal: South American blastomycosis
- Live virus vaccinations: measles, mumps, polio

Nutritional factors: severe protein depletion
Diseases affecting lymphoid organs: Hodgkin's lymphoma, chronic lymphocytic leukemia
Drugs: corticosteroids and other immunosuppressive agents
Age: newborns, older adults
Stress: surgery, burns, mental illness, graft-versus-host reactions

Persons for whom tuberculin testing is routinely indicated are listed in the Screening Recommendations/Guidelines 9.1.

The most accurately and widely used method for skin testing is the Mantoux technique of injecting intermediate-strength PPD intradermally (TST). The reaction to intradermally injected tuberculin is the classic example of a delayed cellular hypersensitivity reaction. These reactions begin at 5 to 6 hours after injection and are maximal at 72 hours. In older adults or in persons who are being tested for the first time, the reaction may develop more slowly and may not peak until after 72 hours. Older adults should be checked initially at 72 hours, and then 1 and 2 days later. A number of factors related to a decreased ability to respond to the tuberculin are included in Table 9.11. These factors do not negate testing in these situations because only a fraction of infected persons with these conditions may have falsely nonreactive results. If the lack of reaction to the testing is suspected to be a false response, a repeat TST should be done. If generalized inability to respond is suspected, it may be necessary to test delayed hypersensitivity using several other antigens to which the person has had a likely exposure. Anergy should be suspected if the person fails to respond to any of the antigens. Many infectious disease specialists think that anergy testing is no longer useful, because patients may have selective anergy to TB but not to other antigens, so they are not helpful in ruling out TB.

As mentioned above, the IGRAs only require a single patient visit to conduct the test and the results can be available within 24 hours. The widely used bacille

Calmette-Guérin (BCG) vaccination does not cause a false-positive IGRA test result, given its greater specificity. Limited data are available on the use of IGRAs for children younger than 5 years of age and immunocompromised persons.

It is possible to obtain an inaccurate interpretation of the patient's tuberculin response when the administration of the skin test is done incorrectly. Factors that may contribute to an inaccurate reading of the test include improper handling of the tuberculin, improper administration technique, and inaccurate reading of tuberculin test (e.g., by an inexperienced reader). To minimize reduction in potency by adsorption, tuberculin should never be transferred from one container to another, and skin tests should be given soon after the syringe has been filled. Tuberculin should be kept refrigerated and stored in the dark as much as possible. The TST (0.1 mL) should be injected into the volar or the dorsal surface of the forearm, away from veins and into intact skin, free of lesions. The injection should be made just beneath the surface of the skin, with a one-quarter- to one-half-inch 27-gauge needle and a tuberculin syringe. A discrete, pale elevation of the skin (a wheal) 6 to 10 mm in diameter should be produced when the injection has been done correctly. If the first test was improperly administered, another test dose can be given immediately, but in a site several centimeters from the original injection.

Tests should be read 72 hours after injection, using good lighting with the forearm slightly flexed at the elbow. The basis of reading the test is the presence or absence of induration, which is determined by inspection and palpation. The diameter of the induration is measured transversely to the long axis of the forearm and recorded in millimeters. The size of the TST reaction has nothing to do with erythema, but is based solely on induration, because it is a type IV T-cell–mediated immune response. Because immunity from BCG wanes over time, if it has been many years since the vaccination, a TST may be performed and accurately read. To avoid any questions about the results, however, the IGRA test is preferred.

Persons with sensitivity to tuberculin are known as reactors. The definition of a tuberculin reaction size that is indicative of an infection with *M tuberculosis* is influenced by the dose, dilution, and nature of the tuberculin preparation being used, immunological factors, and the relative prevalence of tuberculin sensitivity resulting from infection with *M tuberculosis* and that resulting from other mycobacteria in the population being studied. Reactions caused by infections with mycobacteria other than *M tuberculosis* (cross reactions) are common in many parts of the world. Generally, a reaction to *M tuberculosis* will be a larger reaction than would be seen in a cross reaction. Guidelines for the classification of reactions to intradermal Mantoux tests have established three categories of positive reactions (5-, 10-, and 15-mm induration) based on the patient's immunosuppressive status, risk factors for exposure, and probability of cross reaction (see Table 9.12). A positive reaction in any patient represents only the presence of TB infection. In the United States, a positive TST without clinical TB infection (negative chest x-ray findings and no symptoms) should be treated to minimize the possibility of reactivation (secondary) TB. Standard regimens are INH for 9 months (least hepatotoxic regimen), rifampin for 4 months, or rifampin plus pyrazinamide for

Table 9.12 Interpretation of Tuberculin Skin Testing

Diameter of Induration	Positive Results
>5 mm	• Persons with HIV infection or persons with risk factors for HIV infection and unknown HIV status • Persons who were recently exposed to clinically active TB, persons with organ transplants • Persons with chest films indicating healed TB
>10 mm	• Recent arrivals (<5 years) • Foreign-born persons from high-risk countries in Africa, Asia, Latin America • Medically underserved low-income populations and high-risk racial or ethnic minority populations • IV drug abusers • Residents and employees of high-risk congregate settings: prisons and jails, nursing homes and other residential settings for elderly people and/or AIDS patients, homeless shelters • Mycobacteriology laboratory personnel • Persons with medical conditions known to increase the risk for TB: diabetes, renal failure, silicosis, immunosuppressive therapy, hematological disorders (e.g., leukemia, lymphoma), gastrectomy, 10% or more below ideal body weight
>15 mm	• All other persons

2 months (but this is the most hepatotoxic regimen). Liver function test (LFT) screening is needed while the patient is on therapy.

Subsequent Testing In patients in whom there is a clinical suspicion of TB, the first diagnostic step should be a combination of a standard anterior-posterior and lateral chest x-ray film and a sputum examination for mycobacteria. The initial radiographic manifestation of an initial infection in the adult or a child is usually parenchymal infiltration accompanied by ipsilateral lymph node enlargement. The parenchymal lesions may be seen in any portion of the lung, but are seen most commonly in the apical and posterior segments of the upper lobes or in the superior segments of the lower lobes. Lesions may be dense and homogeneous, with lobar, segmental, or subsegmental distribution. Patients with HIV disease tend to have atypical radiographic findings. These patients tend not to have cavitations, and infiltrates are less likely to occur in the upper lobes. Cavitations are also seen infrequently in older patients and in those who may be immunosuppressed. Hematogenous TB is characterized by diffuse, finely nodular, uniformly distributed lesions on the chest x-ray film. The term *miliary* is applied to this appearance, because the nodules are about the size of a millet seed (approximately 2 mm in diameter).

Chest x-ray films that show no change in findings over a 3- to 4-month interval can generally be interpreted as showing a past TB infection or another disease. The use of a single chest x-ray film as a guide to the nature or the stability of the underlying disease is questionable. The words "old" and "fibrotic" are not accurate terms to use when interpreting a single chest x-ray film. Any persistent infiltrate in an older person should be considered suggestive of TB. This form of TB is often missed in older adults, especially among patients residing in a nursing home.

In pulmonary TB, examination of sputum provides the most convenient method of identifying the presence of bacilli, in terms of low cost, widespread availability, ease of performance, and reliability. The patient must be instructed to produce material brought up from the chest by coughing. A series of at least three single specimens on different days should be collected from patients who have a productive cough. When a patient is unable to produce an adequate amount of sputum, it is possible to obtain by gastric lavage the bronchopulmonary secretions that the patient has unknowingly swallowed during the night. Gastric aspiration is done following a period of fasting for 8 to 10 hours; it should be performed before the patient arises. About 50 mL of gastric contents is required for this test, which is best performed in the hospitalized patient.

It is possible to induce sputum production by inhalation of hypertonic saline. These specimens will be thinner and more watery than sputum produced spontaneously. Sputum induced by this method may produce a violent and uncontrolled cough, so special methods of air control may be indicated. Occasionally, a pooled specimen, collected over a period of 10 to 24 hours, may be helpful if the methods previously described are not effective or appropriate. This type of specimen is more subject to contamination and is best collected in an institutional setting.

Bronchial washings obtained with fiberoptic bronchoscopy may be indicated in patients who are unable to produce sputum or in those who are thought to have TB despite negative culture reports. When extrapulmonary TB is suspected, it is necessary to collect less common clinical specimens from sources such as urine; peritoneal, pericardial, and pleural fluids; bones and joints; and lymph nodes.

The detection of acid-fast bacilli (AFB) in stained smears examined by direct microscopy provides the first evidence of the presence of mycobacteria in a clinical specimen. It is estimated that 50% to 80% of patients with pulmonary TB will have positive sputum smears. The sputum smear is the easiest and quickest procedure and provides the practitioner with a preliminary confirmation of the diagnosis. The smear also provides the practitioner with a quantitative estimate of the number of bacilli being excreted by the patient. These estimates should be described as rare, few, or numerous. The lowest concentration of organisms that can be detected by microscopic examination is 10 per milliliter of sputum. For direct microscopy of sputum, the most widely used method is the Ziehl-Neelsen staining method.

All clinical specimens suspected of containing mycobacteria must be inoculated onto culture media. Culture yield seems to be associated with the clinical presentation of the patient. One study reported that patients with cavitary disease tend to have a higher rate of positive cultures than do patients with focal infiltrates. The cultures should be incubated at 37°C and examined at weekly intervals. The time from the laboratory's receipt of the specimen to the report of the culture is usually 3 to 6 weeks. In rare situations, such as repeated contaminated specimens or patients with positive Gram stains and negative cultures, guinea pig inoculation may be necessary.

Susceptibility of tubercle bacilli to various anti-TB drugs may be determined via either the direct or the indirect test. The direct drug-susceptibility test is performed by using clinical specimens of AFB, which are inoculated directly onto a drug-containing culture medium. Growth is then compared with growth on a non–drug-containing medium. An indirect test is performed by using a subculture from the primary isolation as the inoculum. Although the direct test is preferred, because it is more representative of the bacterial population of the patient, the indirect test may be useful when the initial smear is negative but the culture is positive, when growth on the control medium is inadequate for a reliable test, or when a reference culture is submitted

by another laboratory. In the past, the previously untreated patient with newly diagnosed TB was started on chemotherapy without prior drug-susceptibility testing. Recommendations for drug-susceptibility testing have been modified because of the emergence of drug-resistant bacilli and are discussed in the section on clinical management.

Differential Diagnosis

Difficulties in a differential diagnosis arise when the tubercle bacilli cannot be isolated by smear or culture and in situations in which other diseases such as carcinoma or pulmonary mycosis exist. Pulmonary lesions of small extent, particularly the solitary nodule or coin nodule, need to be differentiated from early carcinoma of the lung, pulmonary infarction, localized pulmonary fibrosis, and pneumonia of fungal, viral, mycoplasmal, or bacterial origin with delayed clearing or resolution. In extensive forms of pulmonary TB, bronchopneumonia and lobar pneumonia must be considered. The acute cavitary forms of TB must be differentiated from lung abscess. Other chronic pulmonary diseases that frequently are characterized by cavity formations include the systemic mycoses, particularly coccidiomycosis and histoplasmosis.

Pulmonary TB of hematogenous origin must be differentiated from other types of infection that may manifest in similar fashion: silicosis, berylliosis, asbestosis, sarcoidosis, diffuse interstitial fibrosis, scleroderma, metastatic neoplasms, or alveolar cell carcinoma. From the perspective of clinical manifestations, the advanced practice registered nurse (APRN) must consider other conditions that may cause prolonged or obscure fevers, such as lymphoma, brucellosis, and HIV infection.

Management

The development of specific chemotherapeutic agents revolutionized the prognosis of TB and TB infection, making the disease truly curable and preventable. Drug treatment of TB should be viewed as both a personal health measure intended to cure the ill patient and as a public health measure intended to interrupt transmission of tubercle bacilli in the community.

Initial Management

In patients in whom the clinical and radiographic findings suggest a diagnosis of TB and the sputum examination reveals the presence of mycobacteria, a working diagnosis can be made and anti-TB chemotherapy can be started. For patients in whom TB is suspected but whose smear results are negative, an alternative is to begin therapy and wait for culture results. Initiating chemotherapy in the absence of a definitive diagnosis is a valid approach, but caution needs to be exercised in doing so in patients with HIV infection and multidrug resistance. X-ray findings in patients with AIDS are often atypical and may be indicative of a range of diagnostic possibilities. A presumptive diagnosis of TB in these patients may be more speculative.

The main goal of therapy is to eliminate all tubercle bacilli from the patient while avoiding the situation of clinically significant drug resistance. The treatment consists of administering multiple drugs that the organism is susceptible to, adding new drugs to the regimen when it is suspected that treatment is not working, providing the maximum therapy in the shortest amount of time, and insisting on patient compliance. While curing the individual patient, the transmission of *M tuberculosis* to other persons needs to be minimized.

The current minimal acceptable duration of treatment for all children and adults with culture-positive TB is 6 months. The initial phase of a 6-month regimen should consist of a 2-month course of isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB) or streptomycin in children who are too young to be monitored for visual acuity, until the results of drug-susceptibility studies are available, unless there is little possibility of drug resistance (e.g., less than 4% primary resistance to INH in the community and the patient has had no previous treatment with anti-TB medication, is not from a country with a high prevalence of drug-resistant TB, or has no known exposure to a drug-resistant case). The second phase of therapy should consist of INH and RIF for a total of 4 months (daily treatment or two to three times per week). Therapy should be prolonged if the response is slow or otherwise suboptimal.

An alternative regimen for persons who cannot take PZA (e.g., pregnant women) consists of a 9-month regimen of INH and RIF. Ethambutol should also be included until the results of the susceptibility studies are available unless there is little possibility of drug resistance. Drug resistance is most common in HIV patients and immigrants. If INH resistance is confirmed, rifampin plus PZA plus ethambutol should be continued for a minimum of 6 months. For rifampin resistance, INH plus ethambutol should be used for 18 months or INH, PZA, and streptomycin for 9 months. In HIV patients, rifabutin should always be used because rifampin interacts with protease inhibitors and nonnucleoside retroviral inhibitors.

Adverse reactions and prescribing considerations for the common TB drugs are shown in Drugs Commonly Prescribed 9.2.

Directly observed therapy (DOT) should be considered for all patients because of the difficulty in predicting which patients will adhere to a prescribed regimen. When TB is initially diagnosed, the practitioner should explain to the patient about the disease, the treatment, and the necessity of completing the recommended therapy. If DOT is considered to be indicated, the patient and the practitioner should agree on a method that ensures the greatest rate of adherence and maintains confidentiality. DOT may require an outreach worker to go

Drugs Commonly Prescribed 9.2 Tuberculosis

	Adverse Reactions and Prescribing Considerations
FIRST-LINE TB DRUGS	All must be taken on an empty stomach to facilitate absorption—if unable to comply, may take medicine with food that does not contain fat or oils (may ease nausea).
isoniazid (INH or H)	May cause peripheral neuropathy (pyridoxine may be given prophylactically). May be associated with increased risk of seizures in patients with epilepsy. May be hepatotoxic (potentiated by rifampin).
rifampin (RIF, RMP, or R)	May cause thrombocytopenia. Commonly causes rash without itching during the first few weeks; usually resolves on its own. May cause an elevation in bilirubin which usually resolves in 10 days; potentiates INH hepatotoxicity.
pyrazinamide (PZA or Z)	May cause rash. May be hepatotoxic. If the patient will not take due to tablet size, PZA syrup may be substituted.
ethambutol (EMB or E)	Periodic vision screens required, given ocular toxicity (optic neuritis).
streptomycin (SM, STM, or S)	Use with caution in patients with mild to severe kidney problems. Periodic hearing screens required, given aminoglycoside-related ototoxicity.
SECOND-LINE TB DRUGS	Choice of agent should be guided by resistance testing.
aminoglycosides (e.g., amikacin [AMK], kanamycin [KM])	Use with caution in patients with mild to severe kidney problems. Chronic use may cause ototoxicity (audiologic and vestibular dysfunction).
polypeptides (e.g., capreomycin, viomycin, enviomycin)	Capreomycin may cause nephrotoxicity.
fluoroquinolones (e.g., ciprofloxacin [CIP], levofloxacin, moxifloxacin [MXF])	Commonly causes nausea, vomiting, or other gastrointestinal symptoms. May also cause tendinitis/tendon rupture. Associated with QTc prolongation.
thioamides (e.g., ethionamide, prothionamide)	Gastrointestinal side effects may occur. Central nervous system and psychiatric effects.
cycloserine (only antibiotic in its class)	Gastrointestinal side effects may occur.
p-aminosalicylic acid (PAS or P)	Potential cause of drug-induced hepatitis.

into the community and administer each dose of medication to the patient. Many patients can, however, receive the treatment at a center agreed on by the practitioner and the patient. Common community settings include TB clinics, community health centers, migrant clinics, homeless shelters, jails or prisons, nursing homes, schools, drug treatment centers, hospitals, HIV/AIDS clinics, or occupational health clinics. In some situations, a responsible person other than a health-care worker may be able to administer the chemotherapy. Possible resources in the community include correctional facility personnel, social and welfare caseworkers, clergy, teachers, and reliable volunteers. Adequate medication adherence is critical to the complete clearance of all infectious organisms and to the prevention of drug-resistant strains of TB. See Box 9.1 for information about multidrug-resistant TB.

HIV infection and other factors that compromise a patient's immune system are important considerations when practitioners select the most effective regimen. These factors are particularly important with drug-resistant TB because of the potential for rapid disease progression and death when patients receive inadequate treatment. DOT and experienced TB/HIV caregivers are considered to be critical to the effective treatment of both conditions. Given the propensity for rifampin to upregulate and induce the hepatic cytochrome p450 metabolic pathway, the dosage of several antiretroviral

Box 9.1 Drug-Resistant Tuberculosis: MDR-TB and XDR-TB

MDR-TB

Multidrug-resistant TB: Tuberculosis resistant at least to isoniazid and rifampin

XDR-TB

Extensively drug-resistant TB: Tuberculosis resistant to both isoniazid and rifampin, as well as fluoroquinolones and at least one of the injectable second-line anti-TB agents (kanamycin, capreomycin, or amikacin)

Principles of Treatment

The principles of treatment for both MDR-TB and XDR-TB are the same, focused on antimicrobial sensitivity testing and the selection of active agents.

Given resistance to second-line agents, XDR-TB has a higher mortality rate due to a reduced number of effective treatment options.

Treatment lasts for a minimum of 18 months and may last for years.

medications must be increased when administered with rifampin. However, substituting rifabutin (Mycobutin) for rifampin (Rimactane, Rifadin) allows for the concurrent administration of anti-TB and antiretroviral drug regimens, with no dose adjustments in the latter. Currently, most guidelines indicate that HIV-infected patients should be treated for a total of 9 months and for at least 6 months following sputum conversion. In general, intermittent anti-TB therapy is not recommended for TB/HIV–co-infected patients. See the recommendations for the treatment of TB and antiretroviral dose adjustments among HIV-infected patients in Chapter 17.

Effective therapy for TB is essential for pregnant women. Untreated TB represents a greater hazard to a pregnant woman and her fetus than does treatment of the disease. Initial treatment should consist of INH and RIF. Ethambutol (Myambutol) should also be included unless primary INH resistance is unlikely. Streptomycin should not be prescribed for pregnant women because it may cause congenital deafness in the fetus. PZA is recommended by international TB organizations for use in pregnant women. In the United States, PZA is not currently recommended because it has not been determined if there is a risk of teratogenicity. Breastfeeding does not need to be discouraged because the small concentrations of anti-TB drugs in breast milk are not adequate to produce toxicity in the newborn. TB during pregnancy is not an indication for a therapeutic abortion.

Regimens that are adequate for treating adults with pulmonary TB should be effective in treating extrapulmonary disease. Bacteriological evaluation of extrapulmonary TB may be limited by the relative inaccessibility of the disease site. Response to treatment often must be judged on the basis of clinical and radiographic findings. Surgery may be necessary to obtain specimens for diagnosis and to treat such processes as constrictive pericarditis. Corticosteroid therapy has been shown to be of benefit in preventing cardiac constriction from TB pericarditis and in decreasing the neurological sequelae of TB meningitis.

Subsequent Management

Today, the majority of patients with TB may undergo treatment and remain in their own home settings. There may be specific patient situations that mandate the need for hospitalization of the patient with TB. Some of the indications include very ill patients who have no responsible person at home to provide care, patients with advanced pulmonary disease with highly positive sputum smears or severe extrapulmonary disease, or the presence of associated medical problems that require hospitalization.

Adults should have measurements of serum bilirubin, hepatic enzymes, blood urea nitrogen (BUN), and creatinine and a CBC, including platelet count, before starting chemotherapy for TB. Visual acuity and red-green color perception tests are recommended before initiation of ethambutol, and a serum uric acid level should be measured before starting PZA. Patients should be advised to report symptoms suggestive of drug toxicity. For INH-containing regimens, symptoms of concern are anorexia, nausea, vomiting, fatigue or weakness, dark urine, icterus, rash, paresthesias of the hands and feet, fever, and abdominal tenderness. Routine monitoring of laboratory tests for evidence is not recommended, but monthly questioning for symptoms of drug toxicity is indicated. Patients with known liver disease or heavy drinkers may need to have periodic LFTs. Appropriate laboratory tests are mandatory if symptoms of drug toxicity develop.

Periodic examination of the patient is necessary to observe for changes in symptoms, signs, body weight, and temperature. The single most important laboratory test is the bacteriological examination of bronchopulmonary secretions. A progressive fall in the number of AFB in weekly or biweekly specimens is a good indicator of effective chemotherapy. Periodic laboratory checks of blood, urine, visual acuity, eighth-nerve function, renal function, and hepatic function are desirable based on the severity of the illness and the drugs being administered. Patients should be questioned closely for any symptoms of drug toxicity, as well as the level of adherence.

It is not necessary to restrict physical activity and require bedrest for most patients. Bedrest may help make patients who are experiencing fever, night sweats, anorexia, and bouts of coughing more comfortable. Patients who present with a history of fever should have a normal temperature within 2 to 3 weeks after the initiation of chemotherapy. It may be necessary to suppress the cough reflex in patients who are experiencing severe

coughing. Codeine and hydrocodone are the most useful for temporary treatment. If the patient is producing thick and tenacious secretions, suppression of the cough reflex is not desirable. These patients should be instructed in adequate hydration and air humidification and prescribed an expectorant. Chest pain may manifest if the patient develops pleuritis. Occasionally chest pain may be caused by a fractured rib resulting from hard coughing. An instillation of a local anesthetic about the rib fracture is preferred over the older method of strapping the chest. Coughing resulting in occasional episodes of streaked or bloody sputum requires no specific treatment other than managing the cough. There may be significant hemoptysis with bronchogenic spread of the TB; however, it tends to be self-limiting. In advanced chronic cavitary TB, fatal pulmonary hemorrhage or shock can occur if large pulmonary arteries or Rasmussen's aneurysm slough or ulcerate.

Follow-up and Referral

The response to anti-TB chemotherapy in patients with positive bacteriology is best evaluated by repeated examinations of sputum. Sputum cultures should be done at least once monthly until sputum conversion is documented. After 2 months of treatment with regimens containing both INH and RIF, the majority of patients should convert to negative cultures. Patients whose sputum cultures have not become negative after 3 months of treatment should be carefully reevaluated and referred to a pulmonologist. Drug-susceptibility tests should be repeated, and treatment should be administered or continued under direct observation. If organisms are found to be resistant, the treatment regimen should be modified to include at least two drugs to which the organisms are susceptible and administered using DOT. For patients whose sputum no longer contains *M tuberculosis,* at least one further sputum smear and culture should be performed at the completion of therapy. X-ray evaluations during treatment are less important than sputum examination. A chest x-ray film at completion of treatment will provide a baseline comparison for any future films.

Shortness of breath in a patient without underlying pulmonary disease is suggestive of complications of pulmonary TB and requires further diagnostic inquiry. Sudden breathlessness may be a symptom of acute pleurisy with pleuritic pain, a pleural effusion, spontaneous pneumothorax, a massive extension of the TB, or an atelectasis. Patients who have coexisting emphysema or pulmonary disease may become dyspneic with only minimal involvement of the lungs.

Preventive Therapy

The ATS has identified risk groups for whom preventive therapy is indicated (see Table 9.13). Patients infected with *M tuberculosis* who do not have the active disease still harbor organisms. In turn, prophylactic or preventive treatment of latent TB infection significantly reduces the probability of reactivation TB later in life. INH given for 9 months is effective in asymptomatic adults (300 mg per day) or children (10–14 mg/kg per day up to 300 mg per day) with LTBI infection demonstrated by a positive TST reaction. Concurrent pyridoxine administration (25–50 mg per day in adults and 1–2 mg/kg daily in children) may reduce the potential for neuropathic complications associated with INH, and adjustments with intermittent dosing (900 mg twice weekly) or an overall shortened duration (6 months)

Table 9.13 Groups for Whom Preventive TB Therapy Is Recommended

Group	Comments
The following high-risk groups should be given treatment if their reaction to the Mantoux tuberculin skin test (PPD) is ≥5 mm:	
1. Persons with known HIV infection and those suspected of having HIV infection (persons with risk factors for HIV infection whose status is unknown)	HIV-infected persons who are at high risk for TB but have negative skin tests should be considered for preventive therapy.
2. Close contacts of persons with newly diagnosed infectious TB 3. Persons with fibrotic changes on chest x-ray exam consistent with old TB	Household members and other close contacts have a 2%–4% chance of developing TB within the first year of exposure to the index case. The risk for very young children and adolescents may be twice that of the adult. People who do not develop TB disease within the first year will continue to be at risk for the disease throughout their life. Children should be treated, even if their initial skin tests are negative. Skin testing should be repeated after 3 months of INH therapy. If the skin test becomes positive, INH preventive therapy should be continued for a total of 9 months.

Continued

Table 9.13 Groups for Whom Preventive TB Therapy Is Recommended—cont'd

Group	Comments
4. Recent tuberculin skin test converters	A skin test conversion is defined as an increase in induration of 10 mm or more within 2 years for those younger than age 35 years and 15 mm or more for those age 35 years or older.
5. Persons with medical conditions that increase the risk of TB with a PPD 10 mm or greater	
• Diabetes mellitus	The risk for this group may be 2–4 times that of the general population. Particularly at risk are poorly controlled insulin-dependent diabetics.
• Prolonged therapy with adrenocorticosteroids	TB that develops during corticosteroid therapy tends to be disseminated or presents in an obscure fashion. Prednisone (or equivalent) given daily at 15 mg or higher for 2–3 weeks markedly reduces tuberculin reactivity.
• Immunosuppressive therapy	Persons receiving other forms of immunosuppressive therapy are at an increased risk for TB.
• Hematological and reticuloendothelial diseases	Diseases such as leukemia and Hodgkin's disease may be associated with suppressed cellular immunity and an increased risk of TB.
• IV drug users known to be HIV-negative	Persons injecting illicit drugs may be at increased risk of TB even if not infected with HIV.
• End-stage renal disease (ESRD)	Persons with ESRD are predisposed to developing extrapulmonary TB with disseminated disease. Because these patients may be anergic, a documented history or positive skin test is an indication for preventive INH therapy unless they have been treated previously.
• Clinical conditions associated with substantial rapid weight loss or chronic malnutrition	These conditions include intestinal bypass surgery for obesity (which carries an increased risk for disseminated TB), postgastrectomy, chronic peptic ulcer disease, chronic malabsorption syndromes, chronic alcoholism, and carcinomas of the oropharynx and upper gastrointestinal tract that prevent adequate nutritional intake. The postgastrectomy state may increase the risk of developing TB even without weight loss.
Persons in the following groups who are younger than age 35 years and have a positive tuberculin skin test (≥10 mm):	
• Foreign-born persons from high-prevalence countries	These countries include those in Latin America, Asia, and Africa that have a high prevalence of TB. Recent arrivals (<5 years).
• Medically underserved low-income groups, especially high-risk racial or ethnic minority populations	These groups include African Americans, Native Americans, Hispanics, Asians, and Pacific Islanders.
• Residents of facilities for long-term care	These residents include those in correctional facilities, nursing homes, and mental health facilities. Staff of such facilities should also be considered for preventive therapy.
• Residents and staff of high-risk congregate settings (nursing homes, jails, homeless shelters)	
• Migrant farmworkers	
• Children younger than 4 years of age	
• Mycobacteriology laboratory personnel	

Table 9.13 Groups for Whom Preventive TB Therapy Is Recommended—cont'd

Group	Comments
• Persons with clinical conditions that make them high risk	HIV infection, substance abuse, recent infection with *M tuberculosis* (within past 2 years), previous TB, silicosis, prolonged immunosuppressive therapy, low body weight (<90% of normal), ESRD, chronic malabsorption
Persons with no known risk factors for TB may be considered for therapy if their reaction to the tuberculin test is ≥15 mm. This group should be given lower priority than the groups listed above.	

Source: Adapted from Chapter 6 of the CDC Curriculum: Preventive therapy: Treatment of TB infection. Retrieved July 1, 2013, from www.cdc.gov/tb/education/corecurr/pdf/chapter6.pdf

may be used for adult patients with medication adherence issues. For patients intolerant of INH or in whom INH-resistant LTBI is suspected, rifampin may be used as an alternative in adults (600 mg per day for 4 months) or children (10–20 mg/kg per day for 6 months).

All persons with known HIV infection or suspected of having HIV who have positive TST results should receive preventive therapy for TB. HIV-infected persons who are at high risk for TB but have negative skin tests should also be considered for preventive therapy. Preventive regimens are similar to those for non–HIV-infected individuals. However, a full course of daily INH (9 months) or rifampin (6 months) is recommended, with the latter reserved for suspected cases of INH-resistant, rifampin-sensitive LTBI.

Household members and other close contacts have a 2% to 4% risk of developing TB within the first year of exposure to the index case. The risk for very young children and adolescents may be twice the risk of the adult. People who do not develop TB disease within the first year will continue to be at risk for the disease throughout their lives. Children should be treated even if their initial skin tests are negative. Skin testing should be repeated after 3 months of INH. If the skin test becomes positive, INH preventive therapy should be continued for a total of 9 months.

Persons with medical conditions such as diabetes, long-term use of adrenocorticosteroids, use of immunosuppressive therapy, IV drug use, hematological disease, end-stage renal disease, and conditions associated with rapid weight loss or chronic malnutrition are also at risk for TB. Other risk groups include foreign-born persons from high-prevalence countries (Asia, Africa, Latin America); medically underserved groups, especially high-risk racial or ethnic populations (African Americans, Native Americans, Hispanics); and residents of long-term care facilities (e.g., prisons, nursing homes, mental health facilities).

Bacille Calmette-Guérin (BCG) vaccination is an antimycobacterial vaccine developed from an attenuated strain of *Mycobacterium bovis.* Millions of persons worldwide have been vaccinated with BCG. It is not currently recommended because of multiple factors, including its variable effectiveness against pulmonary TB. BCG vaccination in the United States should be used only after consultation with the local health department. The BCG vaccination should not be used in persons with impaired immune responses.

Because BCG vaccination has been widespread in the majority of countries outside the United States, the clinician will undoubtedly encounter patients who may be at risk for TB who have been vaccinated. Previous vaccination with BCG typically results in tuberculin test conversion, producing a reaction that may be difficult to distinguish from a natural mycobacterial infection. A large reaction to PPD tuberculin in BCG-vaccinated persons, especially among persons from countries with a high prevalence of TB, should be considered indicative of a possible TB infection, and the patient should be evaluated appropriately. Reasons for not assuming that a large reaction to tuberculin testing is due to the BCG vaccination include the following: (1) conversion rates after vaccination may be much less than 100%, (2) the mean reaction size among vaccines is often less than 10 mm, and (3) TB sensitivity tends to wane after vaccination.

To keep abreast of changes in treatment recommendations for TB, visit the Division of TB Elimination Web site at www.cdc.gov/nchstp/tb.

Patient Education

The necessity of educating the patient and the family about the disease, treatment, and importance of completing the recommended regimen is critical to the management of TB. The patient and family should understand the information and continue to be provided with reinforcement and encouragement throughout the course of therapy. Patients should be offered the option of participating in DOT. For patients who are administering their own medications, strategies that may be helpful for improving adherence include use of a weekly pill dispenser, marking off each day on a calendar as medicine is taken, taking pills at the same time

every day (e.g., with breakfast or at coffee break), and asking a friend or family member to remind the patient to take pills.

Patients are typically considered to be infectious for about 2 to 3 weeks after initiation of drug therapy. If the patient is being cared for at home, he or she should not go to work or school. These patients should be instructed in controlling the spread of tubercle bacilli in microdroplets by using good hygienic measures, appropriate ventilation, and avoiding close contact with family and friends. Patients should sleep in a separate room until no longer considered infectious. Patients should be taught to always cover their mouths when they cough, sneeze, or laugh. Used tissues should be placed in a plastic or paper bag and discarded. If the weather is warm enough, patients should be instructed to place a fan in an open window to blow out air that may be contaminated with TB. Opening other windows in their room will help pull in fresh air.

Patients should be asked to identify any people who may need to be tested for TB infections, including coworkers, family members, and friends. All close contacts will need to undergo tuberculin skin testing and may require preventive INH therapy. Assurance should be provided to the patient and family by stressing that the majority of properly treated patients with TB are cured.

Some problems associated with TB among foreign-born patients stem from communication barriers, cultural and cognitive dissonance between practitioners and patients, and gaps in provider training. Education needs to be targeted to patients, providers, and community workers.

There are excellent TB control strategies available to the public from the CDC. Patients may access these guidelines at www.cdc.gov and obtain guidelines written in an easily understood manner.

However, the problems of multidrug-resistant TB and issues of compliance with therapy among all populations remain a significant challenge for health-care providers. Practicing within a *Circle of Caring* enables the provider to approach these problems in a meaningful way.

LUNG CANCER

Lung cancer arises from the epithelium of the respiratory tract. The four major histological types are squamous-cell (epidermoid) carcinoma, small-cell (oat-cell) carcinoma, large-cell carcinoma (including giant-cell and clear-cell carcinoma), and adenocarcinoma. Squamous-cell carcinoma is named for the resemblance of cells to the epidermis of the skin. These cells usually contain the skin protein called keratin. Squamous-cell carcinomas arise most often from the bronchial lining and may grow to obstruct air passages. Adenocarcinoma, the most prevalent carcinoma of the lung of both sexes, resembles poorly formed glandular tissue. It may be difficult to determine whether an adenocarcinoma is a primary lung cancer or a metastatic tumor from elsewhere in the body. Fifty-five percent to 60% of adenocarcinomas are located in the periphery of the lung, not obviously related to any bronchus. Many organs in the body can develop adenocarcinoma that may metastasize to the lungs. Large-cell carcinomas, also called undifferentiated carcinoma, are characterized by a collection of poorly formed large cells that have abundant cytoplasm. These tumors may exhibit a glandlike structure and produce mucin.

Small-cell lung carcinomas (SCLCs) (oat-cell, intermediate, and combined carcinomas) are characterized by very small cells with scant cytoplasm. SCLC is a very rapidly growing tumor that usually metastasizes to distant tissue while the tumor is quite small. The clinical effect of SCLC is much different from that of the other three forms of lung cancer, which is why lung cancers are usually classified in terms of small-cell and non–small-cell lung carcinomas (NSCLCs) (Table 9.14).

Because the lung area is so large, tumors may go undetected for some time. Early symptoms such as coughing and fatigue are so common that patients often attribute these symptoms to other causes, rather than lung cancer. Because of this, early-stage lung cancer (Stages I and II) is difficult to detect, and most patients are diagnosed at Stages III and IV.

Epidemiology and Causes

Lung cancer is preventable, common, and lethal once it comes to clinical attention, and it is relatively resistant to current therapeutics. Lung cancer is the most frequent cause of cancer death in men and women in North America and accounts for 28% of all cancer deaths. In 2013, the National Cancer Institute at the National Institutes of Health reported that more than 228,190

Table 9.14 Cellular Classification of Lung Cancer

Major Classification	Subclassification
Small-cell lung carcinomas (SCLCs)	• Oat-cell carcinoma • Intermediate-cell carcinoma • Combined small-cell carcinoma (with squamous-cell carcinoma or adenocarcinoma)
Non–small-cell lung carcinomas (NSCLCs)	• Squamous-cell (epidermoid) carcinoma Well-differentiated Moderately well-differentiated Poorly differentiated • Adenocarcinoma Well-differentiated Moderately well-differentiated Poorly differentiated Bronchoalveolar • Large-cell carcinoma Giant-cell Clear-cell

people were diagnosed with lung cancer and 159,480 of them died from it. Eighty-six percent of patients die within 5 years. The death rate for women is now higher than from any other cancer because of increased cigarette smoking by women and because they may be more susceptible to the carcinogenic effects of tobacco smoke than are men. In every ethnic group, men still have higher lung cancer incidence and mortality rates than women, although women are rapidly closing the gap. African American men have the highest lung cancer incidence and mortality rates. Lung cancer is the leading cause of cancer death in most racial and ethnic groups of women except Native American, Filipino, and Hispanic women. New lung cancers and lung cancer deaths peak in individuals aged 55 to 65 years old.

Tobacco use, especially cigarettes, is the main cause of the progressive rise in mortality from lung cancer. Ninety percent of the lung cancer cases in men and 70% in women are attributed directly to cigarette smoking. The risk of lung cancer increases with the duration of smoking, with earlier age at onset of smoking, and for smoking unfiltered or high-tar cigarettes. Of continued note are the effects of environmental tobacco smoke, also called secondhand smoke, sidestream smoke, involuntary smoke, or passive cigarette smoke. Exposure to secondhand smoke is thought to increase the risk of dying from lung cancer by 30%.

Lung cancer also occurs in association with occupational and environmental exposure to carcinogenic agents from sources other than smoking. Environmental or occupational risk factors associated with lung cancer include benzpyrene and radon, mustard gas, and nickel and chromium particles associated with uranium mining, asbestos, arsenic fumes, radiation, and nuclear bombs. The combination of cigarette smoking and environmental exposure produces an additive effect such that smokers exposed to asbestos increase their risk of lung cancer 92 times.

Pathophysiology

The bronchial walls have three layers: an epithelial lining, a smooth muscle layer, and a connective tissue layer. The epithelial lining of the bronchi contains single-celled exocrine glands (the mucus-secreting goblet cells) and ciliated cells. High columnar pseudostratified epithelium lines the larger airways, changing to columnar cuboidal epithelium in the bronchioles. It is hypothesized that at sites of segmental bronchial bifurcations, airflow and mucus production are altered and bronchial epithelium becomes very susceptible to injury. Carcinogenic agents, such as tobacco smoke, are likely deposited and absorbed in these areas. Particle size in environmental tobacco smoke is smaller, and inhaled particles may travel to peripheral lung regions more readily than with mainstream smoke. This is thought to explain the excess of peripheral adenocarcinomas seen in passive smokers.

Cigarette smoke contains tumor initiators, promoters, and cocarcinogens. DNA-mutating agents in cigarettes produce alterations in both oncogenes (a class of genes that encodes proteins involved in normal cell-growth processes) and tumor-suppressor genes. Multiple genetic events occur, first resulting in dysregulated growth and eventually in a malignant cell. These alterations include bronchial epithelial changes progressing from squamous cell alteration, or metaplasia, to carcinoma in situ. Repeated carcinogenic irritation to the bronchial epithelium may cause increased rates of cellular replication. Healthy ciliated cells are replaced with a proliferation of basal cells, resulting in hyperplasia, dysplasia, carcinoma in situ, and invasive carcinoma.

Small-Cell Lung Cancer

SCLC, which accounts for 15% of lung cancers, invades the submucosa and is centrally located, developing around a main bronchus as a whitish gray growth that invades surrounding structures, eventually compressing the bronchi externally. SCLC results from smoking more so than NSCLC, grows more rapidly, and metastasizes earlier than NSCLC. SCLC is also more responsive to chemotherapy than NSCLC. The most striking difference between small-cell carcinoma and other forms of malignant lung neoplasms is the aggressiveness of this tumor, resulting in a more rapid growth and early local and distant metastasis via the lymphatic and blood vessels. Oat-cell carcinoma, one of the three types of SCLC, is composed of cells with round to oval nuclei. The tumors are soft in consistency and have shiny gray cut surfaces. The more common intermediate cell type is characterized by cells with larger, more vesicular, fusiform or spindled nuclei. The third type is the combined type, in which small-cell carcinoma is combined with another cell type. The most important variant is the small-cell and large-cell, which is regarded as small-cell carcinoma for treatment purposes. It lacks sensitivity to radiation and chemotherapy but retains the aggressiveness of the "pure" small-cell carcinoma.

Non–Small-Cell Lung Cancer

NSCLC comprises approximately 85% of all primary lung carcinomas in the United States. The tumor suppressor gene p53 has been reported to be associated with human cancer more commonly than any other gene. The gene is mutated in about 60% of all cases of NSCLC. It encodes for a protein with a central role in the regulation of transcriptional events in the cell nucleus, particularly in response to DNA-damaging agents, such as ionizing radiation and a variety of other carcinogens. The central role of normal p53 protein has led to its description as the "guardian of the genome." Although many efforts to improve survival have focused on expanding indications for both radiotherapy and surgery, little progress has been made.

Squamous-Cell Carcinoma Squamous-cell carcinoma is the second most common lung cancer, accounting for

25% to 35% of cases. It is more common in men than in women and occurs almost entirely in cigarette smokers.

These tumors arise from the basal cells of the bronchial epithelium and usually present as masses in the segmental, lobar, or mainstem bronchi. The tumors tend to be bulky and invade cartilage and the adjoining lymph nodes. Based on the degree of differentiation, these tumors are divided into three subtypes: well-differentiated, moderately well-differentiated, and poorly differentiated tumors. Well-differentiated tumors may show epithelial pearl formation, whereas poorly differentiated tumors are characterized by keratinization. Because it is a relatively slow-growing tumor, several years may elapse between the development of a carcinoma in situ and clinical detection. Metastases of squamous-cell carcinomas are initially to hilar and mediastinal lymph nodes and then to the liver, adrenals, bones, and brain.

Adenocarcinoma Adenocarcinoma, which represents 35% to 40% of all lung cancers, is the most prevalent carcinoma of the lung in both sexes and in nonsmokers. It forms acinar or glandular structures. Histologically, this tumor is divided broadly into well-differentiated, moderately well-differentiated, poorly differentiated, and bronchioalveolar types. They arise from the bronchial epithelium and may form in lung scars or fibrous tissue. Adenocarcinoma usually presents as a non-small cell lung cancer in the peripheral portion of the lungs, although rapidly progressive multifocal disease may be present at diagnosis. Although adenocarcinomas are usually slow-growing tumors, they invade lymphatics and blood vessels early, and thus produce early metastases; nearly half are considered to be unresectable at the time of diagnosis. Grossly, central cavitation is uncommon. Areas of metastasis commonly include the brain, liver, bone, and adrenal glands. Patients with adenocarcinomas may have an associated history of chronic interstitial lung disease such as scleroderma, rheumatoid arthritis (RA), recurrent pulmonary infections, and other necrotizing pulmonary disease.

The bronchoalveolar subtype of adenocarcinoma represents approximately 2% to 4% of all lung cancers. Often, it is associated with prior lung disease leading to fibrosis, including repeated pneumonias, idiopathic pulmonary fibrosis, asbestosis, scleroderma, and Hodgkin's disease. There is little correlation with this type of cancer and smoking. Bronchoalveolar carcinoma commonly arises in the periphery of the lung and it grows in a scale-like fashion along the alveolar septa. Grossly, these tumors may be categorized as solitary, multinodular, or diffuse. The solitary, well-differentiated bronchoalveolar cell carcinoma has a much better prognosis than the other forms; diffuse and multinodular forms usually are not amenable to therapy.

Large-Cell Carcinoma

Large-cell carcinoma, also called undifferentiated carcinoma, is the least common type of lung cancer, representing approximately 5% to 10% of cases. It is classified into two types: clear-cell carcinoma and giant-cell carcinoma. Large-cell carcinomas include all tumors that show no evidence of differentiation to small-cell carcinoma, squamous-cell carcinoma, or adenocarcinoma. These tumors tend to form large, bulky, somewhat circumscribed and necrotic masses in the major or intermediate-sized bronchi or in the periphery, invade locally, and disseminate widely. The giant-cell variant of large-cell carcinoma is composed of huge, multinucleated, bizarre cells that are frequently associated with an extensive inflammatory cell infiltration. These tumors are usually large and peripheral and are very aggressive, highly malignant, and most often found at a late stage. These lesions show an ability to metastasize widely, with a predilection for the small intestine. Table 9.15 summarizes the characteristics of the types of lung cancer.

Clinical Presentation

Past history of a patient with suspected lung cancer must include any history of chronic respiratory problems, as well as any prolonged exposure to environmental carcinogens. Habits must be assessed to determine the patient's risk of developing lung cancer. Smoking history includes the age when smoking started, the average number of packs smoked per day, and the number of years smoked. The type of tobacco (cigar, cigarette, snuff, or chewing tobacco) used by the patient must be determined. A positive family history of lung cancer may indicate that the patient is at a slightly higher risk to develop lung cancer. The genetic link, however, is not clear. A review of systems reexamines all pertinent present and past symptoms that relate to the chief complaint and usually completes the health history.

Clinical manifestations of lung cancer are dependent on the location of the tumor and the extent of spread. Ten percent to 25% of patients are asymptomatic at the time of diagnosis. Symptoms may be divided into four categories: intrathoracic or local–regional symptoms, symptoms resulting from extrathoracic involvement, nonspecific systemic symptoms, and paraneoplastic syndromes. Some cases of lung cancer are picked up during a routine chest x-ray study done for other reasons, for example, a preoperative physical for an unrelated surgery, or for a work physical, and so forth.

Intrathoracic or Local–Regional Symptoms

Subjective The most common symptoms of local–regional disease are ambiguous and insidious; they include cough, sputum production, dyspnea, chest pain, hemoptysis, wheezing, postobstructive pneumonia, and pleural effusions. Cough resulting from bronchial irritation occurs in 60% of patients and often is attributed to a cold. The cough frequently goes away after a few days and returns intermittently. Cough may be produced by a small tumor acting as a foreign body or by ulceration

Table 9.15 Characteristics of Lung Cancer

Lung Cancer Type	Tumor Type	Growth Rate	Metastasis	Manifestations	Treatment
SCLC	• 15%–20% • Neuroendocrine cells: Oat-cell carcinoma Combined small-cell (with squamous-cell carcinoma or adenocarcinoma)	Very rapid	Very early, via lymphatic and blood vessels	Obstruction of main bronchus; associated with paraneoplastic syndrome	• Not resectable • Treated with chemotherapy and radiation
NSCLC	• Squamous-cell (epidermoid) carcinoma • 25%–35% • Keratin-producing cells: Well-differentiated Moderately well-differentiated Poorly differentiated	Slow	Hilar and mediastinal lymph nodes, liver, adrenals, bone, brain	Most often in cigarette smokers; bulky mass in main stem bronchi	• Stage I and II: Resectable • Stage III: Chemotherapy and radiation • Stage IV: Chemotherapy (Refer to Table 9.18 for staging)
	• Adenocarcinoma • 35%–40% • Columnar cells: Well-differentiated Moderately well-differentiated Poorly differentiated Bronchoalveolar	Slow to moderate	Early and most frequently via lymphatic and blood vessels to brain, liver, bone, adrenal glands	Form glandular structures in scar or fibrous tissue; single distal pulmonary nodule	• Stage I and II: Resectable • Stage III: Chemotherapy and radiotherapy • Stage IV: Chemotherapy
	• Large-cell carcinoma • 5%–10% • Undifferentiated cells: Giant-cell Clear-cell	Rapid	Early and widespread to small intestine	Large, bulky necrotic masses in major or intermediate-sized bronchi or in periphery	• Stage I and II: Resectable • Stage III: Chemotherapy and radiotherapy • Stage IV: Chemotherapy

of the bronchial mucosa. Severe paroxysms of coughing may lead to cough-induced rib fractures, rupture of an emphysematous bleb, or cough syncope. Cough and sputum production are not specific symptoms because the majority of lung cancer patients also suffer from chronic bronchitis and emphysema due to cigarette smoking; however, a change in the character of the cough, a change in the quality and quantity of sputum, or unresponsiveness to previously effective therapy (e.g., bronchodilators, antibiotics, steroids) should raise the suspicion that a tumor is present.

Many patients with lung cancer experience dyspnea as a result of multiple disruptions in physiological function of the respiratory system. Dyspnea has been reported in 26% to 60% of patients presenting with NSCLC and is often an ominous development, signifying intrathoracic extension or dissemination. Some patients may have dyspnea resulting from underlying pulmonary disorders such as pulmonary fibrosis or COPD. These patients may experience difficulties in airway clearance associated with excessive tracheobronchial secretions, thick tenacious secretions, muscle weakness, and chest pain. Central lung cancers cause dyspnea by means of obstruction, with or without postobstructive pneumonitis. Large pleural effusion or paralysis of a hemidiaphragm resulting from phrenic nerve involvement may also cause dyspnea. The assessment of dyspnea should include a description of the onset, duration, magnitude, and precipitating events. It is especially important to identify any interventions the patient has discovered that are helpful in relieving the dyspnea. Usually the chest radiograph in dyspneic patients demonstrates a sizable effusion, atelectasis of a lobe

or entire lung, or clear evidence of intrapulmonary dissemination.

Chest pain with deep inspiration or coughing may be reported, as well as fatigue and anorexia. Chest pain in lung cancer may indicate local invasion of the pleura, ribs, and nerves. Pain may be dull, constant, and debilitating or intermittent and sharp, varying with the respiratory cycle. It may localize to the chest wall, or it may radiate to the midback, scapula, shoulder, or arm on the side of the tumor. The pain is usually a dull intermittent ache lasting from minutes to hours on the same side as the tumor and is not related to cough or respiration. Intercostal retractions, supraclavicular retractions, and/or use of accessory muscles on inspiration indicate obstruction to air inflow, whereas bulging interspaces on expiration are associated with outflow obstruction; either may be an indication of tumor. It is important to distinguish the chest pain that accompanies direct contiguous chest wall extension from painful rib metastases that are anatomically remote from the primary lesion.

Chest discomfort can be associated with atelectasis. Atelectasis develops in the patient with lung cancer secondary to mechanical obstruction of the airways, compression of lung tissue, and shallow breathing patterns. When the tumor obstructs the airway, it prevents or reduces alveolar ventilation to a region of the lung and produces atelectasis in that region. The size of the atelectic area depends on the size of the obstructed airway and the degree of obstruction. Localized compression of lung tissue occurs with large tumors and with large pleural effusions secondary to metastases.

Hemoptysis is seen in up to 30% of patients and occurs when the tumor erodes the epithelial layer or invades a blood vessel. It occurs more often in squamous-cell carcinoma and large-cell carcinoma than in SCLC. Typically, hemoptysis consists only of blood-streaked sputum, which is sometimes erroneously attributed to chronic bronchitis. The quantity of blood is usually small, but it can become massive and life-threatening. Hemoptysis usually prompts the patient to seek medical attention and is suggestive of endobronchial tumor. Inspection very seldom reveals any changes in the chest wall. Palpation may reveal lymph node enlargement.

Nonspecific Systemic Symptoms

Systemic symptoms of lung cancer include generalized weakness and fatigue, anorexia, cachexia, weight loss, and anemia. These nonspecific signs and symptoms are common in both SCLC and NSCLC. Weight loss, which usually (but not always) is accompanied by anorexia, occurs in more than one-half of the patients, and generalized weakness occurs in one-third. Fever and anemia occur in about 20% of patients. Fever generally is not considered to be paraneoplastic in patients with lung cancer; if present, it usually is associated with a documented infection or liver metastases.

Table 9.16 presents a summary of these clinical manifestations of lung cancer.

Objective Auscultation may reveal wheezing if an airway is partially obstructed. The wheezing is usually monophonic and localized and does not disappear after a cough. Wheezing may be heard on both inhalation and exhalation. Absent or decreased breath sounds can be heard when normal lung tissue is replaced by tumor or when the patient has a pleural effusion. Percussion reveals diminished resonance over lung tissue affected by a large tumor, pleural effusion, or pneumonia (consolidation). Decreased tactile fremitus may be associated with pleural effusion and tumors of the pleural cavity, whereas increased tactile fremitus may indicate a lung mass.

The most frequent peripheral sign of lung cancer is clubbing of the fingers, which at times is associated with

Table 9.16 Clinical Manifestations of Lung Cancer

Nonspecific systemic manifestations	Weakness Fatigue Fever Anorexia Cachexia Anemia Symptoms associated with paraneoplastic syndromes
Intrathoracic or local-regional manifestations	Cough Dyspnea Hemoptysis Wheezing Chest pain Stridor Hoarseness Vocal cord paralysis Hiccups Atelectasis Pneumonia Pancoast's syndrome Horner's syndrome Pleural effusion Pericardial effusion Superior vena cava syndrome
Manifestations resulting from extrathoracic involvement	Bone pain Headache Dizziness Lymphadenopathy CNS disturbances Gastrointestinal disturbances Jaundice Hepatomegaly Abdominal pain

generalized hypertrophic pulmonary osteoarthropathy (HPO), also known as Bamberger-Marie disease. HPO often resembles RA. The clinical syndrome consists of swelling of the soft tissues of the terminal phalanges, with curvature of the nails, pain and swelling of the joints, and periostitis of the long bones, with elevation of the periosteum and new bone formation. The incidence of HPO, almost exclusively in patients with NSCLC, has been reported to be from 2% to 12%. It occurs only rarely, if ever, in small-cell tumors. Its occurrence is distributed equally among the other three major cell types of NSCLC. Removal of the pulmonary lesion may give dramatic remission of the arthralgia and peripheral edema.

Physical examination evidence for surgical nonresectability includes hoarseness, facial edema, arm pain, or changes in mental or emotional status. Hoarseness suggests vocal cord paralysis caused by recurrent laryngeal nerve compression by the tumor. Facial edema suggests compression of the superior vena cava by the tumor. Superior vena cava syndrome occurs when a lung tumor, usually SCLC, presses on the superior vena cava, partially or completely occluding it and impeding venous return from the head, neck, arms, and upper chest. Symptoms are related to venous obstruction, airway obstruction, and increased cerebral venous pressure. The most common symptoms include edema of the face, neck, arms, and upper torso. The conjunctiva may also be engorged. If the compression is untreated, neurological symptoms related to increased intracranial pressure may ensue, including headache, dizziness, visual disturbances, and occasionally alterations in mental status. Associated upper airway obstruction or signs of cerebral edema are very poor prognostic signs.

Tumor compression of the cervical sympathetic nerve plexus causes Horner's syndrome, which consists of unilateral ptosis, miosis, and ipsilateral anhidrosis (lack of sweating due to extension of the tumor into the paravertebral sympathetic nerves). Horner's syndrome is often associated with radiographic evidence of destruction of the first and second ribs. Pancoast's syndrome, manifested as arm and shoulder pain, suggests invasion of the brachial nerve plexus by a superior sulcus tumor. In addition, there may be muscular atrophy and decreased range of motion in the arm and shoulder; the patient may walk supporting the elbow of the affected arm.

Symptoms Due to Extrathoracic Involvement

Extrathoracic metastatic spread most often occurs in the lymph nodes, brain, bones, liver, and suprarenal glands. Bone pain caused by metastasis occurs in approximately 25% to 40% of patients although pathological fractures are rare. Neurological symptoms resulting from intracranial metastases are present in 3% to 6% of patients. These include hemiplegia, epilepsy, personality changes, confusion, speech defects, gait disturbances, or only nonspecific headache. Symptoms that relate to liver involvement (right upper quadrant pain) are less common or nonspecific (e.g., nausea, weight loss, anemia). Rarely, jaundice, ascites, or an abdominal mass is the major complaint. Neck, muscle, or subcutaneous tissue masses are present infrequently. Involvement of adrenal glands often is asymptomatic, and most adrenal metastases are discovered incidentally, either during staging evaluation or at autopsy. If symptomatic, it presents with unilateral pain in the flank, abdomen, or costovertebral angle. Although adrenal metastases are fairly common, signs of adrenal insufficiency are rarely seen.

Paraneoplastic Syndromes

Associated with lung cancer are approximately 21 identified syndromes that meet the usual definition of the term *paraneoplastic*. Approximately 2% of patients with lung cancer seek medical advice for systemic symptoms and signs not related to metastatic spread of the tumor, the so-called paraneoplastic syndromes shown in Table 9.17. The major categories of paraneoplastic

Table 9.17 Paraneoplastic Syndromes Associated With Lung Cancer

Type of Cancer	Associated Paraneoplastic Syndrome
SCLC	• Ectopic adrenocorticotropic hormone (Cushing's syndrome) • Inappropriate antidiuretic hormone secretion • Lambert-Eaton myasthenic syndrome • Atrial natriuretic factor • Hyperpigmentation
NSCLC	• Humoral hypercalcemia • Hypertrophic pulmonary osteoarthropathy • Nephrotic syndrome • Hypoglycemia • Gynecomastia • Nonbacterial thrombotic endocarditis
All Lung Cancers	• Hypercoagulable state • Disseminated intravascular coagulation • Erythrocytosis • Granulocytosis • Neurological and myopathic syndromes (dementia, limbic encephalitis, optic neuropathy, sensory neuropathy, sensorimotor peripheral neuropathy) • Dermatological syndromes (acanthosis nigricans, acquired ichthyosis, dermatomyositis)

syndromes include endocrine, neurological, cardiovascular, skeletal, and cutaneous manifestation.

Paraneoplastic syndromes are often the first indication of the presence of a tumor and may antedate the demonstrable tumor by a period ranging from months to years. SCLC is associated with paraneoplastic syndromes more frequently than the NSCLCs. The majority of metabolic manifestations are the result of secretion of endocrine or endocrine-like substances by the tumor.

Hyperadrenocorticism, in association with ectopic secretion of adrenocorticotropic hormone, is a frequently observed hormonal syndrome in lung cancer, particularly with SCLC patients. It manifests as severe weakness, weight loss, edema, hypertension, hypokalemia, and hyperglycemia. The syndrome of inappropriate antidiuretic hormone secretion, seen in 5% to 10% of all SCLCs, results from antidiuretic hormone secretion by the tumor and is associated with symptoms of water intoxication (anorexia, nausea, and vomiting). Symptoms include hyponatremia and low serum osmolality, characterized by mental status changes, lethargy, seizures, and confusion. Hyponatremia resulting from the secretion of atrial natriuretic factor also can occur in some patients.

Hypercalcemia may be caused by bony metastases or excessive secretion by the tumor (usually a squamous-cell tumor) or parathyroid hormone–related protein, so-called humoral hypercalcemia of malignancy. Although squamous-cell carcinoma is most commonly associated with hypercalcemia, other histological types can cause the syndrome as well. An accompanying hypophosphatemia is also frequently found. Clinically, the hypercalcemic patient may have somnolence, irritability, confusion, or coma, as well as anorexia, nausea, vomiting, constipation, and weight loss. The Eaton-Lambert myasthenic syndrome occurs in about 6% of patients with SCLC. This pseudomyasthenic syndrome is thought to be an autoimmune disorder in which the release of acetylcholine by the motor nerve terminals is impaired. Symptoms include proximal limb muscle weakness and fatigue (especially in the pelvis, thighs, arms, and shoulders), peripheral paresthesia, dry mouth, dysphagia, diplopia, ptosis, difficulty chewing, and double vision.

Diagnostic Reasoning

Early detection is the key to successful resection of the NSCLC tumors, but mass screening programs have failed to affect mortality rates. The histological cell type and the stage of the disease are the major factors that influence choice of therapy for individuals. The currently accepted system for the staging of lung cancer is the tumor-node-metastasis (TNM) classification presented in Table 9.18. This system is a code in which T denotes the extent of the primary tumor (ranging from T0 to T4), N indicates the nodal involvement (ranging from N0 to N3), and M describes the extent of metastasis (M0 or M1). The stage of disease (also in Table 9.18) is based on a combination of clinical (physical exam, radiological, and laboratory studies) and pathological (biopsy of lymph nodes, bronchoscopy, mediastinoscopy, or

Table 9.18 Lung Cancer Staging

Tumor-Node-Metastasis (TNM) Stage Grouping for Lung Cancer	
Occult cancer	TX N0 M0
Stage 0	Tis N0 M0
Stage I	T1 N0 M0; T2 N0 M0
Stage II	T1 N1 M0; T2 N1 M0
Stage IIIA	T1 N2 M0; T2 N2 M0; T3 N0 M0; T3 N1 M0; T3 N2 M0
Stage IIIB	Any T N3 M0; T4 Any N M0
Stage IV	Any T Any N M1

TNM Definitions of Primary Tumor (T) Characteristics in Lung Cancer	
Primary (T)	
TX	Primary tumor cannot be assessed, or tumor proved by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy.
T0	No evidence of primary tumor.
Tis	Carcinoma in situ.
T1	A tumor that is 3.0 cm or less in greatest diameter, surrounded by lung or visceral pleura and without evidence of invasion more proximal than the lobar bronchus (e.g., not in the main bronchus). (*Note:* The uncommon superficial tumor of any size with its invasive component limited to the bronchial wall, which may extend proximal to the main bronchus, is also classified as T1.)

Table 9.18 Lung Cancer Staging—cont'd

T1a	Tumor 2 cm or less in greatest dimension.
T1b	Tumor more than 2 cm but less than 3 cm in greatest dimension.
T2	A tumor with any of the following features of size or extent: more than 3.0 cm in greatest dimension; involving the main bronchus, 2.0 cm or more distal to the carina; invading the visceral pleura; associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung.
T2a	Tumor more than 3 cm but less than 5 cm in greatest dimension.
T2b	Tumor more than 5 cm but less than 7 cm in greatest dimension.
T3	A tumor of any size with direct extension to the chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium; a tumor in the main bronchus less than 2.0 cm distal to the carina but without involvement of the carina; associated atelectasis or obstructive pneumonitis of the entire lung.
T4	A tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, carina; or tumor with a malignant pleural effusion.
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis.
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes, including direct extension.
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s).
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s).
Distant Metastasis (M)	
M0	No (known) distant metastasis.
M1	Distant metastases present; specify sites.
M1a	Separate tumor nodule(s) in a contralateral lobe, tumor with pleural nodules or malignant pleural (or pericardial) effusion.
M1b	Distant metastasis (in extrathoracic organs).

Note: Most pleural effusions associated with lung cancer are due to tumor; however, there are a few patients in whom multiple cytopathological examinations of pleural fluid are negative for tumor. In these cases, fluid is nonbloody and is not an exudate. When these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging element and the patient should be staged as T1, T2, or T3.

paramedian sternotomy or other type of thoracotomy) staging.

The diagnostic approach for SCLC is the same as that for NSCLC, but the staging system is different. SCLC staging still focuses on disease extent but broadly classifies it as limited state (limited to one hemothorax with hilar and mediastinal nodes that can be included within a radiation therapy port) or extensive stage disease. The TNM staging system is not typically used for SCLC staging. The anatomical detail of the TNM classification system is unnecessary because surgical resection is not a recommended treatment modality.

Diagnostic Tests

Initial Testing A complete blood count (CBC) should be ordered because anemia may be associated with lung cancer, along with a basic metabolic panel and hepatic panel checking for abnormalities in Na, K, Ca, and liver enzymes, and a prothrombin time, partial thromboplastin time, and platelet count to assess for coagulopathies. An electrocardiogram (ECG) should be done, as well as baseline pulmonary function tests (PFTs). Anterior-posterior and lateral chest x-ray films remain the simplest method for identifying patients with lung cancer. The heart and other thoracic structures

obscure large portions of the lung tissue, so it is important to evaluate both a frontal and a side view. The chest x-ray film may demonstrate asymptomatic lung cancer and is almost always abnormal when the patient is symptomatic. A tumor nodule must be at least 2 to 3 mm before it is visible on the chest radiograph. Associated atelectasis, postobstructive pneumonitis, abscess, bronchiolitis, rib erosion, pleural effusion, or bulky mediastinal lymphadenopathy may be identified on radiographs, thus raising a suspicion of primary lung malignancy. The four most common types of lung cancer usually present with slightly different chest radiographic patterns, but there is so much overlap that only biopsy and histological examination provide reliable evidence about the cell type. Mediastinal changes on radiograph may suggest lymphadenopathy or pleural effusions, and an elevated diaphragm may be seen with phrenic nerve involvement.

A chest computed tomography (CT) scan with infusion of contrast material has become widely accepted as the primary cross-sectional modality for evaluation of the thorax and is recommended to stage NSCLC. The CT scan should extend inferiorly to include the liver and the adrenal glands. Because of its earlier metastases and unresectability, staging for SCLC is less useful for treatment and prognosis. A contrast-enhanced chest CT scan will (1) characterize the size and location of the primary tumor and its relationship to other thoracic structures, (2) identify pathologically enlarged hilar and mediastinal lymph nodes, (3) identify satellite and other ipsilateral or contralateral pulmonary nodules, and (4) identify potential metastases to the liver and adrenal glands, both common metastatic sites.

Cytological evaluation of sputum, bronchial washing, bronchial brushings, and fine-needle aspirations have a high diagnostic value, but the positive and negative predictive values of each, as well as their accuracy of diagnosis, depend on sampling error, tissue preservation, processing quality, and observer experience. Sputum cytology remains a simple test with a positive predictive value that can approach 100%, but it has a sensitivity rate of only 10% to 15%. If a diagnosis can be established through collective sputum cytology, invasive tests often can be averted. Automated sputum screening is currently being evaluated and may play an increasingly important role in early diagnosis. The highest yield occurs in patients with large, centrally located tumors. It is much less helpful in diagnosing peripheral lesions because relatively few cells are released from the lesion, and those that are released rarely get to the central airways. Early-morning sputum samples are collected for 3 to 5 days; deep coughing is recommended because coughing dislodges cancer cells into the sputum.

Flexible fiberoptic bronchoscopy is an essential and standard technique for the evaluation of patients with pulmonary neoplasms. It remains the most important procedure for determining the endobronchial extent of disease. The extent and operability of the tumor are assessed by observing the site of the tumor and extent of airway involvement. When lesions are visible endobronchially, bronchial washings have a diagnostic yield of approximately 90%; bronchial brushings and bronchial mucosal forceps biopsy samples provide diagnosis of tissue in nearly 98% of visualized tumors. Under fluoroscopic control, transbronchial forceps biopsies, brushings, and washings can diagnose peripheral, parenchymal lesions up to 80% of the time. The visual assessment of the primary tumor can also provide a clinically useful estimate of the probability of tumor complications such as airway obstruction, postobstructive pneumonia, or hemoptysis.

Transthoracic percutaneous fine-needle aspiration (fine-needle aspiration biopsy) is used when lung lesions cannot be visualized by bronchoscopy but are accessible percutaneously. A needle guided by CT or fluoroscopy is inserted into the lesion for aspiration of cells. This procedure is most suitable for peripheral pulmonary nodules. Pneumothorax is the most common complication, with an increased risk in the patient with COPD. A positive pleural fluid cytology proves the spread of malignancy to the pleural space. Thoracentesis and pleural biopsy combined provide up to a 90% diagnostic yield in patients with malignancy.

Mediastinoscopy is an invasive procedure used for the diagnosis and staging of lung cancer. A biopsy is recommended if mediastinal lymph nodes are found on chest CT scan that are greater than 1.0 cm for the patient with clinically operable NSCLC. The patient with lymphadenopathy on chest CT scan will most likely have positive nodes on biopsy. Anterior cervical mediastinoscopy allows direct visualization and biopsy of mediastinal nodes with less risk than an exploratory thoracotomy.

Video-assisted thoracoscopic surgery is used for the staging and diagnosis of lung cancer when less invasive techniques fail to yield a diagnosis. Small thoracotomy incisions are made through which thoracoscopic instruments are inserted. Visualization of the chest and mediastinum and assessment of pleural effusions are superior to that achieved using older scopes, which may help improve diagnostic accuracy.

Thoracoscopy is useful for pleural evaluation but less useful for evaluating the lung. It is more than 90% sensitive for the diagnosis of pleural-based malignancies and peripheral lung nodules, with a specificity of 99%. With a thoracoscope, the mediastinum can be entered and nodes biopsied. Thoracoscopy affords the potential for more complete staging of patients with suspected mediastinal nodal spread and it has become a valuable adjunct to cervical mediastinoscopy and anterior mediastinotomy. There is a concern, however, about seeding the thoracoscope entrance site with tumor cells.

Subsequent Testing A head CT scan or brain magnetic resonance imaging, with and without infusion of contrast material, is recommended only in patients who have signs or symptoms of central nervous system disease. The finding of an isolated adrenal mass on ultrasonographic or CT exam requires biopsy to rule out metastatic disease if the patient is considered to be potentially resectable. NSCLC metastasizes to the adrenal glands in 18% to 38% of cases. A bone scan should be performed only in patients who complain of bone pain or chest pain or who have an elevated serum calcium level or an elevated serum alkaline phosphatase level. It is estimated that between 9% and 15% of patients with newly diagnosed NSCLC have bony metastases at presentation, with the vertebral bodies most commonly being affected. Finally, the finding of an isolated hepatic mass on ultrasonographic or CT exam requires a biopsy to rule out metastatic disease if the patient is otherwise considered to be potentially resectable.

Differential Diagnosis

The symptoms of lung cancer develop gradually in most cases and are often attributed by the patient to a smoker's cough or cold and by the patient's health-care provider to tracheobronchitis, pneumonia, influenza, pulmonary infarction, or lung abscess. Thus, it is common for a patient to delay seeking medical attention for several months from the first recognizable onset of symptoms. Several additional months of symptomatic treatment and antibiotics frequently pass before the health-care provider establishes the correct diagnosis. Much of the initial diagnostic task is to differentiate if this is a primary tumor or a metastatic cancer. This is evaluated on biopsy. Other differential diagnoses include tuberculosis, lymphoma, *Mycobacterium avium* complex, sarcoidosis, or a foreign body aspiration that has been retained.

Management

Active patient participation in decision making respects the fundamental ethical and legal doctrine of autonomy and is especially important for the patient with unresectable NSCLC, because the prognosis is often poor and symptom palliation is a central concern. Fewer than half of patients with lung cancer are candidates for resection, and only a small percentage of these are cured, so most patients with the disease require some form of palliation. Therapy should include efforts to slow the growth of the tumor and to treat complications as they arise, but above all, symptoms should be relieved.

Surgery

Surgical resection offers the best chance of cure for lung cancer. The patient with stage I or II NSCLC is routinely resected via a thoracotomy. Pneumonectomy (removal of a whole lung) and lobectomy (removal of a single lobe) are the most common of these surgical procedures. The nature of the tumor dictates the procedure, whereas pulmonary function determines if the patient can withstand the procedure. Pneumonectomy is required when the tumor or lymph nodes involve proximal structures such that a lung-conserving operation will not allow complete resection. Lobectomy is the most common resection performed for lung cancer. Such a resection allows removal of the primary tumor, associated disease, and lymph node–bearing areas while leaving a significant amount of residual functional parenchyma. Survival is equivalent for patients undergoing lobectomy or pneumonectomy for all stages of disease when a complete resection is performed. For lesions close to the lobar orifice, an adequate margin of resection often cannot be achieved. In such circumstances, a portion of the main bronchus must be included with the resection. This type of resection is termed *sleeve resection,* and it is performed as a parenchyma-sparing procedure avoiding pneumonectomy.

Very limited resection in the treatment of lung cancer has been reserved for patients with extremely poor pulmonary function who could tolerate no more than a very limited resection because of their underlying medical condition or low pulmonary reserve. Limited resections include segmentectomy, wedge resection, or lumpectomy. Segmental resection is the removal of a lung segment, and wedge resection is the removal of a small, V-shaped wedge of lung tissue. Lesions that reside more deeply within the pulmonary tissue often are not amenable to wedge resection and may require precise, local excision with laser or electrocautery assistance (e.g., lumpectomy). These techniques are used to preserve as much lung tissue as possible, and they are performed for the removal of small tumors located close to the surface of the lung. The guiding principle of surgical therapy in lung cancer is to remove the tumor completely, leaving as much functioning pulmonary tissue as possible. The aim of most operations is curative, and procedures that leave gross tumor are not warranted. Resection is abandoned if the tumor extends beyond the lung, when pleural seeding is evident, or when fixed mediastinal nodes are present.

Patients with stage I disease have a 50% to 80% 5-year survival and patients with stage II disease have a 25% to 50% survival at 5 years. However, 75% of patients present with advanced disease and significant comorbidities. Treatment decisions should consider symptom control, quality of life, the patient's value or meaning of life, and the patient's perceptions and attitudes about a specific treatment.

Chemotherapy

Neoadjuvant chemotherapy involves giving antineoplastic drugs before surgery or radiation therapy. Adjuvant chemotherapy involves administering antineoplastic

drugs after surgery or radiation therapy. Given that chemotherapy for advanced disease is marginally beneficial and noncurative, its use must be governed judiciously, with each decision evaluated individually for each patient.

Current chemotherapeutic approaches consist initially of defining new combinations of established chemotherapeutic agents that may act synergistically (Table 9.19). In addition, new drugs with novel mechanisms of action are also being investigated, both as single agents and, subsequently, as agents to be used in combination with established drugs.

Non–Small-Cell Lung Cancer Chemotherapy

Chemotherapy modestly improves median survival with distant metastatic NSCLC compared with best supportive care, but it is not curative.

If a patient has Stage I disease, there is no agreement on the role of adjuvant chemotherapy. It is more widely used with patients with Stage II and IIIA disease. Patients with Stage I and N0 Stage II disease treated with multidrug platinum-based chemotherapy show improved survival of 3 months at 5 years. Because of the toxicity, risks versus benefits must be discussed with the patient and family. Newer drugs with less toxicity are currently being studied. With patients in advanced stages, chemotherapy has shown to improve the patient's quality of life by decreasing bothersome symptoms.

For patients with Stage III lung cancer that cannot be removed surgically, chemotherapy is typically combined with definitive high-dose radiation treatments. In Stage IV lung cancer, chemotherapy is typically the main treatment, because radiation is used only for palliation of symptoms. Chemotherapy usually consists of a combination of dugs including cisplatin (Platinol) or carboplatin (Paraplatin) plus docetaxel (Taxotere), gemcitabine (Gemzar), paclitaxel (Taxol), vinorelbine (Navelbine), or pemetrexed (Alimta).

The newest developments in lung cancer treatment are targeted treatments. Whereas chemotherapy drugs cannot differentiate between normal cells and cancer cells, targeted therapies are designed specifically to attack cancer cells by attaching to or blocking targets that appear on cancer cell surfaces. Patients with advanced lung cancer with certain molecular biomarkers may receive treatment with a targeted drug alone or in combination with chemotherapy. Some of these targeted treatments include erlotinib (Tarceva), bevacizumab (Avastin), and crizotinib (Xalkori).

Table 9.19 Chemotherapeutic Agents Used to Treat Lung Cancer

Small-Cell Lung Cancer	Non–Small-Cell Lung Cancer
cisplatin* (Platinol) plus etoposide* (Vepesid, Toposar) carboplatin (Paraplatin) plus irinotecan (Camptosar)	*Localized disease:* cisplatin* (Platinol) or carboplatin* (Paraplatin) plus docetaxel* (Taxotere), gemcitabine (Gemzar), paclitaxel (Taxol and others), vinorelbine (Navelbine and others), or pemetrexed (Alimta). *Targeted treatments:* erlotinib (Tarceva) bevacizumab (Avastin) crizotinib (Xalkori)

*Current treatment of choice.

Small-Cell Lung Cancer Chemotherapy

Combination chemotherapy is capable of effecting high objective response rates in SCLC. Furthermore, the simultaneous administration of multiple agents is superior to the sequential administration of the same drugs. Chemotherapy is most effective in SCLC with an 80% to 100% response in limited-stage disease (50%–70% complete response) and 60% to 80% response in extensive stage disease (15%–40% complete response). Remissions last a median of 6 to 8 months. If the cancer recurs, the median survival time is 3 to 4 months. Among the regimens, cisplatin plus etoposide (Toposar or Vepesid) is the current treatment of choice for many reasons. In the setting of relapsed SCLC, the combination of cisplatin and etoposide is capable of producing objective response rates of equal to or more than 50% in patients who have experienced a recurrence after cyclophosphamide-based therapy. No other drug combination has yielded response rates of this magnitude in a similar setting. Further, in previously untreated patients, cisplatin plus etoposide yields excellent overall response rates and survival results that are equivalent to cyclophosphamide- or doxorubicin-based regimens, albeit with less host-related toxicity. Cisplatin plus etoposide is particularly well suited for the simultaneous administration of radiotherapy, given its lower incidence of toxicity and the putative radiation-sensitizing effect of both drugs. Thus, for many clinicians, cisplatin plus etoposide has become the de facto standard induction regimen for the patient with SCLC. Occasionally, some may use carboplatin (Paraplatin) plus irinotecan (Camptosar).

Radiation

The basic indication for radiation therapy is inoperability; in addition, radiation is sometimes used to help prevent metastasis to the brain as prophylactic cranial irradiation. Radiation therapy can modify the natural course of the disease, relieve distressing symptoms, and produce an apparent cure in an occasional patient. Long-term results, however, have been generally disappointing. One-year and 5-year overall survival rates range from 25% to 55% and from 4% to 10%, respectively.

It is used as adjunctive therapy after surgery to improve tumor control, and it is used as palliative therapy to control symptoms in others.

Non–Small-Cell Lung Cancer Radiation Radiation therapy is commonly offered to the patient with inoperable NSCLC when the cancer has not spread beyond the thorax. In this case, the asymptomatic patient or the patient who is still functioning at a high level is most likely to benefit. In addition, radiation therapy is used to shrink the tumor and control symptoms in the patient with inoperable lung cancer and to prevent brain metastasis. Treating the tumor with radiation therapy may relieve hemoptysis, shoulder and arm pain, chest pain, and dyspnea. It can be used in superior vena cava obstruction to reduce the tumor size and alleviate obstruction. Although there are currently no data that demonstrate a survival advantage for postoperative adjuvant therapy in patients with completely resected Stage II disease, regardless of whether the patient receives radiation therapy alone or radiation therapy and chemotherapy, most of these patients are treated with postoperative radiation therapy to decrease local recurrence. Unfortunately, prevention of local recurrence has not been shown to translate into survival benefit. The patient with a malignant pleural effusion or with distant metastatic disease is not appropriate for definitive thoracic radiotherapy.

Small-Cell Lung Cancer Radiation SCLC is quite sensitive to both radiation and chemotherapy. In limited-stage SCLC, the addition of both radiation and chemotherapy can increase the 5-year survival rate from about 11% to 20%. Most oncologists consider thoracic radiation therapy in combination with chemotherapy for limited-stage disease to be the standard of care. The major contribution of thoracic irradiation is local tumor control, and local control of the intrathoracic tumor is a sine qua non for cure. Thoracic radiation therapy does reduce the risk of dying of SCLC but at the price of increased toxicity. Concurrent or alternating treatment schedules appear to improve response rates over sequential chemotherapy and radiation therapy, although toxicity is more intense with concurrent therapy.

A summary of the treatment of NSCLC is shown in Treatment Flowchart 9.3.

Follow-up and Referral

When lung cancer is first detected, the patient should be referred to a specialist for staging and treatment decisions. The patient who has been successfully treated for lung cancer needs to be followed routinely. The goal of monitoring patients with unresectable lung cancer in complete remission is to detect symptomatic progression of their disease that may benefit from therapeutic intervention or symptom management. However, the great majority of patients with unresectable Stage III and Stage IV disease will not achieve a complete remission, or, if achieved, the duration of remission will be short.

A history and physical examination should be performed every 3 months during the first 2 years, every 6 months thereafter through year 5, and yearly thereafter. For the patient treated with curative intent, there is no clear role for routine x-ray evaluation in the asymptomatic patient and for those in whom no interventions are planned. A yearly chest x-ray film to evaluate for potentially curable second primary cancers may be reasonable. CT of the chest/abdomen, bronchoscopy, CBC, and routine chemistries, including liver function tests, should be performed only as indicated by the patient's symptoms. These tests do not appear to detect asymptomatic recurrent disease with a high frequency.

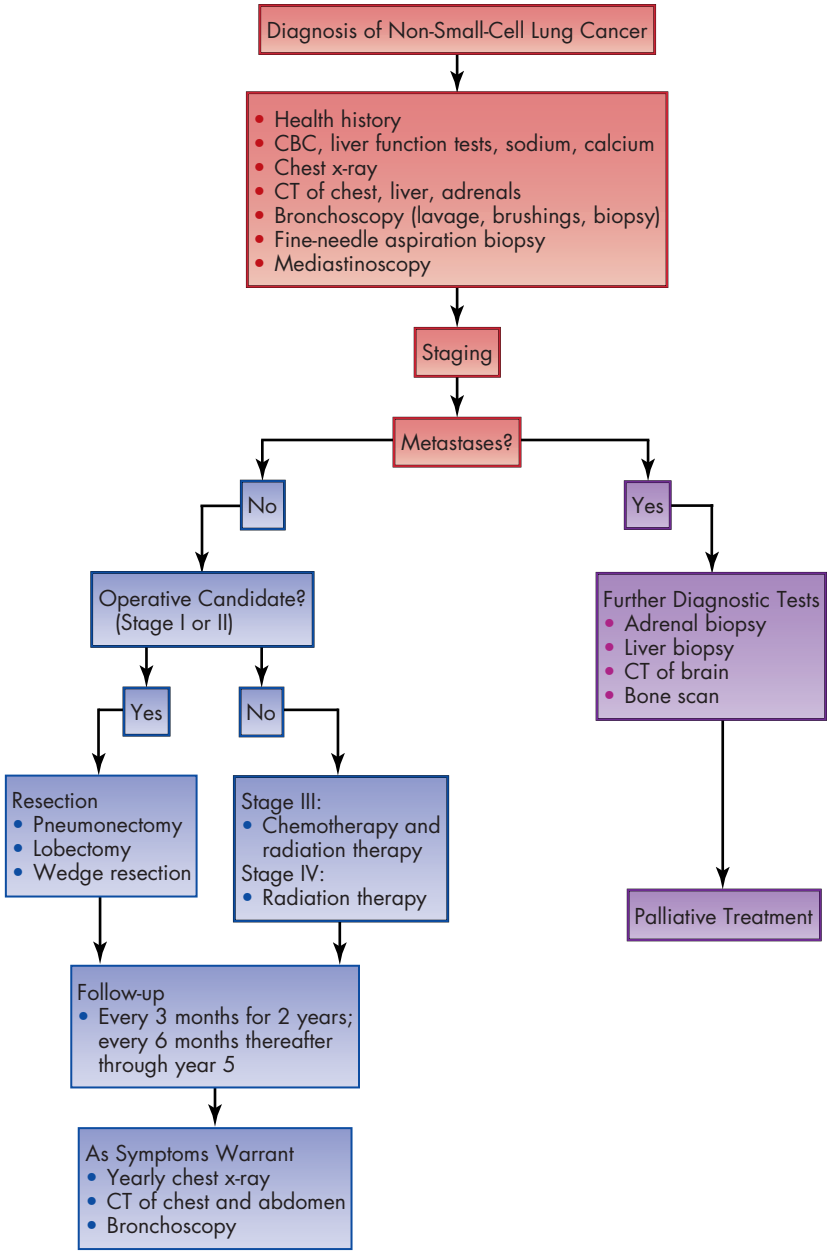
Patient Education

Assessment of learning needs and provision of information is likely to be of paramount importance for the patient at the time of initial biopsy, between diagnosis and definitive treatment, and at discharge. These are highly stressful times for patients, and they may be easily overwhelmed by the information regarding treatment options. It is important to assess what level of participation in the decision-making process is desired by the patient because that will help direct informational interventions and can reduce anxiety and psychological distress. This is particularly important for patients who have a choice between two treatment options or are deciding between participating in a clinical trial or receiving standard therapy.

Smoking cessation, never initiating smoking, and avoidance of occupational and environmental exposure to carcinogenic substances are recommended as effective interventions to reduce the risk of a second primary lung cancer in the curatively treated patient. For the patient with distant metastatic disease, the outlook is poor, and smoking cessation has little effect on overall prognosis but may improve respiratory symptoms. A tapering nicotine patch or other delivery system has been proved to increase the odds of smoking cessation when combined with behavioral interventions.

Recommendations for lifestyle change are the same for the patient with a history of lung cancer as for those who have no previous history of lung cancer. Epidemiological studies also suggest that people who consume relatively large amounts of fruits and vegetables have a lower risk of both cancer and cardiovascular disease. Antioxidant vitamins contained in fruits and vegetables prevent carcinogenesis by interfering with oxidative damage to DNA and lipoproteins; however, the use of antioxidants and/or chemopreventive agents for lung cancer (retinoic acid, beta-carotene, and selenium) is investigational.

When medical care for the patient with lung cancer shifts from curative to palliative, the patient and family must choose a care setting. Home or hospice care can provide familiar surroundings, feelings of normalcy, involvement of family, and a more comforting situation as they participate in readiness for death activities. Although



Treatment Flowchart 9.3 Treatment of Non–Small-Cell Lung Cancer

hospice has proved to be an extremely effective model for terminal care, referrals to a hospice often are not made until the final days of life. The difficulty lies in predicting when death will occur, because Medicare reimbursement requires that a hospice patient have a life expectancy of 6 months or less. Many states now have an "open access" model that allows for patients seeking curative care to still receive hospice services. Supportive resources for self-care should be provided as required by the individual situation. Patients will be able to manage less self-care as the disease progresses, and family members will require education with demonstration of care techniques and opportunities for questions and verbalization of feelings about caring for the one who is ill. Within the *Circle of Caring* model, collaborative planning is essential in helping the patient and family make informed choices and live in the moment.

INTERSTITIAL LUNG DISEASE

Interstitial lung disease (ILD) encompasses nearly 200 clinical disorders that affect the epithelium, the endothelium, or both cell surfaces of alveolar wall and satellite structures, including terminal and respiratory bronchioles. ILD comprises a heterogeneous group of diseases that cause inflammation and fibrosis of the lower respiratory tract. The term *pulmonary fibrosis* is also applied to these diseases because fibrosis of the lung is the ultimate result of ILD. The term *interstitial* is misleading in that most of these disorders have extensive alteration of alveolar and airway architecture as well. *Diffuse*

parenchymal lung disease is, perhaps, a more appropriate descriptive term for this heterogeneous group of lung diseases, because the term *interstitium* usually refers to the microscopic anatomical space bounded by the basement membranes of epithelial and endothelial cells. The entire lung parenchyma is affected, however, in ILD.

The ILDs have many common features, including similarity of patient symptoms, comparable appearance of chest x-ray films, consistent derangements in pulmonary physiology, and typical histological features. Four different infections may be associated with the cause or onset of most of the various diseases: disseminated fungus (coccidioidomycosis, blastomycosis, histoplasmosis), disseminated mycobacteria, *Pneumocystis* pneumonia, and certain viruses.

Although all of the diffuse ILDs share the common morphological characteristic of an abnormal lung interstitium, a satisfactory classification has been elusive because about 150 individual diseases have a component of interstitial lung involvement, either as primary disease or as a significant part of a multiorgan process, such as a collagen-vascular disease. Generally, ILDs are classified according to the type of agent that caused the lung injury. About one-third of patients with ILD have an identifiable agent responsible for inducing lung injury; however, the large majority of patients have disease attributable to no known cause. Therefore, ILDs are classified as those with a known cause and those with an unknown etiology; each of these groups is further subclassified according to the presence or absence of granuloma in interstitial or vascular areas.

Epidemiology and Causes

As many as 81 of every 100,000 Americans have some form of ILD. For patients with usual interstitial pneumonia, there is a slight male predominance with occurrence between ages 55 and 60. There is a slightly younger age distribution associated with some of the other ILDs (age 40–45 for respiratory bronchiolitis–associated ILD and age 45–55 for nonspecific interstitial pneumonitis). ILDs of known cause can be divided into several major subcategories. By far the largest group comprises occupational and environmental inhalant diseases; these include diseases resulting from inhalation of inorganic dusts, organic dusts, gases, fumes, vapors, and aerosols. Other categories include ILDs caused by drugs, irradiation, poisons, neoplasia, and chronic cardiac failure. The major subgroups within the category of unknown causes are idiopathic pulmonary fibrosis (IPF) and connective tissue (collagen vascular) disorders with ILD, including rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), progressive systemic sclerosis, polymyositis-dermatomyositis, and Sjögren's syndrome. Systemic vasculitides often have granulomas in tissue and include a variant of polyarteritis nodosa called allergic granulomatosis, lymphomatoid granulomatosis, and hypersensitivity vasculitis.

Seven major entities that are most frequently associated with diffuse ILD are (1) idiopathic pulmonary fibrosis, (2) bronchiolitis obliterans organizing pneumonia, (3) connective tissue (collagen vascular) diseases (SLE, RA, progressive systemic sclerosis, and polymyositis-dermatomyositis), (4) systemic granulomatous vasculitides (Wegener's granulomatosis [WG], lymphomatoid granulomatosis, and allergic angiitis and granulomatosis), (5) drug-induced pulmonary disease, (6) sarcoidosis, and (7) hypersensitivity pneumonitis.

Pathophysiology

ILD denotes a diverse group of conditions characterized by the common pathological finding of pulmonary fibrosis and similar clinical presentation of restrictive lung findings (i.e., dyspnea on exertion and chronic nonproductive cough). The term *interstitial* used to describe this group of diseases is misleading because inflammation and fibrosis affect bronchioles, alveoli, and capillary endothelia, as well as the interstitium of the lower respiratory tract. Thus, a more illustrative term for this disease is *pulmonary fibrosis.* Sarcoidosis, hypersensitivity pneumonitis, pulmonary fibrosis in connective tissue disorders (e.g., SLE, RA, tuberous sclerosis, scleroderma), and occupational pulmonary diseases are all categorized as ILDs. Tissue injury and acute inflammation are believed to be the initial pathological processes. In some conditions, such as sarcoidosis, the inciting antigen is unknown, whereas occupational pulmonary diseases are caused by repeated inhalation of environmental irritants, inorganic and organic dusts, fumes, or gases. For most ILDs, including idiopathic conditions, cigarette smoking is a primary risk factor.

In the majority of ILDs, there is a perpetuation of the inflammatory process with repeated tissue injury and aberrant wound healing with subsequent remodeling of the lung architecture. Infiltration of the lung parenchyma by various combinations of immune cells mediates this process, including neutrophils, lymphocytes, plasma cells, eosinophils, basophils, mast cells, and alveolar macrophages. Cytokine production (e.g., granulocyte colony-stimulating factor, transforming growth factor–β1, interleukin (IL)–1β, IL-8, tumor necrosis factor–alpha) drives these inflammatory and wound-healing processes. Regions of chronic inflammation can develop granulomas consisting specifically of discrete masses of lymphocytes, macrophages, and fibroblasts. In turn, fibroblast proliferation and differentiation into myofibroblast forms (i.e., cells with both fibroblast and smooth muscle cell features) lead to fibrosis (collagen deposition) or scarring of the lungs and the development of cystic airspaces known as "honeycombing."

Such pathological pulmonary tissue becomes less compliant and increasingly rigid, with consequential impedance of ventilation and gas exchange, characteristic of a progressive, minimally reversible restrictive lung disease. Diffusion capacity also worsens with increasing fibrosis

of the lung parenchyma. In turn, ventilation–perfusion mismatch, hypoxemia, and pulmonary vasoconstriction develop, and increased resistance on the right ventricle may lead to cor pulmonale (right ventriculomegaly). Hypercarbia typically manifests only in end-stage disease. Total lung capacity, functional residual capacity, residual volume, and forced expiratory volumes (FEV and FEV_1) are all commonly decreased on pulmonary function testing; however, because fibrotic lung tissue is stiffer with greater elastic recoil, rapid exhalation of a major portion of the expiratory volume may be seen, as reflected in a normal or increased FEV_1/FVC ratio on pulmonary function tests (PFTs)—a key feature distinguishing restrictive from obstructive pulmonary disease.

Interestingly, recurrent dysregulated wound healing rather than neutrophilic or immune cell–mediated inflammation has been cited as the primary pathophysiological mechanism in ILD, potentially explaining the ineffectiveness of anti-inflammatory and immunosuppressive treatments in many forms of ILD. Lung tissue biopsy is not required for the diagnosis of ILD, which may be made from a combination of clinical and radiographic findings (including PFTs and certain serum markers of underlying connective tissue disease). However, the extent of lung fibrosis observed histopathologically is perhaps the most accurate prognostic indicator for this condition. In turn, much investigation has shifted toward antifibroblast therapies for ILD aimed at decreasing pulmonary collagen deposition.

Clinical Presentation

The typical patient with ILD presents with an insidious onset of dyspnea on exertion, often accompanied by fatigue and cough. This breathlessness has no other obvious cause such as asthma, obstructive airway disease, bronchitis, or heart failure. Although emphasis is usually given to this most common presentation of patients with ILD, the provider must recognize the variability of clinical presentations. Dyspnea is a virtually constant finding in patients with IPF, but it is by no means so consistent in other ILDs. Less common but important and sometimes misleading presentations include the following:

- Fatigue in the absence of dyspnea
- Dry cough without other respiratory symptoms
- Predominant systemic symptoms (e.g., fever, weight loss)
- Abnormal-appearing (90%) chest x-ray film in the absence of symptoms
- Incidental abnormalities of PFTs (discussed in testing)

Respiratory signs such as pleuritic chest pain, visceral chest pain, wheezing, or hemoptysis do not usually occur. Half of the patients have mucus hypersecretion and expectoration. This occurrence has been correlated with glandular hypertrophy in the airway mucosa and accumulated mucus in the airways. Patients with more advanced ILD may have clubbing and cyanosis. Clinical manifestations specific to the various types of ILD are discussed in Table 9.20.

Diagnostic Reasoning

Diagnostic Tests

Initial Testing The symptoms of ILD are similar regardless of the underlying cause. In addition, the symptoms of lung involvement are nonspecific and could

Table 9.20 Interstitial Lung Diseases

Interstitial Pulmonary Fibrosis

A syndrome progressing from alveolitis to interstitial inflammation to fibrosis of the lungs.

Pulmonary Manifestations: Presents with dyspnea, cough, fatigue, adventitious crackles sounding like Velcro, tachypnea, finger clubbing, abnormal PFTs.

Management: No curative medical therapy. Nonspecific anti-inflammatory agents and immunosuppressive drugs are generally ineffective; other treatment options include cytotoxic agents and antifibrotic agents (colchicine or penicillamine).

Bronchiolitis Obliterans Organizing Pneumonia (BOOP)

A disease characterized by masses of granulation tissue in the lumens of small airways with patchy organizing pneumonia distal to these obstructions.

Pulmonary Manifestations: Presents with cough, flu-like illness, inspiratory crackles, expiratory squeaks, restrictive ventilatory defect, and abnormal diffusing capacity; chest x-ray film shows patchy alveolar infiltrates often with a ground-glass appearance.

Management: Corticosteroid therapy.

Collagen Vascular Diseases

- **Systemic Lupus Erythematosus:** Chronic, multisystem inflammatory disease of connective tissue that involves the skin, joints, serous membranes (pleura, pericardium), kidneys, hematological system, and CNS.

  Pulmonary Manifestations: May present with pleuritis with or without effusion, diaphragmatic dysfunction with reduced lung volume, acute lupus pneumonitis, diffuse alveolar hemorrhage, diffuse interstitial disease, pulmonary hypertension, and pulmonary thromboembolism.

  Management: NSAIDs, corticosteroids, immunosuppressive agents (cyclophosphamide [Cytoxan]), plasmapheresis (severe cases).

Table 9.20 Interstitial Lung Diseases—cont'd

- **Rheumatoid Arthritis:** Chronic, systemic disease characterized by recurrent inflammation of the diarthrodial joints and related structures.
  Pulmonary Manifestations: Abnormal PFTs with reduced diffusing capacity and restrictive mechanics, pulmonary nodules, BOOP, pleuritis with or without effusion, ILD.
  Management: Rheumatoid lung disease responds very poorly to drug therapy; a trial of prednisone is usually given but fewer than 10% of patients have a measurable response.
- **Progressive Systemic Sclerosis (Scleroderma):** A disorder of connective tissue characterized by fibrotic, degenerative, and occasionally inflammatory changes in the skin, blood vessels, synovium, skeletal muscle, and internal organs.
  Pulmonary Manifestations: Presents with dyspnea, bibasilar crackles, reduced lung compliance, pleural thickening, and pulmonary fibrosis on x-ray, abnormal PFTs, pulmonary hypertension, recurrent aspiration pneumonia.
  Management: No specific drugs or combination of drugs have been proved effective; in general, corticosteroids are not beneficial, and only a few patients respond to penicillamine (Cuprimine) therapy.
- **Polymyositis-Dermatomyositis:** Diffuse inflammatory myopathies of striated muscle, producing symmetrical weakness, usually most severe in the proximal muscles.
  Pulmonary Manifestations: The three types of lung disease classically described are interstitial pneumonitis, aspiration pneumonia due to esophageal dysmotility, and pneumonia secondary to hypoventilation as a result of respiratory muscle involvement.
  Management: Corticosteroids; cyclophosphamide (Cytoxan).

Systemic Granulomatous Vasculitis

- **Wegener's Granulomatosis:** Characterized by a triad of (1) necrotizing granulomatous vasculitis of the upper and lower respiratory tracts, (2) glomerulonephritis, and (3) variable degrees of vasculitis of small arteries and veins.
  Pulmonary Manifestations: Upper respiratory tract lesions include sinusitis, otitis media, nasal septal ulceration. Pulmonary manifestations vary from focal granulomatous vasculitis to diffuse alveolitis and capillaritis that may present as alveolar hemorrhage. Pulmonary function tests reveal a restrictive pattern.
  Management: Cyclophosphamide (Cytoxan) and prednisone; azathioprine (Imuran) and methotrexate (Folex, Rheumatrex) are alternative agents.
- **Lymphomatoid Granulomatosis:** A systemic disease consisting of angiocentric lymphoid granulomatous vasculitis, primarily of the lungs, with frequent involvement of the kidneys and skin.
  Pulmonary Manifestations: Presenting symptoms are usually cough, dyspnea; chest x-ray reveals multiple, bilateral, ill-defined or nodular densities that may cavitate.
  Management: Cyclophosphamide (Cytoxan) and corticosteroids; chemotherapy regimen if recurrence with malignant lymphoma.
- **Allergic Angiitis and Granulomatosis (Churg-Strauss Syndrome):** Rare disorder characterized by necrotizing angiitis of the lungs, heart, skin, and CNS with involved organs containing infiltration with eosinophils.
  Pulmonary Manifestations: Presents with an allergic history, often with asthma; chest x-ray abnormalities may range from patchy densities to large bilateral nodular infiltrates; cavitation is rare.
  Management: Corticosteroids, prednisone, azathioprine (Imuran), cyclophosphamide (Cytoxan), plasma exchange.
- **Drug-induced Pulmonary Disease:** Iatrogenic and adverse complications of various drugs (cytotoxic agents, antibiotics, immunosuppressives).
  Pulmonary Manifestations: Hypersensitivity pulmonary disease with dyspnea, nonproductive cough, lung crackles, tachypnea, diffuse linear streaks and densities in lower lung zones on x-ray.
  Management: Discontinuation of the drug or reduction in drug dosage in conjunction with corticosteroid therapy.
- **Sarcoidosis:** A multisystem syndrome of unknown etiology, involving complex cellular immune pathways; it most frequently affects the lung.
  Pulmonary Manifestations: Lung most common organ affected; PFTs reveal a restrictive pattern and small lung volumes; tissue biology demonstrates characteristic granulomas.
  Management: Corticosteroids, and other drugs such as hydroxychloroquine (Plaquenil), methotrexate (Folex).
- **Hypersensitivity Pneumonitis (Allergic Alveolitis):** Caused by inhalation of a variety of organic dusts. Dusts can be derived from animal dander and proteins; from fungi that contaminate vegetables, wood bark, or water-reservoir vaporizers; and from dairy and grain products. Colorful, descriptive names for the diseases underscore the frequent occupational nature of exposure.
  Pulmonary Manifestations: In acute form of disease, respiratory and systemic symptoms develop explosively within 4–6 hours after dust is inhaled and consist of dyspnea, cough, chills, fever, and malaise. Symptoms abate in 12 hours. With each reexposure, the acute episode occurs again. The acutely ill patient is dyspneic with inspiratory crackles in lower lung zones. Chest x-ray film shows fine, diffuse alveolar filling and variable interstitial streaks, PFTs are abnormal.
  Management: Avoidance of inhaled substance, corticosteroids (prednisone).

suggest many other causes, including obstructive lung disease, heart disease, or pulmonary vascular disease. The first symptom of ILD is usually progressive dyspnea on exertion or a nonproductive cough. The patient initially notices dyspnea only during heavy exertion; but in very advanced stages of the disease, dyspnea occurs at rest.

The occupational and environmental history is the single most helpful tool to determine whether a respiratory problem may be related to an occupational or environmental exposure (see Focus on History 9.1). A careful history must include a detailed chronological account of the patient's employment activities, social activities, travel, immune status, pets, hobbies, and environment. A thorough review of the patient's past medical history, along with current and previous medications, is also important. The goal of these questions is to determine whether the patient has been exposed to agents known to cause ILD. Many patients have an occupational history that includes exposure to one or a variety of toxic inhalation products, and this may add uncertainty to the precise onset of symptoms and may suggest the contribution of several etiological factors. The temporal relationship to the exposure may be obvious in some cases, but in others a low-grade exposure may provoke chronic illness without acute flares after exposure. The latency may be extremely long (e.g., more than 20 years for asbestosis) so that it is mandatory to take a detailed occupational history, including summer jobs and hobbies, in all patients with suspected ILD. Moreover, a history of smoking is associated with an increased risk for the development of IPF. Finally, the occurrence of familial cases of IPF suggests that genetic factors may modulate responses to causative agents.

Dyspnea in the patient with ILD is the result of increased work of breathing caused primarily by the stiffness of the lungs and by excessive minute ventilation. Hypoxemia, often aggravated by exercise, may amplify the sensation of dyspnea by carotid body stimulation. Unfortunately, patients do not always know what toxins they were exposed to, and exposures to toxins may be easily overlooked so that considerable investigation may be required. For example, fungi in cooling systems or birds in the home may be a source of allergens that can elicit hypersensitivity pneumonitis. History of medication use is also critical to diagnosing ILD. Patients who have been using drugs (e.g., nitrofurantoin) for years may not report them as medications on routine questioning. Mineral oil taken as a laxative or nose or ear drops also may not be considered medications.

Diseases in other organs may present as ILD, so a detailed review of systems is important. With occupational lung diseases, the physical exam is generally unrevealing about specific cause. It is most helpful in ruling out nonoccupational causes of respiratory symptoms or diseases such as cardiac problems or connective-tissue diseases. Chronic heart disease may present as ILD with dyspnea, cough, crackles, and interstitial-type

Focus on History 9.1 Taking an Occupational and Environmental History

General health history	• Does the patient think symptom/problem is related to anything at work? • When was the onset of symptoms, and how are they related to work? • Has the patient missed a day of work, and why? • Prior pulmonary problems • Medications • Cigarette use
Current or most relevant employment	• Job or process: title and description • Type of industry and specific work • Name of employer • Years employed
Exposure information	• General description of job process and overall hygiene • Materials used by worker and others • Ventilation/exhaust system • Use of respiratory protection • Are other workers affected? • Industrial hygiene samples and Occupational Safety and Health Administration (OSHA) data
Environmental nonoccupational factors	• Cigarettes • Diet • Hobbies • Pets
Specific workplace exposures	• Fumes/dust/fibers • Gases • Metals • Solvent • Other chemicals: plastics, pesticides, corrosive agents • Infectious agents • Organic dusts: cotton, wood • Physical factors: noise, repetitive trauma • Radiation • Emotional factors, stress
Past employment	• List jobs in chronological order • Job titles • Exposures • Military service

abnormalities on the chest x-ray film. Malignancies of virtually any organ system may spread to the lungs and present as ILD. The manifestations of the collagen-vascular diseases (e.g., rashes, Raynaud's phenomenon, fevers, arthralgias, muscle weakness) may give important clues on history taking. Dysphagia or regurgitation may relate to either recurrent aspiration or collagen-vascular disease, especially scleroderma. The connective-tissue diseases may be difficult to rule out because the pulmonary manifestations occasionally precede the more typical systemic manifestations by months or years. Patients with AIDS complicated by pneumocystosis or lymphocytic interstitial pneumonia may first present with an insidious onset of dyspnea and fatigue, as do patients with other ILDs. Therefore, sexual orientation and other possible risk factors for AIDS should be identified.

Abnormalities on the chest x-ray film may be the first clue to the presence of ILD; however, the patient with ILD may be asymptomatic with normal or abnormal chest x-ray results, or may be symptomatic with normal or abnormal chest x-ray results. The initial abnormality on the chest x-ray film is usually described as ground glass or a hazy appearance of the lungs. As disease progresses, diffuse abnormalities are found bilaterally. Pulmonary opacities (infiltrates) are usually described as small nodules (nodular), lines (reticular), or both (reticulonodular). Nodules are most commonly found in granulomatous diseases and hypersensitivity pneumonitis. The development of reticular densities is thought to be the result of edema, infiltration, or fibrosis of the septa in the periphery of the lung. A common characteristic of ILD is a progressive worsening in the opacities, with the development of honeycomb lung. The honeycomb-like appearance is created by the cyst-like spaces that characterize the pathology of advanced ILD. Many ILDs have unique radiographic presentations. For example, WG is associated with lower lobe cavities and nodules, and sarcoidosis is associated with swelling of the lymph nodes of the hilum of the lung (hilar lymphadenopathy). The hila are composed of the pulmonary arteries and their main branches, the upper lobe pulmonary veins, the major bronchi, and the lymph nodes.

High-resolution computed tomography (HRCT) has become widely used for evaluating ILDs. In addition, HRCT is unsurpassed in the detection and localization of pericardial and pleural fluid collections. HRCT examines only 1 mm of lung at each level, thus revealing some of the lung parenchyma's delicate architecture. Several signs of ILDs may be noted on HRCT. The most common are interface signs—the thickened and irregular appearance of the normally smooth interface of lung parenchyma with bronchi, blood vessels, and visceral pleura. Although HRCT is an exceptional tool for evaluation of parenchymal lung disease, it is important to note its limitations. It cannot be used to study the entire thorax; conventional CT must be used to avoid missing abnormalities between images. Some HRCT findings may be difficult to interpret without a conventional CT image to use for reference.

Serological tests for antinuclear antibodies and rheumatoid factor are positive in 20% to 40%, although rarely diagnostic, and antineutrophil cytoplasmic antibodies may be diagnostic in some settings.

A transbronchial biopsy has become the leading invasive tool for evaluating and treating patients with a wide spectrum of pulmonary disorders. In addition, the technique of bronchoalveolar lavage through the fiberoptic bronchoscope into a segmental or smaller bronchus provides a means to sample the cellular and soluble components of the lower respiratory tract. The area beyond the bronchoscope is washed with saline. The saline that is then aspirated back through the bronchoscope contains a small number of cells. The cells that are recovered include many from the alveoli and are representative of the cells associated with the inflammatory process. This procedure has aided in the diagnosis, pathogenesis, and assessment of activity of ILDs.

PFTs measure lung volumes and airflow with a spirometer. Whether the patient is symptomatic or not, PFTs should be performed to establish that disease is present, to determine its severity, and to monitor response to treatment. The sensitivity and specificity of these tests to diagnose the various ILDs is low, however. Routine spirometry values and lung volumes are often initially normal, as are resting blood gas measurements; only after exercise are gas-exchange abnormalities evident. The evaluation of the patient during exercise, although not constituting a direct measurement of respiration, gives more information than static measurements of lung volume or diffusing capacity regarding ventilation, blood flow, gas exchange, and control of breathing. PFTs usually show a purely restrictive defect in most patients with ILD. Obstructive lung disease develops gradually in some patients and more commonly in some diseases (sarcoidosis, hypersensitivity pneumonitis).

The compliance of the lungs decreases as lung involvement progresses. This is caused, in part, by fibrosis of the pulmonary parenchyma and the formation of cystic airspace. Diffusion capacity of the lung (DLCO) is a good reflection of alveolar capillary surface area. Destruction of lung parenchyma results in a reduction in DLCO as ILD progresses. An abnormal DLCO may be the earliest evidence of ILD found on standard PFTs.

The use of the thoracoscope in combination with standard surgical instruments has led to the designation video-assisted thoracic surgery or video-assisted thoracoscopy (VATS). VATS provides the same access to the hemithorax as both thoracoscopy and thoracotomy. VATS procedures are particularly useful for obtaining lung biopsies in patients with diffuse ILD. With VATS, the visualization of the lung is better than it is with a limited thoracotomy, and more areas of the lung can be sampled.

Transbronchial lung biopsy involves passing a forceps or needle through the bronchoscope. A specimen is obtained with forceps or aspirated through a needle. Pleural biopsy is useful in diagnosing granulomatous disease or malignancy of the pleura and should be performed only if these two diseases are suspected. If a specific diagnosis is not made by transbronchial biopsy, an open lung biopsy is indicated. Open lung biopsy is the most definitive way to diagnose and stage the disease so that appropriate prognostic and therapeutic decisions can be made. Depending on the age of the patient and the potential risks of the surgery in a compromised patient, empiric therapy may be initiated.

Differential Diagnosis

When confronted with a patient with unexplained dyspnea and fatigue, the differential diagnosis is immense. Pulmonary, cardiac, hematological, renal, neuromuscular, and even endocrine diseases may present with exercise intolerance of dyspnea. A complete work-up of these systems is required to determine the correct diagnosis. Some of the conditions that give rise to dyspnea, diffuse pulmonary infiltration, and granulomatous reaction include the following: extrinsic allergic alveolitis, asbestosis, silicosis, berylliosis, lymphoid granulomatosis, connective-tissue diseases, certain drugs, miliary TB, lymphoma, leukemias, PCP, and coccidiomycosis.

Management

Management of most ILDs is difficult, and different approaches are taken depending on the specific entity. Regardless of etiology, end-stage fibrosis is irreversible and untreatable. An extensive and aggressive diagnostic evaluation early on, even in the patient with relatively few symptoms, is recommended. Early clinical intervention in patients who are more likely to develop lung disease could be of considerable benefit for the patient. A good example is the identification and assessment of disease progression in diffuse lung disease found in systemic sclerosis. The first course of action when faced with a patient with ILD is to determine whether exposure to environmental agents or drugs is the cause and to discontinue the exposure. Therapeutic dilemmas arise because discontinuation of such drugs as tocainide or amiodarone may result in life-threatening dysrhythmias. Second, the best chance for therapeutic success begins with the correct diagnosis. Finally, in cases in which specific medication is employed, such as prednisone or cytotoxic agents, there is usually suppression rather than cure of the primary process. Many patients with ILD are older adults, so the decision to treat them with immunosuppressive drugs should not be taken lightly, because the toxicity and adverse effects of these medications can be substantial. In addition, anti-inflammatory and immunosuppressive treatments may be ineffective because of recurrent dysregulated wound healing rather than neutrophilic or immune cell–mediated inflammation. Investigational studies are looking at a shift toward antifibroblast therapies for ILD aimed at decreasing pulmonary collagen deposition.

Initial Management

Corticosteroids may be initiated in the therapy for ILD. A trial with them is reasonable, even for the patient who is in an advanced stage of the disease with relatively acellular and fibrotic changes in lung tissue. The best predictor of ultimate steroid responsiveness and a better prognosis is early benefit following the initial 1 to 2 months of steroid therapy. The dosage and duration of corticosteroid therapy depend on the specific disorder, but in general relatively high doses are used for the first 6 weeks (1–2 mg/kg per day, or 60–100 mg/day) over the ensuing 3 months. A period of 3 to 6 months is often required to determine the steroid responsiveness of fibrosing alveolitis, although patients with sarcoidosis and cryptogenic organizing pneumonia may respond much more quickly with lower dosages. Certain processes, such as idiopathic pulmonary fibrosis, commonly require therapy for 12 months or longer.

Subsequent Management

For the patient who is not well controlled with or responsive to corticosteroids, additional immunosuppressive therapy may be considered. Cyclophosphamide (Cytoxan), an alkylating drug, is a potent immunosuppressant and seems to be effective in patients with ILD who are not helped with corticosteroids. If improvement in the lung disease is documented after 3 months of this therapy, it should be continued for a 12-month interval. Azathioprine (Azasan, Imuran) has been used as an alternative to cyclophosphamide. Penicillamine (Cuprimine, Depen) has been used in some patients, with the rationale that it might prevent the cross-linking of abnormal collagen being synthesized in the interstitium and prevent or retard fibrosis. Exercise tolerance may be significantly improved with supplemental oxygen.

Because the pulmonary vascular bed is impaired by progressive fibrosis, pulmonary hypertension and cor pulmonale can develop; right-sided congestive heart failure can be difficult to control. Judicious use of diuretics is advised, for a significant decrease in intravascular volume may be deleterious for lung perfusion. Digitalis or antidysrhythmic drugs may be required, although adequate oxygenation is probably the best treatment for heart failure in this situation. Some patients may also develop obstruction to air flow and be troubled with wheezing and coughing that may respond to bronchodilators. Because infection may occur during immunosuppressive therapy, it is important to maintain a high index of suspicion and to treat infection aggressively. Prophylactic use of pneumococcal and influenza vaccines is encouraged. Finally, lung transplantation may be an option for patients with refractory disease limited to the chest.

Follow-up and Referral

Reassessment of disease activity is generally performed at 3, 6, 12, and 24 months and more often if needed. Responsiveness is defined as a decrease in symptoms: radiographic improvement, physiological improvement, or no further decline in clinical, radiographic, or physiological parameters. The patient should be followed for signs of infection that are masked by immunosuppressive drugs, pneumothorax, or development of lung cancer, which occurs in 5% to 10% of patients. The patient on steroids must be monitored closely during times of illness or stress and during steroid tapering or withdrawal. The patient should be encouraged to wear a medical identification bracelet. In view of exercise-related hypoxia, the patient should be assessed for benefit of supplemental oxygen during exercise. Patients with a collagen vascular disorder must be regularly assessed for progression or exacerbations of their chronic illnesses. For example, patients with RA require rest, joint protection, daily heat and exercise, and psychological support. Community resources such as a home care nurse, homemaker services, and vocational rehabilitation may be considered. Self-help groups may be beneficial for the patient. These diseases require the collaborative and integrated approach as emphasized in the *Circle of Caring* model.

Specialized testing should be undertaken and the patient referred to a pulmonologist if no specific cause of dyspnea or cough can be found; if the symptoms exceed the physiological or radiographic abnormalities identified; if empiric management (with bronchodilators, diuretics, smoking cessation) resulted in an atypical or unsatisfactory clinical outcome; if the patient needs an impairment or disability evaluation for workers' compensation or any reason; if specialized cardiopulmonary testing (e.g., lung biopsy) is needed; or if a therapeutic immunosuppressive or cytotoxic drug trial is contemplated.

Patient Education

Patients with ILD must be educated about the nature of their illness, the related diagnostic tests, and the treatment regimen for their particular type of lung disease (see Table 9.21). For example, avoidance of exposure to antigens is paramount for those with hypersensitivity pneumonitis. All patients must be advised and assisted to stop cigarette smoking to prevent further lung damage. In many cases, the most comprehensive patient education occurs within the context of a pulmonary rehabilitation program.

The need to reduce repeated admissions into expensive ICUs brought about the proliferation of formal inpatient and outpatient pulmonary rehabilitation programs in the United States for patients with chronic lung disease. The target population for these programs has been severely disabled patients with COPD or ILD, who require a broad range of comprehensive services to keep them clinically stable and out of the hospital for long periods of time. Appropriate patients with all levels of respiratory impairment, not only the severely disabled, should be referred to such programs.

Table 9.21 Educational Content for the Patient With Interstitial Lung Disease

- Respiratory anatomy and physiology
- Pathophysiology of interstitial lung disease
- Respiratory diagnostic tests:
  - Chest x-ray
  - PFTs
  - Exercise tests
  - Bronchoscopy
  - HRCT
- Self-care measures:
  - Pulmonary medications
  - Diet
  - Fluid intake
  - Smoking cessation
  - Environmental control
  - Signs of infections
- Chest therapy:
  - Relaxation and guided imagery
  - Breathing retraining
  - Controlling dyspneic episodes
  - Postural drainage
- Progressive exercise conditioning:
  - Walking programs
  - Treadmill or bicycle exercise training
  - Arm or leg range-of-motion exercises
- Respiratory equipment:
  - Oxygen therapy
  - Handheld nebulizer

Each program has criteria for referral that generally include the following patient characteristics: dyspnea on exertion, inability to carry out selected activities of daily living, repeated hospitalizations or need for home care services, time lost from work or school, and desire for educational update of self-care techniques. Moreover, the following laboratory features are inclusion criteria for pulmonary rehabilitation: reduced vital capacity in restrictive disease, reduced expiratory flow rates, hypercapnia, and hypoxemia at rest or during exercise.

The team teaches self-care educational content and implements a program of bronchial hygiene and physical conditioning, based on needs identified during the initial assessment. Group and individual instruction and counseling are provided by a variety of personnel. Patient progress is evaluated using respiratory assessment parameters and teaching–learning tools. A final evaluation with recommendations for long-range treatment is forwarded to the referring clinician.

SLEEP APNEA

Sleep apnea is defined as a temporary pause in breathing during sleep that lasts at least 10 seconds to as long as 90 seconds. For a confirmed diagnosis, this should occur a minimum of five times an hour. The three patterns of apnea are central, obstructive, and mixed. Central apnea occurs when both airflow and respiratory efforts are absent. *Central apneas* are a result of an absence of neural output from the brainstem's respiratory centers, which leads to a lack of inspiratory effort. The respiratory center in the brain fails to respond to elevated carbon dioxide concentrations. In contrast, during *obstructive sleep apnea* (OSA), respiratory efforts persist although airflow is absent at the nose and mouth. Airflow obstruction occurs when the tongue and the soft palate fall backward and partially or completely obstruct the pharynx. Finally, many adult patients exhibit mixed apneas in which both central and obstructive patterns occur.

Each apnea results in progressive asphyxiation until an arousal from sleep occurs, with a subsequent restoration of upper airway patency and airflow. A patient then usually returns to sleep quickly, resulting in another occlusion of the upper airway. Apnea and arousal cycles occur repeatedly, as many as 200 to 400 times during 6 to 8 hours of sleep. Sleep hypopnea is a period of hypoventilation, or decreased airflow, defined as a 50% reduction in thoracoabdominal movements, with a 4% fall in oxygen saturation lasting at least 10 seconds during sleep. OSA/hypopnea is present when the respiratory drive is intact but the upper airway intermittently becomes obstructed during sleep. The *respiratory disturbance index* (RDI) (also called the apnea/hypopnea index)—the number of apneas plus hypopneas per hour of sleep—may be used to define and quantify the severity of OSA. The RDI is obtained by dividing the total number of events throughout the entire night by the total sleep time in hours. An index greater than 5 is abnormal, although it probably does not become clinically significant until it reaches 20. In general, as the RDI increases, so does the severity of symptoms.

Patients with OSA may experience a number of potentially adverse physiological and neurobehavioral problems. Consequences of OSA are the result of daily exposure to abnormalities in breathing during sleep and result in long-term morbidity in the neurobehavioral and cardiovascular domains. Sleep-disordered breathing is an independent risk factor for the development of hypertension and, subsequently, left ventricular dysfunction. The patient with combined coronary artery disease (CAD) and OSA may have an increased cardiac risk because of worsening of the relationship between myocardial oxygen demand and supply as a result of apnea-associated hypoxemia and activation of the autonomic nervous system (Table 9.22).

Moreover, cardiac dysrhythmias, usually occurring during apneic episodes, have been reported to be a significant complication of OSA. In a 2013 long-term study of 10,701 adults conducted by the Mayo Clinic Sleep Disorders Centers, people with sleep apnea had a higher risk of dying from sudden cardiac arrest (Gami et al, 2013). In addition, sleep quality may be influenced by apnea-associated activation of the central nervous system (CNS) (arousals) and ischemia-associated arousals. Timely diagnosis and treatment of CAD, as well as sleep apnea, is necessary for these patients.

Table 9.22 Possible Consequences of Sleep Apnea

Pulmonary hypertension
Systemic hypertension
Cardiac dysrhythmias
Right or left ventricular failure
Right ventricular hypertrophy
Myocardial infarction (increased risk of)
Stroke (increased risk of)
Nocturnal angina
COPD (exacerbation of)
Insulin resistance
Endothelial cell dysfunction

OSA can cause mild pulmonary hypertension, even in the absence of pulmonary disease. Sustained pulmonary hypertension, often associated with clinical evidence of right ventricular failure, has been observed in about 20% of OSA patients. It is hypothesized that repetitive hypoxemia during sleep may lead to vascular remodeling in susceptible patients and thus cause pulmonary hypertension during the day. Further, because the patient with OSA is often obese or has pathological lung function resulting in abnormalities of daytime arterial blood gas (ABG) values, pulmonary vasoconstriction is another mechanism inducing pulmonary hypertension.

Epidemiology and Causes

Sleep apnea is an extremely common clinical disorder; as such, it has major public health implications. Unrecognized and untreated OSA in the general adult population, most of whom are in the most productive period of their lives, contributes to significant and disabling psychomotor deficits. An estimated 40 million Americans are chronically ill with various sleep disorders, and 38,000 cardiovascular deaths annually are directly attributable to OSA; yet the vast majority of Americans with sleep disorders remain undiagnosed and untreated. This, in turn, costs billions of dollars in accidents in the home, at the workplace, and in traffic.

Approximately 4% of women and 9% of men have significant OSA. OSA is most prevalent in men older than age 50 and in postmenopausal women, probably related to hormonal changes, although it is seen in younger people as well. Usually men have a significantly

higher pharyngeal and supraglottic resistance than women, which makes them more susceptible to pharyngeal collapse and OSA and may contribute to the male predominance of the syndrome. Pharyngeal resistance increases with age in normal men, possibly related to greater body weight, and it is widely believed that the risk of developing OSA increases with age in men. This assumption, however, is far from conclusive. Moreover, once a disorder is labeled as predominantly a male condition, clinicians may be less likely to think about it in women and, hence, less likely to refer women to sleep disorder centers. Compared with OSA, central sleep apnea syndrome is uncommon. In most sleep laboratories, patients with central sleep apnea syndrome constitute fewer than 10% of patients tested. The division between central and obstructive sleep apnea is not as clear-cut as it might appear because many patients with central sleep apnea present with clinical features more suggestive of OSA. It is possible that in some patients upper airway occlusion triggers a central, rather than an obstructive, apnea. Support for this notion comes from the finding that some patients with central sleep apnea can be successfully treated with nasal continuous positive airway pressure (CPAP).

The cause of OSA is poorly defined but appears to be multifactorial; upper airway tract malformation, oropharyngeal muscle dysfunction, and abnormal respiratory drive each play a greater or lesser role. A number of recognized anatomical abnormalities are associated with narrowing of the upper airway and predispose patients to OSA. Conditions associated with facial dysmorphism or mandibular abnormalities show a predisposition to OSA and include adenotonsillar hypertrophy, choanal atresia, micrognathia (small mandible), retrognathia, macroglossia, nasal septal deviation, and craniofacial dysostosis. Micrognathia is particularly associated with OSA because a small or retropositioned mandible places the base of the tongue closer to the posterior pharyngeal wall and interferes with the efficiency of the genioglossus muscle in keeping the tongue out of the narrowed pharynx.

There is increasing evidence that sleep apnea has a familial distribution. Relatives of a person with sleep apnea have approximately twice the normal risk of having sleep apnea. Most adult patients with OSA, however, have no specific skeletal or soft tissue lesion obstructing the upper airway, but they often have a small, congested oropharyngeal airway. Symptoms of sleep apnea are present two to six times more frequently in family members of affected patients than in a control population.

Obesity and alcohol consumption are well recognized as aggravating factors. One possible explanation for the relationship between obesity and OSA is that the upper airway is narrowed in the obese patient as a result of increased fat deposition in the pharyngeal walls. Fat in the neck plays the largest role. Neck (or collar) size is the best indicator of the presence of sleep apnea. Approximately 30% of snoring males with a collar size larger than 17 inches will have OSA. Neck size in women is less well investigated, but when it is over 16 inches, it increases the risk for sleep apnea. Another possible explanation for this relationship is the fact that the obese patient often has smaller lung volumes, particularly functional residual capacity, than the nonobese patient; this, in turn, can indirectly influence upper airway size and contribute to upper airway narrowing. About 16% of patients with sleep apnea, however, are not obese. Any factor that interferes with the arousal mechanism, such as alcohol consumption, could lead to more profound and prolonged apneas. Alcohol, which reduces upper-airway muscle tone, and sedatives or hypnotics, which reduce the arousal mechanism, exacerbate OSA. There is considerable evidence that OSA carries a substantial morbidity and mortality, particularly from cardiovascular complications.

Pathophysiology

Sleep is divided into two states—rapid eye movement (REM) sleep and non–rapid eye movement (NREM) sleep. NREM sleep is further divided into four stages, based on changes in the electroencephalogram (EEG) pattern. Normal sleep begins with Stage I, which is characterized by slow eye movements, usually preceding sleep onset. Stage II involves further slowing of the EEG, with the presence of sleep spindles and slow eye movements. Stage III is manifested by low-frequency delta waves with occasional sleep spindles but no slow eye movements. Finally, Stage IV is characterized by high-voltage delta waves. REM sleep is characterized by desynchronized, low-voltage, fast activity that occurs about every 90 minutes beginning after 1 to 2 hours of NREM sleep. The normal adult sleeper alternates between NREM sleep and REM sleep approximately every 90 minutes throughout the night.

Typically, during the lighter stages of NREM sleep, the breathing pattern is irregular because of the decrease in respiratory drive associated with the stimulatory effect of wakefulness and decreased metabolic rate associated with sleep. In the deeper stages of NREM sleep, breathing is typically very regular; however, overall ventilation is reduced compared with that during wakefulness. During REM sleep, the respiratory drive is irregular because of the transient decrease in ventilatory response to chemical and mechanical stimuli. The influence of sleep on the upper airway is similar to its effects on other skeletal muscles, resulting in a general loss of muscle tone and a reduction in tidal volume and minute volume. The sleep structure of the patient with OSA is characterized by the loss of physiological REM/NREM alternation, as well as by a deficit of REM and slow-wave sleep. This can be caused by sleep fragmentation as a result of the high amount of arousals related to respiratory events.

Central Sleep Apnea

Etiological factors of central sleep apnea are found mainly in disturbances in the respiratory control system

in the brainstem. The cause of such disturbances of the breathing control system remains unclear in most cases, however. Central apneas are commonly seen in altitudes where hypoxemia induces hyperventilation with associated alkalosis. Cheyne-Stokes respiration with central apneas may also occur in the patient with congestive heart failure. Neurological diseases affecting the brainstem may cause breathing pattern disorders in sleep. Well-known neurological diseases such as arteriosclerosis in the older adult, infarctions, tumors, hemorrhage, trauma with damage of this region, encephalitis, poliomyelitis, or other infectious diseases may cause central apnea during sleep, even though no abnormalities of breathing patterns are present during wakefulness. If the neural pathways from medullary respiratory groups to motor neurons of the ventilatory muscles are interrupted, the metabolic control of breathing may be disturbed. This may occur after cervical cordotomy.

Obstructive Sleep Apnea

The underlying pathophysiology of sleep apnea is complex and not fully understood. However, it is generally accepted that patency of the upper airway is dependent on the action of oropharyngeal dilator and abductor muscles, which are normally activated in a rhythmic fashion during inspiration. The available evidence indicates that in OSA, the site of upper airway obstruction is the pharynx and that obstruction of the pharynx during sleep is a result of an imbalance between the forces that serve to dilate the pharynx and those that promote pharyngeal closure. The upper airway is subject to collapse when the force produced by these muscles for a given cross-sectional area of the upper airway is exceeded by the negative airway pressure generated by inspiratory activity of the diaphragm and intercostal muscles. Upper airway obstruction can occur if the suction pressure is too high or if the counteracting forces of the dilating muscles are too weak, for any given suction pressure.

The subsequent obstructive apnea results in progressive and sometimes profound hypoxia and hypercapnia. These apnea-associated changes in P_{O_2} and P_{CO_2} stimulate ventilation, resulting in increasing inspiratory efforts. Eventually the progressive hypoxemia and hypercapnia and/or the associated increase in inspiratory effort result in arousal of the patient. With this usually transient arousal occurs augmentation of upper airway dilator muscle activity to an extent proportionately greater than the simultaneous augmentation of diaphragm activity. This leads to deocclusion of the pharynx and restoration of airflow. During the subsequent brief period of ventilation, P_{O_2} rises and P_{CO_2} falls. The rapid resumption of sleep, however, results in reocclusion of the upper airway. This cycle of events may recur hundreds of times each night, triggering repeated arousals that may contribute to many of the clinical features of OSA (Fig. 9.2).

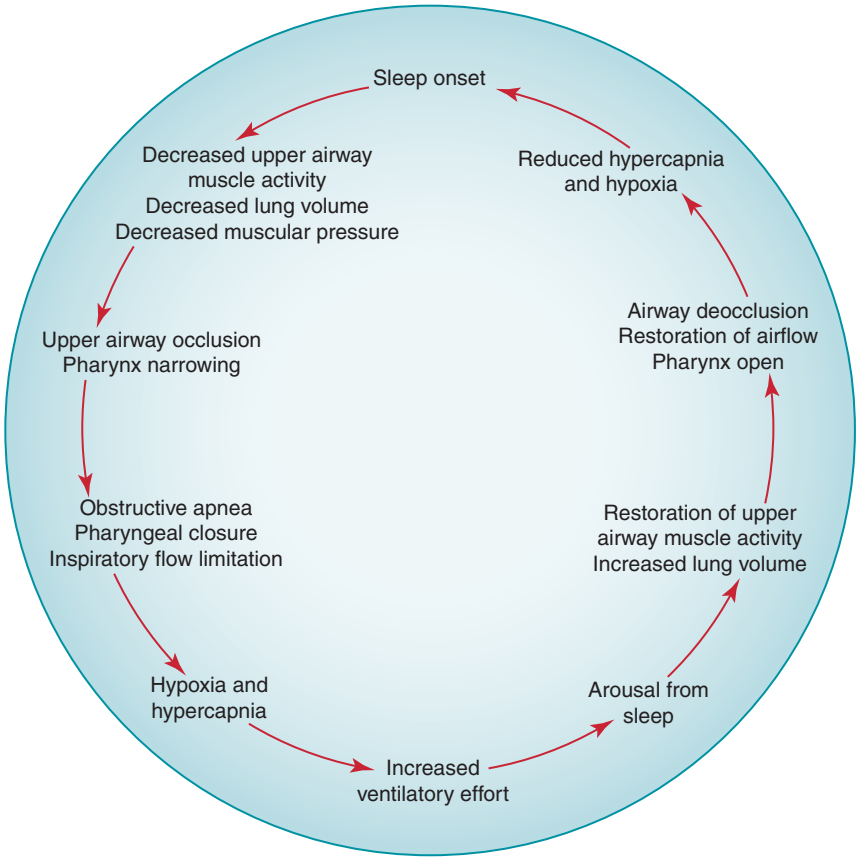


Figure 9.2 Pathogenesis of obstructive sleep apnea.

Clinical Presentation

Subjective

The diagnosis of OSA is not difficult to make: the symptoms are typical, and the major risk factor is relatively obvious. Patients with sleep apnea have both nighttime and daytime symptoms (Table 9.23). Hypersomnolence is the single most important presenting symptom of sleep apnea and frequently identifies which patient will require and accept specific therapy.

Hypersomnolence is not tiredness, fatigue, or lassitude; it is clear-cut, uncontrollable sleepiness. It develops over a long period and is first experienced by a patient as sleep onset when attention is not demanded (e.g., when watching television, sitting in a college lecture, or waiting at a traffic light). Eventually, more alerting situations are affected, such as long-distance driving or quiet conversation. Daytime symptoms include a morning headache (from hypercapnia) and neuropsychological disturbances, including falling asleep while performing purposeful activities. These episodes can occur during work or social functions and can lead to embarrassment, domestic discord, decreased work productivity, loss of employment, and an increased incidence of accidents. The patient may complain of nocturnal restlessness, frequent urination or enuresis, and choking.

The patient usually reports impaired intellectual performance, such as decreased concentration, ambition, and memory loss. Patients with sleep apnea also report limiting social contact because of their fear of sleepiness and falling asleep. Personality changes such as irritability and moodiness are seen in about 50% of patients, and more severe psychiatric disturbances such as major depression and psychosis have been reported. Sexual dysfunction is common (e.g., diminished libido, even though men with apnea can obtain an erection). Persons with sleep apnea may note nocturnal palpitations or skipped heartbeats. OSA is characterized by loud snoring that is repeatedly interrupted by episodes of complete upper airway obstruction and resolves with temporary arousal. The snoring of OSA is both loud (it can be heard in an adjacent room) and habitual (it occurs nightly). Hypoxemia and hypercarbia of varying degrees frequently accompany apnea or hypopnea. It is not uncommon for some patients to regularly desaturate to oxygen saturation levels below 70% and, occasionally, below 60%. Apneas and hypopneas often result in arousal from sleep, which then terminates the breathing disturbance and results in a surge in blood pressure (BP). Once aroused, the CNS can respond appropriately to the partial or complete closure of the pharynx with a brief contraction of the pharyngeal dilating muscles. This restores upper airway patency and permits resumption of airflow, with subsequent reversal of the hypoxemia and hypercarbia. Arousals often last for only 1 to 3 seconds and are not recognized by the patient. Occasionally, during the arousal that terminates the apneic event, the bed partner may witness arm flailing or other gross movements.

On awakening in the morning, the patient is often completely unaware that he or she aroused several hundred times during the night. It is believed that recurrent arousals and the consequent sleep disruption are the causes of many of the daytime symptoms and effects of sleep apnea. Automobile accidents have been reported to occur 2.0 to 2.6 times more frequently among patients with OSA than among other individuals, a consequence that contributes to many unnecessary and costly days in the hospital.

Clinically, patients with central sleep apnea usually show less daytime sleepiness than do patients with other types of apnea. Sleep disruption, frequent awakening, shortness of breath after awakening, and signs of right heart failure such as peripheral edema are observed quite often. The patient with central sleep apnea tends to have a normal body weight. Psychiatric symptoms such as depression may occur as well. As in obstructive apnea, oxygen desaturation and consequent hemodynamic disorders may be observed.

Table 9.23 Conditions Presenting With Excessive Daytime Sleepiness

- Sleep apnea syndrome
- Narcolepsy
- Idiopathic hypersomnia
- Periodic limb movements in sleep
- Psychiatric disorders
- Drug and alcohol dependency
- Insufficient sleep syndrome
- Circadian disorders (jet lag, shift work)
- Obesity-hypoventilation syndrome (Pickwickian syndrome)
- Hypothyroidism
- Seizure disorder
- Depression

Objective

The predominant clinical manifestations of OSA reflect the risk factors: obesity (particularly of the upper body), increased neck size, crowded oropharynx (tonsillar hypertrophy and enlargement of soft palate [uvula] and tongue, as well as lateral peritonsillar narrowing), retrognathia, and micrognathia.

Diagnostic Reasoning

Diagnostic Tests

OSA should be suspected whenever hypersomnia and snoring coexist. The recording of specific historical details from the patient and his or her spouse is crucial to the diagnosis, particularly because the patient sometimes does not realize the severity of the sleepiness. This

is perhaps because he or she finds it socially unacceptable or has slipped into it so gradually. Initial testing may take the form of determining how easy it is for a patient to fall asleep or, alternatively, how difficult it is for the person to remain awake. This type of testing may include both subjective and objective assessments. Two common subjective assessments of sleepiness are the Stanford Sleepiness Score (SSS) and the Epworth Sleepiness Scale (ESS). The SSS is used to record the degree of sleepiness experienced by a patient at a given time and does not necessarily relate to his or her overall propensity to fall asleep. It is an introspective measure of sleepiness where the patient rates his or her alertness on a 7-point scale at different times during the day. If the score falls below a 3 when he or she should be feeling alert, a serious sleep deficit exists. The SSS can be found at www.stanford.edu/-demet/sss.html. The ESS measures sleepiness as a reflection of a patient's tendency to fall asleep during eight specific nonstimulating situations. Each situation is scored from 0 to 3. A total score of 10 is considered abnormal. The ESS can be found at www.stanford.edu/-dement/epworth.html.

The definitive test for sleep apnea is an overnight polysomnogram. This all-night recording of the patient's sleep, performed in a sleep center, is the gold standard for identifying the presence, type, and severity of sleep apnea. The standard raises two major problems, however. First, the test is not accessible to many patients because it is limited to specialized sleep centers; second, it is expensive. The polysomnograph is a multichannel recorder that records the patient's eye movements, airflow, respiratory movements, leg movements, EEG readings, pulse oximetry, electrocardiograph (ECG) readings, and snoring. From such records, apneas, hypopneas, and snoring-related arousals are scored. The RDI is calculated from the number of apneas plus hypopneas per hour. Recently, multichannel devices that record a limited number of parameters (e.g., respiratory movements, airflow, snoring, pulse oximetry, and ECG) have been introduced for home studies, which may be comparable to a full polysomnogram.

The development of large numbers of limited diagnostic systems in recent years represents a recognition of the logistical problems involved in gaining access to large sleep centers. Unfortunately, there is no uniformity among these devices, and the only consistent variable common to all such systems is the oxygen saturation level. Most offer some measure of respiration, based either on nasal flow or chest bands. In the patient with OSA, the polysomnogram demonstrates frequent episodes of apnea with corresponding periods of oxygen desaturation as demonstrated by pulse oximetry. The effort to breathe remains intact during the periods of OSA, as evidenced by the movement of the lower chest and abdomen.

If the polysomnogram is negative for OSA in the patient with significant daytime sleepiness, a multiple sleep latency test (MSLT) should be performed in a sleep center to rule out narcolepsy. The MSLT is performed the day after the polysomnogram. The patient is instructed not to take any medications such as sedatives and certain antidepressants for 2 weeks before the test. The patient is allowed to take four or five 15- to 20-minute naps 2 hours apart. Healthy subjects have a sleep latency of 10 to 20 minutes in the MSLT. A test is considered consistent with excessive daytime sleepiness if sleep onset occurs within 5 minutes. The presence of two sleep-onset REM episodes in the appropriate clinical setting is diagnostic of narcolepsy.

The syndrome of periodic limb movements (PLMs) (also known as nocturnal myoclonus or periodic leg movements) consists of stereotypic periodic leg (or arm) movements during sleep that may or may not be associated with arousals. If enough arousals occur, sleep may be so fragmented that daytime sleepiness results. Because patients with narcolepsy frequently have PLMs, any patient with excessive daytime sleepiness and PLMs on a polysomnogram should be questioned carefully concerning narcoleptic manifestations.

An otolaryngological exam should be performed. In addition, screening with a home nocturnal pulse oximetry has a high negative predictive value if no desaturations are seen. Erythrocytosis is common. A hemoglobin level and thyroid function tests should also be performed.

Differential Diagnosis

A number of disorders present with excessive daytime sleepiness (see Table 9.23). Drug addiction and depression can masquerade as sleep apnea, especially in the older adult patient, in whom a number of apneas during sleep may be considered normal. Certain diagnostic tests, such as ABGs, thyroid function testing, PFTs, the ECG, and chest x-ray exam, are routinely indicated to determine the potential cause, presence, or severity of signs of hypoxic exposure occurring as the result of repetitive apneas during sleep. A recording of the patient's usual amount and pattern of sleep may be instructive.

Management

Obstructive Sleep Apnea

Currently, the first line of treatment for OSA is medical management. The treatments for OSA include the following:

- General measures: Avoidance of alcohol, sedatives, and hypnotics; weight loss; and other (less effective) measures, including pharmacological agents, oxygen therapy, and nasal dilators
- Specific measures: Position therapy, positive airway pressure (CPAP, bi-level systems, auto-CPAP), and oral appliances

OSA and its treatment are highly dependent on patient behavior. Clinicians have both an opportunity and

a responsibility to advise patients of the profound influence that their behavior can have on disease severity and outcome. For patients who cannot tolerate medical treatment or who do not desire long-term medical therapy, surgical treatment of sleep apnea should be considered.

Elimination of Risk Factors A reasonable first step in the management of the patient with sleep-disordered breathing is to identify and subsequently eliminate, or avoid, the risk factors. The adverse effects of alcohol on upper airway stability during sleep and the arousal response to chemical stimuli mandate that the patient with OSA be instructed to abstain from alcohol. Although not invariably associated with OSA, obesity is usually present in this patient population. Weight reduction may result in significant improvement in OSA and sleep quality, and may obviate the need for further therapeutic interventions. Efforts in this regard represent a major, lifelong therapeutic challenge, best approached by utilizing the multidisciplinary resources of the physician, nutritionist, psychologist, and a peer support system. It is difficult to accomplish and maintain weight loss, but it is very beneficial to patients with sleep apnea when they do so. Benefits of weight loss in obese patients with sleep apnea include reduced RDI, reduced BP, and optimal CPAP pressure; improved pulmonary function, daytime ABGs, polycythemia, sleep structure, and oxygen saturation; elimination of snoring; and prevention of relapse after surgical treatment.
