CBs have been found associated with the aggregates formed in CAG triplet expansion diseases and ataxin-1; mutated in ►Spinocerebellar ataxia type 1 (SCA1) it has been shown to interact with coilin. The role of these findings in the disease pathogenesis is yet to be established.

Spinal Muscular Atrophy (SMA) is an autosomal recessive disease characterized by motor neuron degeneration associated with muscular atrophy and paralysis; it is usually caused by mutations of the surviving motor neurons 1 gene (SMN1). SMN is a 294 amino acid protein, ubiquitously expressed; it bears no homology to other known proteins and its function is still unknown. It is localized both in the cytoplasm and in the nucleus where it is found in two different nuclear organelles: Cajal bodies (CBs) and Gems (for Gemini of CBs). Pathogenesis of SMA is not clearly understood but reduction of SMN levels results in an alteration of CB structure.

Alteration of CBs in cancer has not been thoroughly studied yet and a role for these organelles in cancer has not been clearly established. However cancer cell lines often show an increased number of CBs and some alteration of CBs can be found in specific cancers. In ►MLL-ELL leukemia (►Acute myeloid leukemia) the presence of the MLL-ELL fusion protein results in alteration of CBs structure and altered localization of coilin. The TLS/CHOP fusion protein generated by the t(12;16) translocation (►Chromosome Translocations), found in liposarcomas shows high transforming capacity and is in part localized in CBs.

In conclusion, while recent studies have started to shed light on the function of CBs and on the interrelationship between these organelles and other nuclear structures, more work is required to clearly understand the molecular mechanisms involved in their formation and clarify their different roles in nuclear function. This in turn will provide information on their potential role in the pathogenesis of a range of human diseases.

CAK1 Antigen

►Mesothelin

Cal

Definition

Is a member of the ►zyxin family of proteins. Also known as migfilin.

►Lipoma Preferred Partner

Calcineurin

Definition

Is a highly conserved, Ca^{2+}/calmodulin-dependent serine/threonine phosphatase, also called protein phosphatase 2B (PP2B). Calcineurin is best known for its role in the Ca^{2+}-dependent regulation of the nuclear factor of activated T-cells (NF-AT) pathway which is involved in T-cell activation.

►Calreticulin

Calcitonin

Girish V. Shah
Department of Pharmacology, University of Louisiana College of Pharmacy, Monroe, LA, USA

Definition

Calcitonin (CT) is a 32-amino acid peptide synthesized in mammals by the C cells of the thyroid gland. Several extrathyroidal sites including the prostate gland, gastrointestinal tract, thymus, bladder, lung, pituitary gland, and central nervous system (CNS) also produce this peptide molecule.

Characteristics

Almost all cells of human body synthesize and secrete procalcitonin (proCT), a precursor of the CT peptide, in response to infection/►inflammation. Only cells of the thyroid and ►neuroendocrine organs can process proCT to produce mature CT molecule. CT sequence among various species shows remarkable divergence. However, all sequences contain 32 amino acids, a carboxy-terminal proline amide, and a disulfide bridge between cysteine residues at positions 1 and 7. In addition to CT, other biologically and chemically diverse molecules such as CT gene-related peptide (CGRP), ►adrenomedullin (►ADM), and ►amylin (AMY) are considered as CT family of peptides because of their ability to interact with CT receptor (CTR) and induce biological response. Each of these peptides displays selective tissue distribution and distinct physiological effects. For example, CGRP is predominantly present in central and peripheral nervous system, and is important for neurotransmission and neuromodulation. ADM is relatively abundant in vascular space, and plays an important role in the regulation of cardiovascular and respiratory functions, and CT is essential for calcium balance. However, CT does not regulate calcium in extrathyroidal tissues but is implicated to play an important role in cell growth, cell differentiation, and other regulatory functions.

Biosynthesis

Four CT genes, CALC-I, CALC-II, CALC-III, and CALC-IV with significant nucleotide homologies have been identified. However, CT is encoded by only CALC-I gene. CALC-I and CALC-II encode two different forms of CGRP, CGRP-I and CGRP-2. CALC-III is thought to be a pseudo gene, and CALC-IV produces AMY. Human (h) CT (CALC-I) gene is located in the p14qter region of chromosome 11. CT gene encodes two distinct peptides CT and CGRP, which arise by tissue-specific alternative splicing of the same primary mRNA transcript. The primary mRNA transcript is spliced almost exclusively to CT mRNA in thyroid, and to CGRP in the nervous system.

CT is synthesized as part of a larger precursor protein of 136 amino acids. The DNA sequence of the hCT gene predicts that the hormone is flanked in the precursor by N- and C-terminal peptides. Both N-terminal and C-terminal flanking peptides are detected in the plasma and thyroidal tissues of both normal and ►medullary thyroid carcinoma (MTC) patients. However, no biological function for either of these two peptides has been conclusively determined. Cyclic adenosine monophosphate (cAMP), pentagastrin, and progesterone are potent stimulators of CT gene expression. In contrast, testosterone and estrogens have inhibitory effect.

There is evidence for ►polymorphisms in CALC-I gene that leads to increased risk for ovarian ►cancer in carrier women (T-C 624 bp upstream of translation initiation codon); and 16 bp microdeletion polymorphism has been reported in a family multiple cases of unipolar and bipolar depressive disorders.

Biological Actions

Actions on Bone

CT is the only hormone that inhibits bone resorption by direct action on osteoclasts in the bone. It is characterized by the rapid loss of osteoclast ruffled borders, reduced cytoplasmic spreading, decreased release of lysosomal enzymes, and inhibition of collagen breakdown. This role is physiologically more relevant at times of stress on skeletal calcium conservation such as pregnancy, lactation, and growth, when bone remodeling by osteoclasts and the consequent release of calcium stores in the bone need to be tightly regulated to prevent unnecessary bone loss. In normal adult humans, even large dose of CT has little effect on serum calcium. However, in pathologies created by increased bone turnover such as thyrotoxicosis, ►metastatic bone disease, or Paget's disease, CT treatment effectively inhibits bone resorption and lowers serum calcium.

Renal Actions

CT increases urinary excretion rate of sodium, potassium, phosphorus, and magnesium. CT also enhances 1-hydroxylation of 25-hydroxy vitamin D in the proximal straight tubule by stimulating the expression 25-hydroxy vitamin D 1-hydroxylase.

Central Actions

Central administration of CT produces analgesia, affects sleep cycles producing insomnia, major reduction in slow wave sleep and long period of alteration of rapid eye movement (REM) sleep and wakening. The centrally mediated actions of CT correlate well with the location of CT binding sites. CT also demonstrates multiple hypothalamic actions such as modulation of hormone release, decreased appetite, gastric acid secretion, and intestinal motility. Administration of CT in clinical situations of bone pain is very effective in ameliorating the pain symptoms.

Other Actions

CT and its receptors have been identified in a large number of other cell types and tissue sites suggesting multiple roles for CT–CTR axis. CTR binding sites have been identified in the kidneys, brain, pituitary, testis, prostate, spermatozoa, lung, and lymphocytes. There is evidence to suggest the involvement of CT in cell growth and differentiation, tissue development and tissue remodeling. CT appears to be important for blastocyst implantation and development of the early blastocyst.

CT in Cancer

Overexpression of CT has been reported in cancer-derived cells from ►thyroid, ►lung, ►breast, ►prostate, ►pancreas, ►pituitary, ►bone (osteoclastoma, osteogenic sarcoma), and embryonal carcinoma, suggesting the deregulation of CT expression is an important event in several malignancies. The results from our laboratory have shown that CT and CTR are present in undifferentiated basal cells, but absent in differentiated secretory cells of normal human prostate gland. However, CT and CTR become detectable in malignant secretory epithelium suggesting malignancy-associated deregulation of CT/CTR expression. CT and CTR transcripts in malignant human prostate become detectable as early as high-grade ►PIN, and progressively increase with increase in tumor grade. In human pancreas, CTR is present in benign as well as malignant regions but CT is exclusively detected in malignant sections of multiple pancreatic carcinomas, including ductal adenocarcinomas.

Mechanism of CT Action

Receptors

CT acts by binding to receptors on the plasma membrane of responding cells. CTR cDNA has been cloned in multiple mammalian species. Analysis of the protein translated from CTR cDNA sequence reveals the size of approximately 500 amino acids, and the receptor belongs to the class B family of G protein-coupled receptors (►GPCRs), which also includes numerous potentially important drug targets. The human CTR gene is located on chromosome 7 at 7q21.3. The CTR gene exceeds 70 Kb in length, comprises of at least 14 exons, separated by introns ranging in size from 70 nucleotides to >20,000 nucleotides.

Multiple polymorphic sites in CTR gene have been identified, and several of them lead to lower bone mineral density in postmenopausal women.

Receptor Isoforms

Human CTR (hCTR) is known to exist in mutiple isoforms that arise from alternative splicing of the same primary transcript. The two most common hCTR variants arise by alternative splicing of intracellular domain 1. The most common variant (Type 1 hCTR) leads to the addition of a 16 amino acid insert in the first intracellular loop. Alternative splicing of this small exon leads to the expression of type 2 hCTR, which differs from type 1 hCTR (abundant in the brain and the kidneys) by the absence of a 16-amino acid insert in the first intracellular loop. Type 2 CTR is predominantly expressed in malignant prostate and pancreatic cells. It has been shown that the lack of 16-amino acid insert in

first intracellular loop enables type 2 hCTR to coactivate both adenylyl cyclase and phospholipase C. In addition, another receptor referred as calcitonin receptor-like receptor (►CRLR) has been reported.

Modulation of CTR Specificity

CTR displays high affinity for CT, but low affinities for other CT family peptides. However, the ligand specificity of CTR is significantly altered when it binds to a ►RAMP protein. Several ►RAMPs have been identified but three (RAMP1, RAMP2, RAMP3) are investigated. hCTR displays low affinity for AMY, but association with RAMPs enables hCTR to bind AMY with high affinity. Similarly, ligand specificity of CRLR depends on the complexed RAMP. For example, CRLR-RAMP1 serves as CGRP receptor whereas CRLR-RAMP2 acts as ADM receptor. CRLR-RAMP3 displays high affinity for ADM as well as CT. This phenomenon opens up a possibility that ligand specificity of CTRs can be regulated by modulation of RAMPs expression.

CTR Signaling

G protein-Mediated Signaling

The intracellular mechanisms by which CTR produces biological effects are still being elucidated. However, the signaling pathways appear to vary with cell type as well as animal species. As with most other GPCRs, the CTRs show coupling with multiple G proteins, which also depends on the isoform of CTR. For example, type I CTR preferentially couples to ►Gαs, leading to the activation of adenylyl cyclase and elevation in the intracellular levels of cAMP. The inhibitory action of CT on osteoclasts is accompanied by increase in cAMP levels. Forskolin, a direct activator of adenylyl cyclase, as well as dibutyryl cAMP, which elevates intracellular cAMP levels independent of adenylyl cyclase, mimic CT actions on bone resorption. Similarly, CTR is known to activate adenylyl cyclase in kidney as well as in cancers of lung, breast, and bone.

Unlike type 1 CTR, type 2 CTR simultaneously couples with Gαs and ►Gαq, leading to the coactivation of adenylyl cyclase and phospholipase C. This results in the elevation of intracellular levels of cAMP, as well as inositol triphosphates, and thence increased cytosolic calcium levels. This, together with coliberated diacyl glycerols, activates protein kinase C. In brain tissue, CT couples to G proteins other than Gαs as indicated by limited activation of adenylyl cyclase in neural tissues. In hepatocytes, CT increases cytosolic calcium levels without activating adenylyl cyclase. In LLC-PK1 kidney cells, CT increases either intracellular cAMP levels or cytosolic calcium levels in a cell cycle-dependent manner; and in pituitary lactotrophs, CT inhibits TRH-induced increases in cytosolic levels and activation of protein kinase C. In ►prostate cancer cells, CT coactivates protein kinases A and C, and pathways activated by these enzymes play an important role in CT-stimulated growth, invasiveness and tumorigenicity of prostate cancer cells.

G Protein-Independent Signaling

Recent evidence suggests that GPCRs also activate G protein-independent signaling by interacting with proteins referred as GPCR interacting proteins (GIPs). GPCRs activate this signaling by binding to GIPs through one or more of structural interacting domains such as ►Src homology 2 (SH2) and SH3, plackstrin homology, ►PDZ and Eva/WASP homology (EVH) domains.

Examination of CTR sequence reveals that the last four amino acids at the extreme C-terminus of the ►C-tail form E-S-S-A tetramer (amino acids 447–50), which conforms to the canonical type I ►PDZ ligand. A single serine-to-alanine substitution in the PDZ ligand of prostate CTR almost abolished CT-elicited increase in invasiveness and tumorigenicity of PC-3 prostate cancer cell line, raising a strong possibility that metastasizing ability of CTR is dependent upon its ability to interact with intracellular proteins containing ►PDZ domain(s). CTR seems to induce ►metastasis by disassembly of tight junctions on prostate cancer cells, which leads to the loss of cell polarity, activation of proteases such as urokinase type plasminogen activator, matrix metalloproteinases 2 and 9. These results raise a possibility that the prevention of interaction between CTR and its intracellular partner through the PDZ ligand can be an effective strategy to prevent CT-mediated metastasis. With current advances in medicinal chemistry and peptide mimetics, it should be possible to design a small peptide of 4–6 amino acids or a small molecule to prevent this interaction.

CT also activates ►phosphoinositol-3-kinase (PI3K)–Akt–Survivin pathway and induces chemoresistance and ►apoptosis in multiple prostate cancer cell lines through as yet uncharacterized mechanism. CT activated protein kinase A plays a key role in multiple actions of CT on prostate cancer cell lines, suggesting that both, G protein-dependent and G protein-independent actions of CTR may act in concert to increase oncogenicity of prostate cancer cell lines.

Significance of CT–CTR axis in Cancer: Clinical Aspects

CT is "Oncogene" for Prostate Cancer but "Tumor Suppressor" for Breast Cancer

Although growing body of evidence suggests elevated expression of CT and CTR in multiple cancers, extensive studies on CT actions have been conducted only in ►prostate cancer and ►breast cancer (►tumor suppressor) cell lines. Interestingly, CT displays sexual dimorphism in these two cancers, raising a possibility

of the modulatory role of sex hormones on CT actions in these two organs. For example, CT is a potent ►oncogene for prostate cancer as indicated by the progressive increase in CT and CTR expression in primary prostate cancers with tumor progression, and potent stimulatory actions of CT on tumorigenicity of prostate cancer cell lines. In contrast, CT and CTR is constantly expressed in normal mammary ductal epithelium, the loss of CTR expression is associated with the progression of breast cancer to ►metastatic phenotype, and CT inhibits growth of some breast cancer cell lines. Although opposing actions of CT on prostate and breast cancer cell lines remain to be thoroughly investigated, initial studies in the author's laboratory suggest that CT protects junctional complexes in breast cancer cell lines, and estradiol attenuates the actions of CT in estradiol receptor-positive breast cancer cell lines. These results emphasize the importance of CTR actions on junctional complexes in cancer, and its significance in cancer cell growth and metastasis.

CT is an Angiogenic Factor

►Angiogenesis, the process of new vessel formation or neovascularization, has aroused increasing interest over last 25 years. Expansion of the tumor cell mass is dependent on both the degree of tumor vascularization and the rate of angiogenesis. Our recent results have demonstrated the presence of CTR in ►HMEC-1 cell line, and that CT stimulates in vivo angiogenesis in nude mice, and directly stimulates all major phases of in vitro angiogenesis including endothelial cell migration, invasion, proliferation, and tube morphogenesis. The stimulatory actions of CT on in vitro angiogenesis are comparable to the actions of ►vascular endothelial growth factor (VEGF). Importantly, silencing of CTR in HMEC-1 cells completely abolishes CT-induced tube morphogenesis. Furthermore, ►prostate and thyroid cancer cell lines expressing high levels of CT form large, highly vascular tumors. In contrast, the silencing of CT expression in these cell lines markedly reduces tumor growth and vascularity. These results may also explain the findings that malignancies displaying high levels of CT expression (such as MTCs and ►multiple endocrine neoplasias) also produce highly vascular tumors. Considering that therapeutic use of CT for pain relief is fairly widespread in cancers as well as other diseases, it will be important to consider oncogenic and angiogenic effects while determining CT therapy in these patients.

In summary, CT and CTR expression has been well-investigated in ►breast and prostate carcinomas. CT is a potent stimulator of tumor growth, angiogenesis, and metastasis in prostate cancer cell lines. In contrast, CTR expression is lost with breast cancer progression, and CTR attenuates growth of breast cancer cell lines. Significant expression of CT and CTR has also been reported in MTCs, multiple endocrine neoplasias, and ►carcinomas of lung, ►pancreas, ►gastrointestinal tract, ►thymus, and ►bladder. However, the significance of CT–CTR axis in these carcinomas remains to be investigated.

Calcitriol

David Feldman, Aruna Krishnan, Jacqueline Moreno, Srilatha Swami
Division of Endocrinology, Department of Medicine, Stanford University School of Medicine, Stanford, CA, USA

Synonyms

CALCITRIOL; Activated vitamin D; 1α,25-Dihydroxy-vitamin D_3

Definition

Calcitriol, the hormonally active form of vitamin D, is the major regulator of calcium homeostasis in the body and is critically important for normal mineralization of bone. Calcitriol is produced by sequential hydroxylations of vitamin D in the liver (25-hydroxylation) and the kidney (1α-hydroxylation) to produce the active hormone. Like other steroid hormones, calcitriol, working through the vitamin D receptor (VDR), functions by a genomic mechanism similar to

the classical steroid hormones to regulate target gene transcription. In other words, vitamin D is converted into a hormone that acts similarly to other hormones (steroids, thyroid hormone, retinoids, etc.) whose mechanism of action is via nuclear receptors. The traditional actions of calcitriol are to enhance calcium and phosphate absorption from the intestine in order to maintain normal concentrations in the circulation and to provide adequate amounts of these minerals to the bone-forming site to allow mineralization of bone to proceed normally. This action is critical to prevent rickets in children and osteomalacia in adults. However, in the past two decades, it has become increasing clear that calcitriol has many additional functions that implicate the hormone in a wide array of actions relating to bone formation as well as to other areas unrelated to bone or mineral metabolism including antiproliferative, prodifferentiating and immunosuppressive activities. Pharmaceutical companies and academic centers have actively studied analogs of calcitriol in an attempt to design a drug with increased potency to treat osteoporosis, cancer or autoimmune diseases while being less likely to cause hypercalemia and renal stones, the predictable side-effects of high doses of calcitriol, Several recent reviews of the mechanism of action and function of calcitriol have been published as well as a comprehensive book addressing all areas of vitamin D.

Characteristics

Vitamin D exists in two forms, vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol). When written without a subscript the designation vitamin D denotes either D_2 or D_3. Sunlight, in the form of UV-B rays, cleaves the B ring between carbon-9 and 10 to open the ring and create a secosteroid structure. By this process the precursor (provitamin) molecules, 7-dehydrocholesterol in animals and ergosterol in plants, are converted to the secosteroids, vitamin D_3 and vitamin D_2, respectively. The two secosteroids differ only in the presence of a methyl group at carbon 28 and a double bond between carbon 22 and 23 on the side chain of vitamin D_2. Vitamin D_2 and vitamin D_3 are handled identically in the body and converted, via two hydroxylation steps, first in the liver and then in the kidney to the active hormones, $1,25(OH)_2D_2$ or $1,25(OH)_2D_3$ (calcitriol). Calcitriol then acts in multiple target tissues throughout the body by binding to its nuclear receptor, the vitamin D receptor (VDR) to regulate gene expression. Since few dietary sources contain high levels of vitamin D, sunlight exposure or ingestion of supplements or vitamin D-supplemented food is essential to maintain adequate vitamin D levels. In recent years it is being increasingly recognized that vitamin D deficiency in many people is related to inadequate sunlight exposure, dark skin, living in northern latitudes or other life-styles that limit vitamin D production.

Calcitriol and Cancer

A number of epidemiologic studies have found a protective relationship between vitamin D status and decreased risk of cancer. Higher rates of cancer mortality have been observed in regions with less sunlight UV-B radiation, among African-Americans and among overweight people, each associated with lower levels of circulating 25(OH)D, the precursor of calcitriol. These data suggest that there is a beneficial effect of vitamin D on cancer development and mortality. The preponderance of observational studies of vitamin D status in relation to the risk of colon, breast, prostate and ovarian cancers has found that vitamin D sufficiency lowers cancer risk. Several studies have demonstrated an inverse relationship between sunlight exposure and the incidence of colon and prostate cancers. Studies correlating the measured plasma levels of vitamin D metabolites with cancer incidence have shown an inverse relationship between plasma 25(OH)D levels and colorectal cancer whereas in the case of prostate cancer, the results have been variable. Several studies have also examined the association between polymorphisms in the VDR gene and the risk for colon and prostate cancers and the results have also been variable but suggestive that some forms of VDR alter the risk of developing cancer.

Mechanisms

VDR, the receptor through which calcitriol exerts its actions, is expressed in many normal and malignant cell types indicating a wide array of previously unrecognized potential targets for calcitriol action. In many of these normal and malignant cells, calcitriol and its analogs exert pleiotropic actions to inhibit cell proliferation and promote differentiation. A number of important mechanisms have been implicated in calcitriol-mediated growth inhibition. A primary mechanism appears to be the induction of cell cycle arrest in the G_1/G_0 phase, due to an increase in the expression of cyclin-dependent kinase inhibitors such as $p21^{Waf/Cip1}$ and $p27^{Kip}$, inhibition of cyclin-dependent kinase activity and regulation of the phosphorylation status of the retinoblastoma protein (pRb). As the loss of the expression of cell cycle regulators has been associated with a more aggressive cancer phenotype and decreased prognosis and poorer survival, these observations suggest that calcitriol may be a suitable therapy to inhibit cancer progression. In addition, calcitriol induces apoptosis in some cancer cells and down-regulates anti-apoptotic genes like *bcl-2*. Other mechanisms include the stimulation of differentiation, modulation of growth factor actions and regulation of the expression and function of oncogenes and tumor

suppressor genes. The inhibition of invasion and metastasis of tumor cells as well as the suppression of angiogenesis have also been shown to contribute to the anti-tumor effects of calcitriol. Recent studies in prostate cancer have revealed anti-inflammatory effects of calcitriol through the inhibition of prostaglandin synthesis and actions as well as the inactivation of stress-induced kinase signaling and down-stream production of inflammatory cytokines. Since inflammation and prostaglandins are associated with carcinogenesis and cancer progression, these anti-inflammatory actions suggest yet another role for vitamin D in cancer chemoprevention and treatment.

Role of Vitamin D or Calcitriol in Cancer Prevention or Therapy

Because of its actions to inhibit cell proliferation and promote differentiation, calcitriol has been considered a good candidate for possible "chemoprevention" or "differentiation" therapy in a number of malignant cell types that possess VDR.

Colon Cancer

VDR are present in the colon, in colon cancer cell lines as well as in surgically removed colon cancers. The possibility that calcium and/or vitamin D may be active in decreasing colon cancer has been examined by several groups and an adequate intake of calcium (in the range of 1,800 mg/day) and vitamin D (800–1,000 IU/day) has been found in some studies to have a protective effect against the development of colon cancer. Studies in a number of colon cancer models have demonstrated the tumor inhibitory and pro-differentiation effects of calcitriol or its analogs both *in vitro* and *in vivo*. A recent study in the APC(min) mouse model has demonstrated that both vitamin D and calcium individually exert inhibitory effects on the development of precancerous polyps and exhibit a synergistic effect when used together. VDR expression correlates with colon cancer prognosis: high VDR levels are associated with favorable prognosis and VDR expression is down-regulated in high grade tumors.

Breast Cancer

VDRs are present in normal breast and breast cancer cell lines and in many human cancer specimens. Adequate calcium and vitamin D intake has been shown to enhance survival rates among breast cancer patients in some studies. Calcitriol suppresses the growth of human breast cancer cell lines in culture and also *in vivo* in xenografts of human breast cancer cells in nude mice and carcinogen-induced breast cancer in rats. A number of investigators have shown that calcitriol or its analogs exhibit antiproliferative effects in cultured breast cancer cells through a number of different mechanisms. Calcitriol has also been shown to decrease estrogen receptor-alpha levels in breast cancer cells and inhibit estrogen stimulation of breast cancer cell growth. In addition to its antiproliferative effects, calcitriol stimulates apoptosis in some breast cancer cells and may enhance the responsiveness of breast cancer cells to conventional cytotoxic agents. Studies in VDR null mice (mice in which the VDR was genetically deleted) reveal that calcitriol participates in the negative growth control of normal mammary gland. Disruption of VDR signaling results in abnormal morphology of the mammary ducts, an increase in preneoplastic lesions and accelerated mammary tumor development suggesting that vitamin D compounds may play a beneficial role in the chemoprevention of breast cancer.

Prostate Cancer

In a prediagnostic study with stored sera, calcitriol blood levels were found to be an important predictor for palpable and anaplastic tumors in men over 57 years of age but not for incidentally discovered or well differentiated tumors. VDR are present in prostate cancer cell lines and in normal prostate. Calcitriol inhibits the growth of all these cell types in culture. Calcitriol and vitamin D analogs exert antiproliferative effects in multiple prostate cancer models and several mechanisms mediate these effects. The induction of apoptosis may also play some role in the growth inhibitory activity of calcitriol in some prostate cancer cells. One of the recently discovered molecular mechanisms mediating calcitriol effects in prostate cells is the inhibition of the synthesis and actions of growth-stimulatory prostaglandins, through multiple calcitriol actions including a decrease in the expression of the pro-inflammatory molecule, cyclooxygenase-2 (COX-2). Moreover calcitriol has been shown to cause synergistic inhibition of prostate cell growth when combined with non-steroidal anti-inflammatory drugs (NSAIDs), suggesting that a combination of vitamin D or its analogs with NSAIDs may be useful in prostate cancer therapy. Calcitriol also induces the expression of MAP kinase phosphatase-5 in primary prostate cells leading to the inactivation of the stress kinase p38 and inhibition of interleukin-6 production. These new mechanisms of action support an anti-inflammatory role for calcitriol in prostate cancer and suggest that it may have beneficial prostate cancer chemopreventive effects. The efficacy of calcitriol as a chemopreventive agent has recently been evaluated using mutant mice, that recapitulate stages of prostate carcinogenesis from the pre-cancerous lesion known as prostate intraepithelial neoplasia (PIN), to high-grade PIN, to adenocarcinoma. The findings reveal that calcitriol is beneficial at the early-stage preventing the development of high-grade PIN, providing support for its use in the chemoprevention of prostate cancer.

Several vitamin D analogs exhibit greater antiproliferative potency than calcitriol, raising the possibility of the therapeutic potential of these drugs in the treatment of prostate cancer. Clinical trials have begun to address the utility of calcitriol or its analogs in treating prostate cancer patients. Recent studies have demonstrated that intermittent administration of very high doses of calcitriol are well tolerated by prostate cancer patients without significant toxicity or renal stones. In combination with the chemotherapy drug docetaxel, calcitriol given at extremely high doses once weekly, produced favorable effects on the time to disease progression and survival. An unanticipated benefit of the combination therapy was decreased side-effects of docetaxel. A phase III placebo-controlled randomized trial is currently under way testing the safety and efficacy of this combination in prostate cancer patients.

Other Malignancies

Calcitriol or other related vitamin D compounds have been shown to exhibit anti-cancer effects in multiple other malignancies as well. The growth inhibitory action of calcitriol on tumor cells was first demonstrated in human melanoma cells. Since then a large body of evidence has accumulated indicating the antiproliferative and pro-differentiation effects of calcitriol in melanocytes as well as malignant melanoma cells and melanoma xenografts. Evidence for a potential beneficial role of vitamin D compounds in hematologic, ovarian, pancreatic, and lung cancers has also been developed. Clinical trials employing calcitriol or vitamin D analogs are currently under way to evaluate the benefits of vitamin D therapy in chemoprevention or therapy of a number of cancer types.

Note Added in Proof

After this article was written the phase III trial in advanced prostate cancer patients to compare docetaxel plus calcitriol with docetaxel plus placebo was halted because of safety concerns in the clacitriol arm of the study. The details are not yet available to explain the nature of the problem.

Calcium-Binding Proteins

Meenakshi Dwivedi, Joohong Ahnn
Department of Life Science, Hanyang University, Seoul, Korea

Definition

Calcium-binding proteins are ►proteins that participate in calcium signaling pathways by binding to Ca^{2+}. The most ubiquitous Ca^{2+}-binding protein, found in all eukaryotic organisms including yeasts, is calmodulin. With their role in signal transduction, Ca^{2+}-binding proteins contribute to all aspects of the cell's functioning, from homeostasis to ►cancer.

Characteristics

Normal cell cycle division is a highly coordinated progression of molecular events that is subject to control mechanisms from both outside and inside the cell. Commitment to cell cycle initiation is made from outside and occurs as a response to extracellular signals such as growth factors. Inside the cell, control mechanisms exist to determine the timing of intracellular events such as nuclear and cytoplasmic cleavage. Under normal conditions, growth-regulating mechanisms endeavor to maintain homeostasis. Homeostasis within a cell is regulated by the balance between proliferation, growth arrest, and ►apoptosis. Intracellular Ca^{2+} is an important modulator of a variety of biochemical processes associated with cell cycle progression. With few exceptions, the controls exerted by intracellular Ca^{2+} are transduced through site-specific interactions with specialized Ca^{2+}-binding proteins. There exist at least three main families of Ca^{2+}-binding proteins. The first of these is represented by proteins that possess one or more EF-hand helix–loop–helix structural motifs predicting Ca^{2+}-binding domains as typically found within calmodulin. The second class of Ca^{2+}-binding proteins is known generically as annexins. A possible third family of Ca^{2+}-binding proteins is the "calreticulin-like" group of proteins that include ►calreticulin, Grp78, endoplasmin, and protein disulfide isomerase. Ca^{2+} has also been implicated in cell growth under pathological states. An

altered cellular response to extracellular calcium ion concentration is one of the earliest changes induced in mouse epidermal cells by chemical carcinogens. However, whereas some human breast cancer cell lines and leukemia cell lines exhibit Ca^{2+}-induced cell proliferation, other carcinoma cell lines exhibit retarded growth in the presence of Ca^{2+} or no sensitivity to Ca^{2+} at all. In a human breast cancer cell line, which is sensitive to Ca^{2+}, the administration of calcium channel antagonists lowered intracellular (Ca^{2+}) and inhibited cell proliferation. A sustained physiological elevation of intracellular calcium ion concentration (Ca^{2+}i) may be responsible for a loss of proliferative potential in neoplasmic keratinocytes. It appears from preliminary evidence that Ca^{2+} is not only important to cell cycling and growth in normal cells, but the abnormal regulation of Ca^{2+} may also contribute to changes in these processes in disease conditions like cancer.

EF-Hand Motif Calcium-Binding Proteins

The ►EF-hand protein structural motif was first discovered in the crystal structure of parvalbumin. It consists of two alpha helices positioned roughly perpendicular to one another and linked by a short loop region (usually about 12 amino acids) that often binds calcium ions. A consensus amino acid sequence for this motif has aided the identification of new members of this family that now has over 200 members. A few of these proteins are present in all cells, whereas the vast majorities are expressed in a tissue-specific fashion. Some members, like S100 family, calcineurin, calmodulin, etc. have proved to be useful therapeutic markers for a variety of cancers.

S100 family: The S100 ("Soluble in 100% saturated solution with ammonium sulfate") family, the largest family within the EF-hand protein, comprises at least 26 members, 19 of which (S100A1–16, profillagrin, trychohyalin, and repetin) are located in the epidermal differentiation complex situated at 1q21, while S100B, S100G, S100P, S100Z, and S100A7L2–S100A7L4 are present at other genomic locations (21q22, xp22, 4p16, 5q14, and 1q22, respectively). Their gene structure is highly conserved, in general comprising three exons and two introns, of which the first exon is noncoding. The S100 family is a remarkable group of proteins that acquired highly specialized functions during their evolution, even though they are small proteins (9–13 kDa acidic proteins) with a single functional domain. S100 proteins, which exhibit dramatic changes in the expression, are involved in tumor progression and include S100A1, S100A4, S100A6, S100A7, and S100B (11–14), whereas S100A2 has been postulated to be a tumor suppressor (Table 1). Such changes might be caused by rearrangements and deletions in chromosomal region, which are frequently observed in tumor cells. Although in most cases, the function of S100 proteins in cancer cells is still unknown, the specific expression patterns of these proteins can be used as a valuable prognostic tool.

The other members of EF-hand motif Ca^{2+}-binding family involved in cancer are calcineurin, recoverin, calretinin, oncomodulin, etc. (Table 2).

Annexins and Other non-EF-Hand Motif Proteins

Annexin (AnxA1) is a Ca^{2+}-binding and acidic phospholipid binding protein with antiinflammatory properties. AnxA1 has been found in leukocytes, tissue

Calcium-Binding Proteins. Table 1 S100 proteins involved in cancer with characteristic features

S100 protein	Previous name	Cancer type	Characteristic features
S100A2	CAN19, S100L	Esophageal SCC	Function in carcinogenesis is dependent upon the context of tissue and associated tumor type as well as stage of malignancy
		Thyroid	
		Oral SCC	
		Laryngeal SCC	
		Melanoma	
		Skin tumors (other)	
		NSCLC	
		Lung SCC	Marker of patient prognosis
		Gastric	
		Lymphoma	
		Prostate	
		Ovarian	
		Breast	
S100A3	S100E	Astrocytomas	Level of S100A3 protein expression identified pilocytic astrocytomas

Calcium-Binding Proteins. Table 1 S100 proteins involved in cancer with characteristic features (Continued)

S100 protein	Previous name	Cancer type	Characteristic features
S100A4	CAPL, Calvasculin, MTS1, Metastasin, p9Ka, FSP1	Thyroid carcinoma	Stimulate angiogenesis
		NSCLC	Overexpression is associated with many different cancer types
		Colorectal	
		Gastric	
		Prostate	Poor patient prognosis in breast, colorectal, NSCLC and bladder cancers
		Breast	
		Gallbladder	
		Bladder	
		Pancreas	
		Esophageal SCC	
		Melanoma	
		Oral SCC	
S100A5	S100D	Meningioma	Expression can be associated with prognostic value in recurrence of meningiomas
S100A6	CABP, CACY, Calcyclin, MLN 4, PRA, Prolactin receptor-associated protein	Thyroid	Upregulation of S100A6 appears to be an early event in progression towards pancreatic cancer
		Pancreas	
		Breast	
		Lung	
		Melanoma	Potentially act as a predictor of clinical outcome
		Colorectal	
S100A7	PSOR1, Psoriasin	Breast	Expression is restricted to keratinocytes and breast epithelial cells
		Esophageal SCC	
		Bladder SCC	
		Melanoma	Overexpression has a role in early breast tumor progression
		Skin SCC	
		Gastric	
S100A8	Calgranulin A, MRP-8, MIF, NIF, P8, CFAG, CGLA, CP-10, Calprotectin	Prostate	Upregulated in PIN and in prostatic adenocarcinomas
		Breast	
		Esophageal SCC	
		HNSCC	
		Gastric	
		Pancreas	Early involvement of the proteins in prostate cancer
		Bladder TCC	
		Endometrial	
		Ovarian	
		Colorectal	
S100A9	Calgranulin B, MRP-14, P14, Calprotectin	Prostate	Upregulated in PIN and in prostatic adenocarcinomas
		Breast	
		HNSCC	
		Esophageal SCC	
		Liver (hepatocellular)	
		Gastric	
		Lung	
		Ovarian	

Calcium-Binding Proteins. Table 1 S100 proteins involved in cancer with characteristic features (Continued)

S100 protein	Previous name	Cancer type	Characteristic features
S100A10	CAL1L, CLP11, GP11, p10, ANX2LG	NSCLC	Annexin 2 protein ligand
		Gastric	Overexpressed in human renal cell carcinoma
		Renal cell carcinoma	
		Lymphoma	
S100A11	Calgizzarin, MLN70, S100C	Breast	Downregulated at transcriptional level in malignant bladder cells
		Bladder	
		Prostate	
		Thyroid	Expression may be involved in tumor suppression and better prognosis
		Lymphoma	
		Gastric	
		Colon	Cytoplasmic staining pattern in Papillary carcinomas
S100A12	Calgranulin C, MRP6, p6, CAAF1, ENRAGE	Esophageal SCC	Downregulated
S100A14	BCMP84, S100A15, S114	Esophageal SCC	Used for CTC monitoring in peripheral blood
		Circulating tumor cells	
S100A16	S100F, DT1P1A7	Circulating tumor cells	Used for CTC monitoring in peripheral blood
S100B	S100, S100 protein (beta chain), NEF	Melanoma	Putative cancer biomarker
S100P	S100E, MIG9	NSCLC	Isolated from placenta
		Pancreas	
		Prostate	Upregulation is early event in pancreatic cancer valuable marker for the prediction of clinically relevant early pancreatic lesions
		Breast	
		Colon	

SCC, squamous cell carcinoma; HNSCC, head and neck SCC; NSCLC, nonsmall cell lung carcinoma; TCC, transitional cell carcinoma; CTCC, circulating tumor cells.

Calcium-Binding Proteins. Table 2 Other EF-hand motif family members

EF-hand motif protein	Cancer type	Characteristic features
Recoverin	Cancer-associated retinopathy	Autoimmune response
Calretinin	Colon adenocarcinoma and mesothelioma of epithelial type	Belongs to the calbindin subgroup, autoantigen in a paraneoplastic disease
Sorcin	Ovarian carcinoma	Overexpression leads to paclitaxel resistance
Calcineurin B	Squamous cell carcinoma of cervix, pancreatic cancer	Calcineurin B subunit appears to be a significant biological response modifier due to its anticancer effects
Oncomodulin/ Parvalbumin	Carcinoma cell lines characterized by translocative activity	Related to motile behavior of carcinoma cells, can be a possible candidate for tumor marker
Calmodulin	Osteoclast apoptosis	Calcium ion receptor in neoplastic cells

macrophages, T-lymphocytes, and epithelial cells of the respiratory and urinary systems. Cellular functions of AnxA1 include regulation of membrane trafficking, cellular adhesion, cell signaling, and membrane fusion in exocytosis and endocytosis. The AnxA1 protein is involved in maintaining normal breast biology. The *AnxA1* gene expression may provide data about the future therapeutic plan of breast carcinomas. The

decreased expression of *ANXA1* gene in normal histological sections of breast may warn the clinician that a malignant version of the cancer is about to form from the benign gland. This observation carries an important prognostic clinical value on microscopic reading of the surgical specimen, especially if these normal glands are adjacent to surgical margins. Similar result was reported as a prognostic factor with down-regulation of AnxA1 and other Anxs in the development of the lethal prostatic carcinoma phenotype.

The other major protein that belongs to this category is clusterin (CLU). CLU is a disulfide-linked heterodimeric protein associated with the clearance of cellular debris and apoptosis. In prostate, breast, and colorectal cancers, the CLU was found to have anti- or proapoptotic activity regulated by calcium homeostasis. Reports so far suggest "two faces" of CLU activity: the calcium-dependent cytoplasmic localization of CLU positively correlates with cell survival, whereas nuclear translocation of this protein promotes cell death in calcium-deprived cells. The cytoplasmic retention and high level of the 50-kDa CLU protect tumor cells from apoptotic stimuli induced by chemotherapeutic drugs or natural ligands, such as FasL, whereas its nuclear localization (nCLU) enhances cell apoptosis. The 50-kDa CLU isoform is mainly overexpressed in cancer cells and retained in the cytoplasm, promoting cancer progression and aggressiveness. Cytoplasmic CLU could easily translocate into the nucleus in the presence of various inducers, such as IR, chemotherapy, hormones, or cytokines, or depletion of cellular calcium. These findings support CLU as a valid therapeutic target in strategies employing novel multimodality therapy for advanced prostate cancer.

Calreticulin-like Proteins

Calreticulin is a 46-kDa Ca^{2+}-binding chaperone protein found across a diverse range of species. The human gene for calreticulin is located on chromosome 19 at locus p13.3–p13.2 and the homologous gene in the mouse maps to chromosome 8. Calreticulin at the cell surface may play a role in cell adhesion, cell–cell communication, and apoptosis. Calreticulin has also been implicated in the pathology of some cancers. The protein also plays an important role in autoimmunity and cancer. For example, it appears that calreticulin might be an excellent molecular marker for prostate cancer. The expression of calreticulin is downregulated in metastatic melanoma and ►squamous cell carcinoma, whereas significantly upregulated in colon cancer. Further, the N-domain of the protein has been reported to have inhibitory effects on tumors and to inhibit ►angiogenesis on endothelial cells. This observation is of great interest because the development of angiogenesis inhibitors is currently a highly promising approach in anticancer therapy.

Definition

The calpains represent a unique class of intracellular protein degrading enzymes. This class of ►proteases was named "calpains" to reflect their dependency upon calcium ions for proteolytic activity, and homology to the ►papain family of cysteine proteases. In mammalian species, the calpain protein family is comprised of 15 members, of which nine are ubiquitously expressed in all tissues and the remainder are expressed in a tissue-specific manner. The ubiquitously expressed calpain 1 and calpain 2 are the most well characterized isoforms. Calpain 1 and calpain 2 function as heterodimeric enzymes composed of a large catalytic subunit (calpain 1 and calpain 2) bound to a small regulatory subunit (calpain 4). Calpain activity *in vivo* is tightly regulated by the ubiquitously expressed endogenous inhibitor ►calpastatin. Calpains result in the proteolysis of a broad spectrum of cellular proteins. No unique consensus amino-acid sequence has been identified as a calpain-binding or -cleavage site, rather, it appears that calpains target substrates for cleavage by recognition of unidentified tertiary structure motifs. Another distinguishing feature of calpain proteases is their ability to confer limited cleavage of protein substrates into stable fragments, rather than complete proteolytic digestion. Thus, the calpain-calpastatin proteolytic system represents a major pathway of post-translational modification of proteins, that influences various aspects of cellular physiology. The recent application of pharmacological and molecular intervention strategies against calpain activity demonstrates a broad role for this class of proteases in the control of proliferation, ►migration and ►apoptosis in most cell types.

Characteristics

Cell proliferation, migration and apoptosis are key processes that have to be tightly regulated in order to maintain optimal tissue homeostasis, required for development and viability of multicellular organisms. Deregulation of any of these cellular processes will ultimately result in pathological outcomes, such as cancer. A number of studies have identified a correlative link between modulation of calpain gene expression and/or activity with cancer development and progression *in vivo*. For example, in human renal cell carcinomas, significantly higher levels of calpain 1 expression are found in tumors that metastasized to peripheral lymph nodes relative to tumors that had not metastasized. In addition, elevated calpain activity was detected in breast cancer tissues relative to normal breast tissues and was determined to be greater in estrogen receptor (►ER)-positive tumors than ER negative tumors. Calpain-mediated proteolysis of the tumor suppressor protein neurofibromatosis type 2 (NF2 or ►Merlin) is associated with the development of schwannomas and menigiomas. Experimental studies performed *in vitro* demonstrate that total cellular calpain activity is elevated upon transformation induced by the *v-src*, *v-jun*, *v-myc*, *k-ras* and *v-fos* oncogenes. Furthermore, calpain activity is necessary for full cellular transformation induced by such oncogenes. A number of intervention studies utilizing small molecule inhibitors or oligonucleotides that impair calpain activity have demonstrated a role for calpain during tumor cell progression *in vitro* and *in vivo*. Cell proliferation, migration and apoptosis are controlled by a plethora of regulatory proteins that participate in complex biochemical signaling cascades, of which calpain is a pivotal regulator. Thus, targeting calpain activity may represent an effective strategy for cancer prevention and/or treatment.

Calpain and Cell Proliferation

Studies using pharmacological inhibitors of calpain activity, overexpression of calpastatin and cells expressing depleted levels of calpain activity have all implicated calpain in the promotion of cell proliferation. Sequential progression through G1, S, G2 and M phases of the cell-cycle is required for mitosis and cell proliferation. Several studies indicate that calpain can cleave a number of cell-cycle control proteins such as ►cyclin D, cyclin E and $p27^{kip1}$ all of which regulate progression through G1 and S phase. Calpain has also been demonstrated to cleave upstream regulators of cell-cycle control proteins such as p53 and p107. Consequently, elevated calpain levels and activity in tumors may contribute to cancer cell proliferation through cleavage of cell-cycle control proteins and deregulation of normal cell cycle control.

More detailed mechanistic studies also demonstrate that calpain 2 is an important downstream component of many growth factor receptor and non-receptor tyrosine kinase signaling pathways that include signaling kinases such as, epidermal growth factor receptor (►EGFr), platelet derived growth factor receptor (►PDGFr), Src and ►focal adhesion kinase (►FAK). Such signaling molecules play an important role in transmitting extracellular signals to intracellular mediators that control cell proliferation, and are often constitutively activated in cancer cells. Activation of receptor and non-receptor kinases subsequently leads to activation of the Ras/►MAPK pathway, which results in

►ERK-mediated phosphorylation of calpain 2 on a serine residue (Ser 50). Phosphorylation of calpain 2 on Ser 50 initiates a conformational switch culminating in enhanced proteolytic activity. This evidence, together with pharmacological and molecular intervention studies targeting calpain activity, suggests that activation of calpain, in part, mediates growth factor receptor and non-receptor induced cell proliferation and migration of cancer cells.

Calpain and Cell Migration

The interaction between cell surface adhesion receptors known as ►integrins and their ►extracellular matrix substrates controls the migration of all cells. Integrin-linked ►focal adhesions are large complexes of structural and signaling proteins that provide both a structural and biochemical link between the extracellular environment and intracellular proteins. Dynamic spatial and temporal regulation of focal adhesion assembly and disassembly is required for optimal cell motility. Several studies indicate that calpains localize to integrin-associated adhesions. Furthermore, many of the protein components of focal adhesions are known substrates of calpain. Calpain-mediated cleavage of the focal adhesion components, FAK, paxillin, talin and possibly others promotes the disassembly of these complexes, contributing to reduced cell adhesion and increased migration. In fact calpain-mediated cleavage of talin has been reported to represent the rate-limiting step in adhesion turnover. In addition to mediating focal adhesion turnover, emerging evidence suggests a role for calpain in regulating components of the actin cytoskeleton involved in cell spreading and membrane protrusion, mechanisms that are also essential for persistent and directed cell migration. It is likely that calpain cleavage of actin-binding and -regulatory proteins such as, ezrin, rhoA and cortactin influences the dynamic formation and retraction of membrane structures known as ►filipodia and ►lamellipodia thereby influencing cancer cell migration and ►invasion. Pharmacological and molecular inhibition of calpain activity has been shown to impair cancer cell migration across experimental two-dimensional substrates and invasion into three-dimensional extracellular matrix substrates *in vitro*. Furthermore, a recent intervention study demonstrates that antisense-mediated suppression of calpain 2 gene expression reduced the invasion of prostate cancer cells both *in vitro* and in a mouse model *in vivo*. Thus, evidence strongly indicates that calpain activity contributes to the invasion and ►metastasis of cancer cells.

Calpain and Apoptosis

Apoptosis is defined as the process of programmed cell death. Apoptosis often follows activation of the caspase family of cysteine proteases, which degrade numerous proteins that are essential for cell viability. Regulated apoptosis is critical for the development of multicellular organisms and also restricts the growth and spread of malignant cancer cells. Conflicting roles for calpain activity in the promotion and suppression of cell apoptosis have been proposed. Calpain activity has previously been shown to play a pro-apoptotic role through the activation of caspase 3 and caspase 12 and cleavage of Bax and ►Bid proteins to their pro-apoptotic forms. Enhanced calpain activity has also been implicated as the major proteolytic pathway resulting in breakdown of essential proteins during caspase-independent mechanisms of apoptosis. Conversely, calpain-mediated cleavage of caspase 7 and caspase 9 has been found to suppress their activity and subsequent apoptosis. In addition, calpain-mediated cleavage of IκBα can lead to activation of the NFκB transcription factor resulting in subsequent expression of anti-apoptotic survival proteins. Many chemotherapeutic agents such as cisplatin induce their tumoricidal effect *via* inducing apoptosis of cancer cells. Tumor cell resistance to cisplatin-induced apoptosis is a common feature frequently encountered during chemotherapy of cancer patients. Inhibition of calpain activity has been shown to sensitize resistant tumor cells to cisplatin-induced death, whereas other studies suggest that calpain potentiates cisplatin induced cell death. Thus, the role of calpain during cell apoptosis is context dependent and determined by cell type, the apoptotic stimuli and status of intrinsic regulators of cell apoptosis.

In contrast to the aforementioned studies suggesting a pro-tumorigenic role for calpain activity, an anti-tumorigenic role is also supported by studies indicating that calpain degrades a number of oncogene-generated protein products such as PDGFr, EGFr, c-Jun, c-Fos, c-Src, and c-Mos. Also, calpain-mediated cleavage of protein kinase C (►PKC), a downstream effecter for tumor promoting phorbal esters, inhibits malignant transformation. Furthermore, specifically calpain 9 (nCL-4) activity contributes to the suppression of cell transformation in vitro and gastric tumors in vivo. Although the calpain 9 substrates that mediate this anti-tumor effect remain to be determined.

A substantial body of evidence has accumulated demonstrating that activity of the calpain family of proteases plays a broad and important role in the physiology of both normal and cancer cells. Further investigation into the complex and multifaceted role of calpain in cancer may lead to the discovery of novel therapeutic approaches targeting calpain activity that may impact on the development, progression and prevention of cancer.

Calpastatin

Definition

Is an endogenous protease inhibitor that acts specifically on calpain. It consists of four repetitive sequences of 120–140 amino acid residues (domains I, II, III and IV), and an N-terminal non-homologous sequence (L).

►Calpains

Calreticulin

Definition

Is the molecular chaperone that binds initially to ►MHC class I, MHC class II, and other proteins that contain immunoglobulin-like domains, such as the T-cell and B-cell antigen receptors.

►Sjögren Syndrome
►Molecular Chaperones

Calreticulin

Yoshito Ihara
Department of Biochemistry, School of Medicine, Wakayama Medical University, Wakayama, Japan

Synonyms

CRP55; calcium-binding reticuloplasmin of molecular weight 55 kDa; Calsequestrin-like protein; CaBP3; ERp60; HACBP; high affinity Ca^{2+} -binding protein; Reticulin; CRT

Definition

Calreticulin (CRT) is a Ca^{2+} -binding multifunctional ►molecular chaperone in the endoplasmic reticulum (ER). CRT is a 46-kDa soluble protein with a cleavable N-terminal amino acid signal sequence and the C-terminal sequence Lys-Asp-Glu-Leu (KDEL), a retrieval signal in the ER. ►Calnexin (CNX), a membrane-binding paralog of CRT, shares the ►chaperone function in the ER. CRT is expressed in a variety of tissues and organs, but its levels are particularly high in the pancreas, liver, and testis. It is also a highly conserved protein with over 90% amino acid identity in mammals including humans, rabbits, rats and mice. The CRT gene has been mapped to human chromosome 19 at p13.2, and its expression is upregulated by ER stress such as unfolded protein responses and deprivation of Ca^{2+} in the ER.

Characteristics

Structure of CRT

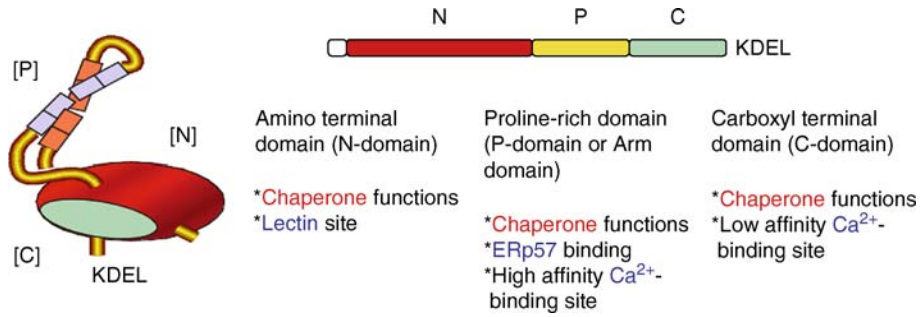
Based on structural and functional studies, CRT can be divided into three distinct domains; N-terminal [N], proline-rich [P], and C-terminal [C]. The proline-rich P-domain shows a characteristic structure with an extended and curved arm connected to a globular N-domain. The N-terminal region encompassing the N and P-domains of CRT interacts with misfolded proteins and glycoproteins, binds ATP, Zn^{2+}, and Ca^{2+} with high affinity and low capacity, and is likely to be involved in the chaperone function of the protein. The C-domain binds Ca^{2+} with high capacity and plays a role in the storage of Ca^{2+} in the ER in vivo, though no structural information is available at present (Fig. 1).

Functions of CRT in the Cell

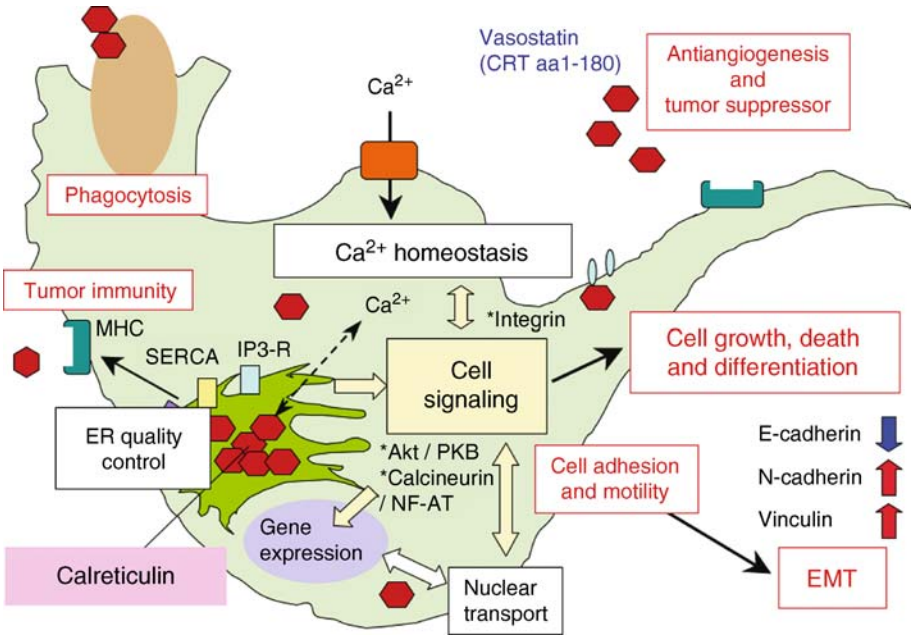
CRT is involved in a number of biological processes including the regulation of glycoprotein folding, Ca^{2+} homeostasis and intracellular signaling, cell adhesion, gene expression, and nuclear transport (Fig. 2).

CRT, a Lectin-like Molecular Chaperone in the ER

A molecular chaperone function of CRT has been reported for several protein substrates. In the biosynthesis of glycoproteins bearing ►N-linked glycans in the ER, the oligosaccharide Glc3Man9GlcNAc2 (Glc, glucose; Man, mannose; GlcNAc, N-acetylglucosamine) is attached to the Asn residue contained in the consensus sequence Asn-X-Ser/Thr, of newly synthesized polypeptides. CRT or CNX binds the Glc1Man5–9GlcNAc in glycoproteins after the processing of sugar chains. The N-domain of CRT and CNX is speculated to be the oligosaccharide-binding site (►lectin site). If the glycoprotein is completely folded in the ER, the terminal glucose is removed by glucosidase-II and the glycoprotein is released from the CNX/CRT chaperone cycle. However, if the glycoprotein is not properly folded, the terminal glucose is once again attached by



Calreticulin. Figure 1 Schematic structure of calreticulin.



Calreticulin. Figure 2 Functions of calreticulin in the cell. CRT is involved in a variety of cellular processes including the quality control of glycoprotein synthesis in the ER, Ca^{2+} homeostasis, intracellular signaling, gene expression, and nuclear transport. In cancer cells, the altered expression of CRT may lead to alterations in cellular characteristics, such as growth, adhesion, motility, immune responses, and susceptibility to apoptosis. Furthermore, extracellular CRT fragments (i.e., vasostatin) elicit antiangiogenic or tumor-suppressing activities.

the action of UDP-Glc: glycoprotein glucosyltransferase, which discriminates between folded and unfolded substrates. Together, CRT and CNX form a specific chaperone cycle for the biosynthesis of glycoproteins in the ER. Because of the preference of CNX/CRT for oligosaccharides as substrates, CNX and CRT are called "lectin-like chaperones." CRT and CNX function with the help of other chaperones such as ►ERp57 and ►BiP/GRp78. The binding site for ERp57 has been identified in the P-domain of CRT or CNX. As a chaperone, CRT plays an important role in the formation of major histo-compatibility complex (►MHC) class I to aid in antigen presentation.

CRT, a Regulator of Ca^{2+} Homeostasis in the ER

The ER is the main reservoir of intracellular Ca^{2+} and plays an important role in Ca^{2+} homeostasis. CRT has two Ca^{2+} -binding sites and this characteristic contributes to the function of the ER as a Ca^{2+} reservoir. Ca^{2+} is released from the ER by receptors for inositol-1,4,5-trisphosphate (IP3) and ryanodine, and taken up into the ER by sarcoplasmic and endoplasmic reticulum Ca^{2+} -ATPase (SERCA). With respect to the regulation of the Ca^{2+} level, the involvement of CRT and SERCA2b or the IP3-receptor has been reported. Furthermore, the store-operated release of Ca^{2+} from the ER was shown to be suppressed by overexpression of CRT protein. These

findings indicate that CRT is not only a reservoir of Ca^{2+} but also a regulator of Ca^{2+} -homeostasis in the ER.

Other Miscellaneous Functions of CRT In and Out of the ER

CRT is involved in cell ►adhesion by affecting integrin-related cell signaling. In CRT-deficient embryonic stem cells, integrin-mediated Ca^{2+} influx was impaired leading to a decrease in cell adhesion to fibronectin and laminin. It is still not clear whether CRT affects integrin directly or indirectly to regulate cell adhesion signaling.

Cell surface expression of CRT has also been reported in various cell types, and may be related with cell adhesion and ►migration. The cell surface CRT may modulate cell adhesion by binding with extracellular matrix proteins, such as ►fibrinogen, ►laminin, and ►thrombospondin. Furthermore, extracellular CRT is implicated in the pathological processes of autoimmune diseases. ►Autoantibodies against CRT were found in ~40% of patients with systemic lupus erythematosus, patients with secondary Sjogrens syndrome, rheumatoid arthritis, celiac disease, complete congenital heart block, and halothane hepatitis. CRT is known to bind to complement, C1q, and compete with antibodies for binding to C1q and inhibition of C1q-dependent hemolysis. In autoimmune diseases, impairment of the classical pathway of compliment causes a failure to clear immune complex, resulting in progression of the disease. Therefore, extracellular CRT may contribute to the progression of autoimmune diseases by preventing the clearance of immune complex. Furthermore, it has been reported that cell-surface CRT is involved in the mechanism for clearance of viable or apoptotic cells through the trans-activation of LDL-receptor-related protein (LRP) on phagocytes. However, it is still controversial whether CRT is exported from necrotic cells or apoptotic cells under pathologic conditions.

Cytosolic CRT functions as an export factor for multiple nuclear hormone receptors, such as steroid hormone, non-steroid hormone, and orphan receptors. This function is consistent with previous findings that CRT suppresses the transactivation of nuclear hormone receptors including ►androgen receptor and vitamin D. However, the mechanisms by which CRT molecules are transported into, and retained in, the cytosol/nucleus are not fully defined.

CRT and Development

CRT is essential for cardiac and neural development in mice. CRT-deficient embryonic cells showed an impaired nuclear import of nuclear factor of activated T cell (NF-AT3), a transcription factor, indicating that CRT functions in cardiac development as a component of the Ca^{2+}/►calcineurin/NF-AT/GATA-4 transcription pathway. Actually, cardiac-specific expression of calcineurin reversed the embryonic lethality of CRT-deficient mouse.

CRT transgenic mice suffer a complete heart block and sudden death, and CRT-dependent cardiac block involves an impairment of both the L-type Ca^{2+} channel and gap junction ►connexins (Cx40 and Cx43). Phosphorylated Cx43 was also decreased in CRT transgenic heart, suggesting that the functions of protein kinases are altered via the regulation of Ca^{2+} homeostasis. Collectively, CRT plays a vital role in cardiac differentiation and function, though how has not been fully clarified.

CRT and Cancer

Expression of CRT in Cancer

In terms of the relationship between CRT and cancer, proteomic analysis has revealed a new functional role of CRT in the early diagnosis of cancers. CRT is proposed to be a new tumor marker of bladder cancer. In addition, it was reported that the expression of CRT is up-regulated in a variety of malignant cells or tissues including progressive fibrosarcoma cells, colorectal cancer cells, and pituitary adenomas. Furthermore, autoantibodies to CRT isoforms have utility for the early diagnosis of pancreatic cancer. These reactions are not indicative of malignant properties of CRT, but rather are markers of immunogenicity and anticancer responses. On the other hand, another report demonstrated that CRT is over-expressed in the nuclear matrix in ►hepatocellular carcinoma, compared with normal liver tissue, suggesting a relationship between over-expressed CRT and malignant transformation. In contrast, it was also reported that CRT expression correlates with the differentiation of ►neuroblastomas to predict favorable patient survival.

Pathophysiological Relevance of CRT in Malignant Disease

Susceptibility to ►apoptosis is important in terms of cancer treatments including the use of antibiotics and irradiation. In embryonic fibroblasts from CRT knock-out mice, susceptibility to apoptosis was significantly suppressed, indicating that CRT functions in the regulation of apoptosis. Furthermore, it was found that overexpression of CRT modulates the ►radiation sensitivity of human glioma U251MG cells by suppressing ►Akt/protein kinase B signaling for cell survival via alterations of cellular Ca^{2+} homeostasis. These findings suggest that the expression level of CRT is well correlated with the susceptibility to apoptosis. In contrast, overexpression of CRT provides resistance to oxidant-induced cells death in renal epithelial LLC-PK1 cells. The function of CRT in the regulation of apoptosis may differ in specific cell types, and is still controversial.

As for cell adhesion, it was reported that CRT expression modulates cell adhesion by coordinating up-regulation of N-cadherin and vinculin. Recently, it has been reported that overexpression of CRT induces ►epithelial-mesenchymal transition (EMT)-like morphological changes and enhances cellular invasiveness in renal epithelial MDCK cells. The enhanced invasiveness mediated through ►E-cadherin gene repression was regulated by the gene repressor, ►Slug, via altered Ca^{2+} homeostasis caused by overexpression of CRT in MDCK cells. This study suggests that expression of CRT may play some causative role in the gain of invasiveness during the process of malignant transformation. In addition, it has been reported that cellular migration and binding to collagen type V are apparently suppressed in embryonic fibroblasts from CRT knock-out mice, indicating that the cellular level of CRT is important for the regulation of cell motility.

Furthermore, CRT protein binds to GCN repeats in mRNA of the myeloid transcription factor ►CCAAT/enhancer-binding protein α (CEBPA), and thereby impedes translation of the CEBPA mRNA, suggesting that CRT plays a functional role in the differentiation block in ►acute myeloid leukemia through suppression of CEBPA by the leukemic ►fusion gene *AML1-MDS1-EVI1*. Together, these findings suggest that CRT is involved in the regulation of cancer characteristics, although the overall mechanisms are still not clear.

CRT as a Tool for Cancer Therapy

CRT can form complexes with peptides in vitro to elicit peptide-specific CD8+ ►T cell responses. In addition, peptide-bound CRT purified from tumor extracts elicits an antitumor effect specific to the source tumor. Antigen-specific cancer immunotherapy is an attractive approach to the eradication of systemic tumors at multiple sites in the body. It has been reported that vaccination with DNA encoding chimera for CRT and a tumor antigen, ►human papilloma virus type-16 (HPV-16) E7 [CRT/E7], resulted in a significant reduction in the number of lung tumor nodules in immunocompromised mice. All together, the use of CRT represents a feasible approach for enhancing tumor-specific T cell-mediated immune responses.

Therapeutic agents that target the tumor vasculature may prevent or delay tumor growth and even promote tumor regression or dormancy. As another approach to cancer therapy, CRT or a fragment thereof (amino acids 1–180) (i.e., ►vasostatin) inhibits ►angiogenesis and suppresses tumor growth. The combination of vasostatin and IL-12 as well as vasostatin and interferon-inducible protein-10 had a suppressing effect on the cell growth of Burkitt lymphoma and colon carcinoma in mouse metastasis models. Although this suggests some potential for use in cancer therapy, the molecular mechanism of CRT actions at the cell surface is not fully understood.

CAMTA1

Kai-Oliver Henrich, Frank Westermann
DKFZ, German Cancer Research Center, Heidelberg, Germany

Definition

CAMTA1 is a candidate ►tumor suppressor gene encoding a member of a protein family designated as calmodulin-binding transcription activators (CAMTAs). It resides within a distal portion of chromosomal arm 1p that is frequently deleted in a wide range of human malignancies.

Characteristics

CAMTA1 maps to 1p36.31-p36.23 and its 23 exons are spread over 982.5 kb. The 6,582 bp cDNA encodes a protein of 1,673 amino acids. The protein's primary structure contains a nuclear localization signal, two DNA-binding domains (CG-1 and TIG), a transcription activation domain, calmodulin binding motifs (IQ motifs), and ankyrin domains. Although the expression of *CAMTA1* is seen in various organs, highest levels are found in neuronal tissues. Information on the physiologic roles of CAMTAs is scarce and most data derive from plant and drosophila studies.

CAMTAs are transcription factors that typically bind to CGCG boxes via their CG-1 domain. An alternative mechanism of transcriptional activation has been described for CAMTA2, the second human CAMTA homolog. It acts as a coactivator of another transcription factor, Nkx2-5, to stimulate gene expression. This function is inhibited by binding of class II ►histone deacetylases to the ankyrin-repeat region of CAMTA2. Upstream signaling components can activate CAMTA2 by promoting the export of class II histone deacetylases to the cytoplasm, relieving their repressive influence on CAMTA2.

The sole fly homolog of CAMTA1 induces the expression of an ►F-box gene, the product of which inhibits a Ca^{2+}-stimulating ►G-protein-coupled receptor (GPCR). The controlled deactivation of Ca^{2+}-stimulating GPCRs is needed to tune Ca^{2+}-mediated signaling and prevent abnormal cell proliferation. As CAMTA activity is increased by the Ca^{2+}-sensor calmodulin, the Ca^{2+}/calmodulin/CAMTA/F-box protein pathway may mediate a negative feedback loop controlling the activity of Ca^{2+}-stimulating GPCRs. This regulatory loop is of special interest taking into account the fundamental links between GPCR-mediated pathways and cancer biology.

Clinical Relevance

Deletions within 1p occur in various types of human malignancies, ranging from virtually all types of

solid cancers to leukemias and myeloproliferative disorders. Functional evidence for a role of 1p in tumor suppression derives from experiments in which the introduction of 1p chromosomal material into ►neuroblastoma cells resulted in reduced tumorigenicity. In neuroblastoma and other cancers, deletion of 1p36 is a predictor of poor patient outcome. Therefore, it is widely assumed that distal 1p harbors a gene (or genes) with tumor suppressive properties. To define the DNA, deleted from 1p, more precisely in pursuit of identifying the gene(s) of interest, substantial mapping efforts have been undertaken with the most detailed picture being worked out for neuroblastoma. In this tumor entity, the combination of ►loss of heterozygosity (LOH) fine mapping studies allowed to considerably narrow down a smallest region of consistent deletion spanning only 261 kb at 1p36.3 and pinpointing the *CAMTA1* locus. Sequence analysis revealed no evidence for somatic mutations in the remaining *CAMTA1* copy of neuroblastomas with 1p deletion. However, a rare sequence variant leading to amino acid substitution within the ankyrin domain was seen in a subgroup of neuroblastomas. More importantly, low *CAMTA1* expression is significantly associated with markers of unfavorable tumor biology and is itself a marker of poor neuroblastoma patient outcome. Moreover, *CAMTA1* expression is a neuroblastoma predictor variable that is independent of the established molecular markers including 1p deletion. Thus, the measurement of this variable should allow an additional biological stratification of neuroblastomas and help to assign patients to the appropriate therapy.

Additional evidence for a role of CAMTA1 in tumor development comes from ►glioma and ►colon cancer in which 1p is frequently deleted. In glioma, a 1p minimal deleted region spans 150 kb and resides entirely within *CAMTA1*. In colorectal cancer, a genome-wide analysis of genomic alterations revealed that loss of a 2 Mb recurrently deleted genomic region encompassing *CAMTA1* has the strongest impact on survival when compared with other genomic changes. Furthermore, as in neuroblastoma, low expression of *CAMTA1* is an independent marker of poor patient outcome. The high prevalence of *CAMTA1* deletion in neuroblastoma, glioma, and colorectal cancer together with the independent predictive power of low *CAMTA1* expression for neuroblastoma and colorectal cancer outcome are consistent with the idea that low CAMTA1 levels mediate a selective advantage for developing tumor cells.

Cancer

Manfred Schwab
DKFZ, Tumour Genetics, Heidelberg, Germany

Definition

Cancer is a deregulated multiplication of cells with the consequence of an abnormal increase of the cell number in particular organs. Initial stages of the developing

cancer are usually confined to the organ of origin whereas advanced cancers grow beyond the tissue of origin. Advanced cancers invade the surrounding tissues that are initially connected to the primary cancer. At a later stage, they are distributed via the hematopoetic and lymphatic systems throughout the body where they can colonize in distant tissues and form ►metastasis. The development of cancers is thought to result from the damage of the cellular genome, either due to random endogenous mechanisms or caused by environmental influences.

The origin of cancers can be traced back to alterations of cellular genes. Genetic damage can be of different sorts:

- Recessive mutations in ►tumor suppressor genes
- Dominant mutations of ►oncogenes
- Loss-of-function mutations in genes, involved in maintaining genomic stability and ►repair of DNA (resulting in ►genomic instability)

History

Human cancer is probably as old as the human race. It is obvious that cancer did not suddenly start appearing after modernization or industrial revolution. The world's oldest documented case of cancer comes from ancient Egypt, in 1500 BC. The details were recorded on a papyrus, documenting eight cases of tumors occurring on the breast. It was treated by cauterization, a method to destroy tissue with a hot instrument called "the fire drill." It was also recorded that there was no treatment for the disease, only palliative treatment. The word cancer came from the father of medicine, Hippocrates, a Greek physician (460–370 BC). Hippocrates used the Greek words, carcinos and carcinoma to describe tumors, thus calling cancer "karkinos." The Greek terms actually were words to describe a crab, which Hippocrates thought a tumor resembled. Hippocrates believed that the body was composed of four fluids: blood, phlegm, yellow bile and black bile. He believed that an excess of black bile in any given site in the body caused cancer. This was the general thought of the cause of cancer for the next 1,400 years. Autopsies done by Harvey in 1628 paved the way to learning more about human anatomy and physiology. By about the same time period, Gaspare Aselli discovered the lymphatic system, and this led to the end of the old theory of black bile as the cause of cancer. The new theory suggested that abnormalities in the lymph and lymphatic system as the primary cause of cancer. The lymph theory replaced Hippocrates' black bile theory on the cause of cancer. The discovery of the lymph system gave new insight to what may cause cancer, it was believed that abnormalities in the lymphatic system was the cause. Other theories surfaced, such as cancer being caused by trauma, or by parasites, and it was thought that cancer may spread "like a liquid" (Bentekoe, 1687; Heinrich Vierling, personal communication). The belief that cancer was composed of fermenting and degenerating lymph fluid was predominant.

The discovery of the microscope by Leeuwenhoek in the late seventeenth century added momentum to the quest for the cause of cancer. By late nineteenth century, with the development of better microscopes to study cancer tissues, scientists gained more knowledge about the cancer process. It wasn't until the late nineteenth century that Rudolph Virchow, the founder of cellular pathology, recognized that cells, even cancerous cells, derived from other cells. The early twentieth century saw great progress in our understanding of microscopic structure and functioning of the living cells. Researchers pursued different theories to the origin of cancer, subjecting their hypotheses to systematic research and experimentation. John Hill first recognized an environmental cause from the dangers of tobacco use in 1761 and published a book "Cautions Against the Immoderate Use of Snuff." Percivall Pott of London in 1775 described an occupational cancer of the scrotum in chimney sweeps caused by soot collecting under their scrotum. This led to identification of a number of occupational carcinogenic exposures and public health measures to reduce cancer risk. This was the beginning of understanding that there may be an environmental cause to certain cancers.

A virus causing cancer in chickens was identified in 1911 (Rous sarcoma virus). Existence of many chemical and physical carcinogens were conclusively identified during later part of the twentieth century. The later part of the twentieth century showed tremendous improvement in our understanding of the cellular mechanisms related to cell growth and division. The identification of ►transduction of oncogenes with the discovery of the ►*SRC* gene, the transforming gene of Rous sarcoma virus, led to formulating the oncogene concept of tumorigenesis and can be viewed as the birth of modern molecular understanding of cancer development. Subsequently, tumor suppressor genes were identified. Many genes that suppress or activate the cell growth and division are known to date, their number is ever growing. It is conceivable that in the end the confusing situation may arise to recognize that all genes of the human genome, in one way or another, take part in signaling normal or cancerous cellular growth.

Characteristics

A large proportion of genetic changes appears to arise by mechanisms endogenous to the cell, such as by errors occurring during the replication of the ~3×10^9 base pairs present in the human genome. Environmental factors have a major role as well, predominantly as:

- Chemical carcinogens (e.g. aflatoxin B1 in liver cancer (►liver cancer, molecular biology), tobacco smoke in lung cancer; ►tobacco carcinogenesis)
- Radiation
- Viruses (such as ►hepatitis B virus (►Hepatitis viruses) in liver cancer, or ►human papillomavirus in cervical cancer)

Types of Genetic Damage

Damage to oncogenes and tumor suppressor genes can be of different sorts:

- Point mutations resulting in the activation of a latent oncogenic potential of a cellular gene (e.g. ►RAS) or in the functional inactivation of a tumor suppressor gene by generating an intragenic stop codon that leads to premature translation termination with the consequence of an incomplete truncated protein (e.g. ►p53) or the failure for maintaining genomic stability (►mismatch repair genes in ►HNPCC)
- ►Amplification leading to an increase of the gene copy number beyond the two alleles normally present in the cell (copy number can reach 500 and more; example: ►*MYCN* in human ►neuroblastoma)
- Translocation, which is defined as an illegitimate recombination between non-homologous chromosomes, the result being either a fusion protein (where recombination occurs between two different genes such as *BCR-ABL* in Chronic Myclogenous Leukemia) or in the disruption of normal gene regulation (where the regulatory region of a cellular gene is perturbed by the introduction of the distant genetic material such as ►*MYC* in Burkitt lymphoma (►Epstein-Barr virus))
- Viral insertion by the integration of viral DNA into the regulatory region of a cellular gene. This integration can occur after a virus has infected a cell. Viral insertion is well documented in animal tumors (HBV integration in the vicinity of ►*MYCN* in liver cancer in experimental animals; liver cancer, molecular biology)

Cellular Aspects

Cancer in solid tissues (solid cancer) usually develops over long periods (often 20–30 years latency period) of time. An exception are solid cancers (such as neuroblastoma) in children, which often are diagnosed shortly after birth. Malignant cancers are characterized by their ability to develop metastasis (i.e. secondary cancers at distance from the primary tumor), often they also show multidrug resistance, which means that they hardly react to conventional chemotherapy. It is thought that the development of a normal cell to a metastatic cell is a continuous process driven by genetic damage and genomic instability, with the progressive selection of cells that have acquired a selective advantage within the particular tissue environment (►multistep development). Studies of colorectal cancers have identified 6–7 genetic events required for the conversion of a normal cell to a cell with metastatic ability. This is in contrast to leukemias, which usually require one genetic event, most often a translocation, for disease development.

Sporadic Versus Familial Cancer

The vast majority of cancers are "sporadic," which simply means that they develop in an individual. Descendants of this individual do not have an increased risk because the cellular changes that have resulted in cancer development are confined to this individual. In contrast, ~10% of cancer cases have a hereditary background, they show familial clustering (prominent examples include retinoblastoma (►Retinoblastoma, ►cancer genetics), ►breast cancer, FAP (►APC gene in Familial Adenomatous Polyposis) and HNPCC as familial forms of colorectal cancer (►colon cancer), ►melanoma). Familial cancers have been identified to result from germline mutation of genes. These germ line mutations do not always directly dictate cancer development, although they are considered "strong" hereditary determinants. They represent susceptibility genes that confer a high risk for cancer development to the gene carrier. The relative risk of the individual carrying the mutant gene can vary considerably. For instance, the risk of carriers of one of the breast cancer susceptibility genes ►*BRCA1* or ►*BRCA2* for breast cancer development can vary between approximately 60 and 90%. In reality this means that the risk for cancer development is difficult to predict, and individuals may not develop cancer at all in spite of the presence of a mutated gene in their germ line. The molecular basis for the differences in risk are unknown. Formally the activity of modifying factors, either environmental or genetic, has been suggested. Such modifying factors appear to be less important for some other familial cancers, such as retinoblastoma, where the risk is constant between 90 and 95% for gene carriers.

Polygenic Determinants of Risk

The relative risk of the individual for cancer development can also be determined by so called "weak" genetic factors. Normal cells contain a number of genes involved in ►detoxification reactions. Different allelic variants of these genes exist in the human population that encode proteins with slightly different enzymatic activities. Although the exact contribution of individual allelic variants to cancer development is difficult to assess, it is reasonable to assume that individuals that have inherited "weak" enzymatic activities in different detoxification systems are likely to have a higher risk. It is likely, therefore, that the risk for such cancers is "polygenic."

►Toxicological Carcinogenesis

Cancer and Cadmium

Tim S. Nawrot, Jan A. Staessen
Division of Lung Toxicology, Department of Occupational and Environmental Medicine (T.S.N.) and the Studies Coordinating Centre (J.A.S.), Division of Hypertension and Cardiovascular Rehabilitation, Department of Cardiovascular Diseases, University of Leuven, Leuven, Belgium

Definition

Cadmium is a metal that has the symbol Cd and atomic number 48 in the periodic table. Cadmium has high toxic effects, an elimination half-life of 10–30 years, and accumulates in the human body, particularly the kidney. Roughly 15,000 tons of cadmium is produced worldwide each year for nickel-cadmium batteries, pigments, chemical stabilizers, metal coatings, and alloys.

Characteristics

Urinary excretion of cadmium over 24 h is a biomarker of lifetime exposure. Exposure to cadmium occurs through intake of contaminated food or water, or by inhalation of tobacco smoke or polluted air. Occupational exposures can be found in industries such as electroplating, welding, smelting, pigment production, and battery manufacturing. Other exposures to cadmium can occur through inhalation of cigarette smoker. Gastrointestinal absorption of cadmium is estimated to be around 5–8%. Inhalation absorption is generally higher, ranging from 15 to 30%. Absorption after inhalation of cadmium fume, such as cigarette smoke, can be as high as 50%. Once absorbed, cadmium is highly bound to the metal-binding protein, metallothionein. Cadmium is stored mainly in the kidneys and also the liver and testes, with a half-life in the body of 10–30 years. In general, nonsmokers have urinary cadmium concentrations of 0.02–0.7 μg/g creatinine, which increase with age in parallel with the accumulation of cadmium in the kidney. Cadmium is a global environmental contaminant. Populations worldwide have a low-level intake through their food, causing an age-related cumulative increase in the body burden of this toxic metal. Environmental exposure levels to cadmium, that are substantially above the background, occur in areas with current or historical industrial contamination for instance in regions of Belgium, Sweden, UK, Japan, and China.

As an environmental carcinogen, cadmium could have substantial health implications. Three lines of evidence explain why the International Agency for the Research on Cancer classified cadmium as a human carcinogen. First, as reviewed by Verougstaete and colleagues, several, albeit not all studies in workers showed a positive association between the risk of lung cancer and occupational exposure to cadmium; discrepancies between these studies should not be ascribed to the better design of the more recent studies. Verougstraete and colleagues suggested that such inconsistencies might be attributed to the high relative risk of cancer in the presence of coexposure to ►arsenic, nickel, or toxic fumes, and that the increasingly stringent regulations with regard to levels of exposure permissible at work might be a confounding factor (►Lead exposure, nickel carcinogenesis). Second, data from rats showed that the pulmonary system is a target site for carcinogenesis after cadmium inhalation. However, exposure to toxic metals in animal studies have usually been much higher than those reported in environmentally exposed humans to toxic metals. Third, several studies done in vitro have shown plausible pathways, such as increased oxidative stress, modified activity of transcription factors, and inhibition of DNA repair. Most errors that arise during DNA replication can be corrected by DNA polymerase proof reading or by postreplication mismatch repair. In fact, inactivation of the DNA repair machinery is an important primary effect, because repair systems are required to deal with the constant DNA damage associated with normal cell functions. The latter mechanism might indeed be relevant for environmental exposure because Jin et al. found that chronic exposure of yeast to environmentally relevant concentrations of cadmium can result in extreme hypermutability. In this study the DNA-mismatch repair system is already inhibited by 28% at cadmium concentrations as low as 5 μM. For example, the prostate of healthy unexposed humans accumulates cadmium to concentrations of 12–28 μM and human lungs of nonsmokers accumulate cadmium to concentrations of 0.9–6 μM. Further, in vitro studies provide evidence that cadmium may act like an estrogen, forming high-affinity complexes with estrogen receptors, suggesting a positive role in breast cancer carcinogenesis.

Along with this experimental evidence, two epidemiological studies in 2006 gave important positive input into the discussion on the role of exposure to environmental cadmium in the development of cancer in human beings. First, the results of a population-based case-control study noticed a significant twofold increased risk of breast cancer in women in the highest quartile of cadmium exposure compared with those in the lowest quartile. Second, we conducted a population-based prospective cohort study with a median follow-up of 17.2 years in an area close to three zinc smelters. Cadmium concentration in soil ranged from 0.8 to 17.0 mg/kg. At baseline, geometric mean urinary cadmium excretion was 12.3 nmol/day for people in the high-exposure area, compared with 7.7 nmol/day for those in the reference (i.e, low exposure) area. The risk of lung cancer was 3.58 higher than in a reference population from an area with low exposure. 24-h urinary

excretion is a biomarker of lifetime exposure to cadmium. The risk for lung cancer was increased by 70% for a doubling of 24-h urinary cadmium excretion. Confounding by coexposure by arsenic could not explain the observed association. Epidemiological studies did not convincingly imply cadmium as a cause of prostate cancer. Of 11 cohort studies, only 3 (33%) found a positive association.

In conclusion, recent experimental and epidemiological studies strongly suggest environmental exposure to cadmium as a causal factor in the development of cancer of the lung and breast.

Cancer Antigen

Definition

Cell surface proteins specific for cancer cells.

►Cytokine Receptor as the Target for Immunotherapy and Immunotoxin Therapy

Cancer Antigen 15-3 (CA 15-3)

Definition

Carbohydrate antigen 15-3 is a tumor marker associated with breast cancer, and has much less specificity and sensitivity in patients with ovarian, lung, or prostate cancers. Increased levels may be associated with pregnancy and lactation, benign breast or ovarian disease, endometriosis, pelvic inflammatory disease, and hepatitis.

►Serum Biomarkers

Cancer Associated Antigen 19-9 (CA 19-9)

Definition

Serum levels of CA 19-9, an intercellular adhesion molecule, was initially found in patients with colorectal cancer, and subsequently also identified in patients with pancreatic and biliary tract cancers, and less often in gastric, ovarian, lung, breast and uterine cancer. Non-cancerous conditions that may elevate CA 19-9 include gallstones, cholecystitis, pancreatitis and cirrhosis of the liver.

►Serum Biomarkers

Cancer Associated Antigen 27-29 (CA 27-29)

Definition

Cancer antigen 27-29 (synonym: BR 27-29) is a normal epithelial cell mucin-1 (MUC1) apical surface glycoprotein. Elevated serum levels are highly associated with breast cancer. However they can also be found in cancers of colon, stomach, kidney, lung, ovary, pancreas, uterus and liver and in a number of noncancerous conditions, including first trimester pregnancy, ►endometriosis, ovarian cyst, benign kidney, liver and breast disease.

►Serum Biomarkers

Cancer of B-lymphocytes

►B-cell Tumors

Cancer Cachexia Syndrome (CCS)

Definition

Loss of weight in the form of lean body mass and fat which results from a complex interaction between cytokines and tumor factors.

►Nutrition Status

Cancer Causes and Control

Graham A. Colditz
Washington University in St. Louis, St. Louis, MO, USA

Synonyms

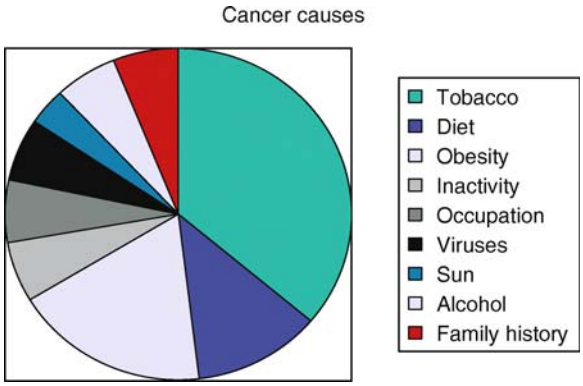
Etiology; Prevention

Definition

The process of identifying causes of cancer and developing strategies to change cancer risk through health care providers, regulations that reduce risk, or individual and community level changes.

Characteristics

Over 6 million people around the world die from cancer each year. There is overwhelming evidence that lifestyle factors impact cancer risk and that positive, population-wide changes can significantly reduce the cancer burden. Current epidemiologic evidence links behavioral factors to a variety of diseases, including the most common cancers diagnosed in the developed world – ►lung cancer, ►colorectal cancer, ►prostate cancer and ►breast cancer. These four cancers account for over 50% of all cancers diagnosed on western countries. As summarized in Fig. 1, ►tobacco causes some 30% of cancer, lack of physical activity 5%, obesity 15%, diet 10%, ►alcohol 5%, ►viral infections 5%, and ►UV light by excess sun exposure 3%. Because of the tremendous impact of modifiable factors on cancer risk, especially for the most common cancers, it has been estimated that at least 50% of cancer is preventable. Currently in the US not all risk factors are equally distributed across race and social class. Trends in risk factors should also be considered when assessing potential for prevention. To bring about dramatic reductions in cancer incidence, widespread lifestyle changes will be necessary.



Cancer Causes and Control. Figure 1 Causes of cancer.

Rose advocates the need for population approaches for prevention of chronic disease. He emphasizes that when the relation between a lifestyle factor or biological predictor of risk is continuous, the majority of cases attributable to the exposure will likely arise in those who are not classified as being at high risk. He illustrates this with examples of blood pressure and rates of coronary heart disease. Specifically, even small changes in blood pressure at the population level can translate into large reduction in the rates of coronary disease and stroke. To reduce the risk of disease in the population-substantial benefits can be achieved by a small reduction for all members of the society rather than just focusing on the high-risk groups. Because population wide trends in cardiovascular risk factors show continuing improvement, the rate of coronary heart disease incidence and mortality continues to decrease.

When we consider population approaches to cancer prevention, we must address the etiologic process, which covers a different time course and sequence from coronary heart disease. Although cardiovascular disease is the end point of the chronic process of atherosclerosis, treatment focuses on the reversal and subsequent prevention of the acute thrombotic process of myocardial infarction. Cancer, on the other hand, is the result of a long process of accumulating DNA damage (►multistep development), leading ultimately to clinically detectable lesions such as in situ and invasive cancer. For example, studies of the progression in ►colon cancer from first mutation to invading malignancy suggest that DNA changes accumulate over a period of as long as 40 years. The goal of cancer prevention is to arrest this progression; different interventions interrupt carcinogenesis at different points in the process. Further, most cancers do not have a late "acute" event, analogous to thrombosis, which can be prevented with medical interventions.

The benefits of cancer prevention and control programs take time to be observed. The fact that different

interventions will impact at different points along the pathway to cancer, that can stretch over nearly half a century, has implications for when we can expect to see pay-off in terms of lower cancer rates. Research has demonstrated that those who initiate smoking during early adolescence greatly increase risk of lung cancer even when one takes into account both the dose and duration of smoking. If we could delay the age at which most adolescents first start to smoke, we would probably substantially reduce lung cancer rates, but this benefit will not be observable for 20–40 years after the intervention. Adult cessation, on the other hand, reduces risk more rapidly, but fails to address the continuing recruitment of the next generation of smokers. Recent declines in the incidence of lung cancer among younger men and women in the United States reflect reductions in the rate of smoking among younger adults. Other lifestyle interventions may act as preventive early in the DNA pathway to cancer. For example, ►aspirin and ►folate appear to act early in the pathway inhibiting colon cancer.

Population-wide prevention strategies for cancer do work. For example, reductions in lung cancer rates in the United States mirror changes in cigarette smoking patters, with marked decreases seen first in young men, then older men, and finally in women. Introduction of the Papaniculou test for cervical cancer in the 1950s was followed by a dramatic decline in cervical cancer in those countries that made wide-spread ►screening available. The decline in Australian ►melanoma mortality for those born after 1950 is an additional example of effective intervention at the population level. Behavior change is possible and offers great potential for cancer prevention. The recommendations for cancer risk reduction include reducing tobacco use, increasing physical activity, maintaining a healthy weight, improving diet, limiting alcohol, avoiding excess sun exposure, utilizing safer sex practices, and obtaining routine cancer screening tests.

Age is the dominant factor that drives cancer risk; for all major malignancies, risk rises markedly with age. The importance of age is exemplified by the fact that the aging U.S. population together with projected population growth will result in a doubling of the total number of cancer cases diagnosed each year by the year 2050, assuming that incidence rates remain constant. With this estimated growth in cancer from 1.3 million to 2.6 million cases per year, it is expected that that both the number and proportion of older persons with cancer will also rise dramatically.

Tobacco

Tobacco is the major cause of premature death around the world accounting for some 5M deaths each year. In the United States, adult smokers lose an average of 13 years of life because of smoking, and approximately half of all smokers die of tobacco-related disease. Smoking is well known to cause over 90% of lung cancers in addition to a range of other malignancies (►tobacco carcinogenesis). It causes about 30% of all the cancer in the developed world, including lung cancer, ►mouth cancer, larynx cancer, ►esophagus cancer, ►pancreas cancer, ►cervix cancer, ►kidney cancer, and ►bladder cancer. Smoking also increased risk of cancers of the colon, stomach, cervix, liver, and prostate, as well as to leukemia. In addition, smoking leads to many other health problems, including heart disease, stroke, lung infections, emphysema, and pregnancy complications.

Tobacco may act on multiple stages of carcinogenesis; it delivers a variety of carcinogens, causes irritation and inflammation, and interferes with the body's natural protective barriers. The health risks of tobacco use are not limited to cigarette smoking. Cigar and pipe use increase the risk of disease, as does exposure to second-hand smoke and smokeless tobacco use.

Avoiding initiation of tobacco use clearly offers the greatest potential for disease prevention. However, for those who use tobacco products, there are substantial health benefits that come with quitting. There are numerous effective cessation methods, and in the past 25 years, 50% of all living Americans who have ever smoked, have successfully quit.

Quitting smoking has immediate and significant health benefits for men and women of all ages. For example, former smokers live longer than individuals who continue smoking. Those who quit before age 50 have approximately half the risk of dying in the next 15 years. This decline in mortality risk is measurable shortly after cessation and continues for at least 10–15 years.

Strategies to assist smoking cessation and decreasing youth initiation from both a population and clinical perspective are essential steps to reducing the burden of cancer.

Trends

Current smoking among US adults has remained steady over the past decade.

Once quite pronounced, gender disparity in smoking rates is now relatively small and has been stable since 1990. In 2002, 25.7% of men were current smokers compared to 20.8% of women. Given the profound impact of smoking on cancer, disparities in smoking rates and in access to effective cessation methods will continue to translate directly into differences in the burden of smoking-related cancers.

Physical Activity

Lack of physical activity causes over 2M deaths each year around the world. People in the US and in other developed nations are extremely inactive – over 60% of

the US adult population does not participate in regular physical activity, which includes 25% of adults who are almost entirely sedentary. Fortunately, the negative effects of a sedentary lifestyle are reversible: increasing one's level of physical activity, even after years of inactivity, can reduce mortality risk.

Lack of physical activity increases the risk of colon and breast cancer and likely endometrial cancer, as well as diabetes, osteoporosis, stroke, and coronary heart disease. Overall, sedentary lifestyles have been linked to 5% of deaths from cancer. Among both men and women, high levels of physical activity may decrease the risk of colon cancer by as much as half. Using a variety of measures of activity, studies have consistently shown higher physical activity lowers risk of colon cancer. Physical activity also appears to lower the risk of large adenomatous polyps, precursor lesions for colon cancer, suggesting that it may influence the early stages of the adenoma-carcinoma sequence. In addition, the relationship between physical activity and breast and colon cancer are seen across levels of obesity, indicating that physical activity and obesity have separate or independent effects on cancer incidence. Growing evidence suggests that physical activity may also be protective against lung and prostate cancer.

Several mechanisms have been proposed to explain these associations. Physical activity reduces circulating levels of insulin, a growth factor for colonic epithelial cells. Additionally, it is postulated that cancer risk is reduced through alterations in prostaglandin levels, improvement in immune function, and modification of bile acid metabolism.

Potential mechanisms for the reduction of breast cancer risk include physical activity's lowering of the cumulative lifetime exposure to circulating estrogens and improving immune pathways.

The benefits of physical activity include the prevention of cancer and a large number of other chronic diseases. Increasing levels of physical activity, even after years of inactivity, reduces mortality risk. As little as 30 min of moderate physical activity (such as brisk walking) per day significantly reduces disease risk.

Trends

One major determinant of activity level that has changed over time is the amount of activity required for work and daily living. With advances in technology and the development of labor-saving devices, there is now a greatly reduced need for physical activity for transportation, household tasks, and occupational requirements. Overall, the prevalence of physical inactivity in the United States is remarkably high; in 1996, about 28% of Americans reported absolutely no participation in leisure-time physical activity. In addition, physical activity in schools has declined, and almost half of young Americans between the ages of 12–21 are not vigorously active on a routine basis.

Given the trends in our society, it is unlikely that this decreasing energy expenditure will reverse rapidly. Accordingly, the burden of cancer due to lack of physical activity will increase in the years ahead unless new strategies to promote activity are rapidly implemented.

Weight Control and Obesity Prevention

Overweight and obesity is increasing at epidemic rates in the United States, around the world, and is estimated to account for 2.6M deaths each year. Currently almost 65% of American adults are overweight (body mass index (BMI) $\geq$25 kg/m^2), and over 30% are considered obese (BMI $\geq$ 25 kg/m^2).

Overweight and obesity cause a variety of cancers; colon, postmenopausal breast, endometrial, renal, and esophageal. The proportion of cancer caused by obesity ranges from 9% for postmenopausal breast cancer to 39% for endometrial cancer. One large US study suggested that obesity influences an even broader range of cancers, increasing the risk of death from cancers of the colon and rectum, prostate, breast, esophagus, liver, gallbladder, pancreas, kidney, stomach, uterus, and cervix in addition to non-Hodgkin's lymphoma and multiple myeloma. Overall, obesity causes 14% of cancer deaths among men and 20% of cancer deaths among women. Excess body fat may act by altering levels of hormones and tumor growth factors. It is clear that excess weight has severe health consequences.

In addition to raising the risk of cancer, overweight and obesity also increase the risk of a multitude of other diseases and chronic conditions, such as stroke, cardiovascular disease, type 2 diabetes, osteoarthritis, and pregnancy complications.

The International Agency for Research on Cancer has proposed a comprehensive set of recommendations to address the issue of weight control at multiple levels, including steps by health care providers, regulatory approaches to create adequate access to safe places for exercise (including school, worksite, and community), and family and community level actions.

Trends

In the U.S., the prevalence of overweight and obesity has increased so dramatically and so rapidly, it is frequently referred to as an obesity epidemic. The trend is also being seen among children and adolescents.

This epidemic has affected people of all ages, races, ethnicities, socioeconomic levels, and geographic regions. Given limited long-term success in weight reduction programs, the cancer burden due to obesity will likely continue to follow the rising prevalence of this risk factor in the coming years.

Dietary Improvements

Fruit and vegetable intake has been most consistently evaluated as a cancer prevention strategy. The global burden of inadequate intake is estimated to account for over 2M deaths each year. While evidence for cardiovascular benefits and reduced risk of diabetes are clear, evidence for cancer risk reduction has become less convincing with the results of numerous prospective cohort studies showing weaker associations with cancer risk. Low intake of fruits and vegetables are probably related to increased risk of pancreas, bladder, lung, colon, mouth, pharynx, larynx, esophagus and stomach cancer.

Although the effect of fruit and vegetable consumption on the risk of prostate cancer has been examined in nearly twenty studies, data remain inconsistent. The majority of studies suggest that overall fruit and vegetable intake has little effect if any on the risk of prostate cancer. However, individual fruits and vegetables may offer the potential for greater risk reduction, with tomatoes being the most promising, with a 40–50% reduction in risk among men who consumed large amounts of tomatoes and tomato products. The carotenoid ►lycopene is hypothesized to be responsible for the protective effect.

A number of mechanisms have been suggested to explain the protective effect of fruits and vegetables, but it is not known if specific agents, such as ►carotenoids, folic acid, and vitamin C, or a special combination of factors create anticarcinogenic effects. It is also possible that diet in childhood and adolescence is more important than later in life in driving risk of cancer.

A number of studies have found that as folate intake increases, the risk of colorectal cancer (as well as polyps) decreases. The Nurses' Health Study found that a high intake of folate from fruits and vegetables was sufficient to lower risk but that supplementation with a multivitamin that contained folate offered even greater reductions. The underlying biologic role of folate and its interaction with the MTHFR gene add support to the causal relation between low folate and colon cancer.

In addition to the reduction in risk of colon cancer, growing evidence points to folate also reducing the adverse effect of alcohol on breast cancer. Based on this evidence and the benefits for prevention of neural tube defect and cardiovascular disease, use of a daily vitamin supplement containing folate is recommended.

Dietary Fat

Variations in international cancer rates have often been attributed to differences in total fat intake, yet evaluation has shown no clear link between dietary fat and breast, colon or prostate cancer. Although dietary fat overall does not appear to impact cancer risk, there is some evidence to suggest that certain types of fat, such as animal fat, may increase risk.

Fiber has been shown to reduce the risk of heart disease and diabetes, but it does not appear to offer protection against cancer. Long believed to help prevent colon cancer, the data do not support this hypothesis.

Red Meat

High intake of red meat, including beef, pork, veal and lamb is associated with an elevated risk of colorectal cancer. The mechanism of this increased risk is not well understood, but it may be related to the high concentrations of animal fat or to carcinogens such as heterocyclic amines produced when the meat is cooked at high temperatures.

Calcium

Higher calcium intake has been linked to a reduced risk of colorectal adenomas and colorectal cancer. However, increased dietary calcium is also associated with an increased risk of prostate cancer. Research indicates that there may be a moderate intake of calcium that provides protection against colorectal cancer risk without causing a large increase in prostate cancer risk.

Excess Caloric Intake

One consistent dietary finding is that excess calories from any source result in weight gain and increased cancer risk. As the obesity epidemic continues to spread, the importance of balancing caloric intake with caloric expenditure becomes even more evident for the prevention of cancer and other chronic diseases.

Whole Grains

Although grain products in general have not been shown to affect cancer risk, whole-grain foods may provide some protection against stomach cancer. Grains such as wheat, rice, and corn form the basis for most diets worldwide. Some grain products, such as whole-wheat bread and brown rice, are consumed in the "whole-grain" form, while others, like white bread and white rice, are more refined. During the process of refining grain, most of the fiber, vitamins, and minerals are removed, thus whole-grain foods tend to be more nutrient-rich than refined foods and may offer more in terms of disease prevention. The benefits of whole-grain foods in reducing cardiovascular disease and ischemic stroke are well established.

Vitamin A and Carotenoids

Isolated ►vitamin A and carotenoids are not likely to play a large role in cancer prevention. Some observational data support a probable inverse relation with lung cancer risk, but randomized trials of beta-carotene intake found either no effect or an increased risk of lung cancer. It has also been suggested that beta-carotene impacts breast cancer risk, however, it seems that at

best, there is only a small decrease in breast cancer risk associated with a high intake of carotenoids.

Selenium

Ecological studies have suggested that increased ►selenium intake is associated with decrease risk of colon and breast cancer. A randomized control trial of selenium for skin cancer prevention showed no effect of selenium on skin cancer incidence, however it did show a reduction in incidence of lung, colon and prostate cancer. Despite these promising results, the impact of selenium remains unclear. Fortification of the soil in Finland in the mid-1980s led to higher blood selenium levels, but no decline in incidence or mortality has been noted for prostate or colon cancer.

Vitamin D

Growing evidence relates lower levels of ►vitamin D to increased risk of cancer and to poor survival after diagnosis.

Trends

The proportion of adults consuming the recommended five servings of fruits and vegetables a day varies between 8 and 32%. While these estimates are clearly low for the entire population, certain groups, as defined by gender, race/ethnicity, education, and income, are of particular concern.

Given constraints due to both financial resources and physical access to markets that provide fresh fruit and vegetables, it remains likely that SES gradients in diet will continue. Interventions are needed to overcome these existing barriers and make healthy foods readily available to all.

Limitation of Alcohol Use

Globally, alcohol intake in excess is responsible for 1.8M deaths each year. Clear benefits of moderate alcohol intake have been shown in terms of reducing cardiac and diabetes risk, but alcohol remains a risk factor for cancer mortality.

Alcohol is a known carcinogen that may raise cancer risk in several ways. For example, it may act as an irritant, directly causing increased cell turnover, or it may allow for improved transport and penetration of other carcinogens into cells. Alcohol use is a primary cause of esophageal and oral cancer, and it is associated with an increased risk of breast, liver, and colorectal cancer. Multiple other risks are also associated with alcohol use, including the risk of hypertension, addiction, suicide, accident, and pregnancy complication.

To balance the cardiovascular benefits with the risks of cancer and other negative consequences, it is recommended that those who drink alcohol should do so only in moderation. Intake should be limited to less than one drink per day for women and less than two drinks per day for men.

Safer Sex and Decreased Viral Transmission

►Unsafe sex is responsible for 2.9M deaths each year, primarily due to the transmission of ►HIV. However, unprotected sexual contact also results in the spread of multiple other sexually transmitted infections including oncogenic viruses. Some of these viruses may also be spread through exposure to blood and blood products.

►Human papillomavirus causes cervical cancer, vulvar, penile and anal cancer; ►hepatitis B virus and ►hepatitis C virus cause ►hepatocellular cancer; human lymphotropic virus-type 1 is associated with adult T cell leukemia (►human T-cell leukemia virus); human immunodeficiency virus-type 1 causes ►Kaposi sarcoma and non-Hodgkin lymphoma; and human herpes virus causes Kaposi sarcoma and body cavity lymphoma.

Prevention strategies to contain the spread of these viruses should include behavioral and educational interventions to modify sexual behavior, and structural and regulatory changes to promote safer sex and make condoms readily available. Biomedical interventions to administer vaccines are also needed. For example, it is estimated that vaccination programs could reduce the global burden of liver cancer by 60%. Additional strategies to prevent viral spread include needle exchange programs for intravenous drug users; regulation of tattooing and acupuncture; screening of blood donors, and the development of artificial blood products.

Trends and Disparities

Current U.S. data on the prevalence of these different viruses is not adequate to predict trends in cancer incidence. In addition, the recent development of new technologies such as vaccines against HPV, suggest a new era in prevention of cervical cancer. However, for success, such vaccines must be available and accessible to the entire population. Assuring access remains a policy priority to maximize the potential benefit of this cancer prevention strategy.

Sun Protection

The American Cancer Society estimates over 50,000 melanoma diagnoses each year in the U.S. The incidence of melanoma is rising more rapidly than that of any cancer in this country. Exposure to the sun (►UV radiation) is the major modifiable cause of melanoma and other skin cancers. For most people, the majority of lifetime sun exposure occurs during childhood and adolescence, and migrant studies clearly show that age at migration to high-risk countries has a strong impact on risk of this malignancy. For this reason, early intervention has the greatest potential for prevention.

The risk of melanoma and other less aggressive forms of skin cancer exists for all racial and ethnic groups, but skin cancers occur predominantly in the non-Hispanic white population. Constitutional characteristics including hair color, mole count, and family history contribute to risk of melanoma. However, studies show that established risk factors alone do not identify a sufficient proportion of cases to focus prevention efforts on only a subset of the population. Because identifying high-risk individuals will miss the majority of cases, population-based efforts provide greater protection. There is tremendous potential to substantially reduce the burden of this common malignancy through effective prevention efforts.

Screening

Screening for cancer can provide protection in several ways. In the case of colorectal and cervical cancers, screening can detect premalignant changes that can be treated to prevent cancer from developing. This primary prevention has the potential to substantially reduce the burden of cancer. With colorectal screening the mortality from colon cancer is reduced by a half or more.

If cancer is already present, screening can act as a secondary prevention (►early detection), such as mammography for breast cancer, facilitating early diagnosis and treatment, thereby decreasing morbidity and mortality. This type of prevention is an added benefit of colorectal and cervical screening, and is the main goal of breast cancer and prostate cancer screening.

Trends and Disparities

Trends in cervical cancer screening have been impacted by the breast cancer cervical cancer screening act which provided resources to states, via the Centers for Disease Control and Prevention, to bring screening services to low income women. Despite these efforts, national data suggest that low income and Hispanic women are less likely to be current with screening recommendations. Lack of access to care, defined as not having a usual source of health care, was associated with significantly lower compliance with cervical screening. Evidence from the 1998 Health Interview Survey indicates that all US born women have comparable and high compliance with screening for cervical cancer. Foreign born women, however, appear to be under-screened, accounting for the disparity among Hispanic women and suggesting a priority area for prevention as the U.S. continues to have a large immigrant population at risk of cancer. Surveys of colorectal screening suggest that the rates of screening have been rising and that Caucasians are more likely to be up to date with screening than other racial or ethnic groups.

Conclusion

Lifestyle changes offer tremendous potential for prevention of cancer and multiple other chronic conditions. This potential is often underestimated. To achieve the maximal benefit through behavioral change, interventions are necessary at multiple levels. Societal changes are needed to support and encourage the behavior modification of individuals. Approaches are needed to target individuals, communities, and systems, and create an environment less inductive to high-risk lifestyles. Social systems and regulatory efforts must complement individual behavior changes if these changes are to be sustained and the benefits of reduced disease burden realized.

Overall, the major lifestyle factors considered here account for the majority of cancer and could be modified to prevent at least half of all cancers. However, the burden of cancer is not limited to just the major lifestyle factors considered here. For example, occupational and environmental exposures also account for a relatively small number of cancer cases compared to the lifestyle factors considered above. Yet the burden of exposure to these harmful agents may be disproportionately high among low-income populations, accentuating their cancer risk. In large part, these exposures can be prevented through adequate enforcement of regulatory changes, and this should remain a high priority.

Small individual changes can result in large population benefits, but efforts to create prevention programs for only certain members of our society limits the potential for prevention. We must largely reframe our approach to the issue. Identifying risk factors and setting goals for reduction is only the beginning. Research and policy must now focus on bringing about population-wide lifestyle change, addressing the issues of disparities, and leaving no group or community behind.

Population-based cancer research

Definition

Knowledge about causes and preventive strategies for malignant neoplasms has greatly advanced during the last decades. This is largely attributable to the development of cancer epidemiology. In parallel to the identification of the causes of cancer, primary and secondary preventive strategies have been developed. A careful consideration of the achievements of cancer research, however, suggests that the advancements in knowledge about causes and mechanisms have not been followed by an equally important reduction in the burden of cancer. Part of this paradox is explained by the long latency occurring between exposure to carcinogens and development of the clinical disease. In addition, the most important risk factors of cancer are linked to lifestyle, and their modification entails cultural, societal and economic consequences. The failure to identify valid biomarkers of cancer risk is another reason of the limited success in cancer control.

Cancer epidemiology investigates the distribution and determinants of cancer in human populations. Although the main tool in cancer epidemiology is the ►observational study, ►the intervention study, of experimental nature, is conducted to evaluate the efficacy of prevention strategies, such as screening programs and chemoprevention trials (clinical trials are usually considered outside the scope of epidemiology). Intervention studies follow the randomized trial design. Observational epidemiology can be broadly divided in ►descriptive epidemiology and analytical studies. Analytical studies can be based on data collected at the individual or population level. The former consist of ►cohort study, ►case-control study and ►cross-sectional study (and a few variations on these themes), the latter of so-called ►ecological study. Family-based studies are used in ►genetic epidemiology to identify hereditary factors. An additional useful distinction among etiological studies concerns the nature of the information on exposure: while some studies use information routinely collected for other purposes, such as censuses and medical records, in other circumstances exposure data are collected ad-hoc following a variety of approaches including questionnaires, pedigrees, environmental measurements, measurement of biological markers. A method-oriented (rather than subject- or design-oriented) approach has lead to the identification of specific sub-disciplines such as ►molecular epidemiology.

Characteristics

A distinctive feature of cancer epidemiology is the availability in many countries of a population-based ►cancer registry, which allow the calculation of valid and reliable estimate of the occurrence of cancer (incidence, mortality, prevalence, survival). Typically, registries collect routinely demographic data of patients, which are used to generate statistics according to period of diagnosis, age, sex, and other characteristics. These studies of descriptive epidemiology have been critical in developing etiological hypotheses. One particular type of descriptive studies concerns migrants from low- to high-risk areas, or vice-versa: the repeated demonstration of rapid changes in the risk of many cancers among migrants (from that prevalent in the area of origin towards that of the host area) provided very strong evidence of a predominant role of modifiable factors in the etiology of human cancer. While cancer registries were initially established in high-resource countries, a growing number of population s in middle- and low-resource countries are now covered by good-quality registries, thus providing a solid infrastructure for most ambitious research projects.

Other routinely collected data are used in epidemiology. Mortality statistics are available in many countries of the world, and provide a good approximation of the incidence of the most fatal cancers. In a growing number of populations, automatic linkage is possible between incidence or mortality data and other population-based registries (e.g., hospital discharges, use of medications). ►Record-linkage study may represent an efficient alternative to investigations based on ad-hoc collection of data.

The number of new cases of cancer which occurred worldwide in 2002 has been estimated at about 10,800,000. Of them, 5,800,000 occurred in men and 5,000,000 in women. About 5,000,000 cases occurred in developed countries (North America, Japan, Europe including Russia, Australia and New Zealand) and 5,800,000 in developing countries. Among men, lung, prostate, stomach, colorectal, and liver cancers are the most common malignant neoplasms, while breast, cervical, colorectal, lung and stomach cancers are the

most common neoplasms among women. The number of deaths from cancer in 2002 was estimated at about 6,700,000 and that of 5-year prevalent cases at about 24,600,000.

Epidemiology has been instrumental to identify the causes of human cancer. In several cases, the epidemiological results preceded the elucidation of the underlying mechanisms. In other areas, however, epidemiological techniques are not sufficiently sensitive and specific to lead to conclusive evidence on the presence or absence of an increased risk. As for other branches of the discipline, the observational nature of epidemiology represents an opportunity for bias, including that generated by confounding, to generate spurious results. Techniques have been developed to prevent, control and assessment the presence and extent of bias in epidemiological studies.

Cancer epidemiology has lead to the identification of tobacco smoking and use of smokeless tobacco products, chronic infections, overweight, alcohol drinking and reproductive factors as major causes of human cancer. Other important causes include medical conditions, some drugs, perinatal factors, physical activity, occupational exposures and ultraviolet and ionizing radiation. A role of diet in cancer risk has been suggested, but for very few dietary factors there is conclusive evidence of an effect on cancer risk. With a few exception of little relevance in most populations, the role of pollutants on cancer is not established. Tobacco smoking is the main single cause of human cancer worldwide. It is a cause of cancers of the oral cavity, pharynx, esophagus, stomach, liver, pancreas, nasal cavity, larynx, lung, cervix, kidney and bladder, and of myeloid leukemia. The proportion of cancers in a population attributable to tobacco smoking depends on the distribution of the habit a few decades earlier. Therefore, in populations in which the tobacco epidemic has not fully matured (e.g., men in many low-income countries and women in most European countries), the full effect of tobacco smoking on cancer burden is not yet observed.

The notion that genetic susceptibility plays an important role in human cancer is old, and genetic epidemiology studies have characterized familial conditions entailing a very high risk of cancer have been identified, such as the Li-Fraumeni syndrome and the familial polyposis of the colon, and have identified high-risk cancer genes responsible for these syndromes. However, such high-risk conditions explain only a small fraction of the role of inherited susceptibility to cancer. The remaining fraction of genetic predisposition is likely explained by the combination of common variants in genes involved in one or more steps in the carcinogenic process, such as preservation of genomic integrity, repair of DNA damage. The identification of such low-penetrance susceptibility genes and of their interactions with exogenous factors (so-called ▶gene-environment interactions) represents a challenge to genetic epidemiology.

Advances in molecular biology and genetics offer new tools for epidemiological investigations, and have lead to the development of new methodological approaches, broadly defined as molecular epidemiology. The application of biomarkers to epidemiology has lead to advances in the identification of human carcinogens (e.g., the role of aflatoxin in liver cancer) and in the elucidation of mechanisms of carcinogenesis (e.g., *TP53* mutations in tobacco-related carcinogenesis).

Exposure to most known carcinogens – at least in theory – be avoided or reduced. This is true in particular for tobacco smoking and chronic infections, the two major known causes of cancer. Tobacco control measures have been implemented in most countries, and effective vaccination is today available against two of the main carcinogenic viruses, Hepatits B and Human Papilloma. Control of workplace exposure to known and suspected carcinogens in high-resource countries is another example of successful primary prevention of cancer. In many instances, however, primary prevention of cancer would require major changes in lifestyle, which are difficult to achieve.

Detection of preclinical neoplastic lesions before they have developed the full malignant phenotype, and notably the ability to metastasize is a highly appealing approach to control cancer. The effectiveness of screening has been demonstrated via epidemiological studies for cervical cancer (cytological smear), breast cancer (mammography) and colorectal cancer (colonoscopy). The development of effective strategies for the early detection of other neoplasms is an active area of research.

Cancer epidemiology exemplifies the strengths and the weaknesses of the discipline at large. Cancer epidemiology has the privilege of using complete and good quality disease registries available in many populations and covering a broad spectrum of rates and exposures. In many occasions, cancer epidemiology has been the key tool to demonstrate the causal role of important cancer risk factors. The best example is the association between tobacco smoking and lung cancer, which lead in the early 1960s to the establishment of criteria for causality in observational research. These findings have brought important regulatory and public health initiatives as well as lifestyle changes in many countries of the world. These epidemiological "discoveries" share two important characteristics: they involve potent carcinogens and methods are available to reduce misclassification of exposure to the risk factor of interest and to major possible confounders. It has been therefore possible to demonstrate consistently an association in different human populations. Note that it is not necessary for the prevalence of exposure to

be high (although this obviously has an impact on the population ►attributable risk): examples are the many occupational exposures and medical treatments for which conclusive evidence of carcinogenicity has been established on the basis of epidemiological studies conducted in small populations of individuals with well characterized exposure.

When these conditions are not met, however, the evidence accumulated from epidemiological studies is typically inconsistent and difficult to interpret. The history of cancer epidemiology presents many examples of premature conclusions, which have not been confirmed by subsequent investigations and have damaged the reputation of the discipline. Exposure misclassification, uncontrolled confounding, emphasis of positive findings generated by chance, and inadequate statistical power are the most common limitations encountered in epidemiological studies. Several solutions have been proposed to overcome these problems. First, epidemiological studies should be very large in size. This is achieved either by conducting multicentric studies including thousands of cases of cancer, or by performing pooled and meta-analyses of independently investigations. Second, as mentioned above, the use of biological markers of exposure and early effect might contribute to reduce exposure misclassification, increase the prevalence of the relevant outcomes and shed light on the underlying mechanisms. Finally, guidelines have been developed to improve and standardize the conduct are report of observational epidemiological studies.

Although relatively young, epidemiology has become a key component in cancer research. Most cancer centers have an epidemiological research group, and cancer is a major subject of research in most academic departments of epidemiology. Epidemiologists are more and more often invited to meetings of clinicians and basic researchers not only to provide an introduction to the distribution and the risk factors of a given cancer, but to participate in interdisciplinary discussions on clinical, preventive or mechanistic aspects of the disease. The strongest cancer epidemiology groups in the world are those combining different lines of expertise, from biostatistics to molecular biology and genetics to medical oncology. Despite its limitations, cancer epidemiology remains one of the most powerful tools at the disposal of the research community to combat cancer at all levels.

Cancer Epigenetics

Berna Demircan, Kevin Brown
University of Florida College of Medicine, Gainesville, FL, USA

Definition

►Epigenetics is defined as chromatin modifications that can alter gene expression, are heritable during cell division, but do not involve a change in DNA coding sequence.

Characteristics

In the context of normal biological processes, epigenetic mechanisms establish regions within the genome containing transcriptionally active (termed euchromatin) and silent (termed heterochromatin) DNA. Further, epigenetic mechanisms are responsible for stably inherited patterns of gene expression such as X chromosome inactivation and genomic imprinting (i.e., selective expression of maternal or paternal alleles). Chromatin modifications that alter gene expression are both changes to the methylation state of DNA and post-translational modifications to histone complexes.

It is well recognized that genetic mutations occur in cancer cells and that these events can exert profound and disease-associated changes in gene expression and/or function. However, it is becoming widely accepted that cancer cells also exhibit aberrant epigenetic alterations and that these changes can play a prominent role in disease initiation and progression. Epigenetic changes are potentially as important as genetic mutations in causing cancer since chromatin alterations can exert an influence regional gene expression, thereby changing the transcriptional profile of multiple genes. In this chapter we summarize the principal epigenetic alterations that occur in cancer cells: regional DNA hypermethylation and ►histone modifications, and global DNA hypomethylation.

DNA Hypermethylation

Chromatin structure is influenced by cytosine ►methylation, the only known naturally occurring base

modification in DNA. Cytosine methylation occurs at 5′-CG-3′ dinucleotides (referred to as CpGs) and is catalyzed by a class of enzymes termed ►DNA methyltransferases (DNMTs). Several DNMTs have been characterized in mammalian cells including DNMT1, DNMT3a and DNMT3b. These enzymes catalyze the transfer of a methyl group from S-adenosylmethionine (SAM) to the 5-carbon position of cytosine, forming 5-methycytosine. DNMT3a and DNMT3b appear to be principally involved in methylating previously unmodified cytosines (termed de novo methylation). In contrast, DNMT1 preferentially methylates hemimethylated DNA and is thus viewed as the DNA methyltransferase principally responsible for continuation of DNA methylation patterns in daughter cells (termed *maintenance* methylation).

From a statistical standpoint, the human genome is depleted in CpG dinucleotides; however, ~60% of genes in our genome are associated with regions ranging from 200 to 4,000 bases in length containing high density of CpG dinucleotides relative to the bulk genome. These regions are referred to as ►CpG islands and are usually located within upstream promoter regions or gene transcriptional start sites. In normal somatic cells, gene-associated CpG islands are usually unmethylated and associated with genes in a transcriptionally active euchromatic state. In cancer cells, hypermethylation of such CpG islands is strongly correlated with the transcriptional silencing of genes. Thus, through this epigenetic mechanism, tumor cells can dramatically down regulate expression of numerous genes, including ►tumor suppressor genes (TSGs). At present, numerous TSGs have been characterized as targets for epigenetic silencing through hypermethylation of associated CpG islands. Table 1 is a partial listing of characterized TSG whose promoter regions have been shown to be hypermethylated in various tumor types. Given the wide spectrum of tumor types that display epigenetic silencing of TSGs, mounting evidence clearly supports the assertion that epigenetic silencing is a prominent mechanism driving the process of tumorigenesis.

Cancer cells often over express DNMTs. Compared to normal tissues, the expression of DNMT1 is almost always increased in tumors. However, since DNMT1 expression is normally regulated during the cell cycle with increased abundance paralleling entry into S-phase, much of this increased expression may simply reflect increased cell proliferation within the tumor. Although demonstrable in model experiments, it remains unresolved if increased expression of DNMT1 is responsible for aberrant methylation in cancer cells. In contrast, increased expression of DNMT3a and DNMT3b observed in some tumors is likely significant, since these enzymes are normally expressed at low levels in somatic cells. However, it is still unclear to what extent over expression of these enzymes is responsible for cancer-associated DNA hypermethylation especially when one considers that cancer cells exhibit overall genome hypomethylation (discussed below). Thus, it remains unclear how CpG islands associated with specific TSG are targeted for hypermethylation during the process of tumorigenesis.

One mechanism by which DNA methylation can negatively impact gene expression is by simply blocking the binding of essential transcription factors to gene promoter sequences. While several examples of this are documented, it is also apparent that CpG methylation is also capable of directing transcriptional repression through promoting additional layers of chromatin alteration. Specifically, several proteins have been characterized that bind to methylated CpG dinucleotides and are capable of promoting further chromatin condensation and consequential transcriptional repression through recruitment of chromatin-modifying activities.

Cancer Epigenetics. Table 1 Genes subject to epigenetic silencing in cancer

Gene	Function	Tumor types
APC	Regulation of β-catenin, cell adhesion	Colorectal, gastrointestinal
BRCA1	DNA repair	Breast, ovarian
CDH1 (E-cadherin)	Homotypic epithelial cell–cell adhesion	Bladder, breast, colon, liver
MGMT	DNA repair	Brain, colorectal, lung, head and neck
MLH1	DNA repair	Colorectal, endometrial, ovarian
CDKN2A (p16)	Cell cycle control	Lung, brain, breast, colon, bladder, melanoma prostate
PTEN	Regulation of cell growth and apoptosis	Prostate, brain, endometrial, melanoma
VHL	Inhibits angiogenesis, regulates transcription	Renal cell carcinoma
ATM	DNA damage response	Breast, colorectal, head and neck

Histone Modification

Owing to technical considerations, DNA methylation is the most widely analyzed type of epigenetic alteration in human tumors. However, another extremely important epigenetic modification capable of altering gene expression during carcinogenesis involves various types of histone modifications.

The fundamental packing unit of chromatin within the nucleus is termed the ►nucleosome. A single nucleosome unit contains 146 base pairs of DNA wrapped around eight histone subunits (histone octamer). The histone octamer contains two copies each of histones H2A, H2B, H3 and H4. Structural studies have determined that each histone possesses an amino-terminal tail rich in the amino acid lysine. These lysine residues can undergo a variety of post-translational modifications including acetylation, methylation, phosphorylation, and ubiquitination. Such modifications are recognized by various proteins and protein complexes and combinations of histone modifications constitute a proposed histone code important in establishing a given gene's transcriptional profile.

Perhaps the best-studied histone modifications is acetylation of the ε-amino group of lysine residues within the amino-terminal tail of H3 and H4 although acetylation of both H2A and H2B occurs as well. This is a reversible modification that is carefully controlled by two large enzyme families: histone ►acetyltransferases (HATs) and ►histone deacetylases (HDACs). The net positive charges carried by these lysine residues are proposed to contribute to the high affinity of histones for negatively charged DNA. Acetylation of lysine residues by HATs neutralizes this positive charge thus decreasing histone/DNA interaction. This raises molecular access to DNA and promotes gene transcription. Conversely, HDACs promote transcriptional repression by supporting chromatin condensation into a heterochromatic conformation.

Several proteins that bind specifically to methylated CpG through a conserved methyl-binding domain (MBD) motifs have been discovered. The first such protein to be characterized, termed MeCP2, is capable of recruiting the co-repressor molecule mSin3 to the sites of methylated DNA. In turn, mSin3 binds to HDAC1 and HDAC2, thus promoting localized histone deacetylation. The importance of HDAC activity in transcriptional repression is underscored by the observation that repression of several gene promoters that can be partially relieved by HDAC inhibitors. A functionally similar complex termed MeCP1 binds to methylated DNA via an associated protein termed MBD2. The MeCP1 complex contains multiple subunits besides MBD2, including components of the NuRD complex, a characterized repressor complex containing both chromatin remodeling and HDAC activities.

In addition to acetylation, lysine residues within histone tails can be methylated and exist in either mono-, di-, or trimethylated states. Similar to the effects of histone acetylation/deacetylation, methylated lysine 4 of H3 (H3K4) is associated with transcriptionally active chromatin, while transcriptionally silent chromatin generally contains methylated lysine 9 of H3 (H3K9). H3K9 is methylated by a number of histone methyltransferases including ESET, Eu-HMTase, G9a, and the closely related methyltransferases SUV39-H1 and SUV39-H2. Histone methylation is likely a dynamic process since a histone demethylase, termed LSD1, was recently characterized. Methylated H3K9 binds to the chromodomain protein heterochromatin protein 1 (HP1) which promotes heterochromatin formation and gene silencing. Moreover, since H3K9 methylation cannot occur when this position is acetylated, it is clear that H3K9 acetylation and methylation represent opposing forces in determining chromatin conformation.

In a broad view, it is reasonable to propose that CpG methylation and histone acetylation/deacetylation act synergistically in the progressive silencing of genes. One model that accounts for tumor-suppressor gene silencing by epigenetic mechanisms invoke abnormal hypermethylation of the promoter CpG island followed by recruitment of MBD proteins, including complexes such as MeCP2 and MeCP1 that recruit HDACs to the area of hypermethylation and promote further transcriptional repression through histone modification. An alternate model proposes that transcriptionally repressive histone modifications are the first event in gene silencing and subsequently promote CpG methylation resulting in further transcriptional repression. Experimental evidence supports both of these models and may be reflective of the variety of gene promoters and model systems used for study. Less equivocal is the fact that DNA methylation appears the dominant silencing mechanism since inhibition of DNA methylation generally restores gene expression while HDAC inhibitors generally exert more modest effects on gene silencing.

DNA Hypomethylation

While CpG islands associated with gene promoters are generally unmethylated in normal adult somatic cells, the majority of CpG dinucleotides elsewhere in the genome are generally methylated. Moreover, despite the fact that many CpG islands are subject to hypermethylation in cancer cells, it is equally well documented that tumor cells display an overall loss of methylated cytosines compared to normal tissue. This tumor-associated global DNA hypomethylation predominantly occurs in repetitive DNA sequences within the human genome although the molecular mechanisms responsible for this loss of DNA methylation are poorly understood.

Recent work on a human genetic disorder has underscored an important role for DNA methylation in maintenance of genome stability. The immunodeficiency, centromeric region instability, facial anomalies (ICF) syndrome is a rare autosomal recessive disease characterized by germline mutation of the DNMT3B gene. Loss of DNMT3B activity in ICF leads to hypomethylation of repetitive satellite DNA sequences within heterochromatin adjacent to the centromeric region of chromosomes. The loss of methylation is most prominent within the pericentric regions of human chromosomes 1 and 16 and leads to multiple chromosomal abnormalities including chromatin decondensation, chromosomal translocations and deletion, and multiradial chromosomal structures. These observations, as well as those made on cells with engineered disruption of DNMTs, clearly support the view that DNA methylation is critical in maintaining normal chromosome structure. Since cancer cells often show chromosomal rearrangements, it is likely that cancer-associated DNA hypomethylation allows for heightened rates of chromosomal instability.

Retrotransposon sequences of the LINE (long interspersed nuclear element) and SINE (short interspersed nuclear element) classes as well as human endogenous retroviruses (HERVs) are major targets of tumor-associated DNA hypomethylation. Mobility of these DNA elements is kept in check in normal tissues owing, in part, to dense methylation of CpG dinucleotides within their genomic structure. It follows that increased mobility of these dormant mobile elements occurs as a result of cancer-associated DNA hypomethylation and there have been reports of retrotransposition-like insertions involving LINE-1 sequences in tumors although retrotransposition of endogenous elements seemingly occurs more often in rodents than humans.

In addition to the hypomethylation of CpG dinucleotides present within repetitive DNA elements, cancer-associated hypomethylation also occurs in regions of the genome encoding single-copy genes. Dysregulation of allele-specific methylation will result in the loss of imprinting (LOI) and allow for both maternal and paternal gene expression. Perhaps the best-studied example of this is the insulin-like growth factor 2 (IGF2) gene where LOI occurs in primary tumors and in patients with the inherited, cancer-prone ►Beck-with-Wiedemann. While not as well-studied as gene silencing due to DNA hypermethylation, it is likely that additional examples of cancer-promoting increased gene expression stemming from DNA hypomethylation will be uncovered in the future.

Epigenetic Alterations as Targets for Diagnosis and Therapeutic Intervention

Sequencing data obtained from the human genome project are currently undergoing analysis to construct a human epigenetic map based on CpG content. This knowledge coupled with cross-species comparisons of the epigenome will be invaluable in deciphering the epigenetic elements involved in gene regulation. Epigenetic alterations typically occur early during the oncogenic process, and detection of such early abnormalities may aid in early diagnosis and/or preventing cancer progression through dietary alterations or pharmacological intervention. With increasing awareness of the importance of epigenetics in tumorigenesis, and the advent of sensitive laboratory approaches to analyze epigenetic alterations, it is likely that epigenetic profiles will ultimately be used in the clinical setting to provide information useful in predicting an individual's predisposition to cancer, assisting in tumor staging, and guiding optimal therapeutic approaches.

A promising feature of alterations in DNA methylation patterns and chromatin structure in cancer cells is their potential for reversibility, because these modifications occur without changing the primary nucleotide sequence. At present, two major pharmacological targets associated with these epigenetic changes are DNMTs and HDACs. The DNMT inhibitor 5-aza-deoxycytidine (5-azadC) and related compounds cause transcriptional reactivation of endogenous genes with hypermethylated promoters. This drug, also termed Decitabine, is currently used to treat certain types of hematological malignancies, especially advanced ►myelodysplastic syndromes (MDS). HDAC inhibitors, such as trichostatin A and sodium butyrate, have been shown to increase the level of histone acetylation in cultured cells, and to cause growth arrest, differentiation and apoptosis. Based on these observations, the potent HDAC inhibitor suberoylanilide hydroxamic acid (SAHA) is in clinical trials.

Cancer Genome Project

Definition

The Cancer Genome Project (CGP) was founded at the Wellcome Trust Sanger Institute in 2000 and aims to establish an unbiased catalogue of mutations involved in human tumorigenesis by complete sequencing of candidate genes. By sequencing the human *BRAF* gene, the CGP discovered a hitherto unknown mechanism of oncogenic activation of B-Raf that is not only found in 7% of human cancers, but also provided more insight into the complex process of B-Raf activation.

Cancer-testis (CT) antigens; CG antigens

Definition

CG ►antigens (Cancer-testis (CT) antigens) are a class of immunogenic tumor antigens encoded by genes expressed in ►gametogenic cells of the testis and/or ovary and in human cancer.

Characteristics

Identification

The main criterion for classification of a gene as a CG antigen pertains to its expression pattern in gametogenic, somatic, and tumor tissues. A gene is generally considered to be a CG antigen if it is expressed in the gametogenic cells of the testis or ovary (including fetal ovary) and in some proportion of human cancers, but is expressed in two or fewer normal somatic tissues. CG antigen genes are also commonly expressed in ►trophoblast tissue. CG antigens were originally identified from searches for auto-antigens expressed in human cancer. The original method for antigen screening used ►autologous typing, in which ►T-cells (T-lymphocyte) from a ►melanoma patient were screened for reactivity with tumor cells from the same patient; this method led to the identification of MAGE-A (named for ►melanoma antigen)/CT1 genes. In later studies, another immunological assay was developed to identify tumor antigens and this method, ►SEREX (Serological analysis of recombinant cDNA expression libraries), was used to successfully identify a variety of important CG antigen genes, including NY-ESO-1/CT6 and SSX/CT5. Recognition of the unique expression pattern of CG antigen genes has led to the use of gene expression analyses (including EST or SAGE database searching) to identify CG antigen genes. This method has led to the identification of additional CG genes, including XAGE-1/CT12 and SCP-1/CT8. Although formally classified as CG antigen genes, genes identified by the latter non-immunological method may not be antigenic in cancer patients.

Nomenclature

A nomenclature system for CG antigens has been devised, which is based on their chronology of discovery, and also accounts for the numerous family members that exist for certain CG antigens. In this system, CG antigen genes are referred to by their original given names and also are assigned a separate CT identifier or CT#. Currently, over 40 CG antigen gene families are recognized, comprising more than 89 distinct mRNA transcripts. CG antigen genes have been assigned into two groups on the basis of chromosomal localization. ►CG-X antigens: These genes reside on the X-chromosome where, interestingly, close to 10% of the total number of genes encode CG antigens. CG-X genes are typically members of large multigene families, e.g. MAGE-A/CT1, MAGE-B/CT3, and MAGE-C/CT7. In normal tissues, CG-X genes are often expressed in pre-meiotic spermatocytes in the testis. All of the current important targets of CG antigen ►cancer vaccines are members of this group, including MAGE-A1/CT1.1, MAGE-A3/CT1.3, and NY-ESO-1/CT6.1. ►Non-X CG antigens: A number of CG antigen genes are located on autosomal chromosomes. Unlike CG-X genes, these genes are highly dispersed in the genome and do not exist in multigene families. In normal tissues, non-X CG genes are often expressed during meiosis, where some members play roles in DNA recombination, including SCP-1/CT8 and SPO11/CT35. The members of this gene group do not include any currently validated cancer antigens, although certain members are expressed at high levels in cancer.

Regulation of Expression

Certain cancer types appear to expresses CG antigen genes frequently, while others rarely express them. Tumor types that frequently express CG antigens include melanoma, lung, ovary, and ►bladder cancer; tumors that rarely express CG antigens include ►colon cancer, renal cancer, and leukemia/lymphoma. CG antigen genes show coordinate expression in human cancer. That is, the great majority of tumors either do not express CG antigen genes or express two or more CG antigen genes simultaneously, while relatively few tumors express only one CG antigen gene. Another characteristic of CG antigen gene expression in cancer (revealed by immunohistochemical staining) is that tumors that express CG antigens show heterogeneous expression within the tumor: often only focal staining is observed. The coordinate but heterogeneous expression of CG antigens in cancer has led to the intriguing hypothesis that CG antigen expression is indicative of the activation of a normally dormant gametogenic program in tumor cells (possibly corresponding to tumor stem cells).

The observation of coordinate expression of CG antigen genes suggests that CG antigen gene activation may be controlled by a common molecular mechanism. Supporting this idea, a number of studies

have suggested a key role for ►DNA methylation in regulating CG antigen gene expression. Promoter DNA hypermethylation has been observed to correlate with CG antigen gene repression in normal tissues and non-expressing tumors, while treatment of tumor cell lines *in vitro* with DNA methyltransferase inhibitors such as ►5-aza-2′-deoxycytidine (DAC) leads to CG antigen gene activation, coincident with promoter DNA ►hypomethylation. Conversely, tumor cell lines and tissues that endogenously express CG antigen genes often display promoter DNA hypomethylation. Many CG antigen genes have CpG-rich promoter regions that serve as targets for regulation by DNA methylation. Other studies have shown that ►histone deacetylase (HDAC) inhibitors can either augment DAC-mediated CG antigen gene activation or can activate CG antigen genes on their own. As DNA ►methylation and ►chromatin structure (in the form of histone modification status) are intimately linked, it is not surprising that both of these ►epigenetic mechanisms serve as important regulators of CG antigen gene expression. Consistent with the model that epigenetic mechanisms regulate CG antigen gene expression is the observation that DNA hypomethylation occurs during gametogenesis, which is the normal setting for CG antigen gene expression.

Function

CG antigens are a rare group of genes in that clinical studies designed to target these antigens for ►immunotherapy of cancer are more advanced than is our basic knowledge of the function of the gene products. However, some information about CG antigen gene function has recently come to light. As mentioned earlier, many non-X CG antigens have roles in germ cell maturation, including mediating the structure of synaptonemal complexes (SCP1/CT8), facilitating DNA recombination during meiosis (SPO11/CT35), and contributing to spermatid function (ADAM2/CT15, OY-TES-1/CT23). In tumors, the function of CG antigen genes is less clear, but recent studies of the MAGE-type antigens, which share a region referred to as the MAGE homology domain (MHD), indicate that these proteins might serve as transcriptional repressors via interactions with other transcriptional regulatory proteins that themselves recruit co-repressors such as HDACs. CG antigen genes have also been reported to play a role in the evolution of ►chemotherapy resistance in cancer cell lines, suggesting that the CG antigen gene products could serve as viable targets for anticancer therapy. An recent report appears to link these two observations by showing that MAGE-A2/CT1.2 disrupts ►p53 function by recruiting HDAC3 to p53, leading to chemotherapy resistance in cancer cells.

Clinical Studies

The identification of CG antigens as tumor-specific antigens has led to a great deal of interest in treating cancer by targeting CG antigens via vaccine-based immunotherapy. In particular, MAGE-A1/CT1.1, MAGE-A3/CT1.3, and NY-ESO-1/CT6.1 have been developed as targets for this approach. In early studies, the antigenic peptides from CG antigens that elicited ►T-cell dependent responses were mapped, and these peptides were utilized for vaccination. Because responses to peptide-based vaccine formulations are limited by patient ►HLA type, more recent vaccination approaches targeting CG antigens have utilized full-length ►recombinant proteins. These recombinant proteins can be introduced using viral vectors, including vaccinia and fowlpox viruses. Alternatively, recombinant CG antigen proteins can be assembled with ►adjuvants such as ISOMATRIX, which further enhances immune responses. A common finding in CG antigen vaccine clinical studies is that the treatment is safe and elicits both ►antibody and T-cell mediated immune responses *in vivo*. In particular, NY-ESO-1/CT6.1 vaccine trials have shown encouraging results, with durable and multifaceted immune responses, as well as suggestive data indicating clinical benefit, in terms of disease stabilization and prolonged time to recurrence. Many of the patients targeted in these clinical trials have had malignant melanoma, and a proportion of these patients displayed evidence of immune recognition to the target antigen prior to vaccine therapy. In virtually all cases, patients have been selected for inclusion in CG antigen vaccine trials based on the expression of the antigenic target in tumor biopsies. To expand the patient population that would benefit from this immunotherapy approach, a number of investigators have proposed using DNA methyltransferase and/or HDAC inhibitors (which are FDA approved and known to augment CG antigen gene expression) in combination with CG antigen directed vaccines. The potential benefit of this multi-modality approach awaits clinical testing.

Tumor initiating cells

Definition

Cancer stem(-like) cells are those cells that possess the capacity for self-renewal and for causing the heterogeneous lineages of cancer cells that comprise the tumor.

Characteristics

The definition follows a consensus at a workshop on cancer stem(-like) cells (CSC) organized by the American Association for Cancer Research (AACR). There is considerable debate and some controversy on the CSC concept, so that a consensus definition is required. The importance of the debate is proportional to its relevance to the change in our perception of cancer, intirinsic to the CSC paradigm, implying that not all cancer cells are equal but that only a small fraction of them is endowed with the properties of perpetuating the disease. This hierarchical model has not only important biological consequences but also relevant therapeutic implications, as we discuss in this essay.

The CSC paradigm fits in a model of cancer as a caricature of an organ that is already present in the literature as suggested by data published 30 to 40 years ago. In particular, Hamburger and Salmon established growth conditions for cancer cells in soft agar medium and found that tumor stem cell colonies, arising from different types of cancer with 0.001–0.1% efficiency, had differing growth characteristics and colony morphology. Studies by Dick and co-workers in the 1990s showed that in several forms of acute myeloid leukemia (AML) cells that could engraft in immunodeficient mice are restricted to a minority subpopulation defined as [$CD34^{+}/CD38^{neg}$]: these cells, therefore, shared a cell surface phenotype with normal human primitive hematopoietic progenitors, suggesting that they may have originated from normal stem cells rather than from committed progenitors. Also of interest was the observation that leukemic cells engrafted in NOD-SCID mice (non obese diabetic-severe combined immunodeficiency: an immunodeficient mouse strain characterized by lack of B, T and NK lymphocytes) showed similar phenotypic heterogeneity to the original donor: thus, [$CD34^{+}$, $CD38^{neg}$] retain the differentiating capacity necessary to give rise to $CD38^{+}$ and Lin^{+} cells (lineage positive).

The presence of CSC has also been demonstrated in chronic myeloid leukemia (CML). This disease has a chronic phase and a terminal stage; the blast crisis and molecular events underlying this evolution are not completely understood. In the chronic phase, the chromosomal translocation t(9:22)BCR-ABL, a diagnostic marker of CML, can be detected in most circulating mature lineages. In the blast crisis, however, highly undifferentiated BCR-ABL^{+} cells accumulate in the blood. In particular, an expansion of granulocyte-macrophage progenitors (GMP) is present in blast cells, showing aberrant acquisition of self-renewal properties and nuclear expression (i.e. activation) of beta-catenin, a key, positive regulator of stem cell self-renewal. These observations imply that during progression of CML the GMP subfraction of leukemic progenitors acquire stem cell characteristics. Thus, the functional hierarchy of CSC can be modified during the natural history of this tumor as a result of its progression.

The requirement for a periodical renovation is not only present in blood but also in the skin and epithelia of the respiratory, gastrointestinal, reproductive and genito-urinary systems. Other tissues like brain, previously considered as exclusively post-mitotic, contain stem cells that can be mobilized and activated under conditions of stress, such as hypoxia. Thus the CSC model could also be applied to solid tumors, and a series of recent papers report data supporting the identification of a stem cell population in different cancers (see Table 1). Initial data were gained in breast cancer where a small population of cells with a $CD44^{+}$ /$CD24^{neg\text{-}low}$ phenotype appears exclusively capable of tumor initiation.

The most malignant of brain tumors, glioblastoma multiforme (GBM), was also found to contain a fraction of neoplastic cells identified and selected on the basis of CD133 expression. Not only could $CD133^{+}$ cells self-renew and differentiate into different neural lineages but also, in vivo, only the $CD133^{+}$ cells were able to re-initiate malignant gliomas with phenotype similar to the original tumor.

The CSC paradigm may also help to explain intra-tumor heterogeneity, a frequent finding in most cancers: heterogeneity could be consequent to functional diversity of cells at different states of differentiation. On the other hand, the patterns of tumor heterogeneity and gene expression profiles can be highly similar in the original tumor and in distant metastasis.

It is rather obvious that the existence of cancer stem cells may provide novel therapeutic targets of increased effectiveness in contrasting or even eliminating cancer. Brain tumors have provided a highly fertile ground to start verifying this hypothesis, as outlined in Table 2. Data are piling up indicating that $CD133^{+}$ GBM CSC are highly pro-angiogenic, because of the high levels of VEGF expression, and have greater resistance to chemotherapy and radiotherapy. As a consequence,

specific therapeutic strategies can be attempted and combined to overcome CSC. Upon radiotherapy $CD133^{+}$ GBM CSC activate checkpoint kinases 1 and 2 and repair mechanisms more effectively than $CD133^{neg}$ cells. Resistance to chemotherapy can be linked to an intriguing aspect of the CSC phenotype, the side population (SP) phenotype. SP cells have the ability to extrude the DNA binding dye Hoechst 33342 via the drug transporter BCRP1/ABCG2. Interestingly, the BCRP1/ABCG2 pump can also effectively extrude chemotherapeutic drugs such as mitoxantrone.

Also related, although of less immediate relevance in the clinical setting, are the observations reported by Pellegatta et al. using glioma neurospheres as a target for dendritic cell (DC, the most potent of antigen presenting cells) immunotherapy. Normal neural stem cells may grow as neurospheres (NS) in the absence of serum and in the presence of two critical growth factors, EGF and bFGF. NS are enriched in neural stem cells but also contain partially committed progenitors as well as a differentiated progeny. Oncospheres with similar characteristics were obtained from GBM but also from other solid tumors like breast or colon carcinomas. Pellegatta et al set up a murine model showing that DC loaded with GBM NS are much more effective in protecting mice against the GBM challenge than DC loaded with GBM cells where CSC are poorly represented. Thus, CSC targeting by immunotherapy is feasible and highly effective, opening new scenarios for clinical immunotherapy and supporting the idea that CSC are at the heart of malignant growth. Also of interest is the observation by Piccirillo et al. that treating GBM CSC with the differentiating factor BMP4 can block growth in vitro and avoid tumor formation in the majority of mice in vivo.

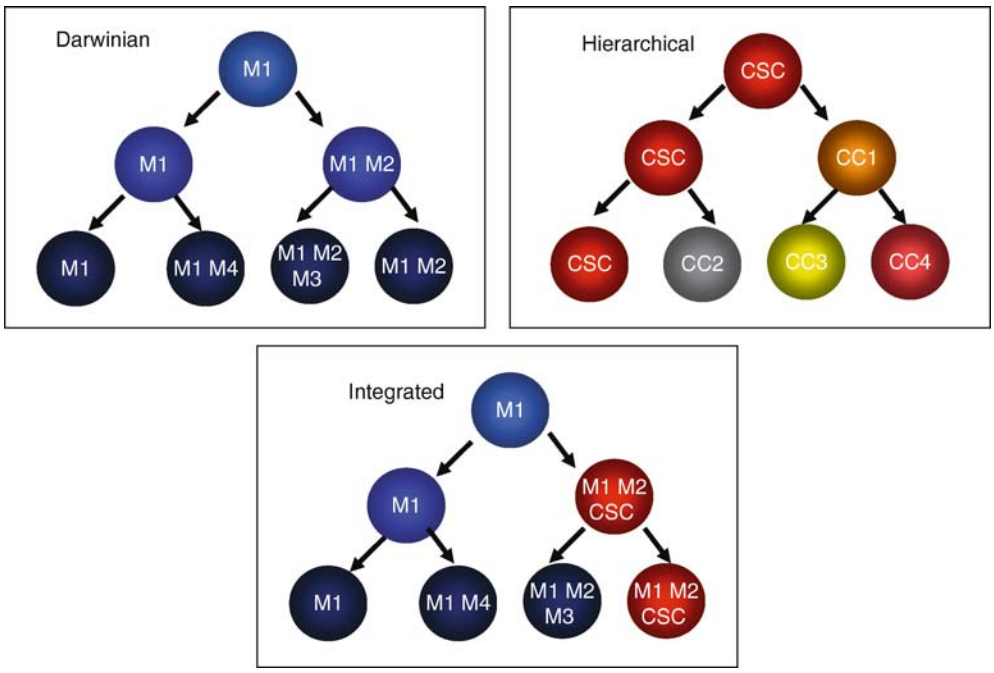
Given the increasing number of observations supporting the CSC paradigm in different tumors, it is expected that more therapeutically relevant observations will be proposed in the near future.

Together with therapeutic and clinical implications the CSC concept seems to have important consequences for our understanding of tumor biology. Modern genetics and molecular biology have given a definition of cancer as a genetic disease in which a growing burden of mutations leads to a progressively more aggressive and ultimately lethal phenotype (Fig. 1). A Darwinian selection for these mutations, privileging those that can confer resistance to different challenges, like hypoxic stress or immune attack, appears to be the most plausible rationale for making sense of this evolutionary catastrophe. The hierarchical, CSC model seems to introduce an element of rigidity in this highly flexible scenario, implying that only cells endowed with stem cell properties can afford tumor perpetuation (Fig. 1). Are these two models different or are they compatible? A convincing answer to this tough question will undoubtedly require a lot of robust science in the time to come but comments can be given on the basis of data that are already available. One important issue that the CSC model addresses is that of the cell of origin for cancer(s): stem cells, because they are long-lived and self-renewing, are excellent candidates to play the "cell of origin" role. A stem cell hosting a critical mutation could be quiescent for years and then be engaged in a repair response requiring mobilization and proliferation. For example, hypoxic stress may activate the CXCR4 pathway that not only attracts stem cells but may also favour their proliferation, thus being the spark initiating the cancer fire. However, an initiating mutation could also arise in a more committed progenitor (see the integrated model in Fig. 1): acquisition of a stem-like phenotype could in this context be the consequence of environmental challenges; in vivo, for instance, hypoxia could play an important role in de-differentiation; in vitro, the modification of growth factors could have similar consequences. Epigenetic changes could play important roles in mediating rapid and genome-wide changes that can substitute for genetic mutations and lead to de-differentiation.

In the *Darwinian model* different mutations (M1 through M4) accumulate during evolution and confer heterogeneity.

In the *Hierachical model* tumor arises in a stem cell, thus becoming a cancer stem cell (CSC): heterogeneity is conferred by asymmetrical divisions creating different types of cancer cells (CC1 through 4).

In the *Integrated model* a first mutation (M1) can arise in a progenitor or even a committed cell. During progression, though, external stimuli may give rise



Cancer Stem-Like Cells. Figure 1 Biological models for tumor evolution.

to a cancer stem cell that through asymmetric division will create other CSC as well as more differentiated tumor cells.

Cancer Testis Antigens

Definition

Cancer Testis Antigens are genes that can be defined by predominant expression in various types of cancer and undetectable expression in normal tissues except germ cell.

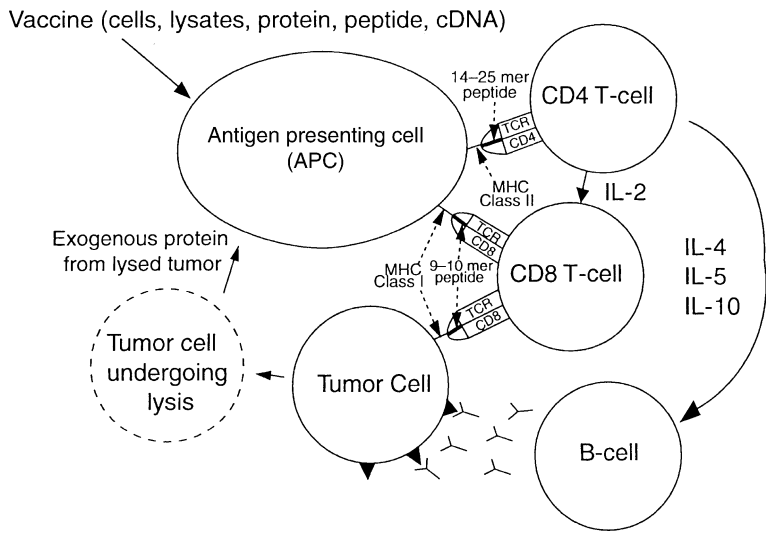
Definition

A vaccine should activate a unique lymphocyte (B and/or T cell) response, which has an immediate anti-tumor



Cancer Vaccines. Figure 1 T-cell activation. T-cells recognize antigens as fragments of proteins (peptides) presented with major histocompatibility complex (MHC) molecules on the surface of cells. The antigen presenting cell processes exogenous protein from the vaccine or from the lysed tumor cell in to a peptide, and presents the 14/25 mer peptide to CD4 helper-T-cells on a class II molecule. There is also data that suggests that exogenous proteins can be processed into 9/10 mer peptides that may be presented on MHC class I molecules to CD8 cytotoxic T-cells. Activated Th1 CD4 helper T-cells secrete Th1 cytokines such as IL-2 that upregulate CD8 cytotoxic T-cells. Activated Th2 CD4 helper T-cells secrete Th2 cytokines such as IL-4, IL-5 and IL-10 that activate B cells.

effect as well as memory response against future tumor challenge (Fig. 1). The primary role of a cancer vaccine is the treatment of cancer or in prevention of recurrence in a patient with surgically resected cancer, rather than "prevention" of cancer in a person who has never had cancer. Therefore, cancer vaccines are not thought of in the traditional sense of vaccines that are used for infectious diseases. If the current cancer vaccines prove to be useful in the above respects, then they may have a future role in preventing cancer in persons who have never had cancer but are at high-risk for a particular type of cancer.

Characteristics

The first and most obvious types of vaccines are prepared from autologous or allogeneic tumor cells. Alternatively, membrane preparations from tumor cells may be used. In some instances, tumor cell vaccines have been combined with cytokines such as granulocyte macrophage-colony stimulating factor (GM-CSF) and interleukin-2 (IL-2). More recently, with advances in molecular biological approaches, gene modified-tumor cells expressing antigens designed to increase the immune response, or gene modified to secrete cytokines have been an additional tool used in vaccination. In addition, increase in our knowledge of tumor associated antigens (TAA) have led to the use of purified TAAs, DNA-encoding protein antigens, and/or protein derived peptides. All of these approaches are currently being tested in the clinic.

Mechanistically, the ultimate aim of a vaccine is to activate a component of the immune system such as B lymphocytes, which produce antibodies or T lymphocytes, which directly kill tumor cells. Antibodies must recognize antigens in the native protein state on the cell's surface. Once bound, these molecules can mediate antibody-dependent cellular cytotoxicity or complement-mediated cytotoxicity, both mechanisms which are capable of destroying tumor cells. T lymphocytes, on the other hand, recognize proteins as fragments or peptides that vary in size, presented in the context of major histocompatibility (MHC) antigens on the surface of the cells recognized (Fig. 1). The proteins from which the peptides are derived may be cell surface or cytoplasmic proteins. MHC antigens are highly polymorphic, and different alleles have distinct peptide binding capabilities. The sequencing of peptides derived from MHC molecules have led to the discovery of allele-specific motifs that correspond to anchor residues that fit into specific pockets on MHC class I or II molecules.

T Lymphocytes

There are two types of T lymphocytes, helper T lymphocytes and cytotoxic T lymphocytes (CTLs) that recognize antigens through a specific T cell receptor (TCR) in close conjunction to the CD3 molecules, which is responsible for signaling. CD4 helper T cells recognize antigens in association with class II MHC gene products, and CD8 positive CTLs recognize

antigens in association with class I MHC gene products. CD4 helper T cells are activated by binding via their TCR to class II molecules that contain 14–25 amino acid peptides in their antigen-binding cleft. Specialized antigen presenting cells (APCs), such as dendritic cells (DCs), macrophages, and B lymphocytes, capture extracellular protein antigens, internalize and process them, and display class II-associated peptides to CD4 helper T cells. The CD8 positive CTLs are activated by binding via their TCR to class I molecules that contain 9–10 amino acid peptides in their antigen-binding cleft. All nucleated cells can present class I-associated peptides, derived from cytosolic proteins such as viral and tumor antigens, to CD8 positive T cells.

There are two types of CD4 helper T cells capable of generating either antibody or cell-mediated immune responses, based on the type of signaling they receive. Th1 CD4 helper T cells stimulate cell-mediated immunity by activating CTLs through the release of cytokines such as IL-2. Th2 CD4 helper T cells mediate an antibody response through the release of cytokines such as IL-4 and IL-10.

Tumor Cells

The most straightforward means of immunization is the use of whole tumor cell preparations (either autologous or allogeneic tumor cells). The advantage of this approach is that the potential TAAs are presented to the immune system for processing and presentation to the appropriate T cell precursors. The difficulty with this approach lies in the availability of fresh autologous tumor material and the sparcity of well-characterized long-term tumor cell lines. Regardless, whole tumor cell vaccines have been an area of intense interest. A variety of trials using autologous tumors for colon cancer and malignant melanoma have been reported. In one trial, freshly thawed autologous colon cancer cells were inactivated with radiation, mixed with ►BCG (bacille Calmette-Guerin) and injected into patients who had their primary colon cancer resected but were at risk for recurrence. This study did reveal disease-free survival and overall survival trends in favor of the vaccine arm. In a melanoma study, autologous tumor cells were mixed with dinitrophenyl (DNP) and mixed with BCG. Promising results were reported for patients with metastatic disease and for patients with locally resected melanoma.

The weakness of autologous cell vaccines can be overcome with the allogeneic approach: First an allogeneic vaccine is generic and developed from cell lines selected to provide multiple TAAs and a broad range of HLA expression. Second, allogeneic cells are more immunogeneic than autologous cells. Third there is no requirement to obtain tumor tissue by surgical resection for a prolonged course of immunotherapy.

A polyvalent melanoma cell vaccine called CancerVax developed for allogeneic viable melanoma cell lines has demonstrated promising results for patients with resected metastatic disease and for resected local disease. Randomized phase III studies are ongoing in the United States comparing CancerVax plus BCG versus BCG for patients with stage III melanoma.

Another variation of cell vaccines is using "shed" antigen vaccines. These are vaccines that are prepared from the material shed by viable tumor cells into culture medium. The potential advantage is that it contains a broad range of antigens expressed on the surface of melanoma cells and the shed antigens are partially purified. Trials of such vaccines in melanoma patients have demonstrated specific humoral and cellular immune responses in patients and promising early clinical results.

Another approach to tumor cell vaccines is the introduction of foreign genes encoding cytokines such as IL-2 and GM-CSF into tumor cells. Alternatively, molecules designed to increase the immunogenicity of the tumor cell such as CD80 and CD86. Gene transfer can be accomplished by transfection of plasmid constructs (electroporation) or transduction using a viral vehicle such as a retrovirus or an adenovirus. Another option tested for gene transfer is physical gene delivery in which a plasmid or "naked" DNA is delivered directly into tumor cells. There are a number of mechanisms to carry this out including liposomes as gene carriers, use of a "gene gun," electroporation and calcium phosphate-mediated gene transfer. In one phase I trial, 21 patients with metastatic melanoma were vaccinated with irradiated autologous melanoma cells engineered to secrete human GM-CSF. Metastatic lesions resected after vaccination were densely infiltrated with T lymphocytes and plasma cells and showed extensive tumor destruction.

Peptides and Carbohydrates

An advantage to peptide vaccines is that they can be synthetically generated in a reproducible fashion. The major disadvantage is that they are restricted to a single HLA molecule and are not of themselves very immunogenic. To increase their immunogenicity, peptides may be injected with adjuvants, cytokines or liposomes or presented on DCs. Whole proteins have the advantage over peptides in that they can be processed for a wider range of MHC class I and II antigens.

Mucins such as MUC I are heavily glycosylated high molecular weight proteins abundantly expressed on human cancers of epithelial origin. The MUC I gene is over-expressed and aberrantly glycosylated in a variety of cancers including colorectal cancer. MUC 1 is being widely used as a focus for vaccine development.

Using expression-cloning techniques, several groups have cloned the genes encoding melanoma antigens

recognized by T cells and have identified the immunogenic epitopes presented on HLA molecules. Ten different melanoma antigens have been identified. Direct immunization using the immunodominant peptides from the tumor antigens or recombinant viruses such as adenovirus, fowlpox and vaccinia virus encoding the relevant genes have been pursued to immunize patients with advanced melanoma. Initial results have demonstrated increased anti-tumor T cell reactivity in patients receiving peptide immunization. Immunization in melanoma patients with melanoma antigens have been reported. One study showed that immunization of melanoma patients with MAGE-1 peptide pulsed on DCs induced melanoma-reactive and peptide specific CTL responses at the vaccination sites and at distant tumor deposits. Administration of the gp-100 molecule in conjunction with high-dose bolus IL-2 to 31 patients with metastatic melanoma revealed an objective response of 42%. This is compared with the typical response of high-dose systemic IL-2 without peptide of only 15%. Based on these data, a randomized trial was initiated to compare the peptide vaccine plus IL-2 versus IL-2 alone in metastatic melanoma patients.

Immunization against tumor-associated carbohydrate antigens has also been attempted. Carbohydrate antigens typically bypass T cell help for B cell activation. Investigators demonstrated that some carbohydrates may activate an alternative T cell pathway. Vaccine studies have been reported using the GM-2 ganglioside vaccine. Patients were pretreated with low dose cyclophosphamide. After a minimum follow up of 72 months, there was a 23% increase in disease-free interval and a 17% increase in overall survival in patients who produced antibody against GM-2. This suggested a benefit to the GM-2 ganglioside vaccine which has led to a current phase III trial.

Recombinant Vaccines Expressing Tumor Antigens

The carcinoembryonic antigen (CEA) is highly expressed on colorectal cancer and on a variety of other epithelial tumors, and is thought to be involved in cell-cell interactions. A recombinant vaccinia virus expressing human CEA (rV-CEA) stimulates specific T cell responses in patients. This was the first vaccine to demonstrate human CTL responses to specific CEA epitopes and class I HLA-2 restricted T cell mediated lysis, and demonstrated the ability of human tumor cells to endogenously process CEA to present a specific CEA peptide in the context of a MHC for T-cell mediated lysis.

Anti-idiotype Vaccines

The idiotype network offers an elegant approach to transforming epitope structures into idiotypic determinants expressed on the surface of antibodies. According to the network concept, immunization with a given TAA will generate production of antibodies against these TAA, which are termed Ab1; the Ab1 is then used to generate a series of anti-idiotype antibodies against the Ab1, termed Ab2. Some of these Ab2 molecules can effectively mimic the three-dimensional structure of the TAA identified by the Ab1. These Ab2 can induce specific immune responses similar to those induced by the original TAA and therefore can be used as surrogate TAAs. Immunization with Ab2 can lead to the generation of anti-anti-idiotypic antibodies (Ab3) that recognize the corresponding original tumor-associated antigen identified by Ab1. The anti-idiotype antibody represents an exogenous protein that should be endocytosed by APCs and degraded to 14–25 mer peptides to be presented by class II antigens to activate CD4-helper T cells. Activated Th2 CD4-helper T cells secrete cytokines such as IL-4 that stimulate B cells that have been directly activated by Ab2 to produce antibody that binds to the original antigen identified by Ab1. In addition, activation of Th1 CD4-helper T cells secrete cytokines that activate T cells, macrophages and natural killer cells that directly lyse tumor cells, and in addition, contribute to ADCC. Th1 cytokines such IL-2 also contribute to the activation of a CD8-CTL response. This represents a putative pathway of endocytosed anti-idiotype antibody. The anti-idiotype antibody may be degraded to 9/10 mer peptides to present in the context of class I antigens to activate CD8-cytotoxic T cells, which are also stimulated by IL-2 from Th1 CD4-helper T cells.

Anti-idiotype antibodies that mimic distinct TAAs expressed by cancer cells of different histology have been used to implement active specific immunotherapy in patients with malignant diseases including colorectal carcinoma, malignant melanoma, breast cancer, B cell lymphoma and leukemia, ovarian cancer, or lung cancer. A murine monoclonal anti-idiotype antibody, 3H1 or CeaVac, which mimics CEA was developed by the authors and was used in a phase I clinical trial. Among 23 patients with advanced colorectal cancer, 17 patients generated anti-anti-idiotypic Ab3 responses, and 13 of these responses were proven to be true anti-CEA responses. The median survival of 23 evaluable patients was 11.3 months, with 44% 1-year survival. Toxicity was limited to local swelling and minimal pain. In another clinical trial, 32 patients with resected colorectal cancer were randomized to treatment with CeaVac. All 32 patients entered into this trial generated high-titer IgG anti-CEA antibodies, and ~75% generated CEA specific T cell responses. These data demonstrated that 5-fluorouracil based chemotherapy regimens did not have any adverse effect on the immune response developed by CeaVac. TriGem, an anti-idiotype monoclonal antibody that mimics the disialoganglioside GD2 was used as a vaccine in

clinical trial consisting of 47 patients with stage IV melanoma. Forty of 47 patients developed high-titer IgG anti-GD2 antibodies. Seventeen patients were stable on the study from 8 to 34 months. Disease progression occurred in 27 patients on the study from 1 to 9 months. For the 26 patients with soft tissue disease, the median overall survival has not been reached. For 18 patients with visceral metastasis, the median overall survival was 15 months. These results exceed historical controls with stage IV melanoma. Another anti-idiotype monoclonal antibody, TriAb, which mimics the human milk fat globule (HMFG) membrane antigen, is highly overexpressed on breast cancer cells and a variety of other cancer cells, including ovarian cancer, non small-cell lung cancer, and colon cancer. Immunizations with this anti-idiotype antibody elicited both anti-HMFG antibodies and idiotype specific T cell responses in patients with breast cancer in the adjuvant setting as well as in patients with advanced disease following autologous bone marrow transplantation. Although these initial clinical data are promising, active specific immunotherapy with anti-idiotype antibodies need to be tested in combination with other conventional and experimental therapies to overcome the multiple mechanisms by which tumor cells escape immune recognition and destruction. The anti-idiotype vaccine therapy for patients with minimal residual disease might be curative in the adjuvant setting and may improve the quality of patients' life.

Dendritic Cell-based Vaccines

DCs are the professional APCs of the immune system and are present in peripheral tissues, where they capture antigens. These antigens are subsequently processed into small peptides as the DCs mature and move towards the draining secondary lymphoid organs. There the DCs present the peptides to naïve T cells, thereby inducing a cellular immune response that involves both CD4 T helper 1 (Th1) cells and cytotoxic CD8 T cells. DCs are also important at inducing humoral immune response through their capacity to activate naïve and memory B cells. DCs can also activate natural killer (NK) cells and natural killer T (NKT) cells. Therefore, DCs can conduct all of the elements of the immune orchestra, and they are therefore a fundamental target and tool for vaccination.

The development of ex vivo techniques for generating large numbers of DCs in vitro from mouse bone marrow cells supplemented with either GM-CSF alone or GM-CSF plus IL-4 allowed the approach of DC-based tumor vaccination to be fully exploited. Numerous studies in mouse tumor models have shown that DCs pulsed with tumor antigens can induce protective and therapeutic anti-tumor immunity. In 1996, Hsu et al reported the first DC-based clinical trial of follicular B cell lymphoma patients who were treated with peripheral blood-derived DCs pulsed with a tumor-specific idiotype (Id) protein. Of these ten patients, eight developed a proliferative cellular response to Id and one patient developed an Id-specific CTL response. However, tumor regression was not reported in these DC-vaccinated patients. In several other trials a correlation between immunological and clinical outcome has been demonstrated. However, the efficacy of therapeutic DC-based vaccination has been modest and these trials have had similar clinical outcome: mainly, immunized patients often demonstrate significant activation of adaptive immunity to the targeted tumor antigen(s) as shown by various methods such as tetramer analysis, IFN-γ ELISPOT, and ^{51}Cr-release assay; but only a limited number of immunized patients demonstrate significant tumor regression.

The complexity of the DC system requires rational manipulation of DCs to achieve protective or therapeutic immunity. Further research is needed to analyze the immune responses induced in patients by distinct ex vivo generated DC subsets that are activated through different pathways. These ex vivo strategies should help to identify the parameters for in vivo targeting of DCs. Overall, we remain optimistic that improved cancer vaccines will ultimately yield favorable clinical results, particularly after these approaches have been modified in a manner that integrates recent progress related to the physiology of DCs and our improved understanding of how tumors and the host immune system interact with each other.

Conclusion

There exist several promising immunologic approaches to vaccine therapy of cancer. The challenge of immunotherapy research is to determine which combination of approaches leads to a favorable clinical response and outcome. Several studies have shown enhanced survival of patients receiving vaccines; however, a randomized phase III clinical trial has yet to show a statistically significant improvement in the survival of such patients.

Cancer-Testis-Antigens

Definition

Tumor antigens which are only expressed by malignant tumor cells as well as by germ line cells in the testes. The MAGE1 protein was one of the first cancer-testis antigen originally identified in melanoma cells but also expressed by various other tumor types. It belongs to a large family of "MAGE-related" proteins whose biological function is still unclear. It is thought that common epigenetic alterations in tumors lead to re-expression of genes which are normally only expressed in the germ line.

Cannabinoids

Guillermo Velasco, Manuel Guzmán
Department of Biochemistry and Molecular Biology I, School of Biology, Complutense University, Madrid, Spain

Synonyms

Phyto-cannabinoids; Endocannabinoids; Synthetic cannabinoids; Marijuana

Definition

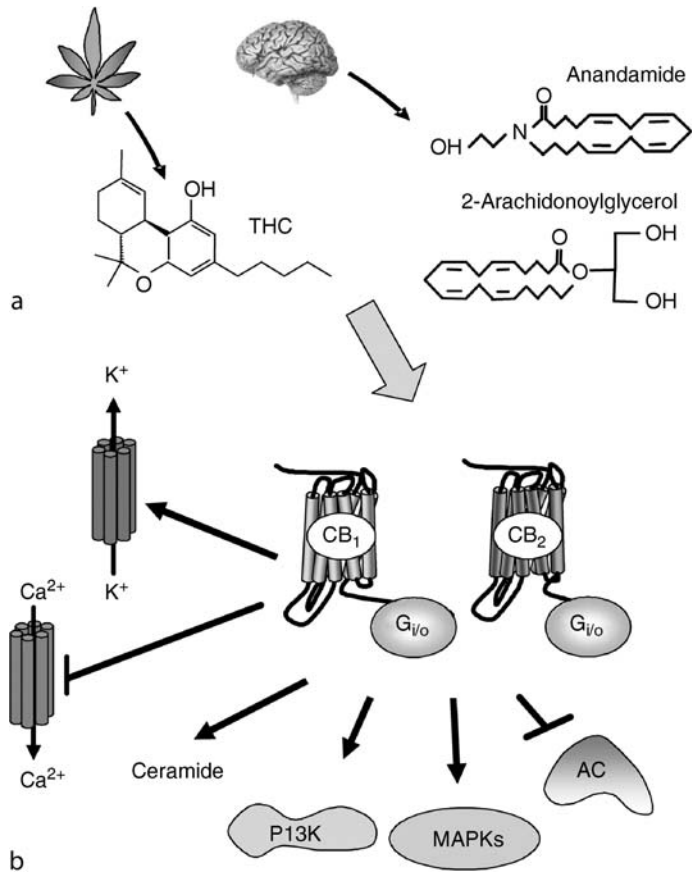
Cannabinoids are a family of lipid molecules that comprises a series of metabolites produced by the hemp plant *Cannabis sativa* (the phyto-cannabinoids); several fatty-acid derivatives endogenously produced by most animals (the endogenous ligands for cannabinoid receptors), and different synthetic compounds structurally or functionally related with the natural cannabinoids. Activation of cannabinoid receptors by some of these molecules reduce the symptoms associated to cancer chemotherapy and inhibit the growth of tumor cells in culture and in animal models of ►tumor xenografts.

Characteristics

The hemp plant *Cannabis sativa* produces approximately 70 unique compounds known as cannabinoids, of which Δ^9-tetrahydrocannabinol (THC) is the most important owing to its high potency and abundance in cannabis. THC exerts a wide variety of biological effects by mimicking endogenous substances – the endocannabinoids anandamide and 2-arachidonoylglycerol – that bind to and activate specific cannabinoid receptors (Fig. 1a and b). So far, two cannabinoid-specific ►G-protein-coupled receptors have been cloned and characterized from mammalian tissues: The CB_1 receptor is particularly abundant in discrete areas of the brain, but is also expressed in peripheral nerve terminals and various extra-neural sites. In contrast, the CB_2 receptor was initially described to be present in the immune system, although recently it has been shown that expression of this receptor also occurs in cells from other origins including many types of tumor cells.

Signaling Pathways Modulated by Cannabinoid Receptors

Most of the physiological, therapeutic and psychotropic actions of cannabinoids rely on the activation of CB_1 and CB_2 receptors (Fig. 1a and b). Extensive molecular and pharmacological studies have demonstrated that cannabinoids inhibit adenylyl cyclase through CB_1 and CB_2 receptors. The CB_1 receptor also modulates ion channels, inducing, for example, inhibition of N- and



Cannabinoids. Figure 1 Cannabinoids, cannabinoid receptors and its mechanisms of action. (a) Δ^9-tetrahydrocannabinol (THC), the main active component of marijuana, and the endocannabinoids anandamide and 2-Arachidonoylglycerol are ligands of cannabinoid receptors. (b) Both CB_1 and CB_2 receptors belong to the family of G-protein-coupled receptors. Binding of cannabinoids to cannabinoid receptors leads, among other actions and depending on the cell context, to: inhibition of adenylyl cyclase, modulation of the activity of several ion channels, modulation of phosphatidylionsoitol-3 kinase (PI3K) and of mitogen activated protein kinase cascades, or stimulation of ceramide generation.

P/Q-type voltage-sensitive Ca^{2+} channels and activation of G protein-activated inwardly rectifying K^+ channels. Besides these well-established signaling events that mediate – among others – the neuromodulatory actions of the endocannabinoids, cannabinoid receptors also modulate several pathways that are more directly involved in the control of cell proliferation and survival, including extracellular signal-regulated kinase, c-Jun N-terminal kinase and p38 mitogen-activated protein kinase, ►phosphatidylinositol 3-kinase/Akt and focal adhesion kinase. In addition, cannabinoids stimulate the generation of the bioactive lipid second messenger ceramide via two different pathways: sphingomyelin hydrolysis and ►ceramide synthesis *de novo*.

Palliative Effects of Cannabinoids in Cancer

Cannabinoids have been known for several decades to exert palliative effects in cancer patients, and nowadays capsules of THC (Marinol-TM) and its synthetic analogue nabilone (Cesamet-TM) are approved to treat nausea and emesis associated with cancer chemotherapy. In addition, several clinical trials are testing other potential palliative properties of cannabinoids in oncology such as appetite stimulation and analgesia.

Mechanism Involved in the Antiemetic Effect of Cannabinoids

One of the most important physiological functions of the cannabinoid system is to modulate synaptic transmission. Thus, activation of cannabinoid receptors at presynaptic locations leads to reduced neurotransmitter release. As the CB_1 receptor is present in cholinergic nerve terminals of the myenteric and submucosal plexus of the stomach, duodenum and colon, it is likely that cannabinoid-induced inhibition of digestive tract motility is due to blockade of acetylcholine release in

these areas. There is also evidence that cannabinoids act on CB_1 receptors localized in the dorsal vagal complex of the brainstem – the region of the brain that controls the vomiting reflex. In addition, endocannabinoids and their inactivating enzymes are present in the gastrointestinal tract and may play a physiological role in the control of emesis.

Mechanism Involved in Appetite Stimulation by Cannabinoids

The endogenous cannabinoid system may serve as a physiological regulator of feeding behavior. For example, endocannabinoids and CB_1 receptors are present in the hypothalamus, the area of the brain that controls food intake; hypothalamic endocannabinoid levels are reduced by leptin, one of the most prominent anorexic hormones; and blockade of tonic endocannabinoid signaling with the CB_1 antagonist rimonabant – inhibits appetite and induces weight loss. CB_1 receptors present in nerve terminals and adipocytes also participate in the regulation of feeding behavior.

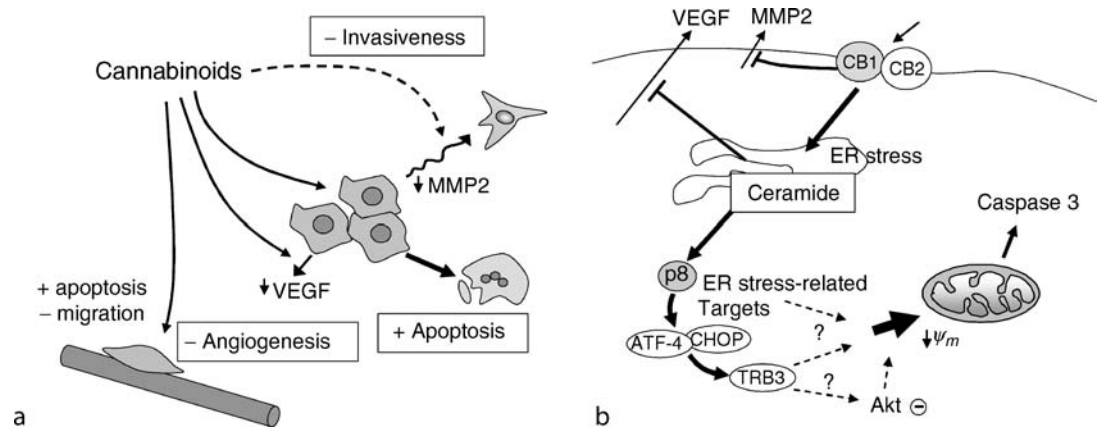
Mechanism Involved in the Analgesic Effect of Cannabinoids

Cannabinoids inhibit pain in animal models of acute and chronic ►hyperalgesia, ►allodynia and spontaneous pain. Cannabinoids produce antinociception by activating CB_1 receptors in the brain (thalamus, periaqueductal grey matter, rostral ventromedial medulla), the spinal cord (dorsal horn) and nerve terminals (dorsal root ganglia, peripheral terminals of primary afferent neurons). Endocannabinoids serve naturally to suppress pain by inhibiting nociceptive neurotransmission. In addition, peripheral CB_2 receptors might mediate local analgesia, possibly by inhibiting the release of various mediators of pain and inflammation, which could be important in the management of cancer pain.

Antitumoral Effects of Cannabinoids

Cannabinoids have been proposed as potential antitumoral agents on the basis of experiments performed both in cultured cells and in animal models of cancer. A number of plant-derived, synthetic and endogenous cannabinoids are now known to exert antiproliferative actions on a wide spectrum of tumor cells in culture. More importantly, cannabinoid administration to nude mice curbs the growth of various types of tumor xenografts, including lung carcinoma, glioma, thyroid epithelioma, lymphoma, skin carcinoma, pancreatic carcinoma and melanoma. The requirement of cannabinoid receptors for this antitumoral activity has been revealed by various biochemical and pharmacological approaches, in particular by determining cannabinoid receptor expression in the tumors and by using selective cannabinoid receptor agonists and antagonists.

Although the downstream events by which cannabinoids exert their antitumoral action have not been completely unraveled, there is substantial evidence for the implication of at least two mechanisms: induction of ►apoptosis of tumor cells and inhibition of tumor ►angiogenesis (Fig. 2a).



Cannabinoids. Figure 2 Mechanism of cannabinoid antitumoral action. (a) Cannabinoid administration decreases the growth of tumors by several mechanisms, including at least: (i) reduction of tumor angiogenesis, (ii) induction of tumor cell apoptosis, and perhaps (iii) inhibition of tumor cell migration and invasiveness. (b) Cannabinoid treatment induces apoptosis of several types of tumor cells via ceramide accumulation and activation of an ER stress-related pathway. The stress-regulated protein p8 plays a key role in this effect by controlling the expression of ATF-4, CHOP and TRB3. This cascade of events triggers the activation of the mitochondrial intrinsic apoptotic pathway through mechanisms that have not been unraveled as yet. Cannabinoids also decrease the expression of various tumor-progression molecules such as VEGF and MMP2.

Induction of Apoptosis

Different studies have shown that the pro-apoptotic effect of cannabinoids on tumor cells relies on the stimulation of cannabinoid receptors and a subsequent activation of the proapoptotic ►mitochondrial intrinsic pathway. In glioma and pancreatic tumor cells, treatment with cannabinoids leads to accumulation of the pro-apoptotic sphingolipid ceramide which in turn leads to up-regulation of the stress-regulated protein ►p8, which belongs to the family of ►HMG-I/Y transcription factors. The acute increase of p8 levels after cannabinoid treatment triggers a cascade of events that involves the up-regulation of several genes involved in the ►endoplasmic reticulum (ER) stress response including the activating transcription factor 4 (ATF-4) and the C/EBP-homologous protein (CHOP). These two transcription factors cooperate in the induction of the ►tribbles homologue 3 (TRB3), a ►pseudokinase that is involved in the induction of apoptosis (Fig. 2b).

The processes downstream of ER stress activation involved in the execution of cannabinoid-induced apoptosis of tumor cells are not completely understood yet but include inhibition of the anti-apoptotic kinase Akt and activation of the mitochondrial intrinsic pathway.

Of interest the pro-apoptotic effect of cannabinoids is selective of tumor cells. For instance, treatment of primary cultured astrocytes with these compounds does not trigger ceramide accumulation, induction of the aforementioned ER stress-related genes or apoptosis. Furthermore, cannabinoids promote the survival of astrocytes, oligodendrocytes and neurons in different models of injury, supporting the notion that cannabinoids activate opposite responses in transformed and non-transformed cells.

Inhibition of Tumor Angiogenesis

To grow beyond minimal size, tumors must generate a new vascular supply (angiogenesis) for purposes of cell nutrition, gas exchange and waste disposal, and therefore blocking the angiogenic process constitutes one of the most promising antitumoral approaches currently available. Immunohistochemical analyses in mouse models of glioma, skin carcinoma and melanoma have shown that cannabinoid administration turns the vascular hyperplasia characteristic of actively growing tumors to a pattern of blood vessels characterized by small, differentiated and impermeable capillaries. This is associated with a reduced expression of ►vascular endothelial growth factor (VEGF) and other proangiogenic cytokines such as angiopoietin-2 and placental growth factor, as well as of type 1 and type 2 VEGF receptors, in cannabinoid-treated tumors. Pharmacological inhibition of ceramide synthesis *de novo* abrogates the antitumoral and antiangiogenic effect of cannabinoids *in vivo* and decreases VEGF production by glioma cells *in vitro* and by gliomas *in vivo*, indicating that ceramide plays a general role in cannabinoid antitumoral action.

Other reported effects of cannabinoids might be related with the inhibition of tumor angiogenesis and invasiveness by these compounds (Fig. 2a and b). Thus, activation of cannabinoid receptors on vascular endothelial cells in culture inhibits cell migration and survival. In addition, cannabinoid administration to glioma-bearing mice decreases the activity and expression of ►matrix metalloproteinase-2, a proteolytic enzyme that allows tissue breakdown and remodeling during angiogenesis and metastasis. In line with this notion, cannabinoid intraperitoneal injection reduces the number of metastatic nodes produced from paw injection in lung, breast and melanoma cancer cells in mice.

Therapeutic Potential of Cannabinoids as Antitumoral Agents

On the basis of these preclinical findings, a pilot clinical study of THC in patients with recurrent ►glioblastoma multiforme has been recently run. Cannabinoid delivery was safe and could be achieved without significant psychoactive effects. Also, although the limited number of patients involved in the trial did not permit the extraction of statistical conclusions, median survival of the cohort was similar to other studies performed in recurrent glioblastoma multiforme with temozolomide and carmustine, the drugs of reference for the treatment of these tumors. In addition THC administration correlated with decreased tumor cell proliferation and increased tumor cell apoptosis.

The significant antiproliferative action of cannabinoids, together with their low toxicity compared with other chemotherapeutic agents and their ability to reduce symptoms associated to standard chemotherapies, might make these compounds promising new antitumoral agents.

Capecitabine

Definition
Capecitabine is a 5-fluorouracil (Fu) oral ►prodrug.

►Erlotinib (Tarceva®)

CapG

Definition
Is, a 45-kDa protein composed of 348 amino acids, is a member of the gelsolin/villin actin-modulating protein family. The subcellular localization of CapG protein is largely nuclear, though other ►gelsolin family members localize only in cytoplasm, suggesting that CapG may have a function in addition to cytoskeleton modulation. The human *CapG* gene, mapped at 2p11.2, is ubiquitously expressed in normal tissues, but down-regulation of the expression was observed in roughly one third of melanomas, stomach, and lung cancers. Furthermore, CapG has been shown to possess tumor suppressor activity when transfected into certain cancer cell lines.

►Reductases

Carboplatin

Definition
Second-generation platinum compound with a broad spectrum of antineoplastic properties. Carboplatin contains a platinum atom complexed with two ammonia groups and a cyclobutane-dicarboxyl residue. This agent is activated intracellularly to form reactive platinum complexes that bind to nucleophilic groups

such as GC-rich sites in DNA, thereby inducing intrastrand and interstrand DNA ►cross-links, as well as DNA-protein cross-links. These carboplatin-induced DNA and protein effects result in ►apoptosis and cell growth inhibition. This agent possesses tumoricidal activity similar to that of its parent compound, ►cisplatin, but is more stable and less toxic.

Carboxylesterase

Definition

Carboxylesterases, present in serum, in the epithelial lining of the intestines, in tumor tissue, and in high content in the liver, are enzymes responsible for metabolizing (hydrolysis) a wide variety of drugs and ►xenobiotics. The carboxylesterase genes are located on chromosome 16q13-q22 and are supposed to be highly conserved during evolution.

►Irinotecan

Carboxypeptidase

Definition

A type of protease or hydrolase that removes the amino acid at the free carboxyl end of a polypeptide chain.

►Prostate-Specific Membrane Antigen

Carcinoembryonic Antigen

Peter Thomas
Departments of Surgery and Biomedical Sciences, Creighton University, Omaha, NE, USA

Synonyms

CEA; CD66e; CEACAM5

Definition

CEA is a glycoprotein of approximately 150–180 kDa. It's measurement in serum is used clinically as a ►biomarker for a number of cancers (pancreas, breast, stomach, ovary, lung and medullary carcinoma of the thyroid) but its primary use is in monitoring cancers of the colon and rectum.

Characteristics

Protein Structure

CEA was discovered in 1965 in ►colon cancer and fetal tissue extracts and was described as an ►oncofetal antigen. Many of the advances in tumor marker research lead directly back to the discovery of CEA The protein component of CEA is 79 kDa in size and the balance of 70–100 kDa is made from up to 28 complex N-linked multi-antennary carbohydrate structures containing *N*-acetyl-glucosamine, mannose, galactose, fucose and sialic acid. Low resolution X-ray studies have shown an elongated monomeric structure that could be described as a bottle brush. The molecule is composed of a series of six disulphide linked immunoglobulin like domains (IgC2-like) of either 93 (type A) or 85 (type B) amino acids and a seventh N-domain of 108 amino acids which is an IgV (variable antigen recognition domain) structure without the stabilizing disulphide bridge. CEA can attach to the cell membrane and this is achieved by post translational modification of a small (26 amino acids) hydrophobic C-terminal domain to a ►glycosyl phosphatidyl inositol linkage (see Fig. 1A). Cleavage of this linkage by ►phospholipases releases CEA into the lumen of the intestine or other extra-cellular compartments.

The CEA Gene Family

The complete gene for CEA has been cloned and it includes a promoter region that confers cell type specific expression. The ►CEA gene family comprises of 29 genes or pseudogenes located between the q13.1 and q13.3 regions of chromosome 19. The family can be divided into three groups: The CEA group of 12 genes, the pregnancy specific glycoprotein group (PSG) of 11 genes and a third group composed of 6 pseudogenes. Only 16 of the 29 genes are expressed. Sequence data has shown that the CEA family is a subset of the Immunoglobulin supergene family. Comparative sequence studies of the CEA gene family from various species suggest that the CEA family have a common ancestry and arose relatively recently in evolution.

Function of CEA in Normal and Cancerous Tissue

In general members of the CEA family subgroup have a ubiquitous distribution in adult tissues. However CEA itself has a more restricted expression being found only in colon, pyloric mucus cells, epithelial cells of the prostate, in sweat glands and in squamous cells in the tongue, cervix and esophagus. In the colon CEA is located at the apical surface of colonic enterocytes and is associated with the ►glycocalyx or fuzzy coat. In the normal colon CEA is maximally expressed on columnar cells at the level of the free luminal surface. CEA is also found in goblet cells in association with mucins. The function of CEA in the normal individual is not well understood and has been the subject of much

An arrow marks the position of the PELPK receptor recognition sequence. (b). Shows homotypic binding between two CEA molecules with attachment between the N and A3 domains. (Structures are modified from the CEA Homepage http://cea.klinikum.uni-meunchen.de)

speculation. It has been estimated that the normal person can produce 70 mg or more of CEA a day and excrete it in the feces. CEA has been shown to bind to various fimbriated gut pathogens and therefore it has been suggested that it has a function in protecting the gut epithelia. In cancer cells CEA may perform a number of functions. Unlike the normal colonocyte where CEA expression is highly polarized in cancers this polarity is lost and its expression occurs through the whole of the cell surface. It has been shown that CEA can act as a Ca^{2+} independent homotypic adhesion molecule binding with itself through an interaction between the N and A3 domains (Fig. 1B) and causing aggregation of tumor cells. This allows the malignant epithelium to adopt a multi-layered structure and may disrupt the normal pattern of differentiation. CEA can also bind heterotypically to other members of the gene family including the ►nonspecific cross reacting antigen (NCA, CD66c, CEACAM6) and the ►biliary glycoprotein (BGP, CD66a, ►CEACAM1) of which seven different forms have been identified. It is unlikely that CEA functions as a ►cell adhesion molecule in the normal colon because of its apical expression. CEA is cleared from the circulation by the hepatic ►macrophages (►Kupffer cells). A cell surface receptor identical to the heterogeneous nuclear RNA binding protein ►hnRNP M4 recognizes a penta-peptide (Pro–Glu–Leu–Pro–Lys (PELPK)) located at the hinge region between the N and first immunoglobulin loop domain (A1) of CEA. Patients with a mutation in the region coding for this peptide have extremely high circulating CEA levels presumably due to the inability of Kupffer cells to clear the protein from the blood. CEA has also been implicated in the development of hepatic ►metastasis from colorectal cancers by the induction of a localized inflammatory response that affects retention and implantation in the liver. Cytokines produced also protect the tumor cells against the toxic effects of hypoxia. CEA producing cells therefore have a selective advantage for growth in the liver. Recent studies have also shown that CEA can protect cancer cells from a form of programmed cell death called ►anoikis and this also seems to involve the PELPK motif and inhibition of Trail-R2 (►DR5) signaling. CEA is also protective against other forms of ►apoptosis including drug and UV light induced programmed cell death. The related protein CEACAM-1, however, is a pro-apoptotic protein.

Clinical Aspects

The main clinical use for CEA is as a tumor marker especially for cancers in the colon and rectum and approximately 90% of these cancers produce CEA. CEA has also been used as a marker for breast and small cell cancer of the lung. Approximately 50% of breast and 70% of small cell cancers express CEA. Accurate immuno-assays are commercially available for its measurement in body fluids. Immunohistochemistry on biopsy or resection specimens is also often carried out, for example the intensity of CEA staining has been associated with a worse prognosis for breast cancer. Normal serum levels are <2.5 ng/ml unless the subject is a heavy smoker when the normal cutoff becomes <5 ng/ml. CEA levels can be elevated in a number of non-malignant conditions such as pancreatitis, inflammatory bowel disease including ►Crohn disease, hereditary polyposis including ►Gardener

syndrome, polycystic disease of the liver and a variety of other liver diseases including ►cirrhosis, hepatitis and benign biliary duct obstruction. Rarely do these diseases result in a CEA elevation over 10 ng/ml. CEA levels above 20 ng/ml almost always indicate the presence of a malignant tumor. Patients with colorectal cancer who present with a CEA level of over 5 ng/ml have a poorer prognosis and are at higher risk for developing metastasis to the liver. However, because the CEA assay lacks sensitivity for early stage colorectal cancer it cannot be used as a population screen. CEA is most useful for the early detection of liver metastasis in colorectal cancer patients. It is not as effective in detecting loco-regional or pulmonary metastases. Elevated CEA levels that fall to normal following tumor resection are an indication of a successful surgery; however, a rising CEA level post operatively indicates a progression or recurrence of the tumor. There is no clear agreement on how often CEA measurements should be taken following curative surgery. The guidelines put out by the American Society of Clinical Oncologists (ASCO) recommend measurements every 2–3 months for a minimum of 2 years. CEA measurements can give a lead time of up to a year before the onset of clinical symptoms of recurrence. Serial serum CEA measurements have been shown to be useful in the follow up of patients with breast cancer and small cell cancer of the lung. The reverse transcriptase-polymerase chain reaction (RT-PCR) has been used to detect CEA producing circulating cancer cells. More recently a real time PCR method has been developed for the quantitative detection of CEA mRNA transcripts in blood, peritoneal washings and lymph nodes. These methods can be used for a more exact staging and prognosis in cancer patients. CEA has been used as a target antigen for both ►radio-immunodetection and ►radio-immunotherapy of cancers. Imaging after administration of radiolabeled anti-CEA antibodies provides information on the location and extent of disease. Radio-labeled anti CEA antibodies have shown therapeutic effects in reducing tumor size in metastatic disease. Radio-labeled anti-CEA antibodies are also used to guide second look surgery and can detect occult disease. More recently CEA has been used as the antigen of choice for cancer vaccines against colorectal cancers. Clinical trials have been conducted using recombinant ►CEA-vaccine virus and recombinant ►ALVAC-CEA vaccines. The vaccines were well tolerated and elicited CEA specific T-cell responses. This promises to be a useful addition to standard therapies.

Carcinoembryonic Antigen (CEA)

Definition

Is a normal mucosal cell oncofetal glycoprotein involved in cell adhesion. It is overexpressed in gastric, pulmonary, breast, pancreatic and predominantly colorectal adenocarcinomas. It may also be elevated in the serum of heavy smokers and patients with ulcerative colitis, pancreatitis and cirrhosis. Its role as a screening tool of colorectal carcinoma remains uncertain because of poor sensitivity and specificity. In patients with established disease, the absolute serum level of CEA correlates with disease burden and has prognostic value.

Carcinogen

Definition

The causal agent which induces tumors. They include external factors (chemicals, physical agents, viruses)

and internal factors such as hormones. Chemical carcinogens are structurally diverse and include naturally-occurring substances as well as synthetic compounds. An important distinction can be drawn between 'genotoxic' carcinogens and 'non-genotoxic' carcinogens or between 'direct-acting' carcinogens and 'indirect-acting' carcinogens.

Definition

Carcinogen macromolecular adducts are chemical modifications ("addition products") of nucleic acids and proteins that form in tissues and cells exposed to reactive chemical species.

Characteristics

Chemical carcinogens that induce macromolecular damage may be exogenous or endogenous (Table 1). Exogenous chemicals, including environmental pollutants or drugs most often require activation, and before they are activated they may be referred to as ►procarcinogens. Following the generation of a chemically reactive species, spontaneously or more commonly through metabolism, covalent binding to nucleic acids and proteins can occur resulting in adduct formation. In the case of reactive chemical species forming adducts with DNA, a mutation can result if the DNA is not properly repaired. When reactive chemical species bind covalently to a protein, the resulting adducts persist for the lifetime of the protein. Formation of DNA adducts is considered necessary for carcinogenesis, while protein modification is considered an indicator of exposure and a surrogate for DNA adduct formation.

Sometimes, normal physiological (endogenous) processes require chemical modification of nucleic acids. For example, selective 5-methylation of cytosine in DNA regulates normal gene expression, and 7-methylation of guanosine in 5′ cap structures of mRNA is necessary for efficient protein synthesis in eukaryotes. Normal endogenous metabolic processes, including ►redox cycling, lipid peroxidation, nitric oxide metabolism and endogenous nitrosation can produce oxygen free radicals, oxidative-DNA adducts, etheno-adducts and nitrosamine adducts.

Exogenous carcinogenic agents that form macromolecular adducts can be direct-acting if they are highly reactive. Examples are the nitrosoureas, some nitrosamines, ethylene oxide and ozone. However, most are inert, like the polycyclic aromatic hydrocarbons (PAHs), and require biotransformation through ►metabolic activation. Examples of some chemical carcinogens responsible for macromolecular adduct formation, their origins and how humans become exposed are presented in Table 1.

Carcinogen Metabolism Leading to Macromolecular Adduct Formation

In order to form macromolecular adducts, exogenous agents that can be inhaled, ingested or absorbed through the skin, are altered metabolically by families of enzymes. These enzymes convert a small fraction of the initial dose to highly reactive intermediate metabolites that become bound covalently to specific bases in DNA or amino acids in protein.

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous environmental contaminants composed of variable numbers of fused benzene rings that are chemically unreactive and insoluble in water. The prototype PAH, benzo[*a*]pyrene (BP), forms macromolecular adducts in the body by metabolism to simple epoxides through the action of ►cytochrome P450 enzymes, hydration through the action of epoxide hydrolase and epoxidation (cytochrome P450s) to form unstable dihydrodiol-epoxides. The unstable metabolites spontaneously convert to a positively charged, highly reactive free radical called a carbocation (the ►ultimate carcinogen), which binds

Carcinogen Macromolecular Adducts. Table 1 Selected chemical carcinogens involved in DNA and protein adduct formation, their origins and routes of exposure

Chemical class	Examples	Occurrence
Polycyclic aromatic hydrocarbons (PAHs)	Benzo[a]pyrene, dibenz[a,h]anthracene, 5-methylchrysene	Charbroiled foods[a], water[b], coke oven emmissions[c], urban air[b], soil[b], tobacco smoke[d], coal tar ointment[e]
Nitro-PAHs	1-Nitropyrene, 1,8-dinitropyrene	Diesel exhaust[b,c], coal smoke[b]
	3-Nitrobenzanthrone	
Aromatic amines	4-Aminobiphenyl, benzidine	Tobacco smoke[d], dyes[c], urban air[b]
	2-Acetylaminofluorine	Candidate pesticide
Heterocyclic amines	2-Amino-3-methyl-imidazo-[4,5-f]quinoline (IQ)	Fried or broiled meats and fish[a,g]
	3-Amino-1-methyl-*5H*-pyrido[4,3-b]indole (Trp-P1)	
	2-Amino-1-methyl-6-phenyl-imidazo[4,5-b]pyridine (PhIP)	
Nitrosamines	*N*-nitroso-*N*-methylethylamine	Tobacco smoke[d], alcoholic beverages[d]
	N-nitrosodimethylamine	Various foods[a], urban air[b], soil[b]
	4-(methylnitrosamino)-4-(3-pyridyl)-1-butanone (NNK)	Tobacco specific nitrosamine (see below)
Nitrosoureas	*N*-nitroso-*N*-methylurea	Cancer chemotherapeutic agents[e]
Naturally occurring molecules	Aflatoxins, ochratoxin, free radicals (O_2, OH, NO) ozone, tobacco specific nitrosamines (e.g., NNK)	Molds/fungi[a] (*Aspergilius, Penicillium*)
		Immune response/microbes[f] (*H. Pylori*)
		Urban air[b]
		Plant: tobacco[e], tobacco smoke[e]
Miscellaneous	Vinyl chloride, ethylene oxide, benzene	Manufacture of polyvinylchloride[c]
		Sterilization of medical equipment[c]
		Petrochemicals/glues/solvents[c]

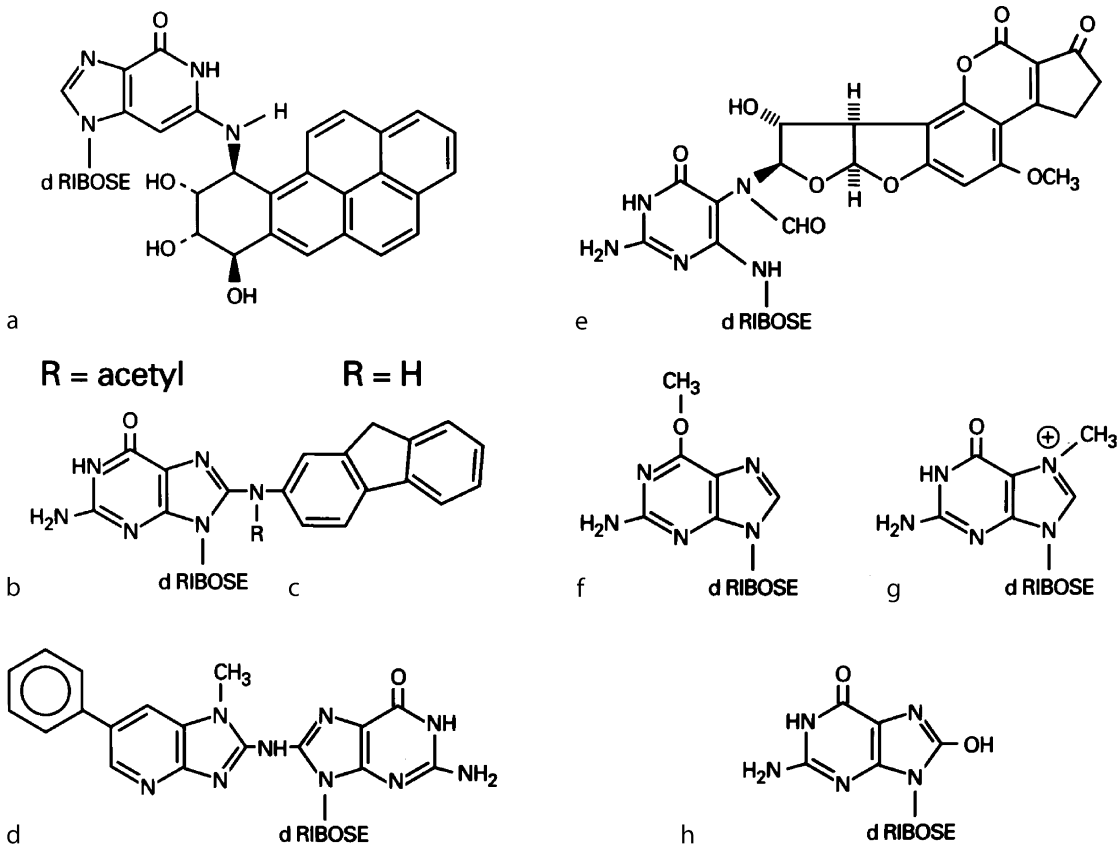
covalently to DNA and protein. The structure of the major DNA adduct formed by BP with deoxyguanosine is shown in Fig. 1a. BP also forms adducts with protein (Fig. 2).

Aromatic amines are characterized by the presence of benzene rings and an exocyclic nitrogen. A prototypical aromatic amine, 4-aminobiphenyl (4-ABP), is implicated in human bladder cancer. An additional class of environmental contaminants, nitrated polycyclic aromatic hydrocarbons are related to aromatic amines by nitroreduction. The presence of the amino-group, which can be either acetylated or non-acetylated, bestows a complex variety of metabolic options for aromatic amine metabolism. Activation of aromatic amines proceeds by *N*-oxidation with sulfotransferase catalysis resulting in the formation of acetylated and non-acetylated guanine adducts as shown in Fig. 1(b and c) for the carcinogen *N*-2-acetylaminofluorene. Aromatic amine adducts with protein were among the first protein adducts to be identified and characterized.

Heterocyclic amines, such as 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP), are a class of aromatic amines that are formed during high temperature cooking of meat and fish (Table 1). These compounds constitute the so-called "food ►mutagens." To form DNA adducts these compounds undergo *N*-hydroxylation (cytochrome P450) and enzymic *O*-esterification. The major guanine adduct of PhIP is shown in Fig. 1d.

Fungal mycotoxins contaminate cereals, grains and nuts, and ingestion of the prototype aflatoxin B_1, is correlated with a high incidence of liver cancer. Aflatoxins are hetercyclic and contain several endocyclic oxygen molecules. They are activated by simple epoxidation (cytochrome P450) across the olefinic double bond at the 8,9-position giving rise to a carbocation. Some addition products with DNA are unstable and lead to purine ring-opening followed by non-mutagenic depurination. The major aflatoxin-guanine adduct is shown in Fig. 1e. Serum and albumin



Carcinogen Macromolecular Adducts. Figure 1 (a) (7R)-N2-{10-[r-7, t-8, t-9-trihydroxy-7,8,9,10-tetrahydrobenzo(a)pyrene]-yl}-deoxyguanosine; (b) *N*-deoxyguanosin-(8-yl)-2-acetylaminofluorene; (c) *N*-deoxyguanosin-(8-yl)-2-aminofluorene; (d) *N*-deoxyguanosin-(8-yl)-2-amino-1-methyl-6-phenylimidazo[4,5-b] pyridine; (e) Aflatoxin B1-N7-deoxyguanosine; (f) O6-Methyl-deoxyguanosine; (g) N7-Methyl-deoxyguanosine; (h) 8-Hydroxy-deoxyguanosine.

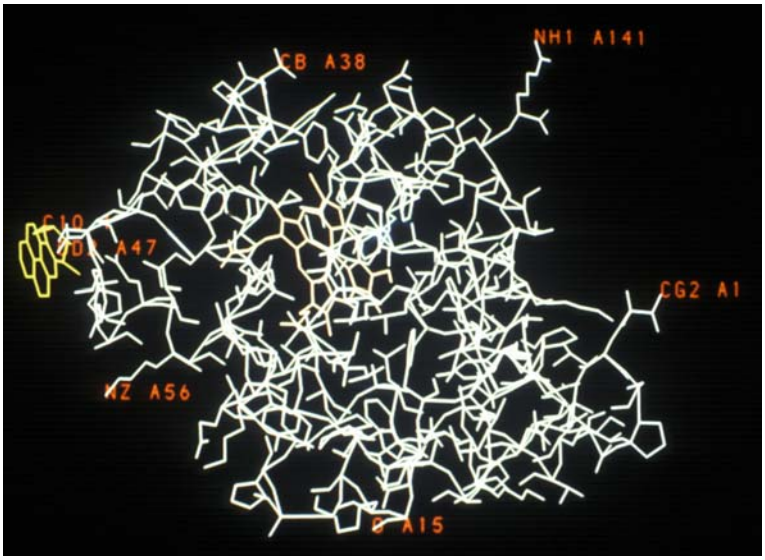
adducts of aflatoxin have been characterized and used extensively as human ►biomarkers.

Carcinogenic *N*-nitrosamines can be found in many substances including food, alcoholic beverages and tobacco. *N*-nitrosodimethylamine is activated (cytochrome P450) through α-hydroxylation to produce an unstable α-hydroxy-nitrosamine, which forms formaldehyde and methyl diazohydroxide. The methyl diazohydroxide becomes a free radical and a powerful methylating agent, which leads to the production of multiple DNA modifications (e.g., Fig. 1f and g). Some nitrosamines such as the tobacco-specific nitrosamine, 4-[methylnitrosoamino]-1-[3-pyridyl]-1-butanone (NNK), are asymmetrical and also give rise to the formation of bulky DNA adducts. Nitrosamines are also known to form protein adducts.

Oxygen radical damage produced by both endogenous and exogenous events can result in the formation of macromolecular adducts. Pathways that lead to the formation of oxygen radicals include degradation of organic peroxides (catechol, hydroquinone, and 4-nitroquinoline-*N*-oxide), hydrogen peroxide, lipid peroxidation and the catalytic cycling of some enzymes (e.g., ►redox cycling). Stomach cancer has been associated with *Helicobacter pylori* infection, and consequent oxidative damage linked with the inflammatory process is thought to contribute to carcinogenesis. Treatment with certain drugs or exposure to plasticizers can stimulate peroxisome proliferation, also giving rise to oxyradicals. Exposure to tumor promoters indirectly increases oxyradical formation; examples include the action of phorbol esters, mediated by protein kinase C and chronic inflammation, mediated by nitric oxide. Oxygen free radicals produce multiple DNA adducts including 8-hydroxydeoxyguanosine (Fig. 1h).

Structural Modification of DNA to Form Carcinogen-DNA Adducts

The structure of DNA bases can be modified through various mechanisms. These include oxidation, alkylation, dimerization, deamination and reaction with large, bulky aromatic-type carbocations. Endogenous



Carcinogen Macromolecular Adducts. Figure 2 Hemoglobin α-chain modified with benzo(a)pyrene-7, 8-diol 9,10-epoxide (BPDE) (yellow structure) on aspartate residue 47 (see Chem Res Toxicol (1991) 4:359–363). (The model shown here was provided by Billy Day and Steven R. Tannenbaum, Massachusetts Institute of Technology, Cambridge, MA).

and exogenous pathways lead to the formation of oxygen free radicals and the formation of oxidative DNA damage. Examples of oxidative DNA adducts include thymine glycol, 8-hydroxydeoxyguanosine, uracil glycol, 5-hydroxyuracil, 5-hydroxy-methyluracil and 6-hydroxy-5,6-dihydrocytidine.

Alkyl-radicals form during the ►metabolic activation of certain *N*-nitrosamines or spontaneously in the case of *N*-alkylureas (*N*-methyl-*N*-nitrosourea) or *N*-nitrosoguanidines. Protonated alkyl-functional groups, which become available to modify DNA, attack nucleophilic centers. There are ten of these: N1, N3, and N7 of adenine; N3 of cytosine; N2, O6 and N7 of guanosine; O2, N3, and O4 of thymidine. Repair of some of these lesions is correlated with mutagenicity. For example, O6-methyl-deoxyguanosine (Fig. 1f) can be repaired and is a promutagenic lesion, whereas N7-methyl-deoxyguanosine (Fig. 1g) is neither repaired nor mutagenic.

Larger, bulky aromatic-type adducts bind to DNA producing three-dimensional structures that reside either in the minor or the major groove of the DNA helix. Activated BP binds preferentially to the exocyclic (N2) amino group of deoxyguanosine (Fig. 1a). While guanine is a preferred site for PAH modification, covalent binding to deoxyadenosine and deoxycytosine are also possible. Aromatic amines form adducts at the C8, N2, and O6 positions of deoxyguanosine and deoxyadenosine but the major aromatic amine adducts form at the C8 position of deoxyguanosine (Fig. 1b and c). Evidence suggests that activation of aflatoxin B_1 produces adduction primarily at the N7-position of deoxyguanosine (Fig. 1e).

Methods to Measure Carcinogen-DNA Adducts

Single methods currently in use for carcinogen-DNA adduct detection include radiolabeling, immunoassays, immunohistochemistry, ^{32}P-postlabeling, fluorescence and phosphorescence spectroscopy, mass spectrometry, atomic absorbance spectrometry and electrochemical conductance. Single methods are typically not able to chemically characterize specific adducts in human tissues, although they work well for animal models exposed to a single chemical agent. Using human samples, greater success in DNA adduct characterization has typically been obtained by combining preparative methods (immunoaffinity chromatography, high performance liquid chromatography or gas chromatography) with immunoassays, ^{32}P-postlabeling, synchronous fluorescence spectrometry or mass spectrometry. These assays are typically able to detect as little as 1 adduct in 10^9 nucleotides using ~5–100 μg of DNA. Accelerator mass spectrometry, can detect 1 adduct in 10^{12} nucleotides but requires administration of exceedingly low levels of carcinogens labeled with a distinguishing isotope (e.g., ^{13}C or ^{2}H).

Importance of DNA Adducts in Chemical Carcinogenesis

The presence of a DNA adduct in a critical gene provides the potential for occurrence of a mutagenic event, resulting in subsequent alterations in gene expression and a loss of growth control. A substantial

period of time is required for a tumor to become evident, and DNA damage is considered to be necessary but not sufficient for tumorigenesis since other events, such as mutagenesis and cell proliferation, must also take place. DNA adduct levels, measured at any point in time, reflect tissue-specific rates of adduct formation and removal, which depend upon carcinogen activation, ►DNA repair, adduct instability and tissue turnover. In experimental models dose-response associations have been observed for DNA adduct formation, mutagenesis, and tumorigenesis induced by chemicals, while reductions in DNA adduct levels have been associated with chemoprevention. However, some adducts are highly-mutagenic and associated with carcinogenesis, while others are not. Studies in animal models have demonstrated an association between mutation "hot-spots" in proto-oncogenes or tumor suppressor genes, and specific adducts. Mutations considered potentially carcinogen-specific have been observed in *p53*, *ras*, and other reporter genes in humans. An important example is the *p53* codon 249 G to T mutation associated with aflatoxin B_1-N^7-deoxyguanosine formation and liver cancer in Qidong PRC. Molecular epidemiologic studies involving DNA adduct measurements have the potential to elucidate the role of DNA adduct formation in human cancer risk.

Significance of Carcinogen-Protein Adducts

In the same way that DNA can be modified by reactive chemical species, endogenous or exogenous carcinogens can become bound to proteins after direct interaction or metabolic activation. Typically, a reactive cation binds covalently at a nucleophilic amino acid. Alkylating agents most commonly attack the amino acid cysteine, however, aspartate, histidine, valine, tryptophan, glutamate, and lysine residues are also targets.

Because protein adducts are not repaired, protein adduct measurements are considered to reflect ►carcinogen dosimetry. Chemically-stable adducts are thought to provide a measure of dose integrated over the life time of a given protein. The blood proteins hemoglobin and serum albumin have been most studied as human ►biomarkers because they are readily accessible and have known rates of turnover. However, histone and collagen adducts have been explored as indicators of longer-term exposures.

Methods to Measure Carcinogen-Protein Adducts

The earliest animal model studies that examined hemoglobin or serum albumin adducts involved the use of a radiolabeled carcinogen. More recent approaches have included immunoassays, HPLC with fluorescence detection and various mass spectrometry approaches. These methods are particularly powerful because of the ability to determine the specific chemical structure of the purified protein adduct. In addition, sensitivity can be typically as low as ~0.1 fmole of adduct in mg quantities of protein. The strengths of this approach are the specificity of the methods and the availability of large quantities of sample material.

Significance of Protein-Adducts

The utility of proteins for human dosimetry in environmental and occupational chemical exposures was first demonstrated by the kinetic relationship between protein adduct persistence and protein lifetime. This important principle was established for hemoglobin modified by ethylene oxide or alkylating agents. It provided the basis for subsequent studies that investigated associations between carcinogen-protein adduct levels and carcinogen exposures. Protein adduct formation is a valuable surrogate for DNA adduct formation since many chemical carcinogens bind to both DNA and protein in blood with similar dose-response kinetics. In addition, blood proteins are available in large quantities, enhancing the feasibility of measuring carcinogen-protein adducts in human biomonitoring studies.

Many protein adduct studies have considered human exposures to different chemicals including ethylene, methylmethane sulfonate, BP, aflatoxin B_1, 2-amino-3-methylimidazo[4,5-f]quinoline (IQ), dimethylnitrosamine, ethylene and propylene oxide, NNK and styrene. Hemoglobin adducts formed through the metabolic activation of aromatic amines have proven to be excellent indicators of tobacco smoking. Tobacco smokers are readily distinguished from non-smokers, and a dose response has been observed between smokers of black tobacco containing high levels of 4-ABP and blonde tobacco containing low levels of 4-ABP. Protein adducts have been measured for twenty aromatic amines contained in cigarette smoke. The 3-aminobiphenyl-hemoglobin is a unique marker for passive smoking because 3-aminobiphenyl is present in side-stream but not main stream tobacco smoke. Hydroxyethylvaline in hemoglobin is also a dosimeter of tobacco smoking, but it is less specific because ethylene oxide has other environmental origins in addition to tobacco smoke. Although questions remain concerning the relationship between protein adduct levels and disease risk, measurement of protein adducts has been, and will continue to be, a valuable tool in ►molecular epidemiology studies.

Carcinogen Metabolism

Frederick Peter Guengerich
Department of Biochemistry and Center in Molecular Toxicology, Vanderbilt University School of Medicin, Nashville, TN, USA

Definition

The transformation of chemicals is important in carcinogenesis both in terms of bioactivation as well as detoxication. Most chemical carcinogens need to be activated within the body. Such reactive forms can then cause biological damage (Fig. 1). As an example for competing processes aflatoxin B_1 was chosen (Fig. 2) (►Adducts to DNA). Exactly what proportion in human cancers is the result of chemical exposure is not clear. However, in most countries at least one third of cancer cases are due to tobacco carcinogens (►Tobacco carcinogenesis, ►tobacco-related cancers). A significant number of cancer cases may be related to diet, although it is unknown exactly which chemicals in food cause or influence cancer. As a result of precautions adapted in the course of the last century, the number of cases due to industrial exposure seems to be very low.

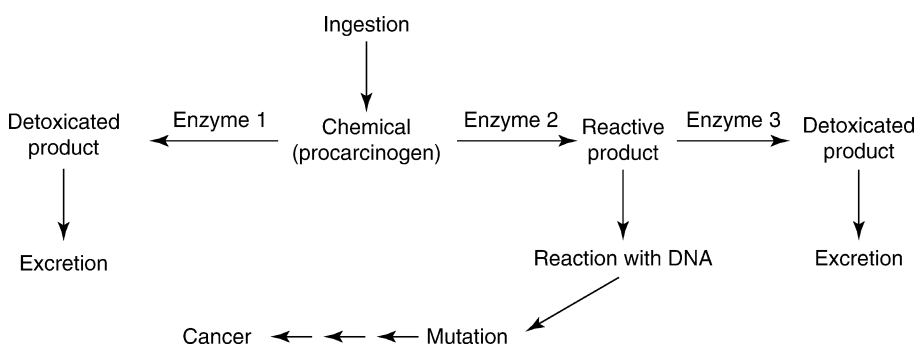
Characteristics

History

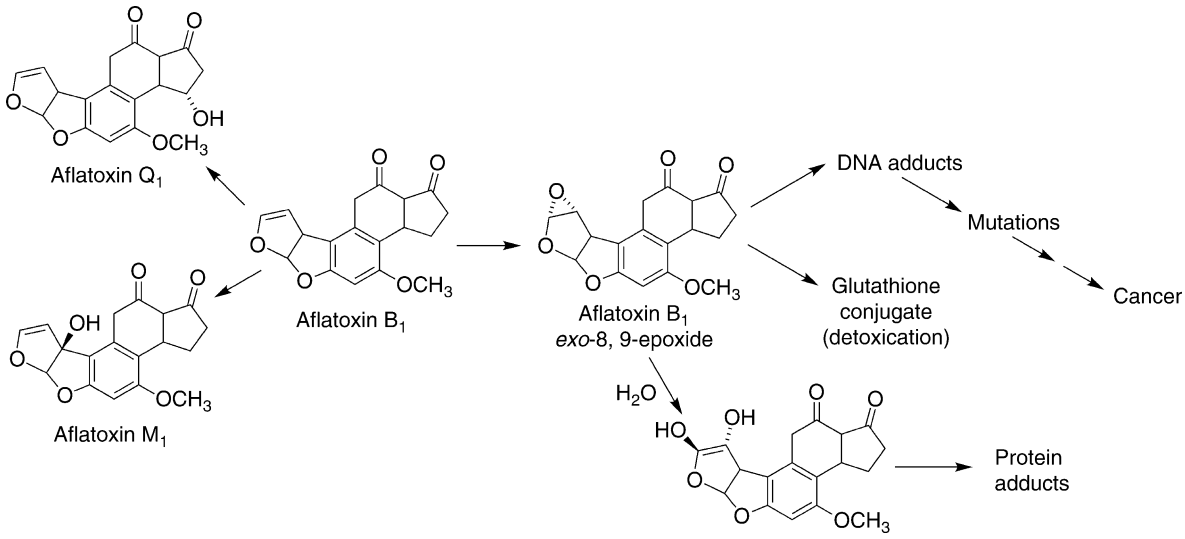
In 1761, the London physician J. Hill associated the use of snuff with nasal cancers (tobacco carcinogenesis, tobacco-related cancers). More than one hundred years later in 1895, Rehn and others reported a link of large-scale arylamine exposure of workers in the aniline dye industry in Germany and Switzerland to bladder cancer (►Aromatic amines). In Japan, Yamagiwa and Ichikawa were in 1915 the first to demonstrate the formation of tumors in rabbits exposed to coal tar, a mixture of polycyclic hydrocarbons (►Polycyclic aromatic hydrocarbons). The concept that metabolic processes are a necessity for the bioactivation of chemical carcinogens was primarily developed by J. A. and E. C. Miller at the University of Wisconsin in the early 1940s (►DNA damage). Over the next few decades, they and others provided further insight, defining metabolically derived carcinogenic products that react with DNA ("ultimate carcinogens") (Adducts to DNA). However, although the relationship between carcinogens and mutagenesis had been considered, it was not clearly defined. It was only after B. N. Ames developed a (still widely used) bacterial mutation system in which rat liver extracts are able to transform carcinogens into mutagens that the correlation between carcinogenesis and mutagenesis became obvious (►Genetic toxicology). Advances in enzymology and recombinant DNA technology made it possible to discern the role of individual human enzymes in various steps in carcinogen metabolism. Using inbred mouse strains and knockout mice it was possible to demonstrate the critical role of mouse orthologues in carcinogen activation.

Metabolism

Metabolism of carcinogens occurs in many tissues throughout the body (►ADMET screen). Many in vitro studies utilize liver tissue samples because many enzymes of interest are concentrated there. However, for tumors that originate elsewhere, extrahepatic sites are of greater interest. The question of which kind of tissue is most important is related to the site of entry of a carcinogen, as well as how much the activated form(s) of the carcinogen are able to circulate within the body before reacting with the target tissue. Examples of



Carcinogen Metabolism. Figure 1 General paradigm for carcinogen metabolism, including both bioactivation and detoxication reactions.



Carcinogen Metabolism. Figure 2 Major events in the metabolism of the hepatocarcinogen aflatoxin B_1.

important carcinogens and their metabolism are given below (►Xenobiotics).

- Polycyclic aromatic hydrocarbons are systems of fused benzene rings that are found in carcinogenic soots, tars, and tobacco smoke (Polycyclic aromatic hydrocarbons). A widely studied member of this class of compounds is benzo[*a*]pyrene. It is widely believed that the main metabolic pathway involves the oxidation of benzo[*a*]pyrene by cytochrome P450 (P450) to an epoxide. The hydrolysis of this epoxide to a dihydrodiol is followed by another oxidation by P450 that generates highly reactive diol epoxides (►Cytochrome P450). The latter can either react with DNA or are detoxicated by glutathione transferase.
- Aflatoxin B_1 is a mycotoxin and a prominent contributor to human liver cancer (►Hepatocellular carcinoma). A critical feature of its metabolism is the formation of an epoxide by P450 enzymes Fig. 2. The epoxide (with a half life in water of $t_{1/2}$ = 1 s) is able to react with DNA or can be conjugated with glutathione. P450 enzymes can also detoxicate aflatoxin B_1 by catalyzing several other oxidation steps (e.g., the oxidation to 3α- and 9α-hydroxylated products).
- Olefins (alkenes) can be oxidized to epoxides (►Alkylating agents). A member of this group is vinyl chloride, a carcinogenic substance that was shown to cause a rare liver hemangiosarcoma in people working in the rubber industry.
- Another problematic group of substances are *N*-nitrosamines. They can result from some industrial settings but that are also produced endogenously from amines and nitrites in the acidic environment of the stomach. Sources are the so-called tobacco-specific nitrosamines as well as sodium nitrite that are used to preserve processed meats (Tobacco carcinogenesis, tobacco-related cancers). As in the examples stated above, P450 activates *N*-nitrosamines by oxidation. The formation of an alcohol on the adjacent carbon atom yields an unstable product that decomposes and alkylates DNA.
- Another group of chemicals of concern presents in food and tobacco is heterocyclic amines, substances that derive from creatinine and amino acids following pyrolysis (Aromatic amines). Amine activation involves its oxidation by a P450 enzyme to a hydroxylamine (–NHOH). An unstable compound (–NHOAc) is the result of the enzymatic transfer of an acetyl group (►Arylamine *N*-acetyltransferases (NAT) and cancer, ►biomarkers). It ultimately breaks down to a nitrenium ion ($-NH^+$) that can react with DNA. Detoxication involves other P450 enzymes, glutathione transferases, and UDP glucuronosyl transferases.

Mechanisms

Conjugation reactions (including those catalyzed by the enzyme *N*-acetyltransferase) (Arylamine *N*-acetyltransferases (NAT) and cancer) are usually involved in detoxication reactions; they can, however, also be part of bioactivation schemes (►Sulphotransferases). An example is the pesticide ethylene dibromide ($BrCH_2Cl_2Br$) and related compounds where the enzymatic conjugation of ethylene dibromide with endogenous tripeptide glutathione yields a molecule (in this case

glutathione-CH_2CH_2Br) that can react with DNA (►Glutathione-S transferase).

Cancers

Numerous studies support the important role of carcinogen metabolism in human cancers.

First, substances, such as aflatoxin B_1, whose metabolic products can cause cancers Fig. 2, have been identified in foods (Xenobiotics). Second, it has been shown in animal models that either the absence or the induction of certain enzymes that are involved in carcinogen metabolism can have a dramatic effect on chemical-caused cancers. Third, humans are known to show great phenotypic variation in many enzymes involved in carcinogen metabolism. Dramatic effects on the metabolism of drugs have been demonstrated with these enzymes. Large international and other inter-individual differences in cancer incidence, as well as the documented effects of diet on cancer, justify the considerable interest to study carcinogen metabolism, particularly in humans. Research in carcinogen metabolism and its applications can be divided into several areas. Investigating cancer cause and cancer etiology depends upon the understanding of basic chemistry, enzymology, and physiology of metabolic processes as well as how the chemicals react with DNA once they are activated (►Carcinogen macromolecular adducts). Molecular epidemiology utilizes information about carcinogen metabolism in order to establish their relevance in human cancer (►Biomarkers). A related topic is risk assessment, which uses the knowledge of carcinogen metabolism derived from animal bioassay studies and sometimes epidemiology, to determine critical exposure levels of environmental carcinogens in humans (►Cancer epidemiology).

Metabolism mechanisms play an important role in cancer safety assessment studies of prospective new drugs, including those used to treat cancer. Another important area is chemoprevention where beneficial effects of certain chemicals are investigated, e.g., their ability to change the metabolism of carcinogens.

Carcinogenesis

I. Bernard Weinstein
Columbia University, New York, NY, USA

C

Definition

Carcinogenesis is the process by which cancer develops in various tissues in the body.

Characteristics

In most cases carcinogenesis occurs via a stepwise process that can encompass a major fraction of the lifespan (►multistep development). These progressive stages often include hyperplasia, dysplasia, metaplasia, benign tumors and then, eventually, malignant tumors. Malignant tumors can also undergo further progression to become more invasive and metastatic, autonomous of hormones and growth factors and resistant to chemotherapy or radiotherapy.

Causes

Known causes of carcinogenesis include various chemicals or mixture of chemicals present in several sources. This includes cigarette smoke, the diet, the workplace or the general environment, ultraviolet and ionizing radiation, specific viruses, bacteria and parasites and endogenous factors (►oxidative DNA damage), DNA depurination, deamination). According to the International Agency for Research on Cancer (IARC) 69 agents, mixtures, and exposure circumstances are known to be carcinogenic to humans (group 1), 57 are probably carcinogenic (group 2A) and 215 are possibly carcinogenic to humans. Some of these agents, or their metabolites, form covalent ►adducts to DNA and are ►mutagenic. Others act at the epigenetic level by altering pathways of signal transduction and gene expression. These include tumor promoters, growth factors and specific hormones. Dietary factors also play an important role. Fruits and vegetables often have a protective effect. Excessive fat and/or calories may enhance carcinogenesis in certain organs. Hereditary factors can also play an important role in cancer causation. Indeed, human cancers are often caused by complex interactions between these multiple factors. An example is the interaction between the naturally occurring carcinogen ►aflatoxin and the chronic infection with hepatitis B virus in the causation of liver cancer in regions of China and Africa.

Molecular Genetics

Recent studies indicate that the stepwise process of carcinogenesis reflects the progressive acquisition of

activating mutations in dominant acting ►oncogenes and inactivating recessive mutations in ►tumor suppressor genes. It is also apparent that epigenetic abnormalities in the expression of these genes also play an important role in carcinogenesis. Thus far over 100 oncogenes and at least 12 tumor suppressor genes have been identified. Tumor progression is enhanced by genomic instability due to defects in DNA repair and other factors. The heterogeneous nature of human cancers appears to reflect heterogeneity in the genes that are mutated and/or abnormally expressed. Individual variations in susceptibility to carcinogenesis are influenced by hereditary variations in enzymes that either activate or inactivate potential carcinogens, variations in the efficiency of DNA repair and other factors yet to be determined. Age, gender and nutritional factors also influence individual susceptibility.

Clinical Relevance

Prevention

Cancer is a major cause of death throughout the world. Therefore, the prevention of carcinogenesis is a major goal of medicine and public health. The carcinogenic process can be prevented by avoidance of exposure to various carcinogenic factors (i.e. cigarette smoking, excessive sunlight, etc.), dietary changes, early detection of precursor lesions and chemoprevention.

Carcinogenicity Studies

Definition

Are conventionally conducted in rats and mice where several groups of animals are administered drug for a period typically of 2 years which is a large part of the lifetime of these species. The route chosen is that of the intended clinical dosage route where practicable. The high dose group is usually at or near the maximum tolerated dose when physically achievable. Group sizes are larger (50 per sex per group) so that any effect on tumor development can be detected. Old rodents develop tumors naturally so that it requires a sufficient numbers of animals for an effect of the drug to be seen against this background. These animals are simply housed and treated without any other intervention for the period of the experiment, killed humanely either when sick or at 2 years and subject to a detailed autopsy. From each animal at least 30 tissues and all tumors are examined and diagnosed by a pathologist. The numbers and types of tumors would be evaluated and statistical analysis conducted to detect any increases in the incidence of tumors in drug-treated animals. These studies are not normally performed with anticancer drugs that are strongly mutagenic in short term tests. This would be considered evidence of carcinogenic activity and the clinical use of such drugs would be limited to life-threatening conditions.

Synonyms

Neuroectodermal tumor; NET; neuroendocrine carcinoma; Argentaffin carcinoma

Definition

Carcinoid tumors represent a family of diseases derived from ►neuroendocrine cells. These tumors were first described by Langhans in 1867 but were not described in detail until Lubarsch described them in 1888. The name *karzinoide* was not used until 1907 by Oberndorfer, and was chosen to reflect his idea that these were benign growths. However, these tumors have a wide range of clinical presentations and outcomes from benign to malignant. Clinicians must recognize the nature of carcinoid disease, because these often have a significantly different clinical course than typical carcinomas occurring within the body. Additionally, with few exceptions, neuroendocrine tumors (NETs) comprise a tiny fraction of tumors within any specific organ. These neoplasms cause <1% of all malignancies in the United States, currently occurring at a rate of 2.5–4.5/100,000 people.

NETs can arise in almost any tissue within the body, but most are derived from the embryonic ►foregut, ►midgut, and ►hindgut with over two-thirds of these occurring in the gastro-entero-pancreatic axis, with approximately 25% occurring in the foregut. NETs of the ►midgut (true carcinoids) are the only ones which secrete ►serotonin and only these tissues give rise to tumors causing carcinoid syndrome. Carcinoid syndrome is the most recognized complication of carcinoid tumors, originally described in 1890 by Ransom. This manifestation was not recognized as an endocrine or paraneoplastic syndrome until 1914 by Gosset. Carcinoid syndrome is caused by carcinoid in the midgut which secretes serotonin. In its localized state, venous drainage of tumor secretions are metabolized by the liver and serotonin is deactivated. However, upon metastasis to the liver, secretions are not as readily processed, serotonin not deactivated, and so is released into systemic circulation, causing the syndrome. This is often characterized by flush, diarrhea, and cramping.

Characteristics

Within the GI system, the small intestine is the most frequent site of NETs, followed by the rectum. Overall, 32–45% of NETs will spread, but the propensity for these tumors to metastasize also varies individually by the organ in which they develop. As with most neoplasms, the set of symptoms that each tumor will cause the patient is dependent on where the tumor begins, and thus NETs will probably present in different stages depending on site. For instance, >70% of NETs starting in the cecum and pancreas spread regionally or distantly, compared to NETs of the rectum and stomach, which spread less than 18 and 33% of the time, respectively. Overall 5-year survival rates for NETs are 67%, with survival rates after spread to localized or distant sites exceeding 75% and below 40% respectively. Accordingly, 5-year survival rates vary by site, with the highest and lowest rates being in the rectum (88%) and liver (18%), regardless of stage.

Risk for developing NETs can also be part of inherited familial cancer syndromes. Although rare, this most frequently occurs in ►Type I multiple endocrine neoplasia (►Multiple endocrine neoplasia Type 2) and ►Type I neurofibromatosis, with isolated case reports in other inherited cancer syndromes. However, the site of NETs in these syndromes is most often the duodenum or pancreas, and not the midgut, which is the site of most sporadic carcinoids. The molecular genetics of *MEN1* (the gene which is mutated MEN I) in carcinoids is complex, but includes point mutation as well as loss of one allele. In lung NETs, for example, 4/11 tumors showed both point mutation as well as deletion of one allele. Additionally, *MEN1* is located on chromosome 11q13, which is frequently lost from NETs and will be discussd later. *MEN1* which encodes the protein menin, is frequently altered in sporadic carcinoid, in addition to Type I MEN. Menin behaves as a nuclear protein when consisting of the wild-type sequence, but does not localize to the nucleus in many mutated forms. As with almost all genes which are implicated in familial cancer syndromes, Menin predictably behaves as a tumor supressor gene. It has been shown to dampen transcriptional transactivational activity of such oncogenes as NF-κβ and JunD. However, menin is also known to behave as an oncogene, and in fact is required for mixed lineage leukemogenesis in relevant models of the disease. Menin interacts with the Mixed-Lineage Leukemia (MLL) protein, which is also known to regulate transcription. Indeed, deletion of the Menin-interaction domain from MLL results in failed leukemogenesis in a validated model for this disease. MLL behaves as a ►histone methyltransferase for histone H3-K4, and H3-K4 methylation is known to be strongly associated with transcriptional activation. Therefore, it appears Menin retains transcriptional activating as well as repressing activity, and behaves in oncogenic as well as tumor suppressive signaling pathways. Only

a handful of other genes are known to be definitively mutated in NET and carcinoid, including succinate-ubiquinone oxidoreductase subunit D (*SDHD*) and ►β-catenin (►APC/►β-Catenin Pathway). Notably, mutation of "classical" oncogenes and tumor supressors like ►*RAS* and ►*TP53* are not present in NETs.

Much more work has been done to identify chromosomal losses in NETs or carcinoid tumors. Identification of regions of DNA which are consistently lost in carcinoid tumors implies that carcinoid- or NET-specific tumor suppressors may reside in these deleted regions. These regions most frequently include 11q, which contains *MEN1* as previously discussed, but this region may contain other tumor suppressors as well. Another chromosomal region frequently lost in these malignancies is18q. This occurs in 33–88% of NETs and varies by NET site. For instance, lung NETs, like carcinoids, often have loss of 11q, but rarely have loss of 18q. Several known tumor suppressors reside on 18q which include two transcription factors in the ►TGF-β signaling pathway (►Smad proteins in TGF-β signaling) (*SMAD2* and *SMAD4*) and *DCC*, all of which are known to be altered in pancreatic and colorectal cancer. At least one study has delimited the region of lost genomic DNA in midgut carcinoids to the sequence between 18q22 and the 18q ►telomere. Interestingly, *SMAD2*, *SMAD4*, and *DCC* do not reside in the region of recurrent loss in carcinoid, strongly suggesting that other genes in 18q22-qter are carcinoid tumor suppressors. Less evidence is available regarding the loss of 9p21 (which contains *p16/ARF*), 3p (which contains ►peroxisome proliferator-activated receptor and cancer, *RASSF1A*, ►von Hippel-Lindau tumor suppressor gene, ►*FHIT*, and ►retinoic acid) and 16q21.

The ability to measure chromosomal abnormalities and point mutation of specific genes in NETs combined with the fact that NETs are often multifocal has led to the question of whether each tumor focus originated as an independent event or if multifocality is secondary to local invasion and metastasis. This question can be answered in a variety of ways, but currently the most definitive method is based on molecular analysis of the genomic content of each individual focus. By analyzing regions which are frequently lost and/or genes which are commonly mutated in each tumor individually, inferences regarding the clonality of multiple tumor foci can be drawn. If multiple tumors form independently, then one would expect that genetic alterations at specific loci would occur randomly. However, If the same genetic alterations are seen in a majority of tumors from the same patient, then it is likely that the tumors do not form independently. This was shown by Katona et al using microdissected tissues from patients with multiple pancreatic NETs or carcinoids. Seventy-two tumors from 24 patients were analyzed using LOH analysis. The results of this study showed that indeed at least some tumors show identical patterns of allelic loss, indicating that carcinogenesis in these patients probably occurred once and that each tumor focus represents a locally invasive metastasis. However, the largest fraction of patients had tumors with non-identical LOH pattern in each tumor, indicating that these tumors actually formed independently. Other groups have shown a similar pattern of evidence with different genetic markers implicating multiple independent foci in carcinoid carcinogenesis.

The implications of identifying the mechanism of multiple tumor formation are directly related to therapy, especially with regard to surgical intervention. This is directly related to the pathogenesis of NET formation. One would surmise that multiple tumors arise independently in an organ for one of a few reasons: cells were exposed to an endogenous mitogen or trophic factor; cells were exposed to a genotoxin, causing genetic damage to accumulate in many cells which independently acquire further mutations; or intrinsic germline ►polymorphisms provide a propensity for tumors to form in multiple independent cells. In all three cases, the idea of a ►field defect, first described by Slaughter in 1953 plays a significant role. A field defect may be thought of as normal-looking tissue which, at a gene-by-gene level, is not normal. In other words, it is a pre-benign lesion. If the entire organ at the site of NET formation harbored pre-malignant genomic changes, then more aggressive surgical intervention would predictably result in better outcomes for patients, because the procedure would leave behind tissue with a propensity to continue to undergo carcinogenesis. However, if multiple NETs arise in an organ due to local spread, then wider surgical margins would probably not result in higher survival rates, assuming the procedure was able to remove all of the malignant tissue.

Much has been learned about carcinoid since its original description over 100 years ago. Much is left to be learned about this disease as well, including exactly which signaling pathways are altered in the disease and identification of genes which are in chromosomal regions of frequent alteration. As yet, there are very few reports of experimental carcinoid models which to study, both at the cell line or animal level. Detailed epidemiological studies become difficult to perform due to the rare nature of this disease, which also complicates prospective studies. Overcoming or averting these obstacles will significantly speed the rate of progress in carcinoid research.

Carcinomatosis

François Noël Gilly, Olivier Glehen
Department of Digestive Oncologic Surgery, Hospices Civils de Lyon–Université Lyon 1, Lyon, France

Synonyms

Peritoneal carcinomatosis; Peritoneal malignancy; Peritoneal tumor

Definition

Until 1980s, "Carcinomatosis" was a condition typically characterized by widespread dissemination of malignant metastases throughout the body. It was then used to describe conditions with more limited spread as in "►leptomeningeal carcinomatosis," "►lymphangitic carcinomatosis," and "peritoneal carcinomatosis." Since 2000, due to the worldwide diffusion of cytoreductive surgery combined with intra abdominal chemotherapy, "carcinomatosis" is a word now describing tumoral spreading within the peritoneal cavity.

Peritoneum is the mesothelial tissue (serosa) that covers most of the organs in the abdominal cavity as well as the interior part of the abdominal wall (parietal peritoneum covers the abdominal walls and visceral peritoneum covers intra abdominal organs like stomach, colon, gallbladder, spleen, liver, etc). Peritoneum, which is now regarded as an organ by itself, could be the site for "peritoneal carcinomatosis" arising from primary peritoneal tumors or from metastatic nonperitoneal tumors.

Characteristics

Etiology of Peritoneal Carcinomatosis

Primary peritoneal carcinomatosis could arise (i) from pseudomyxoma: a rare border line or malignant mucinous tumor, generally originating from the appendix, incidence of which is estimated 1/million/year and sometimes called the "jelly-like fluid disease" – only the histopathologic analysis is able to determine the grade 1(peritoneal adenomucinosis, 84% 5-year survival), the grade 3 (peritoneal mucinous adenocarcinoma,

7% 5-year survival), and the grade 2 (intermediate, 37% 5-year survival), (ii) from mesothelioma: peritoneal location of mesothelioma is not so frequent as pleural location, and about 250 new cases are diagnosed in USA each year; contrary to pleural mesothelioma, its asbestosis exposure relation remains controversial mainly in women, and other carcinogenic agents were reported such as virus, abdominal irradiation, chronic peritonitis, mica or thorium dioxide exposure, (iii) from primary serous carcinoma (a very rare disease mostly diagnosed in women and sometimes related to a chromosome deletion), (iv) from desmoplastic tumors, or (v) from psammocarcinoma (the estimated incidence for these three last diseases remains unknown and is probably <1/10 million/year).

Metastatic peritoneal carcinomatosis is common; it mainly arise from colorectal cancer (detected in about 10% of patients at the time of primary cancer resection), ovarian cancer, and gastric or pancreatic cancers. The mechanisms causing carcinomatosis are multifactoral and include peritoneal dissemination of free cancer cells as a result of serosal involvement of the primary tumor, implantation of free cancer cells caused by the presence of adhesion molecules, and presence of cancer cells in lymph fluid or venous blood retained within the peritoneal cavity (the role of laparoscopic approach in malignant cell diffusion, as well as the role of surgeon during the tumor handling is still controversial). Metastatic peritoneal carcinomatosis could also arise from extra peritoneal cancer (lymph and/or blood dissemination) such as breast cancer, uterus cancer, thyroid cancer, etc.

Natural history of metastatic peritoneal carcinomatosis is well known from three international prospective series; without curative treatment the overall median survival is 3–7 months, according to the stage of the peritoneal carcinomatosis.

Diagnosis

Primary and metastatic peritoneal carcinomatosis have no specific symptoms; due to the absence of specific symptoms, clinical diagnosis could be a rather difficult one. Peritoneal carcinomatosis is often diagnosed during surgical exploration of a known primary tumor; if not, symptoms can include abdominal or pelvic pain, changes in bowel functions (up to intestinal obstruction), increase of abdominal volume (caused by ascitis or by tumoral volume itself), abdominal swelling and bloating, infertility (mainly in pseudomyxoma), loss of weight, anorexia, asthenia, etc. Clinical examination of the patient could reveal ascitis or malignant nodules detectable through the abdominal wall.

Abdominal ultrasonography could reveal ascitis or primary ovarian cancer but remains unuseful for detection of peritoneal lesion <1 cm in diameter. While CT scan and MRI help the diagnosis when peritoneal carcinomatosis is made of >5 mm in diameter lesions, PET scan is still under evaluation. Laparoscopic exploration is useful to perform large biopsies and to stage the peritoneal carcinomatosis using Gilly staging system (Fig. 1) and Sugarbaker peritoneal cancer index (Fig. 2); combination of these two scoring systems was demonstrated as an independent survival predictive factor.

Stages carcinomatosis	
Stage 1	< 5mm, one part
Stage 2	< 5mm, diffuse
Stage 3	5mm to 2 cm
Stage 4	Large malignant cakes

Carcinomatosis. Figure 1 Gilly staging system for peritoneal carcinomatosis.

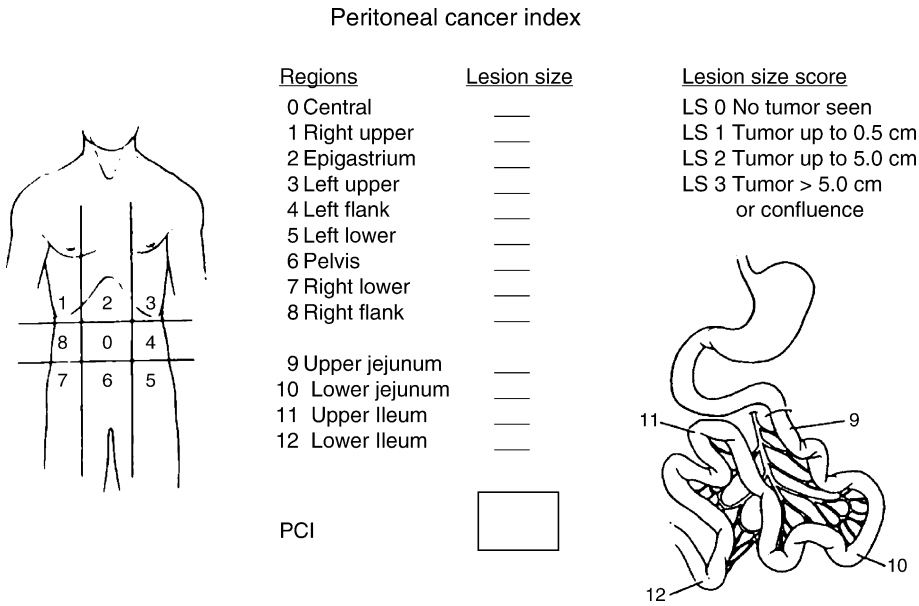
There are no biologic specificity; tumoral markers (CEA, CA 19-9, CA 125, etc) could be increased in relation to or not with the primary tumor and molecular markers are still being evaluated.

Microscopic examination of biopsies (or surgically removed tumor) is the key for the diagnosis and could need immune analysis using calretinine, B72.3, Ber EP4, estrogen, and progesterone receptors (mainly to differentiate mesothelioma and primary serous carcinoma).

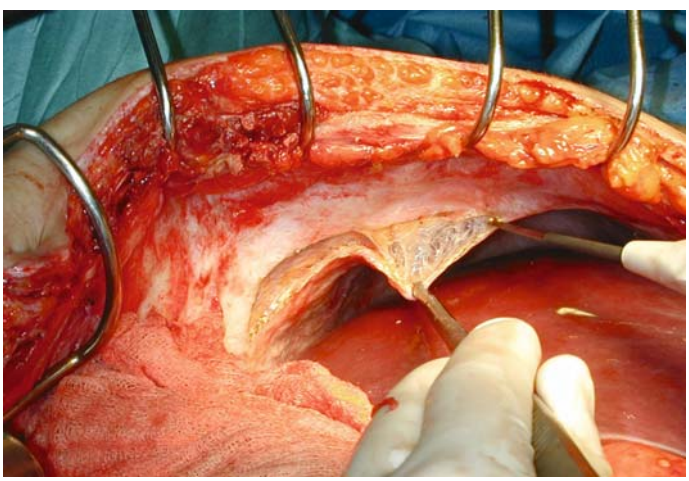
Treatment

While peritoneal carcinomatosis was thought to be a terminal disease for a long time, most oncologists regarded it a condition only to be palliated. Systemic chemotherapy (mainly 5-Fluoro-uracil-, oxaliplatinum-, and irinotecan-based) combined or not with antiangiogenic drugs achieve a 15-month median survival (most of the available trials are related to liver and/or pulmonary metastases with only few information regarding peritoneal metastases). Since the 1980s, a renewed interest in peritoneal surface malignant diseases developed through new multimodal therapeutic approaches, mainly with cytoreductive surgery combined with intraperitoneal chemotherapy (using mitomycin C, cisplatinum, oxaliplatinum, doxorubicin) with or without hyperthermia (42–43°C). Despite these aggressive and multidisciplinary approaches are reserved to experienced teams, many phase II and phase III studies revealed a strong advantage for selected patients with colorectal carcinomatosis, peritoneal pseudomyxoma, and mesothelioma.

Cytoreductive surgery (also called peritonectomy procedure) aims to remove as much tumor as possible within the abdominal cavity. The objective is to clear the entire peritoneal cavity of all macroscopic



Carcinomatosis. Figure 2 Sugarbaker peritoneal cancer index (PCI) for peritoneal carcinomatosis.



Carcinomatosis. Figure 3 Operative view of right diaphragmatic cupula peritonectomy (the parietal peritoneum is stripped to remove all the macroscopic lesions).

detectable disease. Procedures for cytoreductive surgery (Fig. 3) have been described extensively by Sugarbaker: parietal peritonectomy (which is a stripping of the parietal peritoneum) combined with organ resections (where visceral peritoneum is involved) followed by immediate intra peritoneal chemotherapy with or without hyperthermia (using closed or opened technique) aims to clear all potential microscopic residual disease. Whatever the used technique is, intraperitoneal chemohyperthermia is defined as a heated fluid circulation with cytotoxic drugs for 30–90 minutes within the abdominal cavity under a nonstop control of core temperature as well as cardiac flow rate. At least, combination of optimal cytoreductive surgery and intraperitoneal chemohyperthermia is a long surgical, oncologic, and anesthetic procedure (5–10-h long) which requires an experienced multidisciplinary team.

These therapeutic strategies need a strict patient selection (younger than 70 years who have not had cardiorespiratory or renal failure) and need to be done in experienced centers involved in the management of peritoneal surface malignancies. Combination of cytoreductive surgery and intra peritoneal chemotherapy leads to a 1–5% mortality rate and 30% morbidity rate (related to the extent of the carcinomatosis, the duration of surgery and the number of digestive anastomoses performed).

Postoperatively, the patients also received systemic chemotherapy, according to the primary tumor location.

Results are currently encouraging ones. For colorectal carcinomatosis, the Dutch randomized trial showed that 2-year survival was 43% using cytoreductive surgery and intraperitoneal chemohyperthermia versus 16% in the control group; the international registration (including more than 500 patients) showed that 5-year survival was 33% for patients treated by optimal cytoreductive surgery combined with intraperitoneal chemotherapy. Concerning pseudomyxoma (the natural history of this disease is not extensively documented but the prognosis is better than that for colorectal carcinomatosis), the 5-year survival is 80% for patients with complete cytoreductive surgery (whatever the pathologic grade is). Concerning peritoneal mesothelioma (the median survival in the past was approximately 12 months), optimal cytoreductive surgery and intraperitoneal chemohyperthermia achieve a 5-year median survival. Peritoneal carcinomatosis arising from gastric or ovarian cancer, as well as the use of intraperitoneal chemohyperthermia in a prophylactic way for high locoregional recurrence risk tumors are still under evaluation.

Cardiac Myxoma

Definition

Is a benign tumor of the heart and the most common type of heart tumor (►cardiac tumors) in adults. Cardiac myxomas can appear in an isolated case or in families, sometimes as part of an hereditary syndrome called the ►Carney complex.

Cardiac Tumors

Jadish Butany
Laboratory Medicine and Pathobiology, University Health Network/Toronto, Toronto, ON, Canada

Definition

Cardiac tumors, like all other tumors, may be classified as primary and secondary and were previously considered as incidental curiosities seen at autopsy. In comparison to the incidence and range of neoplastic proliferations seen in other organs, tumors of the heart are uncommon and have a fairly limited morphologic spectrum. With the advent of innovative diagnostic techniques such as echocardiography, computed tomography (CT) scan and the magnetic resonance imaging (MRI) and better delineation, this has changed and most tumors are now diagnosed antemortem. With new therapeutic techniques, both surgical and pharmacologic, patients with cancers live longer and show more evidence of cardiac involvement.

Characteristics

The heart was considered the "Royal Organ" and hence immune to damage, including tumors. We know now that the heart is as prone to disease as most other organs and that includes tumors. The prevalence of immunodeficiency states (especially ►human immune deficiency virus infection) has also lead to an increase in some cancers, involving the heart.

Incidence

Secondary tumors or metastases to the heart and pericardium are 100–1,000 times more common than the primary cardiac tumors with an incidence of about 1.23%. In contrast, the frequency of primary neoplasms ranges from 0.001% to 0.030%, and three quarters of these are benign. The types of benign tumors vary with age. The myxoma and papillary fibroelastoma are more common in adults, while in children, the common ones are cardiac rhabdomyoma and fibroma. Primary cardiac cancers comprise the remaining quarter, and most of these are ►sarcomas.

Clinical Features

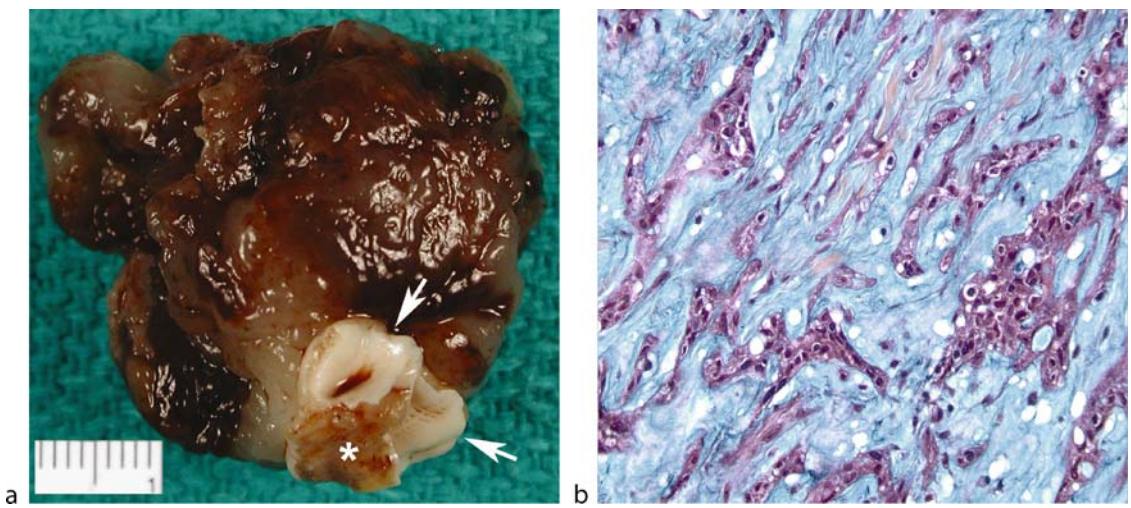
Cardiac tumors, in general, can have a varied clinical presentation, and the pattern depends on the location of the tumor. Most primary tumors, benign and malignant, usually produce intracavitary masses. Such lesions produce one or more patterns of the classic triad of constitutional symptoms, obstruction to the inflow and outflow of the blood within the cardiac chambers and/or complications related to tumor ►embolization. Tumors with significant myocardial involvement may lead to arrhythmias or features related to coronary artery disease due to narrowing or obliteration of small intramyocardial coronary arteries. If the tumor is large or multifocal, it can by itself produce frank, symptomatic cardiac failure. Pericardial tumors are often associated with varying degrees of serous or hemorrhagic effusion with or without ►tamponade. This is also the presentation with ►metastatic tumors, which more commonly involve the pericardium. It is noteworthy that 12% of primary tumors and almost 90% of metastases to the heart are clinically silent and detected only at routine assessment or are a surprise at necropsy.

Primary Tumors

Benign

Cardiac myxoma is the commonest tumor encountered in adults and accounts for nearly half the cases. It is more common in females than in males. While no age is immune, it is more common in the 30–60 years old age group. A familial predisposition has been noted in some of these patients. In the familial form, the tumors appear at younger age, involve the right side of the heart, are often multicentric and have a high rate of recurrence. There is a germline mutation in PRKARIA gene, and other associations such as pigmented adrenal micronodular hyperplasia, cutaneous melanocytic or neurogenic tumors are inherited as autosomal dominant disease. These are collectively known as the ►Carney complex. A majority of myxomas are solitary, arising as smooth surfaced, firm, grey-white sessile polypoid masses on either side of the interatrial septum (Fig. 1a and b). Approximately 75% of myxomas are located in the left atrium, where they produce features related to the classical triad. Patients with this tumor often present with a typical complaint of "hearing a plop" as they bend forward, associated with severe shortness of breath, and that they hear a second "plop" and improvement of symptoms, as they bend backwards. This is due to the tumor "plopping" into the mitral valve orifice and obstructing it. Systemic embolization is often related to the softer, gelatinous, blunt papillary fronds.

Superimposed thrombus or even infection can occur and these can embolize. The cut surface characteristically appears "wet," yellowish white, gelatinous and translucent with foci of fibrosis, hemorrhage, calcification and rarely ossification. Histologically, nestling amidst the mucopolysaccharide (jelly like), are the



Cardiac Tumors. Figure 1 (a) Polypoidal glistening hemorrhagic myxoma in the left atrium, resected with underlying interatrial septal endocardium (*arrows*) and myocardium (*). (b) Myxoma cells in cords within a mucopolysaccharide (greenish blue) rich stroma (b). stain Movat pentachrome, original magnification, ×10.0).

myxoma cells or lipidic cells arranged in the form of cords or form vessel-like structures. Foci of hematopoiesis and intestinal glandular metaplasia may be seen occasionally.

The next common tumor is the papillary fibroelastoma, representing about 8% of cardiac tumors, with no gender predilection. The tumor arises from the endocardium, especially over the cardiac valves, particularly the aortic. The true incidence is not known as they are often small, escaping gross detection; besides the surgically excised native valves are not always subjected to rigorous histological examination. The morphology of this tumor is best appreciated by holding the mass under water, when a short central stalk with multiple papillary fronds (up to 1 cm or more in length) are seen (Fig. 2a and b). The whole tumor resembles a sea anemone. These papillae are delicate and often break off and embolize. Additionally, thrombi can also occur over the surfaces of the papillae with subsequent embolization. In fact, one of the presentations of this tumor is the sudden development of blindness of one eye or the sudden development of chest pain. Sudden death has also been reported. The fronds have a soft myxoid core surrounded by collagen and elastic tissue fibers, lined by endothelial cells.

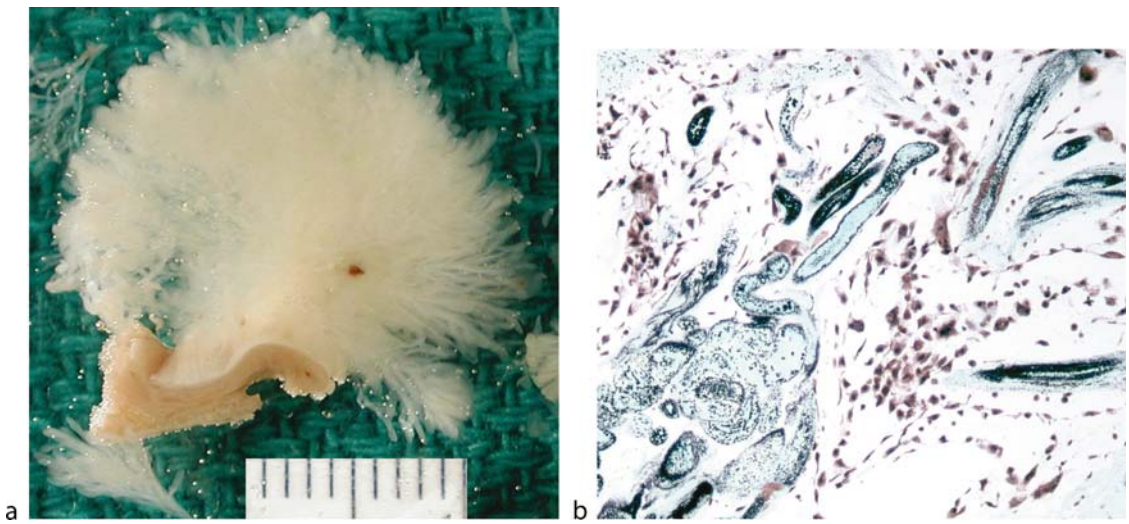
Rhabdomyoma, considered a hamartoma, is the most common tumor found in children, with an overall incidence of about 5%. Sporadic rhabdomyomas are mostly seen as solitary, small or large (0.1 cm or more), firm, opaque white, and well-circumscribed endocardial nodules. They are usually found in the left ventricle and the interventricular septum and produce obstructive symptoms. In contrast to the sporadic variants, about 50% of patients with tuberous sclerosis have multiple rhabdomyomas, leading to intra-uterine hydrops fetalis and stillbirths. It is important to rule out the presence of tuberous sclerosis in not only multiple tumors, but also in patients with solitary lesions. The rhabdomyomas are composed of ballooned out cardiac myocytes with clear vacuolated pink-staining cytoplasm, radiating from the centrally located nucleus to the periphery, and responsible for the "spider-cell" appearance.

Cardiac fibroma, the second common tumor in the pediatric population; is seen as a solitary, circumscribed, firm to hard, grey-white fasciculated tumor occurring in the ventricular chambers with a predilection to affect the interventricular septum. The mean age of presentation is around 13 years and these are the commonly resected tumors at that age. There is a proliferation of innocuous appearing fibroblasts, which characteristically entrap islands of myofibers (pseudo-invasion). With increasing age, the tumors are rendered paucicellular, with multifocal areas of calcification.

Both rhabdomyomas and fibromas are considered as congenital lesions that undergo gradual spontaneous regression or cease to be progressive. Other benign lesions include the hemangioma (vascular) and lipoma (fat-cell tumor). Brief mention must be made of the cystic tumor of the atrioventricular node, the smallest known tumor, associated with sudden death. It is composed of small fluid-filled endoderm-derived spaces in a connective tissue stroma. The spaces may be lined a variety of epithelial and epitheliod cells.

Malignant

Sarcomas are the most common malignant primary tumors of the heart, forming ~10% of the surgically



Cardiac Tumors. Figure 2 (a) "Sea anemone"-like appearance of papillary fibroelastoma, photographed under water. (b) Delicate papillae with a core of collagen and elastic, lined by plump endothelial cells (b) Stain Hematoxylin and eosin, original magnification, ×10.0).

resected cardiac neoplasms. Angiosarcoma is the commonest with an incidence of 35–37%, slight male predominance and occurs in the third to fifth decade of life. Most often, it is seen as an irregular, soft, friable, hemorrhagic mass in the right atrium, projecting into the cavity as well as infiltrating the wall and adjacent structures. Clinical presentation is often with recurrent, hemorrhagic pericardial effusion and/or symptoms related to metastases (seen in more than half the patients), frequently pulmonary or rarely even distant. At times, the angiosarcomas may be purely pericardial, forming a sheet-like mass. Depending on the degree of differentiation, angiosarcomas show irregular, anastomosing vascular channels lined by plump, atypical endothelial cells with papillary projections or sheets of epithelioid or spindled cells. If areas of spindle-shaped cells predominate, presence of red blood cells in the stroma and presence of intracellular vacuoles offer important clues to the diagnosis. Areas of necroses and brisk mitotic activity are evident. Some of the tumors are also associated with chromosomal abnormalities as seen by cytogenetic analysis.

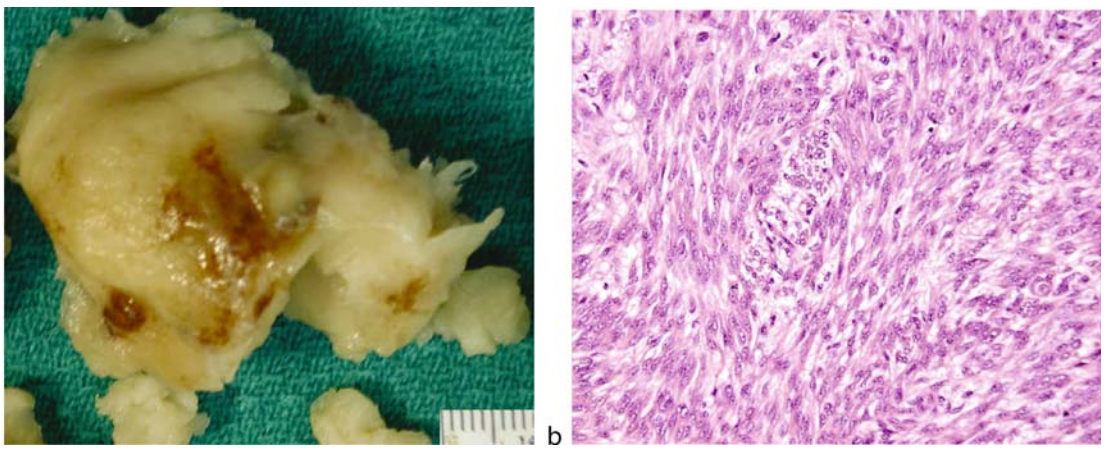
The next common sarcomas are a group of sarcomatous proliferation, which share many morphological and clinical features. These are designated as myofibroblastic sarcomas and include malignant fibrous histiocytoma, fibrosarcoma, fibromyxosarcoma and myxosarcoma (Fig. 3a and b). Many of them in addition can show focal osteosarcomatous or chondrosarcomatous differentiation. The mean age of presentation is around 40 years of age with no gender predilection. They form bulky, lobulated polypoidal grey-white masses projecting into the left atrium with the result that many of these patients present with the left-sided inflow tract obstruction. Most of them resemble their soft-tissue counterparts, but often these tumors in their cardiac location show a prominent myxoid change. Hence at times, many such tumors are misdiagnosed as myxomas.

Undifferentiated sarcomas constitute about 10–24% of these malignant cardiac tumors. They are designated undifferentiated, as they are not associated with specific, classifiable morphological, immunohistochemical or ultrastructural features. These are present as large, lobulated, polypoidal masses, chiefly in the left-sided chambers in middle-aged adults. They can affect either gender, with a wide age range of occurrence. Patients are often symptomatic at an early stage. The tumors are composed of proliferating spindle cells or epithelioid looking cells and pleomorphic cells in varying pattern.

Rhabdomyosarcomas, which constitute about 5% of the tumors, are common in younger patients, especially children. They too form very bulky and infiltrative masses in either of the ventricular chambers. Majority are embryonal rhabdomyosarcomas. The other sarcomas include leiomyosarcoma and synovial sarcoma, though virtually any type of soft tissue sarcoma may occur.

Primary lymphomas of the heart are extremely rare. However, their incidence has increased, in patients who are HIV positive as well as those with other causes of immunosuppression. An important criterion in these patients is the demonstrable absence of lymphomatous proliferation or any other sarcoma at any other site, before they can be categorized as a primary cardiac tumor. These patients therefore require thorough imaging investigations. In this type of lymphoma, there is a slight male predominance, and multiple, soft to firm, creamy white nodules are seen, especially in the right atrium. They mostly exhibit the full range of the neoplastic B cell proliferation, though large cell lymphomas are common.

Sarcomas can also affect the great vessels. Leiomyosarcomas involve chiefly the veins especially the



Cardiac Tumors. Figure 3 (a) Left atrial sarcoma resected in pieces. (b) Malignant spindle-shaped cells arranged in intersecting bundles, suggestive of leiomyosarcoma (b) Stain- Hematoxylin and eosin, original magnification, ×20.0).

inferior vena, and less commonly the superior vena cava and azygous vein. Women with mean age of 49 years are affected, with clinical features of pain and venous obstructions. The growth may be intraluminal or extraluminal. Extraluminal tumors, despite their extension into the surrounding tissues, appear circumscribed and lobulated. Metastases usually involve the lungs, though other organs like liver or kidney can also be affected, especially with inferior ven caval tumors. Sarcomas of the great arteries, pulmonary trunk and the aorta arise from the multipotential mesenchymal cells of the intima, and designated as intimal sarcomas. Despite the intimal origin, the tumor can have an intraluminal or mural growth patterns. The patients are usually elderly and the symptoms depend on the growth pattern. Aortic involvement is more common than pulmonary. The luminal tumors often produce sheet-like or plaque-like growths, which in due course of time can form an intraluminal polyp. There can be superimposed thrombi, which may form the major chunk over the tumor, leading to misleading diagnosis. The patients present with effects of obstruction or embolization. The mural growth pattern is uncommon and there is medial and adventitial infiltration with resultant local invasion. Most of them are of the undifferentiated type, which have 50% shorter survival as compared with the differentiated types. The latter includes myxofibrosarcoma, angiosarcoma, malignant fibrous histiocytoma, leiomyosarcoma or myxoid chondrosarcoma.

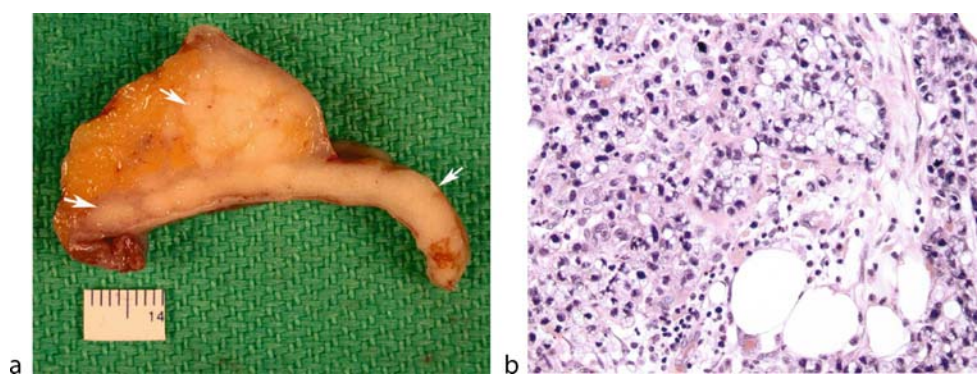
Secondary or Metastatic Tumors

The commonest tumor seen in the heart is the metastatic or secondary tumor, and is seen in at least 3% of patients with cancer, that is at least 3% of patients with a malignancy(usually advanced ones) have cardiac metastases (Fig. 4a and b). Primary cancers can spread to the heart by direct extension from adjoining structures, hematogenous or lymphatic spread and sometimes as extensions through the inferior vena cava and even the pulmonary veins. The non-cardiac solid organ primary cancers may be placed in three groups, depending on their propensity to produce metastases: Uncommon malignant tumors with a high incidence of cardiac metastases (malignant melanoma and malignant germ-cell tumors); common cancers with an intermediate frequency of cardiac involvement (carcinoma of lung in males and breast cancer in females); and, common cancers with rare metastases (cervical carcinoma).

Of all malignancies, leukemias have the highest incidence of cardiac involvement, however this infiltrative process, usually does not produce symptoms. There is a diffuse or patchy interstitial infiltrate of neoplastic cells. On the other hand, the solid tumor metastases produce multiple or single nodules over the epicardial surface. Occasionally, nodules may also be found in the myocardium or on the endocardial surface. The mode of presentation therefore depends on the location of the tumor. The tumors do not pose a diagnostic problem, as the histologic appearance is usually similar to that of the primary site.

Therapy and Prognosis

Benign tumors, which are symptomatic or located at sites that might lead to catastrophic complications, are resected. Primary cancers with limited growth and no evidence of metastases are treated by surgical resection with adjuvant chemotherapy and radiotherapy. The latter may be the only treatment option available in very large tumors which are not amenable to even palliative debulking. Auto-transplantation or orthotopic transplantation may be an option in some cases. Primary lymphomas, on the other hand, are usually best treated by combined chemotherapy and radiotherapy. The prognosis in benign tumors after surgical excision is usually excellent, except for a rare case of recurrences,



Cardiac Tumors. Figure 4 (a) Cut surface(viewed en-face) of an excised piece of pericardium showing metastatic tumor, with diffuse grey-white thickening and a large nodule,with some surrounding yellow adipose (fatty) tissue. (b) Histology shows a metastatic adenocarcinoma composed of clusters of mucin-secreting cells (Stain Hematoxylin and eosin original magnification, ×20.0).

likely due to incomplete resection. The prognosis for cardiac sarcoma is extremely dismal with a mean survival of 3 months to a year.

Cardio-Facial-Cutaneous (CFC) Syndrome

Definition

Is a rare genetic disorder characterized by integumental defects (sparse, brittle and curly hair, skin defects), skull and skeletal abnormalities (macrocephaly; bi-temporal constriction of the head, short stature), congenital heart defects, mental retardation and failure to thrive. CFC syndrome is a autosomal dominant genetic disorder caused by a germ-line mutations in the human BRAF or the MEK1 or MEK2 genes. However, not all affected individuals carry a mutation in one of these genes suggesting that other genes are also associated with CFC. CFC belongs to the neuro-cardio-facial-cutaneous syndrome complex some of which are discussed as pre-disposition for neoplastic diseases.

Definition

The Carney complex (CNC) is a dominant autosomal hereditary multiple neoplasia syndrome characterized mainly by cardiac myxomas, spotty skin pigmentation, and endocrine tumors. It was first described in 1985 by J. Aidan Carney, a pathologist at the Mayo Clinic.

Characteristics

The manifestations of CNC can be numerous and vary between patients. Even in the same kindred, phenotypic variability can be observed. The estimated frequencies of these manifestations are listed in Table 1. Endocrine, dermatologic, and cardiac anomalies are the main manifestations of the disease. The ►lentiginosis is observed in most patients and is so characteristic that can makes the diagnosis. It appears as small brown to black macules typically located around the upper and lower lips, on the eyelids, ears, and the genital area. Multiple blue nevi and junctional or compound nevi may also be observed in CNC, as well as cutaneous myxomas. The skin myxomas present as nonpigmented subcutaneous nodules. Myxomas can also be located in the ear canal.

Table 1 lists the most frequent features of CNC and their estimated frequency. The incidence of each manifestation depends on its presentation and might not reflect true prevalence. For instance, according to autopsy studies, ►primary pigmented nodular adrenocortical disease (PPNAD) is a constant feature in CNC patients, however, reports of ►Cushing syndrome in the literature indicate that only 25–45% of CNC patients have PPNAD.

►Cardiac myxoma is an important manifestation of CNC. It may be the cause of the high rate (16%) of sudden death historically reported in CNC families, thus underlying the importance of its early diagnosis. In the past, underdiagnosis of cardiac myxomas may have accounted for the majority of deaths due to CNC. In contrast with sporadic myxoma, they can develop in any cardiac chamber and may be multiple. Cardiac myxoma can be the cause of stroke due to embolism and cardiac deficiency. It is therefore important to screen regularly (by ultrasound) patients with CNC for the presence of cardiac myxoma. In difficult cases, transesophageal ultrasound and cardiac magnetic resonance imaging (MRI) can be very helpful.

Carney Complex. Table 1 Main manifestations of Carney complex

Main features of Carney complex	Frequency (%)
Primary pigmented nodular adrenocortical disease (PPNAD)	25–60
Cardiac myxoma	30–60
Skin myxoma	20–63
Lentiginosis	60–70
Multiple blue nevus	
Breast ductal adenoma	25
Testicular tumors (LCCSCT: large cell calcifying Sertoli cell tumor) (in male)	33–56
Ovarian cyst (in female)	20–67
Acromegaly	10
Thyroid tumor	10–25
Melanotic schwannoma	8–18
Osteochondromyxoma	<10

Endocrine tumors are also a major manifestation of the disease. Most characteristic is the adrenocorticotropic hormone (ACTH)-independent ►Cushing syndrome due to PPNAD observed in 30–60% of patients with CNC. The disease was named after the macroscopic appearance of the adrenals that is characterized by the small pigmented micronodules observed in the cortex. The disease is usually bilateral with primary involvement of both adrenals. Cushing syndrome due to PPNAD is most often observed in children and young adults, with a peak during the second decade of life. Diagnosis of Cushing syndrome due to PPNAD is often difficult because hypercortisolism can develop progressively over years. In contrast, a large and rapid burst of cortisol excess can be observed in some patients who might spontaneously regress. In some cases of PPNAD, clearly cyclic forms of hypercortisolism have been documented. PPNAD can also be diagnosed by systematic screening in patients with CNC, investigated for other clinical manifestations of the complex, or after familial screening. Despite the unusual time course of Cushing syndrome observed in some patients with PPNAD, clinical signs are quite similar to those observed in patients having other causes of hypercortisolism. Urinary cortisol is increased in most patients at the time of diagnosis of PPNAD, but its level can be highly variable. The circadian rhythm of cortisol secretion is usually completely abolished. As with ACTH-independent Cushing syndrome due to other causes, patients with PPNAD have low plasma levels of ACTH and show no stimulation of cortisol or ACTH secretion after ►corticotropin-releasing hormone (CRH) injection. In addition, dexamethasone fails to suppress cortisol secretion, even after high dose administration. Pathological investigation reveals that adrenal glands from patients with PPNAD are usually normal in size and weight (between 4 and 17 g). In keeping with this finding, adrenals appear normal on computed tomography (CT) scan in one out of three patients. In the other patients, micronodules can be visible and, more rarely, macronodules (>1 cm diameter) in one or both glands. Iodocholestrol scintigraphy, when performed, usually shows a bilateral uptake despite ACTH suppression by endogenous hypercortisolism.

►Acromegaly due to a pituitary ►GH-secreting tumor is not very frequent, but most patients with CNC

present with a mild increase in GH, and sometimes in ►prolactin (PRL) secretion.

Alterations in the rhythm of GH secretion are frequently observed. Thyroid tumors are most often benign, nontoxic adenomas, mostly of follicular type. Some patients present with papillary carcinoma that can be multiple and sometimes quite aggressive. Testicular tumors (►Large cell calcifying Sertoli cell tumors (LCCST)) are easily detected by ultrasound investigation as bilateral microcalcifications. They can be diagnosed by ultrasound. Ovarian cysts and cystadenoma have been observed in CNC patients.

Various other tumors, some of them quite specific for CNC, can be observed. ►Melanotic schwannoma is a rare tumor and occurs mainly in CNC. It is a pigmented tumor that can be misdiagnosed as a melanoma. This tumor can be observed in any peripheral nerve and can be, in rare cases, malignant. Breast ductal adenomas, breast myxomas, and ►osteochondromyxoma are among the tumors also observed in CNC.

CNC is an autosomal dominant hereditary disease and at least two loci have been postulated: 2p16 and 17q22-24. The *CNC1* gene, located on 17q22-24, has been identified as the regulatory subunit (R1A) of the ►protein kinase A (*PRKAR1A*). PRKAR1A is a key component of the cAMP signaling pathway that has been implicated in endocrine tumorigenesis. Heterozygous inactivating mutations of *PRKAR1A* have been detected in about 65% of CNC families. In CNC patients with Cushing syndrome, the frequency of *PRKAR1A* mutations is about 80%, suggesting that families with PPNAD are more likely to carry a 17q22-24 defect. Interestingly, patients with isolated PPNAD and no familial history of CNC may also carry a germline de novo mutation in *PRKAR1A*. In the tumors of CNC patients, loss of heterozygosity (LOH) at 17q22-24 may be observed, suggesting that *PRKAR1A* is a tumor suppressor gene. Somatic mutation of *PRKAR1A* in a patient with PPNAD already carrying a germline mutation may lead to inactivation of the wild-type allele. However, inactivation of the remaining wild-type allele by genetic alteration does not appear to be a constant step in PPNAD and CNC tumor development. In a mice transgenic model with heterozygous inactivation of *PRKAR1A*, tumors may develop without allelic loss. This suggests that the classic model of tumor suppressor gene with a germline inactivating first allelic alteration, followed by a second genetic hit leading to inactivation of the remaining wild-type allele, might to some extent be applicable to PRKAR1A. It is also possible that in PPNAD, a general polyclonal expansion might be stimulated by haploinsufficiency due to the first germline defect; a second genetic hit would then lead to inactivation of the wild-type allele and further stimulate tumorigenesis and the development of adrenocortical nodules. PRKAR1A inactivation in transgenic models is associated with an increased PKA activity. Stimulation of the MAP Kinase pathway as well as mTOR phosphorylation has been observed in experimental models of PRKAR1A inactivation and might be a mechanism for oncogenesis in CNC.

Considering the genetics of isolated PPNAD, the clinical manifestations in a subgroup of very young PPNAD patients may differ from those in older patients with CNC. In these patients the classical pathological finding of pigmented nodules may be absent although micronodules are present. In this subgroup of very young PPNAD patients, Cushing syndrome may occur between birth and the age of 5-years. The main reason for differentiating this group of PPNAD or PPNAD-like patients is the lower rate of germline inactivating mutation. This observation lead to the identification by genome wide screen of a gene responsible for isolated PPNAD: the phosphodiesterase PDE11A4. The affected patient present with a germ line heterozygous mutation of *PDE11A4* gene located at 2q31-35. An allelic loss at 2q31-35 is observed in adrenal tissue from these patients, suggesting also that PDE114 might be a tumor suppressor gene. Inactivating mutations lead to increased cAMP and cGMP levels in keeping with the observation that PDE11A4 is a dual phosphodiesterase.

Carotenes are un-oxidized (oxygen-free) carotenoids such as α-carotene, β-carotene, lycopene.

►Carotenoids

Carotenoids

Heather Mernitz, Xiang-Dong Wang
Jean Mayer USDA Human Nutrition Research Center on Aging at Tufts University, Boston, MA, USA

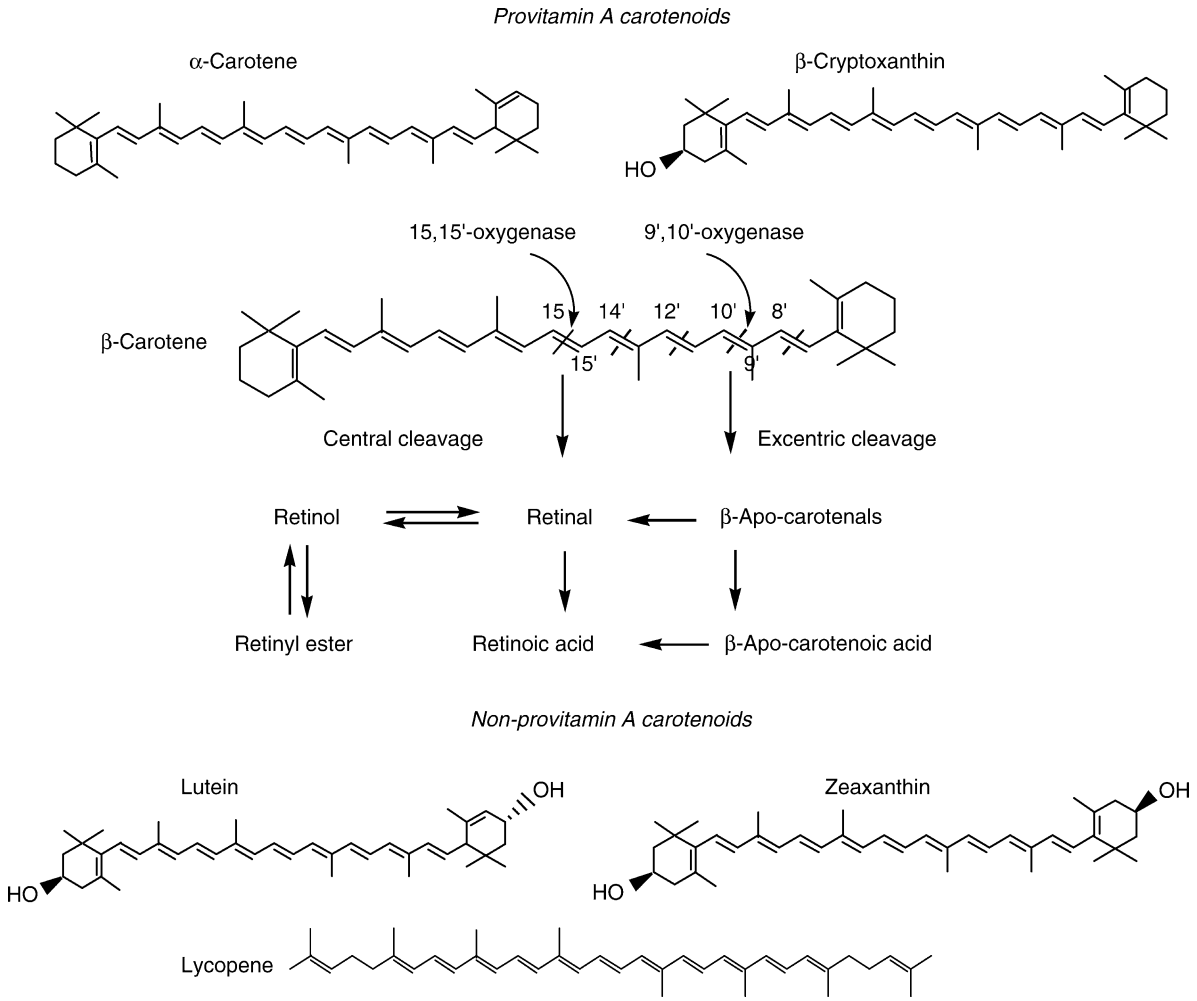
Definition

Carotenoids are lipophilic plant pigments with polyisoprenoid structures that occur naturally in plants and other photosynthetic organisms. There are over 600 known carotenoids with chemical structures characterized by a large (35–40 carbon atoms) conjugated polyene chain, sometimes terminated by ring structures. Carotenoids are divided into to major groups: ►xanthophylls, oxygenated carotenoids including lutein, zeaxanthin, and astaxanthin, and ►carotenes, hydrocarbon carotenoids that are either cyclized, such as α-carotene and β-carotene, or linear like lycopene. The most abundant carotenoids in human plasma include lutein, lycopene, β-carotene, zeaxanthin, β-cryptoxanthin, α-carotene, and α-cryptoxanthin. The two main mechanisms by which carotenoids may influence cancer risk are by exerting ►antioxidant effects and through interaction with ligand-dependent ►nuclear hormone receptors and their signaling pathways. The capacity of carotenoids to act as lipid-soluble antioxidants serves a functional and protective role in plants during photosynthesis, and may protect animals against free radical damage to lipid membranes and DNA. In addition, carotenoids may enhance cell-cell gap junctional communication and induce phase II detoxifying enzymes (see ►carcinogen metabolism). Provitamin A carotenoids (e.g. β-carotene, α-carotene, and β-cryptoxanthin) can be cleaved to generate vitamin A and other metabolites that interact with signaling pathways controlling gene expression. Non-provitamin A carotenoids (e.g. lutein, zeaxanthin, and lycopene) not only have significant antioxidant activity, but their metabolites may also exert effects on gene expression (Fig. 1).

Characteristics

►DNA damage by ►free radicals (including ►reactive oxygen species and reactive nitrogen species) is thought to be a major contributor to ►carcinogenesis, and carotenoids contain an extended system of ►conjugated double bonds that make them efficient scavengers of free radicals. While antioxidant supplements and diets high in antioxidant nutrients, including carotenoids (lycopene, β-carotene, lutein, β-cryptoxanthin), have been shown to reduce DNA strand breaks and other ►biomarkers of ►oxidative DNA damage, it is still unclear whether these changes are sufficient to lower cancer risk in humans with chronic exposure to low levels of carcinogenic compounds over a lifetime. Epidemiological studies suggest that a higher dietary intake of carotenoids and high levels of certain carotenoids in the plasma may offer protection against the development of certain cancers (e.g., lung, prostate, stomach, colon, breast), as well as other health conditions linked to oxidative damage (e.g. heart disease, macular degeneration, cataracts). However, two intervention trials, the Beta-Carotene and Retinol Efficacy Trial (CARET) and the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study (ATBC), have shown that supplementation with high dose β-carotene, alone or in combination with vitamin A, does not reduce the risk of lung cancer and may even increase that risk in smokers and ►asbestos workers. These findings have led to an increased effort to better understand the role of carotenoids and ►retinoids (vitamin A and its derivatives) in the process of carcinogenesis, with special attention to dose and the oxidative environment at the tissue level. Based on the accumulated evidence, it appears that low-dose carotenoids (similar to the amounts consumed in a diet high in fruits and vegetables) may act as antioxidants and protect against cancer, whereas at high doses carotenoids may lose their effectiveness as antioxidants, function as pro-oxidants, and/or interfere with retinoid signaling pathways, increasing cancer risk.

The series of conjugated double bonds in the central chain of carotenoids make them susceptible to oxidative cleavage and isomerization from *trans* to *cis* forms.



Carotenoids. Figure 1 Metabolic pathway of β-carotene, and chemical structures of provitamin A carotenoids (β-carotene, α-carotene, and β-cryptoxanthin) and non-provitamin A carotenoids (lutein, zeaxanthin, and lycopene).

Cleavage can result in the formation of potentially bioactive metabolites, such as retinoids and other biological compounds. For provitamin A carotenoids, such as β-carotene, α-carotene, and β-cryptoxanthin, ►central cleavage by ►carotene 15,15′-oxygenase (formerly called β-carotene 15,15′-dioxygenase), a non-heme iron oxygenase enzyme which can cleave carotenoids at their central 15,15′ double bond, is a major pathway leading to vitamin A formation. An alternative pathway for carotenoid metabolism into vitamin A in mammals is ►excentric cleavage or asymmetric cleavage. Recent characterization and study of ►carotene 9′,10′-oxygenase has demonstrated that this enzyme can catalyze the excentric cleavage of both provitamin A carotenoids and non-provitamin A carotenoids. Since disruption in retinoid metabolism and signaling may play a key role in the process of carcinogenesis, understanding the molecular details behind the actions of these carotenoid oxidative metabolites may yield insights into both physiological and pathophysiological processes in human health and disease, particularly the potential for beneficial effects of small quantities of carotenoids and harmful effects of large quantities of carotenoid metabolites.

Disruption of carotenoid and retinoid metabolism and signaling due to diet and lifestyle factors has been associated with increased risk of cancers at multiple sites (see ►nutritional status and cancer, ►hepatic alcohol metabolism and ►smoking addiction). Cigarette smoking is associated with substantially decreased plasma levels of carotenoids, despite only slightly lower intakes of carotenoids in smokers compared to non-smokers. Several hypotheses have been proposed to explain this increased metabolism of carotenoids in the tissues of smokers, including increased induction of metabolic enzymes, excentric cleavage of β-carotene into harmful oxidative products, and oxidative degradation of cellular antioxidants (e.g. ascorbic acid,

α-tocopherol) that normally serve to stabilize the reduced form of β-carotene. While initial cleavage of provitamin A carotenoids can lead to the generation of ►retinoic acid, a bioactive form of vitamin A, additional oxidation can lead to degradation into polar metabolites. With respect to lung cancer, laboratory studies have demonstrated that the oxidative cleavage products of β-carotene, when formed in large quantities in the cell after supplementation with high-dose β-carotene in the highly oxidative environment of the smoke-exposed lung, enhance catabolism of retinoic acid by their induction of ►cytochrome P_{450} enzymes (CYP enzymes) and facilitate the binding of carcinogen ►adducts to DNA. Lower retinoic acid levels then combine with smoke-induced changes to alter ►signal transduction pathways and promote lung carcinogenesis. On the other hand, low dose β-carotene supplementation, particularly when combined with other antioxidants, inhibits tobacco smoke-induced changes in retinoic acid levels and signaling in the lung tissue, preventing the formation of smoke-induced ►preneoplastic lesions (see ►tobacco carcinogenesis).

Therefore, the effects of provitamin A carotenoids can be mediated by conversion to retinoic acid and transcriptional activation of a series of genes with distinct antiproliferative or proapoptotic activity or by induction of ►apoptosis, eliminating cells with unrepairable alterations in the genome or killing neoplastic cells. Certain carotenoids may also be able to interact directly or indirectly with transcription factors, such as peroxisome proliferator activated receptors (PPARs), nuclear factor E_2-related factor 2 (Nrf2), or orphan receptors, or may indirectly influence transcriptional activity of redox-sensitive transcription systems, such as activator protein-1 (►AP-1), nuclear factor-κB (►NF-κB), and the antioxidant response element (ARE). Greater understanding of the biological functions of carotenoids mediated via their oxidative metabolites through their effects on these important cellular signaling pathways and molecular targets, as well as their significance to cancer prevention, is needed. In considering the efficacy and complex biological functions of carotenoids in human cancer prevention, it seems that provitamin A carotenoids (β-carotene, α-carotene and β-cryptoxanthin) combined with other antioxidants (ascorbic acid, α-tocopherol) would be an effective chemopreventive strategy against cancer development.

Cas

Definition

Crk-associated substrate is a tyrosine-phosphorylated docking protein that is indispensable for the actin cytoskeletal organization and cell migration. Cas binds directly to ►Src, phosphorylated and localized to focal contacts.

►Focal Adhesion Kinase

Case Control Association Study

Ahmed E. Hegab
Department of Geriatric and Respiratory Medicine, Tohoku University Hospital, Sendai, Japan

Synonyms

Case–Control association analysis; Population candidate gene association study; Genetic association study

Definition

Case–control association study aims to detect association between one or more genetic marker (usually a ►polymorphism but also may be a ►microsatellite) and a trait, which might be a disease (e.g., lung cancer), a quantitative characteristic (e.g., serum level of a ►cytokine) or a discrete attribute.

Characteristics

Several genetic methods are used for detecting genes responsible for the development of ►complex human diseases; these are nonparametric ►linkage analysis, case–control association analysis, and ►DNA microarray.

Case–control association analysis involves selecting genes that are likely to be associated with the pathogenesis of disease based on our understanding of its pathophysiology. Then ►genetic polymorphisms in these candidate genes are investigated in a large number of unrelated patients and healthy ethnically matched controls. Significant differences in ►genotype or ►allele frequencies between the two groups suggest either that (i) the polymorphism predisposes one to the disease, (ii) the polymorphism is in ►linkage disequilibrium with a disease susceptibility gene, or (iii) there is a confounding factor such as poor ethnic matching between the cases and controls. When several markers are being examined for association with the same trait, it is advisable to check them for linkage disequilibrium and disease-associated ►genetic haplotypes.

Association studies have greater power than linkage analysis. They can detect genes with a relative risk of 1.5 at nearly 80% probability if several hundred samples are collected. However, since association studies examine much smaller regions than linkage analyses, many more markers would need to be typed to conduct a ►genome-wide association study. This is not possible with current technology. At present, association studies are limited to the investigation of candidate genes and regions identified in linkage analysis. As association studies are not comprehensive, the possibility that the most important genes have been overlooked cannot be excluded. Choosing candidate genes from areas spotted by linkage analysis might be the most fruitful practice.

When performing case–control association studies factors such as study design, methods for recruitment of case and controls, selection of candidate genes, functional significance of polymorphisms chosen for study, and statistical analysis require close attention to ensure that only genuine associations are detected.

Potential Problems in Association Studies

Marked inconsistency can be observed between association studies in different or even the same ethnic groups. The association between tumor necrosis factor alpha promoter polymorphism and gastric cancer is an example for inconsistency while association of head and neck cancers with M1 polymorphism of glutathione S-transferase gene is an example for the reproducible associations. This situation has led some commentators to question the value of genetic association studies, suggesting that association studies should be restricted to polymorphisms that have been shown to have a direct effect on gene function. Possible explanations for these inconsistent results include:

1. Different populations might have different genetic components for the same disease phenotype. Furthermore, the degree of association between the specific gene and disease is different between populations. It is also possible that the different environments to which every population is exposed will interact differently with the genetic components responsible for the development of the disease.
2. Most complex human diseases are heterogeneous disorders, e.g., leukemia. It may happen that patients diagnosed with leukemia in different ethnic groups have distinct types of polymorphisms causing a specific type of leukemia.
3. When the population under study consists of a mixture of two or more subpopulations that have different allele frequencies, associations between genotype and outcome could be confounded by population stratification.
4. Ascertainment errors include undiagnosed affected individuals in the control group or including patients with heterogeneous etiologies for the complex disease in the patient group.
5. Failure to check for ►Hardy–Weinberg equilibrium. The presence of disequilibrium in the control group can result from genotyping errors, inbreeding, small sample size, or mutation.
6. A possible reason for failure to replicate positive findings is that subsequent studies are underpowered.
7. Failure to exclude chance is the most likely explanation for difficulty in replication of reports of genetic associations with complex diseases. Applying a significance level of $p = 0.05$ leads to 1 false positive in 20 results. In order to avoid type I error, p values calculated from association studies must be corrected for the number of loci analyzed (x) and the number of alleles at each loci (y). In the Bonferroni correction, the required significance level should be divided by x ($y-1$). However, this method is too conservative because closely located loci are not usually independent. The appropriate correction for multiple comparisons in association studies remains unclear.
8. Publication bias should be considered. Negative results in association studies may not be submitted for publication.

CASP-8

Definition

►Caspase-8

Caspase

Definition

Are protein degrading enzymes (proteases) that act as mediators of programmed cell death (►apoptosis). Proteins within the large family of these cell-death proteases are all similar to each other. Caspases are highly conserved during evolution and can be found in humans as well as in insects and worms and are even found in lower multicellular organisms. More than a dozen caspases have been identified in humans. Usually caspases selectively cleave a restricted set of target proteins in the primary sequence at one position, or at a few positions at most. Cleavage always occurs behind an aspartate amino acid. The caspase-mediated cleavage of specific substrates supplies an explanation for several characteristic features of apoptosis. Cleavage of the nuclear lamins, for instance, is required for nuclear shrinking. Cleavage of cytoskeletal proteins causes the overall loss of cell shape. In healthy cells, caspases normally lie dormant. In response to diverse stimuli they become activated when cell death is required. Dormant caspases exist as precursor polypeptides or "proenzymes" that are largely activated by proteolytic processing. This involves cleaving of proenzymes at specific points to generate the large and small subunits that associate to the active caspase enzyme. The proenzymes have low protease activity themselves and can therefore process each other when brought into vicinity. This process starts, when an external stimulus, a "death ligand" binds to a receptor (such as CD95/FAS/APO-1) on the cell surface. Ligand binding results in the aggregation of procaspase-8. The high density of caspase-8 proenzymes has the result that they mutually activate each other. Caspase-8 is an initiator caspase that can activate downstream procaspases, in particular procaspase-3, either by direct cleaving or indirectly by cleaving BID and inducing cytochrome C release from mitochondria.

An alternative mechanism of caspase activation in response to death stimuli involves procaspase-9. In this case, the adaptor molecule APAF-1 sequesters several procaspase-9 molecules that, within this complex (often referred to as apoptosome), are activated by a change in conformation, not by proteolysis. In response to that change, they can activate downstream caspases.

In short, initiator caspases become primarily activated by regulated protein-protein interaction, whereas downstream effector caspases are activated proteolytically. Besides caspase pathways, other death-inducing pathways must exist, since developmental apoptosis is

functional in mice that are defective in regard to the ►caspase-8 and caspase-9 pathways.

Synonyms

FLICE; FADD-like ICE; Mach; Mch5

Definition

Caspase-8 belongs to the family of cysteine proteases called caspases that act as mediators of programmed cell death (►apoptosis). It is a protein of 480 amino acids and 55 kDa that is widely expressed in various tissues. Caspase-8 displays 20% identity to the *ced-3*-encoded protein of *Caenorhabditis elegans*. The gene maps to 2q33.

Characteristics

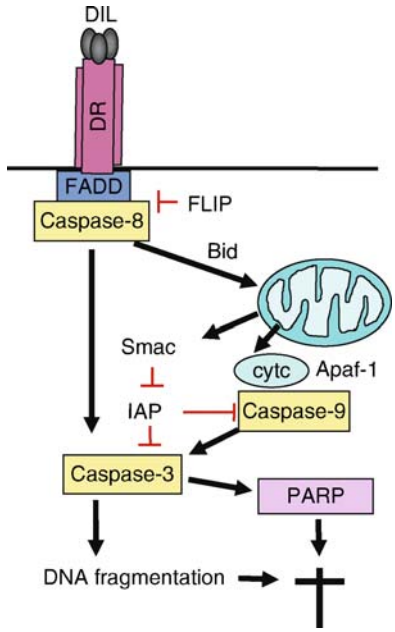
Structure and Physiological Functions of Caspase-8

Caspase-8 contains two ►death-effector-domains (DED) in the N-terminal prodomain that serve as protein–protein interaction sites and a catalytic protease domain at the C-terminus consisting of a large and small subunit. The active caspase-8 molecule is composed of a hetero-tetramer of two of each of the large and small subunits (Fig. 1). The preferred substrate specificity for caspase-8 is I/L/V/E X D (where X is any amino acid).

Caspase-8. Figure 1 Caspase-8 structure. Caspase-8 is a 480 amino acid protein that consists of two death-effector-domains (DED) and a catalytic protease domain with a large subunit (p20) and small subunit (p10).

Caspase-8 exists in different splice variants of which caspase-8a and -8b are expressed in most cell lines and catalytically active. Caspase-8L is generated by ►alternative splicing of intron 8 of the human *caspase-8* gene generating a 136 bp insertion between exon 8 and exon 9 of full-length caspase-8 mRNA. This produces a premature stop codon and a truncated protein that contains only the two N-terminal DED domains, but lacks the C-terminal proteolytic domain.

Caspase-8 is an ►initiator caspase that is expressed as proenzyme (zymogen) in an inactive state and becomes activated during apoptosis through oligomerization in a multimeric complex. Crosslinking of ►death receptors such as CD95 or the agonistic ►TRAIL receptors TRAIL-R1 and TRAIL-R2 by their corresponding ligands CD95 ligand or TRAIL or by agonistic antibodies initiates receptor trimerization, clustering of the receptors ►death domains, and recruitment of adaptor molecules such as ►Fas associated with a death domain (►FADD) through homophilic protein–protein interactions mediated by the death domains (Fig. 2). FADD in turn recruits caspase-8 to activated death receptors through interaction via the DED domains to form the ►death-inducing signaling complex (DISC). Oligomerization of caspase-8 upon DISC formation drives its activation through autoproteolysis. Once activated, caspase-8 cleaves downstream effector caspases such as caspase-3. For the CD95 signaling pathway two distinct prototypic cell types have been identified. In type I cells, caspase-8 is activated upon CD95 ligation at the DISC in quantities sufficient to directly activate downstream effector caspases such as caspase-3. In type II cells, however, the amount of active caspase-8 generated at the DISC is insufficient to fully activate caspase-3. In these cells a mitochondrial amplification loop is required for complete activation of the caspase cascade involving caspase-8-mediated cleavage of ►BH3-interacting death domain agonist (Bid), which translocates to mitochondria to trigger the release of apoptogenic proteins such as cytochrome *c* from mitochondria into the cytosol. Also, a similar cell type dependent organization (type I and type II) of the TRAIL



Caspase-8. Figure 2 Apoptosis signaling pathways. Apoptosis pathways can be initiated by crosslinking of death receptors (DR), e.g., CD95 or TRAIL receptors, by death-inducing ligands (DILs) such as CD95 ligand or TRAIL followed by recruitment of the adaptor molecule FADD and caspase-8, which drives caspase-8 activation through autoproteolysis (receptor/extrinsinc pathway). In type I cells, caspase-8 is activated at the receptor level in quantities sufficient to directly activate effector caspase-3. In type II cells, caspase-8 initiates a mitochondrial amplification loop to activate effector caspases by cleaving Bid, which translocates to mitochondria to trigger the release of cytochrome *c* (cytc) and Smac. The mitochondrial (intrinsic) pathway is initiated by the release of cytochrome *c* or Smac from mitochondria into the cytosol. Cytochrome *c* triggers caspase-3 activation via formation of the cytochrome *c*/Apaf-1/caspase-9-containing apoptosome complex, while Smac neutralizes the inhibitor of apoptosis proteins (IAP)-mediated inhibition of caspase-3 and -9. cellular ►FLICE-inhibitory protein (c-FLIP) inhibits apoptosis by blocking caspase-8 activation.

signaling pathway has been described. Besides its activation at the DISC caspase-8 can also be activated downstream of mitochondria upon initiation of the intrinsic apoptosis pathway, e.g., through cleavage by caspase-6.

In addition to its established role in ►apoptosis signaling, recent evidence indicates that caspase-8 can also exert several nonapoptotic functions. For example, caspase-8 is required to maintain homeostasis of peripheral T cells by controlling T cell proliferation via regulation of IL-2 production. In addition, caspase-8 is involved in the regulation of differentiation and proliferation of B cells, NK cells and hematopoietic progenitors. Also, caspase-8 has been reported to be important for NF-κB activation through the T cell receptor, for CD95 clustering and internalization upon CD95 stimulation as well as for the survival of endothelial cells. Furthermore, it has been shown that caspase-8 can promote cell motility by regulating activation of ►calpains, Rac, and lamellipodial assembly and regulates cell spreading by cleaving the cytolinker plectrin, a component of hemidesmosomes and focal adhesion complexes. Loss-of-function mutation in caspase-8 is lethal to the mouse embryo around day 12.5, an indication of its critical role during normal development. Caspase-8 knockout mice die in utero as a result of defective development of heart muscle and display abdominal hemorrhage and fewer than normal hematopoietic progenitor cells. Together, these findings indicate that constitutive caspase-8 activity is relevant to normal physiology.

Caspase-8 and Cancer

It is well established that the evasion of apoptosis is one of the hallmarks of ►cancer. It is therefore not surprising that some cancers have used the inactivation of caspase-8 to avoid apoptotic signals suggesting that caspase-8 may act as ►tumor suppressor. In principle, caspase-8 expression and/or function can be altered through genetic or ►epigenetic mechanisms or alternatively, caspase-8 function can be compromised in cancers. For example, caspase-8 expression can be impaired by mutations. Such mutant variants of caspase-8 may act in a dominant-negative manner, e.g., by blocking the recruitment of wild-type caspase-8 to activated death receptors, thereby inhibiting apoptosis. Despite the key role of caspase-8 for cell death execution, caspase-8 mutations in human tumors have, however, only been identified at low frequency in some tumors, e.g., in colorectal, head and neck, or vulvar carcinoma. In addition, homo- or heterozygous genomic deletions were found in some neuroblastoma. In contrast to these rare genetic alterations, caspase-8 expression is frequently impaired by epigenetic mechanisms in cancer cells. To this end, caspase-8 expression was found to be inactivated by hypermethylation of a regulatory sequence of the *caspase-8* gene, which maps to the boundary between exon 3 and intron 3. Silencing of caspase-8 was detected in a variety of cancers, e.g., in ►neuroblastoma, ►medulloblastoma, ►malignant glioma, ►rhabdomyosarcoma, ►Ewing sarcoma, ►retinoblastoma, and small lung cell carcinoma both in cell lines and in primary tumor samples. Although this regulatory region of caspase-8 does not meet the criteria of a classical ►CpG island and shows no promotor activity, the ►methylation status of this domain correlated with caspase-8 expression in several human tumors. In

addition, treatment with the demethylating agent 5-aza-2′ deoxycytidine (5-AZA) resulted in demethylation of this regulatory sequence, which in turn led to increased caspase-8 promotor activity and re-expression of caspase-8. This suggests that demethylation of a *trans*-acting factor may be involved in controlling activity of the caspase-8 promotor. Another level of transcriptional regulation of caspase-8 in cancers is alternative splicing, for example in leukemia or neuroblastoma cells. Alternative splicing of intron 8 of the *caspase-8* gene generates caspase-8L that misses the catalytic site but retains the two N-terminal DED repeats. Thus, caspase-8L is recruited to activated death receptors where it acts as a dominant-negative inhibitor of apoptosis in cancer cells by interfering with the recruitment of wild-type caspase-8.

In addition to genetic and epigenetic mechanisms caspase-8 signaling can also be functionally impaired in cancer cells, e.g., by overexpression of antiapoptotic proteins that interfere with caspase-8 activation at the death receptor level. Examples are cellular ►FLICE-inhibitory protein (►c-FLIP) or ►phosphoprotein enriched in diabetes/phosphoprotein enriched in astrocytes-15kDa (►PED/PEA-15) that exert their antiapoptotic function by blocking the recruitment of caspase-8 to activated death receptors. The adenoviral E1B19K early protein has similar properties.

The biological relevance of caspase-8 inactivation in cancers follows from its key role in the apoptotic machinery. Tumor cells with loss of caspase-8 were found to be resistant to death receptor-triggered apoptosis. Similarly, embryonic fibroblasts derived from caspase-8 knockout mice were completely resistant to apoptosis induced by death receptors including CD95, TRAIL receptors, or TNF receptor-1, whereas they retained sensitivity to other apoptotic stimuli such as UV irradiation, ►ceramide, or several anticancer drugs. These findings indicate that caspase-8 plays a necessary and nonredundant role in transducing the death signal from activated death receptor to intracellular effector caspases. In addition, chemotherapeutic drugs can initiate caspase-8 activation in a receptor-dependent and also in a receptor-independent manner. Of note, loss of caspase-8 expression has been reported to significantly correlate with unfavorable survival outcome in medulloblastoma patients, while no correlation with survival or established parameters of poor prognosis was found in neuroblastoma. Restoration of caspase-8 expression by gene transfer or by demethylation treatment in cancer cells where caspase-8 is epigenetically silenced also sensitized resistant tumor cells for death-receptor- or drug-induced apoptosis. In addition, treatment with the cytokine IFNγ caused transcriptional activation of caspase-8 in cancer cells lacking caspase-8 and enhanced expression of caspase-8 through interferon-sensitive response elements within the caspase-8 promotor and ►STAT-1.

Loss of caspase-8 fosters cancer ►metastasis and ►invasion by rendering cancer cells resistant to integrin-mediated cell death. Integrin receptors that are unable to find appropriate ligands can form a large molecular complex containing caspase-8, thereby initiating an apoptosis cascade. In this context, caspase-8 may function as metastasis suppressor gene that, together with integrins, regulates cell death of cancer cells that ►migrate from the primary tumor. Thus, loss of caspase-8 may promote metastasis of cancers by providing a survival advantage in foreign ►microenvironments.

►Protease Activated Receptors

Cathepsin-D

Emmanuelle Liaudet-Coopman
IRCM; INSERM; UMI; CRLC Val d'Aurelle, Parc Euromédecine, Montpellier Cedex 5, France

Definition

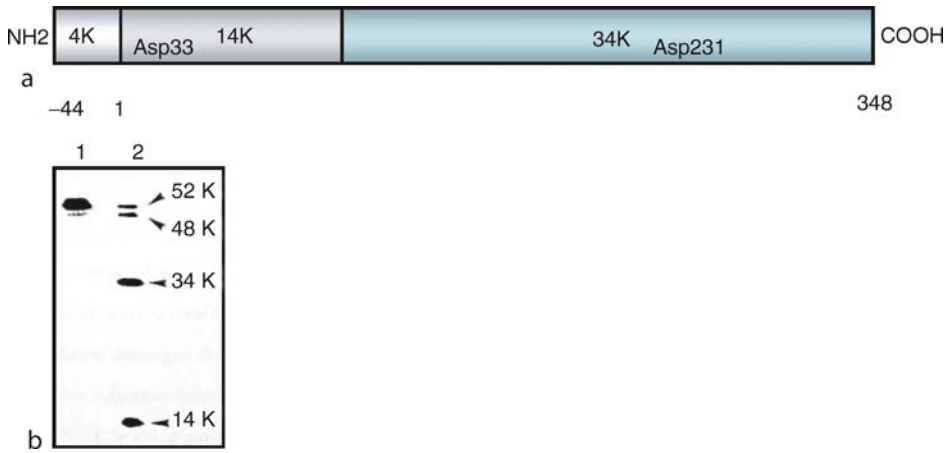
►Cathepsin-D (E.C. 3.4.23.5) is a ubiquitous lysosomal aspartic endo-►proteinase cleaving preferentially -Phe-Phe-, -Leu-Tyr-, -Tyr-Leu-, and -Phe-Tyr- bonds in peptide chains containing at least five amino acids at an acidic pH.

Characteristics

Cathepsin-D is ubiquitously distributed in ►lysosomes. It was considered for a long time that the main function of cathepsin-D was to degrade proteins in lysosomes at an acidic pH. Apart from its function in general protein turnover, cathepsin-D can also activate precursors of biologically active proteins in pre-lysosomal compartments of specialized cells. ►Knock-out of cathepsin-D gene induces death shortly after birth with severe apoptotic and necrotic phenotypes. Its pH optimum depends on the enzyme source and on the substrate used for the determination of the activity and ranges between 2.8 and 5. No endogenous cathepsin-D tissue inhibitor is known in mammals. Pepstatin, a natural inhibitor of aspartic proteases isolated from various species of actinomycetes, inhibits its catalytic activity. Cathepsin-D, like other aspartic proteases such as renin, chymosin, pepsinogen, has a bilobed organization. Crystal structures of native and pepstatin-inhibited forms of mature human cathepsin-D, revealed a high degree of tertiary structural similarity with other members of the aspartic proteinase family (*e.g.* pepsinogen and human immunodeficiency virus protease). The human cathepsin-D gene containing nine exons is located in chromosome 11p15 and expresses a single transcript of 2.2 kb. Cathepsin-D is synthesized as a 52 kDa catalytically-inactive precursor (Fig. 1). During its transport to lysosomes, cathepsin-D can be found in the endosomes where it is present as partially active 48 kDa single-chain intermediate (Fig. 1). This intermediate is subsequently transported to the lysosomes where it is converted into the fully active mature protease that is composed of a 34 kDa heavy and a 14 kDa light chain (Fig. 1). The human cathepsin-D catalytic site includes two critical aspartic residues (amino acids 33 and 231) located on the 34 and 14 kDa chains (Fig. 1a). Mannose-6-phosphate (M6P) receptors are involved in lysosomal routing of cathepsin-D and in the cellular uptake of the secreted pro-cathepsin-D. In ►breast cancer cell lines, over-expressed cathepsin-D is hyper-secreted in the extracellular environment and can be ►endocytosed (Endocytosis) by both ►cancer cells and fibroblasts *via* M6P receptors and other as yet unidentified receptor(s) (Fig. 1b). Endocytosed pro-cathepsin-D also undergoes successive maturations leading to the 48 kDa and 34 + 14 kDa forms. In addition, secreted pro-cathepsin-D, like pepsinogen, is capable of acid-dependent auto-activation *in vitro*, resulting in a catalytically active pseudo-cathepsin-D, an enzyme species that retains 18 residues (27–44) of the pro-segment.

Apoptosis

Cathepsin-D is a key mediator of ►apoptosis induced by many apoptotic agents, such as IFN-gamma, FAS/APO, TNF-alpha, ►oxidative stress, ►adriamycin, etoposide,



Cathepsin-D. Figure 1 Cathepsin-D structure and expression in breast cancer cells. (a) Schematic representation of the human 52 kDa pro-cathepsin-D sequence. Location of 4 kDa cathepsin-D pro-fragment, 14 kDa light and 34 kDa heavy mature chains are indicated. Intermediate 48 kDa form (not shown) corresponds to non-cleaved 14 + 34 kDa chains. Number 1 corresponds to the first amino acid of the mature cathepsin-D. Position of the 2 aspartic acids of the catalytic site is shown. Molecular mass is shown in K (kDa). (b) Expression of Human cathepsin-D in MCF-7 breast cancer cell line. MCF-7 cells were metabolically labeled with [^{35}S]Methionine and human cathepsin-D immunoprecipitated from cell extract (lane 2) and medium (lane 1) was analyzed by SDS-PAGE.

cisplatin and 5-fluorouracil as well as staurosporine. The role of cathepsin-D in apoptosis has been linked to the lysosomal release of mature 34 kDa cathepsin-D into the ►cytosol, leading in turn to the mitochondrial release of cytochrome c into the cytosol and the activation of pro-caspases-9 and -3.

Regulation

Studies on ►estrogen receptor positive breast cancer cell lines revealed that this housekeeping enzyme is highly up-regulated by ►estrogens (Estradiol) and growth factors (*i.e.* IGF1, EGF). In estrogen receptor positive breast cancer cell lines, both estrogens and growth factors stimulate cathepsin-D protein and mRNA accumulation levels. The regulation of cathepsin-D mRNA accumulation by estrogens is mainly due to increased initiation of transcription. Estrogen-responsive elements have been defined in the proximal ►promoter region of the gene, and in conjunction with other regulatory sequences (*e.g.* SP1, AP1), they may be responsible for the stimulation of cathepsin-D gene expression. Studies in estrogen receptor negative breast cancer cell lines that are the more aggressive, invasive and metastatic indicated a constitutive over-expression of cathepsin-D. The mechanism of this over-expression is still unknown but does not seem to involve ►gene amplification or major ►chromosomal rearrangements (►Chromosome translocation).

Cancer

Cathepsin-D over-expressed by cancer cells stimulates tumorigenicity and ►metastasis in nude mice. The direct role of cathepsin-D in cancer metastasis was first demonstrated in rat tumor cells in which transfection-induced cathepsin-D over-expression increased their metastatic potential *in vivo*. In this rat tumor model, the cathepsin-D mechanism responsible for metastasis stimulation seemed to be a positive effect on cell proliferation, favoring the growth of micrometastases. Using an RNA antisense strategy, cathepsin-D was then shown to be a rate limiting factor for the outgrowth, tumorigenicity and lung colonization of MDA-MB-231 breast cancer cells. Several reports have indicated that cathepsin-D stimulates cancer cell proliferation. Purified pro-cathepsin-D from MCF-7 breast cancer cells stimulated MCF-7 cell growth. Moreover, 3Y1-Ad12 rat cancer cells transfected with human cathepsin-D cDNA grew more rapidly both at low or high cell densities *in vitro* and showed an increased experimental metastatic potential *in vivo*. In addition, pro-cathepsin-D was also mitogenic for breast and prostate cancer cells.

Clinical Aspects

Different approaches, such as cytosolic immunoassay, ►immunohistochemistry, *in situ* hybridization, and Northern and Western blot analyses, have indicated that in most breast cancer tumors, cathepsin-D is over-expressed from 2- to 50-fold compared to its concentration in other cell types such as fibroblasts or normal mammary glands. Several independent clinical studies have shown that the cathepsin-D level in primary breast cancer cytosols is an independent prognostic parameter correlated with the incidence of clinical metastasis

and shorter survival times. The major cathepsin-D producing cells appear to be ►epithelial cancer cells ►(Epithelial tumors) and stromal ►macrophages. Cathepsin-D production by fibroblasts appears variable according to various publications. Certain studies have indicated that cathepsin-D production is low relative to cancer cells as shown by immunohistochemistry and *in situ* hybridization with antisense RNA. Other studies have indicated a prognostic role for cathepsin-D over-expression by reactive stromal cells. Pro-cathepsin-D is also increased in the plasma of patients with metastatic breast cancer, indicating that part of the pro-cathepsin-D secreted by tumors can be released into the circulation.

Cathepsins

Definition

Are mainly lysosomal cysteine proteases (human cathepsins B, C, F, H, K, L, O, S, V, X, W), other cathepsins belong to the serine (cathepsin G) and the aspartic (cathepsins D, E) proteases. Cathepsins were long believed to be involved in intracellular protein degradation, recently it has become evident that they are involved in a number of specific cellular processes and that their irregular function is associated with pathological conditions, including cancer. Cathepsins were originally defined as a group of digestive proteases present in lysosomes and involved in lysosomal protein breakdown. From a genetic, biochemical and catalytic point of view, cathepsins constitute an extremely heterogeneous group of proteases. This diversity assures in most tissues complete degradation of ingested proteins. With the identification of select cathepsins in other vesicular compartments of the secretory and endosomal system, however, the definition of cathepsins has evolved to also take into account their capacity to act by limited proteolysis on certain proteins

Caveolins

Klaus Podar, Kenneth C. Anderson
Department of Medical Oncology, Jerome Lipper Multiple Myeloma Center, Dana-Farber Cancer Institute, Boston, MA, USA

Definition

Caveolins are integral membrane proteins responsible for the formation of caveolae, small vesicular invaginations of the plasma cell membrane. They play a key role in membrane trafficking and ►signal transduction.

Characteristics

Caveolae ("little caves") are flask-shaped, "smooth," vesicular invaginations of the plasma membrane

(50–100 nm in diameter) distinct from the larger electron-dense clathrin-coated pits. As a subset of detergent-resistant liquid-ordered lipid rafts, which are clustered protein microdomains within a "sea of homogeneously distributed lipids," they are uniquely enriched in cholesterol, sphingolipids, and phosphatidylethanolamine, and additionally contain essential structural marker proteins termed caveolins. Specifically, caveolins are highly conserved hairpin loop-shaped (both the C-terminus and the N-terminus face the cytoplasmic side of the membrane), oligomeric, integral membrane proteins of 22–24 kDa with a typical short stretch of eight amino acids (FEDVIAEP), the "caveolin signature sequence." Three distinct caveolin genes have been identified: caveolin-1 or VIP-21 (Cav-1), caveolin-2 (Cav-2), and caveolin-3 (Cav-3). Cav-1 exists in two isoforms Cav-1α (containing residues 1–178) and Cav-1β (containing residues 32–178); Cav-2 exists in three isoforms, the full-length Cav-2α, and two truncated variants, Cav-2β and Cav-2γ. Cav-1 and Cav-2, proposed to function as an accessory protein to Cav-1, are co-expressed in most differentiated cells, including adipocytes, endothelial cells, pneumocytes, Schwann cells and fibroblasts; whereas Cav-3 is found specifically in skelatal muscle, the diaphragm, and the heart. Apart from the plasma cell membrane, caveolins are also present in other cellular localizations including endocytic vesicles called caveosomes, mitochondria, the endoplasmatic reticulum (ER), the Golgi/trans-Golgi network (TGN) and secretory vesicles. In addition Cav-1 is secreted by some cells into the extracellular space. Functionally, caveolae and caveolins have been implicated in vesicular transport (transcytosis, pinocytosis, and clathrin-independent ►endocytosis) and cholesterol homeostasis. Moreover, caveolins in general and Cav-1 in particular, interact through the caveolin scaffolding domain (CSD) with a vast variety of proteins thereby sequestering and organizing protein complexes and regulating multiple intracellular signaling pathways. Such molecules include ►Src family tyrosine kinases, ►G protein α subunits, G protein-coupled receptors and ►receptor tyrosine kinases (i.e. receptors for ►epidermal growth factor (EGFR), ►insulin-like growth factor (IGFR), ►placenta-derived growth factor (PDGFR), ►interleukin-6 (IL-6), ►vascular endothelial growth factor (VEGFR)), Ca^{2+} pumps, endothelial ►nitric-oxide synthetase (eNOS), ►integrins, ►Protein Kinase C α, as well as components of the tumor growth factor β (TGFβ/SMAD, ►Wnt/β-catenin/Lef-1 and ►MAP Kinase (e.g. H-Ras, ►Raf kinase, p38) pathway. In addition to the CSD, SH2 domain-containing molecules (i.e. Grb7) interact with Cav-1 *via* the growth-factor/cytokine-triggered phosphorylation of the tyrosine residue 14. Dysregulation of caveolins is associated with the pathogenesis of several human diseases including type II diabetes; Alzheimer's disease; atherosclerosis; muscular dystrophy; and ►cancer.

Clinical Aspects

The ability of Cav-1 to interact with and regulate the activity of proteins involved in cell transformation, growth, invasion, and cytoskeletal rearrangement, renders Cav-1 a key role in tumorigenesis. While initial studies have demonstrated that Cav-1 negatively regulates signaling molecules thereby mediating cell growth inhibition, several recent reports clearly show a positive correlation between high Cav-1 expression, ►tumor grade, ►progression/►metastasis and chemoresistance. One hypothesis for this dual role may be that by Cav-1 downregulation in early tumors stages growth-inhibitory signals pivotal for clonal expansion are avoided, and conversely, by Cav-1 upregulation in progressed ►tumor stages (characterized by increased genomic instability and accumulation of genetic changes) survival benefits are conferred through inhibition of ►apoptosis and acquisition of multidrug resistance (MDR). For example, increased Cav-1 expression has been linked to the progression of tumors including human ►prostate cancer; primary and metastatic human ►breast cancer; progression of ►thyroid cancer; high-grade ►bladder cancer; metastasis of ►lung and ►pancreatic cancer; lymph node metastasis in ►esophageal squamous cell carcinoma; and ►multiple myeloma. Based on these proposed roles of Cav-1 in tumor progression, ongoing studies are now exploring caveolins as novel therapeutic targets in cancer therapies. High levels of Cav-1 expression in vascular endothelial cells additionally provide the rationale for using Cav-1 targeted therapy to inhibit tumor ►angiogenesis. Approaches to target caveolins in general and Cav-1 in particular include the use of Cav-1 antisense and Cav-1 ►siRNA, as well as the use of synthetic CSD, which competitively inhibits protein interactions with Cav-1. Further therapeutic strategies include attempts to inhibit or disrupt caveolae formation using either statins (3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors), which block the production of the cholesterol intermediate mevalonate; or the cholesterol-binding agent methyl-β-cyclodextrin (MβCD). Alternatively, caveolae might be used as a drug and gene delivery transport system to specifically target anticancer therapies to tumor cells thereby reducing required dosages and overall toxicity.

CBP/p300

Definition

Cyclic AMP response element- binding protein (CBP) and its homologue p300 are transcriptional co-activators of various sequence-specific transcription factors that are involved in a wide array of cellular activities, such as DNA repair, cell growth, differentiation and apoptosis. The ability of CBP/p300 to activate transcription resides in its capacity to acetylate the core histone proteins associated with enhanced promoter regions of the genes it activates. This induces conformation changes in chromatin and allows the recruitment of auxiliary proteins to activated promoters. CBP/p300 has the capacity to acetylate and regulate the activity of a variety of transcription factors including p53, NF-B and c-Myc. Acetylation in this context affects both the ability of transcription factors to bind DNA, and also to recruit other binding proteins.

CBP/p300 Coactivators

Andrew S. Turnell
Cancer Research UK Institute for Cancer Studies, The Medical School, The University of Birmingham, Edgbaston, Birmingham, UK

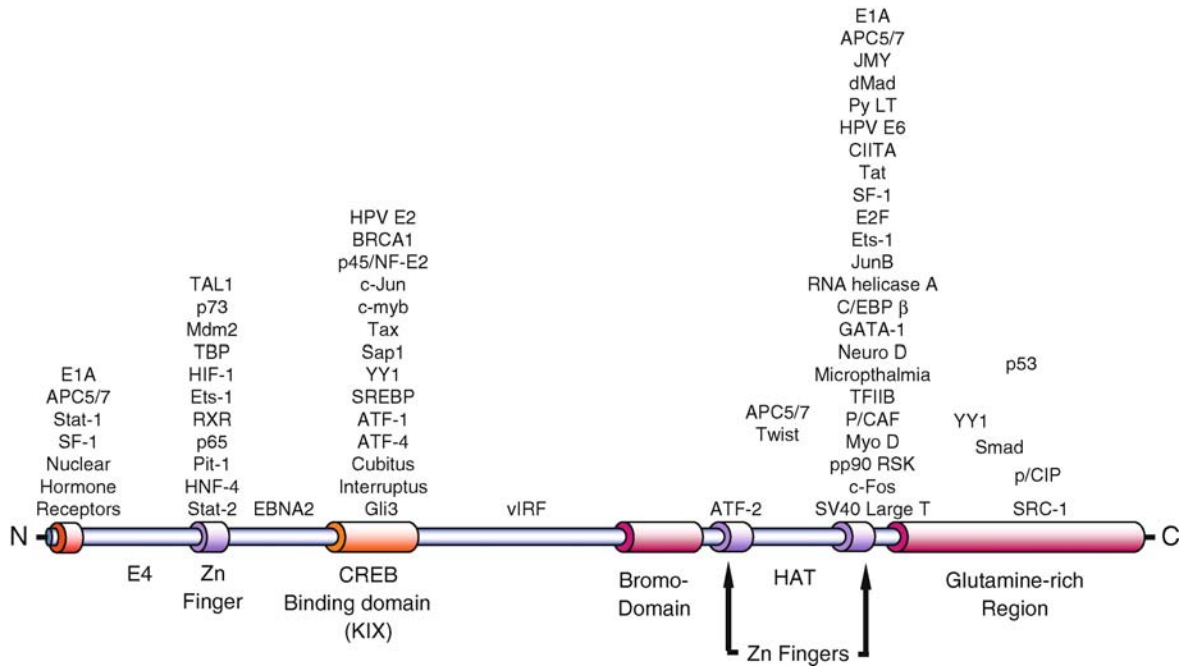
Definition

CBP is an acronym for cAMP-regulated-enhancer (CRE)-binding protein (CREB)-binding protein. p300 is a protein that is highly homologous to CBP, and has been named according to its approximate molecular weight. Coactivators are a group of cellular proteins that enhance transcription factor-dependent transcriptional activation.

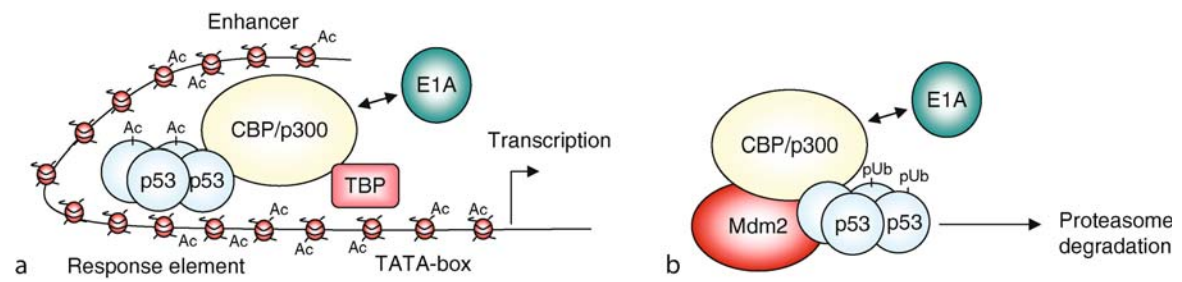
Characteristics

CBP was initially identified as an auxiliary cofactor required for the CREB-mediated activation of cAMP-stimulated gene ►transcription. CBP binds specifically, at CREs, to an activated CREB species which has been suitably modified through phosphorylation by the cAMP-responsive protein kinase, PKA. p300 was subsequently characterized, independently, upon the basis of its interaction with the protein product of the adenoviral transforming *E1A* gene, and like CBP can function as a coactivator in CREB-mediated transcriptional activation. CBP, akin to p300, also binds to E1A. CBP and p300 are highly-related at the amino acid sequence level, sharing approximately 60% identity and both proteins have predicted molecular weights of 265 kDa [1]. Although CBP and p300 bind to a similar set of cellular proteins, share identical enzymic activities (Fig. 1), and overlap functionally in regulating ►cell-cycle and ►differentiation pathways, it is important to note that they also possess distinct biological functions. For example, discrete roles for CBP and p300 during retinoic-acid-induced differentiation, cell-cycle exit and ►apoptosis of embryonal carcinoma F9 cells have been identified. p300, but not CBP, was found to be required for both retinoic-acid induced differentiation, and transcriptional upregulation of the cell-cycle inhibitor $p21^{CIP1/WAF1}$. In contrast, CBP, but not p300, was required for transcriptional induction of $p27^{KIP1}$. Interestingly, both CBP and p300 were required for retinoic acid induced apoptosis.

CBP and p300 function primarily as transcriptional coactivators for many sequence-specific transcription factors. In this capacity both CBP and p300 function as lysine (K)-directed ►acetyltransferases [ATs; (Fig. 2a)]. They modify ►chromatin structure and function through acetylation of the core histones H2A, H2B, H3 and H4 at numerous sites within their N-terminal tail regions. Specific p300-directed acetylation sites within



CBP/p300 Coactivators. Figure 1 Schematic depiction of CBP/p300 primary sequence displaying conserved domains. The diagram shows the binding sites for a number of proteins including the APC/C subunits APC5 and APC7, p53 as well as the adenoviral E1A protein: E4, ubiquitin E4 ligase activity; HAT, histone-directed AT activity.



CBP/p300 Coactivators. Figure 2 Role of CBP and p300 in acetylation and ubiquitylation. (a) CBP and p300 bind to enhancer and promoter regions and promote the acetylation of the core histones in order to promote the recruitment of transcription factors and auxiliary factors to sites of transcription. Acetylation of the transcription factor p53, promotes its binding to p53-response elements, Ac: acetylation (b) CBP and p300 accelerate Mdm2-mediated polyubiquitylation (pUb) of p53 promoting its degradation by the proteasome. The adenoviral E1A protein binds to CBP/p300 to regulate both acetylation and ubiquitylation activities.

►nucleosome-associated histones have been identified. p300 acetylates H2A upon K5, H2B upon K5, K12, K15 and K20, H3 upon K14 and K18, and H4 upon K5, K8 and K12. Histone acetylation by CBP and p300 facilitates further epigenetic histone modifications and the recruitment of other proteins involved in transcriptional activation to promoter/enhancer regions, potentially through reducing the affinity of histone tails for DNA. Interestingly, p300 AT activity itself is enhanced by auto-acetylation of critical lysine residues in an activation loop motif found within its AT domain. Specifically, auto-acetylation of critical residues K1499, K1549, K1554, K1558, and K1560 enhances AT activity.

CBP and p300 also enhance transcription through their ability to interact with, and acetylate non-histone proteins and regulate their cellular activities. Indeed, CBP and p300 acetylate a variety of transcription factors directly, including ►p53, E2F-1, NF-κB and c-Myc. For example, p300 has been shown to enhance p53 transcriptional activity by promoting p53 sequence-specific binding to DNA through the acetylation of multiple residues in p53's C-terminal region.

Lysine residues K370, K372, K373, K381 and K382 have all been found to be substrates for p300-directed acetylation *in vitro*. Consistent with these observations K373 is acetylated *in vivo* in circumstances when p53 transcriptional activity is stimulated by UV- and ionizing-radiation. Interestingly, Mdm2 the ►E3 ubiquitin ligase that targets p53 for degradation, inhibits p300-mediated acetylation of p53. CBP and p300 can also function as transactivators independently of AT activity. Thus CBP and p300 mutants that lack the AT domain can still stimulate transcription. CBP and p300 function in this regard through specific binding to transcription factors such as nuclear receptors, or p53. p300 also possesses an N-terminal ►E4 ubiquitin ligase domain. It has been shown that this domain catalytically enhances the Mdm2-directed poly-ubiquitylation of p53, promoting degradation (Fig. 2b). E1A inhibits p300 function in this regard.

A role for CBP and p300 in cell-cycle and cellular ►transformation was first established during early studies with E1A. E1A mutants incapable of binding to CBP and p300 were found to be defective in their ability to promote S-phase and initiate DNA synthesis in Baby Rat Kidney (BRK) cells; E1A was also shown to induce S-phase by a redundant pathway through its interaction with the protein product of the *Retinoblastoma* gene, pRb. Interestingly, E1A's capacity to induce mitosis in BRKs requires its interaction with both pRb and CBP/p300. Moreover, the ability of E1A to transform primary rodent cells in tissue culture was found to be wholly-dependent upon its interaction with CBP and p300, suggesting that both CBP and p300 might function as ►tumor suppressors. *In vitro* models suggest that E1A inhibits CBP/p300-directed AT activity and represses CBP/p300-dependent transcription programmes. Alternatively, E1A could utilize CBP/p300 acetyltransferases during ►tumorigenesis to promote an altered programme of gene expression. A role for the E3 ubiquitin ligase, the ►APC/C, in CBP/p300 function has recently been determined. E1A and APC/C subunits APC5 and APC7 share evolutionarily conserved CBP/p300-binding domains within their primary sequence. Studies have suggested that E1A de-regulates CBP/p300 during tumorigenesis by disrupting CBP/p300-APC/C cell cycle function. Interestingly, E1A residue K239 is acetylated by CBP/p300 *in vivo* and E1A associates with CBP/p300 AT activity from adenovirus infected and transformed cells. Acetylation of E1A has been proposed to affect its interaction with the corepressor CtBP, and alter its nuclear localization by disrupting E1A association with importin-α. Whether acetylation of E1A is required for transformation with either Ras or E1B is not known. The requirement for the CBP/p300 E4 ligase in E1A-mediated transformation is similarly not known.

There is increasing evidence to suggest that CBP and p300 might be functionally de-regulated in ►cancer. In support of this notion, studies have indicated that both CBP and p300 genes are functionally de-regulated in ►acute myeloid leukemia (AML). Specifically, chromosomal translocations occur during AML tumorigenesis where a significant portion of the gene encoding the monocytic leukemia zinc-finger AT (MOZ) fuses with a large part of the CBP or p300 gene to form MOZ-CBP or MOZ-p300 chimeras. It is proposed that these chimeric proteins possess aberrant AT activity which is important in promoting tumorigenesis. Chromosomal rearrangements are more common for CBP than p300 in this regard. Mixed lineage leukemia (MLL), MLL-CBP and MLL-p300 translocations have also been described. Studies have also indicated that somatic mutations in one p300 allele, accompanied by ►loss of heterozygosity (LOH) of the second wild-type allele also occur in isolated cases of human colorectal and breast tumors. Similarly, biallelic somatic inactivation of CBP has been observed in ovarian tumors, esophageal squamous cell carcinomas and some lung cancers, suggesting that both CBP and p300 might function as classical tumor suppressors in epithelial cancers.

In support of these findings, germ-line monoallelic inactivation of CBP is the genetic basis for Rubinstein Taybi Syndrome (RTS), a disease characterized by pleiotropic developmental abnormalities and an increased incidence of malignancies, usually childhood tumors of neural crest origin. Whether these tumors are characterized by LOH is however, not known. Interestingly, mice displaying monoallelic inactivation of CBP also display characteristics of RTS, whilst mice engineered heterozygous for CBP display hematological developmental abnormalities, and with increased age develop a number of hematological malignancies, that in some instances are characterized by LOH. Germ-line monoallelic mutations in p300 also result in RTS. It is not known at present however, whether these RTS patients also have an increased risk of developing tumors. However, mice heterozygous for p300 do not develop malignancies at a higher frequency. The ability of CBP and/or p300 to function as ►tumor suppressor genes may reside in their capacity to directly interact with tumor suppressor gene products and ►oncogene products, or through regulating, indirectly, multiple signaling pathways that coordinate cell cycle progression and/or differentiation programmes.

Synonyms

CTCF

Definition

CTCF (acronym for a "CCCTC-binding factor") is a highly conserved and ubiquitous protein with multiple functions, which include regulation of transcription, chromatin insulation and genomic imprinting.

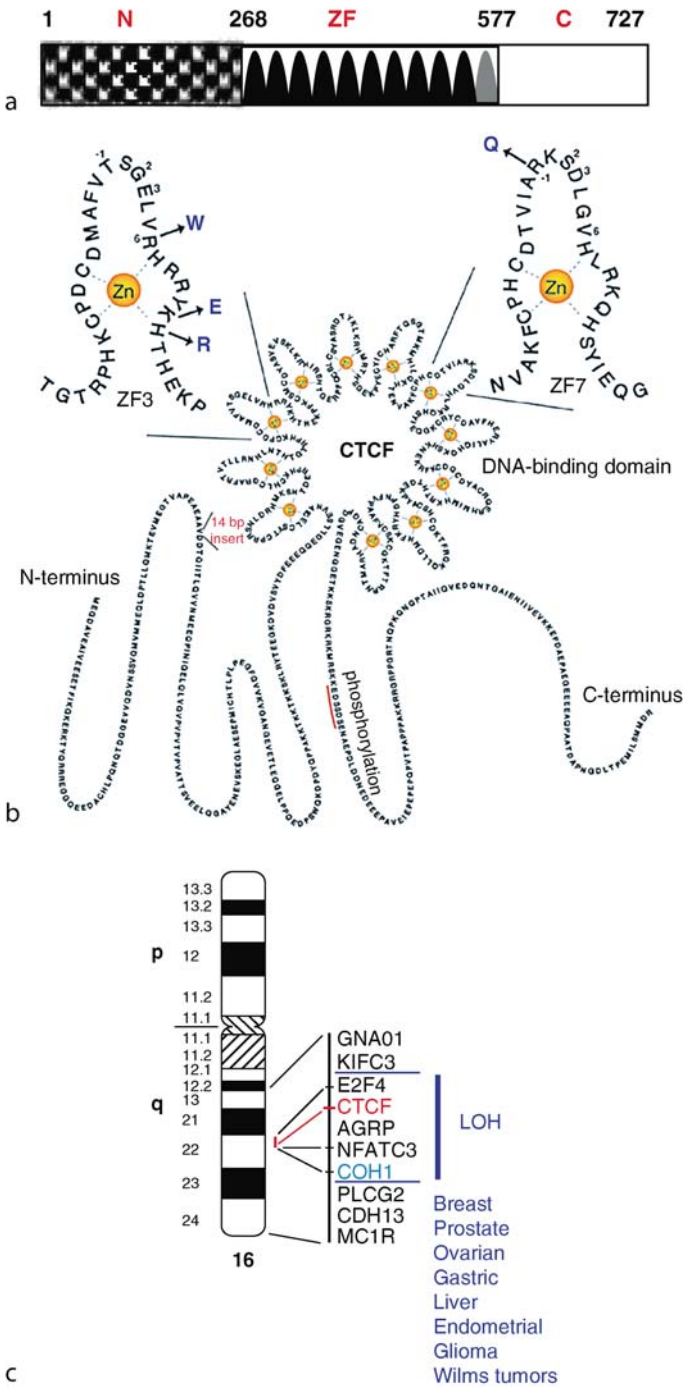
Characteristics

The CTCF protein was originally identified for its ability to bind to a promoter element of the chicken c-myc gene. The sequence recognized by CTCF contained the CCCTC repeats and therefore the protein was defined as CTCF (the CCCTC binding factor). However it was later discovered that other CTCF target sequences (or CTSs) were remarkably dissimilar, and the term "multivalent transcription factor" was coined for CTCF. Another unusual feature of the CTSs is their length: the analysis of binding patterns of CTCF to multiple sites demonstrated that CTCF requires about 50–60-bp-long sequence to form a complex with DNA.

The ability of CTCF to bind such diverse targets has been attributed to its DNA binding domain, which is composed of eleven Zinc Fingers (ZFs), ten of them of the C_2H_2 class and one ZF of C_2HC-class (Fig. 1a and b). According to this model, the combinatorial utilization of different ZFs results in binding to diverse DNA targets. In addition, CTCF-DNA complex formation can be regulated by DNA ►methylation, if symmetrically methylated CpG dinucleotides present on both DNA-strands within any given CTS coincide with the DNA-bases required for the CTS recognition by a particular subset of CTCF fingers. Not all CTCF-target sequences contain CpG bp that can be modified by methylation, nevertheless the capability of CTCF to distinguish differentially methylated DNA targets is one of the major features of CTCF with a broad spectrum of functional implications.

The CTSs have been identified in many genomic elements. It is estimated there may be well over 30,000 of CTSs in the human genome, with ~14,000 localized in potential insulators. Many of these sites are methylation sensitive and map to promoter, intergenic and intragenic regions, and both exons and introns. Examples of CTCF-target promoters include 5′-non-coding regions of the c-*Myc* oncogene, chicken lysozyme, *IRAK2*, ►*BRCA1*, the amyloid precursor protein (*APP*), the exon regions of *hTERT* and the intron regions of the serotonin transporter gene, *SLC6A4*. Other CTCF-driven regulatory elements include vertebrate enhancer-blocking elements (insulators), classic examples of which are chicken *β*-globin insulators that flank *β*-lobin gene cluster. Such intergenic insulators seem to have a consensus binding motif for CTCF. CTCF sites are universally present in all mammalian differentially methylated domains/regions (DMD/DMR) or imprinting control regions (ICR), as exemplified by CTSs in ICRs of such imprinted gene-clusters as *IGF2/H19*, *Rasgfr*, *KvDMR* and other loci, deregulation of which through aberrant (biallelic) CTS-methylation or CTS-demethylation contributes to cancer.

CTCF has now been cloned from various organisms which include insects, fish, amphibians, birds, rodents, and primates. The comparison between the proteins



CCCTC-Binding Factor. Figure 1 (a) Schematic drawing of the CTCF protein. The three domains of CTCF are depicted as follows: N – N terminal domain (Patterned box); ZF – ZF domain (box with half ovals designating 11 Zinc Fingers; the black half ovals refer to the C_2H_2 class and the grey half oval refers to the C_2HC-class); C – C-terminal domain (open box). The amino acid numbers for the start and the end of each domain are indicated above the diagram. (b) The cartoon illustration of the wild-type human CTCF protein represents the N-terminal and C-terminal domains of CTCF and the DNA binding domain of CTCF composed of 10 ZF of C_2H_2-class and one ZF of C_2HC-class. (c) The locations of the tumor specific mutations in the CTCF protein are shown. The mutations CTCFHR, KE, RW are located in ZF3 and the mutation CTCFRQ is located in ZF7. The position of the 14 bp insertion is indicated.

revealed a high degree of homology between the CTCF from different organisms, especially in the ZF DNA binding domain. Thus this domain is 100% identical at the protein level among mouse, man and chicken, whereas the full-length protein is 93% identical in those three species; the *Drosophila* CTCF protein has a 46% identity within the zinc-finger regions and 27% overall identity.

Typically for a transcriptional factor, CTCF is localized to the nucleus. It is ubiquitously expressed in various tissues and cells, in different organisms. Such conservation in the protein composition and also wide representation in cells/tissues signifies the important and general cellular functions mediated by CTCF.

The size of the CTCF protein varies depending on the organism. For example, the human CTCF protein is composed of 727 amino acids, chicken CTCF of 728 and *Drosophila* CTCF of 818 amino acids. The structure of the human CTCF is shown in Fig. 1 (panels a and b). The ZF-DNA binding domain is positioned in the centre of CTCF and accounts for about one third of the protein's size.

The N-terminal domain of human CTCF is composed of 268 amino acids and is rich in proline residues. The C-terminal domain is the smallest part of the molecule (150 amino acids) and is highly negatively charged. These CTCF domains play an important role in the modulation of CTCF functions in the regulation of transcription. In some cases this regulation relies on post-translational modifications. For example, the C-terminal domain contains the sites of phosphorylation by the protein kinase CK2 (former casein kinase II), whereas the N-terminal domain contains the sites for ►poly(ADP-ribosyl)ation by the PARP-1 (poly(ADP-ribose) polymerase-1).

The post-translational modifications and interactions with protein partners have been demonstrated to modulate important functions of CTCF. For example, specific phosphorylation of CTCF by CK2 affects the CTCF functions in transcriptional regulation. Poly (ADP-ribosyl)ation was found to be important for insulator function of CTCF and CTCF-dependant nucleolar transcription. Post-translational modifications of CTCF have also been implicated in human myeloid cell differentiation.

Regulation of CTCF-dependent molecular processes also involves CTCF associations with other proteins. Thus, CTCF interactions with sin3 and YB-1 are shown to modulate CTCF function as a transcriptional repressor. Cooperation of CTCF with nucleophosmin, Kaiso and helicase protein CHD8 has been linked to the control of insulator function of CTCF and epigenetic regulation. Interaction of CTCF with another transcription factor, YY-1, is required to control the X chromosome inactivation and cooperation of CTCF with RNA Polymerase II may be important for regulation of transcription.

A testis-specific paralogue of CTCF has been reported. This protein was termed ►*BORIS* (the acronym for Brother of the Regulator of Imprinted Sites). BORIS possesses the eleven ZF domain homologous to that of CTCF; the flanking N-and C-terminal domain, on the other hand, are dissimilar. These structural features indicate that BORIS could recognize the same set of DNA targets as CTCF, while different flanking domains could be important for regulation of BORIS-specific functions.

CTCF Functions

The diverse nature of the CTSs harmonizes with the multitude of CTCF functions. They include gene activation, repression and silencing; CTCF is also involved in the control of insulator function and ►imprinting. All vertebrate enhancer-blocking elements tested so far contain CTCF binding sites. The importance of the insulator function of CTCF was further demonstrated in the regulation of CTG/CAG repeats in the *DM1* locus and in the X-chromosome inactivation. It is now generally accepted that the molecular basis for the insulator function of CTCF lies in the ability of CTCF to influence chromatin architecture by mediating long-range chromatin looping and modification of histones. Such alterations then settle the balance between active and repressive chromatin.

CTCF binding to many of its targets can be regulated by DNA methylation; the ability of CTCF to read such epigenetic marks contributes significantly to the versatility of CTCF functions. Several findings support the concept of CTCF being a ►tumor suppressor gene (TSG). Firstly, CTCF suppresses cell growth and proliferation, and, further, in some cell systems (for example, myeloid cells) induces cell differentiation. Secondly, the CTCF gene maps within the smallest region of overlap for loss of heterozygosity (LOH) that has been observed at chromosome 16q22.1 in breast, prostate, and Wilms tumors (Fig. 1c). Finally, functionally significant, tumor-specific CTCF mutations in the ZF domain of CTCF were identified in various sporadic cancers including breast, prostate and Wilm's tumors in the remaining allele (Fig. 1b). All four reported tumor specific point mutations in the CTCF Zn finger domain result in a missense codon at a position predicted to be critical for ZF formation or DNA base recognition. Another reported tumor-specific mutation constituted of a 14 bp insertion in the N-terminal domain of CTCF (Fig. 1b). In familial non-*BRCA1*►*/BRCA2* breast cancers, two sequence variants, G240A in the 5′ untranslated region and C1455T (S388S) in exon 4, were also identified.

The CTCF function as a negative regulator of cell growth has been well documented on various cellular models. Thus, over-expression of CTCF leads to inhibition of cell growth and proliferation. Normal embryonic rat cells, made haploinsufficient for CTCF by the retroviral insertion into the intron upstream of the first coding exon, manifest all major features of cancerous transformation in vitro. The mechanism of this function of CTCF, at least in part, lies in the ability of CTCF to control genes responsible for regulation of cell growth and proliferation, negatively ►oncogenes and positively TSG. Examples of such CTCF-target genes include oncogenes ►*MYC*, *PIM-1, PLK, E2F1, TERT, IGF2* and TSGs ►*p19ARF(p16/INK4a)*, BRCA1, ►p53, ►p21, and ►*p27*. Based on these findings, CTCF emerges as a key versatile element linking genetics, epigenetics, development, and disease.

The ability of CTCF to interact with the repeated sequences and read epigenetic marks (DNA methylation) may provide a causal link not only to some forms of neoplasia, but also to degenerative and neurological conditions. Epigenetic disturbances in these diseases are frequently associated with the instability of repeats, which is considered to be the hallmark of this pathology.

Clinical Aspects

A link between CTCF and the disease development has been generally recognized. Various genetic and epigenetic mechanisms that result in CTCF malfunction can lead to pathogenesis.

The tumor specific mutations in CTCF can dramatically change the normal biological functions of the wild type CTCF protein. The sets of the genomic targets of the mutant CTCF variants may alter due to the loss of binding to the usual CTCF targets and/or binding of the mutants to the new targets, especially if the wild type allele is lost. Each ZF mutation abrogate CTCF binding to a subset of target sites within the promoters and/or insulators of certain genes involved in regulating cell proliferation, but do not alter binding to the regulatory sequences of other genes. These observations suggest that CTCF may represent a novel tumor suppressor gene that displays tumor-specific "change of function" rather than complete "loss of function."

The 14 bp insertion in the N-terminal domain, on the other hand, most likely leads to the loss of function of CTCF as it creates a premature stop codon, thus generating a truncated CTCF protein. The significance of the sequence variants in the familial breast cancers, however, is not yet clear.

The genetic alterations in CTCF are rare events therefore considerable efforts are being currently made to identify epigenetic mechanisms responsible for inactivation of CTCF. The rationale behind these studies is that the binding of CTCF to its DNA targets is methylation sensitive, with the current view that the bound CTCF can protect the CpG islands of DNA against methylation. Indeed, it has been reported that de-repression of the maternal *IGF2* allele is linked to abnormal methylation of the CTCF target sites within the *ICR H19* in a wide range of cancer types (breast, prostate, colorectal, Wilm's tumor). This has been explained by the inability of CTCF to bind to the methylated *ICR H19*, and therefore its failure to establish the chromatin insulator function on the maternal allele thus leading to activation of *IGF2*.

There is a growing body of evidence to suggest that even mutations of a single CTCF site leads to dramatic biological consequences. For instance, mutations of the CTCF site in the Xist promoter that alter CTCF binding result in the skewed X chromosome inactivation in affected families. Furthermore, deletions of CTCF sites in human *ICR H19* lead to predisposition to Wilm's tumors in families with Beckwith-Wiedemann Syndrome (BWS). Finally, a mutation of the single CTCF site in the homologous *ICR H19* predisposes the mice carrying such a mutation to colorectal cancer.

Epigenetic inactivation of a number of cancer genes due to aberrant methylation of the CpG islands within their promoters has also been established. Interestingly, many of these genes are regulated by CTCF. As in the case with the *ICR H19*, CTCF may be necessary to protect the promoters of the TSGs from unwanted DNA methylation. According to another, yet to be proven model, CTCF may demarcate the boundary between methylated and unmethylated genomic domains, as may be the case for the BRCA1 promoter.

The utility of CTCF as a cancer ►biomarker is yet to be established, although there are indications that CTCF may be an interesting target for therapy in breast tumors where levels of CTCF were found elevated compared with breast cell lines with finite life span and normal breast tissues. Such up-regulation of CTCF in breast cancer cells has been linked to resistance of these cells to apoptosis. The results of the experiments in breast cancer cell lines point to a possible link between CTCF expression and sensitivity to apoptosis; that is, higher levels of CTCF may be necessary to protect the more sensitive cancer cells from apoptotic stimuli. These findings may be relevant to the potential use of CTCF as a therapeutic target in breast cancers: reducing the levels of CTCF would then result in apoptotic cell death of cancer cells hopefully without affecting normal breast tissue; the effect of CTCF down-regulation may be more dramatic in high grade breast tumors. On the other hand, elevated levels of CTCF in breast tumors may correlate with several clinical and/or pathological parameters, which make CTCF a potential

prognostic marker. More research is needed to clarify the full potential of CTCF as a clinical target and a cancer biomarker.

►Temsirolimus

CCL5/RANTES

Definition

CCL5 (chemokine (C-C motif) ligand 5)/RANTES (regulated upon activation, normal T-cell expressed, and secreted) is a small cytokine belonging to the CC ►chemokine family, binds and activates CCR5, and is chemotactic for T cells, eosinophils and basophils.

►Langerhans Cell Histiocytosis

CCL20/MIP-3α

Definition

CCL20 (chemokine (C-C motif) ligand 20)/MIP-3α (macrophage inflammatory proteins-3α) is a small cytokine belonging to the CC ►chemokine family, binds and activates CCR6, and is strongly chemotactic for lymphocytes.

►Langerhans Cell Histiocytosis

CCND1

Definition

Synonyms PRAD1; Is an oncogene localized to chromosomal band 11q13. This gene encodes the protein Cyclin D1 that functions as a cell cycle regulator. Amplification of CCND1 has recently been reported in several human tumors, including breast and head neck carcinomas.

►Cyclic D

CCR4

Definition

Chemokine (C–C motif) receptor 4; chemokine receptor, expressed selectively on Th2 lymphocytes and its ligand thymus and activation-regulated ►chemokine (►TARC).

CCR6

Definition

CCR6 is ►chemokine receptor for CCL20, and is expressed on unactivated memory T-cells and immature ►dendritic cells.

►Langerhans Cell Histiocytosis

CCRG-81045

►Temozolomide

CCV

Definition
Clatherincoated vesicles.

►Cyclin G-Associated Kinase

CD1a

Definition
Is expressed on the surface of Langerhans cells. It is related to class I MHC molecules and involved in the presentation of lipid antigens to CD1-specific T cells.

►Langerhans Cell Histiocytosis
►CD Antigens

CD2AP

Definition
CD2 associated protein is an adaptor protein that couples endocytic proteins to the actin cytoskeleton.

►Cortactin
►CD Antigens

CD3 Complex

Definition
Is the complex of α:β or γ:δ T-cell receptor chains with the invariant subunits CD3γ, δ, and ε, and the dimeric ζ chains.

►Sjögren Syndrome
►CD Antigens

CD4

Definition
CD4, the cell-surface protein, is important for recognition by the T-cell receptor of antigenic peptides bound to ►MHC class II molecules. It acts as a coreceptor by binding to the lateral face of the MHC class II molecules.

►Sjögren Syndrome
►CD Antigens

$CD4^+$T-Cells

Definition
$CD4^+$ helper T-cells are a sub-group of lymphocytes that plays an important role in establishing and maximizing the capabilities of the immune system. These cells are unusual in that they have no cytotoxic or phagocytic activity; they cannot kill cancer cells. $CD4^+$ helper T-cells are involved in activating and directing anti-tumor immune responses. They are essential in activation and growth of cytotoxic T cells, and in maximizing anti-tumor humoral immune responses.

►DNA Vaccination
►CD Antigens

CD5 B Cells

Definition
Are a class of atypical, self-renewing B cells found mainly in the peritoneal and pleural cavities in adults. They have a far less diverse receptor repertoire than conventional B cells, and since they are the first B cells to be produced they are also known as B-1 cells.

►Sjögren Syndrome
►CD Antigens

CD8

Definition
A the cell-surface protein, is important for recognition by the T-cell receptor of antigenic peptides bound to ►MHC class I molecules. It acts as a coreceptor by binding to the lateral face of MHC class I molecules.

►Sjögren Syndrome

CD8+ Cytotoxic T-Cells

Definition

Synonym TC, CTL, T-Killer cell or killer T cell; belong to a sub-group of T-cells capable of inducing the death of cancer cells. Most cytotoxic T cells express T-cell receptors (TcRs) that can recognize a specific antigenic peptide bound to Class I major histocompatibility complex (MHC) molecules. The binding of CD8 to the MHC molecule keeps the $CD8^+$ cytotoxic T-cells and the target cell bound closely together. Cell death is induced by the release of perforin and granzyme as well as by expression of FAS ligand which induces ►apoptosis of the cancer cell.

►DNA Vaccination

CD8 T Cells

Definition

CD8 T cells are T cells that carry the coreceptor ►CD8. They recognize antigens, for example, viral antigens, that are synthesized in the cytoplasm of a cell. Peptides derived from these antigens are transported by TAP, assembled with ►MHC class I molecules in the endoplasmic reticulum, and displayed as peptides: MHC class I complexes on the cell surface. CD8 T cells differentiate into cytotoxic CD8 T cells.

►Sjögren Syndrome

CD14

Definition

Is a membrane-associated glycosylphosphatidylinositol-linked protein expressed at the surface of cells, especially ►macrophages. CD14 acts as a co-receptor (along with the Toll-like receptor TLR 4) in the cellular response to bacterial endotoxins.

►Kupffer Cells
►CD Antigens

CD15

Definition

Carbohydrate antigen called the X hapten, found in several glycolipids and glycoproteins. The antigen is present on normal myeloid cells and a wide variety of epithelial cells, as well as their corresponding tumors.

►Hodgkin Disease, Clinical Oncology
►CD Antigens

CD20

Definition

Is a non-phosphorylated glycoprotein expressed on all mature B cells and in less density on pre-B cells. CD20 functions as regulator of transmembrane Ca^{2+} -conductance and is thought to play a role in B cell-activation and -proliferation.

►Monoclonal Antibody Therapy
►CD Antigens
►Hodgkin Disease, Clinical Oncology

►CD26/DPPIV in Cancer Progression and Spread

CD26/DPPIV in Cancer Progression and Spread

Jonathan Blay
Department of Pharmacology, Dalhousie University, Halifax, NS, Canada

Synonyms

CD26; Dipeptidyl peptidase IV; DPPIV; ADAbp; ADA-CP

Definition

CD26/DPPIV is a multifunctional protein in the outer membrane of normal and cancer cells, that can (i) remove an amino-terminal dipeptide from many regulatory peptides, terminating their activity, (ii) bind the enzyme adenosine deaminase (ADA) from the extracellular fluid, and (iii) associate directly with proteins of the ►extracellular matrix. Levels of CD26/DPPIV are variable but typically decline as cancer develops, and this has been linked to disease progression and the shift to metastasis.

Characteristics

CD26/DPPIV is a molecule that has been known in different forms since the 1960s, but whose key role in cancer has only been appreciated since the early 1990s when it was shown that the absence or presence of CD26/DPPIV in ►melanocytes determined whether or not those cells showed behavior that was characteristic of a cancer (►melanoma). Our understanding of CD26/DPPIV has an interesting history, as it reflects the collective findings of four different areas of research – in fact directly reflecting the multifunctional nature of the protein itself. The different aspects of the function of this molecule are illustrated in Fig. 1.

Some of the earliest data on this molecule were obtained in studies of the major binding protein for the enzyme adenosine deaminase (ADA) in gastrointestinal epithelia. When ADA was isolated from tissue it was found to exist in both high-molecular-weight and low-molecular-weight forms. The high-molecular-weight form was found to be a complex of ADA itself with a larger, 110-kilodalton protein, subsequently referred to as ADA-complexing protein (ADA-CP) or ADA-binding protein (ADAbp). This anchoring protein for ADA was later shown to be identical to CD26/DPPIV, the extracellular part of which has a region that acts to bind ADA from outside of the cell.

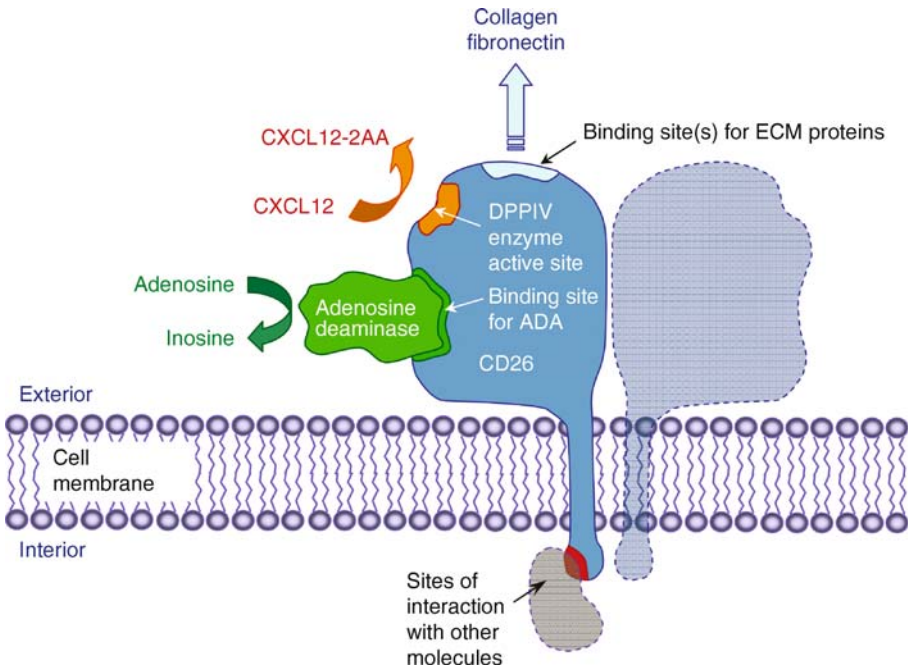
Some of the major substrates for this activity are listed in Table 1. Early studies on CD26/DPPIV also addressed its enzyme activity. The dipeptidyl peptidase IV (DPPIV) activity is an intrinsic part of the molecule itself, and was initially studied mostly at a biochemical level. This very selective form of enzyme activity removes just two amino acids from the N- (amino-) terminus of a peptide, which is why is called a dipeptidase. The characteristic activity of DPPIV requires that the penultimate N-terminal amino acid has a particular identity; usually ►proline and less commonly ►alanine. This is a part of the peptide that often has effects on its stability within the body – the existence of a proline in that position typically confers greater stability. So the removal of this dipeptide by DPPIV is a means of regulating the persistence and bioactivity of important regulatory peptides.

The relative susceptibilities to cleavage of the substrates are given on an arbitrary scale based upon their specificity constants (k_{cat}/K_m). A high number indicates that the peptide is a good substrate for the dipeptidyl peptidase-IV activity of CD26/DPPIV.

The third area of research that led to our present knowledge of CD26/DPPIV involved the way in which lymphocytes become activated. Lymphocytes normally reside in the body within particular tissue structures – specialized structures called lymph nodes or at specific sites within the gut mucosa, for example – in numbers that are necessary to be able to respond to almost all of the threats that may be encountered. In the event of such a challenge, however, the cells that are most able to deal with the threat are mobilized, divide so as to make a larger population of specialized defenders, and become armed to respond in the appropriate way. As these cells become activated, various important proteins are produced at the cell surface. These "activation proteins" are given "CD" numbers as unique identifiers ("CD" refers to "cluster of differentiation" markers, or antigens). The differentiation antigen designated CD26 has proven to be identical to the molecules ADAbp and DPPIV.

The last of the roles for CD26/DPPIV follows from its ability to bind to extracellular matrix molecules, primarily ►collagen and ►fibronectin. These are embedded within the molecular scaffold that surrounds all cells and which provides particular cues for cellular behavior in three dimensions. For the CD26/DPPIV that is present on cancer cells, this opens up the possibility that it may act as an additional anchor to tether cells to the extracellular matrix, along with dedicated cell adhesion molecules such as the ►integrins. The reverse situation may also be important during the process of metastasis. It has been shown that the CD26/DPPIV that is present at the surface of endothelial cells lining blood vessels can interact with a form of fibronectin that is deposited on the surface of cancer cells. This may cause arrest of circulating cancer cells that have become detached from the main tumor, and help to seed the cancer at secondary sites like the lung.

The same molecule therefore has four different functions, and has four different names that have been used



CD26/DPPIV in Cancer Progression and Spread. Figure 1 The different domains and functions of CD26/DPPIV. The CD26 protein is anchored in the plasma membrane of the cell, with the bulk of its molecular structure on the outer face. The enzyme domain that underlies its dipeptidyl peptidase-IV activity, removing pairs of amino acids (AA) from substrates such as the chemokine CXCL12, comprises one of three functional sites in contact with the external environment. A separate domain acts as the major cellular binding site for another enzyme, adenosine deaminase (ADA), which is present in the extracellular fluid. There are also at least two potential sites for the binding of the extracellular matrix proteins collagen and fibronectin. CD26/DPPIV usually exists as a dimer; the second molecule is shown in outline. The intracellular portion of CD26/DPPIV is small and no functional domains have been identified. CD26/DPPIV must signal intracellularly by coupling with other cellular components.

CD26/DPPIV in Cancer Progression and Spread. Table 1 Some of the major substrates for the dipeptidyl peptidase-IV activity of CD26/DPPIV

Molecule	Full name and main function(s) in normal tissues	DPPIV sensitivity (k_{cat}/K_m)
CXCL12	SDF-1α (stromal cell-derived factor-1α): Involved in development of the nervous system, bone marrow and intestine, and in the homing of stem cells.	100
CCL22	Macrophage-derived chemokine: Is an attractant for various types of white cells and functions in immune and inflammatory responses	80
GRP	Gastrin releasing peptide: Released by nerves in the stomach to cause the production of gastrin from G cells in the mucosa.	40
NPY	Neuropeptide Y: Peptide neurotransmitter found in the brain that has a role in regulating normal physiological processes.	20
GLP-1	Glucagon-like peptide-1: Gut hormone secreted by L cells in the intestine, has a role in control of insulin levels.	4
CCL11	The chemokine eotaxin-1: Causes the recruitment of eosinophils into tissues and plays a role in allergic responses.	1.6
CCL5	The chemokine RANTES ("Regulated on Activation, Normal T Expressed and Secreted"): Selective attractant for memory T lymphocytes and monocytes.	0.8
VIP	Vasoactive intestinal peptide: Peptide hormone produced by various tissues, with effects on blood vessels and secretory processes.	0.2

over the years with greater or lesser frequencies. The designation CD26 is probably the most neutral, because although CD proteins have been studied primarily in white cells, they also exist in other tissues, and the nomenclature has no link to function. The abbreviation "DPPIV" refers to its enzyme activity and – given the other activities this talented component incorporates, is not a valid name for the overall molecule. However, as so as much research on this protein has focused upon its enzymatic role, and this facet of its action is of significance in certain diseases such as cancer and diabetes, the term "CD26/DPPIV" serves as a compromise.

CD26/DPPIV is found at the surface of the cells that form the functional barrier (epithelium) in most of the major sites that give rise to cancer in adults (e.g. intestine, lung, breast and prostate). The levels detected in cancer (the "expression") vary from those of the corresponding normal tissue, but the pattern is not consistent across all cancers and within a single cancer type there may be variable findings. So, for example, while the prevailing change in adult solid cancers (lung and prostate cancer, for example) is for CD26/DPPIV to decline, in certain less common cancers such as those of the thyroid and kidney, CD26/DPPIV levels actually increase. This suggests that the absence or presence of CD26/DPPIV does not universally favor or disfavor cancer progression, but that its role depends very much on the tissue type – meaning that changes in CD26/DPPIV as a tissue becomes cancerous will depend very much on its normal role. Additionally, in some cancers (such as colorectal cancer) the expression of CD26/DPPIV is very variable, not just between different tumors but in different regions of the same cancer. This points to a likelihood that CD26/DPPIV levels can be regulated by factors that are generated within the developing cancer tissue.

The ability of CD26/DPPIV to bind the enzyme ADA seems to be part of a fundamental mechanism whereby cells can resist the actions of the purine nucleoside adenosine in certain disease situations. This helps them to resist a threat to their survival by high concentrations of adenosine, or the risk of responding excessively to adenosine when it persists in the environment for an extended period. High concentrations of adenosine can occur persistently in the disorganized environment of a solid cancer (►Adenosine and tumor microenvironment). By retaining ADA close to the cell surface, the cell has a greater chance of scavenging adenosine near to the cell and preventing excessive action through adenosine receptors that are embedded in the cell membrane.

This dynamic situation involving extracellular adenosine production (from ATP breakdown and through cellular export) and breakdown (ADA bound to CD26/DPPIV) next to the cell surface provides substantial opportunity for the cell to modulate other signals that might be acting on it from other sources. Adenosine modulates many of the signals that are produced to act on leukocytes in inflammation and cancer, leaving CD26/DPPIV – as the docking site for ADA – in a unique position to act as one of the central determinants of the overall cellular response. In leukocytes, this seems to allow cells to resist somewhat the immunomodulatory effects of adenosine that may be produced during inflammation. Indeed levels of CD26/DPPIV, either on the surface of leukocytes or in a soluble form (sCD26) that is shed from cells and can be recovered from blood plasma, have been used to indicate levels of inflammation.

In cancer, the status quo is altered by two things. Firstly, as indicated above, adenosine levels in solid cancers are persistently high. Secondly, cellular levels of CD26/DPPIV are altered from normal and (with the exception of a few specific cancers) are typically low. These factors will combine to leave cells within a cancer (the tumor cells, the supporting fibroblastic cells, and infiltrating leukocytes) more susceptible to the effects of adenosine.

The two factors may be linked, as it has been shown that persistently high adenosine levels can cause the amounts of CD26/DPPIV at the surface of cancer cells to decline precipitiously. Adenosine, which is produced regionally within cancers, is likely a major factor responsible for the spatial variations in CD26/DPPIV expression within certain cancers.

Changes in CD26/DPPIV levels in cancer will also have an impact as a result of alterations in the DPPIV enzyme activity available. The substrates of this enzyme are typically hormones and other peptide regulators that are important in controlling the functions of epithelial and nervous cells, as well as cells involved in the body's defenses (Table 1). Amongst the most sensitive of the various mediators that are substrates for this enzyme is a chemokine molecule called CXCL12. (Chemokines are small peptide mediators that play an important role in controlling cellular arrangement in developing tissues and directing cell movement in the immune and inflammatory systems of our body's defenses.) CXCL12 is important in cancer because it seems to be one of the major factors that provides the "right environment" for cancer cells that have left the original tumor to settle into new locations in the process of metastasis. It provides a signal that activates a receptor on cancer cells called CXCR4 to facilitate their seeding and growth in such metastatic sites as the lungs, liver and bone marrow (►CXCR4 chemokine receptor).

Changes in CD26/DPPIV levels in cancer likely help cancers to grow by affecting the activities of these mediators that are substrates for the DPPIV enzyme activity. The result of excising the N-terminal two amino acids in most cases is to inactivate the mediator or cause it to be more rapidly degraded. In the common

cancers in which CD26/DPPIV tend to have declined, there will therefore be a shift to higher levels of the active mediator(s). As mediators such as CXCL12 are strongly linked to cancer progression, this will be one of the many different ways in which cancers can act to encourage their own expansion.

CD30

Definition

Member of the tumor necrosis factor/nerve growth factor receptor superfamily. It is an activation-associated antigen that is most often expressed on lymphoid cells but also found on embryonal carcinoma cells.

►Hodgkin Disease, Clinical Oncology
►CD Antigens

CD33

Definition

Is a glycoprotein expressed on myeloid and myelomonocytic progenitors, but not on pluripotent progenitor cells in normal hematopoesis. In 85–90% of cases of adult and pediatric acute myeloid leukemia CD33 can be detected on leukemia blasts. Functionally, CD33 is involved in cell-cell interactions and signaling in the hematopoietic and immune system.

►Monoclonal Antibody Therapy
►CD Antigens

CD34

Definition

A surface antigen that is present on human hematopoietic stem cells and progenitors but not on more differentiated cells. The presence of CD34 and absence of CD38 characterizes both normal and leukemic hematopoietic stem cells.

►NUP98-HOXA9 Fusion
►CD Antigens

CD39

Definition

A cell-surface protein that removes diphosphates from nucleotides such as ATP (to form AMP); also known as ecto-nucleoside triphosphate diphosphohydrolase (NTPDase-1).

►Adenosine and Tumor Microenvironment

CD44

Ursula Günthert
University Hospital, Institute of Pathology, Basel, Switzerland

Synonyms

Cluster of differentiation 44; Hyaluronan receptor; Homing receptor; ECMRIII; Phagocytic glycoprotein-1; pgp-1; H-CAM; $gp90^{Hermes}$

Definition

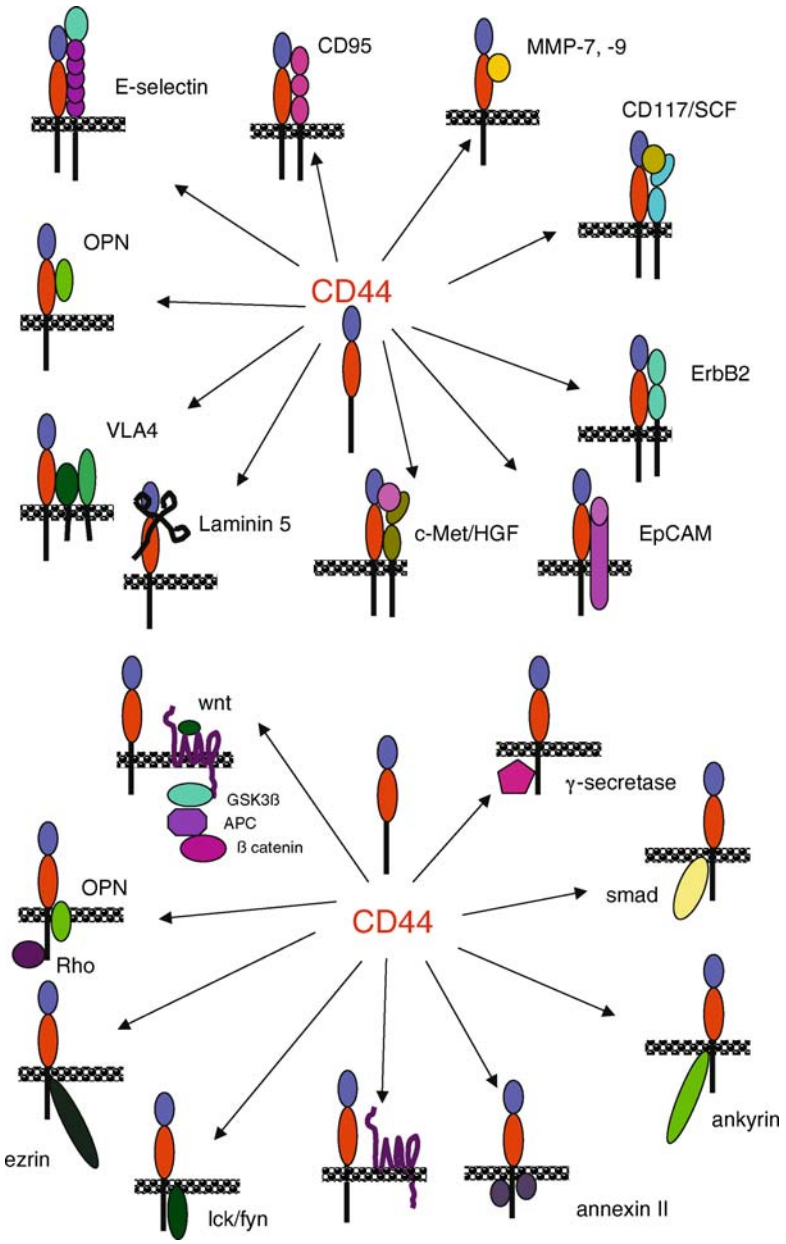
CD44 is a type I transmembrane glycoprotein, which exists in a large number of isoforms. The gene contains 20 exons within a region of ~60 kb on chromosome 11p13 in humans and on chromosome 2 at 56 cM in mice. CD44 is in close proximity to the recombination-activating-genes Rag-1 and -2.

Characteristics

CD44 is the major receptor for ►hyaluronic acid and other ►extracellular matrix molecules (►fibronectin, ►laminin 5, collagen type IV, serglycin). The standard molecule is heavily ►glycosylated by N- and O-linked residues and chondroitin sulfate side chains, while some of the ►variant isoforms carry in addition ►heparan sulfate moieties, which can present various ►growth factors and ►chemokines (for local concentration and activation). The number of extracellular molecules that can associate with CD44 is ever growing, among them ►matrix metalloproteinase-7, -9 (►MMP-7, MMP-9) inducing activation of latent transforming growth factor β (►TGF-β) and hence promote ►invasion and ►angiogenesis. Further associating molecules are ErbB2 (►HER-2/neu), EpCAM, ►E-selectin, ►CD74, and ►VLA-4 (Integrin α4β1). While ►c-met/►scatter factor receptor, c-kit/►stem cell factor receptor, ►osteopontin

(OPN), and ►CD95 have specifically been shown to associate with CD44 variant isoforms, association with the other molecules has not been specified to a CD44 isoform. The association between VLA-4 (integrin α4β1) and CD44 directs cells into ►inflammatory regions, while the c-met/CD44v6 interaction is required for c-met/scatter factor receptor signaling leading to ►Ras activation; and when CD44v6 associates with CD95, trimerization of the death receptor is prevented and hence ►apoptosis signaling is blocked (see Fig. 1).

Upon cellular activation, CD44 localizes to ►plasmamembrane microdomains and associates (see Fig. 1) with nonreceptor ►tyrosine kinases lck and fyn, smad-1, membrane bound OPN, and ►Rho. Via ►ezrin (►ERM protein), ankyrin or annexin II the cytoplasmic region of CD44 is linked to the cytoskeleton. CD44 is involved in the ►wnt signaling pathway. ►P-glycoprotein, the product of the multidrug resistance (MDR) gene has also been demonstrated to interact physically and functionally with CD44, thus promoting cell



CD44. Figure 1 Multiprotein complexes can be formed between CD44 and various cell surface, membrane-linked and intracellular molecules.

►migration and invasion and possibly enforcing resistance to ►chemotherapy. The p-glycoprotein – CD44 interaction is the first hint of a functional association between MDR and ►metastasis formation, involving CD44. Further it is of importance that the presenilin-dependent ►γ-secretase cleaves off the intracellular domain (ICD) of CD44, which then translocates to the nucleus and acts as a transcription factor for genes containing TPA (12-O-tetradecanoyl phorbol 13-acetate) response elements in their promoter. The ICD of CD44 promotes the fusion of ►macrophages, is localized in the nucleus of macrophages, and promotes the activation of ►nuclear factor kappa (NF-κ) B.

Cellular and Molecular Regulation

The standard form of CD44 (CD44s) is expressed in almost all tissues and leukocytes and is encoded by exons s1–s10, yielding a product of 90 kDa. The variant isoforms (CD44v) are generated by ►alternative splicing of the nuclear RNA between exons s5 and s6, and are encoded by exons v2–v10 (exon v1 is silent in humans, but not in mice and rats). Combinations of different variant exons with the standard backbone result in numerous variant isoforms, with masses of 100–250 kDa. All the variant regions are located extracellularly and are highly hydrophilic. In contrast to the ubiquitous expression of CD44s, CD44v isoforms are expressed in a highly restricted manner in nonmalignant tissues: in early embryogenesis, ►stem cells of epithelia and hemopoiesis, activated leukocytes and memory cells. However, in malignant tissues, CD44v isoforms are often upregulated, e.g., in ►carcinoma, various ►hematological malignancies, and in ►autoimmune lesions.

A positive feedback loop was identified which couples Ras activation with alternative splicing of the CD44 variant isoforms. The presence of CD44v6 then sustains ►Ras signaling, which is in turn important for cell cycle progression.

CD44 is implicated in various aspects of ►tumor progression: invasion, migration, and ►apoptosis blockade.

Clinical Relevance

Originally identified by its metastasizing potential in rats, CD44v isoform expression was identified in various human tumors and correlated with clinical relevance. *Upregulation* of CD44v correlates with poor prognosis in ►gastric and colorectal carcinoma, ►nonsmall cell lung tumors, ►hepatocellular carcinoma, ►pancreatic cancer, ►B-cell chronic lymphocytic leukemia, ►multiple myeloma, ►non-Hodgkin lymphoma, and ►acute myeloblastic leukemia. *Downregulation* of CD44v correlates with poor prognosis in ►esophageal squamous cell carcinoma, ►bronchial carcinoid tumors, ►ovarian neoplasms, ►uterine cervical tumors, ►transitional cell bladder tumors, and ►prostate cancers, while downregulation of CD44s correlates with amplification of ►MYCN and is indicative for an unfavorable outcome in ►neuroblastoma patients. In ►breast carcinoma, controversial data between CD44v expression and survival were established and need further evaluation.

Elevated serum levels of CD44v have prognostic value for ►gastric and ►colon carcinoma, non-Hodgkin lymphoma, which are indicative for a poor prognosis.

An emerging new field (although hypothesized some 150 years ago) is the area of cancer-initiating cells, also termed ►cancer stem-like cells. They exist as a small population in every tumor and determine the capability of the ►tumor to grow and propagate. In tumors of the ►breast, the ►pancreas, the ►prostate, ►head and ►neck, the ►brain (►glioblastoma), and in the blood system (►leukemia), the cancer-initiating cells are $CD44^+$. A major goal currently is to identify specific markers (►stem cell markers) that enable to distinguish between normal, benign tissue stem cells and those that are cancer-initiating.

CD44 is also strongly upregulated in ►inflammatory lesions of patients with ►autoimmune diseases(►inflammatory bowel disease (Crohn's disease), multiple sclerosis, rheumatoid arthritis).

CD99

Definition

Cluster definition for a transmembrane cell surface sialoglycoprotein previously named MIC2 or E2 or HBA71 antigen; present on almost every human tissue but most highly expressed on early hematopoietic precursor cells, some lymphomas and all Ewing sarcoma family tumors. Ewing family tumors express at high levels an antigen determined by the *MIC2* gene.

The product of *MIC2* is a glycoprotein (also designated CD99 or p30/32 MIC2) with a molecular weight of approximately 30,000 daltons located on the cell surface and probably involved in cell adhesion. Although immunohistochemical detection of membrane-localized *MIC2* expression is a sensitive diagnostic marker for Ewing family tumors, it lacks specificity in that many other tumors are also immunoreactive with anti-MIC2 antibodies in some cases.

Definition

The human cluster of differentiation (CD) antigens are surface molecules originally detected on white blood cells (►leukocytes) from peripheral blood. The first Human Leukocyte Differentiation Antigen (HLDA) workshop was held in Paris in 1982 where 15 surface molecules were assigned based upon the "►clustering" of submitted antibodies whose reactivities were screened against a panel of cell lines. Different antibodies that showed similar or identical patterns of reactivity against the panel of cell types were considered to be reacting with the same surface molecule. This clustering of antibody reactivity enabled designation of a specific CD number for a particular surface molecule. The identification of CD antigens was facilitated by the prior development by Kohler and Milstein of a procedure for generation of ►monoclonal antibodies against a particular antigen. Meetings of the HLDA group were held approximately every 4 years, culminating in HLDA8 that was held at Flinders University in 2004. At that workshop, further CD antigens were added to the list to give a total of 339 CD antigens, and more have been added since that time. The CD antigen organization has now been renamed Human Cell Differentiation Molecules (HCDM) in recognition that CD antigens are not found uniquely on leukocytes, and a number of additional CD antigens have been designated. Indeed CD antigens are found on all types of human cells in different repertoires controlled by the genetic program of the tissue.

Characteristics

The CD antigens are a diverse group of ►surface glycoproteins with a multitude of functions, providing the interface between a cell and the external environment that includes other cells. The CD antigens may be cell-cell or cell-matrix adhesion molecules, cytokine receptors, ion pores, or nutrient transporters. The CD antigens perform a variety of roles in immune system function. CD1 for example, presents lipids to T-cells and is essential for immunity against the mycobacterial infections that cause tuberculosis and leprosy. CD4 is a

co-receptor in antigen-induced T-cell activation and is a receptor for HIV, CD35 is a complement receptor, CD40 is a member of the TNF receptor family with the ligand CD154, and CD54 is an intercellular adhesion molecule.

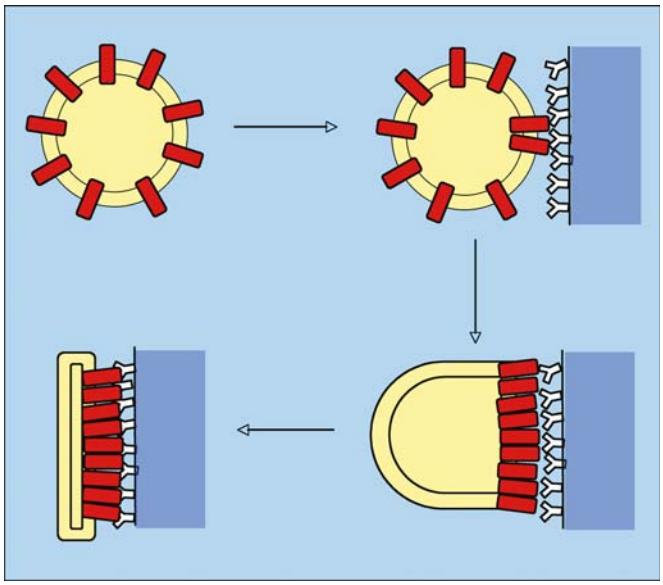
The method of discovery of CD antigens has classically involved testing monoclonal antibodies submitted to a workshop against a panel of 75 cell types using fluorescently-tagged antibodies and ►flow cytometry. Hierarchical cluster analysis is then performed and a dendrogram plotted. Monoclonal antibodies that cluster show similar patterns of interaction with the panel of cells. With recent development of sophisticated procedures for membrane proteomics, this clustering procedure is becoming out-dated and CD antigens may in the future be designated using different criteria. There are certainly several thousand cell surface proteins that could, in principle, be detected and characterized using methods of higher sensitivity. The discovery of further CD antigens will continue to involve raising monoclonal antibodies against antigens on intact cells in the traditional manner, but will certainly utilize modern ►proteomic techniques such as two-dimensional gel electrophoresis and multi-dimensional chromatography with detection and identification of proteins using mass spectroscopy and extensive protein databases.

CD Antigens Provide Immunophenotypes of Leukocytes

The repertoires of surface CD antigens found on different types of leukocytes reflect the genetic programs that operate in particular cell types. Thus, cells may be classified according to their cell surface profile (►immunophenotype). This concept is illustrated in Fig. 1 as a Venn diagram for T-cells, B-cells and myeloid cells. T-cells (yellow) express certain antigens uniquely such as CD2, CD3 and CD4, B-cells (blue) express CD19, CD20, CD21 and CD22, and myeloid cells (red) express CD13, CD14, CD15 and CD33. Certain CD antigens are shared between two lineages of leukocytes, for example, CD5 and CD38 (green), are shared between T-cells and B-cells. The so-called pan leukocyte markers are shared between all 3 categories of leukocytes and include well-known antigens such as CD44 and CD45. All leukocytes originate from stem cells via proliferation and differentiation of cells down lineages to form the many types of mature leukocytes. The stem cell antigen CD34 (black) is a marker of undifferentiated cells.

Classification of Leukemias Using CD Antigens

The principles described above for normal cells can also be applied to cancers such as leukemias. Most leukemias arise as mutations in precursors of leukocytes in the lineages of differentiation found in the bone marrow. A mutation will stop further differentiation of a precursor cell, and there is proliferation rather than differentiation. The resultant identical (monoclonal) cells accumulate in the circulation and the patient is eventually diagnosed with leukemia. Most leukemias are monoclonal and the leukemic cells usually have a similar or



CD Antigens. Figure 1 Venn diagram showing the differential expression of CD antigens on different categories of leukocytes.

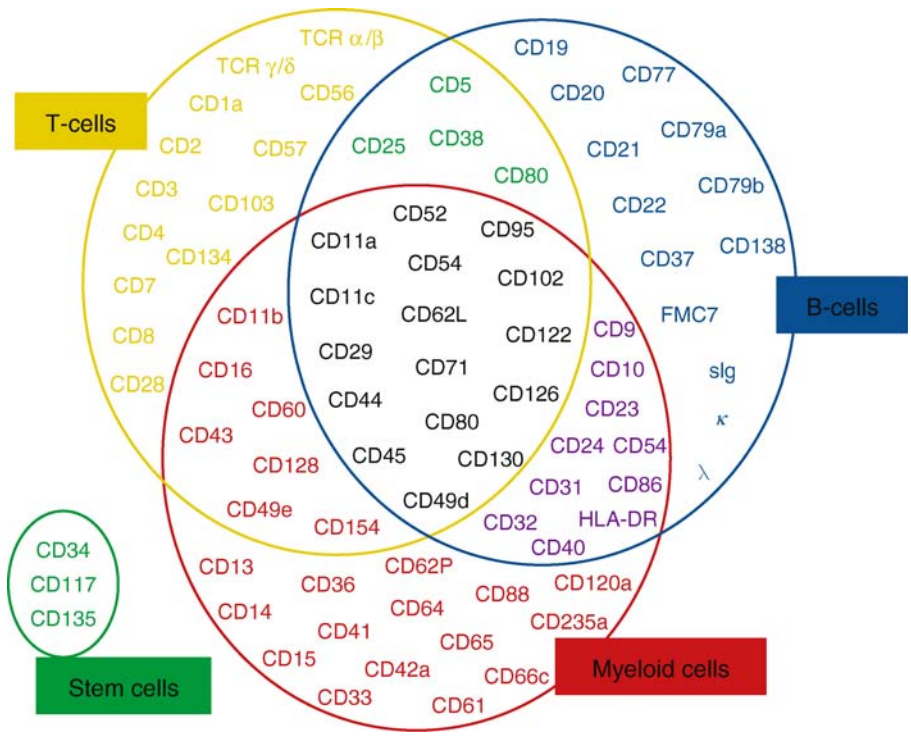
identical surface expression profile (immunophenotype) to that of the precursor cell from which the leukemia arose. Thus, identification of a large number of CD antigens using flow cytometry ►or antibody microarrays may be sufficient to diagnose a leukemia.

CD Antigens as Targets for Therapeutic Antibodies

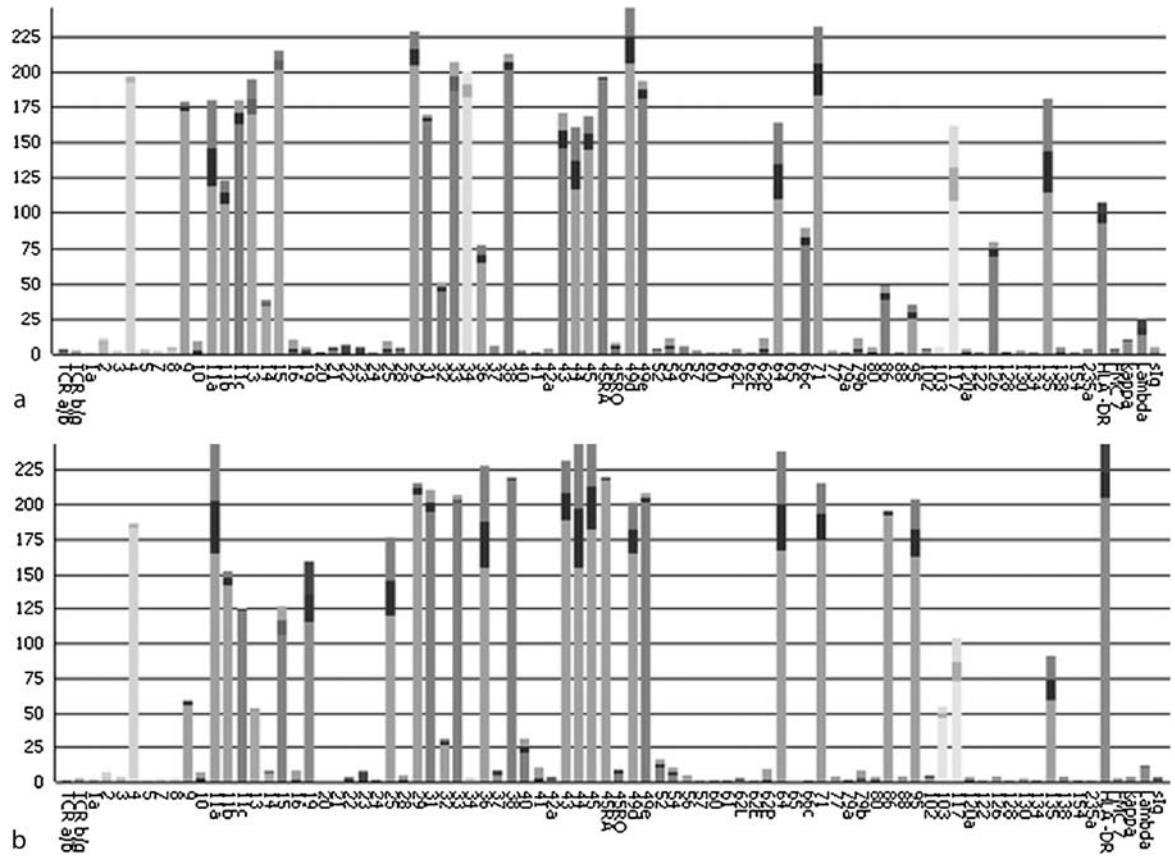
These cell surface proteins are potential targets for therapeutic antibodies. Such antibodies may block the function of a receptor, selectively activate leukocyte sub-populations, carry a toxin or radioisotope, or act as a site for antibody dependent cellular cytotoxicity (ADCC) or complement dependent cytotoxicity (CDC) where the target cell is eliminated by cytotoxic cells such as neutrophils, monocytes and natural killer cells. There are a number of therapeutic antibodies in clinical use for treatment of a variety of leukemias and lymphomas. For example, Rituximab is specific for CD20 and is used to treat chronic lymphocytic leukemia (CLL) and non-Hodgkins lymphoma (NHL). Both are B-cell cancers that express CD20 (Fig. 1) and are killed by this antibody. Mylotarg is specific for CD33, contains a toxin and is used to treat certain types of acute myeloid leukemia (AML). Campath-1H (Alemtuzimab) binds to CD52 and is used to treat NHL. There are many more therapeutic antibodies in development, one of the most rapidly growing area of pharmaceuticals, where monoclonal antibodies are first made against the desired CD antigen and the characteristics of the antibody are then "engineered" to make it suitable for use in patients.

Methods for Identification of CD Antigens

Flow cytometry has been the "gold standard" for identification of a limited number of CD antigens on the surface of leukocytes. In this method, the leukocytes in suspension are mixed with a fluorescently-labeled antibody that is specific for the extracellular portion (epitope) of a surface molecule thought be expressed on the cells. The fluorescently-labeled sample is aspirated into the flow cytometer, and the cells pass singly through a narrow aperture where a laser beam individually excites fluorescent antibodies bound to single cells. The emitted fluorescence is detected and data accumulates for a large number (e.g., 10,000 cells). Flow cytometry can detect three different fluorescent antibodies simultaneously; more sophisticated systems can detect eight and up to 17 CD antigens. To diagnose leukemias, 10–15 CD antigens are usually identified using several cycles of flow



CD Antigens. Figure 2 Capture of live leukocytes on the CD antibody microarray. The *red bars* across the cell membrane represent a CD antigen (e.g., CD20) that forms an initial interaction with antibodies against CD20 that are immobilized on a solid support as a dot in the microarray. Cell capture occurs progressively as CD20 moves in the membrane of the cell and becomes progressively captured by the antibodies on one side of the cell.



CD Antigens. Figure 3 Cell surface expression profiles from an antibody microarray. (a) Acute myeloid leukemia (AML) cells from peripheral blood; (b) AML cells from bone marrow. Numbers on the x-axis refer to antibodies against the corresponding CD antigens. Values on the y-axis are average dot intensities.

cytometry, and the information is combined with other criteria such as cell morphology, cell staining, an image of the chromosomes, and sometimes analysis of the DNA in the cells.

More recently, a ►CD antibody microarray has been developed that detects the presence of 147 different CD antigens on leukocytes in a single assay. This microarray called DotScan (Medsaic Pty Ltd, Eveleigh, NSW, Australia), consists of CD antibodies immobilized on a microscope slide. Live cells (3 million) are placed on the microarray that is ~0.5 cm square and contains more than 300 antibody dots. Cells are captured by an immobilized antibody if the cell has the corresponding CD antigen on its surface (Fig. 2). After one hour, unbound cells are gently washed off and the resultant dot pattern is the immunophenotype (surface expression profile, disease signature) for the leukemia. The dot pattern for a leukemia is stored as a digital image and may be analyzed with a variety of software to provide an expression profile (Fig. 3) that in many cases enables diagnosis of the type of leukemia.

Definition

Cyclin-dependent kinase inhibitor 2A gene (CDKN2A), the first identified ►melanoma predisposition gene, encodes the tumor suppressor proteins p16 and ARF.

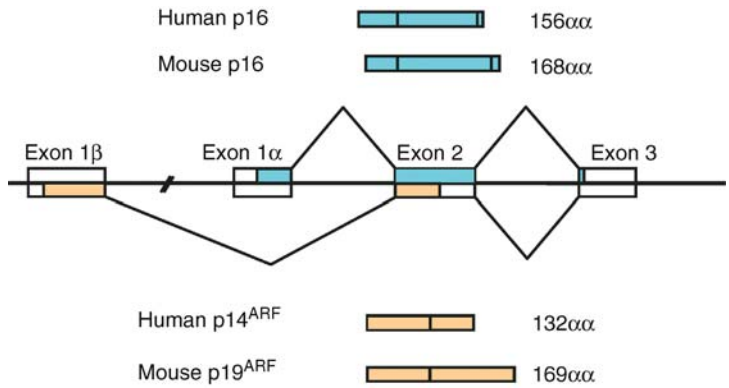
Characteristics

Identification of CDKN2A

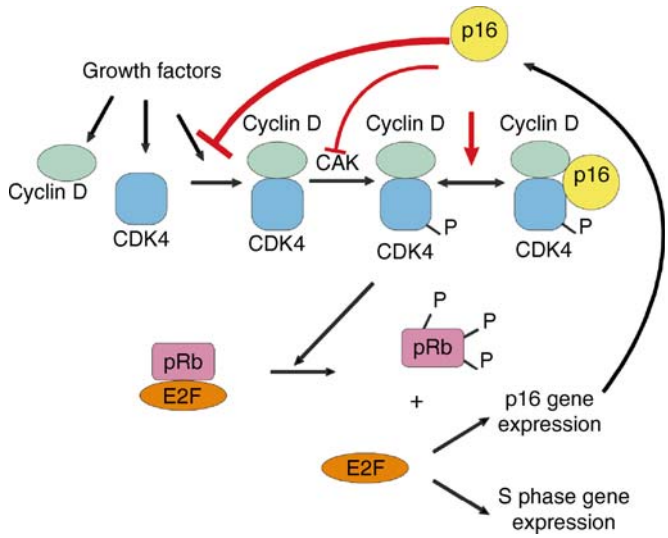
The 9p21-22 chromosomal region was originally implicated in the development of melanomas through a combination of cytogenetic and loss of heterozygosity (LOH) studies. Subsequent linkage analysis in melanoma families indicated that this region harbored a melanoma predisposition locus. Homozygous deletions in cell lines derived from several different tumor types narrowed down the region significantly. This led to the isolation, by two independent groups, of the cell cycle regulatory gene encoding the cyclin-dependent kinase (CDK) inhibitor, p16, which had been previously identified in a yeast two-hybrid screen to identify proteins that bound to CDK4 (Fig. 1).

Gene Structure of CDKN2A

In the original description of human p16 the initiating methionine was incorrectly identified. It was later found that the protein included eight additional amino acids at its amino terminus, although these residues



CDKN2A. Figure 1 Alternative transcripts and products encoded by the CDKN2A locus. The exons of CDKN2A are shown as boxes and identified as exons 1β, 1α, 2 and 3. Alternative splicing occurs as indicated to give rise to two transcripts, exons that splice to encode p16 are shown above and those that encode p14ARF are shown below. The sizes and composition of the respective mouse and human proteins are indicated.



CDKN2A. Figure 2 Schematic representation of the protein interactions in the cyclin D/CDK4/p16/pRb pathway. Through a complex system of signal transduction, growth factors lead to the assembly of cyclin D and CDK4. This complex is then activated through phosphorylation by the CDK-activating kinase (CAK), and cyclin D/CDK4 in turn phosphorylates pRb, leading to the release of transcription factors of the E2F family. These are then capable of transactivating the genes necessary for entry into S phase and p16 has been shown to inhibit this process in several ways; by binding to the complex and inhibiting the kinase activity of CDK4, inhibiting CAK dependent phosphorylation of CDK4, or inhibiting the assembly of the cyclin D/CDK4 complex, with the latter being the principal mechanism of inhibition in vivo. The scheme provided is necessarily simplistic, however, it appears that p16 may also inhibit the phosphorylation of pRb by indirectly inactivating other CDKs, e.g. CDK2, as a consequence of the redistribution of other CDK inhibitors, e.g. p27 and p21. There is also a feedback loop whereby the release of the E2F transcription factor results in the activation of p16 expression, although the absence of E2F binding sites in the CDKN2A promoter preclude direct transactivation by E2F. Aberration of this pathway through either; deletion or mutation of pRb, the binding of viral ►oncogenes to pRb, overexpression or activation of CDK4 or cyclin D, or deletion or mutation of CDKN2A all can result in constitutive transactivation of S phase genes by E2F transcription factors.

are not present in murine p16. Three exons, spread over approximately 7.2 kb of genomic DNA, encode the 156 amino acid protein with predicted molecular weight of 16,533 Da, designated p16. The primary structural feature of p16 is the four tandem ankyrin-like repeats that comprise approximately 85% of the protein. This domain is believed to facilitate protein-protein interactions (Fig. 2).

The sizes of the translated regions encoded by exon 1α, exon 2 and exon 3 are 150, 307, and 11 bp, respectively. The CDKN2A-locus also has the capacity to encode two distinct transcripts from two different promoters. This is achieved by alternative splicing and the use of different reading frames. Each transcript has a specific 5′ exon; exon 1α (E1α) or exon 1β (E1β), which is spliced onto common second (E2) and third (E3) exons. The E1α-containing transcript encodes p16, and the E1β-containing transcript encodes a protein translated into an alternate reading frame initiated in E1β, designated p19ARF in mice and p14ARF in humans. In contrast to p16, where the murine and human genes share 85% amino acid homology, the alternative reading frame (ARF) proteins share only 59% amino acid homology. The different sizes of the encoded proteins are brought about by the earlier truncation of the ARF transcript in exon 2 in humans. Two different translation start sites have been reported for the ARF protein, which has lead to some confusion in the numbering of the ARF protein amino acids in publications.

Tumor Suppressor

CDKN2A is a tumor suppressor gene for multiple tumor types. The frequency of mutations at this locus in various cancers is rivaled only by mutations in TP53. As with other classical tumor suppressor genes, both alleles need to be abrogated for tumorigenesis to occur. A wide variety of mechanisms of inactivation of CDKN2A have been documented, including intragenic mutation, homozygous deletion and transcriptional silencing through methylation of the promoter. Notably in melanomas, many of the intragenic mutations are C > T or tandem CC > TT transitions, implicating ►ultra-violet radiation (UVR) as the causal somatic mutagen. Although CDKN2A is inactivated in the majority of melanoma cell lines examined, deletions and interstitial mutations of CDKN2A are much less common in uncultured melanoma tumors. Present studies indicate that only 5–10% of uncultured melanomas demonstrate mutations in CDKN2A, a surprisingly low figure given the obvious importance of CDKN2A in familial melanoma and the frequency of LOH seen at chromosome 9p21 in melanomas.

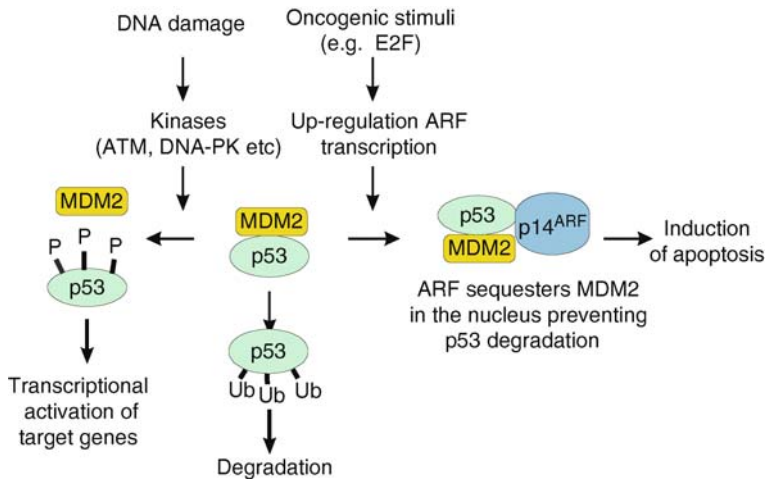
P16 is a CDK Inhibitor

P16 is the archetype member of the ►INK4 (inhibitor of CDK4) family of CDK inhibitors, which is comprised of p16INK4A, p15INK4B, p18INK4C and p19INK4D; encoded by CDKN2A, CDKN2B, CDKN2C and CDKN2D, respectively. Each of the proteins inhibits CDK4- or CDK6-mediated phosphorylation of the ►retinoblastoma susceptibility gene product, pRb, thereby providing a powerful negative signal, or "brake," to progression through the cell cycle.

The ►cyclin D1/CDK4/p16/pRb signaling pathway is the major growth control pathway for entry into the cell cycle. For cells to progress through G1 into S phase they must pass the late G1 restriction point, which controls entry into S phase. For progression past this restriction point, cyclin D/CDK4 must phosphorylate the ►retinoblastoma protein pRb. During G0/G1 the Rb protein exists in a DNA-bound protein complex, where it is bound to the transactivation domain of E2F transcription factors, preventing transactivation of E2F target genes. The phosphorylation of pRb results in the disassociation of this protein complex and the release of E2F such that it can transactivate genes required for entry into S phase. Over-expression of p16, inhibits progression of cells through the G1 phase of the cell cycle by binding to CDK4/cyclin D complexes (or CDK6/cyclin D) and blocking the kinase activity of the holoenzyme. Given that p16 normally functions to inhibit CDK4, it is easy to understand how inactivation of this gene could result in uncontrolled cellular growth leading to cancer. In many tumor types, an inverse correlation between mutations of p16 and pRb has been observed. Since p16 lies upstream of pRb, inactivation of both proteins would be redundant.

Role of the Alternative Reading Frame (ARF) Product

The ARF protein also regulates the G1/S phase transition via a distinct pathway involving the ►TP53 ►tumor suppressor gene product p53, and MDM2, which function upstream of p21 (a cyclin-dependent kinase inhibitor closely related to p16) and the CDK2/cyclin E complex (Fig. 3). p53 is a transcription factor that plays a major role in monitoring the integrity of the genome, and can be activated to inhibit cell cycle progression or initiate apoptosis through two distinct pathways: (i) in response to a variety of cellular stresses including ►DNA damage and ►hypoxia, (ii) via overexpression of viral or cellular oncoproteins such as E1A and c-myc. In this way, cells prevent the repair of mutations in successive generations by inducing apoptosis in incipient cancer cells. ARF plays a crucial role in p53-induced apoptosis. Murine p19ARF is capable of inducing a p53-dependent G1 cell cycle arrest that is not mediated through the direct inhibition of known CDKs. Ectopic expression of ARF leads to stabilization of p53 in multiple cell types, but unlike other known upstream effectors of p53 this activation is not through phosphorylation. Instead, ARF binds to MDM2 and blocks both MDM2-mediated p53 degradation and the transactivational silencing of p53. MDM2 continuously shuttles between the nucleus and the cytoplasm. This shuttling is essential for its ability to promote p53 degradation, indicating that MDM2 must export p53 from the nucleus to the cytoplasm to target p53 to the cytoplasmic proteosome. ARF activates p53 by binding to MDM2 in the nucleus and blocking the



CDKN2A. Figure 3 Schematic representation of the role of ARF in p53 activation by DNA damage and oncogenic stimuli. ARF functions to sequester MDM2 in the nucleus preventing nucleo-cytoplasmic shuttling of the MDM2/p53 complex, however, the details have not yet been fully elucidated and results suggest the mechanism may differ between humans and mice.

transport of the MDM2/p53 complex out of this organelle. Results obtained with murine and human ARF are somewhat different. In murine cells results indicate that p19ARF sequesters MDM2 away from p53 into the nucleolus. In human cells p14ARF moves out from the nucleolus to form discrete nuclear bodies in conjunction with MDM2 and p53, thereby blocking their nuclear export and leading to p53 stabilization. The discovery that ARF transcription is induced by the over-expression of a variety of cellular and viral oncoproteins including c-myc, E1A and E2F has provided the link by which hyperproliferative signals result in p53-dependent apoptosis.

To determine whether mutations in CDKN2A contribute to tumorigenesis via p19ARF in addition to p16, cDNAs carrying a variety of exon 2 mutations have been transfected into cell lines and cell cycle arrest monitored. These mutations have included several that are silent in p16 but caused missense mutations in p19ARF, as well as several deletion mutants that removed either exon 1β or various portions of exon 2. Results indicate that the majority of p19ARF activity is encoded by the exon 1β sequences, as all missense mutations in exon 2 of p19ARF remained fully active in blocking cell cycle progression, and removal of exon 2 sequences only marginally reduced the ability to induce arrest. In contrast, deletion of exon 1β resulted in a transcript that was incapable of inhibiting cell cycle progression. Missense mutations in exon 2 of the human p14ARF transcript similarly did not reduce the growth suppressive function of p14ARF.

Senescence

p16 is not normally expressed at detectable levels in most cycling cells, however, CDKN2A mRNA and p16 protein accumulate in late-passage non-immortalized cells, implicating a role for p16 in cellular ►senescence. This is supported by studies revealing that loss of p16 expression is a critical event in ►immortalization (the flip side to senescence) of a range of cell types. This conclusion was initially alluded to by finding that the frequency of deletions and intragenic mutations of CDKN2A in uncultured tumors was considerably lower than in immortalized cell lines. Growth and survival experiments using cells with impaired CDKN2A function suggest that a p16/pRb-dependant form of senescence may be particularly important in melanocytes. Individuals with defective p16INK4a have been found to have increased numbers of naevi, and it has been speculated that naevi are senescent clones of melanocytes.

Mouse Models

The generation of a CDKN2A "knockout" mouse, carrying a germline homozygous deletion encompassing exons 2 and 3 of the gene, revealed that p16 and p19ARF (since both proteins are eliminated by deletion of exon 2) were not essential for viability or organomorphogenesis. However, the mice did demonstrate abnormal extramedullary hematopoiesis, suggesting that p16 or p19ARF may regulate the proliferation of some hematopoietic lineages. In addition, the mice developed spontaneous tumors at an early age, specifically fibrosarcomas and B cell lymphomas, and were highly sensitive to carcinogens. In contrast to wild-type mouse embryonic fibroblasts (MEFs), cultured MEFs from Cdkn2a nullizygous mice (Cdkn2a−/−) failed to undergo senescence crisis, and could be transformed by oncogenic ras alleles. Although Cdkn2a−/− mice did not develop melanomas, transformation of

Cdkn2a−/− MEFs by activated ras prompted experiments to cross the Cdkn2a−/− mice with a previously generated transgenic mouse in which an activated ras allele was targeted exclusively to melanocytes under the control of the tyrosinase promoter. These mice spontaneous developed melanomas at high frequency and with short latency.

To determine whether p16 or p19ARF was the principal mediator of the above effects, knock-out mice strains with targeted deletions of p16 and p19ARF were generated. In general, p19ARF null animals were observed to develop a tumour spectrum more closely related to p53 null rather than p16 null mice. Tumours observed in p19ARF null mice included lymphomas and an increased incidence of soft tissue sarcomas, carcinomas and osteosarcomas. Mice lacking p16 were found to develop soft tissue sarcomas, osteosarcomas and melanomas. Mouse strains with specific inactivation of either p16 or p19ARF were tumour prone, but neither was as severely affected as animals lacking both p16 and p19ARF, suggesting cooperation between p16 and p19ARF loss in tumourgenesis.

Clinical Aspects

CDKN2A Mutations and Melanoma

Germline CDKN2A mutations have been observed in approximately 20–40% of melanoma families worldwide. However, melanoma appears to segregate with chromosome 9p markers in a far greater proportion of families than have been shown to carry mutations of CDKN2A. This suggests that melanoma predisposition in some of these families is caused by: (i) another gene in the vicinity of CDKN2A, (ii) mutations outside of the p16 coding region, (iii) another gene somewhere else in the genome, with linkage to this region occurring simply by chance. The most parsimonious explanation is that a combination of all these possibilities is likely.

Overall, approximately 40% of pedigrees with 3 or more cases of melanoma have been found to harbor mutations in the CDKN2A gene. This figure varies with location and is lowest in regions of high ►UV radiation (UVR), e.g. Australia (20%) and higher in regions with low incident UVR, e.g. Europe (57%).

There is a significant increase in the yield of CDKN2A mutations with increasing number of affected cases in families with melanoma. In addition, an early age of diagnosis, the presence of family members with multiple primary melanomas or with ►pancreatic cancer have also been shown to be significantly associated with an increased likelihood of finding a CDKN2A mutation.

The population based frequency of CDKN2A mutations in melanoma cases is of the order of 1–2%, even in those individuals that had developed multiple primary tumors, much lower than observed in families selected for multiple cases of melanoma.

Disease associated mutations are distributed along the entire length of the p16 coding region. At least one mutation has been described in the promoter of the gene, and several putative mutations have been identified in the intronic sequences. The most frequent CDKN2A mutations identified to date are c.255_243del19 (also known as p16 Leiden), p.M53I, p.G101W, c.331_332insGTC (p.R112_L113insR), (all in exon 2), c.-34G>T (promotor) and c.IVS2-105A>G (intron). There are considerable differences in the frequencies and distribution of CDKN2A mutations across the world. Many mutations have been shown to arise from a common founder, and are more frequent in particular geographic locations. For example Sweden and the Netherlands have single predominant founder mutations (p.R112_L113insR, and p16 Leiden respectively) involving over 90% of families tested. The G101W mutation, common in Italy, France and Spain, has been calculated to arise from a single genetic event approximately 93 generations ago. Many additional mutations have been repeatedly reported, and where analysis has been performed these have invariably been shown to be due to common founders. The only exception to this appears to be a 24 bp insertion in exon 1a, that has arisen multiple times, presumably because of DNA slippage over a 24 bp repeat region.

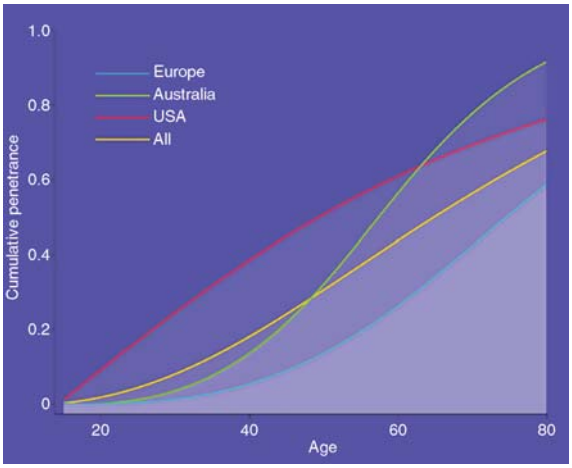
Mutation of ARF

Germline mutations affecting ARF but not p16INK4a have been reported in a small number (~3%) of melanoma families. Whereas the distribution of p16 mutation types (approximately 70% missense or nonsense, 23% insertion or deletion, 5% splicing and 2% regulatory) is consistent with that observed in the Human Genome Mutation Database, the reported ARF specific mutations are almost all either splicing mutations (affecting the 3′ splice site of exon 1b) or large deletions.

Penetrance

The pattern of susceptibility in melanoma pedigrees is consistent with the inheritance of autosomal dominant genes with incomplete penetrance. The overall penetrance of CDKN2A mutations in melanoma families has been estimated to be 0.30 by age 50 years and 0.67 by age 80 years. There is significant variation in the penetrance of CDKN2A mutations with geographical location. By age 50 years penetrance was estimated to be; 0.13 in Europe, 0.5 in the United States, and 0.32 in Australia, by age 80 years; 0.58 in Europe, 0.76 in the United States, and 0.91 in Australia (Fig. 4).

This indicates that the CDKN2A mutation penetrance varies with melanoma population incidence rates, thus the same factors that effect population incidence of melanoma may also mediate CDKN2A penetrance.



CDKN2A. Figure 4 Age specific penetrance estimates for CDKN2A mutations. Penetrance is shown for melanoma pedigrees from Australia, Europe, America (US) and all geographic locations combined.

Multiple Primary Melanoma

General characteristics of inherited susceptibility to many types of cancer are early age of onset and the development of multiple primary tumors. Hence the presence of multiple primary melanomas (MPM) in an individual may be a sign of them being a CDKN2A mutation carrier. This is the case for a small proportion (13/133, 10%) of MPM cases without a family history of the disease. In contrast, analysis of MPM cases with a family history of disease yields CDKN2A mutations in 55/139 (40%) of samples tested. The proportion of CDKN2A mutations in sporadic MPM cases increases with increasing number of melanomas (10/119 (8.5%) of cases with two primary melanomas, compared to 11/83 (33%) cases with 3 or more primary tumors).

CDKN2A Mutations and Non-Melanoma Cancers

Since CDKN2A is a tumor suppressor found to be inactivated in a wide range of different tumors, one might expect individuals carrying germline mutations of CDKN2A to be prone to cancers other than melanoma. ►Breast, ►prostate, ►colon, and ►lung cancers, have been suggested to be associated with CDKN2A mutations, however, these common cancers may occur in CDKN2A positive pedigrees by chance. Convincing evidence for susceptibility to another tumor type has been shown only for pancreatic cancer, which has been shown to be significantly associated with CDKN2A mutations in all regions except Australia, the reason for this is not yet understood.

There appears to be no evidence of an association between neural system tumors (NSTs) and CDKN2A mutations involving p16. However, there is marginal evidence for the association of NSTs with ARF specific mutations.

Modifiers of Penetrance of CDKN2A Mutations

The MC1R gene (16q24) which encodes for the melanocyte-stimulating hormone has been shown to be a risk factor in families with segregating CDKN2A mutations. MC1R variants have been shown to act as modifier alleles, increasing the penetrance of CDKN2A mutations and reducing the age of onset of melanoma.

CDKN2a Polymorphisms as Low Risk Factors

The A148T variant, located in exon 2 of the CDKN2A gene has no observed effect on p16 function, and does not segregate with disease in melanoma pedigrees. The contribution of this polymorphism to melanoma risk remains unclear, an association with increase in risk has been seen in some populations, but not in others.

The 500 C > G and the 540 C > T polymorphisms in the 3′ untranslated region of the CDKN2A gene have been shown to be associated with melanoma risk. The frequencies of the rare alleles at these loci have been shown to be higher in melanoma cases than in controls. It is possible that these variants might alter the stability of the CDKN2A transcript or the level of transcription, or that they may be in linkage disequilibrium with an unidentified variant which is directly responsible for melanoma predisposition. The contribution of these polymorphisms to melanoma risk is likely to be small in comparison to that of CDKN2A inactivating mutations.

CDKN2A and the Atypical Mole Syndrome

Since the description of the "B-K mole syndrome" much debate has ensued regarding the association between melanoma and the ►atypical mole syndrome (AMS). Several authors have concluded that atypical moles segregate independently of CDKN2A mutations, although individuals with high numbers of naevi in melanoma-prone families are three times more likely to be CDKN2A mutation carriers than those with a low number of naevi. Support for the notion that CDKN2A is naevogenic comes from a study of a large series of 12-year-old twins in which total naevus count was found to be tightly linked to CDKN2A. This finding has recently been corroborated by two independent genome wide association studies that have mapped loci responsible for naevi in twin cohorts. Both studies showed peaks of high linkage scores at 9p21 directly over the CDKN2A gene.

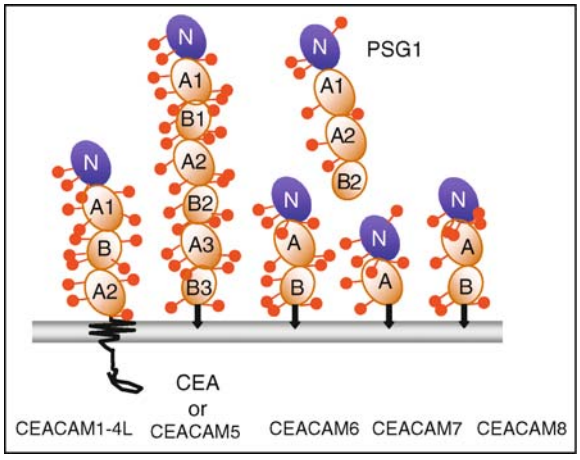
Definition

The Carcinoembryonic Antigen (►CEA) gene family comprises 33 genes, 22 of which are expressed. All family members share similar structural features encompassing immunoglobulin (Ig) variable and/or constant domains and therefore constitute members of the large immunoglobulin superfamily. These proteins are either secreted or membrane-bound. Several CEACAMs function as homophilic or heterophilic intercellular ►cell adhesion molecules. CEA, ►CEACAM1, ►CEACAM6 and ►CEACAM7 also play a significant role as regulators of tumor cell proliferation and differentiation and their overexpression (CEA and CEACAM6) or their down-regulation (CEACAM1 and CEACAM7) contributes to progression of many ►epithelial cancers and immune dysfunctions.

Characteristics

The *CEA* gene family encodes a set of 22 genes and 11 pseudogenes clustered in a 1.8 Mb region on human chromosome 19q13.2 between the *CY2A* and *D19S15* marker genes. The *CEA* genes encompass an N-terminal Ig variable domain followed by one to six Ig constant-like domains. A striking characteristic of these proteins is their extensive ►glycosylation on asparagine residues with multi-antennary carbohydrate chains. CEA and CEACAM1 are further modified by addition of ►Lewis^x and sialyl-Lewis^x high-mannose residues. The proteins differ however, in their C-terminal regions producing either secreted entities such as the pregnancy-specific glycoproteins (►PSG1–11) or others, tethered to the cell surface by either a glycosyl phosphatidylinositol linkage (CEA, CEACAM6–8) or a *bona fide* transmembrane domain (CEACAM1, CEACAM3, CEACAM4, CEACAM18–21) (Fig. 1). The *CEACAM1* gene is unique in this family in that it produces twelve different splicing variants. More information on the structural features of the *CEA* gene family members is available at http://cea.klinikum.uni-muenchen.de. CEA is a monomeric protein adopting a



CEA Gene Family. Figure 1 Schematic representation of some members of the CEA family. Most CEA family members, except the pregnancy-specific glycoproteins (PSG) that are secreted proteins, are associated with the cell membrane (depicted in grey). The immunoglobulin variable-like domains (the N domain) are shown in blue and the immunoglobulin constant-like domains are represented in orange. The N-linked glycosylation sites are indicated by sticks and balls, colored in dark orange. The glycosylphosphatidylinositol membrane anchors are represented by arrows. The *CEACAM1* gene expresses many splice variants. However, only the CEACAM-4L isoform containing four Ig domains and the longer cytoplasmic tail is shown here.

β-barrel cylindrical shape resembling a "bottle brush," whereas CEACAM1 is present as both a monomeric and dimeric protein.

Expression and Functions of CEA Family Members in Normal and Tumor Tissues

Although not ubiquitous, CEA family members exhibit a wide tissue distribution. CEA and CEACAM6 are found mainly in columnar epithelial and goblet cells of the colon in the early fetal period and are maintained in adult life. In the colonic brush border, CEA, CEACAM1, 6 and 7 demonstrate maximal expression at the free luminal surface, although CEACAM1 and 7 are also found at the lateral membrane. In addition to its expression in epithelia, CEACAM1 is located on granulocytes, lymphocytes and on endothelial cells, whereas CEACAM6 is also expressed on granulocytes and monocytes. CEACAM3 and 8 are found exclusively on granulocytes.

CEA, CEACAM1 and CEACAM6 are recognized as cell adhesion molecules contacting each other by antiparallel self-binding (homophilic). Some associations are exclusive, such as ►CEACAM8-CEACAM6. The first Ig domain is crucial in these interactions. Various CEA family members also act as heterophilic partners for ►E-selectin and ►galectin-3. Another striking feature of CEA family members is their ability to act as pathogen receptors binding to outer membrane proteins of *Neisseria* gonococci and *Haemophilus influenzae* as well as fimbriae of *Salmonella typhimurium* and *Escherichia coli*. In addition, CEACAM1 is the receptor for the mouse hepatitis viruses. The bacterial and viral adhesin functions of the CEA family members confer strong immunosuppressive activity in T and B lymphocytes, whereas they enhance integrin-dependent cell adhesion in epithelial cells with concomitant increase of the TGF-β1 receptor CD105. Other functions for CEA and CEACAM6 include inhibition of cellular differentiation as demonstrated in a number of cellular systems and inhibition of the ►apoptotic process of ►anoikis by activation of β1 integrins.

PSG1–11 are mainly expressed in syncytiotrophoblast during the first trimester of pregnancy where they act as immunomodulators and inhibit cell-matrix interactions.

CEA is abundantly expressed in tumors of epithelial origin such as colorectal, lung, mucinous ovarian and ►endometrial adenocarcinomas. For these reasons, CEA has a long history as a marker of colonic, intestinal, ovarian and breast tumor progression and its high expression is associated with poor prognostic and recurrence of disease post-surgically. High pre-operative CEA levels are indicative of a poor prognosis whereas low levels are associated with increased survival of the patients. The tumorigenic potential of CEA and CEACAM6 was recently clarified by transgenic overexpression of a bacterial artificial chromosome fragment of 187 kb encoding the full *CEA*, *CEACAM6* and *CEACAM7* genes. When the *CEABAC* transgenic mice were treated with the azoxymethane ►carcinogen to induce colon cancers, expression of CEA and CEACAM6 was increased by 2–20 fold, a situation reminiscent to that observed in the human cancer. Information on CEACAM7 expression in tumors is more limited. It is down-regulated in colorectal cancers, but increased in gastric tumors. CEACAM6 however, exhibits a broader distribution than in the cancers described above, as it is additionally found in gastric and breast carcinomas, and ►acute lymphoblastic leukemias. In fact, overexpression of CEACAM6 in ►pancreatic cancer confers increased resistance to anoikis and increased metastasis. It also modulates chemoresistance to the ►gemcitabine agent, thereby suggesting that CEACAM6 determines cellular susceptibility to apoptosis.

Expression and Functions of CEACAM1

CEACAM1 expression is more complex. It is down-regulated in colon, prostate, hepatocellular, bladder, endometrial, renal cell and 30% of breast carcinomas, but overexpressed in gastric and squamous lung cell carcinomas and ►melanomas. In thyroid carcinomas, CEACAM1 was shown to restrict tumor cell growth. However, it increases the thyroid cancer metastatic potential. Manipulation of CEACAM1 expression levels in colonic, prostatic and bladder tumor cell lines, negative for CEACAM1, has indeed confirmed that expression of the longer variant, CEACAM1-4L, produces reduction of tumorigenic potential *in vitro* and inhibition of tumor growth in xenograft mouse models. The importance of cell surface CEACAM1 expression for maintenance of normal epithelial cellular behavior has recently been confirmed *in vivo*; a *Ceacam1*-null mouse exhibits a significantly increased colon tumor load compared to the wild-type littermates upon carcinogenic induction of colorectal cancer.

CEACAM1's role as a modulator of tumor progression depends on the involvement of its cytoplasmic domain in signaling via its tyrosine and serine phosphorylation. Two Tyr residues are positioned within Immunoreceptor Tyrosine-based Inhibition Motifs (►ITIM). The membrane-proximal Tyr488 is a phosphorylation substrate of Src-like kinases as well as of the Insulin and Epidermal growth factor receptors. Upon Tyr phosphorylation, CEACAM1-L associates with the tyrosine phosphatases SHP-1 and SHP-2. The SHP-1-CEACAM1-L protein complex regulates its function in various tissues such as inhibition of epithelial cell growth, $CD4^+$ T cell activation and insulin clearance from hepatocytes. CEACAM1-L ►tyrosine phosphorylation also stimulates its association with the cytoskeletal proteins G-actin, tropomyosin and paxillin, thereby

influencing cell adhesion, and with the ►β3 integrin, hypothesized to influence cell motility. The CEACAM1-L cytoplasmic domain also carries seventeen serine residues most of which lie in consensus sequences recognized by serine kinases. However, little is know about their functional implications apart from the CEACAM1-S Thr/Ser452 and Ser456, shown to modulate direct binding to G- and F-actin, tropomyosin and calmodulin, and CEACAM1-L's Ser503 whose mutation to an Ala residue enhances colonic or prostatic tumor development in xenograph models. Additionally, Ser503 renders permissive Tyr488 phosphorylation by the insulin receptor. Transgenic mice overexpressing a Ser503Ala CEACAM1-L mutant in the liver developed hyperinsulinemia, secondary insulin resistance and defective insulin clearance. As a consequence of the decreased insulin receptor endocytosis and altered insulin signaling, the transgenic mice became obese demonstrating increased visceral adiposity, elevated serum free fatty acids and plasma and hepatic triglyceride levels.

CEACAM1-L also contributes to important functions in the immune system. It functions as an inhibitory co-receptor in T lymphocytes. Its conditional deletion in these cells amplified TCR-CD3 signaling, whereas overexpression in T cells was responsible for decreased proliferation, ►allogeneic reactivity and cytokine production *in vitro*, with delayed type hypersensitivity and inflammatory bowel disease *in vivo*. Regulation of this function involves the ITIM motifs and the SHP-1 tyrosine phosphatase. A similar function and mechanism have been described in B lymphocytes and natural killer cells. Indeed, CEACAM1-mediated intercellular adhesion between melanomas with increased CEACAM1 expression and NK cells allows inhibition of NK-cell-elicited killing, thereby conferring upon CEACAM1 a role in tumor immunosurveillance. Similarly, heterophilic engagement of CEACAM1 with CEA, overexpressed in many tumors, also inhibits lymphocyte-mediated and NK-cell-mediated killing having therefore detrimental effects on immune surveillance. In addition, increased expression of CEACAM1 on endothelial cells present in tumors in response to ►VEGF activation and/or hypoxia provokes a pro-angiogenic switch with increased endothelial tube formation and invasion. Therefore CEACAM1's contribution to cancer progression most likely depends on its positive or negative expression and signaling in epithelial tumor cells, on its systemic effects on metabolism and adiposity, on its role in immunosurveillance and most probably on endothelial proliferation and invasion.

Transcriptional Regulation

The upstream promoters of the *CEA* and *CEACAM1* genes have been dissected to identify important binding sites responsible for their transcriptional regulation. These two genes do not encompass classical TATA and CAAT boxes and are considered members of the housekeeping gene family. Their distal promoter regions (> −500 bp) contain highly repetitive elements, whereas their proximal promoter regions are rich in GC boxes and SP1 binding sites. Five footprinted regions have been identified in the *CEA* promoter, the first three binding respectively, to the Upstream Stimulatory Factor (USF), and SP1 and SP1-like factors. Similarly, the human *CEACAM6* promoter is regulated by the USF1 and USF2 as well as SP1 and SP3 transcription factors. A silencer element has also been located in its first intron. In contrast, the human *CEACAM1* promoter does not bind the SP1 factors, but associates with an AP-2-like factor and the USF and HFN-4 transcription factors. The gene is additionally controlled by the hormonal changes (estrogens and androgens) and can be induced by cAMP, retinoids, glucocorticoids and insulin. Moreover, many genes of this large family are triggered by inflammation via interferons, tumor necrosis factors and interleukins. It has been reported more recently that expression of the *CEACAM1* gene is influenced by TPA and calcium ionophore in endometrial cancers, the expression of ►BCR/ABL in leukemias, the expression of the β3 integrin in melanomas and VEGF and hypoxia in angiogenic situations. In prostate cancer, there is an inverse correlation between the down-regulation of CEACAM1 and the increased expression of the transcriptional repressor Sp2 that acts to recruit histone deacetylase to the *CEACAM1* promoter.

The Next Frontier

The diversity of functions of the members of the CEA gene family and their dynamic expression patterns in normal and tumor tissues has slowed the development of effective targeted therapies. More recently, effective strategies have been devised using vaccination with CEA peptide-loaded mature dendritic cells that induced potent CEA-specific T cell responses in advanced colorectal cancer patients. Effective protection from tumor development have also been seen with delivery of adenoviral vectors encoding CEA fused to immunoenhancing agents such as tetanus toxin or the Fc portion of IgG1. Likewise, targeting of CEACAM6 in pancreatic cancer may result in decreased tumor load. The therapeutic and selective targeting of CEACAM1 in melanomas, gastric and lung carcinomas as well as its location in tumor endothelia may prove to be a favorable avenue of future interventions.

Definition

CEACAM1 (CEA-related cell adhesion molecule 1) belongs to the CEA (►Carcinoembryonic antigen, ►CEA gene family) family of cell surface glycoproteins, a subfamily of the immunoglobulin gene superfamily. The CEA family comprises two major groups, the CEA-related molecules and the PSG (pregnancy-specific glycoprotein)-related molecules. Additionally, a number of pseudogenes have been identified. To date, 29 genes are known, which are clustered on human chromosome 19 (19q13.1-19q13.2). The CEA-related members of the CEA family display a complex expression pattern on human healthy and malignant tissues. They are linked to the cell membrane via GPI anchors, or they are transmembrane proteins with a cytoplasmatic tail. The PSG-related molecules are soluble glycoproteins; their expression is restricted to the placenta, more specifically, to the syncytiotrophoblast, which is the outermost fetal component of the placenta. CEACAM1 has been structurally and functionally conserved in humans and rodents.

Characteristics

Properties of CEACAM1

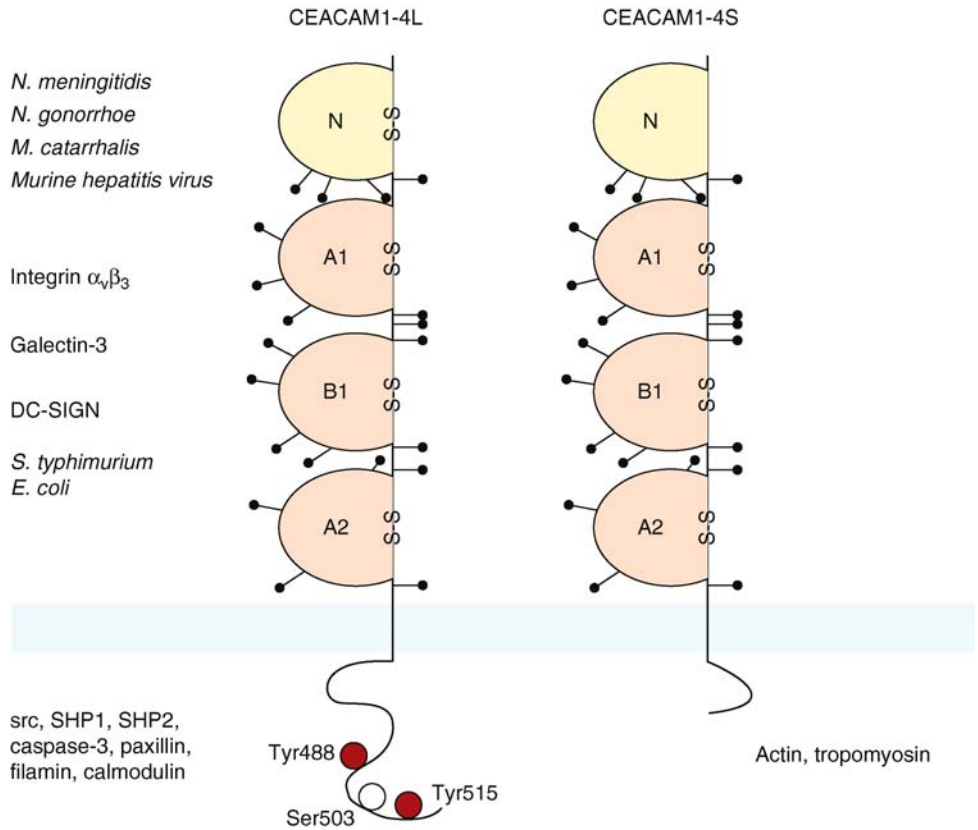
Human CEACAM1 has been originally identified in human bile due to its crossreactivity with CEA-antisera. It was therefore named biliary glycoprotein I or nonspecific cross-reacting antigen at first. Amongst the cluster of differentiation antigens on human leukocytes, CEACAM1 used to be referred as CD66a. However, with the latest revision of the nomenclature for the CEA family, CD66a, BGP, or NCA-160 became CEACAM1. Its structural similarities to CEA and the immunoglobulin superfamily proteins became apparent, once the cDNA sequence for CEACAM1 became available.

CEACAM1 displays the broadest expression pattern amongst CEA family members; it has first been described as a cell–cell ►adhesion molecule on rat hepatocytes. CEACAM1 is expressed on epithelia, endothelia, and on leukocytes.

CEACAM1 is a heavily glycosylated molecule that exists in 11 known isoforms emerging from differential splicing and proteolytic processing. The two major isoforms of CEACAM1 consist of four extracellular Ig-like domains, a transmembrane domain, and either a long or a short cytoplasmic tail, referred to as the long (CEACAM1-4L) and the short isoform (CEACAM1-4S), respectively. In addition to these transmembrane isoforms, soluble CEACAM1 isoforms are found in body fluids, for example, in saliva, serum, seminal fluid, and bile. Glycans on the extracellular domains of CEACAM1 are linked to the protein backbone via N-glycosidic linkages. It is presently unknown whether all of the 19 motifs that may render N-linked ►glycosylation actually harbor sugar moieties. On human granulocytes, CEACAM1 is a major carrier of Lewis^x glycans that are implicated in cellular adhesion to cognate lectins on blood vessels, within the extracellular matrix, or antigen presenting cells. CEACAM1 also elicits cell–cell adhesion via self-association in a homomeric fashion or via formation of heteromers with other CEA-family members and different adhesion molecules that are either located on the same cell or on neighboring cells. The resulting adhesive properties are modulated by differential expression ratios between the long and short CEACAM1 isoform, respectively. Through its long and short cytoplasmic tail, CEACAM1 mediates molecular interactions with cytoskeletal components or adapter proteins, which are integral parts of various key signal transduction pathways (►Signal transduction, cell biology). These interactions are in part dependent on differential phosphorylation of the CEACAM1-4L cytoplasmic domain on tyrosine and serine residues. The overall phosphorylation status of the CEACAM1-4L cytoplasmic domain relays signals, which contribute to cellular motility and differentiation, and thus determine cell fate by promoting proliferation or cell death. Phosphorylation of CEACAM1-4L cytoplasmic tyrosines that are part of an imperfect ITIM (immune receptor tyrosine-based inhibition motif) and serine residues regulate the interaction with kinases, phosphatases, cellular receptors for insulin (►Insulin receptor), the epidermal growth factor (►Epidermal growth factor receptor ligand, epidermal growth factor receptor inhibitor), and other cellular adhesion molecules, for example, integrin $\alpha_v\beta_3$ (►Integrin signaling and cancer). These qualities make CEACAM1 an important tool for cellular communication and they illustrate why so many different biological functions have been attributed to CEACAM1 in different biological contexts (Fig. 1).

CEACAM1 in Cancer

The first report on CEACAM1, in the context of human pathological conditions, was on elevated serum levels of a biliary glycoprotein in patients with liver or biliary tract disease. Later, aberrant CEACAM1 expression in a broad variety of human malignancies has been reported. In the progression of malignant diseases, two general patterns in the changes of CEACAM1 expression levels have emerged. In the first group of tumors, CEACAM1 expression is downregulated in the course of progressing disease. In the second group of tumors, CEACAM1 expression appears to be upregulated; often, this upregulation of CEACAM1 expression is observed in the context with increased invasiveness (►Invasion) of the primary tumor or is found on microvessels in progressing (►Progression) tumor areas (Fig. 2).

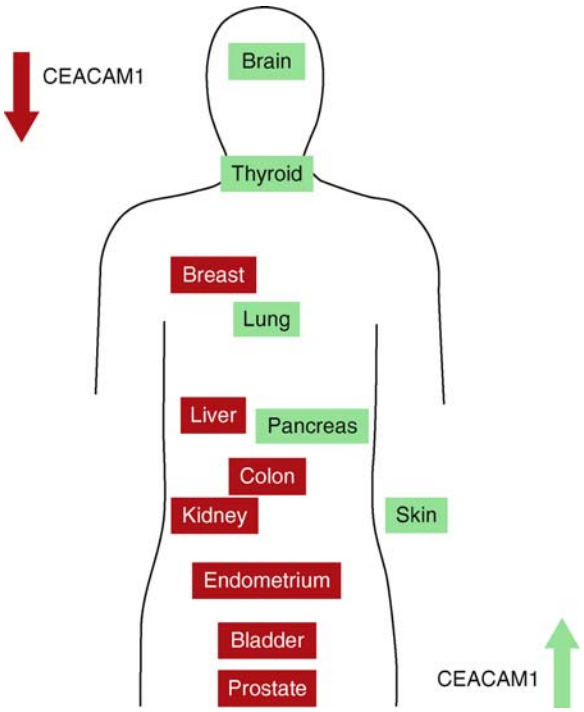


CEACAM1 Adhesion Molecule. Figure 1 Schematic representation of CEACAM1-4L and CEACAM1–4S and their participation in extracellular and intracellular communication. The two major CEACAM1 isoforms consist of four extracellular immunoglobulin-like domains, a transmembrane domain and either a long or a short cytoplasmic tail. The N-terminal domain (N) resembles a variable-like Ig domain but lacks the cystin bond usually found in Ig members. The A1, B1, and A2 domain resemble constant I-type-like Ig domains. Motifs for N-linked glycosylation are represented by lollipops. With its extracellular domains, CEACAM1 mediates recognition of various pathogens, such as *Escherichia coli, Salmonella typhimurium, Moraxella catarrhalis, Neisseria gonorrhoeae, Neisseria meningitidis*. The murine homologue of CEACAM1 is the receptor for the murine hepatitis virus: Additionally, CEACAM1 binds to galectin-3, DC-SIGN (dendritic cell ICAM3-grabbing nonintegrin), and integrin $\alpha_v\beta_3$. Tyrosine and serine residues involved in relaying CEACAM1-4L-mediated signal transduction are indicated by red and grey circles, respectively. Through its long cytoplasmic tail, CEACAM1-4L interacts with intracellular kinases of the SRC-family ►(*SRC*), the tyrosine phosphatases SHP-1 and SHP-2, caspase-3 as well as with paxillin, filamin, and calmodulin. Differential phosphorylation of the CEACAM1-4L cytoplasmic domain is required for its interaction with the insulin receptor, regulating insulin receptor internalization and recycling, and for modulating immune responses elicited by lymphocytes, for example. The short cytoplasmic domain of CEACAM1–4S binds to actin and tropomyosin.

Loss of CEACAM1 Expression in Tumorigenesis and Tumor Progression

Human cancers that show downregulation of CEACAM1 expression in the course of tumor progression are carcinomas of the liver (►Hepatocellular carcinoma), colon (►Colon cancer, colorectal premalignant lesions), kidney (►Renal cell carcinoma, renal carcinoma), urinary bladder (►Bladder cancer, bladder tumors), prostate (►Prostate cancer, clinical oncology), mammary gland (►Breast cancer), and the endometrium (►Endometrial cancer). In general, downregulation and subsequent loss of CEACAM1 expression is more frequent in high-grade tumors that are poorly differentiated, and often associated with a larger tumor size.

On epithelia, especially those that form a lumen, CEACAM1 exhibits a pronounced apical expression, like in the entire gastrointestinal tract, breast, liver, prostate, bladder, and kidney. CEACAM1 expression has been implicated in morphogenesis of lumen formation. In the process of building an asymmetrical epithelium, lateral CEACAM1 expression on neighboring cells is lost and often becomes entirely apical once a lumen or a duct has been formed. The loss of CEACAM1 expression in the context of tumorigenesis



CEACAM1 Adhesion Molecule. Figure 2 Dysregulation of CEACAM1 expression in human cancers. Changes of epithelial CEACAM1 expression in the course tumor progressison: In mammary carcinomas and carcinomas of the liver, colon, endometrium, kidney, bladder, and prostate, CEACAM1 expression is downregulated on tumor epithelium (►Epithelial cancers). Downregulation of CEACAM1 levels often correlates with dedifferentiation of the tumor and loss of tissue architecture. In carcinomas of the thyroid, ►non-small cell lung cancer (Lung cancer), pancreatic tumors (►Pancreas cancer, clinical oncology), and malignant melanomas (►Melanoma), CEACAM1 is induced or upregulated in the course of tumor growth. Here, CEACAM1 expression is found on the invasive front of the tumors and is related to development of metastatic disease (►Metastasis) and poor prognosis. In pancreatic cancer, CEACAM1 has been identified as a novel biomarker (►Biomarker, clinical cancer biomarker) that indicates presence of malignant disease.

has been studied most extensively in the context of breast, colonic, and prostate carcinomas.

A hallmark of carcinomatous lesions is the loss of polarity of their epithelial structures. In colonic epithelium, for example, loss of polarity is accompanied by the loss of apical CEACAM1 expression that occurs in early adenomas and carcinomas. In these tumors, presence and absence of CEACAM1 correlate with normal and reduced apoptosis (►Apoptosis, apoptosis signals), respectively. Furthermore, the naturally occurring process of ►anoikis, once cells lose contact to their substratum, is compromised. This observation and the fact that the *CEACAM1* gene is silenced in the course of aberrant cell growth prompted the hypothesis that CEACAM1 acts as a ►tumor suppressor. In intestinal cells, presence of the long CEACAM1 isoform is required to suppress tumor growth, and lack of CEACAM1-4L expression is accompanied by a decrease in proteins that inhibit cell cycle progression.

In human mammary epithelial cells, CEACAM1 expression is causally related to lumen formation and differentiation. In mammary glands, CEACAM1-4S is the predominating isoform, and only the short cytoplasmic tail induces apoptosis of the central cells and subsequently leads to lumen formation in mammary morphogenesis. During tumor progression, CEACAM1-4S expression is lost and acinar polarity no longer can be observed.

However, since particular mutations or allelic loss of the *CEACAM1* gene in human cancers has not been described so far, it is likely that dysregulation of CEACAM1 expression rather than irreversible loss of the *CEACAM1* gene are linked to tumorigenesis and tumor progression in vivo. Hence, gene silencing may attribute to the loss of the tumor suppressive qualities of CEACAM1. Though there are no changes in promoter ►methylation of the *CEACAM1* gene linked to tumor progression, CEACAM1 promoter activity appears to be regulated by binding of the transcription factor Sp2. In high-grade prostate carcinomas, Sp2 is highly abundant, whereas CEACAM1 expression is lost. Sp2 localizes to the CEACAM1 promoter and imposes repression of gene transcription by recruiting ►histone deacetylase.

Upregulation of CEACAM1 Expression in Malignant Diseases

Opposed to its tumor suppressive functions, certain tumors gain CEACAM1 expression in the course of cancer development. In the case of malignant melanomas and thyroid carcinomas, expression of CEACAM1 correlates with an increase of tumor invasiveness and development of metastatic disease. In primary cutaneous malignant melanomas, for example, CEACAM1 expression is found at the invasive front of the tumors, and its coexpression with integrin $\alpha_v\beta_3$ indicates that CEACAM1 may directly promote on cellular invasion. In a follow-up study, CEACAM1 was identified as an independent prognostic marker, predicting the development of metastatic disease and poor survival. In this context, it is noteworthy that CEACAM1 on melanoma cells forms homophilic cell–cell contacts with CEACAM1 molecules on tumor-infiltrating lymphocytes, and leads to inhibition of their cytolytic function. Similarly, in human non-small cell lung cancer, CEACAM1 expression correlates with advanced disease, whereas it is not expressed on the normal bronchiolar epithelium; this CEACAM1 neoexpression

was identified as an independent prognostic marker, indicating lower incidence of relapse-free survival.

In pancreatic carcinomas, CEACAM1 has been identified as a novel serum biomarker, with an increased CEACAM1 expression on neoplastic cells of pancreatic adenocarcinomas and elevation of serum levels at the same time. Additionally, significant differences in CEACAM1 serum levels were found in patients with either pancreatic cancer or chronic pancreatitis. Opposed to the classical pancreatic tumor marker CA19-9, CEACAM1 was confirmed as an independent marker to distinguish between the presence of malignant disease and pancreatitis.

CEACAM1 and Tumor Angiogenesis

CEACAM1 expression on human blood vessels is restricted to newly formed vessels, and usually, no CEACAM1 is found on mature, large vessels. The first indication that CEACAM1 is related to ►angiogenesis was the description of CEACAM1 neoexpression on newly formed vessels in the human placenta. Furthermore, CEACAM1 is expressed on vessels in wound healing tissues and on tumor vessels of human bladder carcinomas, the prostate, hemangiomas, and ►neuroblastomas. CEACAM1 expression in endothelia is induced by VEGF (►Vascular endothelial growth factor)-dependent pathways and appears to favor vessel maturation.

In human prostate carcinomas, CEACAM1 shows divergent expression on tumoral blood vessels and the tumor epithelium. The presence of epithelial CEACAM1 is observed in the context of poor tumoral blood vessel growth and loss of epithelial CEACAM1 expression parallels enhanced tumor angiogenesis. Especially in high-grade prostate carcinomas, tumor proximal vessels are expressing CEACAM1. Contrary to prostate carcinomas, microvessels in human neuroblastomas are CEACAM1-positive only during tumor maturation, but absent in undifferentiated, high-grade tumors. In ►Kaposi sarcomas, CEACAM1 upregulation is observed, indicating that CEACAM1 might be related to lymphatic reprogramming of the vasculature in these tumors.

Studying CEACAM1 in Cancer: Animal Models

In animal models investigating CEACAM1 function in tumorigenesis in vivo, the observations from human diseases could be confirmed. The focus of the mouse and rat models (►Mouse model) studied to date was set largely on the tumor-suppressive effects or enhancement of metastatic disease of CEACAM1-4L on the progression of colonic cancer, prostate cancer, hepatocellular carcinomas, and malignant melanomas. In CEACAM1-knockout mice, chemically induced colonic tumor growth was significantly increased in terms of tumor numbers and size opposed to CEACAM1-expressing wild type littermates. In syngeneic and xenotypic transplantation of tumor cells of the colon, prostate, and hepatocellular carcinomas, the tumor-suppressive effects of CEACAM1-4L expression could also be validated. After xenotransplantation of human CEACAM1-expressing melanoma cell lines into immune-deficient mice, enhanced metastasis was observed when compared to transplantation of CEACAM1-negative cell lines.

Synonyms

Tripterine; Quione methide friedelane tripterene (2R,4aS,6aS,12bR,14aS,14bR)-10-hydroxy-2,4a,6a,9,12b,14a-hexamethyl-11-oxo-1,2,3,4,4a,5,6,6a,11,12b,13,14,14a,14b-tetradecahydropicene-2-carboxylic acid

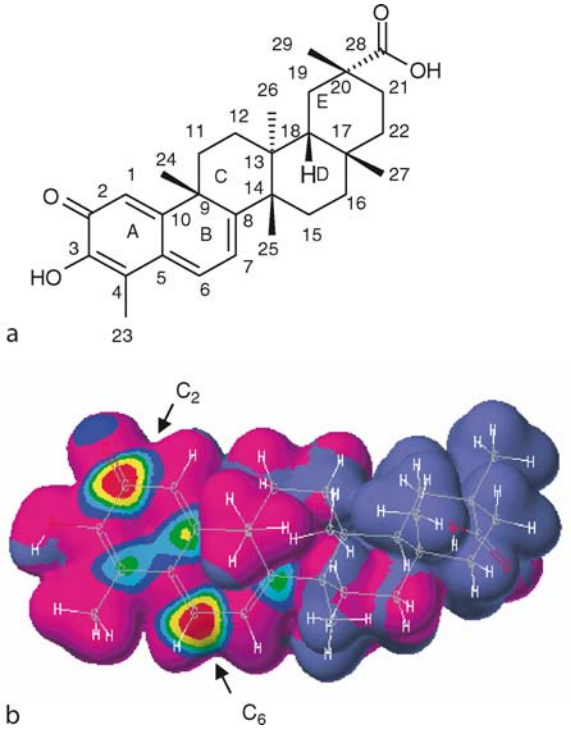
Definition

Celastrol is a natural quione methide friedelane tripterene, widely found in the plant genuses of *celastrus, maytenus* and *tripterygium*, all of which are present in China. For example, celastrol is one of the active components extracted from *tripterygium wilfordii Hook F,* an ivy-like vine also known as "Thunder of God Vine," which belongs to the family of *celastraceae* and has been used as a natural medicine in China for hundreds of years (Fig. 1).

Characteristics

Biological Properties

Celastrol has strong antifungal, anti-inflammatory and antioxidant effects. It has been shown that celastrol isolated from the roots of *Celastrus hypoleucus* (Oliv) Warb f argutior Loes exhibited inhibitory effects against diverse phytopathogenic fungi. Celastrol was also found to inhibit the mycelial growth of *Rhizoctonia solani*



Celastrol. Figure 1 The chemical structure and nucleophilic susceptibility of celastrol. (a) The chemical structure of celastrol is shown. (b) Nucleophilic susceptibility of celastrol analyzed using CAChe software. Higher susceptibility was shown at the C_2 and C_6 positions of celastrol.

Kuhn and *Glomerella cingulata* (Stonem) Spauld and Schrenk *in vitro*. Furthermore, celastrol has good preventive effect and curative effect against wheat powdery mildew *in vivo*.

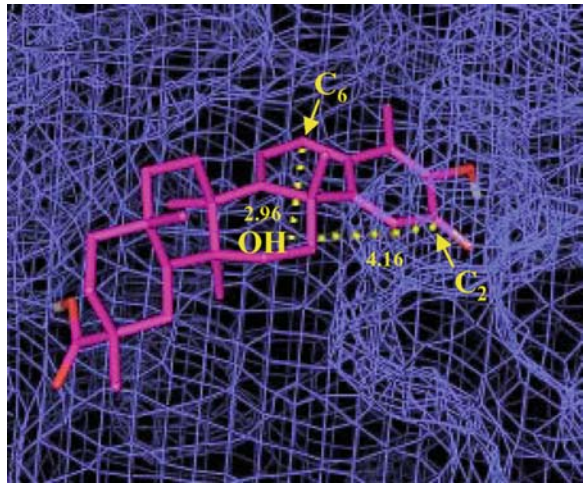
Celastrol in low nanomolar concentrations suppresses the production of the pro-inflammatory cytokines tumor necrosis factor-alpha (TNF-α) and interleukin-1 beta (IL-1β) by human monocytes and macrophages. Celastrol also decreases the induction of class II major histocompatibility complex (►MHC) expression by microglia. In macrophage lineage cells and endothelial cells, celastrol decreases induction of nitric oxide (NO) production. Celastrol also suppresses adjuvant arthritis in the rat, demonstrating *in vivo* anti-inflammatory activity. Low doses of celastrol administered to rats could significantly improve the performance of these animals in memory, learning and psychomotor activity.

In an isolated rat liver assay of lipid peroxidation, the antioxidant potency of celastrol (IC_{50} 7 μM) is 15 times stronger than that of α-tocopherol or vitamine E. Under *in vitro* conditions, celastrol was found to inhibit ►cancer cell proliferation and induce programmed cell death (or ►apoptosis) in a broad range of tumor cell lines, including 60 National Cancer Institute (NCI) human cancer cell lines. As a ►topoisomerase II inhibitor, celastrol was 5-fold more potent than the well-known topoisomerase inhibitor etoposide to induce apoptosis in HL-60 leukemia cells. Celastrol was also found to be a tumor ►angiogenesis inhibitor. In a sharp comparison, celastrol can block neuronal cell death in cultured cells and in animal models. These unique features of celastrol suggest potential use for treatment of cancer and neurodegenerative diseases accompanied by inflammation, such as Alzheimer's disease.

Potential Molecular Targets

Celastrol is a naturally occurring potent inhibitor of the ►proteasome and nuclear factor kappa B (NFκB). Proteasome, or 26S proteasome, is a multicatalytic protease complex consisted of a 20S catalytic particle capped by two 19S regulatory particles. The ubiquitin-proteasome pathway is responsible for the degradation of most endogenous proteins involved in gene transcription, cell cycle progression, differentiation, senescence and apoptosis. Inhibition of the proteasomal chymotrypsin-like, but not trypsin-like activity is associated with induction of apoptosis in tumor cells.

Both computational and experimental data support the hypothesis that celastrol is a natural proteasome inhibitor. Atomic orbital energy analysis demonstrates high susceptibility of C_2 on A-ring and C_6 on B-ring of celastrol toward a nucleophilic attack. Computational modeling shows that celastrol binds to the proteasomal chymotrypsin site (β5 subunit) in an orientation and conformation that is suitable for a nucleophilic attack



Celastrol. Figure 2 Docking solution of celastrol. Celastrol was docked to S_1 pocket of β5 subunit of 20S proteasome. Celastrol was shown in pink while β5 subunit was shown in purple. The selected conformation with 92% possibility showed the distances to the OH group of N-Thr from C_6 and C_2 were 2.96 Å and 4.16 Å, respectively.

by the hydroxyl (OH) group of N-terminal threonine of β5 subunit. The distances to the OH of N-terminal threonine of β5 from the electrophilic C_6 and C_2 of celastrol are measured as 2.96 Å and 4.16 Å, respectively. Both carbons, more probably C_6, of celastrol potentially interact with N-terminal threonine of β5 subunit and inhibit the proteasomal chymotrypsin-like activity (Fig. 2).

Celastrol potently and preferentially inhibits the chymotrypsin-like activity of a purified 20S proteasome with an IC_{50} value 2.5 μM. Celastrol at 1–5 μM inhibits the proteasomal activity in intact human prostate cancer cells. The inhibition of the cellular proteasome activity by celastrol results in accumulation of ubiquitinated proteins and three natural proteasome substrates, ►IκB-α, Bax and p27, leading to induction of apoptosis in ►androgen receptor (AR)-negative PC-3 cells. In AR-positive LNCaP cells, celastrol-mediated proteasome inhibition was accompanied by suppression of AR protein, probably by inhibiting ATP-binding activity of heat shock protein 90 (Hsp90) that is responsible for AR folding. Treatment of PC-3 tumor-bearing nude mice with celastrol (1–3 mg/kg/day, *i.p.*, for 1–31 days) resulted in significant inhibition (65–93%) of the tumor growth. Multiple assays using the animal tumor tissue samples from both early and end time-points demonstrated *in vivo* inhibition of the proteasomal activity and induction of apoptosis after celastrol treatment.

Antitumor activity of celastrol was also observed in a breast cancer mouse model. Celastrol inhibited ~60% tumor growth in breast cancer xenograft through

NFκB inhibition. NFκB inhibition by celastrol includes inhibition of its DNA-binding activity and inhibition of IκBα degradation induced by TNF-α or phorbol myristyl acetate. Further investigation showed that the cysteine-179 in the IκBα kinase was a potential target of celastrol-suppressed IκBα degradation. Since the proteasome is required for the activation of NFκB by degrading IκBα, the proteasome inhibition may also contribute to the NFκB inhibition by celastrol.

TNF could send both anti-apoptotic and pro-apoptotic signals. The effects of celastrol on cellular responses activated by the potent proinflammatory cytokine TNF have also been investigated. Celastrol was able to potentiate the apoptosis induced by TNF and chemotherapeutic agents and inhibited invasion, both regulated by NFκB activation. TNF induced the expression of gene products involved in anti-apoptosis (IAP1, IAP2, ►Bcl-2, Bcl-X_L, c-FLIP, and survivin), proliferation (cyclin D1 and COX-2), invasion (MMP-9), and angiogenesis (VEGF), and celastrol treatment suppressed the expression of these genes. Celastrol also suppressed both inducible and constitutive NFκB activation. Furthermore, celastrol was found to inhibit the TNF-induced activation of IκBα kinase, IκBα phosphorylation, IκBα degradation, p65 nuclear translocation and phosphorylation, and NFκB-mediated reporter gene expression. Therefore, celastrol potentiates TNF-induced apoptosis and inhibits invasion through suppression of the NFκB pathway.

Clinical Relevance

Due to its antioxidant or anti-inflammatory effects, celastrol has been effectively used in the treatment of autoimmune diseases (rheumatoid arthritis, systemic lupus erythematosus), asthma, chronic inflammation, and neurodegenerative diseases. As a bioactive component in Chinese traditional medicinal products from the extract of the roots of *Tripterygium wilfordii Hook F,* celastrol has been used since 1960s in China for autoimmune diseases, but has showed some side effects such as nausea, vomit, *etc*. Celastrol has not been used solely as a medication product. Celastrol has anti-tumor activities *via* inhibition of the proteasome and NFκB activation, indicating that celastrol has a great potential to be used for cancer prevention and treatment. This finding can be applied to various human cancers and diseases in which the proteasome is involved and on which celastrol has an effect.

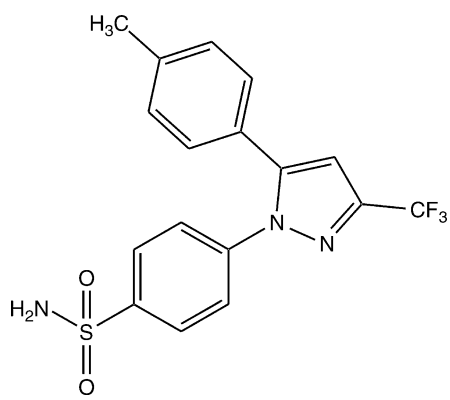
Characteristics

Celecoxib, a diaryl-substituted pyrazole drug, was developed by G. D. Searle & Company, and is currently

marketed by Pfizer Incorporated under the brand names Celebrex and Celebra. Celecoxib is a member of the class of agents known as ►non-steroidal anti-inflammatory drugs (►NSAIDs). NSAIDs are the most commonly used therapeutic agents for the treatment of acute pain, fever, menstrual symptoms, osteoarthritis, and rheumatoid arthritis. Because of their ability to reduce tissue ►inflammation, which is often associated with ►tumorigenesis at various sites in the body (e.g., gastrointestinal tract and lung), celecoxib and certain other NSAIDs are also considered to have a potential in ►cancer chemoprevention as exemplified by their ability to prevent the formation and decrease the size of polyps in ►familial adenomatous polyposis (FAP) patients. Orally administered celecoxib exhibits good systemic bioavailability and tissue distribution with an estimated plasma half-life of approximately 11 h. Celecoxib binds to plasma albumin, and is metabolized primarily by hepatic enzymes prior to excretion. In humans, long-term exposures to celecoxib taken for arthritis pain relief at 100 mg twice daily caused no biologically significant adverse reactions. However, higher doses of 400 mg twice daily recommended for patients with FAP resulted in threefold increased risk of cardiovascular events (Fig. 1).

►*Cyclooxygenase Dependent Mechanisms for Cancer Chemoprevention by Celecoxib*. Cyclooxygenases are enzymes that are indispensable for the synthesis of ►prostaglandins. Prostaglandins are ►hormones generated from ►arachidonic acid, and they are found in virtually all tissues and organs. Prostaglandins typically act as short-lived local cell signaling intermediates that regulate processes associated with inflammation. In the early 1990s, cyclooxygenases were demonstrated to exist as two isoforms, cyclooxygenase-1 (COX-1), and cyclooxygenase-2 (COX-2). COX-1 is characterized as a constitutively expressed housekeeping enzyme that mediates physiological responses like platelet aggregation, gastric cytoprotection, and the regulation of renal blood flow. In contrast, COX-2 is recognized as the inducible cyclooxygenase isoform that is primarily responsible for the synthesis of the prostaglandins that are involved in pathological processes (e.g., chronic inflammation) in cells that mediate inflammation (e.g., macrophages and monocytes). COX-2 is inducible by ►oncogenes (e.g., ►RAS and ►SRC), interleukin-1, ►hypoxia, benzo[*a*]pyrene, ultraviolet light, epidermal growth factor, ►transforming growth factor β, tumor necrosis factor α. Many of these inducers activate nuclear factor kappa B (NF-κB), which controls COX-2 expression and has been associated with tumorigenesis in various cell types.



Celecoxib. Figure 1 The chemical structure of celecoxib.

The COX-2 isoenzyme is frequently unregulated in cancer cells, as well as cells that constitute premalignant lesions, which are important targets for ►cancer chemoprevention. The expression of the inducible COX-2 is enhanced in 50% of colon adenomas and in the majority of human ►colorectal cancers, as opposed to COX-1, which typically remains unchanged. Thus, the increase in COX-2 expression, which is an early event in colon carcinogenesis, is believed to be necessary for tumor promotion. Aberrant COX-2 expression has also been implicated in tumorigenesis in the lung, ►prostate, esophagus, ►breast, ►liver, ►pancreas, and ►skin. The activity of COX-2 to produce arachidonic acid metabolites appears to enhance the proliferation of transformed cells and/or increases their survival through the suppression of ►apoptosis. Furthermore, COX-2 expression by tumor cells can stimulate ►angiogenesis at the tumor site and alter tumor cell adhesion to promote ►metastasis.

Celecoxib is a highly selective inhibitor of COX-2. Traditional NSAIDs (e.g., aspirin) inhibit both COX-1 and COX-2 isozymes. In contrast, celecoxib is approximately 20 times more selective for COX-2 inhibition compared to its inhibition of COX-1. This specificity allows celecoxib, and other selective COX-2 inhibitors, to reduce inflammation while minimizing adverse drug reactions (e.g., stomach ulcers and reduced platelet aggregation) that are common with non-selective NSAIDs. This selectivity for COX-2 is also intimately associated with the putative cancer chemopreventive activity of celecoxib, which has been demonstrated in ►colorectal cancer prevention. Epidemiological studies have shown that persons who regularly take aspirin have about a 50% lower risk of developing colorectal cancer. Celecoxib was the most effective ►NSAID in reducing the incidence and multiplicity of colon tumors in a rat colon carcinogenesis model. Moreover, in a clinical setting celecoxib has been used effectively to suppress the development and/or reduce the number of colorectal polyps in patients with FAP. This inflammatory disease often predisposes individuals to the development of ►colorectal cancers. The anti-inflammatory mediated anticancer effects of

celecoxib may be tissue-specific considering that celecoxib reduced lung inflammation in mice, but failed to inhibit the formation of chemically induced lung tumors in these animals.

Cyclooxygenase Independent Mechanisms for Cancer Chemoprevention by Celecoxib. The results of several *in vitro* and animal studies suggest the celecoxib may suppress tumorigenesis through several COX-2-independent mechanisms, which may account, at least in part, for celecoxib's anti-cancer effects in humans. For example, celecoxib inhibited the proliferation of various cancer cell types *in vitro* irrespective of their expression of COX-2, including transformed haematopoietic cells and immortalized and transformed human bronchial epithelial cells that were deficient in COX-2 expression. Celecoxib also inhibited the growth of human COX-2-deficient ►colon cancer cells that were transplanted as xenografts in nude mice. Thus, the chemopreventive effect of COX-2-specific inhibitors like celecoxib may be due to their effect on COX-2 as well as targets other than COX-2.

One putative COX-2 independent target for celecoxib is the ►phosphatidylinositol 3-kinase (PI3K) pathway, which is often deregulated in tumor cells. Celecoxib appears to directly inhibit the phosphoinositide-dependent kinase-1 (PDK1), and its downstream substrate protein kinase B/AKT, in the ►PI3K pathway. Protein kinase B/AKT inhibits apoptosis through the ►phosphorylation, and thus inactivation, of the proapoptotic ►BCL-2 family protein BAD. During apoptotic stimuli, BAD antagonizes BCL-2 and BCL-X_L activity, which can promote ►mitochondrial membrane permeabilization and cell death. The inhibition of the PI3K pathway by celecoxib is believed to be specific in its ability to promote apoptosis in transformed cells. For example, rofecoxib, another specific COX-2 inhibitor, had only marginal protein kinase B/AKT inhibitory activity in tumor cells during apoptosis induction.

Another presumed COX-2 independent target of celecoxib in tumor cells is ►sphingolipid metabolism. Celecoxib treatment increases the level of the ►sphingolipid ceramide in murine mammary tumor cells irrespective of COX-2 expression. This increase in ►ceramide was considered essential to apoptosis induction in these cells. Ceramide has been shown to mediate apoptosis in response to inflammatory cytokines like Fas and tumor necrosis factor α, and/or conditions associated with ►oxidative stress. During conditions of cell stress, the deregulation of ceramide generating and/or utilizing processes are believed to cause a net increase in cellular ceramide that is sufficient to trigger apoptosis induction via a mitochondrial membrane permeabilization mechanism.

Celecoxib treatment has also been shown to suppress the activity of the ►$Ca^{2\pm}$ ATPase located in the endoplasmic reticulum of human ►prostate cancer cells. The inhibition of the $Ca^{2\pm}$ ATPase by celecoxib disrupted Ca^{2+} homeostasis in the prostate cancer cells. This activity was highly specific for celecoxib, and was not associated with the exposure to other COX-2 inhibitors, including rofecoxib. Microsome and plasma membrane preparations from the human prostate cancer cells showed that only the $Ca^{2\pm}$ ATPases located in the endoplasmic reticulum were the direct targets of celecoxib. The disruption of Ca^{2+} homeostasis played a central role in apoptosis induction in the prostate cancer cells because it was required for the activation of Ca^{2+}-dependet hydrolyses that carried out cellular degradation. Moreover, mitochondrial membrane permeabilization, which releases cytochrome *c* to activate cell death, is sensitive to elevations in intracellular free Ca^{2+}. Consequently, the celecoxib-induced inhibition $Ca^{2\pm}$ ATPases located in the endoplasmic reticulum may provide a link to mitochondrial membrane permeabilization for apoptosis induction much in the same way that Celecoxib inhibition of the PI3K pathway can regulate BAD phosphorylation to trigger mitochondrial-mediated cell death.

It is apparent that the central hypothesis of a dominant role for COX-2 inhibition in cancer prevention by celecoxib may need re-examination. Furthermore, the COX-2 dependent and independent action of celecoxib in cancer prevention may be tissue specific. Since the aberrant expression of COX-2 is implicated in the pathogenesis of various types of human cancers, perhaps this inducible enzyme may be a useful surrogate ►biomarker of the anticancer activity of celecoxib when evaluating the chemoprevention of cancer at various sites in the body. Although the precise molecular mechanism for its chemopreventive effects are still fairly unknown, celecoxib may be still useful as a chemopreventive agent for a variety of malignancies, especially since it triggers less toxicity and adverse side effects during long-tern use when compared to traditional NSAIDs. Celecoxib may be useful when combined with other cancer chemopreventive/therapeutic agents to control the process of tumorigenesis.

Cell Adhesion Molecules

Kris Vleminckx
Department of Molecular Biology,
Ghent University, Department of Molecular Biomedical Research, VIB, Ghent, Belgium

Synonyms

Cell adhesion receptors; Adhesion molecules; CAMs

Definition

Cell ►adhesion molecules are transmembrane or membrane-linked glycoproteins that mediate the connections between cells or the attachment of cells to substrate (such as stroma or basement membrane). Dynamic cell-cell and cell-substrate adhesion is a major morphogenetic factor in developing multicellular organisms. In adult animals, adhesive mechanisms underlie the maintenance of tissue architecture, allow the generation of force and movement, and guarantee the functionality of the organs (e.g. to create barriers in secreting organs, intestines and blood vessels) as well as the generation and maintenance of neuronal connections. Cell adhesion is also an integrated component of the immune system and wound healing. At the cellular level, cell adhesion molecules do not function just as molecular glue. Several signaling functions have been attributed to adhesion molecules, and cell adhesion is involved in processes such as ►contact inhibition, growth and ►apoptosis. Deficiencies in the function of cell adhesion molecules underlie a wide variety of human diseases including cancer. By their adhesive activities and their dialogue with the ►cytoskeleton, adhesion molecules directly influence the invasive and metastatic behavior of tumor cells, and by their signaling function they can be involved in the initiation of tumorigenesis.

Characteristics

At the molecular level, cell adhesion is mediated by molecules that are exposed on the external surface of the cell and are somehow physically linked to the cell membrane. In essence, there are three possible mechanisms by which such membrane-attached adhesion molecules link cells to each other (Fig. 1a). First, molecules on one cell bind directly to similar molecules on the other cell (►homophilic adhesion). Secondly, adhesion molecules on one cell bind to other adhesion receptors on the other cell (►heterophilic adhesion). Finally, two different adhesion molecules on two cells may both bind to a shared secreted multivalent ligand in the extracellular space. Also, cell-cell adhesion between two identical cells is called ►homotypic (cell) adhesion, while ►heterotypic (cell) adhesion takes place between two different cell types. In the case of cell-substrate adhesion the adhesion molecules bind to the ►extracellular matrix (ECM).

Cell Adhesion Molecules and the Cytoskeleton

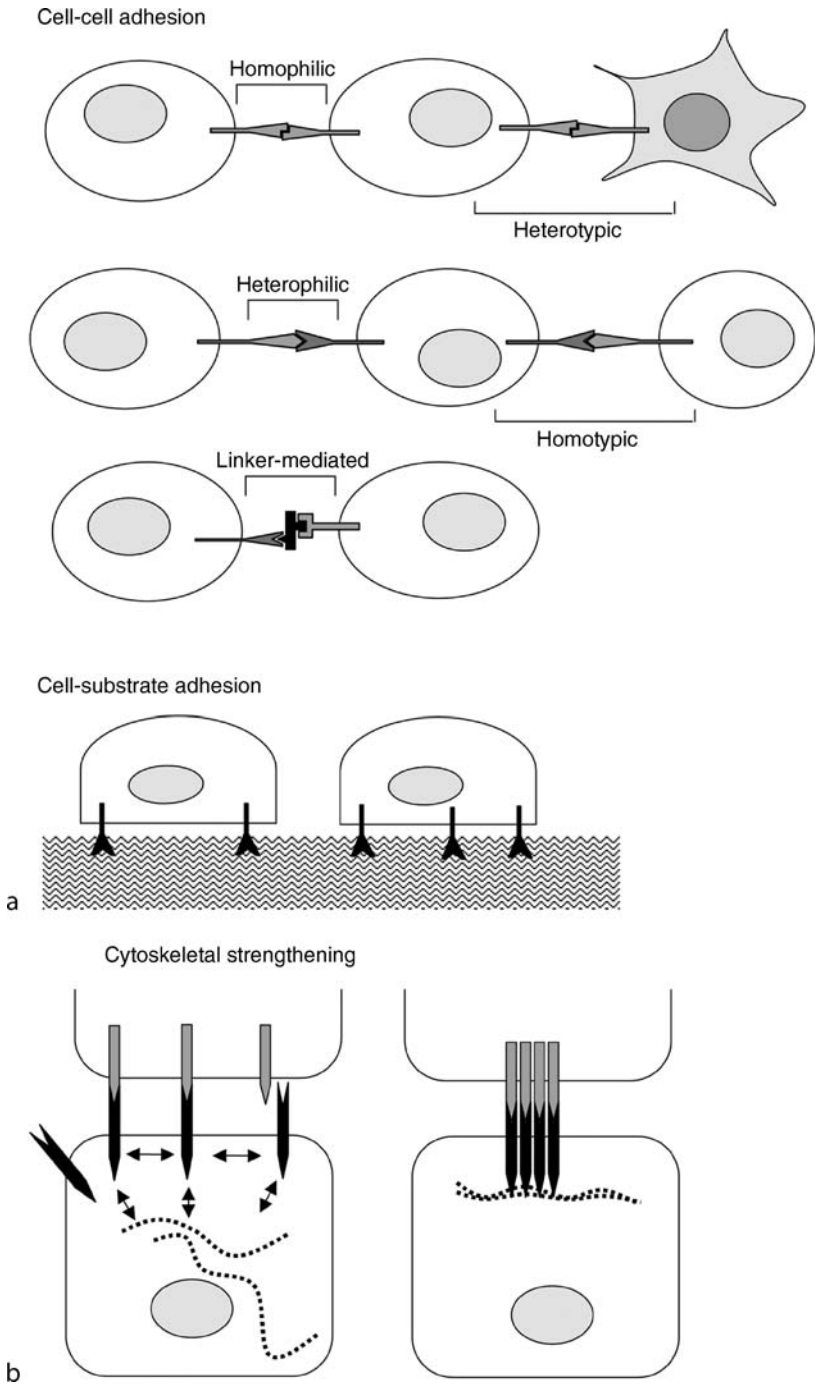
Adhesion molecules can be associated with the cell membrane either by a glycosylphosphatidyl-inositol (GPI) anchor or by a membrane-spanning region. In the latter case the cytoplasmic part of the molecule often associates indirectly with components of the cytoskeleton (e.g. actin, intermediate filaments or submembranous cortex). This implies that adhesion molecules, which by themselves establish extracellular contacts, can be structurally integrated with the intracellular cytoskeleton, and they are often clustered in specific restricted areas in the membrane, the so-called ►junctional complex (Fig. 1b). This combined behavior of linkage to the cytoskeleton and clustering, considerably strengthens the adhesive force of the adhesion molecules. In some cases, exposed adhesion molecules can be in a conformational configuration that does not support binding to its adhesion receptor. A signal within the cell can induce a conformational change that activates the adhesion molecule. Dynamic adhesion can also be mediated via regulated endocytosis of the adhesion molecules. These mechanisms of regulation allow for a dynamic process of cell adhesion that, amongst others, is required for morphogenesis during development and for efficient immunological defense.

Classification of Cell Adhesion Molecules

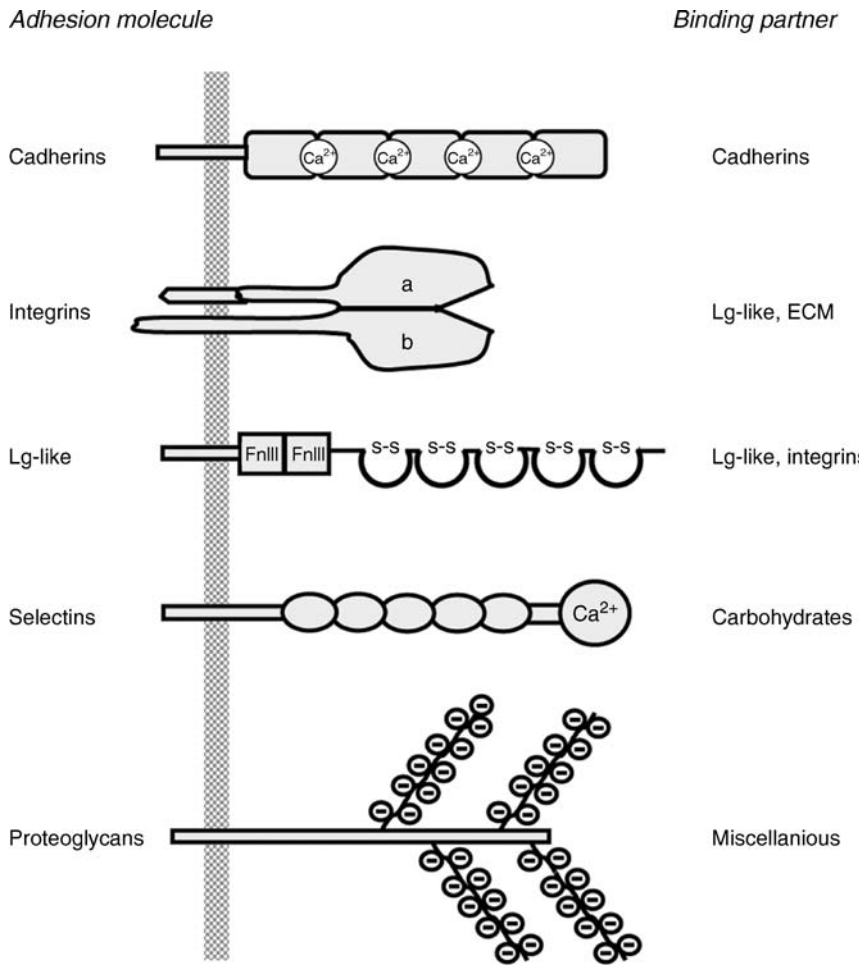
Based on their molecular structure and mode of interaction, five classes of adhesion molecules are generally distinguished; the ►cadherins, ►integrins, immunoglobulin (Ig) superfamily, selectins and ►proteoglycans (Fig. 2).

Cadherins

Cadherins and proto-cadherins form a large and diverse group of adhesion receptors. They are Ca2+-dependent adhesion molecules, involved in a variety of adhesive interactions both in the embryo and the adult. Cadherins play a fundamental role in metazoan embryos, from the earliest gross morphogenetic events (e.g. separation of germ layers during gastrulation) to the most delicate



Cell Adhesion Molecules. Figure 1 Different modes of cell-cell and cell-substrate adhesion and the mechanism of cytoskeletal strengthening. (a) Three possible mechanisms by which cell adhesion molecules mediate intercellular adhesion. A cell surface molecule can bind to an identical molecule (homophilic adhesion) on the opposing cell or can interact with another adhesion receptor (heterophilic adhesion). Alternatively, cell adhesion receptors on two neighboring cells can bind to the same multivalent, secreted ligand (linkermediated adhesion). Intercellular adhesion can take place between identical cell types (►homotypic adhesion) or between cells of different origin (►heterotypic adhesion), independently of the involved adhesion molecules. Cell-substrate adhesion molecules attach cells to specific compounds of the extracellular matrix. Cell-cell and cell-substrate adhesion can occur simultaneously. (b) Intercellular and cell-substrate adhesion can be strengthened by indirect intracellular linkage of the cytoplasmic tail of the adhesion molecules to the cytoskeleton and by lateral clustering in the membrane.



Cell Adhesion Molecules. Figure 2 The five major classes of cell adhesion molecules and their binding partners. Cadherins are Ca2+-dependent adhesion molecules that consist of a varying number of cadherin repeats (five in case of the classical cadherins). The conformation and activity of cadherins is highly dependent on the presence of Ca2+-ions. In general, cadherin binding is homophilic. Integrins are functional as heterodimers and consist of an a- and b-subunit. They interact with members of the immunoglobulin superfamily or with compounds of the extracellular matrix (e.g. fibronectin, laminin). Members of the immunoglobulin superfamily (Ig-like proteins) are characterized by a various number of immunoglobulin-like domains (open circles). Membrane-proximal, fibronectin type III repeats are often observed (gray boxes). They can either bind to other members of the Ig-family (homophilic) or to integrins. Selectins contain an N-terminal Ca2+-dependent lectin domain (circle) that binds carbohydrates, a single EGF-like repeat (gray box) and a number of repeats that are related to those present in complement-binding proteins (ovals). Proteoglycans are huge molecules that consist of a relatively small protein core to which long side chains of negatively charged glycosaminoglycans are covalently attached. They bind various molecules, including components of the extracellular matrix.

tunings later in development (e.g. molecular wiring of the neural network). The extracellular part of vertebrate classical cadherins consists of a number of cadherin repeats whose conformation is highly dependent on the presence or absence of calcium ions. Homophilic interactions can only be realized in the presence of calcium, usually by the most distal cadherin repeat. Classical cadherins are generally exposed as homodimers, and their cytoplasmic domain can be structurally or functionally associated with the actin cytoskeleton. Cadherins are the major adhesion molecules in tissues that are subject to high mechanical stress such as epithelia (►E-cadherin) and endothelia (VE-cadherin). However, finer and more elegant intercellular interactions, such as synaptic contacts, also involve cadherins.

Integrins

Integrins are another group of major players in the field of cell adhesion. They are involved in various processes

such as morphogenesis and tissue integrity, homeostasis, immune response and inflammation. Integrins are a special class of adhesion molecules, not only because they mediate both cell-cell and cell-substrate interactions (with components in the ECM such as laminin, fibronectin and collagen) but also because they function as heterodimers consisting of an α- and β-subunit. To date, at least 16 α-subunits and 8 β-subunits have been indentified. Of the theoretical 128 heterodimeric pairings, at least 21 are known to exist. While most integrin heterodimers bind to ECM components, some of them, more particularly those expressed on leukocytes, are heterophilic adhesion molecules binding to members of the Ig superfamily. The α-subunit mostly contains a ligand-binding domain and requires the binding of divalent cations (Mg2+, Ca2+ and Mn2+, depending on the integrin) for its function. Interestingly, integrins may be present on the cell-surface in a non-functional and a functional configuration. The cytoplasmic domain appears to be responsible for the conformational change that activates the integrin.

The Ig Superfamily

Among the classes of adhesion molecules discussed here, the Ig superfamily is probably the most diverse. The main representatives are the neural cell adhesion molecules (NCAMs) and V(ascular)CAMs. As the name suggests, the members of this family all contain an extracellular domain consisting of different immunoglobulin-like domains. NCAMs sustain homophilic and heterophilic interactions that play a central role in regulation and organization of neural networks, specifically in neuron-target interactions and fasciculation. The basic extracellular structure consists of a number of Ig domains, which are responsible for homophilic interaction, followed by a discrete number of fibronectin type III repeats. This structure is linked to the membrane either by a GPI anchor or a transmembrane domain. The VCAM subgroup, including I(ntercellular) CAMs and the mucosal vascular addressin adhesion molecule (MAdCAM), are involved in leukocyte trafficking (or homing) and extravasation. They consist of membrane-linked Ig domains that make heterophilic contacts with integrins. Other members of this family that are associated with cancer are carcinoembryonic antigen (►CEA), "deleted in colon cancer" (DCC) and platelet endothelial (PE)CAM-1.

Selectins

These types of adhesion molecules depend on carbohydrate structures for their adhesive interactions. Selectins have a C-type ►lectin domain, that specifically binds to discrete carbohydrate structures present on cell-surface proteins. Intercellular interactions mediated by selectins are of particular interest in the immune system, where they play a fundamental role in trafficking and homing of leukocytes.

Proteoglycans

Proteoglycans are large extracellular proteins consisting of a relatively small protein core to which long chains of glycosaminoglycans are attached. Although poorly documented, proteoglycans may bind to each other or may be the attachment site for other adhesion molecules.

Role of Adhesion Molecules in Cancer

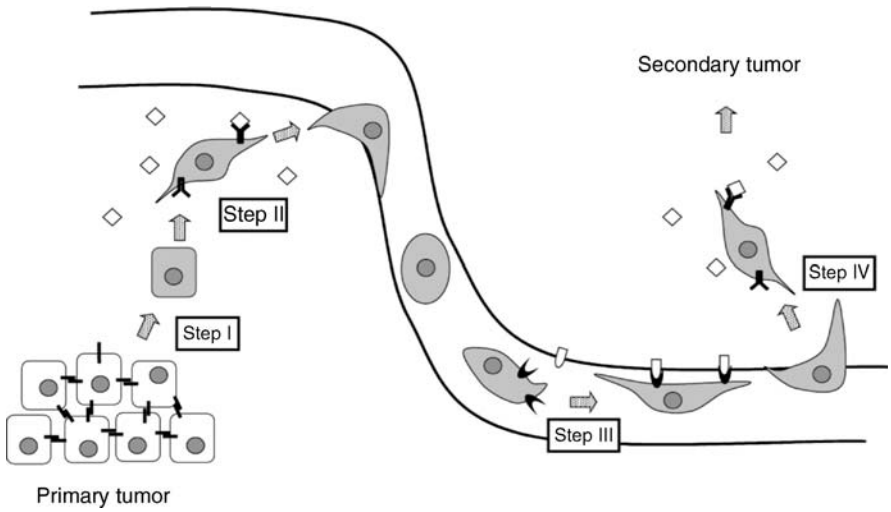
The Metastatic Cascade

Cell adhesion molecules play an important role during the progression of tumors, more particularly in the metastatic cascade (Fig. 3). When a benign tumor becomes malignant, cells at the periphery of the tumor will lose cell-cell contact (step I) and invade the surrounding stroma (step II) (see also ►invasion). Cells then extravasate and enter the vasculature or lymphatic system, where they are further transported. A fraction of the circulating tumor cells survives and is arrested at a distant site, attaches to the endothelium (step III) and extravasates through the blood vessel wall and into the surrounding tissue (step IV). Here the tumor cells grow, attract blood vessels and develop to a secondary tumor (►metastasis).

Adhesive Events in Metastasis

All the classes of cell adhesion molecules play a role in the metastatic cascade. During the first step, tumor cells need to disrupt intercellular junctions in order to detach from the primary tumor. This step often involves suppression of cadherin function. The second step of ►migration through the stroma and into the blood or lymphatic vessels requires dynamic cell-substrate adhesion, mostly mediated by integrins. In the third step, where cells arrest in the circulation by aggregation with each other or attachment to platelets, leukocytes and endothelial cells, critical roles have been attributed to cell adhesion molecules of the Ig superfamily, selectins, integrins and specific membrane-associated carbohydrates. The fourth step is similar to step II and mostly involves integrins. Details on the adhesive events associated with metastasis are outlined below.

- In benign epithelial tumors, cells maintain firm intercellular adhesive contacts, mostly by formation of a junctional complex (including tight junctions, ►adherens junctions and desmosomes). Establishment and maintenance of such a strong junctional complex requires expression and function of cadherins (more particularly E-cadherin). Loss of E-cadherin expression or function appears to be a hallmark of progression of a benign epithelial tumor (adenoma)



Cell Adhesion Molecules. Figure 3 Cell adhesion processes involved in the metastatic cascade. A subset of cells (gray) growing in a primary tumor will reduce cell-cell contacts (Step I) and migrate in the surrounding stroma by increasing specific cell-substrate adhesion (Step II). These invasive tumor cells can extravasate into the circulation and, at distant sites, attach to the endothelial blood vessel wall through specific cell-cell interactions (Step III). Once these cells have extravasated through the vessel wall they use cell-substrate adhesion molecules to invade the surrounding stroma (Step IV). See text for details.

to a malignant one (carcinoma). Epithelial tumor cells often acquire invasive properties by mutational inactivation of E-cadherin or one of its cytoplasmic binding partners (catenins). It is important to keep in mind that cadherin-mediated adhesion is a dynamic process and that E-cadherin can be temporarily inactivated at the functional level, for example by phosphorylation or other posttranslational modifications. E-cadherin and other molecules of the junctional complex are very often suppressed or functionally modulated in the epithelial-mesenchymal transitions (EMT), a hallmark of malignant tumor progression. EMT can be a tumor-intrinsic feature or can be induced by their microenvironment. Paracrine factors such as scatter factor or juxtacrine signaling via Ephrin/Eph receptor or via Semaphorins/plexins can affect adhesion via direct activity on the cell adhesion molecules or via regulation of the cytoskeleton.

- Dynamic cell-substrate adhesion is a critical factor in the migration of invasive tumor cells into the surrounding stroma. Integrins are instrumental in this process. Several studies have correlated the migratory behavior of tumor cells either with an increased or decreased expression of particular integrins. This apparent paradox may be explained by the fact that firm but temporary cell-substrate contacts are required for cells to migrate on a substrate. In order to crawl directionally through the stroma, a cell needs to "grab" the ECM, release after pulling itself forward and then has to establish the next contact. Both inhibiting adhesion and preventing release of the substrate contacts "locks" the cell in its position and prevents migration. It should be remembered that integrins may exist in two functional states and that signals passed through the cytoplasm determine whether membrane-exposed integrins are functional or not.
- In the third step of the metastatic cascade, cell-cell interactions are again the most determining. Homotypic interactions between circulating tumor cells promote formation of aggregates that are preferentially retained in the capillary network. PECAM-1 is a cell adhesion molecule potentially involved in this process. It should be pointed out that (re)expression of the invasion-suppressor molecule E-cadherin would actually promote metastasis formation. Besides these homotypic interactions, heterotypic interactions are also of major importance in the metastatic process. Tumor cells can attach to the blood-vessel wall either directly or indirectly through platelets and leukocytes. The adhesion molecules involved in this process are similar to those involved in the "multistep adhesion cascade" observed during homing and extravasation of leukocytes or trafficking of lymphocytes. Cell adhesion events include interactions of tumor-associated lectins with selectins expressed on platelets, leukocytes and endothelium (P-, L- and ►E-selectins, respectively). These adhesion molecules are also involved in the initial transient low-affinity interactions (rolling) of circulating leukocytes (and probably tumor cells) with the endothelium. Other and

more stringent heterotypic heterophilic interactions in this metastatic stage include the binding of integrins on tumor cells to ICAMs expressed on the surface of the endothelial cells.
- The fourth step in the metastatic cascade is extravasation and invasion at a distant site. This process is very similar to step 2 and the same adhesion molecules are likely to be involved. Specific interactions of the tumor cells with molecules present on the endothelial cells (e.g. N-cadherin) will facilitate the extravasation process.

Other Cancer-Related Functions of Cell Adhesion Molecules

Recently, it has become clear that some cell adhesion molecules are involved in signaling processes that are relevant to cancer. Germline mutations in E-cadherin predispose patients to the development of diffuse gastric carcinomas, and in lobular breast carcinoma E-cadherin seems to act as a tumor suppressor. Interestingly, β-catenin, a protein cytoplasmically linked to cadherins, has a central role in ►Wnt signaling and has oncogenic properties that are counteracted by the adenomatous polyposis coli (►APC) gene product. Signaling by integrins can also be an important factor that prevents cells from undergoing apoptosis (apoptosis upon loss of cell adhesion is called ►anoikis), which might be critical when tumor cells are traveling in the circulation. Interdisciplinary research has revealed new unexpected functions for known cell adhesion molecules. The suspected tumor suppressor DCC, a member of the Ig superfamily of adhesion molecules, turned out to be the receptor for netrin-1, an axonal chemoattractant crucial in neuronal development. Other molecules known to have adhesive or repulsive activities in the axonal growth cone or in migrating neural crest cells, turn out to have similar activities in tumor cells (see also the chapters on ►EPH receptors, ►Ephrin signaling in cancer, ►Semaphorins and ►Plexins).

Definition

Cell biology deals with all aspects of the normal and of the tumor cell, their normal and abnormal multiplication, their differentiation, their stem origins, and their regulated cell death.

Characteristics

The Cell

The intracellular environment is separated from the external environment by a lipid bilayer called plasma membrane. The plasma membrane controls the movement of substances in and out of the cell and it is important for the cell to sense the surrounding environment. Within the cell the nucleus occupies most of the space. The cell nucleus contains genes, which drive all cellular activities and processes. Genes are organized in chromosomes (i.e., genome) and are made of DNA. The genetic information is used to produce proteins, which are the critical effectors required for all cellular processes. The nucleus is separated from the rest of the cellular content by the nuclear membrane,

which remains in contact with the cytoplasm as well as the nucleoplasm. In the cytoplasm, proteins are organized into specific functional structures and also connected with the structural network referred to as cytoskeleton network, which physically sustains the cell. Moreover several intracellular organelles are located in the cytoplasm (e.g., mitochondria, Golgi apparatus) and allow the cells to self sustain. To continuously adjust the intracellular processes and to promptly respond to the demands of the extracellular environment, cells need to exchange matter, energy, and information with the external milieu.

Cell Division and Reproduction

One of the unique features of cell is its ability to divide and produce two daughter cells that are an exact copy of their parental cell, by a process called "mitosis." However, some differentiated cells undergo the process of meiosis. For simplicity, meiotic division can be considered as the sum of two successive mitotic divisions, which result in four daughter cells with half the number of chromosomes and rearranged genes. These specialized cells (i.e., gametes) serve as reproductive cells. The fusion of the female and male gametes (eggs and spermatozoa, respectively) results in a new cell called zygote. The zygote, by definition, is a stem cell. Following mitotic division, it becomes an embryo and, at the end of the embryonic development, results in a new organism.

Cell Proliferation

The physiological functions of an organ require maintenance of homeostasis, a process of regulated balance between cell proliferation and cell death (also known as ►apoptosis), in the differentiated tissue. Indeed, a variety of extracellular stimuli activate specific ►signal transduction pathways that affect the expression and activity of molecules involved in the control of cell proliferation or cell death. Thus, the balance between ►cell cycle progression and apoptosis defines the cell fate, and this process depends on genetic factors as well as the kinetics of signal transduction pathways in exponentially growing cells.

Cell Cycle

In mammalian cells, one cell cycle takes about 24 h in most cell types and can be schematically divided into two stages: mitosis and interphase. Mitosis (M phase) consists of a series of molecular processes that result in cell division. On the other hand, the interphase can be subdivided into three major gaps (G1, S, and G2 phase). The G1 phase of the cell cycle separates the M and S phases. In G1 phase, cells express a specific pattern of gene products required for the DNA synthesis; the G2 phase of the cell cycle resides in between the S and M phases and is important for the completion of processes that are necessary for mitosis. The G0 phase of the cell cycle is entered by the cells from the G1. In the G0 phase, cells are out of the cell cycle and into a quiescent state where they do not proliferate.

Regulation of Cell Cycle Progression

Cell cycle progression is achieved through a series of coordinated molecular events that allow the cells to transit across the restriction points, also known as cell cycle checkpoints. There are three main restriction points in the cell cycle (G2/M, M/G1, and G1/S, respectively). Broadly, these checkpoints are defined as points after which the cell is committed to progress to the next phase in a nonreversible manner. Therefore, the transition between the phases of the cell cycle is strictly regulated by a specific set of proteins. ►Cyclin-dependent kinases (CDK) act in various phases of the cell cycle by binding to its activating proteins called cyclins. For example, both ►cyclin D/CDK4 and cyclin E/CDK2 complexes regulate transition of the cells through G1/S phase whereas cyclin A/CDK1, cyclin A/CDK2, and cyclin B/CDK1 complexes are active during the rest of the cell cycle. On the other hand, another class of regulatory proteins, the cyclin-dependent kinase inhibitors (CKI) (e.g., $p21^{Cip/Kip}$; $p19^{Ink4d}$) antagonizes the activation of CDK activity, thus impeding the progression of the cell cycle.

Programmed Cell Death

Programmed cell death (PCD) is a physiological process of eliminating a living cell. The PCD involves activation of specific intracellular programs that commit cells to a "suicidal route." The process of PCD plays an important role in a variety of biological events, including morphogenesis, maintenance of tissue homeostasis, and elimination of harmful cells. To date, different forms of PCD have been described among which apoptosis, necrosis, and ►autophagy are the most common.

Apoptosis

One of the critical events in apoptosis is the activation of cystein proteases, called caspases, upon a given signal. The initiator caspases (►Caspase 8 and 9) are the first enzymes involved in the activation of the apoptotic cascade. Caspase 8 and 9 activate the downstream effector caspases (caspase 3, 6, and 7) by proteolytic cleavage which in turn results in the hydrolysis and inactivation of the enzymes involved in the processes of DNA repair such as by poly-ADP-ribose polymerase (PARP). Upon stimulation of apoptotic cascade, cells display a specific set of characters, which constitute the hallmark of apoptosis (DNA fragmentation, cell shrinkage, cytoplasmic budding, and fragmentation). The activation of caspases

is achieved through two principle pathways – an extrinsic pathway that transduces signals from the plasma membrane directly to the caspases, and an intrinsic pathway that involves activation of caspases through a series of biochemical events leading to permeabilization of the mitochondrial membrane and release of cytochrome c (►Cytochrome P450) in the cytoplasm. Apoptotic cells are eventually eliminated by the immune system without the activation of inflammatory reactions (►Inflammation).

Necrosis

Necrosis results from a severe physical, mechanical, or metabolic cellular damage. The necrotic phenotype is very different from those of an apoptotic cells. Overall, the cell switches off its metabolic pathways and the DNA condenses at the margins of the nucleus and the cellular constituents start to degrade. In general, necrosis consists in a general swelling of the cell before it disintegrates. Furthermore, upon leakage of the intracellular content, necrotic cells stimulate an inflammatory response that usually damages the surrounding tissue.

Autophagy

Autophagy, i.e., autophagic cell death, occurs by sequestration of intracellular organelles in a double membrane structure termed autophagosome. Subsequently, the autophagosomes are delivered to the lysosomes and degraded. Autophagy is responsible for the turnover of dysfunctional organelles and cytoplasmic proteins and thus, contributes to cytosolic homeostasis. Autophagy can occur either in the absence of detectable signs of apoptosis or concomitantly with apoptosis. Indeed, autophagy is activated by signaling pathways that also control apoptosis.

Signal Transduction

Extracellular signals are transduced by the activation of a series of phosphorylation-dependent intracellular pathways initiated by cell surface receptors. Eventually, such signals feed into the nucleus, stimulate transcription factors, and regulate gene transcription.

Signaling Targets

Signaling pathways regulate gene transcription by triggering the promoter activity of the target gene. For example, regulation of cyclin D is critical for cell cycle progression. The extracellular signal-mediated activation of specific signal transduction pathways stimulates the activity of transcription factors such as AP-1, SP-1, and NF-κB, which coordinate the activation of the cyclin D1 promoter and thus lead to cyclin D1 expression. On the other hand, signaling molecules can also change the activity of a preexisting protein. For example, activation of p21-activated kinase (PAK) induces the phosphorylation of phosphoglucomutase (PGM) that stimulates its enzyme activity and the phosphorylation of ►estrogen receptor alpha (ERα) thus inducing its transcriptional activity. One of the most studied signaling pathways is the extracellular-regulated kinase (ERK) (►MAP kinase) cascade. It consists of three steps of sequential phosphorylations that impact on diverse cellular effectors. The ERK cascade is activated by mitogenic stimuli (e.g., growth factors (►Fibroblast growth factors)) and plays a critical role both in cell proliferation and cell survival. Indeed, activation of ERK induces the activation of AP-1 transcription factor, which, in turn, regulates cyclin D1 expression in addition to many of other proliferative molecules. Further, ERK activity leads to an increased expression of the antiapoptotic protein ►Bcl-2 and inactivation of the proapoptotic protein ►Bad. Conversely, the JNK/SAPK (►JNK subfamily and cancer) and the p38/MAPK (MAP kinase) pathways mediate stress and apoptotic stimuli (e.g., UV, ischemic-reperfusion damage). Activation of JNK/SAPK and p38/MAPK often results in an increased expression of proapoptotic proteins (e.g., Bax), and in the activation of the caspase cascade and cytochrome c release from the mitochondria.

Systems Biology

Systems biology represents a new analytical tool that has begun to emerge for balanced comprehensive analyses of cellular pathways at the level of genes and proteins. Signal transduction pathways often cross-talk and influence each other, and the functionality of the effector molecule is influenced by the overall outcome of a set of signaling pathways. Thus, cells form a web of intracellular interactions that are critical for a timely and dynamic response. The intracellular signaling network is considered a complex system rapidly adapting to extracellular challenges. Therefore, an additional level of complication is the evaluation of the network as a whole, rather than the individual pathway.

Cell Motility and Migration

►Motility and ►migration are important components for the functionality of a variety of cell types, and are involved in physiologic processes such as embryonic development, immune response, as well as in pathologic processes such as ►invasion and ►metastasis. Cell motility and migration are coordinated physiological processes that allow the cells to move or to invade the surrounding tissues, respectively. They occur as a result of a complex interplay between the focal ►adhesion sites (cell-to-substrate contacts) and the ►extracellular matrix (ECM) (substrate). Phenotypically, migratory cells develop motile structures such as pseudopodia, lamellipodia, and filopodia. An ordered sequence of events (protrusion of motile structures, formation and disruption of focal contacts) generate the traction forces

that drive the cell movement. Moreover, when migration is required, cells secrete specific proteolytic enzymes (matrix metalloproteinases, MMPs) that digest the ECM, thus opening a passage across the substrate. Cytoskeleton is critical for the correct occurrence of cell motility and migration.

Cytoskeleton

Cytoskeleton is a network of cytoplasmic proteins, which define the cell "bones." Many different protein filaments are important for cytoskeleton functions. In particular, microtubules, built from different types of tubulin, originate from specific intracellular structures called microtubules organizing centers (MTOC). Dynamic changes in the polymerization and depolymerization of tubulin maintain microtubule integrity and resulting functions. Furthermore, actin microfilaments form a network of cytoskeleton-associated proteins and connect the focal adhesion with the intracellular cytoskeleton. The dynamic remodeling of microtubules and microfilaments has an impact on cell motility, migration and cell–cell adhesion, ►endocytosis, intracellular trafficking, organelle function, cell survival, gene expression, and cell division.

Signaling Regulation

At the focal adhesion sites, cells accumulate receptors (e.g., growth factor receptors), adaptors (e.g., vinculin), and signaling molecules, as well as structural and motor proteins (e.g., actin, myosin). Migration-specific stimuli (e.g., integrins engagement of ECM, growth factor stimulation, and mechanical stimuli) activate specific biochemical pathways. ►Focal adhesion kinase (FAK), integrin-linked kinase (ILK), PAK, and ►Src play key roles in modulating cell migration and invasion. The FAK/Src complex regulates the assembly and disassembly of focal contacts, F-actin cytoskeleton remodeling, and the formation of lamellipodia and filopodia through the activation of specific downstream cytoskeleton-associated signaling pathways. Further, ILK is also implicated in cell motility and migration by linking integrins with cytoskeleton dynamics through the ►PI3K signaling pathway. Also, PAK1 dynamically regulates cytoskeletal changes by coordinating upstream signaling with multiple effectors. By acting on actin reorganization, PAK1 drives directional cell motility and migration.

Tumor Biology

Cancer is a progressive disease that arises from the clonal expansion of a single transformed cell into a mass of uncontrolled proliferating cells. Tumorigenesis is a multistep process and involves progressive conversion of a normal cell into a malignant cell, which subsequently invades the surrounding tissues. The process of tumorigenesis consists of major steps (initiation, promotion, and progression), each involving specific molecular mechanisms, often interlaced with each other, that drive tumor development.

Initiation and Promotion

In general, initiation of tumorigenesis is referred to as the first oncogenic stimulus. However, such as initial event is not sufficient for tumor induction. In most cases, a second oncogenic stimulus must occur in a restricted time frame, thus promoting an irreversible effect. Chemical (e.g., aromatic compounds (►Polycyclic aromatic hydrocarbons)), physical (e.g., ►UV radiation), as well as biological (e.g., viruses as ►human papillomavirus) stress have impact on the cells and can induce DNA mutations (e.g., point mutations). In addition, gene deletion or duplication also alters gene function and contributes to the process of tumorigenesis. These genomic changes result in the production of proteins with altered functions or in the overexpression or downregulation of specific proteins, which affects the associated cellular functions.

Protooncogenes or oncogenes are genes that encode for proteins involved in the induction of cell proliferation (e.g., *cyclin D1*, *CDK*, *EGFR*, *Src*, *Ras*, etc.) and whose overexpression or hyperactivation leads to an uncontrolled cell proliferation. On the other hand, tumor suppressor genes are genes encoding for proteins that negatively regulate cell proliferation (e.g., *p53*, *PARP*, *CKI*, etc.). Inactivating mutations or downregulation of tumor suppressor genes are also critical for enhanced cell proliferation. In addition to DNA damage, oncogenes and tumor suppressor genes, abnormal changes in the epigenetic cellular information (e.g., DNA► methylation) can also participate in clonal evolution of human cancers.

Progression

The modified balance between the growth-inhibitory programs and proliferative networks allow the cell to escape the physiological growth restrains. These selective growth advantages produce a population of more aggressive or transformed cells that resist clearance by the immune system (i.e., immune defense escape), and in turn, contributes to the accumulation of additional mutations and eventually, in tumor growth. In this context, an in situ tumor develops, that is the uncontrolled mass of transformed cells stays within the limit of the tissue in which the first cell resided. During this phase, tumor volume increases in parallel with an increased dedifferentiation of the cells that also secrete angiogenic factors (►Angiogenesis) to promote blood vessels formation in the tumor.

Metastasis

Metastasis is the process by which highly vascularized tumor cells acquire the ability to invade the

blood-stream and seed in distant organs. Deregulation of cytoskeleton-associated proteins and secretion of protein factors play a critical role in the functionality of the metastatic cells.

Stem Cell Biology

In 1998, the group of Prof. James Thomson reported the isolation of a human embryonic stem cell line from the blastocyst stage of a human embryo. This cell line showed stability in a specifically developed culture medium and, upon transplantation in the nude mice, had the ability to form tumor-like structures made up of all the major human tissue types. This pioneer study opened the field of stem cell biology. Since then, enormous research efforts have been focused on the understanding of stem cell biology as well as their potential medical and therapeutic implications. Nonetheless, although the last 10 years witnessed an enormous progress, the field of stem cell research is in its infancy. The first controversy is the definition of stem cell itself. For simplicity, a stem cell is a clonal self-renewing entity that is multipotent and can generate several different cell types. This definition introduces three major characteristic of the stem cells: self-renewal, clonality, and potency.

Self-Renewal and Clonality

Self-renewal is the process by which a stem cell undergoes an asymmetric mitotic division that produces, rather than two identical daughter cells, one cell that is completely identical to the parental stem cell and another cell that is already committed to a more restricted developmental path and more specialized abilities. Thus, stem cells have both the ability to self-maintain their clonal cell population and to produce a population of clones with more differentiated characteristics. In this way, stem cells form a hierarchy of potency.

Potency

Stem cells have the ability to give rise to a population of daughter stem cells with a reduced differentiation. The totipotent cells are the first embryonic cells that can become any kind of cell type (e.g., zygote). These cells become pluripotent cells, which can differentiate in most but not all cell types (e.g., embryonic stem cells). Next, cells that are committed to produce only a certain lineage of cell types (e.g., ►adult stem cells) are the multipotent cells. Some multipotent cells can only generate one specific kind of terminally differentiated cell type and thus, such cells are called unipotent cells.

Environmental Regulation

The molecular mechanism by which regulatory processes occur in stem cells are not clear but are believed to be tightly regulated to avoid imbalance in stem cell population or mutation that can lead to tumorigenesis. One possibility is that the asymmetric division produces two daughter cells and, because of intrinsic factors, such cells follow different fates in spite of residing in the same ►microenvironment. Alternatively, the two daughter cells become functionally different because they are exposed to different extrinsic factors. Most likely, both intrinsic and extrinsic factors are integrated in the milieu of the surrounding microenvironment, also known as the stem cell niche. Signals from the niche determine the type of gene regulation that allows the asymmetric division to take place. In this model, one daughter cell stays in the niche and the other one moves out. Indeed, the importance of the microenvironment in stem cell biology is highlighted by the ability of a particular stem cell to transdifferentiate or to dedifferentiate when put in a different niche. Although the concept of plasticity is debated in the literature, it is part of the "stemness" of a cell, which is the hallmark for a cell to be defined as a stem cell.

Social Implications

The ability to scientifically manipulate the human embryo or human adult stem cells has opened new perspectives for treatment of several human diseases. However, it has also initiated intense philosophical and political debates on the ethical issues associated with the use of such potential tools in medical practice.

Cell Block

Definition

Consists of a paraffin block made from the cellular material of cytologic specimens (most commonly fine needle aspiration biopsies and body fluids) and is processed similar to histology. Can be a useful adjunct in cytology because it gives a better idea of tissue

architecture and allows for multiple sections for ancillary stains.

►Fine Needle Aspiration

Cell Cycle

Definition

The sequence of cellular transformations that accompany transition from one mitotic cell division to another. The cell cycle is composed of four phases known as G1, S, G2 and M. S is the period of DNA synthesis, M is mitosis when sister chromatids are condensed and segregated to two daughter cells. G1 lies between M and S and is a phase of preparation for DNA synthesis, G2 is between S and M and is a phase of preparation for mitosis. G_0 refers to a quiescent state into which some cells in multicellular organisms enter from G_1. Cells typically achieve full differentiation in the G_0 phase.

Cell-Cycle Checkpoint

Definition

The cell-cycle checkpoint is a mechanism for stopping progression through the cell cycle when a key event, such as DNA replication, is not completed or when the genome is damaged. It is a restriction point during the cell cycle in which a cell monitors if preceding events required for cell division have been correctly completed. It is a regulatory mechanisms that monitors the progression of the cell cycle, so that one phase is not started before another has finished. The activation of checkpoints, for example by damaged DNA, arrests cell cycle progression.

Cell-Cycle Targets for Cancer Therapy

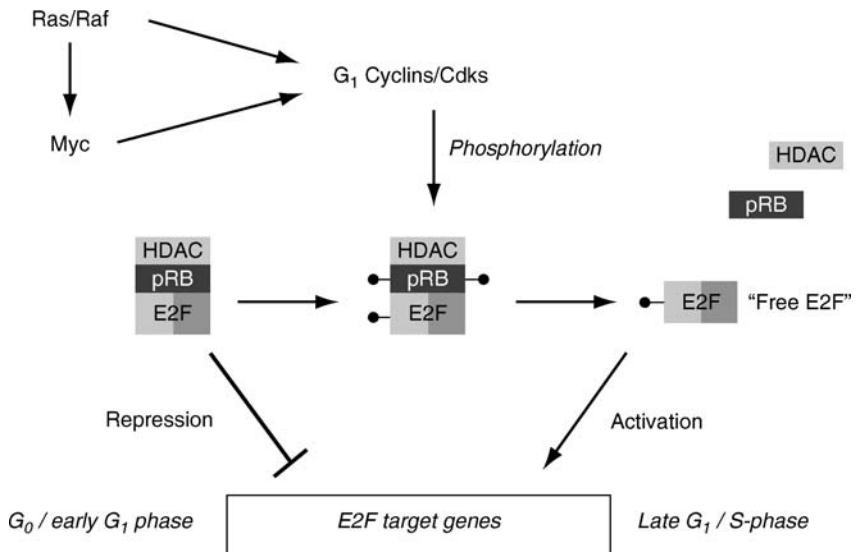
Rolf Müller
Institute of Molecular Biology and Tumor Research (IMT), Philipps-University Marburg, Marburg, Germany

Definition

Knowledge of the molecular mechanisms governing the mammalian ►cell cycle and their dysfunction in cancer cells has grown considerably in the last decade. It is now clear that the cell utilizes two distinct kinds of regulatory mechanisms to control cell-cycle progression: while progression past the ►restriction point in late G1 is solely governed by extracellular signals, ►checkpoints sense cellular damage or dysfunctions that are not compatible with a proper cell division, such as DNA damage. The detailed knowledge of the underlying molecular mechanisms, pathways and molecules provides the basis for a new approach to cancer therapy.

Characteristics

Cell-cycle progression in mammalian cells is controlled through fundamentally different regulatory pathways. Progression through G1 across the restriction point (R-point) is controlled by external signals that are transmitted, for example, by mitogens or through cell adhesion processes. Beyond this point, cell-cycle progression is governed by a genetic program that is largely independent of extracellular signals but regulated by internally controlled checkpoints. These checkpoints ensure proper DNA replication, DNA integrity, progression through G2 and mitosis. A central role in cell-cycle progression is exerted by the ►cyclin-dependent kinases (CDKs), which are composed of a regulatory cyclin subunit (e.g., cyclin A, B, D or E) and a catalytic kinase subunit (e.g., CDK1, 2, 4 or 6). The activity of CDKs is controlled by phosphorylation, phase-specific expression and proteolysis as well as the

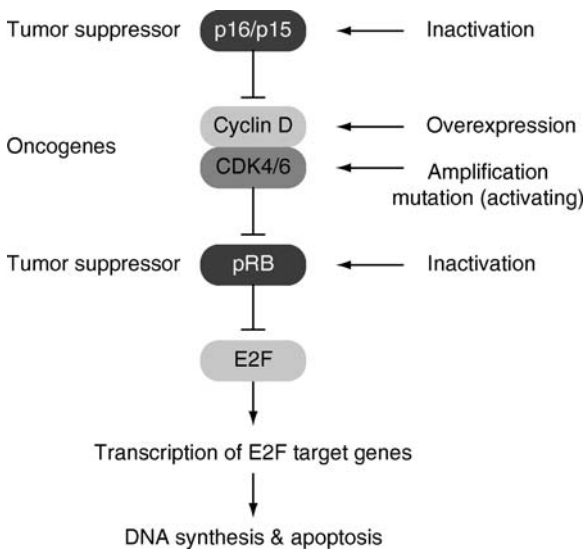


Cell-Cycle Targets for Cancer Therapy. Figure 1 The E2F pathway and its regulation by Rb and G1 CDKs.

association with CDK inhibitors (CDIs) belonging to the INK4 (p15, ►p16, p18, p19) or KIP (p27, p57)/CIP (p21) families.

Restriction Point Control

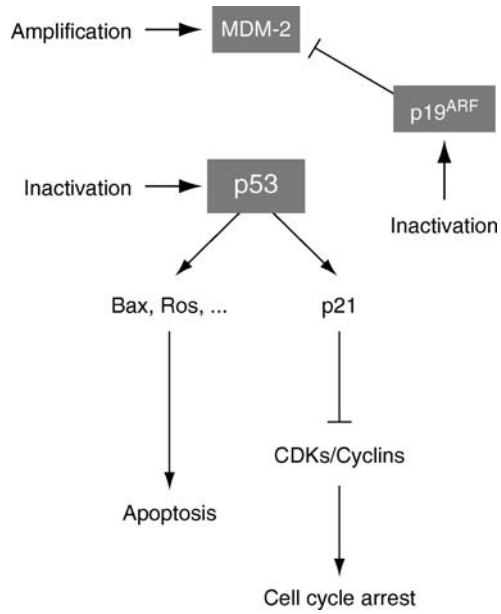
The G1 CDK-cyclin complexes regulate progression across the restriction point through phosphorylation of the ►retinoblastoma protein Rb and its kins p107 and p130. In early-mid G1 the transcription factor ►E2F is found in complexes with Rb and ►histone deacetylase (HDAC). These complexes actively repress transcription via E2F binding sites in the respective target genes. The phosphorylation of the E2F-Rb-HDAC complexes by ►cyclin D-CDK4/6 and cyclin E-CDK in mid-late G1 leads to the disruption of these complexes and the generation of transcriptionally active "free" E2F, which results in the induction of numerous E2F target genes (Fig. 1). The relevance of R-point control for tumorigenesis is emphasized by the fact that the ►INK4-cyclin D-CDK4-Rb pathway is defective in the vast majority of human tumors due to genetic alteration of its components (Fig. 2). Therefore, this pathway is of major interest with respect to therapeutic intervention.



Cell-Cycle Targets for Cancer Therapy. Figure 2 Deregulation of E2F activity in cancer cells through impairment of the INK4-cyclin D-CDK 4–8211; Rb pathway.

Checkpoint Control

A major role in checkpoint control is exerted by the ►p53 tumor suppressor pathway. In response to DNA damage (or other insults to the cell) p53 induces a number of genes that either invoke cell-cycle arrest (such as the CDI p21/CIP) or trigger apoptosis (Fig. 3). The activity and the steady-state level of p53 is regulated by ►MDM-2, a oncoprotein that associates with p53, inhibits its transcriptional activity and targets p53 for degradation by the proteasome. MDM-2 itself is targeted for proteolysis by the tumor suppressor ►p14ARF (or p19ARF in mice). The importance of this pathway is demonstrated by the fact that each of its components can be a target for genetic alterations in human tumors, and that a defective p53 pathway is found in more than 50% of all human malignancies. This emphasizes the relevance of p53 for the development of new anti-cancer therapies.



Cell-Cycle Targets for Cancer Therapy. Figure 3 Loss of p53 function in human cancer cells.

Another checkpoint activated in G2 in response to DNA damage is governed by the checkpoint kinase-1 (►CHK1; Fig. 4). CHK1 phosphorylates the CDC2 (CDK1) phosphatase CDC25C, which results in the association of CDC25C with a p53-induced specific isoform of 14–3–3. This renders CDC25C inactive, so that the cyclin B-CDC2 complex remains in its phosphorylated inactive form. As a consequence, progression into mitosis is prevented and DNA repair can occur. Since many anti-cancer drugs exert their function through DNA damage, this checkpoint may have a negative impact on their efficacy. An analogous checkpoint operating in G1 has recently been identified. This checkpoint is activated when the CDK2 phosphatase CDC25B is targeted for degradation in response to DNA-damage that will leave the cyclin E kinase in an inactive (phosphorylated) state. As a consequence, cell-cycle progression into S-phase is prevented.

Clinical Relevance

Cancer is clearly a proliferative disease resulting from deregulated cell-cycle progression. The inhibition of specific proteins driving the cell cycle is therefore an obvious strategy for the rational discovery of new anti-cancer drugs. In this context it is of particular interest that the interference with coordinated cell-cycle progression can result in apoptosis of tumor cells. This is exemplified by the observation that the deregulated expression of proteins, such as ►Myc or E2F-1, in conjunction with a non-physiological cell-cycle block is incompatible with cell survival. It has also been shown that the direct inhibition of CDKs, for example by CDIs or through ►antisense nucleic acid, can trigger programmed cell death in tumor cells. These and other findings have laid the foundation for the definition of a new class of anti-tumor agents that function through a direct inhibition of proteins driving the cell cycle.

One of the prototypes of this class of compounds is the synthetic flavone ►Flavopiridol. Flavopiridol is a general inhibitor of CDKs, induces cell-cycle arrest and apoptosis, and is not influenced by many of the genetic alterations conferring resistance on human tumor cells. Accordingly, Flavopiridol has shown promising tumor responses in preclinical models and is currently undergoing clinical trials. Numerous other chemical CDK inhibitors have recently been identified and are currently being evaluated for their anti-tumor properties. It can be anticipated that CDK-inhibiting drugs will constitute a new class of powerful chemotherapeutics.

Other interesting targets for therapeutic intervention are the proteins governing checkpoint control, for instance in response to DNA damage. Checkpoint control can invoke a transient cell cycle block, but can also trigger apoptosis. Both types of checkpoints are of relevance to tumor therapy. While the functionality of an apoptosis-inducing mechanism in response to drug- or radiation-induced cellular damage is desirable, checkpoint control leading to cell-cycle arrest is counterproductive for any therapy that relies on cell proliferation, such as radiation or conventional therapy.

The p53 checkpoint is lost in many tumor cells, and thus the ability to undergo apoptosis in response to chemo- or radiotherapy. The restoration of this checkpoint could therefore sensitize many tumor cells to conventional therapies. Strategies along these lines involve the development of compounds that can reactivate mutant p53 or inhibit MDM-2, or the use of gene therapeutic approaches for the reintroduction of functional p53 genes.

Other drug-based strategies aim to improve the efficacy of existing therapies that rely on DNA-damage, such as radiation or DNA-damaging chemotherapy. A prime candidate in this context is the kinase ►CHK1 that regulates the G2 checkpoint (Fig. 4). First results obtained with an inhibitor of the G2 checkpoint, UCN-01, suggest that this may indeed be the case.

Numerous other mechanisms controlling cell-cycle progression have been discovered, and approaches for therapeutic intervention are being developed, pointing to the great potential of targeting the cell cycle for the development of new anti-cancer drugs. It can be anticipated that this new class of anti-cancer drugs will lead to a clear advance in clinical oncology.

Cell Differentiation

Definition

This is a concept from developmental biology describing the process by which cells acquire a "type". The morphology of a cell may change dramatically during differentiation, but the genetic material remains the same, with few exceptions.

A cell that is able to differentiate into many cell types is known as pluripotent. These cells are called stem cells in animals and meristematic cells in higher plants. A cell that is able to differentiate into all cell types is known as totipotent. In mammals, only the zygote and early embryonic cells are totipotent, while in plants, many differentiated cells can become totipotent with simple laboratory techniques.

►Orphan Nuclear Receptors and Cancer

Cell Division

Definition

Synonym cell proliferation; Is the process of cell doubling by which a cell, called the parent cell, divides into two cells, called *daughter cells*. Cell division is a physiological process that occurs in almost all tissues. However, a process of pathological cell division can be seen in cancers.

►Cell Cycle

Cell Fate

Definition

The ultimate differentiated state to which a cell has become committed.

►Polycomb Group

Cell-free Circulating Nucleic Acids

►Circulating Nucleic Acids

Cell Lines

Definition

Are cell populations with the feature of dividing indefinitely when growing in culture. There are tumor and non-tumor cell lines from different organisms including humans.

Cell Locomotion

►Migration

Cell-Mediated Immunity

Definition

Synonym Cell-mediated immune response describes any adaptive immune response in which antigen-specific T cells have the main role. It is defined operationally as adaptive immunity that cannot be transferred to a naïve recipient with serum antibody.

►Sjögren Syndrome

Cell Membrane

Definition

►Plasma membrane

Cell Migration

A highly complex process, regulated by multiple gene pathways enabling the motility of cells through the adhesion and invasion of extracellular matrices.

►Tissue Inhibitors Of Metalloproteinases (Timps)

Cellular Atypia

Definition

Histological features associated with epithelial dysplasia, the degree of which is determined by the number of atypia present in the dysplastic lesion. Atypia include densely stained nuclei, pleomorphic nuclei, altered nucleus:cytoplasm ratio, aberrant mitosis, frequent mitosis, supra-basal mitosis, disorganized tissue architecture, de-differentiation, loss of cellular adhesion, loss of cellular polarity, keratinization within the deeper areas of the epithelium.

►Squamous Cell Carcinoma

Cellular Immortalization

Definition

The process by which cells cultured in vitro, or in the organism, escape from cellular senescence and grow forever. This can happen spontaneously, or can be caused by chemical carcinogens, oncogenic viruses, or radiations.

►Chemically Induced Cell Transformation
►Senescence and Immortalization

Cellular Immunity

Definition

Immune protection provided by the direct action of immune cells (as distinct from soluble molecules such as antibodies).

Cellular Self-Cannibalism

►Autophagy

Cellular Senescence

Definition

The process of programmed cell aging, by which cells die after a specific number of population doublings, usually 60 population doublings.

►Chemically Induced Cell Transformation
►Senescence and Immortalization

Cellular Transformation Assay

Definition

Cell biological test to demonstrate oncogenic activity of a candidate gene. Typically the gene in question is cloned into a mammalian expression vector, transfected into appropriate recipient cells and expressed. The transforming activity is detected on the basis of morphological alterations such as the loss of the typical fibroblastic or epithelial cell shape, anchorage independent proliferation, as determined in semi-solid agar medium, or tumor formation following injection of transfected cells into nude mice. The classical cellular transformation assays were done with donor DNA prepared from tumors and pre-neoplastic mouse NIH/3T3 cells as recipients.

►RAS Transformation Targets

CENP-E

Definition

Centromeric protein E; Is a kinetochore-associated kinesin-like motor protein that is responsible for chromosome movement and alignment in mitosis. In animal model, CENP-E deletion in mice causes early embryonic lethality, with embryos unable to implant or develop past implantation.

►Mitotic Arrest-Deficient Protein 1 (MAD1)

Censoring

Definition

Censoring, particularly in survival studies, occurs when the outcome of interest is not measured fully as, for example, when a trial is ended after a specified period of time so that failure times are not precisely measured.

►Kaplan–Meier Survival Analysis

Central Cleavage

Definition

Central cleavage refers to the symmetric cleavage of ►carotenoids at their central 15,15′ double bond by carotene 15,15′-oxygenase, a main pathway for vitamin A formation from provitamin A carotenoids.

Central Nervous System

Definition

The brain and spinal cord.

Centrosome

Kenji Fukasawa
Molecular Oncology Program, H. Lee Moffitt Cancer Center and Research Institute 12902 Magnolia Dr. Tampa, FL 33612-9416, OH, USA

Synonyms

Major microtubule organizing center; MTOC; Spindle pole body; SPB, in yeast

Definition

The centrosome is a nonmembranous organelle (1–2 μm in diameter) normally localized at the periphery of nucleus, and its primary function is to nucleate and anchor microtubules.

Characteristics

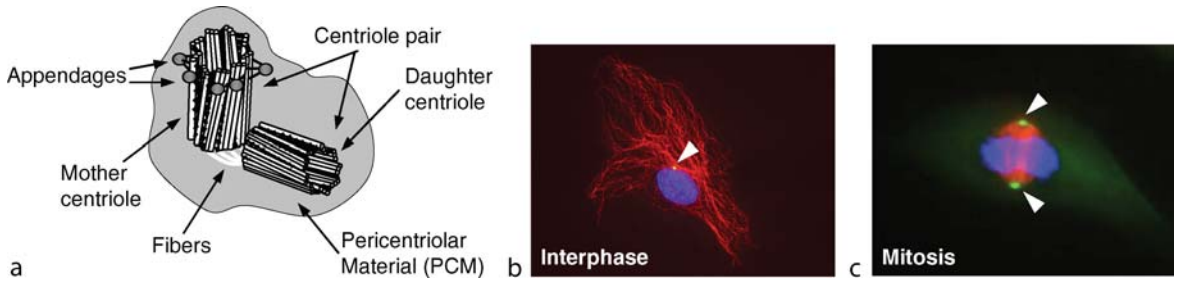
Structure and Function

The centrosome in mammalian cells consists of a pair of centrioles and the surrounding protein aggregates consisting of a number of different proteins (known as pericentriolar material; PCM). The centrioles in the pair structurally differ from each other; one with a set of appendages at the distal ends (mother centriole) and another without appendages (daughter centriole). These appendages are believed to be important for nucleating and anchoring microtubules. The daughter centriole acquires the appendages in late G2-phase of the cell cycle. As the primary function of the centrosome is to nucleate and anchor microtubules, centrosomes organize the cytoplasmic microtubule network during interphase, which is involved in vesicle transport, proper distribution of small organelles, and establishment of cell shape and polarity. In mitosis, centrosomes become the core structures of spindle poles and direct the formation of mitotic spindles. (Fig. 1).

Centrosome Duplication

Upon cytokinesis, each daughter cell receives only one centrosome. Thus, the centrosome, like DNA, must duplicate once prior to the next mitosis. In other words, cells have either one unduplicated or two duplicated centrosomes at any given time point during the cell cycle. Since DNA and centrosome are the only two organelles that undergo semiconservative duplication once in a single cell cycle, cells are equipped with a mechanism that coordinates these two events, likely to ensure these two organelles to duplicate once, and only once. In late G1/early S-phase, the centrosome initiates duplication by physical separation of the paired centrioles, which is followed by the formation of a procentriole in the proximity of each preexisting centriole. During S and G2, the procentrioles elongate and two centrosomes continue to mature by recruiting PCM. By late G2, two mature centrosomes are generated.

The coupling of the initiation of DNA and centrosome duplication is in part achieved by late G1-specific activation of cyclin-dependent kinase 2 (CDK2)/cyclin E. CDK2/cyclin E triggers initiation of both DNA synthesis and centrosome duplication. The activation of CDK2/cyclin E is controlled by the late G1-specific expression of cyclin E as well as the basal level expression of p53 and its transactivation target $p21^{Waf1/Cip1}$ (p21), a potent CDK inhibitor. Several



Centrosome. Figure 1 Structure and function of centrosomes. (a) The centrosome consists of a pair of centrioles and surrounding protein aggregates (PCM). (b and c) Mouse embryonic fibroblasts were immunostained for γ-tubulin (one of major centrosomal proteins, green – appearing in yellow) and α- and β-tubulin (primary constituents of microtubules, red). Cells were also counterstained for DNA with DAPI. Panel b: interphase cell, panel c: mitotic cell.

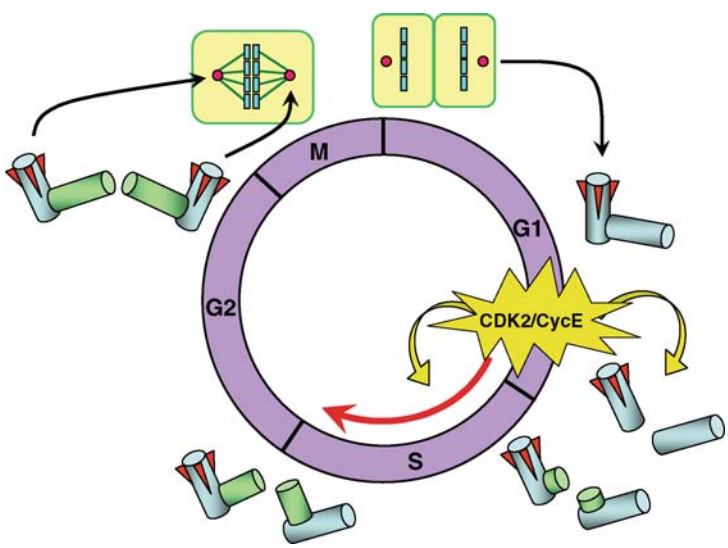
potential targets of CDK2/cyclin E for centrosome duplication have been identified, including nucleophosmin, Mps1 kinase, and CP110. For instance, nucleophosmin localizes between the paired centrioles, likely functioning in the pairing of the centrioles. CDK2/cyclin E-mediated phosphorylation promotes dissociation of nucleophosmin from the centriole pairs, leading to physical separation of the paired centrioles. (Fig. 2).

Abnormal Amplification of Centrosomes and Chromosome Instability in Cancer

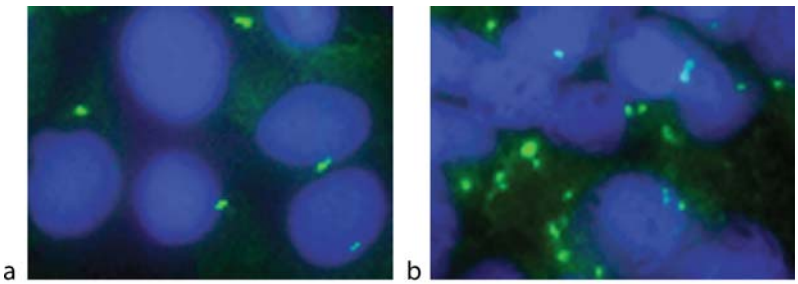
The presence of two centrosomes at mitosis ensures the formation of bipolar mitotic spindles. Since chromosomes are pulled toward each spindle pole, the bipolarity of mitotic spindles is essential for the accurate chromosome segregation into two daughter cells during cytokinesis. Abrogation of the regulation underlying the numeral homeostasis of centrosomes (i.e., regulation of centrosome duplication) results in abnormal amplification of centrosomes (presence of >2 centrosomes), which in turn increases the frequency of mitotic defects (i.e., formation of >2 spindle poles) and chromosome segregation errors/chromosome instability (see [1] for the full description of the mechanisms for generation of centrosome amplification). Chromosome instability has been recognized as a hallmark of cancer, and contributes to multistep carcinogenesis by facilitating the accumulation of genetic lesions required for acquisition of various malignant phenotypes. To date, a number of studies have shown that centrosome amplification is a frequent event in almost all types of solid tumors, including breast, bladder, brain, bone, liver, lung, colon, prostate, pancreas, ovary, testicle, cervix, gallbladder, bile duct, adrenal cortex, and head and neck squamous cell, to name a few. Centrosome amplification has also been observed in certain cases of leukemia and lymphoma. Many studies have also shown the strong association between the occurrence of centrosome amplification and a high degree of aneuploidy. Thus, centrosome amplification can be reasonably considered as a major contributing factor for chromosome instability in cancer. (Fig. 3).

Loss of Tumor Suppressor Proteins and Centrosome Amplification

In view of carcinogenesis, it is important to mention that loss or inactivating mutation of certain tumor suppressor proteins, most notably p53 and BRCA1, results in centrosome amplification. For both p53 and BRCA1, they were initially implicated in the control of centrosome duplication and numeral homeostasis of centrosomes by the observations that centrosome amplification and consequential mitotic aberrations were frequent in the embryonic fibroblasts (as well as various tissues) of p53-null mice as well as mice harboring BRCA1 mutation, which implies that destabilization of chromosomes due to centrosome amplification contributes to the cancer susceptibility



Centrosome. Figure 2 The centrosome/centriole duplication cycle. Late G1-specific activation of CDK2/cyclin E triggers initiation of both DNA and centrosome duplication. Centrosome duplication begins with the physical separation of the paired centrioles, which is followed by formation of procentrioles. During S- and G2-phases, procentrioles elongate, and two centrosomes progressively recruit PCM. In late G2, the daughter centriole of the parental pair acquires appendages (shown as red wedges), and two identical centrosomes are generated. During mitosis, two duplicated centrosomes form spindle poles, and direct the formation of bipolar mitotic spindles. Upon cytokinesis, each daughter cell receives one centrosome.



Centrosome. Figure 3 Representative immunostaining images of centrosome amplification in human cancer. The touch preparations of G3 tumor grade bladder cancer specimens and the adjacent normal bladder epithelium samples were subjected to immunostaining for γ-tubulin (centrosome, green) and counterstained for DNA with DAPI (blue). No centrosome amplification can be seen in normal bladder epithelium (a), while a high frequency of centrosome amplification in the G3 tumors (b).

phenotype associated with loss or mutational inactivation of p53 as well as BRCA1.

Centrosome Amplification and Cancer Chemotherapy

In cells inhibited for DNA synthesis (i.e., by exposure to DNA synthesis inhibitors such as aphidicolin (Aph) or hydroxyurea (HU)), centrosomes undergo multiple rounds of duplication in the absence of DNA synthesis, resulting in abnormal amplification of centrosomes. However, this phenomenon preferentially occurs when p53 is either mutated or lost. In the presence of wild-type p53, centrosome duplication is also blocked by exposure to DNA synthesis inhibitors; p53 is upregulated upon prolonged exposure to Aph or HU, leading to transactivation of p21, which in turn blocks the initiation of centrosome duplication via continuous inhibition of CDK2/cyclin E. In contrast, in cells lacking p53, p21 fails to be upregulated in response to the cellular stress imposed by DNA synthesis inhibitors, allowing "accidental" activation of CDK2/cyclin E, which triggers initiation of centrosome duplication. Considering the high frequency of p53 mutation in human cancer, it is important to address the effect of commonly used anticancer drugs targeting S-phase (DNA replication) on centrosomes. When p53-null cells were exposed to subtoxic concentrations of the S-phase targeting chemotherapeutic agents (i.e., 5′-fluorouracil, arabinoside-C), centrosome amplification was efficiently induced. Moreover, after removal of drugs, these cells resumed cell cycling, and suffered dramatic destabilization of chromosomes. This finding may be significant in the context of cancer chemotherapy using the S-phase targeting drugs. During chemotherapy, not all cells in tumors receive a maximal dose of drugs – such cells may not be killed, but only arrested for cell cycling. If these cells harbor p53 mutations, centrosome amplification occurs during the drug-induced cell cycle-arrest. Upon cessation of chemotherapy, these cells resume cell cycling in the presence of amplified centrosomes, and suffer significant mitotic aberrations and chromosome instability, which increases the risk of acquiring further malignant phenotypes. This may in part explain why the recurrent tumors after chemotherapy are often found to be more malignant than the original tumors. Many S-phase targeting anticancer drugs have been found to be effective, and there is no doubt that DNA duplication should be one of the major targets for future development of more effective anticancer drugs. However, the possibility that the S-phase targeting drugs may exacerbate a chromosome instability phenotype by inducing centrosome amplification should be taken into consideration.

Another important issue to be addressed is the concept of centrosome duplication as a target of cancer chemotherapy. Like DNA replication, centrosome duplication occurs only in proliferating cells. Inhibition of centrosome duplication will not only suppress centrosome amplification and chromosome instability, but also block cell division and possibly induce cell death – cells with one centrosome fail to form bipolar mitotic spindles, and are often undergo cell death. Moreover, in contrast to genotoxic drugs which impose an increased rate of secondary mutations through interfering with DNA metabolisms, such side effects will likely be minimal in the protocol designed to block centrosome duplication.

Ceramide

Erich Gulbins
Department of Molecular Biology, University of Duisburg-Essen, Essen, Germany

Definition

Ceramide belongs to the group of sphingolipids and is constituted by the amide ester of the sphingoid base D-erythro-sphingosine and a fatty acid of C_{16} through C_{32} chain length. At present, the differential biological function of different ceramide species is unknown and, thus, the term ceramide is used collectively to represent all long chain ceramide molecules.

Characteristics

Formation of Ceramide

Ceramide molecules are very hydrophobic and exclusively present in membranes. Sphingomyelin, the choline-ester of ceramide is hydrolyzed by acid, neutral and alkaline sphingomyelinases to release ceramide. Ceramide is also de novo synthesized via a pathway involving the serine-palmitoyl-CoA transferase. Under some circumstances ceramide can be also formed from sphingosine by a reverse activity of the acid ceramidase.

Ceramide-Induced Changes of Biological Membranes

The formation of ceramide within biological membranes results in a dramatic change of the biophysical properties of the lipid bilayer. Ceramide molecules have the tendency to self-associate and to form small ceramide-enriched membrane microdomains. These membrane microdomains spontaneously fuse to large ceramide-enriched membrane macrodomains that constitute a very hydrophobic and stable membrane domain. Furthermore, ceramide molecules seem to compete with and displace cholesterol from membrane domains. Ceramide-enriched membrane platforms serve to re-organize and cluster/aggregate receptor molecules in the membrane resulting in a very high density of receptors within a small area of the cell membrane. At least for some receptors the transmembranous domain of the receptor determines its preferential partitioning in ceramide-enriched membrane platforms.

Ceramide-enriched membrane macrodomains are also involved in the recruitment or exclusion, respectively, of intracellular signaling molecules that mediate transmission of signals into the cell via a particular receptor. In general, clustering of receptors in ceramide-enriched membrane domains serves to amplify a weak primary signal. For instance, it was shown that ceramide-enriched membrane platforms amplify CD95 signaling ~100-fold.

Ceramide in Receptor-Mediated Signaling

Death receptors, in particular CD95 or DR5, activate the acid sphingomyelinase and trigger the translocation of the enzyme onto the extracellular leaflet of the cell membrane. Translocation of the acid sphingomyelinase onto the extracellular leaflet of the cell membrane may occur by fusion of intracellular vesicles that are mobilized upon receptor stimulation with the cell membrane. Surface exposure and stimulation of the acid sphingomyelinase results in very rapid release of ceramide in the cell membrane. Ceramide forms membrane platforms and mediates clustering of the death receptors, which is required for the induction of cell death via these receptors (Fig. 1).

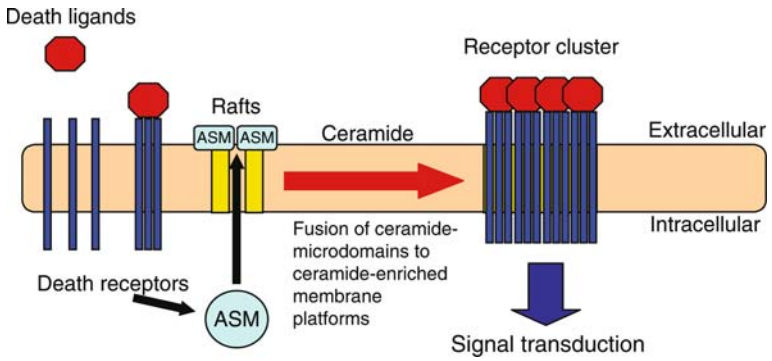
However, ceramide is not only involved in the mediation of apoptotic stimuli, but also many other stimuli trigger the release of ceramide including CD40, CD20, FcγRII, CD5, LFA-1, CD28, TNFα, Interleukin-1 receptor, PAF-receptor, infection with *P. aeruginosa*, *S. aureus*, *N. gonorrhoeae,* Sindbis-Virus, Rhinovirus, γ-irradiation, UV-light, doxorubicin, cisplatin, gemcitabine, disruption of integrin-signaling and some conditions of developmental death.

Signaling Molecules Regulated by Ceramide

Ceramide interacts with and activates phospholipase A_2, kinase suppressor of Ras (KSR; identical to ceramide-activated protein kinase), ceramide-activated protein serine-threonine phosphatases, protein kinase C isoforms and c-Raf-1. Furthermore, ceramide inhibits the potassium channel Kv1.3 and calcium release activated calcium (CRAC) channels. Lysosomal ceramide specifically binds to and activates cathepsin D resulting in translocation of cathepsin D into the cytoplasm and induction of cell death via the pro-apoptotic proteins Bid, Bax and Bak.

Ceramide in Mitochondria and Cell Death

Besides a function of ceramide in the plasma membrane and lysosomes for the induction of cell death, ceramide is also generated in mitochondria via the de novo synthesis pathway, a reverse activity of the ceramidase and/or activity of the acid sphingomyelinase. Although at present the function of ceramide in the mediation of mitochondrial pro-apoptotic events is poorly defined,



Ceramide. Figure 1 Receptors cluster in ceramide-enriched membrane domain to transmit signals into cells. The interaction of a ligand with its receptor results in translocation of the acid sphingomyelinase onto the extracellular leaflet and a concomitant release of ceramide. Ceramide spontaneously forms ceramide-enriched microdomains that fuse to large ceramide-enriched macrodomains. These domains trap activated receptor molecules finally resulting in clustering of many receptor molecules within a small area of the cell membrane. The high density of receptor molecules and associated intracellular molecules amplifies the primarily weak signal, permits the generation of a strong signal and, thus, efficient transmission of the signal into the cell. Modified from A. Carpinteiro et al. Cancer Letters.

it was suggested that C_{16}-ceramide molecules form large channels in mitochondrial membranes that may permit the exit of cytochrome c from mitochondria to execute death.

Genetic Evidence for a Function of Ceramide in Apoptosis

The role of the acid sphingomyelinase and ceramide for CD95 and DR5-triggered apoptosis was evidenced by studies on acid sphingomyelinase-deficient cells or mice, respectively, that revealed a resistance of these cells to CD95- and DR5-triggered apoptosis, but also γ-irradiation- and UV-light- or *P. aeruginosa*-triggered cell death.

Ceramide in γ-Irradiation- and UV-A Light-Induced Apoptosis

The acid sphingomyelinase and ceramide are critically involved in the response of cells to γ-irradiation. Animals or cells lacking the acid sphingomyelinase are resistant to γ-irradiation-induced cell death. In particular, endothelial cells in acid sphingomyelinase-deficient mice are resistant to γ-irradiation.

Ceramide also plays a critical role for UV-light induced apoptosis. UV-A and UV-C light activate the acid sphingomyelinase, trigger the release of ceramide and the formation of large ceramide-enriched membrane domains in the cell membrane to initiate.

Ceramide and Chemotherapy

In addition to a central role of ceramide in γ-irradiation-induced cell death, ceramide is also critically involved in the induction of cell death by at least some chemotherapeutic drugs. Thus, doxorubicin-, cisplatin- und gemcitabine-induced cell death of malignant and non-malignant cells requires expression of the acid sphingomyelinase, release of ceramide and/or the formation of ceramide-enriched membrane platforms to trigger death. Rituximab, an anti-CD20 antibody, requires expression of the acid sphingomyelinase and the generation of ceramide to kill leukemic cells.

Short Chain Ceramide

Short chain ceramide molecules composed of a fatty acid chain with C_2 through C_{12} length are water-soluble and, thus, very much differ from endogenous long ceramide molecules (C_{16}-C_{32}). However, they are very efficient reagents to kill tumor cells in vitro. Cationic pyridinium-ceramides seem to accumulate in mitochondria of tumor cells and may, thus, serve as a new class of anti-tumor reagents, although at present no convincing concepts are available to selectively target tumor cells in vivo by and to avoid effects of short chain ceramide on normal cells.

Cervical Cancers

Jiro Fujimoto
Department of Obstetrics and Gynecology, Gifu University School of Medicine, Gifu City, Japan

Definition

The regions of the uterus are the corpus and the cervix. Cancer originating from the cervix is defined as cancer of the cervix. When cancers are simultaneously detected in the cervix and corpus, squamous cell carcinoma (SCC) is designated as a cancer of the cervix and adenocarcinoma is designated as a cancer of the corpus. When cancer occupies both the cervix and vagina without the junctional area (the fornix), the cancer extending to the exocervix is recognized as a cancer of the cervix. Thus, cervical cancer is defined apart from cancer of the uterine corpus (cancer of the uterine endometrium) and cancer of the vagina.

Characteristics

The main gynecological cancers originate from the cervix, endometrium, and ovary. Among them, cervical cancer is the most common malignancy in women.

Main risk factors are

- Young age at first intercourse, especially shortly after the menarche
- High number of sexual partners
- High number of sexual partners of the partner
- High number of children
- Excessive douching

Smoking appears to increase the incidence of SCC, but not of adenocarcinoma or adenosquamous carcinoma. Immunosuppression by smoke-derived nicotine and its metabolite cotinine in the cervical mucus may enhance

the effects of sexually transmitted disease (STD) including human papillomavirus (HPV) infection. Most epidemiological risk factors for cervical cancer are associated with STDs. HPV induces an STD, human venereal condyloma, which is associated with cervical, vaginal and vulvar dysplasia, and invasive carcinomas. HPV particles and DNA, especially HPV-16, HPV-18, and HPV-33, are detected in cervical and vulvar dysplasia and in invasive carcinomas. Additionally, it has been demonstrated that HPV transforms human cell lines. HPV infection of the cervix is a main etiology of cervical cancer.

Symptoms

Main symptoms of cervical cancer are

- Vaginal bleeding, which may be recognized as postmenopausal bleeding, irregular menses, or postcoital bleeding
- Abnormal vaginal (watery, purulent or mucoid) discharge

In advanced cases, corresponding local symptoms occur. A Pap smear even in unsymptomatic cases is useful for the early detection of cervical dysplasia and cancers. Among women over the age of 18 who have had sexual intercourse, high-risk women should be screened at least yearly.

Pathology

Histopathological types in cervical cancers are mainly SCC and adenocarcinoma, which account for about 90% of all cervical cancers (adenosquamous carcinoma, glassy cell carcinoma, adenoid cystic carcinoma, adenoid basal carcinoma, carcinoid, small cell carcinoma, and undifferentiated carcinoma also occur). SCCs are keratinizing or nonkeratinizing in most cases and may be verrucous, condylomatous, papillary, or lymphoepithelioma-like carcinomas in a few cases. Adenocarcinomas are classified into mucinous, endometrioid, clear cell, serous, and mesonephric adenocarcinomas; mucinous adenocarcinomas are subclassified with endocervical type into adenoma malignum and villoglandular papillary adenocarcinoma, and intestinal type adenocarcinoma.

Staging

Clinical staging represents the degree of advancement of the tumor, and is defined by the FIGO classification established in 1994 and by the TNM classification of malignant tumors set by the UICC in 1997 as follows (classified by FIGO [TNM]):

- Stage 0 (Tis): carcinoma in situ (preinvasive carcinoma).
- Stage I (T1): cervical carcinoma confined to the uterus.
- Stage II (T2): tumor invades beyond the uterus but not to the pelvic wall or to the lower third of the vagina.
- Stage III (T3): tumor extends to the pelvic wall and/or involves the lower third of the vagina and/or causes hydronephrosis or nonfunctioning kidney.
- Stage IVA (T4): tumor invades the mucosa of the bladder or rectum and/or extends beyond the true pelvis.
- Stage IVA (Ml): distant metastasis.

Stage IA (TIa) has been further classified by microinvasive depth and width into stage IA1 (Tlal) (depth of stromal invasion ≤3 mm, horizontal spread ≤7 mm) and stage IA2 (Tla2) (depth of stromal invasion >3 mm, ≤5 mm; horizontal spread ≤7 mm). Stage IB (Tlb) has been further classified by tumor size into stage IB1 (Tlbl) (greatest dimension ≤4 cm) and stage IB2 (Tlb2) (greatest dimension >4 cm). In cases staged IA2 (Tla2) or less advanced, colposcopically directed biopsy in the transformation zone of the cervix, endocervical curettage or cervical conization are required.

Prognosis

Unfavorable prognostic factors include younger age, advanced clinical stage, certain histopathological types, vessel permeation, large tumor volume, parametrium involvement, and lymph node metastasis. Nodal metastasis is an especially critical prognostic factor after curative resection. Vascular endothelial growth factor (VEGF)-C and osteopontin contribute to the aggressive lymphangitic metastasis in uterine cervical cancers. Platelet-derived endothelial cell growth factor (PD-ECGF) contributes to the advancement of metastatic lesions as an agiogenic factors. PD-ECGF, VEGF-C, and osteopontin levels in metastatic lesions are prognostic indicators. Furthermore, serum PD-ECGF level reflects the status of advancement of cervical cancers and is recognized as a novel tumor marker for both SCC and adenocarcinoma of the cervix, while the tumor marker SCC is well known only as an indicator for SCC of the cervix. VEGF-C and osteopontin contribute to the aggressive lymphangitic metastasis in uterine cervical cancers.

Therapy

The treatment for cervical cancer consists mainly of surgery and radiation. Chemotherapy is performed in combination with surgery and/or radiation for advanced cases, and immunotherapy is an adjuvant treatment for surgery, radiation, and chemotherapy. The standard treatment for carcinoma in situ is cervical conization or total hysterectomy. The standard treatment for microinvasive carcinoma stage IA (Tla) is modified radical hysterectomy regardless of regional lymphadenectomy. The standard surgical treatment for

invasive carcinoma is radical hysterectomy with regional lymphadenectomy. Although oophorectomy can be avoided in some cases during the reproductive period, ovarian metastasis must be considered especially in adenocarcinoma of the cervix. When ooporectomy is avoided, the ovary is better shifted out of radiation area. For patients who undergo oophorectomy, hormone replacement therapy can be useful. In more advanced cases, extended radical hysterectomy or pelvic exenteration is appropriate. After surgery external irradiation is followed in some cases. The standard radiotherapy without surgery for invasive carcinoma is intra-cavitary and/or external irradiation. Recently, neoadjuvant therapy (chemotherapy) has been tried in order to make surgery more successful, and concurrent radio-chemotherapy has been tested for the purpose of enhancing the effect of radiation.

Cetuximab

Definition

Is a chimeric IgG1κ monoclonal antibody specifically binding to epidermal growth factor receptor (EGFR).

Epidermal growth factor receptor (EGFR) (EGFR; ErbB-1; HER1 in humans) is the cell-surface receptor for members of the epidermal growth factor family (EGF-family) of extracellular protein ligands. Ligands which induce activation of EGFR are epidermal growth factor and transforming growth factor α, for example. Upon activation by its growth factor ligands, EGFR undergoes a transition from an inactive monomeric form to an active homodimer. EGFR dimerization stimulates its intrinsic intracellular protein-tyrosine kinase activity resulting in activation of several signal transduction cascades which lead to DNA-synthesis and cell proliferation. EGFR mutations can lead to EGFR overexpression or overactivity and consequently result in uncontrolled cell division. Mutations of EGFR have been identified in several types of cancer, such as lung cancer and colorectal cancer.

Cetuximab is approved for treatment of EGFR-positive, irinotecan-refractory ►metastatic colon cancer.

c-FLICE-like Inhibitory Protein

Definition

c-FLIP, also known as FLAME-1/I-FLICE/CASPER/CASH/MRIT/CLARP/Usurpin, is a death-effector-domain (DED)-containing protein that exists in three different isoforms, $FLIP_L$, $FLIP_S$, and $FLIP_R$. All c-FLIP isoforms contain two N-terminal DEDs, whereas only $FLIP_L$ also harbors a C-terminal part of catalytically inactive caspase-like domains homologous to caspase-8. $FLIP_L$, $FLIP_S$, and $FLIP_R$ function as inhibitors of apoptosis by blocking caspase-8 activation at the death-inducing signaling complex (DISC). In addition, $FLIP_L$ may promote ►apoptosis at low expression levels by facilitating autocatalytic activation of procaspase-8 and is also involved in nonapoptotic pathways, e.g., NF-κB or MAPK signaling.

ζ Chain

Definition
A transmembrane protein associated with key functional receptors of the immune system, the T cell antigen receptor (TCR) and NK killing receptors (NKP30, NKP46 and CD16). The ζ chain has a key role in receptor assembly, expression and signaling function. Down-regulation of ζ chain expression associated with immunosuppression has been shown in various chronic pathologies characterized by chronic inflammation, including cancer, autoimmune, and infectious diseases.

►Inflammation

Channels

Definition
Channels are pores in biological membranes that have a rather limited specificity. Substance flow through channels is controlled by the channels' open probability so that high transport rates of 10^7–10^9 molecules per second can be achieved.

►Membrane Transporters

Chaperone

Definition
Molecular chaperones are proteins that aid the proper folding and assembly of proteins incompletely folded under conditions of cellular stress or protein synthesis. Molecular chaperones include small Hsp, Hsp40, Hsp60, Hsp70, Hsp90, Hsp100, the calnexin/calreticulin families, and so forth.

Checkpoint

Definition
Checkpoints represent intrinsic mechanisms that are activated when cell-cycle progression would be detrimental to the cell, as in case of DNA-damage, incomplete DNA synthesis, metabolic dysfunctions or mitotic spindle damage. In such cases, cell-cycle progression is transiently halted until the respective problem is fixed, for instance by the DNA repair

machinery. Major checkpoints are governed by the tumor suppressor gene product p53 or the ►check point kinases CHK1 and CHK2. Control mechanism that ensures that the next step in the cell cycle does not proceed until a series of preconditions have been fulfilled including the completion of all previous steps; this is particularly true for all pathways associated with DNA replication and chromosome formation; impaired chromosome checkpoints can result in chromosomal.

Definition

Iron is an element fundamental for life. Many vital cellular processes such as energy metabolism and DNA synthesis consist of reactions that require catalysis by iron-containing proteins. These proteins include ►cytochromes, and ►ribonucleotide reductase (RR). The latter is more significant in the context of cellular proliferation due to its role in catalyzing the rate-limiting step of DNA synthesis. Ultimately, the importance of iron is highlighted by the fact that iron-deprivation leads to G_1/S ►cell cycle arrest and ►apoptosis. Cancer cells in particular, have a higher iron requirement because of their rapid rate of proliferation. In order to satisfy their iron requirement, some cancer cells have altered iron metabolism. In addition, iron ►chelators also demonstrate the ability to inhibit growth of aggressive tumors such as ►neuroblastoma. For these reasons, iron-deprivation through iron chelation is seen as an exploitable therapeutic strategy for the treatment of cancer.

Characteristics

Iron Metabolism in Cancer Cells

In order to attain more iron, cancer cells have higher numbers of the transferrin receptor-1 molecule (TfR1) on their cell surface. The TfR1 binds the serum iron transport protein, transferrin (Tf). Hence, cancer cells are able to bind more Tf, and thus, take up iron at a greater rate than their normal counterparts. This is reflected by the ability of tumors to be radiolocalized using a radioisotope of gallium, ^{67}Ga, which binds to the iron-binding site on Tf for delivery *via* TfR1. ^{67}Ga can bind to iron-binding sites of Tf due to the similar atomic properties between gallium(III) and iron (III). Additionally, gene therapy by administration of anti-sense TfR1 targeted to the sequences of *TfR1* mRNA also showed selective anti-cancer activity, further demonstrating the importance of TfR1 in mediating cancer cell growth.

Apart from TfR1 up-regulation, the expression of the iron-storage protein ferritin is also often altered in neoplastic cells, especially neuroblastoma (NB) and breast carcinoma. In childhood NB, serum ferritin levels are elevated at stages III and IV of the disease.

In a longitudinal study, it was found that the elevated level was associated with a markedly poorer prognosis of the disease. In addition, serum ferritin levels also exceeded the normal limit in ►hepatocellular carcinoma and were found to be directly related to axillary lymph node status, presence of metastatic disease (►metastasis) and clinical stages of breast cancer.

Desferrioxamine, an Iron Chelator with Some Anti-Cancer Activity

Desferrioxamine (DFO) is a natural ligand secreted by the bacterium *Streptomyces pilosus* to selectively sequester iron for biological use (Fig. 1). DFO is used clinically for the treatment of iron overload disorders such as the transfusion-related iron overload in β-thalassemia.

DFO is active against aggressive tumors including NB and leukemia in cell culture and clinical trials. The cytotoxicity of DFO *in vitro* was prevented by co-incubation of the cells with iron or iron saturated DFO, indicating that its anti-proliferative activity was due to depletion of cellular iron. Furthermore, DFO induces a block in cell cycle progression. Therefore, it was proposed that the mechanism of action of DFO involved the depletion of cellular iron, leading to the inhibition of ribonucleotide reductase for DNA synthesis and cell cycle arrest. In human NB cells, 5 days of exposure to DFO resulted in approximately 90% cell death. In contrast, the effect of DFO was minimal on non-NB cells, suggesting that it had selective anti-NB activity. A clinical trial showed that seven of nine NB patients had up to 50% reduction in bone marrow infiltration after a course of DFO administered for 5 days. Other clinical trials using DFO as a single agent and in combination with other chemotherapeutic drugs confirmed the anti-cancer potential of this chelator. However, in some animal studies and clinical trials, DFO was found to exhibit limited or no activity.

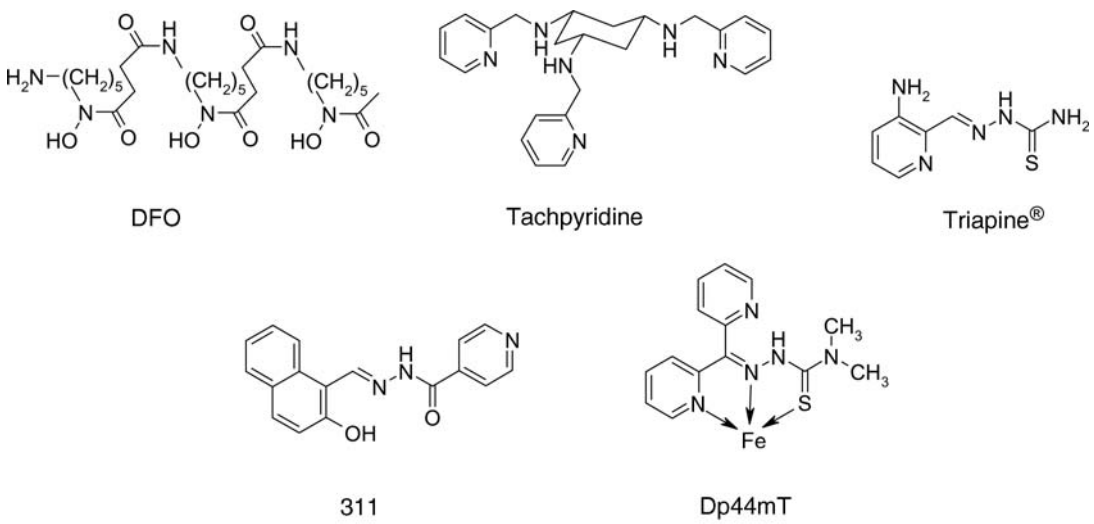
DFO also suffers a number of limitations as a result of its highly hydrophilic nature. It has poor gastrointestinal absorption and a short plasma half-life of about 12 min due to rapid metabolism. As a result, DFO is not orally active and needs to be administered via subcutaneous infusion for prolonged periods ranging from 8 to 12 h for five to seven times per week. The prolonged infusion results in pain and swelling, which consequently leads to poor patient compliance. DFO is also expensive to produce.

Despite these limitations and mixed results in clinical trials, DFO nonetheless provides "proof of principle" that iron chelation therapy may be specific and useful for cancer treatment.

Other Chelators with Anti-Cancer Potential

The limitations of DFO as an anti-cancer agent have encouraged the search for other active iron-chelating drugs against cancer.

Other experimental iron chelators include Triapine® (3-AP; Fig. 1), an iron-binding thiosemicarbazone-based drug currently in clinical trials for cancer therapy. Triapine® is a chelator that binds iron via a sulfur and two nitrogen donor atoms, and is suggested to be one



Chelators as Anti-Cancer Drugs. Figure 1 Chemical structures of the iron chelators desferrioxamine (DFO), *N,N′,N″*-tris(2-pyridylmethyl)-*cis,cis*-1,3,5-triaminocyclohexane (tachpyridine or tachpyr), 3-aminopyridine-2-carboxaldehyde-thiosemicarbazone (3-AP or Triapine®), 2-hydroxy-1-napthaldehyde isonicotinoyl hydrazone (311) and di-2-pyridylketone-4,4,-dimethyl-3-thiosemicarbazone (Dp44mT) showing coordination to iron (Fe) through pyridyl nitrogen, aldimine nitrogen and thionyl sulfur donor atoms.

of the most potent inhibitors of RR yet identified. In clinical trials, high doses of Triapine® (160 mg/m^2/day) resulted in dose-limiting toxicities, including reduction in white blood cells, jaundice, nausea and vomiting. Lower doses of Triapine® administered as a 96-h iv infusion at 120 mg/m^2/day every 2 weeks was found to be well tolerated. In clinical trials with patients with advanced cancer, Triapine® was combined with the cytotoxic cancer drug gemcitabine, which also targets DNA synthesis. Of the 22 patients examined after treatment with gemcitabine and Triapine®, three were observed to have an objective response, and one patient had evidence of tumor reduction. In this trial, Triapine® was suggested to cause oxidation of hemoglobin to methemoglobin. This may have led to or contributed to the hypoxia, acute hypotension, and electrocardiogram changes in patients receiving this chelator. An asymptomatic myocardial infarction was also observed in one individual administered Triapine® and this may also be related to its oxidative effects. Triapine® continues to be examined in clinical trials, particularly in combination with standard chemotherapy drugs. However, these deleterious effects must be considered when designing future studies with compounds of this class.

Tachpyridine, (or tachpyr; Fig. 1) is a novel chelator based upon the framework of the triamine *cis,cis*-1,3,5-triaminocyclohexane. Tachpyridine is cytotoxic to cultured bladder cancer cells with an activity approximately fifteen times greater than that of DFO. Although tachpyridine has the potential to chelate a number of metals, including calcium(II), magnesium (II), manganese(II), copper(II) and zinc(II), toxicity studies on tachypyridine complexes suggest that iron and zinc depletion mediates its cytotoxic effects.

Similar to Triapine®, Tachpyridine induces apoptotic cell death independent of functional p53 (see Iron Chelation and Cell Cycle Control Molecules, below) (►p53 gene family). In addition, tachpyridine-iron complexes produce toxic free-radicals (►reactive oxygen species), which was also thought to contribute to its anti-tumor activity.

Tachpyridine arrests cells at the G_2 phase, whereas the majority of iron chelators arrest cells at the G_1/S phase due to inhibition of ribonucleotide reductase. The G_2 phase stage of the cell cycle is particularly sensitive to the effects of radiation. Ionizing radiation increases the sensitivity of tumor cells to the action of tachpyridine. Currently, tachpyridine is in preclinical development with the National Cancer Institute, USA.

PIH Chelators

The most comprehensively assessed alternate chelators for cancer treatment are the pyridoxal isonicotinoyl hydrazone (PIH) analogues. This class of chelators bind iron through the carbonyl oxygen, imine nitrogen, and phenolic oxygen (Fig. 1).

Originally conceived for the treatment of iron overload disorders, several chelators of the PIH class were found to inhibit the growth of cancer cells. In fact, the chelator 311 (Fig. 1) was found to be highly active against a range of cancer cells. These compounds also showed marked ability to remove Fe from cells and prevent cellular Fe uptake from transferrin. The marked anti-cancer activity of chelator 311 was attributed to its relatively high ►lipophilicity, which facilitates entry into the cell. Indeed, a general trend observed with the PIH analogues was that anti-cancer activity increased as the chelator became more lipophilic. Mechanistically, PIH analogues have multiple modes of anti-cancer activity, aside from chelation of iron and inhibition of ribonucleotide reductase. Some members of the PIH class of chelators (e.g. DpT chelators, see below) increase the generation of toxic free-radicals (reactive oxygen species) in cancer cells and affect the expression of cell-cycle control molecules (see Iron Chelation and Cell Cycle Control Molecules, below). Additional studies with 311 have also shown that it can markedly induce the expression of the metastasis suppressor protein, ►Drg-1 in tumor cells. The Drg-1 protein is known to play a critical role in suppressing tumor growth and metastasis. Hence, induction of Drg-1 by potent iron chelators such as 311 may significantly contribute to the anti-cancer activity of these analogues.

The DpT Chelators: Dp44mT

The DpT class of chelators are structurally-related to PIH analogues, but feature a sulfur donor atom instead of the hydrazone oxygen donor atom (Fig. 1). The chelator Dp44mT has recently been shown to be the most effective of the DpT series of ligands in terms of anti-cancer activity. It acts with selectivity against tumor cells and has much less effect on the growth of normal cells. Dp44mT also showed high iron chelation efficacy and prevented cellular uptake of iron from iron-labeled Tf. Another mechanism of its action involves the generation of toxic free-radicals (reactive oxygen species) when Dp44mT interacts with cellular iron pools.

Initially, *in vivo* studies of Dp44mT in mice bearing chemotherapy-resistant M109 lung carcinoma showed a reduction in the size of the tumor by 53% after 5-days of treatment. A later investigation also found marked inhibition of the growth of human lung, neuroepithelioma and melanoma xenografts growing in mice. In fact, a 7-week administration of Dp44mT in mice bearing human melanoma xenografts resulted in the decrease of tumor growth to 8% of that in untreated control mice. At the dose given, no hematological abnormalities were detected, although at a higher dose, myocardial fibrosis was identified. This side effect at a high dose may be due to the marked redox activity of the Dp44mT-iron complex. However, at a lower dose

Dp44mT was well tolerated with no hematological abnormalities and less cardiotoxicity. Other studies with Dp44mT showed that it also markedly increased the expression of the metastasis suppressor protein, Drg-1 in tumor cells. Induction of Drg-1 could potentially be a very significant component of the anti-cancer mechanism of Dp44mT. Further development of DpT series chelators is currently underway.

Iron Chelation and Cell Cycle Control Molecules

Iron-deprivation generally leads to G_1/S phase cell cycle arrest as a result of inhibition of ribonucleotide reductase. This has prompted many studies assessing the effect of iron chelation by DFO and chelator 311 on the expression of many cell cycle control molecules, namely, cyclins, ►cyclin dependent kinases (cdks), cdk inhibitors and p53 (p53 gene family). Consistently, these studies found that iron chelation markedly decreased the expression of ►cyclin D (D1, D2 and D3), and to a lesser extent cyclin A and B. The expression of cdk2 and cdk1, but not cdk4, were also decreased upon iron chelation. These effects were dependent on iron-deprivation, as iron-chelator complexes were unable to induce such effects.

Cyclins D, E, A and cdks 2, 4 and 6 are involved in progression through the G_1 phase, although cyclin E, A and cdk2 are also involved in S phase progression. The formation of the cyclin A-cdk2 complex is essential for G_1/S progression. Cyclin B and cdk1 on the other hand, are important for mitosis. During the G_1 phase, cyclin D and E bind to cdk4 and cdk2 respectively to phosphorylate (►phosphorylation) the ►retinoblastoma protein (pRb) (►Biological and Clinical Functions). This results in the release of molecules such as the ►E2F transcription factor from pRb that promotes the expression of genes for S phase. The decrease in the expression of these cyclins upon iron chelation causes hypophosphorylation of pRb, which in turn leads to the G_1/S phase arrest.

In addition to cyclins and cdks, iron chelation also affects the expression of cell cycle modulatory molecules. In particular, iron chelators caused a marked increase in the expression of the cyclin-dependent kinase inhibitor $p21^{WAF1/CIP1}$ (►p21(WAF1/CIP1/SDI1)) at the mRNA level. $p21^{WAF1/CIP1}$ mediates G_1/S phase arrest by directly binding the cyclin-cdk complexes. It was speculated that the increased level of $p21^{WAF1/CIP1}$ upon iron chelation was consistent with its potential role in the G_1/S phase arrest. However, an increase of $p21^{WAF1/CIP1}$ expression only occurred at the mRNA level, with either no change or a decrease in $p21^{WAF1/CIP1}$ protein expression being observed. This was unexpected and it was subsequently demonstrated that $p21^{WAF1/CIP1}$ protein level could be controlled by proteasomal (►proteasome) degradation after iron chelation.

In contrast, investigations examining p53 showed that its protein expression and DNA-binding activity were increased after chelation. p53 is a tumor suppressor and acts as a transcription factor that is involved in the transcription of a variety of genes involved in cell cycle arrest, differentiation, apoptosis and DNA repair. An increase in p53 after iron chelation may be the result of a decrease in deoxyribonucleotide levels due to inhibition of RR activity or changes in intracellular redox status. Despite the fact that $p21^{WAF1/CIP1}$ is a down-stream effector of p53, elevated expression of $p21^{WAF1/CIP1}$ upon iron chelation occurs through a p53-independent pathway. The ability of chelators to potentially inhibit tumor cell growth by a p53-independent pathway is significant, since p53 is the most frequently mutated gene in cancer. This also explains why cells with wild-type or mutant p53 are similarly sensitive to the growth inhibitory effects of iron chelators. However, the function of increased p53 expression after chelation remains a subject for further investigation.

Conclusions

The demonstration that some iron chelators may be clinically useful for cancer treatment followed on from initial observations that rapid cancer cell proliferation requires iron. Currently, the iron chelator, Triapine®, is being examined in a variety of clinical trials, with focus on a potential role in combination chemotherapy. The search for more effective anti-cancer Fe chelators than DFO has also led to the development of other potent Fe chelators, including Dp44mT and tachpyridine, and significant progress has been made towards understanding their molecular targets. However, further *in vivo* experiments and pre-clinical studies will be necessary to build upon the promise of these agents.

Chemical Carcinogenesis

Joseph Richard Landolph, Jr.
Department of Molecular Microbiology and Immunology, and Dept. of Pathology; Cancer research Laboratory, USC/Norris Comprehensive Cancer Center, Keck School of Medicine; Department of Molecular Pharmacology and Pharmaceutical Sciences, School of Pharmacy, Health Sciences Campus, University of Southern California, Los Angeles, CA, USA

Definition

►Chemical carcinogenesis (►carcinogenesis) is the process of the genesis of a ►tumor (carcinoma), and the series of sequential steps that occur when lower animals or humans are treated with ►chemical carcinogens that leads to tumor development. After all these steps are accomplished, the physiological mechanisms regulating control of growth in the normal cells are degraded, and the normal cells are degraded and converted into tumor cells. The tumor cells then grow in an unregulated fashion and evade the host immune system, leading to development of visible tumors.

Characteristics

Normal Cell Types in Animals and the Tumors They Give Rise to

During embryogenesis in mammals (warm-blooded animals), there are three primary germ layers of the early embryo which develop into all the basic cell types, tissues, and organs in the body. These are the ectoderm, the endoderm, and the mesoderm. The ectoderm and endoderm are epithelial layers. Most of the epithelial organs in the body are derived from the endodermal and the ectodermal germ layers. The epidermis of the skin, the corneal epithelium, and mammary glands develop from the ectoderm. The endoderm layer develops into the liver, pancreas, stomach, and intestines. The mesoderm develops into the kidney and linings of male and female reproductive tracts. Three types of cells are important in chemical carcinogenesis. These cell types are (i) ►epithelial cells, which form the coverings and internal parts of organs, (ii) ►fibroblasts, which are connective tissue cells derived from primitive mesenchymal cells, and (iii) cells of the hemato-lymphopoietic series, which are derived from the blood-forming elements. These cell types all have special, specific characteristics.

In humans, 92% of the tumors that arise are derived from epithelial cells (►Epithelial cell tumors). These tumors are called carcinomas. The remaining 8% of the tumors are derived from a combination of tumors derived from fibroblasts, called sarcomas, and tumors derived from white blood cells, called leukemias (►Leukemia diagnostics) and lymphomas.

Carcinogens

There are a group of molecules and radiations referred to as "carcinogens." A ►carcinogen (►Carcinogen macromolecular adducts) is any molecule, or group of molecules, such as viruses (►Virology), or radiation (►Radiation carcinogenesis; ►radiation oncology) that can cause tumors in lower animals and humans, when they are exposed to this agent. This happens when carcinogens cause normal cells to transform, or convert into transformed cells and tumor cells during experiments in vitro, called chemical transformation experiments.

Chemicals referred to as chemical carcinogens (chemical carcinogenesis) can cause tumors in lower animals in humans exposed to them. Examples of chemical carcinogens are vinyl chloride, aflatoxin B1 (a metabolite and biocide of the fungus, *Aspergillus flavus*) (►Aflatoxins), benzo(a)pyrene (a polycyclic aromatic hydrocarbon formed when organic matter is pyrolyzed in the absence of oxygen) (►Polycyclic aromatic hydrocarbons), and beta-naphthylamine (an aromatic amine used to manufacture dyestuffs that causes bladder cancer in animals and humans) (►Aromatic amines). Nitrosamines are another class of chemical carcinogens. An example is dimethylnitrosamine (DMN). Many nitrosamines are synthetic compounds. Some are believed to form in the stomach of humans when amines (derived from fish in the diet) contact nitrous acid (formed from the nitrate from fertilizer that is used to grow foodstuffs) in the acidic conditions (acid pH) of the stomach. Chemicals in all these classes of carcinogens can cause tumors in humans and in lower mammals.

There are also a number of radiations that cause tumors in humans and lower animals. These include ionizing radiations, such as alpha particles (charged helium nuclei), beta particles (naked electrons), and gamma particles. There are also tumor viruses, consisting of RNA (RNA tumor viruses) and DNA (DNA tumor viruses). When animals are treated with these viruses, tumors are formed. Examples of RNA tumor viruses are the Rous sarcoma virus, the Abelson leukemia virus, and the Kirsten Ras virus. Examples of DNA tumor viruses are the polyoma virus, the SV40 (simian virus 40) (►SV40) virus, the ►Epstein Barr virus, and the human papilloma viruses 16 and 18 (►Human papilloma viruses).

Mechanisms of Chemical Carcinogenesis

There are two broad mechanisms of chemical carcinogenesis. In the first type, which we refer to here as "►complete carcinogenesis," a mammal is treated with a large dose of a chemical carcinogen, such as 7,12-dimethylbenz(a)anthracene, and the animals treated eventually develop tumors. Carcinogenesis with complete carcinogens is usually dose-dependent, such that the higher doses of carcinogens that the animals are treated with, the high the yield of tumors per animal and in the percentage of animals with tumors.

The second mechanism of chemical carcinogenesis, discovered by Dr. Isaac Berenblum of the Weizmann Institute in Israel, is referred to as ►"two-step carcinogenesis," or "initiation and promotion". In initiation and promotion experiments, Berenblum treated mice on the skin of their shaved backs with chemical carcinogens at low doses and also with ►tumor promoters. Berenblum was testing the hypothesis that carcinogenesis was due to irritation and inflammation. Hence, he used croton oil, a product of the plant, Euphorbia lathyris, which the plant uses as a biocide against insects. Croton oil is a very irritating substance, which is important in the plant's use of it as a biocide against insects. When mice were treated with low doses of 7,12-dimethyl-benz(a)anthracene (DMBA, a carcinogenic PAH), one time, they exhibited no tumors. A second group of animals was treated with the tumor promoter, croton oil, once per week, and the animals also exhibited no tumors. When the mice were treated with a low dose of DMBA, and then once weekly with croton oil, they developed many tumors. If the latter treatment was reversed, i.e. the animals were treated first with croton oil once per week, and then later treated with a low dose of DMBA, the animals showed no tumors. If the animals were treated with a low dose of DMBA, then no treatment was performed for a significant amount of time, then the animals were treated with croton oil once per week, the animals also developed a high yield of tumors. In this system, treatment of the animals with the low dose of DMBA is referred to as the "initiation step," and later treatment with croton oil is called the "promotion" step. Initiation is believed to be a ►genotoxic event, likely a ►mutation, and is an irreversible step. Initiated cells can be promoted to tumors cells if they are treated with croton oil long enough. The promotion step is believed to be due to the binding of tetradecanoyl-phorbol acetate (TPA, the most active constituent of the mixture of phorbol esters in croton oil), to protein kinase C, triggering signal transduction and cell division in cells bearing mutations in ►proto-oncogenes. If promotion is interrupted, then tumorigenesis is reversible, i.e. the cellular death rate will equal the cellular growth rate, and the tumor will regress. If promotion is continued long enough, the tumor becomes fixed and will not regress. Eric Hecker of the German Cancer Research Center (Deutsch Krebs Forschung Zentrum) in Heidelberg, Germany, fractionated croton oil used by Berenblum, by high pressure liquid chromatography, and found that TPA was the most active tumor promoter in it.

From experiments with high doses of chemical carcinogens, and experiments with initiation and promotion, we now have evidence that chemical carcinogens such as DMBA cause mutations in proto-oncogenes, such as ras genes, converting them into activated ►oncogenes. In complete carcinogenesis experiments, further mutations in other proto-oncogenes can also occur, leading to activation of additional oncogenes. In addition, activated metabolites of the carcinogens (formed in the animals/mammals by cytochrome P450 or other enzymes of metabolic activation), also cause mutational inactivation of ►tumor suppressor genes, or breakage of chromosomes bearing them, leading to loss of these tumor suppressor genes. Together, activation of oncogenes and inactivation of tumor suppressor genes is believed to lead to the genesis of tumors in mammals.

Insights into Mechanisms of Chemical Carcinogenesis from Studies of Chemically Induced Neoplastic Transformation

Studies of the abilities of chemical carcinogens to convert normal cells into tumor cells in cell culture dishes have given us substantial insight into the molecular mechanisms of chemical carcinogenesis. In cell culture, normal fibroblasts and normal epithelial cells grow if they are fed properly, until they eventually fill the culture dish, and touch each other. Growth then ceases. This process is called contact inhibition of cell division. Cells can then be removed from the cell culture dish with a protease called trypsin, diluted, and replated into new cell culture dishes. This process can be repeated many times, until the population of total cells has undergone sixty population doublings. At this point, the cells senesce (►Senescence and immortalization), or die. This is due to progressive shortening of telomeres (►Telomerase), structures at the end of chromosomes, with each successive DNA replication

and cell division. Telomere shortening acts as a cellular and molecular "clock," to mark the lifetime of the cell. This process aids in the control of the normal physiology of the organism, by removing old cells which accumulated many mutations, which could eventually lead to cancer.

►Chemically induced cell transformation is the process by which normal cells are treated with chemical carcinogens in vitro in a cell culture dish or flask, and then their growth control mechanisms degrade, converting or transforming them into transformed cells. There are two mechanisms by which cells can be converted by chemical carcinogens into transformed cells. Firstly, cells can be treated with genotoxic (DNA-damaging) (►Genetic toxicology) chemical carcinogens. Many of these genotoxic carcinogens are ►mutagens (►Mutation rate). These carcinogens either already are direct mutagens (rare), or more commonly they are pre-carcinogens, and can be converted into mutagenic proximate carcinogens by ►cytochrome P450 enzymes or other enzyme systems that activate the pre-carcinogens into mutagens. The carinogens (benzo(a)pyrene, aflatoxin B1, and nitrosamines are all examples of pre-carcinogens that are metabolically activated into mutagens by various types of cytochrome P450 enzymes. Most pre-carcinogens are hydrophobic (fat-loving) compounds that would bioaccumulate in the body, and cause alterations in the properties of enzymes and membranes in cells. Mammals must therefore derive strategies to eliminate hydrophobic pre-carcinogens. The cytochrome P450 enzyme system, and other enzyme systems, have evolved in order to metabolize these pre-carcinogens, to make them water-soluble, so they can be excreted in the urine and removed from the body. Since these compounds are inherently chemically inert, a necessary first chemical reaction step has evolved, in which cytochrome P450 enzymes attack pre-carcinogens like benzo(a)pyrene (BaP) with molecular oxygen and reducing equivalents (NADPH and NADH) to generate epoxides and diol epoxides from it. These metabolites are mutagens, and this step results in "metabolic activation." In a second step, which is closely coupled to the first step, these active metabolites are reacted with and conjugated to, molecules of water by the enzyme, epoxide hydrolase, converting them to trans-dihydrodiols and tetraols, which are highly water-soluble, so they are excreted in the urine. The small amount of epoxides and diol epoxides derived from BaP then bind covalently to DNA bases, resulting in mutations in proto-oncogenes, activating them into oncogenes, and mutations in tumor suppressor genes, inactivating them.

In a second mechanism of ►carcinogenesis, chemicals called "non-genotoxic carcinogens," transform normal cells into tumor cells in a different way, by non-mutagenic mechanisms. One example is the chemical, 5-azacytidine, a chemical analog of a normal base. 5-azacytidine binds to DNA methyltransferases (►Methylation), inhibiting them. This results in a loss of methylation of the cytidine in DNA. If this occurs in quiescent proto-oncogenes, then these can become transcriptionally activated, leading to cell transformation. Other examples of non-genotoxic carcinogens include hormones, such as testosterone and estrogen. Higher steady-state levels of testosterone and estrogen are believed to lead to aberrantly high numbers of cell divisions in prostate and breast tissue. The resultant spontaneous mutations that occur are believed to lead to prostate cancer and breast cancer, respectively.

The process by which a normal cell is converted into a tumor cells, or chemically induced ►neoplastic transformation (►Neoplastic cell transformation), occurs in four steps. In the first step, when cells are treated with mutagenic chemical carcinogens, there occur mutations in proto-oncogenes, activating them to oncogenes, and mutations in tumor suppressor genes, inactivating them. The cells then develop the ability to grow in multi-layers, and form foci. This is particularly true for fibroblastic cells, less so for epithelial cells. This first step in cell transformation is called morphological cell transformation, or focus formation. Further genetic changes occur in the transformed cells. The second step that occurs is that the cells become immortal, and do not die or senesce. Some activated oncogenes (v-myc) can cause cells to become immortal. This step would be called transformation to cellular immortality. In the third step, cells develop the ability to grow in soft agar, in three dimensional suspension. This step is called anchorage-independent cell transformation, or transformation to anchorage independence. A final step that develops after further genetic change is that cells develop the ability to form tumors when injected into athymic (nude) mice. This step is called neoplastic transformation, or the ability of cells to be transformed so that they form neoplasms, or new growths, which we call tumors. Often, a number of activated oncogenes, two or more, may cooperate together to perturb normal cellular physiology, to cause neoplastic transformation of normal rodent or human cells in culture. It is now believed by scientists that activation of proto-oncogenes into oncogenes, and inactivation of tumor suppressor genes, such that approximately eight total genes are genetically altered, leads to the aberrant expression of approximately 150 genes or more in the tumor cells. This then leads to neoplastic transformation of cells in culture, hence to chemical cacinogenesis in the animal. We believe that chemically induced neoplastic transformation is a good model for how cells in the animal become converted (transformed) into tumor cells when the animal is treated with chemical carcinogens.

Significance of Chemical Carcinogenesis

The significance of the process of chemical carcinogenesis is two-fold. Firstly, the assay for chemical carcinogenesis in lower animals, usually mice and rats, can be used to test chemicals to determine whether they are carcinogens by virtue of their ability to induce tumors in mice and rats. Those chemicals that are able to cause a reproducible, dose-dependent induction of tumors in mice and/or rats, are presumed to be human carcinogens. This presumption is due first to the relationship that rodents and humans are both warm-blooded animals, or mammals. As such, their biochemistry and physiology is similar. In addition, many chemical carcinogens were first found to be carcinogenic in rodent carcinogenesis bioassays, and later found to be carcinogens in humans. Almost all carcinogens that have been shown to be carcinogenic in humans are also carcinogenic in rodents (aflatoxin B1, vinyl chloride, asbestos, cigarette smoke, asbestos, polycyclic aromatic hydrocarbons).

Secondly, the process of chemical carcinogenesis as studied in rodents has led to unique insights into the mechanisms of carcinogenesis. Investigators frequently use whole animal carcinogenesis bioassays to study how proto-oncogenes are activated into oncogenes, how tumor suppressor genes are inactivated by chemical carcinogens, and how oncogene activation and tumor suppressor gene inactivation leads to induction of tumors in mammals. Studying the mechanisms of carcinogenesis in rodents has also led to the identification of agents that interfere with this process, and may eventually be used to prevent the induction of cancer in humans.

Chemical Castration

Definition

Removal of the gonads (ovary and testis) is required to ablate serum levels of sex steroids (progesterone, estrogen, and testosterone). As continuous administration of GnRH analogs removes the influence of the pituitary to regulate gonadal function, this inhibitory effect became known as "Chemical castration."

Chemical Tool

Definition

A chemical tool is a small, drug-like molecule that can be used to identify new targets in a ►signal transduction pathway. The chemical tool is usually identified through the screening of a cell-based or *in vivo* assay, and then used as an affinity probe to identify its molecular target. The chemical tool provides the link between the target and the desired phenotype in the assay.

Definition

►Chemically induced cell transformation is the series of sequential steps that occur when mammalian cells are treated with ►chemical carcinogens, and converted into tumor cells.

The intermediate cell phenotypes (cell properties) are acquired one at a time, including first morphological ►transformation (change in cell shape, leading to criss-crossing of cells in abnormal patterns), then anchorage independence (growth of cells as colonies or balls of cells in three dimensional suspension of agar, without attachment to the plastic dishes cells are usually grown on), and finally ►neoplastic transformation (►Neoplastic cell transformation), or the ability of cells to form tumors when injected into nude (athymic) mice.

Characteristics

Normal Growth of Normal Cells

In the mammalian organism (warm-blooded animals), there are many types of cells. In general, these cell types are divided into (i) ►epithelial cells, which form the coverings of organs, (ii) ►fibroblasts, which are connective tissue cells, and (iii) cells of the hemato-lymphopoietic series, which are derived from the blood-forming elements. These cell types all have special, specific characteristics.

These three general cell types can be grown outside the body in an artificial situation, in cell culture medium in plastic cell culture dishes. This constitutes a model system in which the physiology of cells can be studied outside of the complicated conditions of the body. When grown in cell culture, epithelial cells and fibroblastic cells attach to the cell culture dish, by virtue of the surface charge of the cell relative to that of the plastic of the cell culture dish. These normal fibroblastic and epithelial cells must anchor to the bottom inside of the cell culture dish in order to be able to replicate their DNA and divide. This is called anchorage dependence of cell growth. These cells continue to grow if fed properly with cell culture medium, containing 5–10% fetal calf serum and cell culture medium. Cell culture medium consists of sugars, amino acids, salts, and buffers, along with an indicator to detect the acidity of the culture medium (pH indicator), all dissolved in water. In cell culture, the normal fibroblasts and normal epithelial cells continue to grow if they are fed properly, until they eventually fill the culture dish, and touch each other. Growth then ceases. This process is called ►contact inhibition of cell division. These cells can then be removed from the cell culture dish with a protease called trypsin, diluted, and replated into new cell culture dishes. This process can be repeated many times, until the population of total cells has undergone approximately 60 population doublings. This is called the "Hayflick Limit," after Dr. Leonard Hayflick, who discovered it. At this point, the cells undergo ►cellular senescence (►Senescence and cellular immortalization), or die. This is due to progressive shortening of telomeres (►Telomerase), structures at the end of chromosomes that are progressively shortened with each successive DNA replication and cell division. Hence, telomere shortening acts as a cellular and molecular "clock," to mark the lifetime of the cell. This process is believed to aid in the control of the normal physiology of the organism, and to rid it of old cells which have many ►mutations, which could eventually lead to cancer. If these normal cells are injected into mice lacking an immune system (athymic or "nude" mice), they will not grow and will not form tumors.

In contrast, cells of the hemato-lymphopoietic series grow in three-dimensional suspension (the blood) in vivo. Hence, when grown in vitro (outside the body), these cells must also be grown in three-dimensional suspension. A common practice is to grow the cells in varying concentrations of agar. When injected into athymic or "nude" mice, these normal cells, whether cells of the hematopoietic (red blood cell) or lymphoid (white blood cell) lineages, will not form tumors.

Carcinogens

There are a group of molecules and radiations referred to as "carcinogens." A ►carcinogen (►Carcinogen macromolecular adducts) is any molecule or group of molecules, such as viruses (►Virology) or radiation (►Radiation carcinogenesis; ►radiation oncology) that can cause tumors in lower animals when they are treated with this agent. These agents can also cause normal cells to transform (convert) into transformed cells and tumor cells.

There are a group of chemicals referred to as chemical carcinogens (►Chemical carcinogenesis). These are specific chemicals that can cause tumors in animals treated with them. Examples of these are vinyl chloride, aflatoxin B1 (a metabolite and biocide of the fungus, *Aspergillus flavus*) (►Aflatoxins), benzo(a)-pyrene (a polycyclic aromatic hydrocarbon formed when organic matter is burned in the absence of

oxygen) (►Polycyclic aromatic hydrocarbons), and beta-naphthylamine (an aromatic amine used to manufacture dyestuffs that causes bladder cancer in animals and humans) (►Aromatic amines). Another class of chemical carcinogens is called nitrosamines. An example is dimethylnitrosamine (DMN). Many nitrosamines are synthetic compounds. Some are believed to form in the stomach of humans when amines (derived from fish in the diet) contact nitrous acid (formed from the nitrate from fertilizer that is used to grow foodstuffs) in the acidic conditions (acid pH) of the stomach. Chemicals in all these classes of carcinogens can cause tumors in humans and in lower mammals.

There are also a number of radiations (Radiation carcinogenesis) that can cause tumors in humans and lower animals. These include ionizing radiations, such as alpha particles (charged helium nuclei), beta particles (naked electrons), and gamma particles.

In addition, there are also tumor viruses, consisting of RNA (RNA tumor viruses) and DNA (DNA tumor viruses). When animals are treated with these viruses, tumors are formed. Examples of RNA tumor viruses are the Rous sarcoma virus, the Abelson leukemia virus, and the Kirsten Ras virus. Examples of DNA tumor viruses are the polyoma virus, the SV40 (simian virus 40) (►SV40) virus, the ►Epstein Barr virus, and the human papilloma viruses 16 and 18 (►Human papilloma viruses).

Chemically Induced Cell Transformation – Description and Mechanisms

Chemically induced cell transformation is the process by which normal cells are treated with chemical carcinogens in vitro in a cell culture dish or flask, and they then convert or transform into transformed cells. There are two mechanisms by which cells can be converted by chemical carcinogens into transformed cells. Firstly, cells can be treated with ►genotoxic (DNA-damaging) (►Genetic toxicology) chemical carcinogens. Many of these genotoxic carcinogens are ►mutagens (►Mutation rate). These carcinogens either already are direct mutagens (rare), or more commonly they are pre-carcinogens, and can be converted into mutagenic proximate carcinogens by ►cytochrome P450 enzymes or other enzyme systems that activate the pre-carcinogens into mutagens. The Pre-carinogens benzo(a)pyrene, aflatoxin B1, and nitrosamines are all examples of pre-carcinogens that are metabolically activated into mutagens by various types of cytochrome P450 enzymes. The perspective for this process is that most pre-carcinogens are hydrophobic (fat-loving) compounds that would bioaccumulate in the body, and cause alterations in the properties of enzymes and membranes in cells. Hence, the organism must derive a strategy to eliminate these hydrophobic pre-carcinogens. Therefore, the cytochrome P450 enzyme system, and other enzyme systems, have evolved in order to metabolize these pre-carcinogens, to make them water-soluble, so they can be excreted in the urine and removed from the body. Since these compounds are inherently chemically inert, a necessary first chemical reaction step has evolved, in which cytochrome P450 enzymes first attack pre-carcinogens like benzo(a)pyrene (BaP) with molecular oxygen and reducing equivalents (NADPH and NADH) to generate epoxides and diol epoxides from it. These metabolites are mutagens, and this step results in "metabolic activation." In a second step, which is closely coupled to the first step, these active metabolites are reacted with and conjugated to, molecules of water by the enzyme, epoxide hydrolase, converting them to trans-dihydrodiols and tetraols, which are highly water-soluble, so they are excreted in the urine. The small amount of epoxides and diol epoxides derived from BaP then go on to bind covalently to DNA bases, resulting in mutations in proto-oncogenes, activating them into ►oncogenes, and mutations in ►tumor suppressor genes, inactivating them.

In a second mechanism of ►carcinogenesis, chemicals called "non-genotoxic carcinogens," transform normal cells into tumor cells in a different way, by non-mutagenic mechanisms. One example is the chemical, 5-azacytidine, a chemical analog of a normal base. 5-azacytidine binds to DNA methyltransferases (►Methylation), inhibiting them. This results in a loss of methylation of the cytidine in DNA. If this occurs in quiescent proto-oncogenes, then these can become transcriptionally activated, leading to cell transformation. Other examples of non-genotoxic carcinogens include hormones, such as testosterone and estrogen. Higher steady-state levels of testosterone and estrogen are believed to lead to aberrantly high numbers of cell divisions in prostate and breast tissue. The resultant spontaneous mutations that occur are believed to lead to prostate cancer and breast cancer, respectively.

The process of chemically induced neoplastic transformation, or the process of generating a tumor cell, falls into at least four steps. In the first step, when cells are treated with mutagenic chemical carcinogens, there occur mutations in proto-oncogenes, activating them to oncogenes, and mutations in tumor suppressor genes, inactivating them. The cells then develop the ability to grow in multi-layers, and form foci. This is particularly true for fibroblastic cells, less so for epithelial cells. This first step in cell transformation is called ►morphological cell transformation, or focus formation. Further genetic changes occur in the transformed cells. The second step that occurs is that the cells become immortal, and do not die or senesce. Some activated oncogenes (v-myc) can cause cells to be come immortal. This step would be called transformation to cellular immortality. A third step that occurs is that the cells develop the ability to grow in soft agar,

in three-dimensional suspension. This step is called ►anchorage-independent cell transformation, or transformation to anchorage independence. A final step that develops after further genetic change is that the cells develop the ability to form tumors when injected into athymic (nude) mice. This step is called neoplastic transformation, or the ability of the cell to be transformed so that it forms neoplasms, or new growths, which we call tumors. Often, a number of activated oncogenes, two or more, may cooperate together to perturb normal cellular physiology, to cause neoplastic transformation of normal rodent or human cells in culture.

Significance of Chemically Induced Neoplastic Transformation

The significance of the process of chemically induced neoplastic transformation is twofold. Firstly, the assay for chemically induced morphological cell transformation can be used an assay to detect chemical carcinogens. Those chemicals that have the ability to induce foci of morphologically transformed cells are highly likely to be able to induce tumors in animals. Hence, this assay can detect chemical carcinogens by virtue of their ability to induce foci of morphologically transformed cells.

Secondly, the study of chemically induced morphological, anchorage-independent, and neoplastic transformation in vitro is frequently used as a model system to study the process of chemical carcinogenesis. Investigators frequently use these assays to study how proto-oncogenes are activated into oncogenes, and how tumor suppressor genes are inactivated by chemical carcinogens, and how oncogene activation and tumor suppressor gene inactivation leads to induction of morphological transformation, cellular immortality, anchorage-independent transformation, and neoplastic transformation.

Chemoattractant

Definition

A molecule that is capable of promoting cell movement by inducing ►chemotaxis.

►Chemokine Receptor CXCR4

Chemoattractant Cytokine

►Chemokine

Chemoattraction

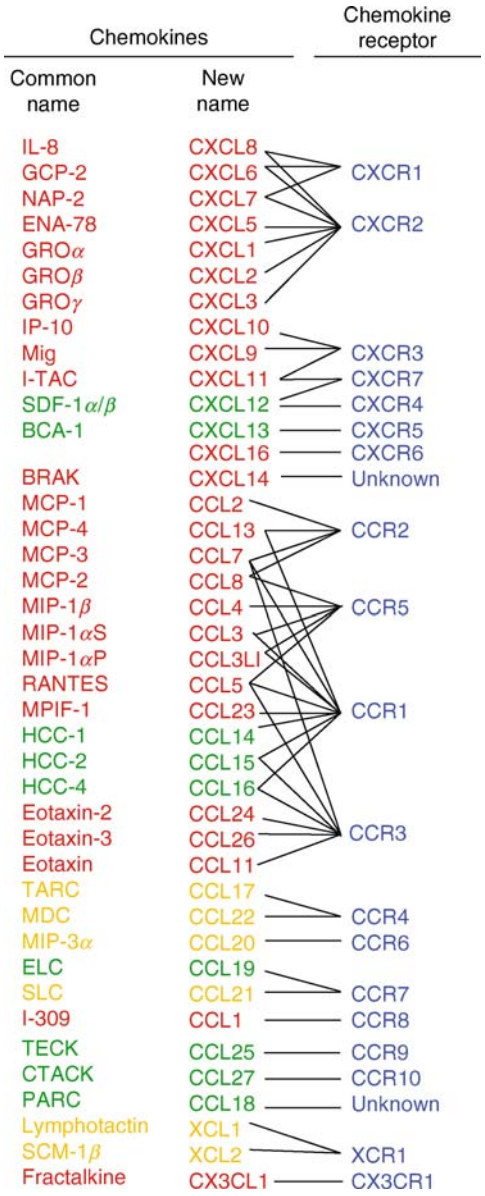
Jose Luis Rodríguez-Fernández
Departamento de Fisiología Celular y Molecular, Centro de Investigaciones Biológicas, Madrid, Spain

Synonyms

Directed migration; Directed motility

Definition

Chemoattraction is the process whereby a cell detects a chemical gradient of a ligand called chemoattractant and, as a consequence, gets oriented and subsequently moves in the direction from a low to a high concentration of the chemoattractant. Chemoattraction is controlled by specific chemoattractant receptors that are able to detect selectively these ligands. Chemoattraction is called ►*chemotaxis* or ►*haptotaxis* when the chemical gradient of the chemoattractant is presented to the cell either in a soluble or bound to a substrate form,



Chemoattraction. Figure 1 Classical and new names of chemokines are included. Red identifies "inducible" or "inflammatory" chemokines, green "homeostatic" agonists and yellow ligands belonging to both realms. BCA, B cell activating chemokine; BRAK, breast and kidney chemokine; CTACK, cutaneous T-cell attracting chemokine; ELC, Epstein–Barr virus-induced receptor ligand chemokine; ENA-78, epithelial cell-derived neutrophil-activating factor (78 amino acids); GCP, granulocyte chemoattractant protein; GRO, growth-related oncogene; HCC, human CC chemokine; IP, IFN-inducible protein; I-TAC, IFN-inducible T-cell α chemoattractant; MCP, monocyte chemoattractant protein; MDC, macrophage-derived chemokine; Mig, monokine induced by gamma interferon; MIP, macrophage inflammatory protein; MPIF, myeloid progenitor inhibitory factor; NAP, neutrophil-activating protein; PARC, pulmonary and activation-regulated chemokine; RANTES, regulated upon activation normal T cell expressed and secreted; SCM, single C motif; SDF, stromal cell-derived factor; SLC, secondary lymphoid tissue chemokine; TARC, thymus and activation-related chemokine; TECK, thymus expressed chemokine.

respectively. As it is not clear which one of these two types of motile processes takes place *in vivo*, it is more appropriate to refer to these directional motile processes with the more general term of chemoattraction.

Characteristics

Chemoattractants use specific chemoattractant receptors to guide different migratory cell types towards specific sites in the organism. These receptors, upon binding to the chemoattractant, transform the information of this ligand in intracellular signals that result in the movement of the migratory cell towards the positions where chemoattractant is present at high concentration. Therefore, the analysis, in a specific context, in one hand, of the type of chemoattractant receptors expressed by a certain migratory cell and, on the other hand, the position in the organism of the chemoattractants recognized by these receptors, allow to make predictions on the potential tissues where this cell can be attracted. Upon arrival to the position where the chemoattractant is at a high concentration, adhesive receptors may contribute to slow down (function largely performed by selectin adhesive receptors for cells in blood vessels) and eventually attach (cells use ►integrin receptors for this function in most cell types) the cells to these sites.

Chemoattractants can be conveniently classified according to the type of receptor that they bind. In this regard, the first and the largest group include chemoattractants that bind members of the ►G-protein coupled receptor (GPCR) superfamily. In this first group is included the family of ►chemokines. A second group is formed by chemoattractants that bind tyrosine kinase receptors (e.g. Epidermal Growth Factor (EGF), Platelet Derived Growth Factor (PDGF)). A third group includes ligands that bind receptors different of the two aforementioned families (e.g. laminin and fibronectin, which bind integrin receptors). This article deals mainly with the chemokines because they have been the chemoattractant family most studied in relation to ►cancer and ►metastasis.

Chemokines

Chemokines (chemotactic chemokines) are a family of peptides (60–100 amino acid (aa)) that includes some 50 members (Fig. 1). Based on the number and spacing

of the conserved Cystein (C) residue in the N-terminus of the protein, chemokines are subdivided in four families (C, CC, ►CXC, CX_3C), where X is any intervening amino acid between the cysteins. Chemokines receptors transmit intracellular signals that can control either chemoattraction or other functions (Fig. 1). The chemokine receptors (some 20 members) are included in the G-protein coupled receptor (GPCR) superfamily. They are classified based on the class of chemokines that they bind, i.e. receptors that bind C, CC, CXC, CX_3C chemokines are called respectively to CR, CCR, CXCR and CX_3CR receptors. Based largely on studies performed in the immune system, chemokines have been classified in three functional groups, homeostatic, inducible and dual function (Fig. 1). The first group, which includes chemokines constitutively produced by "resting cells" in specific organs or in tissues inside these organs, controls homeostatic migratory processes that determinate the correct location of different cell types in the organism under normal conditions. Inducible or inflammatory chemokines are secreted in different tissues in emergency situations and serve to attract to these places specialized cell types that contribute to the resolution of the emergency situation. A third group is formed by dual function chemokines, which can be either homeostatic or inducible depending on the context (Fig. 1). Although chemoattraction is the function most commonly regulated by chemokines, however, studies performed mainly on leukocytes have demonstrated that these peptides, acting through specific chemokine receptors, may control additional cellular functions, including proliferation, ►adhesion, motility, survival or protease secretion, among other functions. By controlling these activities, chemokines may contribute to modulate the functions of leukocytes and other cell types.

Chemokines and Cancer

Cancer is a disease where cells have disrupted the mechanisms that regulate their normal growth and, consequently, proliferate without control. This affliction becomes life threatening when cancer cells become metastatic, that is, they acquire the ability to leave their original sites of growth (primary tumor) and invade other tissues or organs where the uncontrolled growing cells can form new colonies (►metastases) that can interfere with vital functions. The process leading to metastasis formation has been divided into several steps. In a first step, the cancer cells detach from the substrate and from the neighboring cells and escape from the primary tumors. A second step involves the penetration of the cancer cells into the blood or lymphatic vessels and their ►migration through these vessels. In the case of cells that migrate through the afferent lymphatics, they migrate first to the lymph nodes from where they can exit through the efferent lymphatics, eventually ending up in the blood vessels. In a third stage, cancer cells extravasate from blood vessels and home into new sites in the organism where new metastatic colonies can be formed. During these migratory processes the cells undergo changes in their adhesive properties that are regulated by modulation of the activities and/or levels of integrin receptors. Moreover, cancer cells and/or associated stromal cells secrete proteases which, by degrading extracellular matrix (ECM) proteins of connective tissues facilitate the moving of the cells and the ►invasion of other tissues. Finally, at the metastatic sites, the cancer cells attach and grow as secondary colonies. In addition, they may secrete chemokines and other soluble factors that induce new vascular vessel formation (►angiogenesis) and contribute to maintain the growth of the metastatic cells. Although millions of cells may be shed into the blood from primary tumors, however only a reduced percentage of these cells are able form metastases, suggesting that metastatic cells develop mechanisms that increase their survival in the face of a hostile environment.

Chemoattraction: A Key Process to Attract Cancer Cells to New Biological Niches

Since the work of Stephen Paget in the second half of the nineteenth century, it is known that metastatic cells do not move randomly, displaying in contrast a marked tropism toward specific organs (Table 1). A variety of experimental data indicates that chemokines may play an important role in determining this bias of the metastatic cells. Analysis of the phenotype of multiple metastatic cell types shows that these cells express specific sets of chemokine receptors (Table 1). Furthermore, a clear correlation has been observed between the expression of a specific chemokine receptor by a metastatic cell and the presence of its respective ligands in the metastatic sites, suggesting the involvement of these receptors in the homing processes (Table 1). Finally, a direct role for chemokines and their receptors in the control of the tropism of metastatic cells is corroborated in studies that show that interference with the binding to the chemokine receptors impairs the ability to metastasis to specific organs. For instance, antibody neutralization of ►CXCR4 in breast cancer cells reduced the ability of these cells to form metastases in the lung, both upon intravenous injection and after ►orthotopic implantation of the cells. Conversely, over-expression of CCR7 in B16 ►melanoma resulted in a dramatic enhancement in the ability of these cells to form metastases in the draining lymph nodes upon intravenous injection of the cells in mice. From these studies it has also emerged that CCR7 and

Chemoattraction. Table 1 Chemokine receptors involved in cancer metastases

Chemokine/s receptor/s/ligand/s	Site/s of metastases	Cancer cell types	Function/s regulated by chemokine receptor
CXCR3/CXCL9, -10, -11	Lung, bone, lymph node	Acute lymphoblastic leukemia, Chronic myelogenous leukemia, colon, melanoma	Chemoattraction
CXCR4/CXCL12	Lung, bone, lymph node	Breast, ovarian, prostate, glioma, pancreas, melanoma, esophageal, lung (small cell lung cancer), head and neck, bladder, colorectal, renal, stomach, astrocytoma, cervical cancer, squamous cell cancer, osteosarcoma, multiple myeloma, intraocular lymphoma, follicular center lymphoma, rhabdomyosarcoma, neuroblastoma, B-lineage acute lymphocytic leukemia, B-chronic lymphocytic leukemia, non-Hodgkin lymphoma, acute myeloid leukemia, thyroid cancer, acute lymphoblastic leukemia, chronic myelogenous leukemia	Chemoattraction, angiogenesis, survival, growth
CXCR5/CXCL13	Lymph node	Head and neck, chronic myelogenous leukemia	Chemoattraction
CXCR7/CXCL11, -12	Lymph node	Breast, cervical carcinoma, glioma, lymphoma, lung carcinoma	Adhesion, survival, growth
CCR4/CCL17, -22	Skin	Cutaneous T-cell lymphoma	Chemoattraction
CCR7/CCL19, -21	Lymph node	Breast, Melanoma, lung (non-small cell lung cancer), head and neck, colorectal, stomach, chronic lymphocytic leukemia	Chemoattraction
CCR9/CCL25	Small intestine	Melanoma, prostate	Chemoattraction
CCR10/CCL27	Skin	Melanoma, cutaneous T-cell lymphoma	Chemoattraction, growth, survival

CXCR4 are the chemokine receptors most commonly expressed by metastatic cells. This finding contributes to explain the ability of multiple metastatic cell types that express these receptors to colonize the lymph node and other organs where CXCL12 (ligand for CXCR4 and CXCR7) and CCL19 and CCL21 (both ligands of CCR7) are expressed (Table 1).

Premetastatic niche is the name given to the specific regions, whose formation is induced by soluble factors released by primary tumor cells, which eventually become colonized by distant metastatic cells from the primary tumors. It has been shown that chemokines expression may confer premetastatic niches the ability to attract metastatic cells from the distant primary tumor. In this regard, it has been shown that chemokines S100A8 and S100A9, expressed by myeloid and endothelial in premetastatic niches in the lung, are responsible of attracting incoming Lewis Lung carcinoma metastatic cells to these niches because neutralization of the chemokines with antibodies reduced the metastases in these areas. In sum, chemokine/chemokine receptor pairs are important factors that control the colonization of cancer cells to specific sites in the organism.

Other Biological Effects of Chemokines on Cancer Cells Apart from Chemoattraction

Chemokines may affect cancer not only by regulating chemoattraction, but also by regulating other functions that control cancer progression.

Chemokines can Contribute to Regulate the Growth of Cancer Cells

Uncontrolled growth is a hallmark of cancer cells. Considering that chemokines may control cell growth in different cell types, the effect of chemokines on the proliferation of cancer cells is not unexpected. The growth of tumor cells may be affected by chemokines that can be either released in an ►autocrine signaling fashion by the cancer cells or secreted by the stromal tissues associated to the cancer cells. As an example of the first case, it is known that CXCL1, -2, -3, and -8, secreted as autocrine growth factors by melanoma, pancreatic and liver cancer cells, regulate the proliferation of all these cell types. As an example of the second case, it has been reported that CXCL12, which is secreted in lung and lymph nodes, leads to the increase in the growth of ►glioma, ovarian, small cell lung, basal cell carcinoma and renal cancer, all cancer cells

types that colonize the aforementioned organs. The effects of chemokines on growth can be complex because, for instance interference with CCR5 seems to increase the proliferation of ►xenografts of human breast cancer, suggesting that CCR5 inhibits the growth of this cancer cells.

Chemokines can Contribute to Regulate the Survival of Cancer Cells

A reduced susceptibility to ►apoptosis, leading to a concomitant extended survival, is also an important factor to explain the uncontrolled growth and the ability of cancer cells to form metastases. Chemokines have been involved in regulating survival in leukocytes and other cells, therefore these ligands may potentially contribute to regulate the carcinogenic phenotype by modulating this function. Stimulation of melanoma B16 cells expressing CCR10 with its ligand CCL27 enhances the resistance of these cells to the apoptosis induced by stimulation of the death receptor CD95. These *in vitro* results are consistent with *in vivo* experiments that show that the neutralization of CCL27 ligand with antibodies results in the blocking of tumor cell formation. Also, stimulation of glioma cells with CXCL12 protects these cells from the apoptosis induced by serum deprivation. Recently, it has been shown that, CXCR7, a novel second receptor for CXCL12, is expressed in a variety of cancer cells. It has been indicated that CXCR7 may regulate survival, growth and adhesion. Thus, it is possible that CXCR7 may also contribute to control all these functions in cancer cells.

Chemokines can Contribute to Regulate the Adhesion to New Sites in Cancer Cells

Migratory cancer cells experience changes in adhesion, including processes of attachment and detachment, as they move through the organism. Enhanced adhesion is particularly crucial at the final stages of cancer progression where these cells require attaching to the new metastatic sites. Stimulation of cancer cells with chemokines may change the adhesion of these cells either by increasing the activity of ►integrins or by inducing changes in the expression levels on the membrane of these receptors. As an example of the first case, it has been observed that stimulation of B16 melanoma cells with CXCL12 leads to an increase in the affinity of the β1 integrin by the ligand VCAM-1 both in *in vitro* and in *in vivo* experiments. As an example of the second case, stimulation of prostate tumor cells with CXCL12 induces enhanced expression of the integrins α3 and β5.

Chemokines can Contribute to Control Protease Secretion in Cancer Cells

Metalloproteins are largely responsible for ECM remodeling and play key roles in solid tumor cell invasion. In this regard, it has been shown that chemokines enhance in protease secretion in some cancer cell types. For instance, stimulation of myeloma cells with CXCL12 induces metalloproteinase secretion.

Chemokines can Contribute to Control Angiogenesis in Cancer Cells

At metastatic sites cancer cells induce formation of new vessels (angiogenesis), which allow the nourishment of the metastatic colonies. Angiogenesis is a finely orchestrated process where endothelial cells proliferate, secrete proteases, change their adhesive properties, migrate and, finally, differentiate into new vessels. Chemokines can act as positive or negative regulators of the angiogenesis in the tumor microenvironment. In this regard, the members of the ►CXC chemokine family play an important role during this process. The CXC family has been divided into two groups. A first group that includes members that present the triplet Glutamic-Leucine-Arginine (ELR) before the first Cys (ELR^+ CXC chemokines), and a second group that include the members that lack this three amino acids (ELR^- CXC chemokines). Although there are exceptions, by and large, ELR^+ CXC chemokines (including CXCL1, -2, -3, -5, -6, -7 and -8) play proangiogenic roles, promoting vessel formation through the stimulation of the CXCR2 receptor. For instance, in human ovarian carcinoma CXCL8 induces both angiogenesis and tumorigenesis. Furthermore, treatment of mice that bear CXCL8-producing non-small cell ►lung cancer cells with anti-CXCL8 antibodies blunted the growth of these tumors in the mice. Exceptions to the rule ELR^+ CXC=angiogenic chemokines are the ELR^+ CXC members CXCL1 and 2, which are angiostatic i.e. they inhibit angiogenesis.

ELR^- CXC chemokines, including CXCL9, -10, -11, are generally angiostatic. For instance, CXCL9 and CXCL10 inhibit Burkitt's lymphoma tumor formation probably by blocking blood vessel formation. An exception to the rule ELR^- CXC = angiostatic chemokine is CXCL12 that is angiogenic, as suggested by CXCL12 and CXCR4 KO mice that display cardiovascular development defects. It is believed that the angiogenic effects of CXCL12 are mediated by the vascular endothelial growth factor (VEGF) that is secreted by endothelial cells upon stimulation with CXCL12. The latter chemokine can be secreted in the tumor microenvironment by both the cancer cells and associated stromal cells. Finally, apart from CXC chemokines, other chemokines families may also regulate angiogenesis. In this regard, the CC chemokine CCL21 is angiostatic. In contrast, three CC family members (CCL1, -2, -11) and one CX3C family member (CX3CL1) can induce angiogenesis. All these chemokines, secreted inside the tumor, may potentially regulate the growth of the metastatic cells.

Therapeutical Aspects

The multiple points at which chemokines may regulate cancer progression make them attractive targets to develop anti-cancer drugs. Several strategies have been adopted to harness the power of chemokines against cancer, including the use of antibodies against the overexpressed chemokine receptors in the target cancer cells to induce apoptosis of these cells. One common strategy has been the development of inhibitors to block the binding of the chemokines to the receptors and consequently the function of these receptors. The fact that chemokine receptors are on the membrane and that much information is available on the sequences, both on the ligands and on the receptors, necessary for receptor-ligand binding have enabled the development of numerous peptide or small molecule inhibitors that interfere with chemokine function. Some of these inhibitors have been developed against CCR1, CCR5, CXCR7 and CXCR4. Most of these inhibitors relay on their ability to inhibit survival or angiogenesis in the target cells. As CXCR4 is one of the most broadly expressed chemokine receptor in cancer cells, at least six peptides or small molecule inhibitors of the function of CXCR4 have been developed and used in preclinical cancer models. CXCR4 is particularly interesting due to its pro-angiogenic functions. A variety of data indicate that the growth and persistence of tumors and their metastases depend on an active angiogenesis at the tumor sites. In this regard, interference with this process is a powerful strategy to inhibit tumor growth. Interference with CXCR4 has been used in several cancer models, including many of the cancers indicated in Table 1. Although peptide inhibitors of chemokine receptors may not have by itself ►tumoricidal affects, however, along with other strategies may be a powerful therapy against tumors.

Summary and Final Conclusions

Upon becoming carcinogenic and metastatic, a variety of cancer cells up-regulate the expression of chemokine receptors. In this regard, the microenvironment conditions inside the tumors are also known to induce chemokine receptor expression in some cases. For instance, the low oxygen concentration (►hypoxia) inside a tumor induces CXCR4 expression which concomitantly leads to a more aggressive metastatic phenotype in cancer cells. Chemokine receptors endow cancer cells with "postal codes" that determine their migration to tissues where the ligands of these receptors are expressed and therefore are important for the metastatic ability of these cells. In addition, these receptors may confer or modulate cancer cells functions that, by regulating different steps in cancer progression, may contribute to the carcinogenic and metastatic phenotype of these cells. The case of the Kaposi's sarcoma herpesvirus (KSHV), which induces cancer lesions similar to that of Kaposi sarcoma, is a dramatic example that shows the important role that chemokines and their receptors may play in cancer. Interestingly, this virus encodes a constitutively active receptor that displays a high degree of sequence similarity to chemokine receptors CXCR1 and CXCR2 and which can even be further activated by the CXCR2 ligands CXCL1 and/or CXCL8. KSHV is also pro-angiogenic and induces survival effects in the cancer cells where is expressed. Further supporting a causative role of CXCR2 in cancer, a constitutive form of CXCR2 can induce cell transformation in susceptible cell types.

Chemoembolization

Definition

Chemoembolization is a procedure in which the blood supply to a tumor is interrupted through mechanical or surgical interventions (embolization) and cytotoxic drugs are administered directly into the tumor. This technique is used in hepatocellular carcinoma and neuroendocrine carcinomas, among other cancers.

Chemotactic cytokine; Chemoattractant cytokine

Definition

Chemokines are a large group of small proteins that play multiple biological roles, including stimulating directional migration (►chemotaxis) of leukocytes and tumor cells via their membrane-bound receptors.

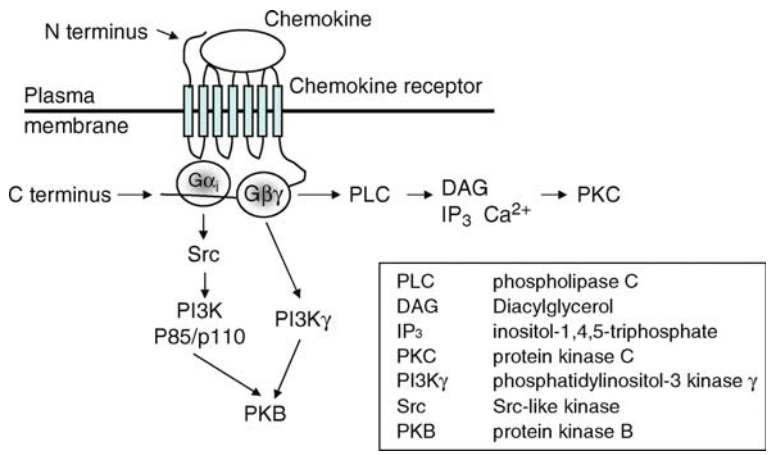
Characteristics

Chemokines are divided into four subgroups (C, CC, CXC, and CX_3C) based on the spacing of the key cysteine residues near the N terminus of these proteins. The CC and CXC families represent the majority of known chemokines. Chemokines signal through seven-transmembrane-domain receptors, which are coupled to heterotrimeric G_i-proteins. Activation of phospholipase C (PLC) and ►phosphatidylinositol-3-kinase γ (PI3Kγ) by βγ subunits of ►G-proteins is well established.

So far, approximately 50 chemokines and 18 chemokine receptors have been identified. Some chemokine receptors bind to multiple chemokines and vice versa, suggesting possible redundancies in chemokine functions. Chemokine receptors permit diverse cells to sense small changes in the gradient of soluble and extracellular matrix-bound chemokines, thus facilitating the directional migration of these cells toward higher relative concentrations of chemokines. While soluble chemoattractants can induce directional migration, chemokines (due to their net positive charges) will often be bound to and presented by negatively charged macromolecules such as endothelial cell-derived proteoglycans *in vivo*. Chemokine gradients bound to solid surfaces are capable of mediating ►haptotaxis of leukocytes and other cells. Chemokine receptor activation can also trigger conformational changes in membrane ►integrins, permitting strong cell–cell adhesion in the presence of appropriate integrin receptors. This signaling pathway is particularly relevant in triggering cellular integrins found on leukocytes and cancer cells to bind to their respective receptors (e.g. ICAM-1) on vascular endothelial cells, facilitating stable binding and spreading of cells to endothelium. The stable binding of metastatic tumor cells to vascular endothelial cells at distant sites of metastasis is likely to be a crucial early step in the process of ►metastasis.

Circumstantial evidence supports the idea that tumor cells use chemokines to promote their own survival and metastasis through multiple mechanisms. For example, certain chemokines secreted by tumor cells contribute to tumor growth and ►angiogenesis. Members of chemokines that contain an ELR motif (Glu–Leu–Arg) act as angiogenic factors, which are chemotatic for endothelial cells *in vitro* and can stimulate *in vivo*. In contrast, members without an ELR motif inhibit angiogenesis. Chemokine-mediated tumor cell activation through cellular kinases such as PI3K, ►Akt kinase, and other downstream mediators (Fig. 1) influences tumor cell resistance to apoptotic death. For example, activation of the chemokine receptor CCR10 prevents ►Fas-mediated tumor cell death induced by cytolytic antigen-specific T cells.

Selected chemokine receptors are upregulated in a large numbers of common human cancers, including breast, lung, prostate, colon, and melanoma. Chemokine receptors expressed on tumor cells coupled with chemokines preferentially expressed in a variety of organs are believed to play critical roles in cancer metastasis to vital organs as well as draining lymph nodes. CXCR4 is by far the most common chemokine receptor expressed on most cancers. In addition, CXCL12, the ligand for CXCR4, is highly expressed in lung, liver, bone marrow, and lymph nodes, which represent the common sites of metastasis of many



Chemokine. Figure 1 ►Chemokine receptor signaling. Upon stimulation by chemokine, βγ subunits of G-protein are dissociated from $G\alpha_i$ subunit. βγ subunits activate phospholipase C (PLC) and phosphatidylinositol 3 kinase γ (PI3Kγ), Whereas $G\alpha_i$ subunit directly activates ►Src-like kinase.

cancers. Chemokine receptor expression on cancer cells may influence the conversion of small, clinically insignificant foci of cancer cells at metastatic sites to rapidly growing, clinically serious secondary tumors. Cancers that upregulate CCR7 expression also facilitate their entry into lymphatic vessels, which strongly express the CCR7 ligand (CCL21), and subsequent retention within CCL21-rich secondary lymphoid organs. Upregulation of chemokine receptors such as CCR7 may be a major reason for efficient lymph node metastasis observed in many epithelial cancers.

Chemokines released by tumor cells have been shown to attract ►regulatory T cells, thus suppressing host responses to invasive tumors. Moreover, chemokine and their receptors are involved in ►dendritic cell maturation, B and T cell development, and ►T_h1 and ►T_h2 polarization of the T cell response. These actions suggest the possibility that chemokines may play a role in altering the magnitude and polarity of host immune responses to cancer cells.

Although individual chemokine and chemokine receptor appear to affect many aspects of cancer cell survival, migration, angiogenesis, and the host response to cancer cells, it is still unclear which of these functions predominate in the multistep establishment of primary tumors and secondary metastases.

Chemokine Receptor CXCR4

Jonathan Blay
Department of Pharmacology, Dalhousie University, Halifax, NS, Canada

Synonyms

Receptor for CXCL12; Receptor for stromal cell-derived factor-1 alpha (SDF-1α); CD184; Fusin

Definition

CXCR4 is a cell-surface protein that acts as a receptor for the molecule CXCL12 (stromal cell-derived factor-1 alpha, SDF-1α). CXCL12 is one of a class of signaling molecules called chemokines that regulate the movement and other activities of cells throughout the body. Although CXCL12 and CXCR4 play major roles in regulating stem cells and cells of the immune system, CXCR4 is also found on many cancer cells and plays a part in metastasis, spread of the cancer cells being influenced by tissue levels of CXCL12.

Characteristics

Chemokines are a class of peptide mediators that play important roles in controlling cellular homing and migration both in embryonic development and in the regulation of cell populations in the adult. There are at least forty different chemokines that fall into four classes depending upon their peptide structure. The different classes are "C", "CC", "CXC" and "CX_3C" chemokines, for which characteristic sequence motifs involve residues of the amino acid cysteine (C) either in sequence or separated by one or three other amino acids (X or X_3). The chemokines themselves are peptides that can exist freely in solution in biological fluids and act by binding to corresponding ►receptors. In the language of molecular interactions a chemokine is therefore known as a ►ligand. Chemokines are denoted by the letter L within their name. CXCL12 is thus a ligand, and a chemokine of the CXC class of chemokine mediators.

The chemokine receptors are named according to the chemokine class of their binding partner (or ligand), with the letter "R" to designate their receptor status. CXCR4 is therefore a receptor. As for chemokines, the numbers serve to distinguish individual members of the overall family. The partnership between chemokine receptors and the chemokines is not monogamous, and some chemokine receptors may bind as many as ten different chemokines. However, most receptors have between one and three distinct partners. With very few exceptions, these partnerships are within a particular chemokine class (e.g., CXCL chemokines bind selectively to certain CXCR receptors). At this point, the only chemokine factor known to bind to CXCR4 is CXCL12, although CXCL12 itself is able to bind to an alternate receptor (CXCR7, previously known as RDC-1) as well as to CXCR4.

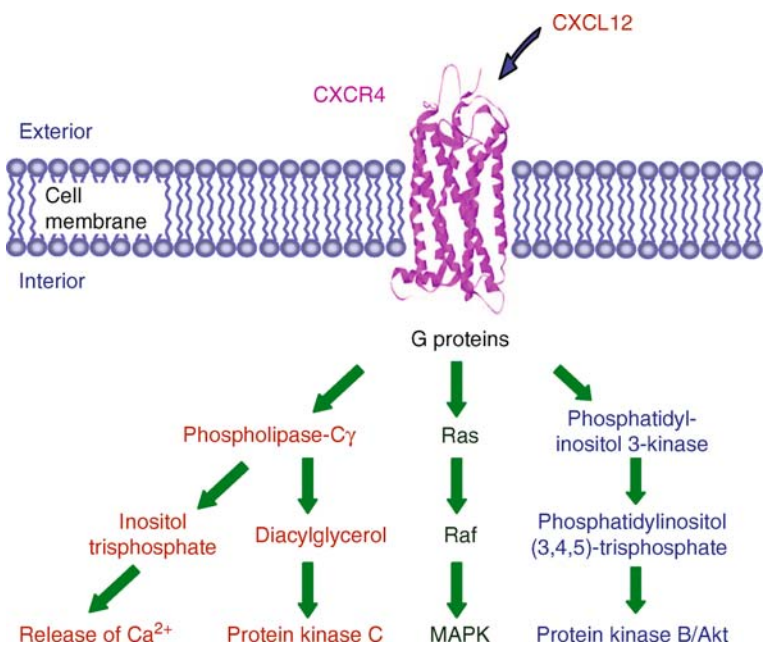
Chemokine receptors such as CXCR4 are seven-transmembrane, ►G-protein-coupled receptors. The protein chain of CXCR4 therefore winds back and forth across the outer membrane of the cell so that it crosses the membrane a total of seven times. One end of the protein chain (the amino terminus) protrudes from the outside of the cell. This region of the protein,

together with certain parts of the three extracellular loops, forms the binding domain for CXCL12. The part of the receptor that protrudes from the inner face of the membrane (composed of the carboxy terminus and three intracellular loops) contains the characteristics that allow it to provoke a cascade of events within the cell (Fig. 1). These steps are initiated firstly by a linkage to one or more of a small family of proteins that interact directly with the receptor, called ►G proteins (in this case primarily $G_{\alpha i}$ and $G_{\alpha q}$). G protein involvement leads to the activation of three major signaling pathways: (i) the phospholipase C-diacylglycerol/IP_3 pathway, (ii) the ras-raf-MAP kinase pathway, and (iii) the PI 3-kinase pathway.

CXCR4 is a crucially important member of the chemokine receptor family. If CXCR4 or CXCL12 is absent during embryonic development, the organism is unable to survive. The key dependence on CXCL12 and CXCR4 reflects the importance of this signal/receptor pair in marshalling the correct formation of cells as tissues are formed from their more rudimentary cellular precursors in the embryo. The CXCL12:CXCR4 axis, as it is often called, is a central part of the normal development of the central nervous system (the brain itself) and the exquisitely organized tissue that replenishes the different cells of the blood through adult life (the ►hematopoietic system). In addition, CXCR4 and CXCL12 seem to play a particular role in the development of the gut, and their participation is important for the proper development of the blood vessel system that is required for efficient intestinal function in the adult. In adult organisms, CXCR4 and CXCL12 partly reprise their developmental role during tissue damage by participating in repair processes.

Once the organism is fully formed, the most evident role for CXCR4 and CXCL12 in a normal individual is that of continued regulation of the hematopoietic system. This takes place mainly in the bone marrow, which acts as a reservoir for the ancestral cells (stem cells and other progenitor cells) that are needed for the continued production of various white cells (leukocytes) and other progeny that are required to ensure a proper defense against infection or injury, or to deal with replacement and remodeling of damaged tissues. These stem cells – which need to be maintained safely by the body until required to respond – are located within the protected environment of the bone marrow and are supported and nourished by a specialized grouping of cells that together are referred to as the "►microenvironmental niche." These supporting cells or "►stromal cells" secrete a number of factors that serve to nourish the stem cells and to keep them within a safe environment in their primitive and "resting" state.

Notable amongst these factors is CXCL12 (the "stromal cell-derived factor"), which can bind to CXCR4 on the stem cells. The binding of CXCL12



Chemokine Receptor CXCR4. Figure 1 The cellular signaling pathways of CXCR4. When the chemokine ligand CXCL12 binds to its receptor CXCR4, one or more of several pathways can be activated through initial links involving G proteins that associate with the receptor. These pathways, which are shown only in outline, involve a further network of interactions that eventually lead to a cellular response that may ensure cell growth, migration or survival.

to its receptor has several effects on cell behavior, but the principal outcome is to attract cells toward the source of CXCL12. In the case of stem cells in the bone marrow, this results in retention within the microenvironmental niche, or directs migrant stem cells back to this location. This ability of the CXCL12:CXCR4 axis to direct cell movement is what underlies its key role in orchestrating tissue development and repair. The phenomenon can be demonstrated in experiments using isolated cells, such that cells that have the CXCR4 receptor can be induced to migrate through pores in an artificial filter in response to an upward concentration gradient of CXCL12 in the fluid. This is a cellular response known as ►chemotaxis, and CXCL12 is referred to as a ►chemoattractant.

Unfortunately, this normal and very important process by which CXCL12 and CXCR4 assist directed cell movement has been subverted by cancer cells to assist the spread of a cancer, or metastasis. Normal tissues that are not subject to inflammation or repair processes typically have very low levels of CXCR4. However, when cancers are formed the affected cells frequently experience a dramatic increase ("upregulation") of CXCR4. This has been shown for the common adult cancers (carcinomas of the breast, colon, lung, prostate, cervix etc), which arise in the membranous linings (epithelia) of certain organs; but CXCR4 levels are also elevated in cancers arising in bone (e.g., osteosarcoma), muscle (e.g., rhabdomyosarcoma), nervous tissue (e.g., glioblastoma) or white cells (various leukemias).

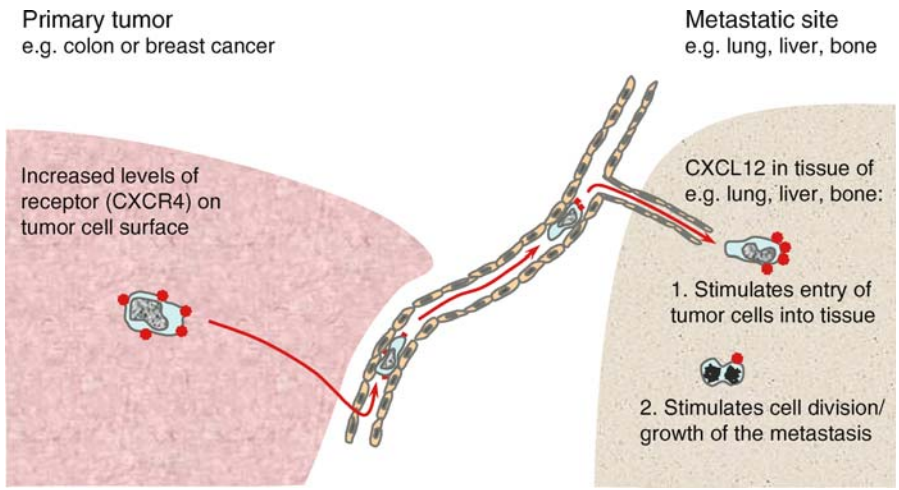
This is such a consistent finding that in many cancers the level, or "expression," of CXCR4 can be used as cancer ►biomarker. The levels of CXCR4 that are present on the cells give an indication of how the cancer is likely to behave in the future, and what therapeutic steps might need to be considered. Levels are assessed using a technique called immunohistochemistry. In this approach very thin slices or "sections" – no more than 0.005 mm thick – are taken from the suspect tissue onto glass slides. Special protein reagents called ►antibodies are used that recognize any molecules of CXCR4 in the tissue, and additional steps in the process generate color wherever the antibody has bound. The resulting picture under a microscope tells the pathologist not only about the architecture of the tissue and the characteristics of the cells, but whether or not they have high levels of CXCR4. High levels (expression) of CXCR4 are associated with cancer aggressiveness, a likelihood that the cancer will spread or metastasize, and means that the outlook for the patient is likely to be poorer.

The link between cancer aggressiveness/metastasis exists because the CXCL12:CXCR4 axis has a similar role of "directing traffic" in cancer as it does in normal circumstances. In this situation it is the cancer cells that possess the receptor – CXCR4 – and have levels at the cell surface that are much greater than are found on their normal counterparts. The exact reasons for these elevated levels of the chemokine receptor are not fully understood. Undoubtably the genetic changes that are characteristic of cancer cells lead to alterations in ►transcription of the CXCR4 gene that may provide certain subpopulations with greater amounts of the CXCR4 protein, and these cells have a selective advantage. However, there are also indications that factors within the environment of the tumor can make the situation worse by stimulating the cell to make even more CXCR4. The hypoxic nature of tumor tissue causes an increase in CXCR4 gene transcription through a pathway involving ►hypoxia-inducible factor-1 alpha (HIF-1α). Various small-molecular-weight and polypeptide mediators have also been shown to enhance the cellular expression of this chemokine receptor.

The cancer cells are therefore equipped to be attracted toward sources of CXCL12 and to be captured within environments that are high in concentrations of CXCL12. Thus, it is no coincidence that the tissues that are high in CXCL12 are also those in which cancers form secondary tumors or metastases. Such tissues include the lymph nodes – central filters in the system that drains fluid from all tissues – as well as the liver, lung and bone marrow. CXCL12 is believed to be one of the major factors driving metastasis (Fig. 2). As a colorectal cancer develops in the large intestine, for example, and small groups of tumor cells are shed into the blood circulation and the lymphatic drainage, circulating cells will find an attractive home as they encounter lymph nodes in the mesenteric fat around the intestinal wall, when they are delivered to the liver through the portal circulation, or as they lodge in the capillary beds of the lung after traversing the systemic circulation. Conversely, they have a much reduced probability of taking up residence in sites such as the heart or skeletal (voluntary) muscle, which are low in CXCL12.

In addition to being attracted and retained in tissues that have high concentrations of CXCL12, the CXCR4-bearing cancer cells may respond in other ways. Although this may not be the case for all cancers, in some types (carcinomas of the colon and prostate, for example) there is evidence that once the cells have settled in to their new location, the presence of CXCL12 acting through CXCR4 also enhances their ability to grow and colonize the tissue. In this way, CXCL12 can also be regarded as a growth factor, alongside other polypeptide growth stimulators that participate in tumor expansion.

One additional factor that makes CXCR4 of interest for many different clinicians and researchers is that it is one of the two major coreceptors by which the AIDS virus infects human cells. One of the proteins that is



Chemokine Receptor CXCR4. Figure 2 How CXCR4 and CXCL12 work together to facilitate metastasis. Tumor cells have increased levels of the receptor at their cell surface. When the tumor grows sufficiently for the cancer cells to find their way into the bloodstream, some cells lodge in tissues (e.g., lungs, liver and bone marrow) that have high concentrations of CXCL12, the molecule for which CXCR4 is the receptor. CXCL12 both encourages the entry of cells into the tissue and promotes growth of the cell population, facilitating metastatic spread. Tissues that have low levels of CXCL12 are much less likely to accept metastases.

present within the outer surface of the HIV-1 virus, called gp120, binds to CXCR4, although at a slightly different site to CXCL12. When the virus binds to its major target (the CD4 protein) on susceptible cells, it requires a coreceptor in order to complete its cellular attack. This allows it to complete the molecular changes that allow it to infect the cell. Depending on the exact cell and viral type, the coreceptor may be CXCR4 or another chemokine receptor, CCR5. While the link with AIDS has limited direct relevance to most cancers, the two fields of research have synergized to extend our present understanding of CXCR4.

Chemokines

Definition

The name comes from "Chemotactic cytokines," these small cytokines induce migration of diverse immune cells. The family of the chemokines is quite numerous, as are the chemokine receptors, and often there is "promiscuity," in that a single chemokine can active multiple receptors and multiple chemokines can activate a single receptor. These molecules direct trafficking of leucocytes. Two chemokine receptors are also the principal co-receptors for HIV involved in viral entry: CCR5, expressed on monocytes and macrophages as well as other cells, and the more widely expressed CXCR4. The tropism of specific chemokine receptors is associated with HIV clinical effects, with CCR5 linked to infection and CXCR4 tropism linked to progression to AIDS.

Chemoprevention

Definition

Chemoprevention involves the use, in healthy people, of natural or laboratory made substances to prevent cancer or reduce cancer risk both in high-risk individuals as well as in the general population. The

aim is to reduce the cancer burden in humans. Most work is being done to reduce the risk for ►oral cancer, ►prostate cancer, ►cervical cancer, ►lung cancer, ►colorectal cancer, and ►breast cancer. The first chemopreventive agent to reach the clinic – and possibly the best known – was ►tamoxifen, which has been shown to cut breast cancer incidence in high-risk women by 50%. It was followed by ►finasteride, found to reduce ►prostate cancer incidence by 25% in men at high risk for the disease. However, the large-scale trials that confirmed these benefits brought to light a troublesome issue: the drugs caused serious side effects in some patients. This is an issue of particular concern when considering long-term administration of a drug to healthy people who may or may not develop cancer. Obviously, this is raising a number of ethical issues. An effective chemopreventive agent should not significantly alter quality of life, and should be ideally inexpensive, safe, well tolerated, and effective in preventing more than one cancer.

Experience with ►celecoxib (Celebrex) and other ►COX-2 inhibitors illustrates the importance of an assessment of the risk/benefit ratio for patients. COX-2 inhibitors have shown impressive efficacy in the prevention of colon cancer and several other forms of cancer, but they also increase the risk of serious cardiovascular side effects.

Attention has focused on ►nutraceuticals and ►phytochemicals as chemopreventive agents. ►Curcumin (found in the curry spice turmeric), has shown dramatic anticancer results in preclinical studies owing to its significant anti-►inflammation properties. Curcumin has been used for thousands of years in the diets of people in the Middle and Far East and therefore is believed to have a low probability of serious side effects. Under investigation for their potential in breast cancer chemoprevention are ►aromatase inhibitors, a class of ►estrogen blockers, which are approved to treat metastatic breast cancer in post-menopausal women. While the idea of cancer chemoprevention is extremely attractive, much research remains to be done to make this a generally applicable option for reducing the human cancer burden. An important element will be to identify informative ►biomarkers to assess individual cancer risk and to possibly provide information of patients tolerance towards individual chemopreventive agents.

Synonyms

Chemoprotection; Chemoprevention

Definition

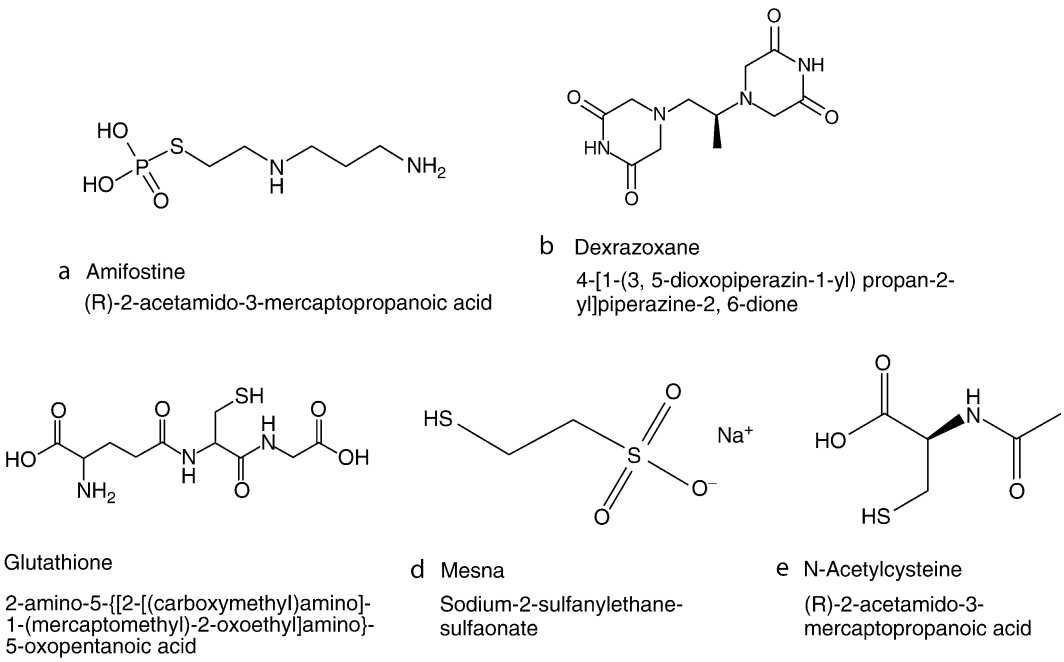
►Chemoprotectants are natural or synthetic chemical compounds which exhibit the ability to ameliorate, mimic, or inhibit the toxic or adverse effects of structurally different chemotherapeutic agents, ►radiation therapy, cytotoxic drugs, or naturally occurring toxins, without compromising the anticancer or antitumor potential of the chemotherapeutic drugs. Chemoprotectants shouldn't affect the ►therapeutic efficacy of the chemotherapeutic agents, radiation or drugs, disrupt the serum enzyme levels, or induce significant injury to the tissues/organs. These chemoprotectants include anticancer, antitumor, anti►angiogenic, and antioxidant compounds and used as an adjuvant in cancer ►chemotherapy.

Characteristics

According to the World Health Organization (WHO), cancer accounts for 7.6 million (or 13%) of all deaths in 2005, and the incidence of cancer is expected to rise with an estimated 9 and 11.4 million deaths from cancer in 2015 and 2030, respectively. Cancer chemotherapy and radiation therapy are the most promising choice available for the cancer patients. The global outlook of cancer therapy has made dramatic improvement since the discovery of various ►synthetic and ►natural chemoprotectants which slows down the progress of this deadly disease and enhances the life span of the cancer patients. Chemoprotectants may exert toxic effects. Thus, it is very important to determine the right dosage and exposure scenario for each chemoprotectant prior to the exposure to demonstrate adequate safety.

Synthetic Chemoprotectants

Amifostine. A white powder, water-soluble organic thiophosphate compound, chemically known as 2-[(3-aminopropyl)amino]-ethanethiol dihydrogen phosphate (ester) or 2-(3-aminopropylamino)ethylsulfanyl phosphonic acid or aminopropylaminoethyl thiophosphate (Fig. 1a), and used as a ►cytoprotective adjuvant in cancer chemotherapy to reduce the incidence of ►neutropenia-related fever and infection caused by



Chemoprotectants. Figure 1 Structures and IUPAC nomenclature of (a) Amifostine, (b) Dexazoxane, (c) Glutathione, (d) Mesna, and (e) *N*-acetylcysteine.

DNA-binding chemotherapeutic agents including cyclophosphamide and cisplatin. ►Amifostine (empirical formula $C_5H_{15}N_2O_3PS$; molecular weight 214.22; trade name Ethyol, synonyms: Ethiofos, Ethanethiol, Gammaphos, WR2721, NSC-296961) is used to decrease the cumulative nephrotoxicity caused by cisplatin in patients with ovarian or lung cancer, as well as to reduce the incidence of moderate to severe xerostomia (dry mouth) in patients undergoing radiotherapy for head and neck cancer. Amifostine is dephosphorylated by alkaline phosphatase in tissues to a pharmacologically active free thiol metabolite, which readily scavenge noxious reactive oxygen species (ROS) generated by exposure to either cisplatin or radiation, as well as detoxify reactive metabolites of platinum and other alkylating agents. Pharmacokinetic studies show that amifostine is rapidly cleared from the plasma with a distribution half-life of <1 min and an elimination half-life of approximately 8 min.

Ethyol is supplied in 500 mg vials and administered intravenously (i.v.). Amifostine induced adverse side effects include nausea, vomiting, flushing, chills, dizziness, shortness of breath, fainting, seizures, cardiovascular problems, skin rash, hives, and swelling of the throat.

Dexrazoxane. A whitish crystalline powder, sparingly soluble in water, and chemically known as (S)-4,4′-(1-methyl-1,2-ethanediyl)bis-2,6-piperazinedione or 4-[1-(3,5-dioxopiperazin-1-yl) propan-2-yl]piperazine-2,6-dione (Fig. 1b). ►Dexrazoxane (empirical formula $C_{11}H_{16}N_4O_4$; molecular weight 268.28; trade names: Zinecard®, ICRF-187, ADR-529, or NSC 169780, synonym: 2,6-piperazinedione) is a cyclic derivative of EDTA that readily penetrates cell membranes and a potent intracellular chelating agent. Dexrazoxane is used to protect the heart against the cardiotoxic side effects of anthracycline chemotherapy, and to reduce the incidence and severity of ►cardiomyopathy associated with doxorubicin administration in women with breast cancer. Dexrazoxane is hydrolyzed by the enzyme dihydropyrimidine amidohydrolase in the liver and kidney to active metabolites, which have been shown to chelate both free and bound intracellular iron, thereby preventing the formation of cardiotoxic ROS and prevent anthracycline-mediated cardiomyopathy. However, dexrazoxane may potentiate hematological toxicity induced by chemotherapy or radiation. Dexrazoxane is rapidly distributed into body's tissues and fluids, while the highest concentration is found in the hepatic and renal tissues. Urinary excretion plays an important role in the elimination of dexrazoxane (half-life, $t_{1/2}$ 2–4 h). Forty-two percent of the 500 mg/m^2 dose of dexrazoxane is excreted in the urine.

Dexrazoxane is available in 250 and 500 mg for i.v. administration. Adverse effects include alopecia, nausea, vomiting, fever, fatigue, anorexia, urticaria, leucopenia, hematologic thombocytopenia, and ►neurotoxicity.

Glutathione A tripeptide, made of the amino acids γ-glutamic acid, cysteine, and glycine, is the predominant nonprotein thiol and functions as a redox buffer

and exhibit diverse antioxidant activities and protects cells from oxidative stress. ►Glutathione (synonyms: reduced glutathione, monomeric glutathione, GSH; empirical formula $C_{10}H_{17}N_3O_6S$; and molecular weight 307.33) is chemically known as *N*-(*N*-L-γ-glutamyl-L-cysteinyl)glycine (Fig. 1c), while its dimer is known as oxidized glutathione, glutathione disulfide, diglutathione, and GSSG, chemically known as L-γ-glutamyl-L-cysteinyl-glycine disulfide (empirical formula $C_{20}H_{32}N_6O_{12}S_2$). The primary function of GSH is to act as a nonenzymatic reducing agent to help keep cysteine thiol side chains in a reduced state on the surface of proteins. GSH levels in intracellular fluids decline dramatically with advancing age, and thus the ability to detoxify ROS diminishes. GSH is available as a single ingredient ►dietary supplement or in combination products. Daily dosage ranges from 50 to 600 mg daily. No adverse effects were reported.

Mesna. A synthetic sulfhydryl compound, chemically known as sodium-2-mercaptoethane sulfonate or sodium-2-sulfanylethane-sulfonate, and forms a clear and colorless aqueous solution. ►Mesna (HS-CH_2–CH_2SO_3–Na^+; empirical formula $C_2H_5O_3S_2Na$; molecular weight 164.18; trade names: Uromitexan, Mesnex) (Fig. 1d) is a thiol uroprotective chemoprotectant used as an adjuvant in cancer chemotherapy to protect the bladder and kidneys from the urotoxic side effects of the chemotherapy drugs ifosfamide (Mitoxana, Ifex, and Holoxan), trofosfamide (Ixoten), and cyclophosphamide (Endoxan). It was developed as a prophylactic agent to reduce or detoxify the risk of hemorrhagic cystitis and ►hematuria (excretion of blood in urine) induced by ifosfamide or cyclophosphamide, and to decrease the incidence of ifosfamide-associated urothelial toxicity. Hematuria can also happen with higher doses of cyclophosphamide chemotherapy, but is less common. Higher doses of mesna are recommended if blood is detected in the urine. Ifosfamide or cyclophosphamide is converted to urotoxic metabolites such as acrolein and oxazaphosphosphorine metabolites, while mesna neutralizes these metabolites by binding through its sulfhydryl moieties, and increases urinary cysteine excretion. Analogous to the physiological cysteine–cystine system, mesna is rapidly oxidized to its biologically inert disulfide metabolite, mesna disulfide or ►dimesna. Both mesna and dimesna are very hydrophilic and, therefore, remain in the intravascular compartment, where they are rapidly eliminated by the kidneys. In the kidney, the mesna disulfide is reduced to the free thiol compound, mesna, which reacts chemically with the urotoxic ifosfamide metabolites including acrolein and 4-hydroxy-ifosfamide, resulting in their detoxification. After oral administration, mesna has a bioavailability of 50–75% and urinary mesna concentrations are approximately one half of those observed after i.v. infusion. The mean terminal half-life of mesna is 0.4 h, and the half-life of dimesna is 1.2 h.

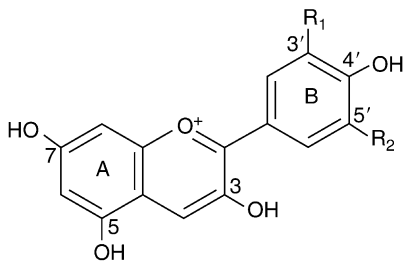
Mesnex Injection contains 100 mg/ml mesna and is recommended for both oral and/or i.v. Adverse effects include nausea, vomiting, taste changes, headache, diarrhoea, weakness, pain, skin rash, itching, irritation, and mood swings.

N-*acetylcysteine*. It is a precursor of intracellular glutathione and cysteine, has an impressive array of mechanisms and protective effects toward DNA damage, carcinogenesis, and other mutation-related diseases. ►*N*-acetylcysteine (empirical formula $C_5H_9NO_3S$; molecular weight 163.19; synonyms: LNAC, NAC, *N*-acetyl-L-cysteine; trade names: ACC, Mucomyst, Acetadote, Fluimucil, Parvolex) (Fig. 1e) is chemically known as (R)-2-acetamido-3-mercaptopropanoic acid and used mainly as a mucolytic (mucus dissolving) in a variety of respiratory conditions or in the management of paracetamol overdose. However, novel applications of NAC, alone and in combination with other anticancer compounds have been shown to be successful in treatment of tumor cell growth. First, it scavenges noxious ROS, and later, NAC is deacetylated in many tissues and cells to form L-cysteine, supporting glutathione biosynthesis that serves directly as an antioxidant or as a substrate in the glutathione redox cycle. Efficacy of different doses of NAC on potent carcinogens such as benzo(a)pyrene, 2-aminofluorene, and alfatoxin B_1 have been reported. NAC, a precursor of intracellular glutathione, is also capable of stimulating phase II enzymes in the glutathione cycle (GSH peroxidase, GSSG, reductase, GSH S-transferase). Repair of DNA damage has also been found to be stimulated by thiols like NAC and glutathione. In a rat hepatocarcinogenesis model, NAC administered by gavage, inhibited the formation of carcinogen–DNA adducts. NAC (250–1500 mg/day) is well-tolerated while mild gastrointestinal upset reported at very high doses.

ORG 2766. A neuroprotective chemoprotectant which slows down the neurotoxic effect or ►neuropathy of the cancer chemotherapy drug cisplatin, while leaving the antitumor activity of cisplatin unaffected. ►ORG 2766, a hexapeptide analog of ACTH-(4-9) [synonym: adrenocorticotropic hormone-(4-9)], prevents taxol-induced neuropathy in rats, and cisplatin-induced ►ototoxicity (ear poisoning). ORG 2766 is given subcutaneously in a dose of 0.25 mg/m^2 (low dose) or 1 mg/m^2 (high dose). No adverse effects were reported.

Natural Chemoprotectants

Berry Anthocyanin. Natural ►anthocyanins (synonyms: anthocyanins, anthocyanidins) including petunidin, malvidin, pelargonidin, peonidin, delphinidin, and cyanidin (Fig. 2), provide pigmentation (color) to fruits (especially berries), vegetables, and red wine, and



R_1 = H	R_2 = H	:	Pelargonidin
R_1 = OH	R_2 = H	:	Cyanidin
R_1 = OH	R_2 = OH	:	Delphinidin
R_1 = OCH_3	R_2 = H	:	Peonidin

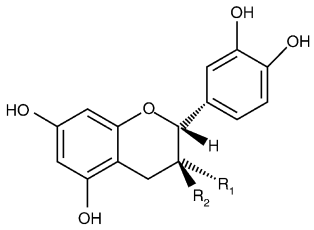
demonstrate novel chemotherapeutic, anticancer, anti-inflammatory, and antimutagenic properties. Blueberry, bilberry, cranberry, strawberry, lingonberry, tart cherry, black raspberry, and red raspberry as such, and their extracts, have exhibited potential cancer chemopreventive properties. Extensive studies were conducted on six edible berry extracts including wild blueberry, wild bilberry, cranberry, elderberry, raspberry, seed and strawberry, and accordingly a novel synergistic combination of these six berry extracts known as "►OptiBerry" was developed. The six berry extracts and OptiBerry demonstrated excellent antiangiogenic properties. OptiBerry was also shown to eradicate ►*Helicobacter pylori*, a causative factor for diverse gastrointestinal diseases including gastric cancer. Anthocyanins can be identified in human blood plasma and serum after consumption of berries.

Grape Seed Proanthocyanidins (GSP). OPC is the acronym for "oligomeric proanthocyanidins" [synonyms: procyanidins, grape seed extract, ►grape seed proanthocyanidins (GSP)], a class of polyphenolic bioflavonoids especially found in grape seeds and the bark of maritime pine trees. Catechin, epicatechin, and OPC dimers, trimers, and tetramers are shown in Fig. 3. GSP exhibited excellent free radical scavenging ability and provided significantly better protection as compared to ►vitamin C, ►vitamin E, and ►β-carotene in both in vitro and in vivo models. GSP exhibited significant protection against acetaminophen-induced hepato- and nephrotoxicity, amiodarone-induced pulmonary toxicity, dimethylnitrosamine (DMN)-induced splenotoxicity, cadmium chloride-induced nephrotoxicity, doxorubicin-induced cardiotoxicity, and *O*-ethyl-S, S-dipropyl phosphorodithioate (MOCAP)-induced neurotoxicity in mice. GSP was shown to induce selective cytotoxicity toward cultured human MCF-7 breast cancer, A-427 lung cancer and CRL-1739 gastric adenocarcinoma cells, while enhancing the growth and viability of normal human gastric mucosal cells and murine macrophage J774A.1 cells. The protective ability of GSP was assessed against chemotherapeutic drug-induced cytotoxicity towards normal human liver cells. Chang liver cells were treated with idarubicin (Ida) (30 nM) or 4-hydroxyperoxycyclophosphamide (4-HC) with or without GSP. GSP dramatically reduced the growth inhibitory effects of Ida and 4-HC on liver cells. Thus, GSP can serve as a potential candidate to ameliorate the toxic effects associated with chemotherapeutic agents used in the treatment of cancer. Another study demonstrated that long-term exposure to GSP may serve as a potent barrier to all three stages of DMN-induced liver carcinogenesis and tumorigenesis by selectively altering oxidative stress, genomic integrity, and cell death patterns in vivo. No adverse effect is known.

Green Tea Catechins and Polyphenols. The history of tea as a beverage is traced by the Chinese to about 2700 BC. The green tea polyphenols (synonym: green tea extract) are composed of seven different kinds of catechin derivatives including (+)-catechin, (−)-epicatechin, (+)-gallocatechin, (−)-epigallocatechin, (−)-epicatechin-3-gallate, (−)-gallocatechin-3-gallate and (−)-epigallocatechin-3-gallate, (Fig. 3). ►Green tea catechins exhibit powerful antioxidant, antitumor, and anticancer properties. These help DNA molecules against oxidative damage, as well as eradicate *H. pylori*. High consumption of green tea and a low incidence of prostate and breast cancers have been reported in epidemiological studies. Case-control studies have demonstrated that high consumption of green tea, especially more than 10 cups a day, is associated with cancer chemoprevention, while consumption of five cups lower the risk of esophageal, stomach, and gastric cancer. Green tea polyphenols increase the activity of both glutathione peroxidase and catalase in the intestines, liver, and lungs of mice, and suppress spontaneous mutagenesis mediated by peroxide in the microenvironment of DNA following a substantial reduction of activated carcinogens. EGCG inhibits the growth and causes regression of human prostate and breast tumors. The advantages of cancer chemoprevention with green tea components are safety, economical, and early to mass-produce.

Lycopene. A bright red carotenoid pigment, chemically a terpene assembled from eight isoprene units, is a natural pigment biosynthesized by and accumulated in various fruits mostly in deep-red color of ripe tomatoes, vegetables, plants, and algae. ►Lycopene (empirical formula $C_{40}H_{56}$; molecular weight 536.87; synonyms: all *trans* lycopene) (Fig. 4a) is one of



(+)-Catechin: R_1=H; R_2=OH
(–)-Epicatechin: R_1=OH; R_2=H
(–)-Epicatechin-3-O-gallate: R_1=OG; R_2=H

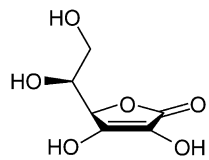
the most potent carotenoid antioxidant in the human body, as well as a potent chemoprotectant. Lycopene exhibits anticancer properties by regulating cancer cell growth by interfering with cell cycle progression thereby inhibiting proliferation. An inverse association exists between intake of tomatoes or plasma levels of lycopene and a lower risk for cancer was strongest for cancers of the lung, stomach, and prostate gland and was suggestive for cancers of the cervix, breast, oral cavity, pancreas, colorectum, and esophagus. Lycopene exhibited a cancer risk reduction of 30–40%. The red color of lycopene is due to many conjugated C = C double bonds, which absorbs most of the visible spectrum. The antioxidant properties are responsible for the anticancer properties of lycopene. Lycopene in combination with vitamin D or ►vitamin E has been reported to inhibit cancer cell growth. It was shown that lycopene, with a half-maximal inhibitory concentration of 1–2 μM, more effectively impaired growth of select cancer cell types as compared with α-carotene or β-carotene. No adverse effects were reported.

Resveratrol. A ►phytoalexin, a natural antibiotic, conferring disease resistance in the plant kingdom and is produced under the conditions of UV radiation, fungal infection, and pathogenic attack. ►Resveratrol (3,4′,5-trihydroxystilbene, 5-[(E)-2-(4-hydroxyphenyl) ethenyl]benzene-1,3-diol; empirical formula $C_{14}H_{12}O_3$; molecular weight 228.25) (Fig. 4b), is mostly found in grapes, berries, nuts, red wine, and Japanese knotweed, and produced with the help of the enzyme stilbene synthase. The *trans*- configuration of resveratrol is the only naturally occurring isomer. Resveratrol was demonstrated to function as a potent antimutagen including the induction of phase II drug-metabolizing enzymes (antiinitiation activity), inhibition of cycloxygenase and hydroperoxidase functions (antipromotion activity), and induction of human promyelocytic leukemic cell differentiation (antiprogression activity). Resveratrol was also found to possess chemopreventive activity by inhibiting ribonucleotide reductase and cellular events associated with cell proliferation, tumor initiation, promotion, and progression. Rapid absorbtion of resveratrol occurs at the intestinal level in both animals and humans, and reaches the highest concentrations in the blood plasma approximately 1 h after administration. No adverse effects were reported.

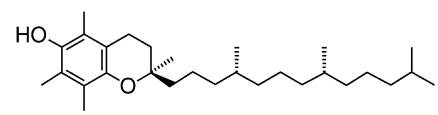
Soy Isoflavonoids. Isoflavonoids, natural plant estrogens (►phytoestrogen), exhibit novel antioxidant and anticancer properties. Soybeans contain beneficial isoflavones such as ►diadzein (empirical formula $C_{15}H_{10}O_4$; molecular weight 254.25; chemical name 4′,7-dihydroxyisoflavone; synonyms: 7-hydroxy-3-(4-hydroxyphenyl)-4H-1-benzopyran-4-one, 4′,7-dihydroxyisoflavone) and ►genistein (empirical formula $C_{15}H_{10}O_5$; molecular weight 270.24; chemical name 4′,5,7-trihydroxyisoflavone; synonyms: 5, 7-dihydroxy-3-(4-hydroxyphenyl)-4H-1-benzopyran-4-one, 4′,5, 7-trihydroxyisoflavone) (Fig. 4c). Being a weak form of estrogen, isoflavones can positively interact at estrogen receptor sites and maintain the requisite amount of estrogen in the blood level to reduce the risk factor for breast cancer and menopausal symptoms. Genistein reduces the risk factor for breast and prostate cancer, and slows down the prostate cancer growth and render prostate cancer cells to die. No adverse effects were reported.

Vitamins C, E, and β-carotene. These antioxidants are associated with decreased risk of cancer.

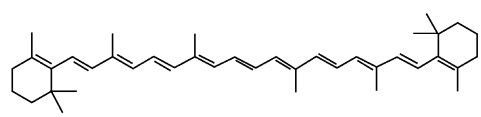
Vitamin C. It is a water-soluble, highly bioavailable antioxidant and chemically known as 2-oxo-L-threo-hexono-1,4- lactone-2,3-enediol *or* (*R*)-3,4-dihydroxy-5-((*S*)-1,2-dihydroxyethyl)furan-2(5*H*)-one (Fig. 5a).



a Vitamin C
2-oxo-L-threo-hexono-1, 4-lactone-2, 3-enediol; (R)-3, 4-dihydroxy-5-((S)-1, 2-dihydroxyethyl)furan-2(5H)-one



b Vitamin E
(R)-2, 5, 7, 8-tetramethyl-2((4R,8R)-4, 8, 12-trimethyltridecyl)chroman-6-ol



c β-Carotene
3, 7, 12, 16-tetramethyl-1, 18-bis(2, 6, 6-trimethyl-1-cyclohexenyl)-octadec; a-1, 3, ,5, 7, 9, 11, 13, 15, 17-nonaene

Chemoprotectants. Figure 5 Structure and IUPAC nomenclature of (a) Vitamin C, (b) Vitamin E, and (c) β-Carotene.

►Vitamin C (synonyms: L-ascorbate, L-ascorbic acid; L-xylo-ascorbic acid; empirical formula $C_6H_8O_6$; molecular weight 176.13) induces antioxidant efficacy in the biological systems. The low one-electron reduction potentials of ascorbate and the ascorbyl radical enable them to react with and reduce ROS and reactive nitrogen species. The ascorbyl radical may scavenge another radical, or rapidly dismutates to form ascorbate and dehydroascorbic acid. Vitamin C acts as a coantioxidant by regenerating α-tocopherol from the α-tocopheroxyl radical. Recommended dietary allowance (RDA) for vitamin C is from 75 to 90 mg/day.

Vitamin E. A fat soluble antioxidant present in cell membranes and lipoproteins, and chemically known as (*2R*)-2,5,7,8-Tetramethyl-2-[(*4R,8R*)-4,8,12-trimethyltridecyl]-3,4-dihydro-2H-chromen-6-ol (Fig. 5b). The term vitamin E (synonyms: α-tocopherol, tocopherol, (±)-α-tocopherol, 3,4-dihydro-2,5,7,8-tetramethyl-2-(4,8,12-trimethyltridecyl)-2H-1-benzopyran-6-ol; empirical formula $C_{29}H_{50}O_2$; molecular weight 430.69) describes a family of eight plant-derived antioxidants, α-, β-, γ-, and δ-tocopherol and α-, β-, γ-, and δ-tocotrienol. Only the *RRR*-stereoisomer occurs naturally. Vitamin E inhibits lipid peroxidation by reacting with lipid peroxyl radicals much faster than these radicals can react with polyunsaturated fatty acids to propagate the chain reaction of lipid peroxidation. The α-tocopheroxyl radical is relatively stable and can be reduced back by a coantioxidant such as vitamin C. RDA for vitamin E is 15 mg/day.

β-Carotene. Another fat soluble vitamin present in cell membranes and chemically known as 3,7,12,16-tetramethyl-1,18-bis(2,6,6-trimethyl-1-cyclohexenyl)-octadeca-1,3,5,7,9,11,13,15,17-nonaene (synonyms: β,β-Carotene, Provitamin A, β-cryptoxanthin, all *trans* β-carotene; empirical formula $C_{40}H_{56}$; molecular weight 536.85) (Fig. 5c). Carotenoids, a class of carotenes, are a group of more than 600 naturally occurring pigments, of which only about 50 can be bioconverted to vitamin A. Carotenoids circulate in the blood with lipids in lipoproteins, while liver and adipose tissue are the major tissues where intact carotenoids accumulate. β-Carotene is the primary provitamin A carotenoid in the human diet. Vitamin A plays essential roles in visual function, immune system function, and cell growth and differentiation. The Institute of Medicine recommends 3–6 mg of β-carotene/day.

Chemoprotection

►Chemoprotectants

Chemoradiation

►Chemoradiotherapy

Chemoradiotherapy

Marcel Verheij, Harry Bartelink
Department of Radiotherapy, The Netherlands Cancer Institute–Antoni van Leeuwenhoek Hospital, Amsterdam, The Netherlands

Synonyms

Chemoradiation; Radiochemotherapy; Combined modality treatment

Definition

►Chemoradiotherapy refers to a combination of cytostatic drugs and external beam irradiation, and can be applied sequentially or concurrently. There are several arguments to combine both modalities. While radiotherapy is aimed at controlling the primary tumor, chemotherapy is used to eradicate distant (micro-) metastases ("spatial cooperation"). Both modalities may be active against different tumor cell populations ("independent cell-killing effect"). In addition, chemotherapy may synchronize cells in a vulnerable phase for radiotherapy, decrease repopulation after radiotherapy, and enhance reoxygenation, by shrinking a tumor, which is advantageous for radiotherapy. However, this concept has failed in most clinical trials, probably due to

fast repopulation of tumor cells after cytoreduction with chemotherapy before the start of radiotherapy. In contrast to sequential regimens, concurrent chemoradiotherapy results in a reduction of the overall treatment time, minimizing the risk of clonogenic repopulation. Moreover, it exploits the ability of chemotherapeutic agents to sensitize radio-resistant tumors to the lethal effect of ionizing irradiation.

Characteristics

In this review we will mainly focus on chemoradiotherapy, the combined use of chemotherapy and ►ionizing radiation therapy, in a number of solid tumors. Several clinical trials carried out during the last decades clearly show that concurrent delivery of both treatment modalities significantly improves local control in a variety of advanced solid tumors. In most of these trials, ►cisplatin alone or in combination with other drugs has been used. This has led to improved survival rates in head and neck, lung, and cervical cancer. An additional important advantage of this combined treatment is the possibility to obtain a higher organ-preservation rate, such as in patients with advanced head and neck or anal cancer. Finally, in the preoperative and ►adjuvant therapy setting, concurrent ►chemoradiation has contributed to a better outcome in terms of tumor downsizing/-staging (esophageal and rectal cancer) and survival (►gastric cancer). Major further improvement can be expected from the combination with biological agents that specifically target deregulated pathways in tumor cells. Examples include ►epidermal growth factor receptor (EGFR) inhibitors and ►antiangiogenic drugs.

Chemoradiotherapy for Non-Small Cell Lung Cancer

For many years radiotherapy has been the standard of care for inoperable stage III non-small cell lung cancer (►NSCLC). These patients, however, show a poor outcome with long-term survival rates of 5–10%. Therefore, many groups have explored the possibility to improve these results by adding chemotherapy to the radiation treatment. In 1992, the EORTC reported the results of a randomized phase III study of concomitant cisplatin (weekly or daily) and radiotherapy versus radiotherapy alone in patients with inoperable NSCLC. The results indicated that the combination of cisplatin with radiotherapy was associated with improved survival and control of local disease. The largest and significant benefit was seen in the radiotherapy/daily cisplatin arm. Two recent meta-analyses confirmed the benefit of concurrent cisplatin-based chemoradiotherapy compared with radiation alone and consolidated this regimen as standard treatment for stage III NSCLC. Whether chemoradiotherapy should be given sequentially or concurrently, has also been the topic of several studies. Four randomized trials have demonstrated that concurrent is better than sequential chemoradiotherapy, but is also associated with more acute toxicity, mainly esophageal. So far, no significant increase in late toxicity has been reported.

Chemoradiotherapy for Small Cell Lung Cancer

In the treatment of limited stage SCLC, the central role of chemotherapy has been widely recognized. To define an additional role of thoracic irradiation, several large phase III studies have been performed. These, together with subsequent meta-analyses established the positive impact of thoracic irradiation in combination with chemotherapy in terms of local tumor control and survival. Regarding the timing of both treatment modalities, it has been shown that early thoracic irradiation during chemotherapy is superior to its late scheduling.

Chemoradiotherapy for Cervical Cancer

The introduction of chemoradiotherapy in the treatment of cervical cancer shows many similarities with that in NSCLC: until the 1980s radiotherapy was the standard therapy for patients with locally advanced tumors. Despite modifications of the total radiation dose and overall treatment time, more than 70% of these patients developed a local regional recurrence. Therefore, improvements of these results were sought into the addition of chemotherapy to radiotherapy. In 1999, three articles were published reporting on studies comparing chemoradiotherapy with conventional radiotherapy for locally advanced cervical cancer. In all three studies, the combination of radiotherapy with cisplatin was significantly better than the control arms. An interesting observation came from Rose and colleagues, demonstrating that the single use of cisplatin was as effective as a combination of three drugs, the latter scheme being much more toxic. In the meantime, three additional trials on the concomitant use of cisplatin in cervical cancer have been published, demonstrating now in five out of six trials a significant improvement of local control and survival when concomitant cisplatin and irradiation was used. This is in contrast with eight out of nine phase III studies of ►neoadjuvant chemotherapy prior to radiotherapy, showing no benefit. Based on these results, concurrent chemoradiotherapy is nowadays the standard of care for cervical cancer. Several open questions persist, however. For example, it is unclear whether patients with very large tumors benefit as much from chemoradiotherapy as those with smaller tumors. Also, it remains to be established what the optimal chemotherapy or combination of cytostatic drug is for combined use with radiation.

Chemoradiotherapy for Head and Neck Cancer

Several chemoradiation trials have been conducted in patients with previously untreated head and neck cancer using cisplatin alone; cisplatin and ►5-fluouracil (5-FU); and other combinations. In eight single institutional studies, the average complete response to concomitant therapy was 67.5%. A recent meta-analysis performed by the MACH-NC group concerning the updated results of 63 randomized trials including 10,717 patients demonstrated a clear benefit of 8% ($p = 0.0001$) improved disease-free survival for the concomitant chemotherapy treatment. In the same analysis adjuvant and neoadjuvant chemotherapy showed no improvement. Subsequent trials confirmed that the concomitant use of cisplatin or carboplatin and irradiation leads to improved local cure and survival when compared with radiotherapy alone, including in the postoperative setting.

Despite these encouraging results, cisplatin-based chemoradiation protocols for advanced head and neck cancer are still associated with too many locoregional recurrences. Besides dose-escalation strategies, molecular targeted drugs represent a new and promising approach to further improve treatment results. One of these is the humanized monoclonal antibody directed against the EGFR which is frequently overexpressed in head and neck cancer and associated with chemo-/radioresistance and poor outcome. In 2006 a large multicenter randomized phase III study was published comparing radiotherapy alone with radiotherapy plus cetuximab in patients with locally advanced head and neck cancer. The results were very encouraging and demonstrated that the addition of cetuximab to radiotherapy significantly improved locoregional control and survival. Whether cetuximab (or other EGFR-blocking strategies) can replace chemotherapy or further improve the results when added to chemoradiotherapy, is subject of ongoing trials.

Chemoradiotherapy for Esophageal Cancer

Surgical resection is currently the preferred treatment for ►esophageal cancer. Neoadjuvant chemotherapy may improve the results of surgery and may prevent patients from recurrent disease. However, a recent Cochrane meta-analysis based on seven phase III randomized trials with neoadjuvant chemotherapy failed to demonstrate such a beneficial effect. In a number of studies sequential chemoradiotherapy or concurrent chemoradiotherapy was compared with radiotherapy alone. The RTOG 85-01 phase III study comparing radiotherapy alone with 5-FU/cisplatin-based chemoradiotherapy showed a statistically significant survival difference in favor of the chemoradiotherapy arm. Treatment-related toxicity was increased in the chemoradiotherapy arm, 44% severe and 20% life-threatening side effects versus 25 and 3% in the radiotherapy alone arm. Late toxicity was not increased as has been reported in other studies with concomitant chemoradiotherapy. Al-Sarraf reported on an additional group of patients treated with the same chemoradiotherapy regime. The 5-year survival was 26% versus 0% in the chemoradiotherapy arm and radiotherapy alone arm, respectively. These studies show that concurrent chemoradiation is recommended compared with radiotherapy alone. In most concurrent chemoradiotherapy studies the classic 5-FU/cisplatin regimen has been used. More recently, studies with taxanes as concurrently administered cytotoxic drugs showed promising results. Preoperative chemoradiotherapy with a weekly schedule of paclitaxel and carboplatin appears highly effective in tumor downstaging and obtaining a radical resection.

Chemoradiotherapy for Gastric Cancer

Surgical resection remains the cornerstone of curative treatment of gastric cancer. However, the long-term prognosis remains poor for patients with locally advanced disease. Therefore, different (neo-) adjuvant strategies have been evaluated in the past decades to improve these results. Adjuvant chemotherapy only resulted in a small survival benefit of 3–5% as shown in multiple meta-analyses. Preoperative radiotherapy also showed a small, but significant improvement in survival. Recently, MacDonald et al. performed a randomized phase III study comparing surgery alone with surgery and postoperative adjuvant therapy, combining radiotherapy with 5FU-leucovorin. In this study of 556 patients a statistically and clinically significant reduced risk of relapse and improved survival were observed. Median overall survival in the surgery alone group was 27 months, compared with 36 months in the chemoradiation group. An update of these results provided at the ASCO GI 2004 meeting showed a persistent positive effect with a 3-year survival rate of 41% versus 50% ($p = 0.005$). In 2005 final results of the MAGIC-study on perioperative chemotherapy have been presented. In this large multicenter study patients were randomized between surgery only and three cycles of preoperative ECF (epirubicin, cisplatin, 5-FU) followed by surgery and then another three cycles of ECF chemotherapy. This regimen resulted in a 10% higher resectability rate and a significant survival benefit of 13% (23% vs. 36% at 5 years). Which of both strategies – postoperative chemoradiotherapy or perioperative chemotherapy – is superior, remains to be determined. Since preoperative-combined chemoradiotherapy has shown a beneficial impact on surgical outcome in esophageal and rectal cancer, this is an attractive approach to explore in operable gastric cancer as well. Because of tumor downsizing by neoadjuvant chemoradiotherapy in gastric cancer the rate of tumor negative surgical resection margins will improve.

Chemoradiotherapy for Rectal Cancer

Surgical resection is the only curative treatment for colorectal cancer. However, following resection, local recurrence rate varies between 5 and 40%. Total mesorectal excision (TME), the standard surgical technique for primary resectable rectal cancer, has significantly improved the outcome of this disease, in particular through the realization of free circumferential margins. The Dutch TME trial demonstrated that short-term preoperative radiotherapy is effective in preventing local recurrences, but not in patients with a positive resection margin. Although positive margins can be partly due to poor surgical techniques, they occur more often in locally advanced tumors. For these stages, a more aggressive (neo-) adjuvant approach is required. Postoperative chemoradiation has been mainly evaluated in the United States. The Gastrointestinal Tumor Study Group conducted a four arms study: surgery only, postoperative chemotherapy, postoperative radiotherapy, and postoperative chemoradiotherapy (GITSG 71-75). Pairwise comparisons showed superior survival and local recurrence rates in the chemoradiation arm versus the surgery-only arm. The North Central Cancer Treatment Group compared radiotherapy with postoperative chemoradiation and demonstrated lower local and distant recurrence rates in the combined treatment arm. Survival was significantly increased (NCCTG 794751). The evidence that the addition of chemotherapy to preoperative radiotherapy improves local control rates has recently been provided by two separate trials. The EORTC 22921 trial has a two by two factorial design and randomized between preoperative radiotherapy versus preoperative 5-FU-based chemoradiotherapy. A second randomization took place for postoperative chemotherapy versus no adjuvant treatment. The results demonstrated an increased local control rate for the chemoradiation arm: 92% versus 87%. A similar result was found in the French FFCD 9203 study, which randomized between preoperative radiotherapy and preoperative 5-FU-based chemoradiotherapy, with local recurrence rates of 16.5 and 8%, respectively. All studies that compare preoperative radiotherapy with preoperative chemoradiotherapy demonstrate an increase in toxicity in the combined modality arm.

Recently, it became clear that apart from cytotoxic agents, biological agents may play a role in the achievement of tumor response. In a recent experimental study, ►VEGF blockade enhanced radiotherapeutic activity, probably due to reduction of tumor vascular permeability and tumor interstitial pressure, thereby increasing the delivery of large therapeutic compounds to the tumor. In an early report on a small number of patients treated with the combination of an anti-VEGF monoclonal antibody, bevacizumab, 5-FU and radiotherapy, significant downstaging occurred in all six patients.

Chemoradiotherapy for Anal Cancer

Over the past decades, the treatment of anal cancer has shifted from a surgical approach toward organ-sparing radiotherapy with or without concurrent chemotherapy. It was shown in two randomized studies that concomitant radiotherapy and 5-FU and ►mitomycin C (MMC) is superior to radiotherapy alone and significantly reduced the number of local recurrences. These anal cancer trials also clearly demonstrated the advantage of organ preservation by combined modality treatment as it results in an improved colostomy-free survival. The enhanced acute toxicity which was observed during these combined regimens did not translate in a significant increase in late side effects. MMC has contributed significantly to these results. In a RTOG study patients were randomized to radiotherapy and 5-FU, or radiotherapy, 5-FU, and MMC. The colostomy-free survival rate at 4 years was significantly better in patients who received both 5-FU and MMC compared with those who received 5-FU only (71 and 59%, respectively). In addition, others found that by deleting MMC from a comparable combined treatment protocol the local tumor control rate at 2 years dropped from 87 to 58%. In order to minimize treatment-related toxicity cisplatin has been evaluated as a replacement for MMC, with good results in nonrandomized studies. Randomized trials are now underway to confirm at least equal efficacy of cisplatin and MMC. At the annual ASCO meeting 2006 Ajani et al. reported the first results of the RTOG 98-11 study. This phase III randomized trial compared 5-FU plus MMC and radiation to 5-FU plus cisplatin and radiation in 632 anal carcinoma patients. Preliminary 5-year estimated disease-free, colostomy-free, and overall survival was not significantly different. Hematological toxicity grade 3/4 was significantly more severe in the MMC-containing arm. Based on these results, it was concluded that MMC, 5-FU, and radiotherapy remain the standard of care for patients with anal canal carcinoma. Further improvements in treatment results are expected from the application of novel biological agents.

Concluding Remarks

The combination of radiotherapy and chemotherapy has resulted in a major step forward in the treatment of patients with advanced solid tumors. The recognition that concurrent chemoradiotherapy is superior to sequential regimens may be viewed as one of the major achievements in clinical oncology of the past decades. In general, the interaction between radiation and cytostatic agents is time-, dose-, and sequence-dependent as shown for cisplatin, the most widely used ►radiosensitizer. In the near future, a number of new drugs will

become available for testing in concomitant chemotherapy and radiotherapy approaches. These agents should be selected based upon their mechanisms of action. Given the results of many randomized clinical studies, it is quite likely that chemoradiotherapy will be the standard of care for an increasing number of advanced squamous cell cancers, but until the best regimen of each disease has been determined, there is now more than ever an urgent need to encourage treatment of patients within the framework of carefully controlled clinical trials.

Synonyms

Resistance modulation; Resistance reversion

Definition

The sensitization to chemotherapeutic agents of resistant tumor cells is known as chemosensibilization.

Characteristics

Chemosensibilization is used when tumor cells no longer respond to chemotherapeutic drugs. This resistance can be inherent to tumor cells or can be acquired during ►chemotherapy treatment, leading to the inefficiency of a wide range of antineoplastic agents. This phenomenon is named multidrug resistance (MDR). Once MDR appears, chemotherapy is not efficient anymore even when using high doses of drugs, which stimulates the resistance mechanism and brings toxic side effects. To overcome this problem, several strategies aiming at restore drug sensitivity are used. The main approach to achieve chemosensibilization is the use of substances capable of bypassing the resistance mechanism, named chemosensitizers or MDR modulators. A typical chemosensitizer should not really have inherent antitumor properties; however, most chemosensitizers exhibit antitumor activity and act synergistically with antineoplastic drugs to kill tumor cells. After the discovery of the mechanisms leading to chemoresistance, much effort has been devoted to discover such candidate molecules. Although numerous chemosensitizers have been developed, few of them have reached clinical trials. MDR is a multifactorial phenomenon and the best characterized mechanisms are resistance to apoptosis and enhanced drug efflux due to the overexpression of ATP-binding cassette transporters (►ABC transporters) such as ►P-glycoprotein (P-gp), MRP, or BCRP in tumor cells.

Chemosensibilization of Tumors by Targeting P-gp

Inhibitors of P-gp Activity

The development of chemosensitizers to overcome chemoresistance mediated by ABC transporters mainly focus on the inhibition of P-gp that is overexpressed in numbers of malignancies (Table 1). Many chemosensitizers are administered simultaneously with anticancer drugs. They overcome drug resistance by functioning as competitive or non competitive inhibitors for P-gp and by binding either to drug modulation sites or to

Chemosensibilization. Table 1 Compounds used to chemosensitize P-gp-mediated MDR tumor cells

Antiarrhythmics	Quinidine, amiodarone, propafenone
Antibiotics	Cephalosporins
Antihistaminics	Terfenadine, azelastine
Antihypertensive	Reserpine
Antimalarials	Quinine, quinacrine, mefloquine
Calcium channel blockers	Verapamil, dexverapamil, nicardipine, azidopine
Calmodulin antagonists	Trifluorperazine, chlorpromazine
Immunosuppressants	Cyclosporin A, SDZ PSC 833, staurosporine, rapamycin
Neuroleptics	Phenothiazine, fluoxetine, haloperidol
P-gp-specific chemosensitizers	MS 209, GF 120918, XR 9576, VX-710, LY 335979
Steroid hormones and synthetic derivatives	Progesterone, tamoxifen
Alkaloids	Cyclopamine, tetrandrine, fangchinoline
Flavonoids and dietary compounds	Quercetin, genistein, curcumin, green tea polyphenols, ginsenoside Rg, indole-3-carbinol, diallyl sulfide
Anti-P-gp antibodies	Monoclonal antibodies, immunization-induced antibodies
siRNA, antisense oligonucleotides	
Anti-MDR1 ribozymes	

other modulator binding sites. Other reversing agents act by interfering with ATP hydrolysis required to P-pg activity.

The first chemosensitizers used to inhibit P-gp-mediated MDR were drugs that possess unrelated pharmacological functions. Among them, verapamil was the first substance that showed chemosensitizing activity. It was originally used as a calcium channel blocker in the treatment of heart disease. Verapamil is a substrate of P-gp and inhibits the transport of chemotherapeutic drugs in a competitive manner without interfering with its catalytic cycle. Cyclosporin A, a commonly used immunosuppressant for organ transplantation, can also sensitize MDR tumor cells by interfering with both substrate recognition and ATP hydrolysis. Unfortunately, the use of these first generation chemosensitizers in clinical studies has been limited. These sensitizers reverse MDR at high concentrations, which brings toxic side effects due to their innate pharmacological function.

The search for nontoxic second generation chemosensitizers resulted in newer analogs of the first generation modulators that were more potent and considerably less toxic. Structural analogs of verapamil show increased reversal activity when used at lower doses and are less cardiotoxic than verapamil. PSC 833, a potent and non immunosuppressive analog of cyclosporine, efficiently reverses MDR and has been used in combination with anticancer drugs in clinical studies. It restores sensitivity to chemotherapy by direct interaction with P-gp. Although these modulators are more efficient than the first generation chemosensitizers, they influence the pharmacokinetics of anticancer drugs, elevating plasma concentration beyond acceptable toxicity.

Third generation chemosensitizers were designed using structure-activity relationships specifically for high transporter affinity and low pharmacokinetic interaction. The latest synthetic compounds, including VX-710, LY 335979, GF-120918, and XR 9576, are currently used in clinical trials in association with anticancer drugs to sensitize tumor cells.

Several other compounds with different pharmacological functions possess chemosensitizing effects in several models of resistant tumor cells expressing P-gp (Table 1).

Other Strategies to Inhibit P-gp

Alternative strategies that include the use of chemicals as chemosensitizers can be applied to restore sensitivity of tumors:

1. *Anti-P-gp Antibodies*. Antibodies specific to P-gp have been developed and are capable of potent reversal of MDR by disrupting P-gp drug efflux activity. These antibodies can be generated by several ways. ►Monoclonal antibodies generated from hybridomas have been developed to target P-gp. The monoclonal antibody UIC2 recognizes a conformational epitope that involves several peptide fragments of the human P-pg. The binding of UIC2 to P-gp induces the blockade of conformational changes required to the activity of the efflux pump, leading to an increase in intracellular accumulation of drugs. Recombinant antibody fragments targeted

to extracellular loops of P-gp are also used in vitro to sensitize MDR cells to chemotherapy, as well as antibodies induced by immunization with P-gp-derived peptides that allow the *in vivo* sensitization of tumor cells to anticancer drugs.

2. *Altered Levels of MDR1 mRNA*. Downregulation of the *MDR1* gene coding for P-gp is another way to overcome chemoresistance. It is based on the use of molecules such as antisense oligonucleotides (ASOs), small interfering RNAs (siRNAs), and ribozymes whose activity leads to altered level of a specific mRNA (►Antisense DNA therapy, ►RNA interference and cancer). They can specifically modulate the transfer of the genetic information from DNA to proteins. ASOs are short single strand DNAs that hybridize to a unique mRNA sequence. Hybridization of ASOs to mRNA leads to the formation of mRNA/DNA hybrid duplexes that become the target of RNase H, an enzyme that catalyzes the cleavage of RNA in RNA/DNA duplexes. siRNAs are small RNAs duplexes that assemble into a RNA-induced silencing complex (RISC). These complexes target a specific mRNA that is cleaved and degraded. The targeting of a unique mRNA can also be achieved by using catalytic RNAs called ribozymes. These small RNAs hybridize to a complementary sequence of mRNA and catalyze site-specific cleavage of the substrate. Specific ASOs, siRNAs, and ribozymes targeted to the MDR1 mRNA are used to prevent P-gp expression in tumor cells and can improve sensitivity toward chemotherapeutic drugs in resistant tumor cells.

Chemosensibilization of Tumors by Triggering Apoptosis

Tumor cells can become resistant to chemotherapy due to a reduced susceptibility to die by ►apoptosis, by the overexpression of antiapoptotic proteins and activation of prosurvival signaling pathways, or by the downregulation of proapoptotic proteins. Cancer treatment by chemotherapy kills cells principally by inducing apoptosis. Therefore, modulation of the key elements of apoptotic signaling directly influences therapy-induced tumor cell death and represents another way to sensitize tumor cells to apoptosis-inducing drugs. Given that antiapoptotic Bcl-2 family members are overexpressed in many types of cancers, specific ASOs directed against these proteins can be useful to improve drug sensitivity. The administration of Bcl-2 and Bcl-x_L antisenses in combination to anticancer drugs results in a decreased level of these antiapoptotic molecules and the subsequent improved efficiency of drugs. In many cases, complete cure of mice bearing Bcl-2 or Bcl-x_L-overexpressing tumors occurs. Downregulation of other proteins inhibiting apoptosis including survivine and XIAP and silencing of prosurvival signaling mediated by the PI-3kinase/Akt pathway and NFκB can also sensitize tumor cells to programmed cell death

A growing interest has been placed upon the use of dietary polyphenols, which induce apoptosis in cancer cells while they protect normal cells. These compounds not only have the capacity to trigger cell death when used as single agents, but also enhance apoptosis triggered by numerous anticancer drugs in several tumor cell lines by interfering with multiple pathways leading to chemoresistance (►Polyphenols and cancer).

Chemotherapy of Cancer

Emil Frei III
Dana-Farber Cancer Institute, Boston, MA, USA

Definition

Chemotherapy is defined as the use of chemical agents for treatment. Chemotherapy as used for cancer generally refers to small molecules that damage proliferating cells. It represents systemic treatment in contrast to radiotherapy and surgery that represent local treatment. Classes of systemic agents may also include hormones, cytokines and vaccines.

Characteristics

The Challenge

Cancer is the most feared, morbid and mortal of diseases. In the United States five million people contract cancer per year, of whom one third, or almost half a million citizens will die of their disease. Most cancers start in a specific location (e.g. breast, lung) and spread to regional lymph nodes; in breast cancer spread is to the armpit and subsequent dissemination by the bloodstream to distant organs. For cancers that are diagnosed before such dissemination, local treatment with surgery and/or radiotherapy may be curative. Most patients who die of cancer die because of disseminated metastatic tumor. These are either clinically present at the time of diagnosis or occur months to years after diagnosis because of microscopic clinically undetectable cancer that only becomes clinically evident following local treatment. Cancer chemotherapy along with hormone therapy and immunotherapy is designed to treat and ideally eradicate metastatic cancer.

The Agents

Most of the currently effective chemotherapeutic agents were discovered by serendipity and/or empiricism (by trial and error). For example, the first effective agent, nitrogen mustard, was a derivative of chemical warfare studies conducted in World War I. Among the side effects of mustard gas was the suppression of normal bone marrow. Because of this, it was given to mice bearing a tumor derived from the bone marrow, i.e. leukemia, and found to be effective. Subsequent clinical trials affirmed this effectiveness. Analogs were synthesized and mustard-like compounds, termed alkylating agents, are effective in many forms of cancer.

The antimetabolites are compounds that are similar to normal metabolites, such that they enter the same metabolic system but because of slight differences, inhibit or antagonize that system. For example, white cells consume high quantities of the vitamin folic acid, and this is particularly true of cancerous white cells, that is leukemic cells. Slight chemical modifications of folic acid have lead to the antifol class of compounds, and these have been found to be active in patients with leukemias, as well as in many solid tumor patients.

Two important classes of compounds are

- The anthracyclines
- The platinum analogs both of which were discovered by serendipity, and developed largely through screening methods. All of the above compounds target DNA and therefore cell proliferation. Another class of compounds target the cytoskeleton of the tumor cell. These are derived from fungi and plants, and include the vinca alkaloids and the recently discovered ►taxol.

These examples of currently used agents, while varyingly effective against human cancers (see below), have a significant limitation in the area of specificity. They attack not only the tumor but also certain rapidly growing normal tissues such as the bone marrow and bowel, and hence produce dose-limiting toxicity relating to depression of the marrow (infection and bleeding), nausea and vomiting and ulceration of the gastrointestinal tract.

The use of high dose combination chemotherapy with stem cell rescue for patients with breast cancer was the subject of considerable enthusiasm during the 1980s and early 1990s. However, in the late 1990s and particularly since the American Society of clinical Oncology (ASCO) reports in 1999 have been considered to be largely ineffective. This paper considers some of the reasons for this change and particularly on the basis of preclinical and clinical models, considers current and future directions. The intensification regimen may produce resistance that could compromise the important intensification component. Microenvironmental and clinical trials of adjuvant chemotherapy strongly indicate that one cycle of intensification is not enough and that two and perhaps three will be required. The components of the intensification regimen are reviewed with respect to dose response and with respect to mechanisms of resistance, cross resistance and potential additive or synergistic effects.

To reiterate, the major limitation of classical cancer chemotherapy is the lack of specificity for the tumor as compared to normal tissue. This limitation is being addressed by basic science particularly relating to molecular biology, a summary of which follows:

Cancer is a genetic disease of somatic cells, following a series of mutations or genetic events incident to lifestyles such as smoking.

►Tobacco carcinogenesis and genetic susceptibility, a sufficient number of events occurs such that a cell becomes transformed into a cancer cell. The vast majority of cancers therefore derive from a single cell. However, the process that produces cancer also results in a marked increase in genetic instability such that daughter cells are variable. This variation permits selection of those daughter variants that have a survival advantage, such as resistance to certain drugs, a higher proliferative thrust or a greater capacity to invade and metastasize. This clonal evolution to heterogeneity is adverse. However, it does lead to events that are unique to the cancer cell, that is, they are not present in normal cells in the same person. For example, chronic myelogenous leukemia is due to white cells being driven to cancer behavior by a product of the fusion of two genes. By advanced pharmacologic techniques including designer drug synthesis and high throughput screening, an agent termed STI571 was developed that inhibits the action of the fusion gene protein product. STI571 has been found to be capable of producing complete regression of leukemia in the majority of patients, and in contrast to essentially all chemotherapy, is non-toxic. There are a number of molecular targets in other tumors that have been identified, and academia and the pharmaceutical industry have given major priority to the development of agents capable of selectively attacking and inhibiting such molecular targets. It is this process more than any other that leads to optimism on the part of cancer investigators concerning the future of cancer treatment.

Clinical Strategies

Although there are numerous different types of cancer, they often share many biological and molecular processes, an important feature to keep in mind.

In the late 1950s a series of integrated clinical trials were conducted. As a result, the cure rate for childhood leukemia increased from 0% to 70% and many scientific principles of cancer therapy were established. These were (in chronological order):

- The application of quantitative clinical trials, involving comparisons and randomizations.
- The use of agents in an appropriate combination can increase the complete remission rate from zero to more than 90%.
- The generation of complete remission as the most powerful discriminant for survival.
- The identification of active agents in an experimental model with the duration of complete remission (DCR) being central parameter of response.
- The use of the DCR model to develop and evaluate optimal doses, schedules, and combinations.
- It was observed that meningeal leukemia occurred with increasing frequency in patients with prolonged complete remission. Pharmacological and clinical trial studies found this be due to the failure of standard anti-leukemia agents to cross the blood/brain barrier. The introduction of intrathecal chemotherapy and radiotherapy to the brain, markedly reduced this type of complication.
- The importance of supportive and symptomatic care; for example, platelet transfusions, antibiotics and anti-emitics, markedly reduced the morbidity and mortality of chemotherapy.

The result of these advances was an increase in the cure rate for childhood leukemia from 0% in 1955, to 35% by 1970, up to 80% within the last 15 years. This experience with childhood leukemia had a profound effect on the field of cancer chemotherapy in general. Most importantly, it established the position that it can be done, that is, systemic cancer could be cured by systemic therapy.

Most patients who die of cancer die because of disseminated metastatic tumor. Today, in major centers and cooperative groups the cure rate of childhood leukemia is close to 80%. It was hoped that the solid tumors would follow on closely behind the leukemias, but they have in the main proven more difficult to treat. This is unfortunate as adult solid tumors such as breast, bowel and lung cancer constitute 80% of all cancer. A major strategy has been to use agents in combination. This is because solid tumor cells are heterogeneous and thus they have multiple targets.

The second rationale for combination chemotherapy is that it works, with essentially all highly effective and certainly curative cancer chemotherapy involving combinations. The best of combinations produce partial responses in 30–50% of patients with, for example, metastatic cancer of bowel and lung. Complete tumor regression rarely occurs.

It has long been known that in experimental tumors, for example in mice, tumor burden is critical to chemotherapeutic effect. Thus, chemotherapy that has a minor effect on palpable tumor, is often curative of the same tumor in microscopic form. This led to the strategy known as adjuvant chemotherapy. Here patients known to be of high risk of having micrometastatic cancer at the time of initial treatment, are given chemotherapy immediately following surgery and/or radiotherapy. This increases the cure rate some 20% for breast and large bowel cancers. In a more recent strategy (termed neoadjuvant chemotherapy), chemotherapy is given prior to surgery. This moves chemotherapy still further forward in the disease. It provides shrinkage of the primary tumor and thus facilitating the use and effectiveness of local treatment. It may decrease the need for radical surgery in certain tumors such as head, neck and bladder cancer. Finally, combination chemotherapy can be given concurrently with radiotherapy as initial treatment. In addition to the above advantages, local control may be superior with many chemotherapeutic agents since some of them, particularly the platinum analogs and fluoriuracil, are highly radiosensitizing.

In addition to combination chemotherapy, dose is a significant factor in cancer chemotherapy. The dose of certain chemotherapeutic agents, particularly the alkylating agents, can be substantially increased if one protects the bone marrow. Protection is provided by harvesting marrow stem cells before the high dose chemotherapy and returning the marrow to the patient following chemotherapy. Such peripheral blood stem cell rescue has been effective in the leukemias and lymphomas, and is under study often in combination with some of the above-mentioned strategies in selected solid tumors.

Supportive Care

Bone marrow or peripheral blood stem cell transplantation is one form of supportive care. The first major advance in supportive care involved platelet transfusions for the treatment and prevention of thrombocytopenic hemorrhage, starting in the late 1950s and early 1960s. The nausea and vomiting associated with cancer, and some forms of cancer treatment, has been markedly reduced by the development of anti-emetics. Pain control has markedly improved and radical surgery has been reduced by neoadjuvant approaches.

Long Term Effects of Cancer Treatment

Perhaps the most worrisome long-term effect has been the development of second cancers, particularly leukemia and leukemia-like illnesses. There is a latent period of 5–10 years for most of these secondary cancers, and for solid tumors it is even longer. Clinical treatment, environmental and genetic factors, and in vitro and in vivo laboratory models are being developed to study these events. The alkylating agents and X-ray are the chief offenders. ►Hodgkin disease was found to be curable by strategies similar to that of acute lymphocytic leukemia, but there was a cumulative long-term risk of secondary cancer. With this knowledge and the development of newer active agents for Hodgkin's disease, the combination regimen that included alkylating agents has been modified without loss of effectiveness, but with major diminution in secondary cancers.

Conclusions

With a marked increase in support for cancer research including both basic and clinical and the extraordinary increase in molecular sophistication of such research, it is expected that major progress in the curative treatment of most, if not all cancers, will be achieved in the next decade. It is the clinical scientist who must translate this progress in basic research to the clinic. This ultimate challenge would require the most sophisticated of treatment methodology and must always be conducted in a setting where the primary beneficiary of such research is the patient.

Definition

Adrenocortical carcinoma (ACC) is a cancer of the cortex of the adrenal gland ►(Endocrine-Related Cancers). There are two types. In one type, the tumor continues to secrete the hormones normally produced by the cortex, including ►glucocorticoids, ►mineralocorticoids and adrenal ►sex hormones. However, these steroids may be produced in excessive amounts, with negative effects on the body. In the other type, the tumor does not produce these hormones and may go undiscovered until it metastasizes.

Characteristics

Incidence

Cancer of the ►adrenal cortex is exceedingly rare: only about 300 cases are diagnosed in the United States each year. ►Adrenocortical tumors (ACT) represent only about 0.2% of all malignancies in children. The frequency of ACT is 0.4 per million during the first 4 years of life, 0.1 per million during the subsequent 10 years, and 0.2 per million during the late teens. These tumors also occur in adults, usually during the fourth to fifth decades of life. The incidence of ACT differs across geographic regions, ranging from 0.1 per million in Hong Kong and Bombay to 0.4 in Los Angeles and 3.4 in southern Brazil.

Causes

Predisposing genetic factors have been found in the majority of children and adolescents with ACT (Table 1).

The most common genetic abnormalities in young children with ACT are germline mutations in various exons of the ►*TP53* tumor suppressor (►Li-Fraumeni Syndrome, or LFS). However, low-penetrant mutant alleles can also reduce, rather than abrogate TP53 tumor suppressor activity and contribute to ACT without being associated with LFS. Strong evidence suggests that one such inherited *TP53* mutation (Arg337His) explains the extraordinarily high incidence of pediatric adrenocortical carcinoma in southern Brazil.

Adrenocortical tumors may also occur in the context of Beckwith–Wiedemann Syndrome (BWS) (►Beckwith–Wiedemann Syndrome Associated Childhood Tumors), which is characterized by a loss of heterozygosity at chromosome 11p15, resulting in the overproduction of ►insulin-like growth factor II (IGF-II) (Insulin-Like Growth Factors) and diminished levels of the cyclin kinase inhibitor $p57^{Kip2}$. ►Carney complex, hemihypertrophy, congenital adrenal hyperplasia, and multiple endocrine neoplasia type I (inherited mutations in the *MENIN* ►tumor suppressor gene) also give rise to pediatric ACT.

Normal Physiology and Tumor Biology

The human fetal adrenal cortex rapidly develops into two morphologically distinct zones (fetal and definitive) and is essentially adult size by midgestation. The outer, definitive zone exhibits high proliferative activity and is thought to be the germinal cell compartment from which the lipid-dense fetal zone cells migrate. Cortisol is also synthesized primarily by the definitive zone.

The inner, fetal zone produces large amounts of dehydroepiandrosterone sulfate (DHEA-S), which maintains placental function and integrity. Soon after birth, the fetal zone atrophies by undergoing massive cell death through an apoptotic mechanism. Remodeling of the cortex in the neonate results in three functional

Childhood Adrenocortical Carcinoma. Table 1 Constitutional syndromes associated with adrenocortical tumors

Condition	Tumor types	Observations
Germline *TP53* mutations, including Li-Fraumeni Syndrome (►IARC TP53 Database) (►p53 Family) (►p53 Protein, Biological and Clinical Aspects)	Adenomas, sarcomas, carcinomas	Penetrance of ACT is about 10% or less
Beckwith–Wiedemann syndrome (Beckwith–Wiedemann Syndrome Associated Childhood Tumors)	Adenomas, carcinomas	ACT is the second most common tumor (~15% of children with this syndrome)
Hemihypertrophy	Adenomas, carcinomas	20% of these tumors are ACT
Congenital adrenal hyperplasia	Adenoma, carcinoma	Very rare occurrence of ACT
Carney complex	Primary pigmented nodular adrenocortical disease	ACT occurs in ~25% of patients; common in children
Multiple endocrine neoplasia I	Nodules, adenomas, carcinomas	ACT very rare in children

regions: (i) zona glomerulosa, (ii) zona fasciculata, and (iii) zona reticularis. The outer zona glomerulosa primarily produces aldosterone, and the zonae fasciculata and reticularis synthesize corticosteroids and androgens, respectively.

Adrenocortical tumorigenesis in children, in contrast to adults, often results in the hyperproduction of steroids, which is readily apparent by marked physical changes (see below and Fig. 1).

The extensive growth of the adrenal cortex during gestation and its postnatal resolution are likely important in the sensitivity of this gland to small losses in TP53 tumor suppressor activity in those carriers of germline *TP53* mutations. An adrenocortical cell that was destined to cease proliferation during the expansion phase or was targeted to die after birth could continue to survive and divide. The timing of tumor development by 3 or 4 years of age is consistent with this hypothesis. The fetal zone or the zona reticularis have been implicated as the source of cells that contribute to ACT formation, although definitive proof is lacking.

Pediatric adrenocortical tumorigenesis relies on the acquisition of multiple genetic hits. In addition to frequent germline *TP53* mutations, *Steroidogenic factor-1* (*SF1*) which encodes a transcription factor required for normal adrenal gland development, is amplified on chromosome 9q34 and overexpressed in ~90% of patients with ACT. Inactivation of the TGFβ-related *Inhibinα (INHA)* on chromosome 2q33 by mutation of one allele and deletion of the remaining wild-type allele is also common in ACT. The gross overexpression of IGF-II in pediatric ACT, regardless of the genetic predisposing factors (LFS or BWS), has been convincingly established. Adult ACT shares this biochemical alteration and clinical trials of drugs to inactivate IGF-II signaling in both childhood and adult ACT are being designed.

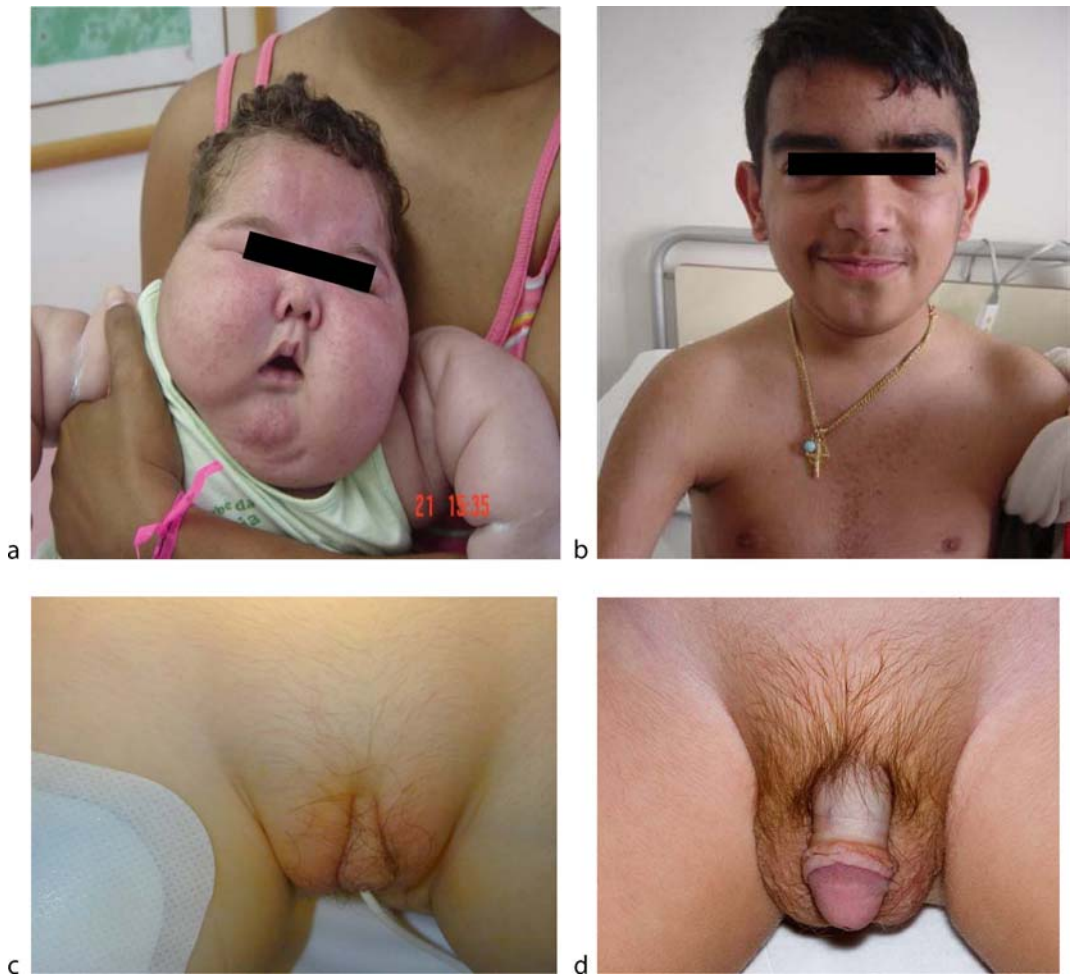
Clinical Manifestations

Features of ►virilization, including pubic hair, facial acne, clitorimegaly, voice change, facial hair, hirsutism, muscle hypertrophy, growth acceleration, and increased penis size are the most common clinical manifestations of ACC. Virilization can be observed either alone (virilizing tumors, 40% of patients) or with clinical manifestations resulting from the overproduction of other adrenal cortical hormones, including glucocorticoids, androgens, aldosterone, or estrogens (mixed type, 45%; Fig. 1). About 10% of patients show no clinical evidence of an endocrine syndrome at presentation (non-functional tumors). Finally, overproduction of glucocorticoids alone (►Cushing Syndrome) is evident in about 3% of patients. Primary hyperaldosteronism (►Conn Syndrome) and pure ►feminization can also occur. In some circumstances, clinical manifestations of ACT can be present at birth.

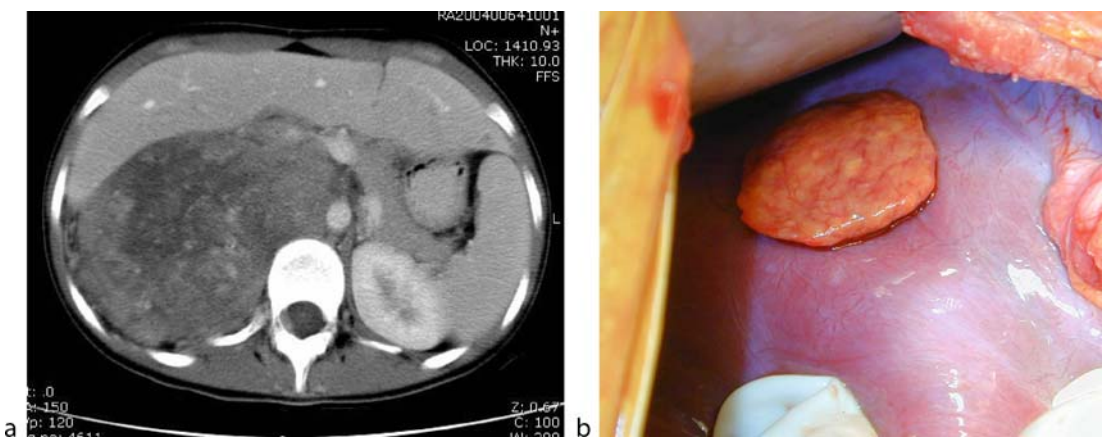
Testing

Routine laboratory evaluation for suspected ACT includes measuring urinary 17-ketosteroids (17-KS), 17-hydroxycorticosteroid (17-OH), and free cortisol, as well as plasma cortisol, DHEA-S, testosterone, androstenedione, 17-hydroxyprogesterone, aldosterone, renin activity, deoxycorticosterone, and other 17-deoxysteroid precursors. Most patients with ACT who are tested have elevated levels of 17-KS. Plasma DHEA-S levels are abnormal in ~90% of cases. Elevated glucocorticoid and androgen levels are strong indications of an adrenal tumor.

Several different imaging modalities are used to diagnose ACT. Computed tomography (CT; Fig. 2), sonography, magnetic resonance imaging (MRI), and



Childhood Adrenocortical Carcinoma. Figure 1 Clinical signs of adrenocortical tumors. (a) Typical facies of a patient with hypercortisolism. (b) Patient with hirsutism. (c) Precocious pseudopuberty (clitorimegaly) in a girl with adrenocortical carcinoma. (d) Precocious pseudopuberty in a boy with adrenocortical carcinoma.



Childhood Adrenocortical Carcinoma. Figure 2 (a) Axial computed tomographic image of a large adrenocortical tumor showing a central area of stellate appearance caused by hemorrhage, necrosis, and fibrosis. Small calcifications are also seen. (b) Regional relapse is apparent adjacent to the liver surface. This patient's initial surgery was complicated by tumor rupture and spillage.

►positron emission tomography (PET) are the most commonly used.

Ultrasound is useful for evaluating tumor extension into the inferior vena cava and right atrium. On CT imaging, ACT is usually well demarcated, with an enhancing peripheral capsule. Large tumors usually have a central area of stellate appearance that is caused by hemorrhage, necrosis, and fibrosis. Calcifications are common. Because ACT is metabolically active, ►fluorodeoxyglucose-positron emission tomography (FDG-PET) imaging is frequently used in patients with ACT. PET imaging can also detect tumor recurrence in areas that routine follow-up CT imaging may miss.

The definitive diagnosis of ACT is made on the basis of the gross and histologic appearance of tissue obtained surgically. Tumors are classified as adenoma or carcinoma, although even an experienced pathologist can find it difficult to differentiate between benign and malignant tumors.

Treatment

Surgery is the mainstay of treatment for ACT. A curative, complete resection may be attempted in patients with local or regional disease (70–75% of cases). *En bloc* resection, including the adjacent structures invaded by the tumor, is required for good local control. Nephrectomy and resection of liver segments and portions of the pancreas may be included. Because of tumor friability, rupture of the capsule with resultant tumor spillage is common (Fig. 2). When ACT is suspected, laparotomy and a curative procedure are recommended rather than fine-needle aspiration, to avoid the risk of tumor rupture.

Infiltration of the vena cava by tumor thrombus occurs in 20% of patients and may make radical surgery difficult; a combined thoracic and abdominal approach may be required in those cases. The pattern of recurrence is locoregional (15–25%), combined local and distant (25–30%), or distant alone (50%). Chemotherapy with ►mitotane is indicated for unresectable and recurrent disease, although it has a small impact on overall outcome. At low doses, mitotane suppresses the secretion of adrenal steroids, providing symptomatic improvement and partial regression of endocrine dysfunction in most patients with functional tumors. Higher doses (>3 g/day) are required for an adrenolytic effect.

Although responses to mitotane alone may occur in 20–30% of cases, most responses are transient, and the prospect for long-term survival is uncertain. The antitumor effect of mitotane is influenced by its pharmacokinetics and by the duration of its therapeutic exposure. Serum concentration plateaus after 8–12 weeks of treatment, and antitumor responses occur only when a serum concentration of at least 14 μg/mL is maintained for a prolonged period. The severe gastrointestinal (nausea, vomiting, diarrhea, and abdominal pain) and neurologic (somnolence, lethargy, ataxia, depression, and vertigo) toxic effects of mitotane reduce patient adherence. Because mitotane is adrenolytic, all patients receiving this agent should be considered to have severe adrenal insufficiency and treated accordingly. ►Cisplatin-based regimens, usually including etoposide and doxorubicin, are used in combination with mitotane, although less than 40% of patients respond.

The use of radiotherapy in pediatric ACT has not been consistently investigated, although ACT is generally considered to be radioresistant. Furthermore, because many children with ACT carry germline *TP53* mutations that predispose them to cancer, radiation may increase the incidence of secondary tumors. For most patients with metastatic or recurrent disease that is unresponsive to mitotane and chemotherapy, repeated surgical resection is the only alternative. However, given the infiltrative nature of the disease, complete resection is difficult. Image-guided tumor ablation with radiofrequency currently offers a valid alternative for these patients.

Prognosis

Complete tumor resection is the single most important prognostic indicator. Patients who have distant or local with gross or microscopic residual disease after surgery have a dismal prognosis. Long-term survival (5 years or more after the diagnosis) is about 75% for children after complete tumor resection. Among those who undergo complete tumor resection, tumor size has prognostic value. The estimated event-free survival is 40% for those with tumors weighing more than 200 g and 80% for those with smaller tumors. Children whose tumors produce excess glucocorticoid appear to have a worse prognosis than children who have pure virilizing manifestations. Classification schemes or disease staging systems (Table 2) are still evolving. Prognosis will likely be further refined by adding other predictive factors, including those from gene expression studies.

Concluding Remarks

Adrenocortical tumors remain difficult to treat, and little progress has been made in developing effective chemotherapeutic regimens. The rarity of ACT hinders the opportunity to conduct adequately powered clinical trials, including biological studies. Therefore, efforts must be coordinated and resources must be consolidated to advance our understanding and treatment of ACT. In this regard, a long-standing international ACT registry and tissue bank has been established [http://www.stjude.org/international-outreach/0,2564,455_2265,00.html]. Short-term goals are to establish tissue culture, xenograft transplants, and genetically engineered mouse models to explore novel therapies. Clinical investigators,

Childhood Adrenocortical Carcinoma. Table 2 Staging criteria for childhood adrenocortical tumor

Stage	Description
I	Tumor totally excised, tumor size <100 g or <200 cm^3, absence of ►metastasis, and normal hormone levels after surgery
II	Tumor totally excised, tumor size ≥100 g or ≥200 cm^3, absence of metastasis, and normal hormone levels after surgery
III	Unresectable tumor, gross or microscopic residual tumor, tumor spillage during surgery, persistence of abnormal hormone levels after surgery, or retroperitoneal lymph node involvement
IV	Distant tumor metastasis

physicians, and basic scientists are encouraged to participate in these studies.

Childhood Cancer

Amal M. Abu-Ghosh, Jeffrey A. Toretsky
Departments of Pediatrics and Oncology, Lombardi Comprehensive Cancer Center, Georgetown University, Washington DC, USA

Definition

Childhood cancer is defined as cancer occurring in children below 20 years of age.

Characteristics

Incidence

The annual incidence of childhood cancer is 150/million/year. Worldwide, cancer is very rare among children compared to adults. There are variations among different populations in the incidence of certain cancers that can provide some insight into etiology. In the United States of America, it is estimated that about 12,400 children (<20 years) were diagnosed with cancer in 1998, and 2,500 died of cancer in the same year. The probability of developing cancer by age 20 in a newborn male is 0.30% (1:300) and for a newborn female 0.32% (1:333). Cancer related deaths ranked forth in children 1–19 years of age after unintentional injuries, homicides and suicides. Reports from the ►SEER (Surveillance Epidemiology and End Results) program on childhood cancer since the 1970s have shown a gradual increase in incidence (although it appears to have leveled off in the past decade) with a decrease in the mortality rate from cancer (Childhood cancer; Fig. 1).

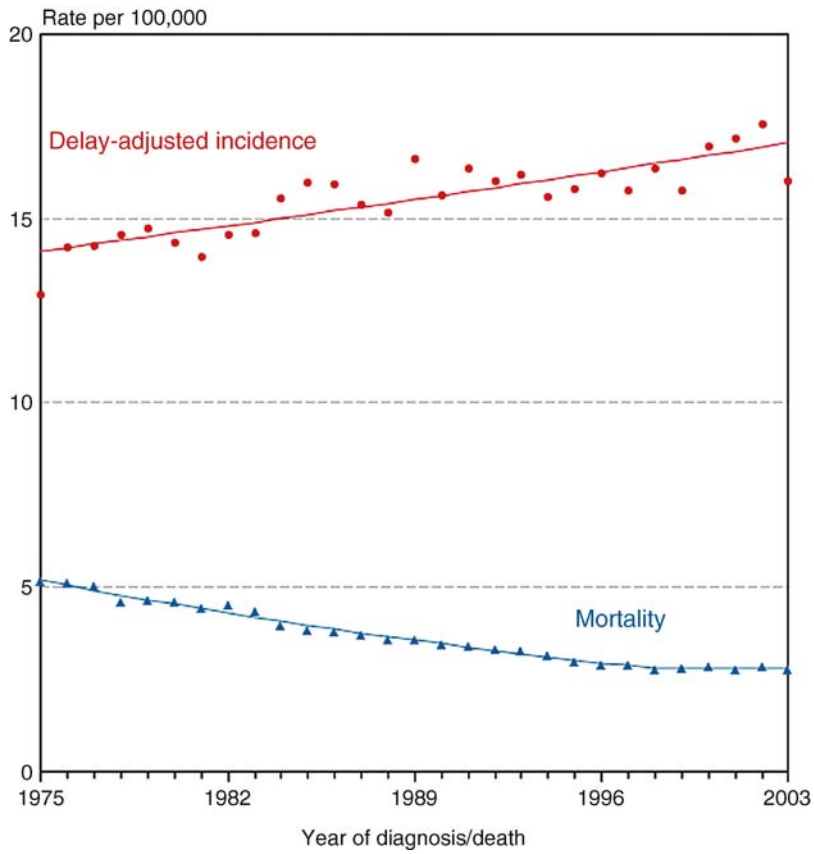
The most common childhood cancer diagnoses are ►leukemia followed by brain tumor and ►lymphoma (Childhood cancer; Fig. 2a and b). The incidence and type of cancers varies with age with certain cancers occurring mostly in early childhood (►retinoblastoma, neuroblastoma, ►Wilms tumor) and others at later ages (lymphoma, bone tumors, germ cell tumors) (Childhood cancer; Fig. 3).

Survival following childhood cancer has improved over the last three decades mainly due to increased survival of childhood acute lymphoblastic leukemia (►ALL) with introduction of multi-agent chemotherapy drugs, central nervous system prophylaxis and most recently development of risk adapted therapy. Additionally, the improvement in supportive care has contributed to an improved survival in all types of childhood cancer.

Causes and Risk Factors

Identifying the causes of cancers in children remains a great challenge for physicians and researchers. However, studying epidemiologic patterns can shed some light over possible causes occurring alone or as part of multiple risk factors that work together and lead to cancer. Some of these factors are discussed below:

1. *Socioeconomic Conditions*: Geographical variations in childhood cancers reflect environmental factors that may play a crucial role in the development of



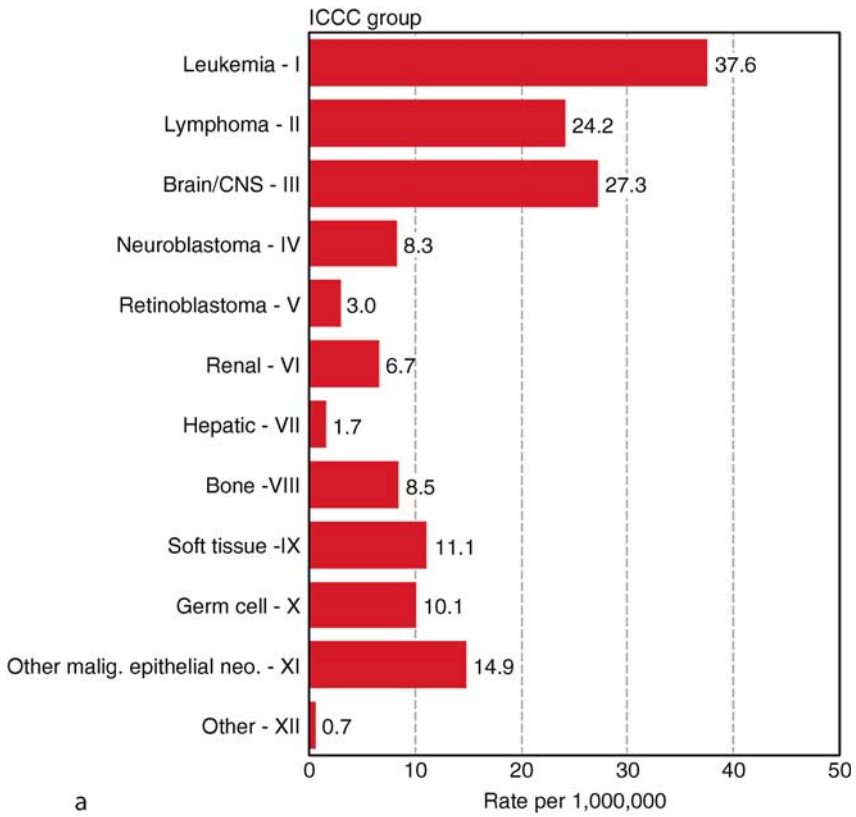
Childhood Cancer. Figure 1 SEER delay-adjusted incidence and US mortality all childhood cancers, under 20 years of age, both sexes, all races, 1975–2003.

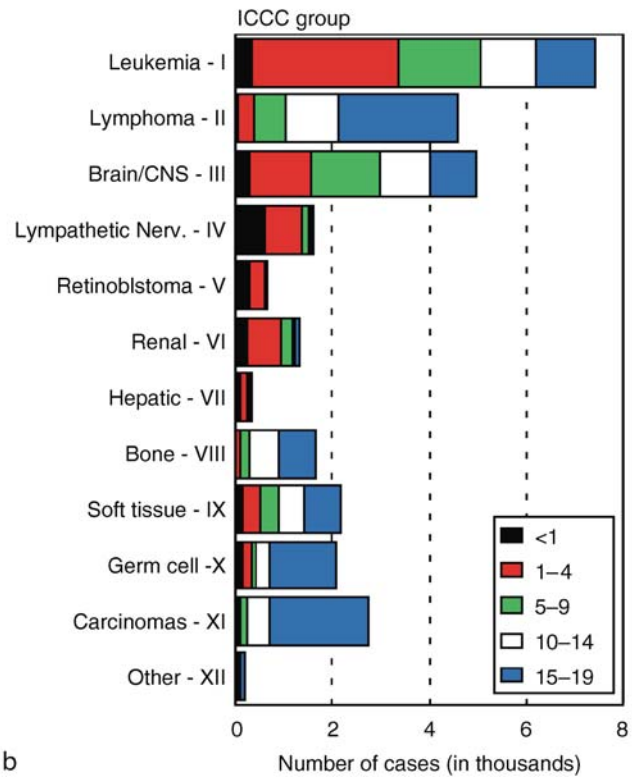
such cancers. The predominant childhood cancers among whites in Europe, the Americas, Oceania, and in East Asia are leukemias accounting for 35–50/million. Lower incidence is seen in South Asia, Middle East, American Blacks and sub-Saharan Africa (<30/million). This variation is mostly due to acute lymphoblastic leukemia (ALL) which accounts for 80% of all childhood leukemias. Higher incidence occurs in higher levels of socioeconomic development. The commonest subtype of ALL (►pre-B ALL) seen in ~70% within the high incidence populations occurs in only a third of cases in the lower-incidence populations where ►T-cell ALL has a higher frequency. With improving socioeconomic conditions, a similar trend is seen as with increasing early childhood peak of common ALL suggesting a strong association between environmental factors and the etiology of ALL.

2. *Infections*: Epidemiological studies of the incidence of Hodgkin's lymphoma (►HD) worldwide have shown the strong association of poor socioeconomic conditions and Epstein-Barr virus (►EBV) infection. EBV is implicated in more than 50% of cases of HD worldwide and EBV positivity in malignant cells is commonly seen in mixed cellularity HD and in cases from developing countries. The development of HD may be a response to both environmental factors and EBV infection.

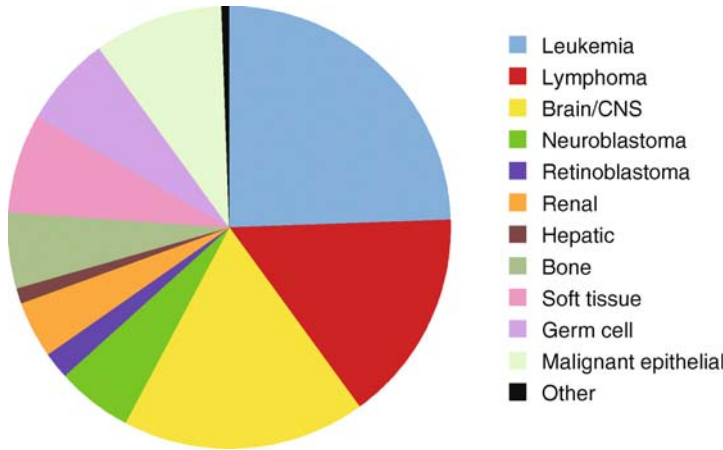
Burkitt Lymphoma (►BL) has also been strongly linked with EBV infection and malaria as a cofactor as seen in all BL cases in tropical Africa and in Papua New Guinea. In other areas of the world, EBV is associated with 50–70% of BL in North Africa and South America and 20% in Europe and North America. In addition, BL can be identified by breakages and translocations involving chromosome 8. Nasopharyngeal carcinoma has the highest incidence in North Africa (3/million) and is also associated with EBV infection. Other unidentified factors may play a role.

Kaposi Sarcoma is the most common soft tissue sarcoma among children in sub-Saharan countries. The incidence with endemic ►HIV (human immunodeficiency virus) infection was 2–2.5/million and this increased to 10–50/million due to the AIDS (acquired immunodeficiency syndrome) epidemic and heightened infection with ►HHV8 (human herpesvirus 8) virus.





Childhood Cancer. Figure 2 (a, b) Childhood cancer SEER incidence rates by ICCC group, 1975–2003, under 20 years of age, both sexes, all races.



Childhood Cancer. Figure 3 Number of cases of all childhood cancers by ICCC and age group, all races, both sexes, 1975–1995.

Hepatocellular Carcinoma (►HCC) is a rare hepatic tumor in Europe and North America, but is still the most common childhood liver tumor in Saharan Africa, East and South East Asia and Melanesia and is associated with chronic hepatitis B infection. Mass immunization against Hepatitis B in Taiwan resulted in a decreased incidence of HCC.

3. *Radiation Exposure*: Following the Chernobyl explosion, areas in Belarus, Russia and the Ukraine contaminated with radiation fallout, reported a significant increase of more aggressive forms of thyroid carcinoma. The incidence fell to pre-Chernobyl levels in children conceived after the explosion.
4. *UV Light Exposure*: Malignant Melanoma has an incidence of 1/million in children. The highest rate is seen in Oceania and is attributable to heavy sunlight exposure in this region.
5. *Ethnic Factors*: Wilms tumor occurs at the lowest rates in East Asia. This low incidence continues in ethnic East Asian groups in California and Hawaii (<5/million) compared to blacks from US and Africa (9–12/million) and Whites (6–10/million) suggesting the role of genetic factors in the incidence of certain cancers. Ewing's Sarcoma is another example of a disease that has markedly different incidences based on race; it is extremely rare in Blacks and East Asians compared to Whites.

Genetic and Chromosomal Syndromes

Genetic factors play a crucial role in the development of cancer. There are several genetic diseases that are associated with increased risk of cancers. Familial neoplastic syndromes, inherited immunodeficiency and bone marrow failure syndromes, miscellaneous genetic syndromes and numerical chromosome abnormalities will be discussed:

1. *Familial Neoplastic Syndromes*: Heritable Retinoblastoma is the classic example where two mutations involving the *RB1* gene locus result in retinoblastoma. Heritable disease is bilateral and is seen often with a family history of retinoblastoma. The first *RB1* mutation is pre-zygotic and is usually inherited, however, sometimes a rare germ-cell mutations can occur. The inheritance is autosomal dominant with 90% penetrance. Additionally, patients with mutant *RB1* are at an increased risk for osteosarcomas in the first three decades of life as well as other types of cancers with advancing age as melanomas and carcinomas of the lung and bladder. Familial Wilms tumor is rare compared to retinoblastoma, occurring in 1.5% of children diagnosed with Wilms tumor in the US. Two genes are associated with familial Wilms tumor; *FWT1* on chromosome 17q12–21 and *FWT2* on chromosome 19q13, but clear patterns of causation are not established. The Li-Fraumeni cancer family syndrome (►LFS) increases the risk of childhood cancers (relative risk of 20) and results in soft tissue sarcoma, adrenocortical carcinomas, premenopausal breast carcinoma, central nervous system tumors and osteosarcomas. Germline mutations of the *TP53* tumor suppressor gene are seen in 77% of LFS families. Other familial neoplastic diseases include Neurofibromatosis type 1(►NF1) that increases the risk for brain tumors (relative risk of >40) and similarly for soft-tissue sarcomas. NF1 patients also have increased risk for juvenile myelomonocytic leukemia (relative risk of 200) and ALL and non Hodgkin's Lymphoma (►NHL) (relative risk of 5). Neurofibromatosis type 2 patients have an increased incidence of meningiomas but less frequently than NF1.

2. *Inherited Immunodeficiency Syndromes*: There is an increased risk for leukemias and lymphomas in patients with inherited immunodeficiency syndromes accounting for a very small fraction (<0.1%) of childhood cancers. Children with ataxia telangiectasia (AT) have a 10% chance of developing lymphoma or leukemia in their first 15 years of life. Similarly, patients with Wiskott-Aldrich syndrome have an increased incidence of NHL. Other immunodeficiency diseases as Bloom syndrome, common variable immunodeficiency, X-linked agammaglobulinemia, IgA deficiency, severe combined immunodeficiency syndrome (►SCID), Duncan's disease and Nijmegen breakage syndrome are associated with a high risk of ALL and NHL. Blooms syndrome is also associated with increased Wilms tumor and osteosarcoma.
3. *Bone Marrow Failure Syndromes*: The bone marrow failure syndromes that demonstrate an increased risk for childhood cancer include: Fanconi anemia (►AML, hepatocellular carcinoma), Diamond-Blackfan anemia (AML, Osteosarcoma), and Shwachman-Diamond syndrome (myelodysplasia).
4. *Non Neoplastic Genetic Syndromes*: Many other syndromic diseases cause patients to have an increased risk of childhood cancer including: Xeroderma Pigmentosa (skin carcinoma and melanoma), WAGR syndrome (Wilms tumor), Denys Drash syndrome (Wilms tumor), Beckwith-Widemann syndrome (Wilms, hepatoblastoma, neuroblastoma, pancreatoblastoma).
5. *Numerical Chromosomal Abnormalities*: Down syndrome (trisomy 21) accounts for the largest number of cancers including leukemias with a 50-fold risk in the first 5 years of life and tenfold risk in the next 10 years. Less commonly, Down syndrome patients are diagnosed at a higher frequency with germ cell tumors, lymphomas and retinoblastoma. Patients with trisomy 18 have an increased risk of Wilms tumor. Turner's syndrome patients are at increased risk for Neuroblastoma and Wilms and patients with Klinefelters have increased risk of germ cell tumors.

Clinical Presentation and Diagnosis

The presenting symptom of childhood cancer can mimic many of the common childhood diseases and may be difficult to diagnose. Different cancers have different symptoms related to the site of disease and type of cancer. The most commonly diagnosed childhood cancer is acute lymphoblastic leukemia (ALL). ALL usually presents with symptoms related to bone marrow infiltration as anemia (fatigue and pallor), neutropenia (fever and infection), and thrombocytopenia (bleeding and petechial rash). A relatively common misdiagnosis occurs when patients present with generalized aches and pains, specifically bone pains secondary to leukemic infiltration, but lack peripheral blood abnormalities. Constitutional symptoms with weight loss, fever and anorexia are frequent symptoms of metastatic disease. Extensive evaluation for an underlying etiology should occur when unexplained symptoms in children last longer than 10–14 days.

Solid tumors present with signs and symptoms related to the organ involved. Brain tumors, the commonest solid tumors of childhood and second common childhood cancer after ALL, usually present with symptoms related to increased intracranial pressure as headaches, vomiting, seizures and change in the level of consciousness, or other neurological signs. The presence of headaches along with other neurological symptoms, such as facial nerve palsy or ataxia warrants more urgent further evaluation.

Young children can present with abdominal masses that may be noticed by the parents, or an adult who gives the child a bath, as a protuberant abdomen. Abdominal masses may cause symptoms such as pain, vomiting, constipation or intestinal obstruction. Abdominal masses can be diagnosed as Wilms tumor, Neuroblastoma, lymphoma or sarcoma, and can sometimes be benign. This heterogeneity of etiology makes surgical biopsy critical when an abdominal mass is discovered. Other symptoms as hypertension and hematuria may develop with renal tumors and neuroblastoma.

Children may present with enlarged lymph nodes in the neck, axilla or groin. The nodes may be asymptomatic, painful or compress local structures as blood vessels and nerves. Lymph node enlargement within the chest or the presence of a mediastinal mass may result in cough and dyspnea. These presentations are common with lymphomas that may also be associated with constitutional symptoms as fever, weight loss and night sweats.

Tumors of the extremities may present with a localized swelling with or without pain, and often unrelated to trauma. Sometimes, a pathological fracture draws attention to a bone tumor.

Primary care physicians are often the first to suspect such a diagnosis. Although many of these symptoms can be seen in common childhood illnesses, it is the duration, unusual associations, course and quality of such symptoms that alerts the physician to the possibility of an underlying oncologic disorder. Once this is determined, then the child needs to be referred to a Pediatric Hematology and Oncology Center urgently for further evaluation to establish the diagnosis. Such an evaluation would include the following:

1. Complete blood counts
2. Liver and kidney function tests
3. Radiological evaluation: X-rays, CT scans, MRI, PET scan, bone scan and MIBG scans as determined by symptoms and location

4. Bone marrow examination or surgical excision or biopsy of the suspected lesions

Treatment

Children with cancer are best cared for at a pediatric comprehensive cancer care center that includes a team of pediatric oncologists, nurses, surgeons, radiation oncologists, pathologists, and supportive care services for the patients and their families. Treatment includes a combination of chemotherapeutic agents with or without local radiation therapy and surgery. Chemotherapy is usually given intravenously, intraspinally, intramuscularly and by mouth. The specific agents depend on the disease being treated based upon 40 years of clinical trial experiences. Side effects include hematological toxicities (anemia, neutropenia and thrombocytopenia), nausea and vomiting, alopecia, infections, cardiac, renal and liver toxicities depending on the chemotherapeutic agents used. Response to treatment is assessed during therapy and treatment is adjusted based upon tumor response and patient side effects.

Outcome and Late Effects

Improved childhood cancer care including the development of combination of chemotherapeutic regimens, supportive care guidelines to minimize infection and bleeding resulted in a dramatic improvement in survival and cure of most childhood cancers and a corresponding drop in the mortality rate (childhood cancer; Fig. 1). However, physicians have become aware of late side effects to therapy that became apparent as early as weeks following completion of treatment up to several decades later. Some of these side effects were related to the cumulative dose of chemotherapy agents and resulted in dose modification or replacement in newer regimens to minimize immediate and late toxicity without affecting efficacy. Similar modifications have been made with radiation therapy by instituting techniques to improve delivery of radiation to the tumor and minimizing damage to neighboring healthy tissues (involved field radiotherapy) as well as reducing the total dose of radiation delivered.

Currently, several pediatric oncology centers have established clinics for childhood cancer survivors where they are followed for life. Patients are given advice about their risks of developing secondary cancers, long term organ toxicities (cardiac, pulmonary, neurological, hepatic and renal), fertility and psychosocial late effects.

Newer clinical trials are underway and will provide more information about childhood cancer survivors and their late effects.

CAR

Definition

A chimeric antigen receptor (CAR) consists of an extracellular antigen-binding exodomain, typically derived from a single-chain antibody fragment (scFv) of a monoclonal antibody (mAb), a spacer (such as an antibody Fc region), a transmembrane region, and one or more intracellular signaling endodomains, which can be genetically introduced into hematopoietic cells, such as T cells, to redirect specificity for a desired cell-surface antigen.

Characteristics

Background on Manipulating T-Cell Responses to Cancer

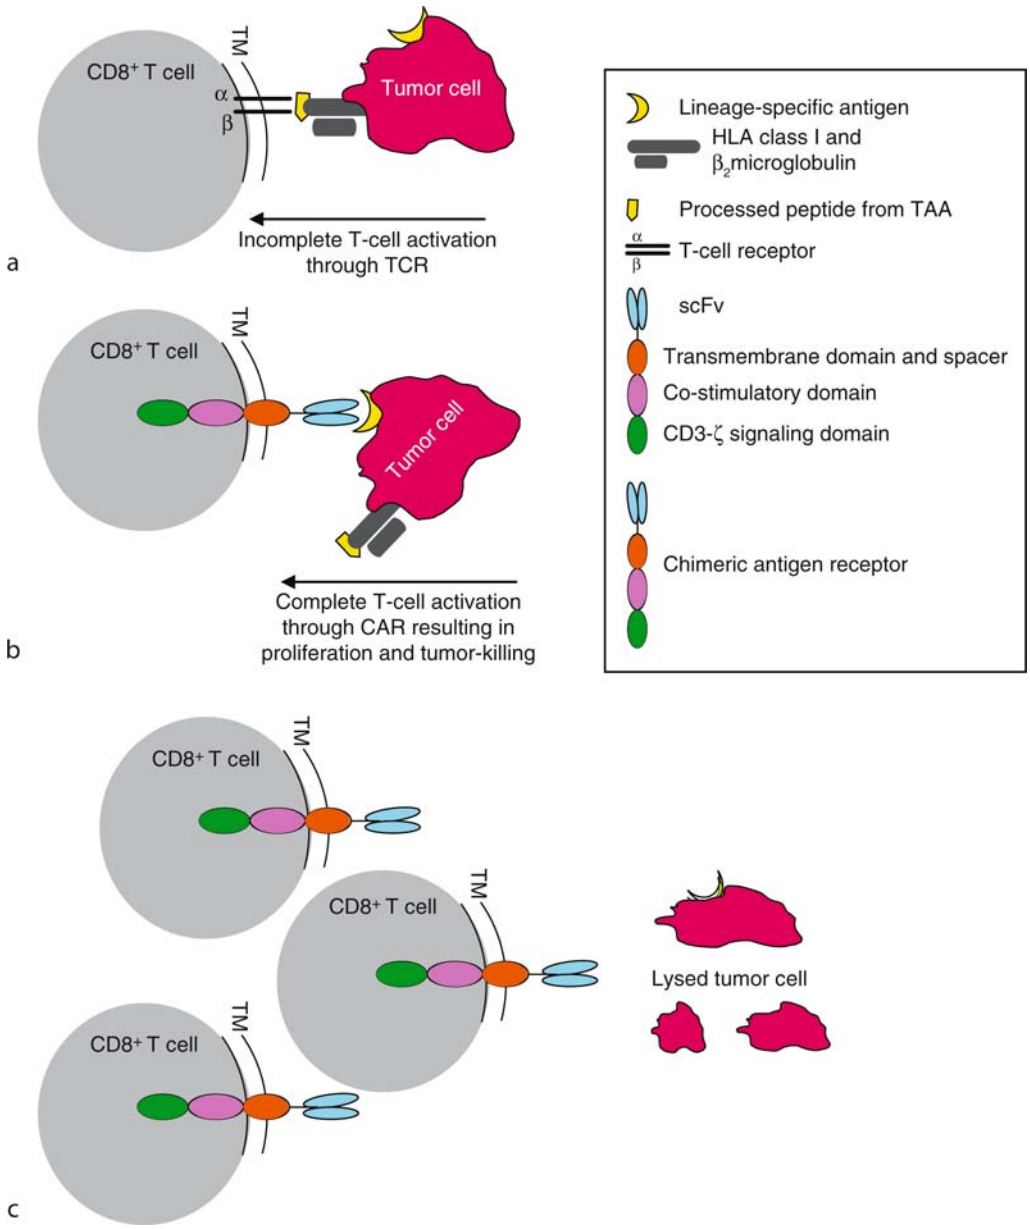
Adoptive transfer of tumor-specific T cells in mouse models can function as potent anti-cancer biological agents leading to elimination of established malignancies. Continued advances in tumor immunology support the premise and promise for ►adoptive immunotherapy as a treatment for human malignancies. Yet, infusion of tumor-specific T cells has only been partially successful in clinical oncology trials. Indeed, most of these trials demonstrate the safety and feasibility of infusing T cells, but with the exception of treating melanoma and chronic myelogenous leukemia (CML), only occasionally show a sustained anti-tumor effect. In contrast, infusing viral-specific T cells has successfully treated and protected patients from opportunistic diseases associated with adenovirus, CMV, and EBV. Why is it that augmenting an immune response against neoplasms by infusing tumor-specific T cells has proven more challenging than engendering an effective anti-viral response? The answer is partly due to the relative inability of T cells to recognize, via an endogenous T-cell receptor (TCR), poorly-immunogenic tumor-associated antigens (TAAs) compared with the highly-immunogenic/stimulatory viral antigens presented in the context of human leukocyte antigen (HLA). While TAAs generally have little or no expression in normal post-natal tissues outside of sanctuary sites, naturally-arising T cells are typically not reactive to tumors expressing a TAA due to immunologic tolerance. However, investigators have been able to manipulate T cells into recognizing TAA in the context of HLA molecules. This has been exploited by injection/infusion of (i) vaccines presenting TAA to overcome tolerance and stimulate T-cell immunity to tumors, (ii) tumor-specific T cells which have been culled from the patient and massively expanded in the laboratory, and (iii) T cells that have redirected specificity for tumor by genetically introducing pre-defined tumor-specific immunoreceptor genes. Clinical trials are currently evaluating all of three approaches.

While vaccines will likely have application for cancer prevention (►cancer vaccines), vaccination to eradicate most established tumors is a difficult challenge at this time due in part to iatrogenic damage of the underlying immune system from chemotherapy and accumulation of large tumor masses in sanctuaries which are functionally protected from immune recognition and response. Rather than vaccinate, or addition to vaccination, investigators have chosen to augment T-cell response through infusion of effector T cells (adoptive immunotherapy). Indeed, isolation, *ex vivo*-expansion of autologous tumor-infiltrating cytotoxic T-lymphocytes (CTLs), and subsequent transfer of these CTLs in lymphodepleted patients can mediate regression of metastatic melanoma. The widespread therapeutic success of adoptive immunotherapy using T cells that have not been genetically manipulated is, however, limited because of (i) difficulties in obtaining sufficient number of tumor-reactive CTLs from patients, (ii) TAAs are typically poor immunogens, (iii) existence of immune-regulatory mechanisms that prevent T-cell dependent reactivity against TAA (such emergence of tumor escape variants with loss of HLA), and (iv) the requirement that patients have pre-existing tumor-reactive cells that can be expanded *ex vivo*.

To overcome these hurdles investigators have combined the endogenous effector function of CTLs with re-directed antigen specificity that results from genetic introduction of an immunoreceptor. This introduced immunoreceptor transgene can be engineered *ex vivo* to provide non-physiologic signaling via a chimeric antigen receptor (CAR) that co-opts the ability of recombinant antibody to bind to tumor targets leading to T-cell activation. The development of CAR^+ T cells can overcome the relative inability of antibodies to localize to and penetrate into tumor masses and provides a self-renewing source of chimeric antibody linked to T-cell effector function.

Tumor-Specific CAR Development

Generally, a CAR consists of an extracellular domain composed of a single chain variable fragment (scFv) derived from a monoclonal antibody (mAb) against a cell-surface tumor-antigen which is typically a lineage specific molecule, such as CD19 on B cells. The scFv is typically suspended from the cell surface by a spacer (e.g. mAb Fc region) and uses a transmembrane (TM) region (e.g. from CD4 or CD28) to affix the scFv–Fc to the cell surface. This TM region is in turn fused in frame to one or more signaling modules that are normally present in an endogenous TCR signaling complex, such as the CD3-ζ chain (Fig. 1). The CAR can confer scFv-mediated antigen-recognition to T cells that is independent of HLA on tumor cells and endogenous TCR. T cells genetically modified to express a CAR can be propagated *in vitro* and demonstrated to exert robust CAR-dependent effector function. Upon antigen-mediated cross-linking of the CAR, the intracellular



Chimeric Antigen Receptor on T Cells. Figure 1 (a) Incomplete activation of T cells recognizing TAA through αβ TCR in context of HLA class I. (b) Fully-competent activation signal by T cells recognizing lineage-specific antigen (e.g. CD19) independent of HLA by introduced CAR. (c) Complete CAR-mediated activation results in T-cell proliferation and tumor lysis.

signaling domain or domains initiate cellular activation which can result in proliferation, cytokine secretion, and specific cytolysis of the antigen-expressing target cells. Several requirements need to be met to enable T cells expressing CAR to exert a pronounced therapeutic effect. These include, (i) expression of the CAR at sufficient density to activate effector function upon binding antigen, (ii) generation of clinically-meaningful numbers of T cells suitable for infusion, (iii) traffic T cells to and within tumor stroma, and (iv) conditional activation upon antigen binding, manifesting appropriate T-cell effector mechanisms such as cytokine secretion, proliferation, and cytolysis leading to tumor destruction. We and others have generated a panel of CARs and demonstrated that T cells (and NK cells) equipped with CAR mediate a highly efficient anti-tumor immune response against antigen-defined tumor target cells *in vitro* as well as *in vivo*. These CAR-grafted T cells, thus are appealing candidates for adoptive immunotherapy.

Clinical Application of CAR-Specific T Cells

Adoptive transfer of T cells for treatment of tumors is an attractive therapeutic option as it has the potential to cure disease refractory to conventional therapies. Successful allogeneic hematopoietic stem-cell transplantation (HSCT) with engraftment of donor derived tumor-specific T cells and adoptive transfer of T cells genetically rendered specific for melanoma antigens currently provide the two cornerstones for the rational application of adoptive transfer of T cells genetically modified to express CAR. Along with other investigators, we have chosen to develop CD19-specific CAR, since the CD19 molecule is widely expressed on most cancers arising from B cells. B-cell tumors are as a class poorly immunogenic with few described TAA, thus isolating and expanding endogenous T cells with specificity for malignant B cells has proven difficult in the context of allogeneic HSCT and near-impossible in the autologous setting. Thus, to target B-lineage neoplasms, an initial CD19-specific CAR (designated CD19R) was generated from the variable regions of a mouse mAb specific for CD19, and T-cell activation was achieved through chimeric CD3-ζ endodomain. The CD19 molecule is a 95-kDa membrane glycoprotein, found on human B lymphocytes at all stages of maturation, although it typically disappears upon differentiation to terminally differentiated plasma cells. It is expressed on B-lineage acute leukemias and lymphomas as well as chronic lymphocytic leukemia and is rarely lost during the process of neoplastic transformation. It is not expressed on hematopoietic progenitor cells or on normal tissues outside the B-lineage and is not thought to be shed into the circulation. An advantage of CD19-directed therapy for lymphomas over targeting CD20, another B-lineage antigen, is that unbound rituximab (CD20-specific therapeutic mAb) will not interfere with binding of CD19-specific T cells. A clinical-grade DNA plasmid vector coding for CD19R and bifunctional hygromycin (Hy) phosphotransferase selection gene fused to thymidine kinase (TK) suicide/imaging fusion gene (HyTK) was developed and produced by the National Gene Vector Laboratory. Using this vector, a gene therapy trial was opened (BB-IND 11411, ClinicalTrials.gov Identifier: NCT00182650) to determine the feasibility and safety of infusing autologous T cells co-expressing CD19R and HyTK transgenes, along with exogenous low dose recombinant human IL-2 (as a surrogate T_h-response) in patients with refractory lymphoma.

Improved Therapeutic Potential of CAR$^+$ T Cells

Ongoing projects in our laboratory to improve therapeutic efficacy have focused on prolonging the survival of the infused CAR$^+$ T cells mainly *via* three approaches.

1. *To produce T cells those are capable of endogenous IL-2 production.* To generate an effective anti-tumor response for CD19-redirected effector T cells in tumor microenvironment we introduced a chimeric CD28 T cell co-stimulatory molecule into the CD19R CAR. This is based on the rationale that T-cell binding of CD28 to B7 molecules on target cells generates critical regulatory signals necessary for full T-cell activation and preventing T-cell apoptosis after CAR engagement. However, massively *ex vivo*-expanded genetically modified T cells may lose endogenous CD28 cell-surface expression. Therefore, to provide genetically modified CD28^{neg} T cells with tandem activation and co-stimulation upon engagement with B7^{neg}CD19$^+$ B-lineage tumors, the CD19R CAR was modified to include CD28-signalling domain. This second generation CAR, designated CD19RCD28, has been expressed in primary T cells and shown to activate genetically modified T cells for killing, IFN-γ, and IL-2 cytokine production, and improve *in vivo* survival of adoptively transferred CD19RCD28$^+$ T cells resulting in a greater anti-tumor effect, compared with first-generation CD19R$^+$ T cells.
2. *To target IL-2 to the tumor micro-environment.* In addition to engineering CAR for T-cell production of IL-2, a cytokine that *ex vivo*-expanded T cells typically depend on for continued *in vivo* persistence, we have directed exogenous IL-2 cytokine to the B-cell tumor microenvironment using a CD20-mAb fused to IL-2 (immunocytokine), and this combination immunotherapy enhanced the anti-tumor effect of infused T cells.
3. *To produce T cells with improved biologic potential.* Shortening the *ex vivo* manufacturing time may improve therapeutic efficacy, as extensively propagated T cells differentiate *in vitro* into cytolytic effectors lacking desired homing receptors and a tendency to undergo replicative senescence. Therefore, we have developed a new rapid propagation technology using a CD19$^+$ immortalized artificial antigen presenting cell (aAPC) that can be lethally-irradiated and used in co-culture to numerically expand cytolytic CD19-specific T cells. To develop non-invasive biomarkers and to evaluate adoptively transferred T-cell distribution and function, we have used radionuclides that are metabolized by TK which acts as a reporter gene for detection of T cells by positron emission tomography (PET).

Future Challenges

There has been a paucity of published data on the safety and feasibility of infusing T cells expressing CAR and at this time there are no reports describing sustained clinical response of adoptive transfer of CAR$^+$ T cells. This will soon change as multiple clinical trials are currently

underway world-wide using adoptive cellular immunotherapy with T cells expressing CAR. To maximize therapeutic efficacy, future trials will likely infuse CAR^+ T cells combined vaccine to deliver a T-cell activation signal though endogenous αβ TCR, or CAR^+ T cells combined with cytokine, such as immunocytokine, to deliver co-stimulatory signal through endogenous cytokine receptors. One of the major advantages of the strategy infusing CAR^+ T cells lies in the modular composition of the CAR molecule that combines an antigen-binding domain with signaling domains for effector-cell activation. This allows investigators to swap the CAR exodomain with a scFv or ligand that recognizes or binds to a desired cell-surface antigen. Future experiments will build on the catalog of antigen-targeting receptors to evaluate expression level, density, and stability of the CAR expression on the T-cell surface, as well as affinity of the binding domain for antigen in the context of tumor targets with varying antigen density. These studies will impact CAR-mediated immunotherapy since low-density antigen-positive tumor cells or low affinity CAR may lead to emergence of tumor escape. Just as genetic engineering can be used to alter the CAR exodomain, so the transmembrane, or endodomain may be altered to provide a fully-competent antigen-dependent T-cell activation signal. The majority of the CARs generated harbor CD3-ζ signaling chain which is currently considered more efficient in activating T cells for cytolysis, compared to chimeric FcεRI-γ. Other CARs have been generated activating T cells through syk, lck, but the full-effect of these receptors with respect to cellular activation and stability of receptor expression on the cell surface has yet to be determined. Similarly the CAR endodomain has been altered to express a co-stimulatory signaling molecule, such as chimeric CD28, to provide a coordinated signal with CD3-ζ to provide a more complete T-cell activation signal than achieved by signaling through CD3-ζ alone. Because different types of co-stimulation may result in different patterns of cellular activation, it will likely be beneficial to explore alternative co-stimulatory pathways in CAR-mediated T-cell activation. Increasingly, investigators are developing the tools to genetically modify T cells using techniques that cause minimal manipulation of the product leaving intact the full range of T-cell homing and proliferation potentials. Finally, genetic modification is being used to accomplish more than redirect T-cell specificity. For example, experiments are underway to render the T cells resistant to the anti-inflammatory and deleterious effects of iatrogenic glucocorticoids and TGF-β secreted by tumor cell.

Conclusion

Although limitations remain, genetic modifications enable investigators to engineer T cells with augmented therapeutic potential. It is expected that infusion of genetically modified T cells will be a center-piece of personalized medicine rivaling the influence of therapeutic mAbs as a treatment for malignancies.

Recombinant T cell receptor; Immunoreceptor; T-body

Definition

Chimeric T cell receptors are recombinant transmembrane receptor molecules, which are derived from the ►T cell receptor (TCR) complex and consist of an extracellular binding domain, a transmembrane domain, and an intracellular domain to initiate T cell activation upon engagement of the specific receptor ligand.

Characteristics

Recombinant TCRs provide the basis to engineer T cells with predefined specificity in order to redirect the ►T cell response toward defined target cells and to break tolerance for use in ►adoptive immunotherapy. Moreover, chimeric TCRs are valuable tools for the analysis of receptor driven activation of immune cells including T and NK cells. Several formats of recombinant TCRs have been designed during the last years, most of them are chimeric molecules composed of an extracellular binding and an intracellular signaling domain.

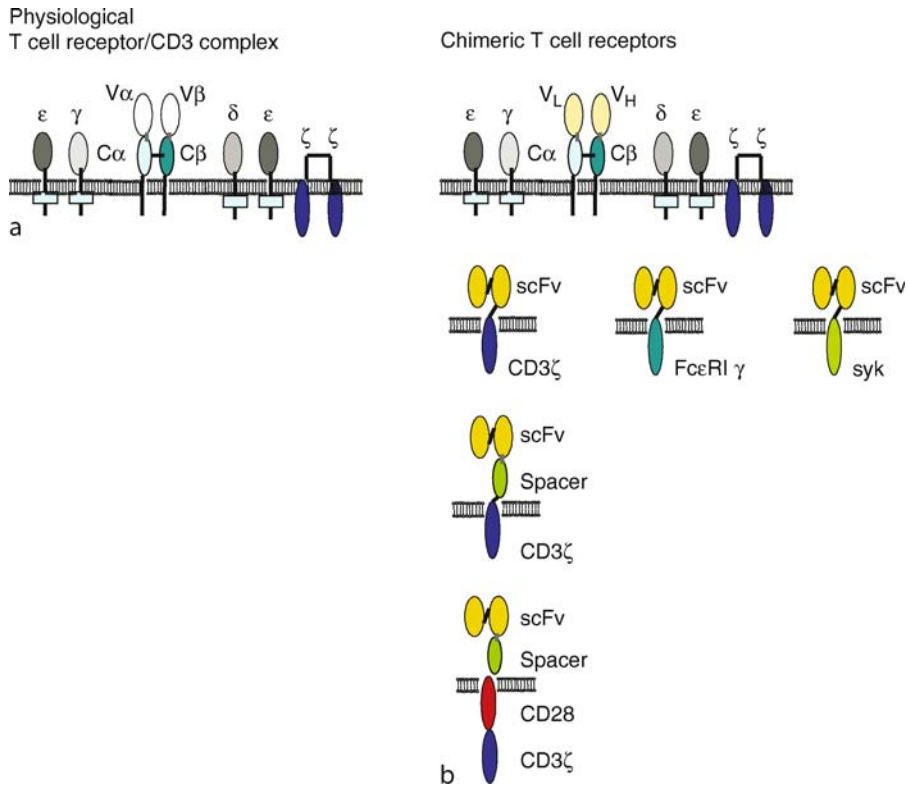
T cells exhibit their binding specificity via the TCR complex. For a number of applications in ►molecular therapy, T cells with predefined specificity would be desirable. By ►viral vector-mediated gene transfer, T cells can be grafted with a recombinant TCR of predefined specificity, which allows to redirect engineered T cells toward defined target cells. The approach, however, is hampered by the fact that the TCR of wanted specificity is frequently not available. In this situation, various formats of recombinant chimeric TCRs with predefined specificity were designed.

The TCR Format

Based on the similarity of the primary structure and the spatial conformation of the variable regions of immunoglobulin (Ig) and TCR α and β chain molecules, antibody derived binding regions V_H and V_L for antigen were grafted on to the constant domain of the TCR α and β chains, respectively (Fig. 1). Thereby, the TCR Vα and Vβ domains are replaced resulting in chimeric TCR molecules with antibody directed T cell recognition. The strategy, however, requires simultaneous expression of two modified TCR chains in engineered T cells. Moreover, the transfected TCR α and β chains frequently heterodimerize with the corresponding chains of the endogenous TCR resulting in chain mispairing and reduced expression of the recombinant TCR.

The Single Chain Format

The alternative format of a chimeric TCR (immunoreceptor, T-body) consists of one polypeptide chain which is composed of an extracellular binding and an intracellular signaling domain (Fig. 1). The single chain format avoids a number of difficulties that rise with the TCR format including simultaneous expression of the two recombinant TCR chains and mispairing with the endogenous TCR. The antigen binding domain is derived from a single chain fragment of variable regions (►scFv) antibody, the signaling moiety is preferentially derived from the CD3ζ chain of the TCR/CD3 complex or, alternatively, from the γ chain of the high affinity IgE Fc receptor (FcεRI). The scFv moiety used for binding is generated from an antibody molecule by genetically joining the V_H and V_L immunoglobulin regions via a flexible peptide linker, e.g., $(Gly_4Ser)_3$, resulting in a continuous polypeptide chain of the V_H-linker-V_L or V_L-linker-V_H type. ►Phage display techniques are applied to isolate scFv antibodies with high binding affinity. Due to the antibody derived binding domain, chimeric immunoreceptors can be generated that bind antigen of any chemical composition or conformation including classical and nonclassical T cell targets like carbohydrates, as far as an antibody exists. Thereby, a broad variety of chimeric TCRs were generated against tumor associated antigens like ►HER-2/neu, or ►cancer germline antigens. Instead of an scFv domain, any polypeptide with specific binding properties, e.g., receptor ligands, may be suitable as targeting domain as well. The majority of chimeric TCRs of the immunoreceptor type harbor antibody derived binding domains that mediate T cell activation independently of MHC. However, antibodies are available that recognize the processed peptide in the context of MHC. MHC/peptide recognizing antibodies when integrated into a chimeric TCR mediate T cell recognition in a MHC dependent fashion. It is so far not elucidated whether MHC dependent or independent, chimeric TCRs are



Chimeric T Cell Receptors. Figure 1 Modular composition of chimeric T cell receptors (TCRs). The physiological TCR complex consists of the α and β chain for antigen recognition and the CD3 complex to initiate intracellular signaling. Fusion of the antibody derived binding domains V_H and V_L to the α and β chains of the TCR creates a chimeric TCR. In an alternative format the chimeric TCR consists of one polypeptide chain with the single chain fragment of variable region (scFv) antibody as antigen binding domain which is fused via spacer and transmembrane (TM) domain to the intracellular signaling domain which is preferentially derived from the CD3ζ chain or the FcεRI γ chain, or alternatively from lck, syk, or CD3ε. Chimeric TCRs of the second generation harbor in addition to the CD3ζ chain a costimulatory domain, e.g., the CD28 domain.

superior in redirecting T cells in vivo. Some advantages of MHC independent chimeric receptors, however, are obvious, including targeting of unconventional T cell antigens like carbohydrates and targeting of cells even when their target antigen is not properly processed or presented in the MHC. Both $CD8^+$ and $CD4^+$ T cells can be redirected by the same immunoreceptor. The latter is of clinical relevance since redirected T cells of both $CD4^+$ and $CD8^+$ subpopulations execute granule-dependent cytolysis of target cells when stimulated via a chimeric TCR that circumvents MHC restriction.

The intracellular signaling domain of the chimeric TCR is most frequently derived from the CD3ζ or the FcεRI γ chain. Both signaling chains contain immunoreceptor tyrosine activation motifs (►ITAMs), the CD3ζ chain three, the FcεRI γ chain one ITAM, which become phosphorylated upon receptor crosslinking. The signaling domains thereby serve as specific adaptors for downstream signaling proteins of the TCR complex. Alternatively, signaling moieties of downstream kinases like lck can be used as activation domains in chimeric TCRs.

Expressed in cytotoxic T lymphocytes (►CTLs), crosslinking of the chimeric receptor by antigen engagement initiates T cell activation resulting in proliferation, cytokine secretion, and specific cytolysis of antigen expressing target cells. Chimeric TCRs define a new specificity of the grafted effector cell. This is indicated by the fact that (i) T cells with immunoreceptor are activated upon coincubation with target cells that express the defined antigen on the cell surface whereas antigen-negative target cells do not initiate receptor signaling in receptor grafted T cells, (ii) T cells without immunoreceptor or with immunoreceptor of other specificity are not activated upon coincubation with antigen expressing target cells, and (iii) receptor triggered activation can be blocked by antibodies directed toward the scFv domain of the immunoreceptor. The efficacy of T cell activation depends on various parameters including the expression level of the

receptor on the effector cell surface, the density of antigen on the target cell, the targeted epitope and the position of the epitope within the antigen.

Chimeric T Cell Receptors with Primary and Costimulatory Signal

Naive T cells, in contrast to preactivated T cells, are not fully activated when stimulated via CD3ζ but require ►costimulation via CD28. When T cells encounter antigen but lack costimulatory signals antigen-specific tolerance or anergy is induced. Current chimeric TCR strategies therefore aim to provide appropriate costimulatory signals on effector T cells in order to avoid induction of anergy. This is done by simultaneous expression of two recombinant immunoreceptors, one with the CD3ζ and the other with the CD28 signaling domain or, technically more convenient, by combining the intracellular CD3ζ chain together with the CD28 signaling domain into one polypeptide chain receptor molecule (Fig. 1). Different costimulatory domains result in different activation profiles. T cells triggered by the combined CD28-CD3ζ signaling chimeric receptor exhibit increased IFN-γ secretion and secretion of substantial amounts of IL-2 whereas T cells equipped with the CD3ζ chimeric receptor secrete lower amounts of IFN-γ and do not secrete IL-2. The specific cytolytic capacity, noteworthy, is not dramatically altered when preactivated T cells are stimulated via the CD28-CD3ζ compared to the CD3ζ signaling receptor.

Clinical Aspects

The major application of chimeric TCR strategy is to redirect cytotoxic T cells (CTLs) toward defined tumor cells or virus infected cells. T cells equipped with a tumor specific, chimeric TCR break tolerance toward autologous tumor cells as demonstrated in mouse models in vivo. Moreover, patient's T cells from the peripheral blood can be redirected in vitro toward the autologous tumor cells isolated from a tumor biopsy of the same patient. The approach is universal since by inserting the appropriate binding domain into the chimeric TCR, T cells can be redirected toward a broad variety of tumor associated antigens expressed on tumor cells of different entities, including ►gastrointestinal tumors and ►pancreas carcinoma (CEA, CA19-9, B72-4), ►melanoma (HMW-MAA, p97, GD3, Mage-1), breast carcinoma and ►epithelial tumors (►Her2/neu ErbB2, Muc1), renal cell carcinoma (G250), ►prostate carcinoma (PSMA), ►ovarian cancer (FBP), ►hematological malignancies including ►multiple myeloma and ►Hodgkin's lymphoma (CD19, CD20, CD30, CD33), and, moreover, toward virus infected cells, including hepatitis B virus infected ►hepatocellular carcinoma cells that express virus encoded proteins on the cell surface.

The strategy of redirecting T cells by chimeric TCRs has advantages over antibody-based therapies. In particular, the strategy makes use of the autologous cellular defense system represented by immunological effector cells that actively penetrate tissues. In contrast to antibodies, the engineered effector cells persist and circulate over long periods of time, i.e., until up to 1 year or even longer, amplify by proliferation upon antigen encounter and interact with numerous target cells by executing their cytolytic attack. Thereby, the chimeric TCR strategy is anticipated to be most powerful in eliminating (micro-) ►metastasis and ►circulating tumor cells. Since T cells in patients with advanced stages of the disease are frequently defective in TCR signaling, the chimeric receptor approach will require repeated administration of "freshly" grafted T cells to substitute burn-out or anergized CTLs. Once initiated the immune reaction is thought to be specifically sustained by chimeric receptor signaling upon repetitive stimulation with antigen. Having target cells eliminated, the immune reaction is supposed to be self-limiting since T cells that do not furthermore interact with their antigen enter apoptosis. It is furthermore anticipated that some engineered T cells convert into memory cells that will be active in ►immunoprevention of tumor relapse.

Clinical trials have been and are currently initiated using engineered T cells equipped with chimeric TCRs in order to eliminate tumor cells, e.g., of ►ovarian carcinoma, renal cell carcinoma, lymphoma, and melanoma. The safety of the immunotherapeutic strategies to redirect T cells by chimeric TCRs is currently explored. One of the major risks of redirecting T cells with chimeric TCRs, however, is the risk of autonomous amplification of engineered T cells independently of antigen. Secondly, there is the risk of an unwanted autoimmune reaction toward healthy tissues that express the same antigen as the target cell, however at lower levels. Costimulatory chimeric TCRs may harbor a higher risk of autoaggression compared to CD3ζ signaling receptors. Crucial questions in the treatment of malignant diseases, however, are whether effector cells with chimeric TCRs have retained their homing capabilities after genetic manipulation in order to accumulate at the tumor site, whether they execute their effector functions at the tumor site and are resistant toward suppression by ►T regulatory cells, and whether they remain silent upon contact with healthy tissues with physiological expression of target antigen.

Definition

Chinese medicine is a patient-oriented medical system that treats the ►cancer patients instead of the malignant diseases. It is believed that ►qi (the Chinese term for vital energy) supports the functional activities and blood supplies nutriments for the whole body. There exists a system of channels within the human body, through which the vital energy and blood circulate, and by which the internal organs are connected with superficial organs and tissues, and the body is made an organic whole. Using these holistic and harmonic approaches, Chinese medicine emphasizes to strengthen the body resistance. It attaches importance to the self-healing ability of human body to remove pathogenic factors and recover health. Many of its cancer therapies, such as Chinese medication (including medicinal decoction, patent medicine, and proprietary medicine), medicated diet, acupuncture, and moxibustion, as well as ►qigong and massage, are employed for enhancing this power.

Western medicine is an evidence-based medical system, in which authorized medical and healthcare professionals struggle to avert the destruction of cancer patients by the unrelenting displacement of normal homeostasis accompanying neoplastic growth. The clinical problems faced by oncologists include overcoming the inherent or acquired resistance of the malignant cell to therapy, ameliorating the toxicities of aggressively applied therapies, as well as exploiting the synergistic potency of surgery, radiotherapy, and chemotherapy. In the last few decades, the limited clinical skills demand the use of destructive agent for cancer therapy. In the post-genomic era, ►targeted therapy and novel therapeutic strategy are applied to complement the conventional treatment for an achievement of optimal anticancer results.

Characteristics

Developing History

The Yellow Emperor's Canon of Internal Medicine is believed to be the earliest medical monograph in China, which appeared during the Warring States period (475–221 BC), first defined the etiology of tumor. Since the ancient times, Chinese medicine has made a great contribution to the health of the Asian people. Based on empirical and clinical experience, Chinese medicine has been systematized and theorized in complex practice. Many safe and effective methods have been developed to diagnose and treat cancer over the past thousands of years.

Hippocrates (460–375 BC), the father of Western medicine, first attributed the origin of cancer to natural causes. Improved microscopes, stimulated cancer researches, and important discoveries in human and animal studies have resulted in a better understanding of neoplasia. The last few decades has witnessed spectacular progress in describing the fundamental molecular basis of cancer following the advent of molecular biology and genetics, which allows the device of advanced or targeted therapy for cancer.

Theories and Principles

The philosophical theories and fundamental principles of Chinese medicine include the theory of ►yin and yang, the five elements concept, the physiological functions of viscera and bowels, the conception of vital energy and blood, as well as the theory of the channels and collaterals. According to the basic theories, the physical structure and physiological phenomena of human body as well as the pathological changes are in adaptative conformity with the variations of the natural environment. Hence considerations of ►personalized cancer medicine are based on the patient's constitution, geographical localities, climatic, and seasonal conditions. The therapeutic principle of cancer is to treat the disease by looking into both its root cause and symptoms. Sometimes different treatments are applied to the same kind of cancer in the light of different physical reactions and clinical manifestations, whereas the same therapy can be used to treat different cancers if they are alike in clinical manifestations and pathogenesis.

According to the theories of Western medicine, cancer is not one illness but a variety of disorders with different pathophysiology that can arise from and spread to almost every organ and tissue in the body. Mechanism of the cancer development varies according to the site of the malignant disease and the precipitating cause. Each cancer has its unique pattern of presentation and approach to diagnosis and treatment. Therapy must be directed not only toward cure of the cancer and control of potential ►metastasis, but also to optimize the quality of life.

Etiology and Pathogenesis

There are two categories of etiological factors for cancer, based on the knowledge of Chinese medicine, which includes exogenous and endogenous factors. The exogenous factors refer to the six excessive and untimely atmospheric influences (wind, cold, summer-heat, dampness, dryness, and fire), as well as unhealthy diet. The endogenous factors refer to the excessive emotional changes (joy, anger, melancholy, anxiety, sorrow, fear, and fright) and the deficiency of functional organ. In general, the pathogenesis of cancer can be summarized as accumulation of ►phlegm dampness, internal noxious heat due to accumulation of pathogenic heat, ►blood stasis due to vital energy stagnancy, dysfunction of internal organs, vital energy, and blood deficiency, as well as yin and yang imbalance.

Extensive epidemiological and prospective studies have allowed Western medicine to identify two categories of etiological factors for cancer, which include environmental and genetic factors. The environmental factors refer to smoking, alcohol, unhealthy diet, ultraviolet light, ionizing radiation, carcinogens, certain viruses, and infections. The genetic factors refer to monogenic and polygenic disorders. In general, cancer is a clonal disease arising by the ►multistep development of genetic or epigenetic changes in ►oncogenes, ►tumor suppressor genes, and ►caretaker genes that favor expansion of the new clone over the old. These changes allow a normal cell to achieve the hallmark features of cancer, which include the capacity to proliferate irrespective of exogenous mitogen, the refractoriness to growth inhibitory signal, the resistance to ►apoptosis, the potential to reactivate ►telomerase resulting in unrestricted proliferation, the capacity to recruit a vasculature, as well as the ability to invade surrounding tissue and eventually metastasize.

Diagnostic Methods

Chinese medicine views the human body as a unity, and a malignant disease reflects both the interior and exterior of the body. The diagnosis of cancer is based on an overall analysis and differentiation of the patient's signs and symptoms, which include observation of the patient's mental state and inspection of the tongue, auscultation and olfaction, interrogation, as well as pulse taking and palpation.

Western medicine diagnoses cancer based on tissue diagnosis, which include tissue biopsy, diagnostic medicine, cytology, histopathology, and immunocytochemistry. The tumor-node-metastases classification is applied to establish the anatomical staging for most cancers. In addition, there are a number of specific ►tumor markers which are useful in diagnosis, such as α-fetoprotein for hepatocellular carcinoma, β-human chorionic gonadotrophin for choriocarcinoma, and prostate-specific antigen for prostate cancer.

Treatment Modalities

The principal methods of cancer treatment by Chinese medicine involve Chinese medication (derived from plant, animal, and mineral substances), medicated diet, acupuncture, and moxibustion, as well as ►qigong and massage. In most cases, the patients are treated with medications to strengthen their resistance and dispel the invading pathogenic factors of cancer. Sometimes the malignancy is treated with poisonous medication to combat poison with poison, such as the application of ►arsenic trioxide. The cancer remedy should be made up in accordance with the physique of an individual, pathologic changes occur in the course of cancer, as well as the geographical and seasonal conditions. The prescription for cancer usually consists of various medicinal ingredients with the purpose to produce the desired therapeutic effect in unison and reduction of toxicity or side effects. The principal ingredient provides the principal curative action, the adjuvant ingredient helps to strengthen the principal action, the auxiliary ingredient relieves the secondary symptom or tempers the strong action of the principal ingredient, and the

conductant directs the action to the affected channel or site. More than 100 species of Chinese pharmaceuticals have been used to treat cancer. As there are up to thousands of compounds in a medication, multitargets are exhibited to the malignant disease and some of the compounds may exert a synergistic anticancer effect.

Using the combined modality approach, the principal methods of cancer treatment by Western medicine involve the combined application of surgery, radiotherapy, combination chemotherapy, hormonal therapy, biological therapy, palliative care, and symptom control. Surgery alone is curative in many early stage neoplastic tumors. Radiotherapy is often used after surgery to reduce the chance of recurrence. It can also be used on its own with curative intent or as a palliative treatment. Chemotherapy is a systemic treatment that can reach any part of the body with an adequate blood supply, and therefore it is normally used to treat disseminated cancer. It can also be used as an ►adjuvant therapy to reduce the volume of advanced cancer, with intent to prolong life and relieve symptom. The development of new less toxic chemotherapeutic drugs and more effective antiemetics have reduced many adverse effects of chemotherapy. Hormonal therapy is performed to manipulate the hormone level, which can result in the regression of a number of cancers, particularly for the breast cancer, endometrial cancer, and prostate cancer. Biological therapy exploits insight into the nature of tumor antigen, the molecular and cellular requirement for immune activation, the role of cytokine in amplifying the immune response, as well as the evolution of recombinant DNA approach to introduce the genetic material into eukaryotic cell. Palliative care aims to achieve the best possible quality of life for patient and their family by controlling the physical symptom, as well as recognizing the psychological, social, and spiritual problems.

Western medicine is currently used as the primary therapy for cancer and Chinese medicine is employed as a supplementary therapy in some Asian nations. There is considerable evidence for the promising benefits of Chinese medicine in alleviating the toxic effect of radiotherapy and chemotherapy, strengthening the anticancer activity, as well as enhancing the immune function. Chinese and Western medicines are obviously two distinct medical systems with different diagnostic and therapeutic methods for cancer. However, with a common goal to eradicate this systemic disease, it may be feasible for a certain degree of complementation and integration of these two medical systems in the realm of clinical practice.

Cholangiocarcinoma

Justin L. Mott, Gregory J. Gores
Miles and Shirley Fiterman Center for Digestive Diseases, Division of Gastroenterology and Hepatology, Mayo Clinic College of Medicine, Rochester, MN, USA

Synonyms

Bile duct carcinoma; Klatskin tumor; Cholangiocellular carcinoma

Definition

Cholangiocarcinoma refers to malignancy within the biliary duct system and is distinct from ►gallbladder cancer. Cholangiocarcinomas generally have features of biliary tract epithelium, such as a glandular appearance, small regular nuclei, and scant cytoplasm. Tumor cells often express cytokeratins, ►CA19-9 and mucin.

- 95% of bile duct tumors are adenocarcinomas
- The remainder is comprised of squamous, carcinoid, sarcomatous, mixed cholangiocellular/hepatocellular tumors, Kaposi's sarcoma, and lymphoma

The characteristics described here refer to the adenocarcinoma cell type of either intrahepatic or extrahepatic bile duct origin.

Characteristics

Etiology

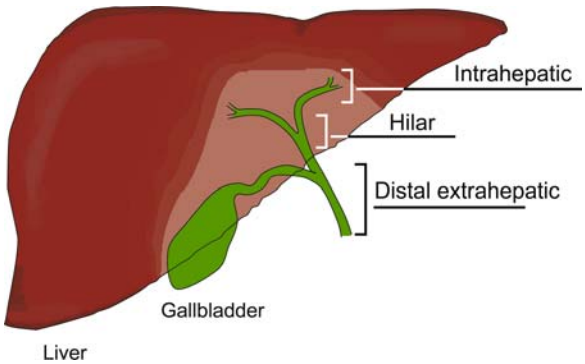
Cholangiocarcinomas are the second most common primary liver cancer, representing 10% of all primary liver tumors. Cholangiocarcinomas occur with an approximate 1:100,000 incidence in the Western world but are more common in Southeast Asia and Japan. There is a slight male preponderance, with tumors occurring most frequently in the seventh decade of life. More than 90% occur sporadically in an otherwise normal liver. Risk factors for the development of cholangiocarcinoma include ►primary sclerosing cholangitis (PSC), congenital dilatation of the biliary tree (i.e. Caroli's disease), ►hepatolithiasis and chronic infestation of the biliary tree by the parasitic ►liver flukes *Opisthorchis viverrini* and ►*Clonorchis sinensis*. Infection with these parasites is endemic in some parts of Southeast Asia, and in part may contribute to the higher incidence of cholangiocarcinoma in this region. These conditions all have in common chronic inflammation of the biliary tree, biliary stasis, or both. The inflammatory milieu likely contributes to two of the cardinal features of cancer, resistance to ►apoptosis, and continuous proliferation.

The cellular origin of malignant cells is not certain. Biliary epithelial cells are long lived under normal circumstances and thus survive long enough to accumulate carcinogenic mutations. Alternatively, multipotent progenitor cells that reside in the ►canals of Hering are not terminally differentiated and have the proliferative capacity that may facilitate malignant transformation. Finally, gland-like structures along the bile ducts can show hyperplasia and dysplasia adjacent to malignant cholangiocarcinoma. It is possible that each of these cellular compartments contributes, depending on tumor focus and carcinogenic insult.

Biology

Grossly, cholangiocarcinomas usually develop at the hilum (60%) and less frequently develop as distal extrahepatic or as intrahepatic tumors (Fig. 1). Lesions can be categorized based on growth pattern as mass-forming, periductal-infiltrating, and intraductal. Microscopically, tumors have relatively few cancer cells in a desmoplastic stroma. This fibrosis leads to a low diagnostic yield of random sampling and the sensitivity of routine cytology from biliary brushings is usually reported in the range of 4–26%.

The mechanistic link between inflammation and the development and progression of cholangiocarcinoma is of interest. Several inflammatory mediators have been shown to stimulate cholangiocyte proliferation, inhibit DNA repair or block apoptosis – all factors important in carcinogenesis. Indeed, interleukin-6 (IL-6) is an effective cholangiocyte mitogen and drives proliferation of this cell type via the MAP-kinase pathway. Additionally, IL-6-driven activation of Signal-Transducer and Activator of Transcription 3 (STAT3) increases expression of ►Mcl-1, a potent anti-apoptotic protein. Mcl-1 acts to protect cancerous cells and may contribute to the refractory nature of cholangiocarcinoma to chemotherapy. Pro-inflammatory cytokines induce cholangiocyte DNA damage and inhibit DNA repair by a nitric oxide-dependent mechanism. In addition, immunohistochemical studies of human cholangiocarcinoma specimens



Cholangiocarcinoma. Figure 1 Diagram of the liver and biliary tree. Cholangiocarcinoma can arise anywhere along the biliary tree, including intrahepatic bile ducts (peripheral cholangiocarcinoma), the hilum (Klatskin tumors), and more distally (distal extrahepatic cholangiocarcinoma). Hilar cholangiocarcinoma can be further subdivided using the Bismuth-Corlette classification depending on the involvement of only the hepatic duct (type I), the common hepatic duct and the confluence of the left and right hepatic ducts (type II), the common hepatic duct and either the left or right hepatic duct (type III), or the common, left, and right hepatic ducts or multifocal tumors (type IV).

have shown the ubiquitous presence of inducible nitric oxide synthase (iNOS). Thus, IL-6 and iNOS with nitric oxide generation in chronically inflamed tissues likely contribute to the initiation and progression of cholangiocarcinoma.

The epidermal growth factor receptor (EGFR) has been implicated in numerous cancers, and activating mutations of EGFR have been described in cholangiocarcinoma. Further, bile acids stimulate signaling through the EGFR, including increasing Mcl-1 protein levels. EGFR activation leads to activation of the survival kinase Akt which is inhibited by phosphatase and tensin homolog deleted on chromosome 10 (PTEN). Experimental PTEN deficiency in mice combined with loss of SMAD4 (a mediator of TGF-beta signaling) leads to cholangiocarcinoma by 4–5 months of age. Thus, dysregulation of EGFR signaling may play a prominent role in cholangiocarcinoma.

Diagnosis

Most patients with cholangiocarcinoma present with signs and symptoms of biliary obstruction, including ►jaundice, pruritis, chalk-colored stools, and dark-colored urine. This is the result of partial or complete blockage of the biliary tract leading to cholestasis, and applies to Klatskin tumors and distal extrahepatic tumors. Intrahepatic tumors do not cause clinically significant biliary stasis.

Because the majority of tumors are not mass-forming, diagnosis by imaging can be difficult. Still, MRI with magnetic resonance cholangiopancreatography (MRCP) can be used to define the location and extent of a lesion. MR angiography is useful for assessment of vascular involvement. CT and CT angiography can also be used to assess tumor location and vascular involvement, as well as lymph node enlargement. Ultrasound is often the initial study used in evaluation of obstructive jaundice. While non-specific, ultrasound can visualize biliary duct dilatation proximal to the obstruction and potentially can visualize an intrahepatic mass.

Endoscopic retrograde cholangiography (ERC) in the case of obstruction is necessary and can be diagnostically and therapeutically useful. ERC can demonstrate the site and extent of a stricture, intraluminal brushings taken within the stricture can provide cells for cytologic and advanced cytologic evaluation, and stenting relieves symptoms due to obstruction. Transluminal or percutaneous biopsy of hilar lesions or lymph nodes is not recommended due to the risk of tumor seeding.

Histologic diagnosis is the gold standard, however often diagnosis is based on the overall clinical picture. Cytologic evaluation has high specificity when positive for malignancy, but due to the desmoplastic nature of the tumor has low sensitivity. Advanced methods of cytologic analysis (digital image analysis and fluorescence in situ hybridization) have recently been used to improve sensitivity without compromising specificity. Serum CA19-9 level can aid in the diagnosis.

Patients with PSC represent a significant diagnostic challenge, as non-cancerous stricture formation is the norm in this disease. Still, with a lifetime incidence of cholangiocarcinoma in PSC patients of 10–20%, a high index of suspicion must be maintained. Stable asymptomatic patients can be surveyed by non-invasive techniques such as MRCP and CA19-9 serum testing.

Treatment and Prognosis

Surgical resection for intrahepatic cholangiocarcinoma is curative for a minority of patients. For extrahepatic tumors (including Klatskin tumors) resectability depends on the extent of biliary and vascular involvement. Involvement of the left and right hepatic lobar structures (bilateral portal vein, main portal vein, or bilateral hepatic ducts) precludes resection, as does underlying liver disease or PSC. In resectable cases, partial hepatectomy improves outcomes. Selected patients with unresectable extrahepatic tumors benefit from liver transplantation; liver transplantation for intrahepatic cholangiocarcinoma is contraindicated due to disease recurrence.

Only a minority of patients present with disease amenable to surgical resection or transplantation. For the remaining patients, palliative treatment improves quality of life. The most important intervention

involves relief of biliary obstruction generally by endoscopic approach or percutaneously. Drainage of one functional lobe is sufficient to relieve obstructive symptoms. Photodynamic therapy in conjunction with stent placement can improve drainage and increase survival by ~1 year. Palliative chemotherapy with gemcitabine leads to only limited responses.

Overall, the prognosis for cholangiocarcinoma remains poor. Five year survival ranges from 10 to 45%, while peri-ampullary tumors have slightly higher 5-year survival (50–60%). Future improvements may come from rationally designed therapy based on the tumor biology, for instance targeting IL-6, EGFR, or Mcl-1.

►Bile Duct Neoplasms

Cholecystectomy

Definition

Is the surgery for removal of the gallbladder. This kind of surgery can be performed with the traditional open incision or can be removed through abdominal incision using a laparoscope (laparoscopic cholecystectomy).

►Gallbladder Cancer

Cholecystitis

Definition

Acute or chronic ►inflammation of the gallbladder. In 90% of cases cholecystitis is associated with the presence of gallstones in the cystic duct (i.e., calculous cholecystitis), while the other 10% represents acalculous cholecystitis.

►Gallbladder Cancer

Cholecystokinin (CCK)

Definition

Gut peptide hormone secreted in response to food, that stimulates gallbladder contraction and pancreatic

enzyme secretion; CCK receptors are shared with another gut peptide, gastrin

►Gut Peptides

Cholera Toxin

Definition

Exotoxin from Vibrio cholerae which ADP-ribosylates the α-subunit of G_s at Arg201 leading to the constitutive activation of the α-subunit by blockade of its GTPase activity. Modification of $G\alpha_s$ in epithelial cells of the gut leads to an increase in cAMP levels which causes watery diarrhea.

►G-Proteins

Cholestasis

Definition

Is a condition caused by interruption in the excretion of bile. Cholestasis is caused by obstruction of bile ducts within the liver (intrahepatic) and/or outside the liver (extrahepatic). Obstruction of bile flow causes bile salts, the bile pigment, bilirubin, and fats (lipids) to accumulate in the blood instead of being eliminated normally.

►Bile Duct Neoplasms

Cholesterol

Definition

Is a white waxy substance that can stick to the inside of blood vessels, resulting in clogged arteries, heart disease, and strokes. Formation of cholesterol can be inhibited by ►statins.

Chondrex

►Serum Biomarkers

Chondroitin Sulfate (CS)

Definition

Synonym dermatan sulfate (DS) is a sulphated glycosaminoglycan, usually found attached to proteins as part of a proteoglycan. CS chains are unbranched polysaccharides of variable length containing two alternating monosaccharides: d -glucuronic acid (GlcA) and *N*-acetyl-d-galactosamine (GalNac), each of which can be sulfated in variable positions and quantities. CS is a major component of extracellular matrix, and is important in maintaining the structural integrity of the tissue. It also readily interacts with proteins in the extracellular matrix due to its negative charges and regulates a diverse array of cellular activities.

►Pleiotrophin

Chondrosarcoma

Yvonne M. Schrage,
Pancras C.W. Hogendoorn,
Judith V.M.G. Bovée
Department of Pathology, Leiden University Medical Center, Leiden, The Netherlands

Definition

Chondrosarcoma of bone is a malignant hyaline cartilage forming tumor (Fig. 1). The term chondrosarcoma describes a heterogeneous group of lesions with diverse morphologic features and clinical behavior. Apart from conventional central and peripheral chondrosarcoma constituting the largest subgroup (~85%) this encompasses rare subtypes such as clear cell chondrosarcoma (~1%), mesenchymal chondrosarcoma (~2%), juxtacortical chondrosarcoma (~2%) and dedifferentiated chondrosarcoma (~10%) as well.

Characteristics

The incidence of conventional chondrosarcoma is about 1:50,000. The incidence in males and females is almost equal, and the mean age of diagnosis is 30–60 years. Chondrosarcomas are mostly found in bones that elongate by ►endochondral ossification with the most common sites being the pelvis followed by the proximal femur, proximal humerus, distal femur and ribs. When comparing histologically the different cartilaginous tumors to the growth plate, parallels between normal and neoplastic chondrocyte growth and differentiation

Chondrosarcoma. Figure 1 Macroscopic photograph of gross specimen of chondrosarcoma of distal femur.

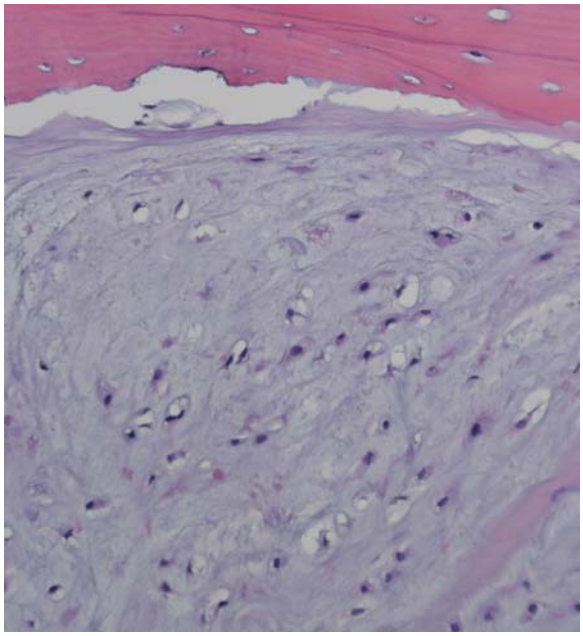
become evident. Resting (primitive, mesenchymal stem-cell like) chondrocytes are found in mesenchymal chondrosarcoma, while clear cell chondrosarcoma consists mainly of hypertrophic chondrocytes. ►Osteochondroma, a benign cartilaginous tumor at the surface of bone, recapitulates all differentiation levels of the growth plate. In contrast, ►enchondroma, a benign cartilaginous tumor in the medullar cavity of bone, and conventional peripheral and central chondrosarcoma mostly contain proliferating chondrocytes, lying in small lacunae. The more rarely occurring dedifferentiated chondrosarcoma is thought to arise from conventional chondrosarcoma in which tumor cells transdifferentiate towards a more spindle-cell phenotype. In addition, the rare subtype juxtacortical chondrosarcoma is recognized, which also contains proliferating chondrocytes. This specific diagnostic term is used as a result of its typical clinicoradiological presentation and its in general relatively favorable prognosis as compared to conventional chondrosarcoma.

There is a clinical as well as a morphological spectrum of cartilaginous tumors. Central chondrosarcoma is the most common subtype (>85%) of conventional chondrosarcoma. Malignant transformation of an enchondroma to a central chondrosarcoma is estimated to be <1%. However, since in 40% of central chondrosarcomas remnants of a pre-existing enchondroma are found, there is considerable debate whether these tumors are secondary to enchondroma or arise mostly primary. The frequency of malignant transformation is significantly higher (15–30%) in patients with multiple enchondromas in the context of the extremely rare non-hereditary disorder ►Ollier disease. Conventional chondrosarcoma at the surface of bone (secondary peripheral chondrosarcoma) per definition develops within a pre-existing osteochondroma. Secondary peripheral chondrosarcomas constitute up to 15% of conventional chondrosarcomas in referral centers. ►Multiple osteochondromas (MO), previously known as hereditary multiple exostoses (HME), is an autosomal dominant disorder and malignant transformation occurs in 1–3% of the cases of MO. In addition, chondrosarcomas may biologically progress: up to 13% of recurrent chondrosarcomas exhibit a higher grade of malignancy than the original neoplasm, with an adverse prognosis.

Diagnosis

Benign cartilaginous tumors are asymptomatic, and are often found by incidence at radiology made for other reasons. In contrast, malignant tumors almost always produce symptoms such as local swelling and pain. The distinction between enchondroma or osteochondroma and low-grade conventional chondrosarcoma is difficult, both at the radiological level (in case of central chondrosarcoma) and the histological level (for both subtypes). Diagnosis should be made in a multidisciplinary setting, based on clinical, radiological and histological aspects. Dynamic MRI has been proven to be informative in distinguishing benign from malignant cartilaginous tumors. Histologically, the distinction between enchondroma and low grade conventional central chondrosarcoma is mainly based on growth patterns and cytomorphological features. Encasement (new shells of reactive bone, formed at the periphery of cartilage nodules), is a feature of benign tumors, while entrapment (permeation of tumor around pre-existing lamellar bone), points to a faster growing process and thus malignancy.

Histologically, chondrosarcomas are divided in three grades of malignancy based primarily on cellularity, nuclear size and chromasia, mitoses and the composition of the matrix. Grade I tumors are moderately cellular and nuclei are uniformly sized and hyperchromatic. Grade II tumors are more cellular and nuclei are atypically shaped, hyperchromatic and larger, and mitoses can be found (Fig. 2). At the end of the spectrum, grade III tumors are hypercellular, with nuclear pleomorphism are found, and mitoses can be frequent. In addition, the extracellular matrix of grade III tumors becomes more mucoid/myxoid compared to the abundant chondroid matrix seen in grade I tumors and their vascularity is increased. Differences in 5 year survival and the occurrence of metastases show the clinical importance of histological grading. While grade I and II tumors rarely metastasize (respectively 0 and 10%), grade III tumors do so in 71% of the cases. 5 year survival is



Chondrosarcoma. Figure 2 Chondrosarcoma of histology.

lowest in patients with grade III tumors (29%) compared to 64% in grade II tumors and 83% in grade I chondrosarcomas.

Therapy

A correct diagnosis is essential for therapeutic decision making. Surgery is the only option for curative treatment since chondrosarcomas are highly resistant to conventional ►chemotherapy and ►radiotherapy. Studies regarding the mechanism underlying resistance are sparse. Therefore, development of targeted therapy for chondrosarcoma would mean a major advance in chondrosarcoma therapy. While for benign lesions a wait and see policy is justified, malignant tumors require more aggressive treatment. Grade I chondrosarcomas are prone to local recurrence but almost never ►metastasize. Therefore, there is a trend in sarcoma centers to treat them by curettage with margin improvement by phenol or ►cryosurgery. In contrast, high grade tumors are usually treated by often mutilating wide en bloc resection or even amputation, since these often metastasize, being lethal in the majority of patients.

Genetics

Although histologically similar, central and peripheral chondrosarcoma have been shown to be genetically, and thereby molecularly, different entities. In Multiple Osteochondromas germline mutations have been identified in the EXT tumor suppressor genes, located on chromosomes 8q24 (EXT1) and 11p11–12 (EXT2), respectively. These ►EXT genes encode glycosyltranferases involved in heparan sulphate biosynthesis. In MO germline mutations in EXT1 or EXT2 with loss of the remaining wild-type allele is found. Recently, in solitary osteochondromas somatic homozygous deletions of EXT1 have been demonstrated. In both hereditary and solitary osteochondromas mRNA expression of EXT1 or EXT2 is decreased. This probably results in intracellular accumulation of heparan sulphate proteoglycans (HSPGs), since the Syndecan2 and the CD44v3 core proteins were shown to aberrantly localize in the Golgi apparatus in solitary and hereditary osteochondroma and peripheral chondrosarcoma. The EXT1 homologue in *Drosophila* (tout velu, ttv) is required for IHH diffusion to its receptor that signals to ►PTHLH and thereby controls chondrocyte proliferation. In contrast to the growth plate, in osteochondroma IHH signaling has become cell autonomous, probably overcoming the diffusion problems caused by defective HSPGs due to EXT inactivation.

Additional genetic alterations are thought to be required for malignant transformation of osteochondroma towards low grade secondary peripheral chondrosarcoma. These additional alterations presumably cause ►chromosomal instability, since peripheral chondrosarcomas are shown to be ►aneuploid with DNA indices ranging from 0.56 to 2.01. At the protein level progression from osteochondroma towards low-grade peripheral chondrosarcoma is characterized by a re-activation of PTHLH signaling. Its downstream target, ►BCL-2, can be used as a diagnostic marker in those cases in which it is hard to distinguish between benign and malignant cases, with osteochondromas being negative in 95% (specificity) and chondrosarcomas scoring positive in 57% (sensitivity). This re-activation of PTHLH is hypothesized to be caused by increased ►TGF-beta signaling, since IHH signaling has been shown to be downregulated in peripheral chondrosarcoma.

Despite the increasing number of genetical studies including peripheral and central chondrosarcomas as separate subgroups, no specific genetic aberrations for the more common central chondrosarcoma have been identified as yet. Mutations in EXT1 and EXT2 have not been reported, and reports on IHH signaling on proliferation in central chondrosarcoma are still inconclusive. A positive relation between histological grade and the degree of karyotypic complexity and aneuploidy was found. Near-diploidy and limited loss of heterozygosity are typical of low-grade central chondrosarcomas rather than of peripheral chondrosarcomas pointing to an oncogenic mechanism with few alterations, sufficient for oncogenesis. Multiple studies report alterations at chromosomal bands 9p21 and 12q13–15. Genetic loss at the 9p21 locus as found by cytogenetics, loss

of heterozygosity analysis and ►comparative genomic hybridization suggest an important role for the CDKN2A/INK4a locus. Loss of protein expression of the tumor suppressor gene p16, encoded by this locus, was found to be associated with increased histological grade in central chondrosarcoma, and thereby to be important for tumor progression.

Rearrangements in the 12q13–14 region have been frequently reported in sarcomas. Several genes in this region have been indicated to be of importance for tumorigenesis, such as SAS (sarcoma amplified sequence), CDK4 (►cyclin dependent kinase 4) and GLI (glioma associated oncogene homologue). Also two other often implicated genes in sarcomas, HMGA2 (high mobility group AT-hook 2) and ►MDM2, are located just outside the 12q13–14 region. Moreover, the progression from low-grade to high-grade central chondrosarcoma is characterized by ►P53 alterations. Despite the large number of studies involving central chondrosarcomas, the exact underlying molecular mechanism is still largely unknown.

Chromatin Remodeling

Yutaka Kondo
Division of Molecular Oncology, Aichi Cancer Center Research Institute, Nagoya, Japan

Synonyms

Nucleosome remodeling; Chromatin modification

Definition

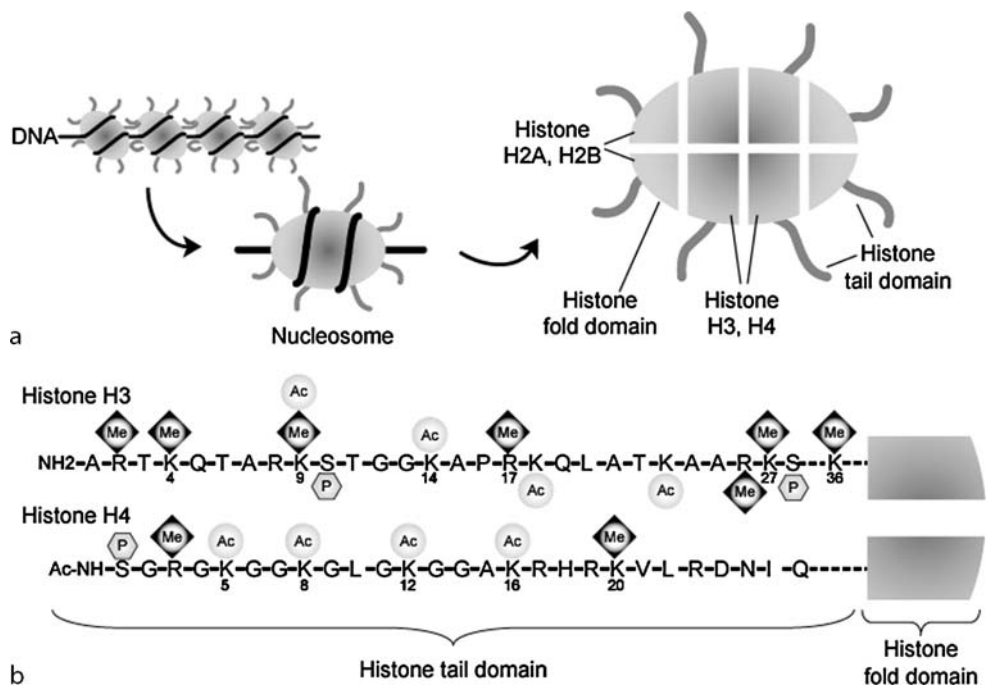
Chromatin remodeling is regulated by reorganization of nucleosome position by ATP-dependent nucleosome remodeling factors (ADNR) and covalent modifications of histone proteins. Because chromatin structure affects the binding of proteins including transcription factors to DNA, it is involved in many essential cellular processes.

Characteristics

Nucleosome (►Nucleosomes) consists of 147 bp DNA wrapped around the histone octamer comprising histone proteins, H2A, H2B, H3, and H4. Since the position of nucleosomes on DNA and the chromatin structure can affect the binding of proteins to DNA, chromatin remodeling is required for all the key processes such as gene expression (►Epigenetic gene silencing), DNA replication, repair, chromosomal recombination, and mitosis. ADNR factors, SWI/SNF type factors, which are the part of multiprotein complexes, shuffle the nucleosomes and change chromatin structure and organization (nucleosome mobility), leading to either activation or repression of gene expression.

The N-terminal domains of all core histones are subjected to chemical modifications, such as acetylation, methylation, and phosphorylation at certain residues (Fig. 1). Histone modifying enzymes (►Histone deacetylases; ►HDACs) bring complexity of posttranslational modifications that can either activate or repress transcription, depending on the type of chemical modification and its location in the histone protein. The modification pattern of histone has been functionally linked to transcription and acts as a "histone code," which alters the structure of higher-order chromatin and helps recruit effector molecules. Various observations have suggested a connection between nucleosome remodeling and covalent histone modifications.

Recent study suggested that histones at transcriptionally active loci can be selectively replaced in a manner



Chromatin Remodeling. Figure 1 (a) DNA is compacted in the nucleus through a hierarchy of histone-dependent interactions. The fundamental repeating unit of chromatin is the nucleosome, which consists of 147 bp of DNA wrapped around an octamer of core histone proteins, H2A, H2B, H3, and H4. (b) Core histone proteins consist of less structured amino-terminal tails (histone tail domain) protruding from the nucleosome and globular carboxy-terminal domains making up the nucleosome scaffold (histone fold domain). Histone tail domain could be a target of a variety of posttranslational modifications, including acetylation (Ac), methylation (Me) and ►ubiquitination of lysine (K) residues, phosphorylation (P) of serine (S) and threonine (T) residues, and methylation of arginine (R) residues.

that is independent of DNA replication; that is, replacement of canonical histone H3 with variant histone H3.3, which is a highly conserved histone variant.

Mutation or dysfunction of these "epigenetic mechanisms" has been implicated in human cancers (►Epigenetics).

Mechanisms and Clinical Aspects

Chromatin Remodeling Complex

In order to obtain the access of proteins to the DNA inside nucleosomes, chromatin remodeling ATPases are required to unwrap the nucleosomal DNA or to slide the nucleosome along the DNA to expose the buried sequences. (Fig. 2) SWI/SNF type chromatin remodeling factors have been shown to be required to this process. These factors are multiprotein complexes containing a central nucleic acid substrate stimulated ATPase belonging to the SWI2/SNF2 family. SWI2/SNF2 family is thought to be involved in gene expression, although their regulation and functions are not fully understood. The mammalian homologues, *Brahma* gene (*BRM*) and *Brahma*-related gene 1 (*BRG1*) are major components with ATPase enzymatic activities in the nucleosome remodeling SWI/SNF complex. BRM and BRG1 have a high degree of homology and either one of them might be contained in each SWI/SNF complex. Mutations or lack of expression of BRG1 have been identified in pancreatic, breast, lung, and prostate cancer cell lines. Germline and somatic mutations in *SNF5* (also called *INI1*), which is another mammalian SWI/SNF complex component but itself does not possess a chromatin remodeling function, cause malignant rhabdoid tumor. Although BRM and BRG1 make a chromatin remodeling complex with SNF5, mutation in SNF5 resulted in more sever phenotype than the tumor harboring either BRM or BRG1 mutations. There could be a degree of functional redundancy between BRM and BRG1, though the functions of SWI/SNF complexes containing BRG1 or BRM might not be interchangeable in some cases. BRG1 is involved in preventing cell cycle progression through its interaction with RB that has been shown to function as a brake on the cell cycle at least in part by establishing stable epigenetic silencing of the target genes. The SWI2/SNF2 family also contains generally one or more domains in addition to helicase-like and ATPase domains. A number of these domains have been shown to interact with surfaces on the nucleosome,

	CHD4	Chromo	Repression
INO80	INOB0	DBINO	DNA repair and gene expression
RAD54	ATRX		Regulation of transcription, DNA methylation
DDM1	HELLS/PASG/Lsh		Repression

Chromatin Remodeling. Figure 2 (a) The nucleosome is a substrate of ATP-dependent nucleosome remodeling factor (ADNR). Nucleosome mobility is regulated by ADNR. (b) The SWI2/SNF2 family of ATP-dependent nucleosome remodeling proteins in mammals is classified into different subfamilies. SWI2/SNF2 family contains one or more domains in addition to helicase-like and ATPase domains. SANT (SWI3, ADA2, N-CoR, TFIIIB), DBINO (DNA-binding domain of INO80), Bromo (bromodomain), and Chromo (chromodomain) might interact with surfaces on the nucleosomes.

which are often the targets of posttranslational modifications (see below). For example, bromodomain and chromodomain could bind acetylated lysine and methylated lysine, respectively.

Histone Modifications

Histone modifications are important in transcriptional regulation and are stably maintained during cell division. The less structured N-terminal domains of all core histones protrude from the nucleosomes and are subjected to chemical modifications, such as acetylation, ►methylation, and phosphorylation at certain residues. The modification patterns of histone have been functionally linked to transcription and act as a "histone code," which implies that transcription states can be predicted simply by deciphering this code. Generally, acetylation of lysine (K) residues on histone H3 and H4 leads to the formation of an open chromatin structure, with transcription factors accessible to promoters. Phosphorylation on serine 10 and acetylation on K14 on histone H3 work antagonistically to K9 methylation on H3 leading to the gene activation. Methylation at lysine is considered as a stable modification. There are the extra complications that histone lysine methylation can be either activating (e.g., H3K4 and H3K36) or repressing (e.g., H3K9, H3K27, and H4K20), and the respective enzymes vary in their potential to induce mono-, di-, or trimethylation. Trimethylation at K9 on histone H3 or K20 on histone H4 has been shown to be a marker of heterochromatin from yeast to human. Dimethylation at K9 is associated with inactivation of gene expression. Trimethylation at histone H3K27 is a distinct histone modification involved in the regulation of homeotic (Hox) genes (►Homeobox genes and cancer) expression and in early steps of X-chromosome inactivation in women. Di- or trimethylation on K4 on histone H3 localizes to sites of active transcription and this modification may be stimulatory for transcription. These different combinations of histone tail modifications influence transcription by affecting chromatin structure. Modifications on the lateral surface of core histone could also affect the histone–DNA interactions as well. Control of nucleosome mobility could be regulated by the valance of modifications of acetylation, methylation, and phosphorylation on the lateral surface amino acid residues.

DNA methylation is a crucial epigenetic mechanism for silencing tumor suppressor genes in human cancers, which also affect the chromatin structures. The link between DNA methylation and the histone modifications is mediated by a group of proteins with methyl DNA binding activity, including MeCP2, MBD1, and Kaizo, these proteins localize to DNA methylated promoters and recruit a protein complex that contains HDACs and histone methyltransferases. The DNA methyltransferases may also play a role in direct repression of transcription through cooperation with HDACs in late S-phase. While evidences for interactions between the DNA methylation and histone modifications are accumulating, the critical initiating events in silencing remain to be defined. In fungi, mutations of a histone H3K9 methyltransferase reduced DNA methylation indicate a simple linear model in which H3K9 methylation acts as an upstream epigenetic mark which signals to DNA methylation. However, in mammalian cells, DNA methylation inhibition could also rapidly changes histone methylation, and in plants histone and DNA methylation play distinct roles depending on the locus studied. The interactions between DNA methylation and histone H3K9 methylation currently best fit a model whereby these two changes form a reinforcing silencing loop, and this may explain why silencing is less stable in organisms that lack DNA methylation.

Histone Variant

At transcriptionally active loci, histone H3.3 variant substitutes for the canonical H3 histones. This replacement is independent of DNA replication. Histone modifications that may change histone–DNA or histone–histone contacts also affect catalyzing histone variant exchange. This Replacement process is also catalyzed by ATP-dependent nucleosome remodeling complexes. Histone replacement, which presumably is associated with activating transcription factors on the promoter region, offers an explanation for gene reactivation that were previously silenced via histone methylation. Whether histone replacement might be perturbed in cancer cells remains an open question.

►Epigenetic Therapy

The most promising aspects of this field are that the restoring gene function silenced by epigenetic changes including chromatin remodeling in cancer. "Epigenetic therapy," has the potential of "normalizing" cancer cells, which may lead to differentiation, senescence, or apoptosis. This could have a novel impact on prevention and treatment of human cancers. HDAC inhibitors (►Valproic acid) lead to the accumulation of acetylation in histones resulted in changes of chromatin status and of transcriptional activity to a normal state. P21 is a good example that is induced by HDAC inhibitors. However, exact mechanism through which the HDAC inhibitors mediate antitumor activity remains to be unclear, although these agents have been known to induce apoptosis and to inhibit angiogenesis and metastasis.

In a mouse model of colonic tumorigenesis, reducing DNA methylation genetically and/or pharmacologically has been shown to have tumor-preventive effects, a finding which was recently confirmed. The cytosine analogues, 5-azacytidine, and 5-aza-2′-deoxycytidine

are powerful inhibitors of DNA methylation, which are incorporated into DNA during cell division and trap DNA methyltransferases and lead to cell differentiation and growth repression. Indeed these demethylating agents have been widely studied in hematological diseases and received FDA approval for the treatment of myelodysplastic syndrome. Further, the synergistic effects between DNA demethylating agent and HDAC inhibitors suggest clinical trials of this approach to restore gene function silenced by aberrant chromatin changes in cancers.

Synonyms

Chromium-induced carcinogenesis; Hexavalent chromium-induced carcinogenesis; Chromium-induced cell transformation; Chromium tumorigenesis

Definition

►Chromium carcinogenesis (►carcinogenesis) is the process of the genesis of tumors (carcinomas) by specific carcinogenic chromium compounds, containing ►hexavalent chromium (Cr^{+6}). It includes the series of sequential steps that occur when lower animals or humans are exposed to specific hexavalent chromium-containing compounds that leads to tumor development. After all these steps are accomplished, the physiological mechanisms regulating control of growth in the normal cells are degraded. Hence, the normal cells are degraded and converted into tumor cells. The tumor cells then grow autonomously in an unregulated fashion and evade the host immune system, leading to development of visible tumors. Chromium carcinogenesis encompasses carcinogenesis by both insoluble and soluble hexavalent chromium-containing compounds.

Characteristics

Chromium, The Chemical Element, and its Ionic Species and Chemical Compounds

Pure chromium, the element, is a white, hard, lustrous, brittle metal with a high melting point (1,903°C). Pure chromium metal is resistant to mild corrosive agents. Therefore, pure chromium metal is used as a protective coating that can be electroplated onto other metals to protect them from corrosive. Chromium can be found in chemicals, in the +6, +5, +4, +3, +2, and 0 oxidation states. Cr(V) is usually a transient state, which can be best detected by ESR spectroscopy during the reduction of Cr(VI).

Chromium is most commonly found in nature in the ore called chromite, or ferrous chromite ($FeCr_2O_4$). In chromite, chromium is in the +3 valence state, a very reduced state. The mineral, chromite, has Cr(III) at octahedral sties and Fe(II) at tetrahedral sites. Chromite can be reduced with carbon in a furnace. This reduction yields iron, chromium, and carbon monoxide in a carbon-containing alloy called ferrochromium.

High purity chromium metal can be obtained by treating ferrous chromite ore with molten alkali and oxygen. This oxidizes Cr(III) to chromate, containing Cr(VI). The chromate can then be dissolved in water and precipitated as sodium dichromate. The sodium dichromate can then be reduced with carbon to Cr(III) oxide (Cr_2O_3). The chromium (III) oxide can then be reduced with aluminum metal to Cr (0) metal and aluminum oxide.

Important Commercial Uses of Nickel and Nickel Compounds

Chromium is also a very important and useful metal commercially. Chromium is used in large quantities in many important alloys, such as stainless steel (consisting of iron, nickel, and chromium) and ferrochromium

(consisting of iron and chromium). Chromium is also used in the manufacture of paints and pigments, where various chromium compounds impart yellow and orange colors to the paints and pigments. Such compounds as ►lead chromate ($PbCrO_4$), strontium chromate, and barium chromate have been used in paints to paint aircraft due to the anti-corrosive properties of these compounds. Lead chromate is very toxic, and hence has been replaced by strontium and barium chromates. Because chromium metal is resistant to corrosive agents, it is extensively used as a protective coating that is delivered onto other metals by an electroplating process.

Biological Aspects of the Essentiality of Chromium (III) in Mammalian Cells

In mammals, Cr(III) is considered an essential trace element. The required daily uptake of Cr(III) is from 50–200 μg/day. Cr(III) is usually ingested by humans from the diet. Cr(III) is considered an essential trace element because it is a component of the complex called glucose tolerance factor, which aids in glucose and lipid metabolism. Glucose tolerance factor, or "low–molecular–weight Cr binding substance" is an oligopeptide. It is thought that a tetranuclear Cr(III) carboxylate complex may be present in glucose tolerance factor. Glucose tolerance factor is believed to aid insulin in mediating the uptake of glucose into mammalian cells. This area of nutrition requires further investigation.

Exposure of Humans to Chromium Compounds

Cr(VI)-containing compounds are very toxic to humans, both insoluble and soluble Cr(VI)-containing compounds. In terms of toxicology, humans are commonly exposed to chromium as Cr(VI)-containing compounds, primarily during the refining of chromium from chromite ore, and also from the manufacture of chromium compounds for use in pigments and paints and during chromium electroplating. In the past, exposures of workers manufacturing chromate compounds to Cr(VI) compounds resulted in higher incidences of nasal and respiratory cancers. In workers who conducted chromium electroplating, there were also increased incidences of nasal and respiratory cancer. There were also increased incidences of various cancers in workers who were employed at tanneries, where they tanned cow hides, where chromate was also used to enhance the tanning process.

When inhaled, insoluble Cr(VI)-containing compounds can enter the airways, and be ►phagocytosed by macrophages and by normal airway epithelial cells. This leads to deposition of a bolus of Cr(VI) inside the cells. When inhaled, soluble Cr(VI) compounds, in the form of chromate $(CrO_4)^{-2}$, bind to and enter mammalian cells on the sulfate-phosphate anion transport carrier. This anion transport carrier is somewhat nonspecific, and chromate can bind to it in place of phosphate and sulfate. Hence, inhalation of both soluble and insoluble Cr(VI)-containing compounds can cause cancer of the respiratory tract, insoluble Cr(VI) compounds via ►phagocytosis and soluble Cr(VI) compounds by entering cells on the anion transport carrier.

To date, we also know that ingestion of soluble Cr(VI)-containing compounds, or drinking them when they are added to or contaminate drinking water, can lead to these compounds being taken up into cells of the alimentary tract, and entering cells on the sulfate-phosphate anion carrier. This can pose a risk for stomach cancer and cancer of the intestines, as well as a cancer risk to many other internal organs, in both lower animals (rodents) and humans.

Genotoxicity of Chromium Compounds

Chromium (VI) compounds are found in both the soluble and insoluble forms. Soluble and insoluble chromium compounds are both taken up by mammalian cells. Insoluble chromium (VI) compounds are taken up into mammalian cells by phagocytosis, and soluble Cr(VI) compounds are taken up into mammalian cells by the phosphate-sulfate transport carrier. Lead chromate, strontium chromate, and barium chromate are examples of Cr(VI)-containing compounds that are only sparingly soluble in water. Calcium chromate and potassium dichromate, are examples of Cr(VI) compounds that are highly water soluble.

There are many insoluble chromium (VI) compounds, such as lead chromate, barium chromate, and strontium chromate. If these insoluble Cr(VI)-containing chromium compounds are found in particle sizes of <10 μm, they are phagocytosed by mammalian cells. Phagocytosis involves an invagination of the plasma membrane around the particles, to form a phagocytic vesicle. The phagocytic vesicle then is internalized into the cell with its entrapped particle of insoluble Cr(VI)-containing compound. Hence, by the process of phagocytosis, a bolus of insoluble Cr(VI)-containing compound can be taken up into mammalian cells. The phagocytosed insoluble Cr(VI) compounds then enter the lysosomal network. The resultant chromium compounds then dissolve into soluble chromate ions and counterions. The chromate ions then migrate through the cell in an attempt to establish chemical equilibrium. Eventually, some chromate ions will travel into the nucleus. Eventually, the Cr(VI) in the chromate ions will be reduced to Cr(V), Cr(IV), and then to Cr(III). In addition, it is thought that Cr(VI) can act as a pseudo-Fenton reagent, that can generate hydroxyl radical from ►superoxide radical (formed during normal metabolism) plus ►hydrogen peroxide (also formed during normal cellular metabolism).

Soluble Cr(VI)-containing compounds can enter mammalian cells on the sulfate-phosphate anion transport carrier, because they are competitive substrates and

therefore inhibitors of sulfate and phosphate uptake into mammalian cells. Following phagocytosis of insoluble Cr(VI) compounds, or uptake of soluble Cr(VI) compounds on the phosphate-sulfate anion transport carrier, the resultant intracellular Cr(VI) ions cause cytotoxicity, DNA strand breaks, DNA-protein cross-links, and ►chromosomal aberrations, in the forms of gaps, breaks, fragments, dicentrics, and satellite associations, to mammalian cells.

Among the soluble Cr(VI) compounds, calcium chromate, sodium chromate, chromium trioxide, and potassium dichromate all induce mutation to 6-thioguanine resistance in diploid human fibroblasts. Lead chromate, an insoluble Cr(VI) compound, induced a weak yield of mutation to 6-thioguanine resistance in cultured diploid human fibroblasts. Induction of mutation to 6-thioguanine resistance by Cr(VI) compounds, both soluble and insoluble, occurred over the range of 0.05 μM – 1.00 μM. For Cr(III) compounds, weak mutation was induced by soluble chromium chloride and insoluble chromium chloride and Cr(III) oxide, but only at the very high concentrations of 50–1,000 μM, which were 1,000-fold higher than those used to induce mutation by Cr(VI) compounds. Hence, Cr(VI) compounds are 1,000-fold more mutagenic, and cytotoxic, than Cr(III) compounds. Cr(III) compounds are not considered significantly toxic at low concentrations, particularly since Cr(III) is considered an essential nutrient and a component of "glucose tolerance factor."

Once inside mammalian cells, Cr(VI) ions are reduced to Cr(V), Cr(IV), and Cr(III) ions. Cr(III) ion binds to DNA and thereby induce mutation to mammalian cells. There is also some evidence that intracellular Cr(VI) ions and more reduced Cr species, can generate ►reactive oxygen species (ROS) intracellularly in mammalian cells. In mammalian cells, superoxide radicals arise from normal cellular oxidative metabolism. Following the dismutation of two superoxide radicals by superoxide dismutase, hydrogen peroxide is formed, particularly in mitochondria (mitochondrial DNA and cancer). There is some evidence that intracellular Cr(VI) ions can catalyze pseudo-Fenton reactions, in which superoxide radical, hydrogen peroxide, and Cr(VI) ions can catalyze the reaction of superoxide radical and hydrogen peroxide to generate hydroxyl radicals and hydroxyl ions. The resultant hydroxyl radicals are able to cause formation of 8-hydroxy-deoxyguanosine and therefore mutations in DNA. However, this latter pathway has not been demonstrated conclusively with rigorous experimentation.

Chromium-Induced Cell Transformation

As noted above, insoluble Cr(VI)-containing compounds can be phagocytosed into mammalian cells, leading to generation of intracellular Cr(VI)-containing ions. Soluble chromium compounds generate soluble Cr(VI)-containing ions, which are taken up on the sulfate-phosphate anion transport carrier and enter mammalian cells. These intracellular Cr(VI) ions can be reduced by intracellular reductants, such as glutathione, which will then generate Cr(V), Cr(IV), and Cr(III) containing ions. These Cr ions can then induce DNA-DNA cross links, DNA-protein cross-links, DNA strand breaks, mutations, and chromosomal aberrations, which are genotoxic events. Many Cr(VI)-containing compounds, including insoluble lead chromate, and soluble Cr(VI) compounds, can induce morphological and neoplastic transformation of mammalian cells, and in particular in rodent cells, in culture. Lead chromate has been shown to induce morphological, anchorage-independent, and neoplastic transformation of C3H/10T1/2 mouse embryo fibroblastic cells.

It is thought that the mechanism of Cr(VI)-induced morphological transformation is due to genotoxic events, including the mutations and chromosomal aberrations that Cr(VI) causes in mammalian cells. These chromosomal aberrations are thought to lead to loss of regions of chromosomes bearing ►tumor suppressor genes, or disrupt areas of chromosomes bearing tumor suppressor genes, which can lead to loss of tumor suppressor genes from cells, contributing to morphological, anchorage-independent, and neoplastic cell transformation. Similarly, intracellular Cr(VI) species can also generate Cr(III) and reactive oxygen species, which can cause mutations in ►proto-oncogenes, leading to activation of oncogenes, which is a part of the mechanism of Cr(VI)-induced morphological and neoplastic cell transformation. In addition, generation of intracellular Cr(III) ions due to reduction of intracellular Cr(VI) by intracellular reductants, such as glutathione and other reductants, is thought to lead to mutations in proto-onocogenes, leading to activation of oncogenes, which also contributes to cell transformation. It is likely a combination of all these events that leads to Cr(VI)-induced morphological, anchorage-independent, and neoplastic cell transformation.

Chromium Carcinogenesis

Specific insoluble Cr(VI)-containing compounds, and also soluble Cr(VI) compounds, are carcinogens in lower animals such as rodents by the inhalation route. Similarly, both insoluble and soluble Cr(VI) compounds are also carcinogenic in humans when humans are exposed to them by the inhalation route. This is particularly true in the context of chrome electroplating and during the manufacture of chromates, where chromates are contacted by inhalation.

Recently, increasing attention has been paid to the risk of cancer when Cr(VI) compounds are ingested or taken in with the drinking water. This is because Cr(VI) compounds have been used to paint aircraft in order to utilize the anti-corrosive properties of the

Cr(VI) compounds. This has led to contamination of drinking water sources in various states in the United States, such as California. In addition, Cr(VI) compounds have been used in the water of cooling towers. Discharge of this water into the drinking water sources has led to contamination of the drinking water sources with Cr(VI) compounds. When Cr(VI) enters humans or lower animals though the drinking water route, a significant amount of the Cr(VI) is reduced to Cr(III) extracellulary, reducing its toxicity, mutagenicity, and carcinogenicitiy. However, while this extracellular reduction is going on, there is a simultaneous, competitive uptake of Cr(VI) by the anion transport carrier into cells. This leads to a significant fraction of Cr(VI) getting into cells in a competitive mechanistic scheme d (i.e. A →B (cells) or C (enzymes of reduction). In rodents, administration of Cr(VI) by the oral route leads to stomach and intestinal tumors. There is weaker epidemiological data which also indicates that when humans drink water containing Cr(VI), the incidence of various internal tumors is increased. This includes a small increased incidence of stomach tumors, tumors of the bones, leukemias, kidney tumors, and liver tumors. Hence, while the cancer risk due to inhalation of Cr(VI) compounds is large, the cancer risk due to ingestion or drinking water containing Cr(VI) is smaller than the inhalation risk but is still of appreciable significance from the standpoint of induction of human cancer.

Mechanisms of Chromium Carcinogenesis

At present, the molecular mechanisms of Cr(VI) carcinogenesis appear to be due largely to genotoxic effects. These genotoxic effects include the ability of intracellular Cr(VI) ions to be reduced to Cr(V), Cr(IV), and Cr(III) ions, and the ability of Cr(III) ions to bind to DNA and cause mutations. There is also some thinking that Cr(VI) ions can act as redox catalysts to cause pseudo-Fenton reactions. The reduction of Cr(VI) ions is believed to lead to generation of reactive oxygen species, such as superoxide, hydrogen peroxide, and hydroxyl radicals, which can cause 8-hydroxyguanosine in DNA, leading to mutations. Generation of 8-hydroxy-deoxyguanosine and the binding of Cr(III) to DNA, would be expected to lead to mutations in many genes, including proto-oncogenes and tumor suppressor genes. This would be expected to result in the activation of proto-oncogenes into oncogenes and the mutational inactivation of tumor suppressor genes, leading to neoplastic cell transformation and eventually carcinogenesis.

Chromophore-Assisted Laser Inactivation

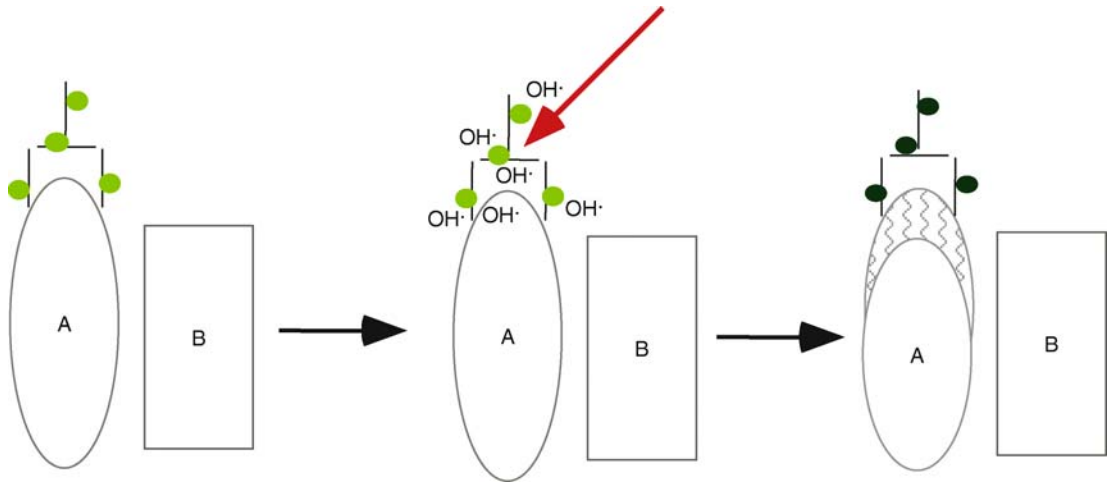
Daniel G. Jay
Tufts University School of Medicine, Boston, Ma, USA

Synonyms
CALI

Definition
Technology to address protein function in situ. CALI uses ►**laser** light of 620 nm, targeted via specific Malachite Green-labeled non-function-blocking antibodies, which generate short-lived protein-damaging free radicals (Fig. 1). This wavelength is not absorbed by cells, such that nonspecific light damage does not occur. The short lifetime of the free radicals generated restricts the damage largely to the bound antigen (~15 Å) such that even neighboring proteins are not significantly affected. Micro-CALI focuses the laser light through microscope optics such that proteins within a 10 μ spot may be inactivated.

Characteristics
The advent of complete genomic information will herald a new revolution in molecular biology to develop a mechanistic understanding of how proteins function together in the living cell. This increased understanding will provide insight into cancer (as well as other diseases) and potentially will help define protein targets for drug discovery. Target validation of proteins of disease relevance (the site of most drugs) is the limiting first step in obtaining drugs of clinical value. In particular, identifying proteins that have essential roles in cancer-relevant cellular processes remains a major challenge. There is a current lack of technology that addresses protein function directly and rapidly, as most functional inactivation approaches target genes or mRNAs. One useful tool to address this is Chromophore-Assisted Laser Inactivation (CALI). CALI uses targeted laser light to inactivate proteins of interest via a dye-labeled antibody that by itself does not block function. CALI provides a high degree of temporal and spatial resolution to acutely perturb protein function in situ.

Advantages
The major advantages of CALI compared to other functional inactivation approaches are its unprecedented temporal and spatial resolution. The range of area for CALI-based inactivation is localized to regions within the beam, between microns to millimeters depending on the focus of the laser. Inactivation occurs acutely upon initiating laser irradiation. Because the loss of protein function is acute and transient, CALI does not appear to be subject to genetic compensation that is occasionally observed in chronic deletion strategies such as gene knockouts in mice. CALI is particularly useful for systems lacking genetic methods. For example, CALI may be used for human tissue culture cells that are disease-relevant. As such, it is not necessary to extrapolate target validation from model systems. Many proteins of interest to cancer research have essential roles in early development and are thus difficult to address by gene knockout. CALI may be used to study the roles of these essential gene products in cellular processes after development is completed. The coupling of micro-CALI with real time imaging has been used for studying dynamic cellular processes. The application of micro-CALI on part of a single



Chromophore-Assisted Laser Inactivation. Figure 1 The principle of CALI. Specific proteins (a) in cells are bound by an antibody and labeled with the chromophore Malachite Green (MG). Irradiation with pulsed laser light of 620 nm (*red arrow*) generates short-lived hydroxyl radicals. These radicals selectively inactivate the bound protein by oxidative damage because their half-maximal radius is about 15 Å due to their short life time in cells. Neighboring proteins (b) are not significantly affected.

cell generates a transient asymmetry of function across a cell, and this has been particularly useful in addressing proteins required for cell motility and migration. The capacity and relative ease of multiplex approaches for CALI (compared to gene knockouts) may lend itself well to whole ►proteome approaches and ►high throughput screens.

Limitations

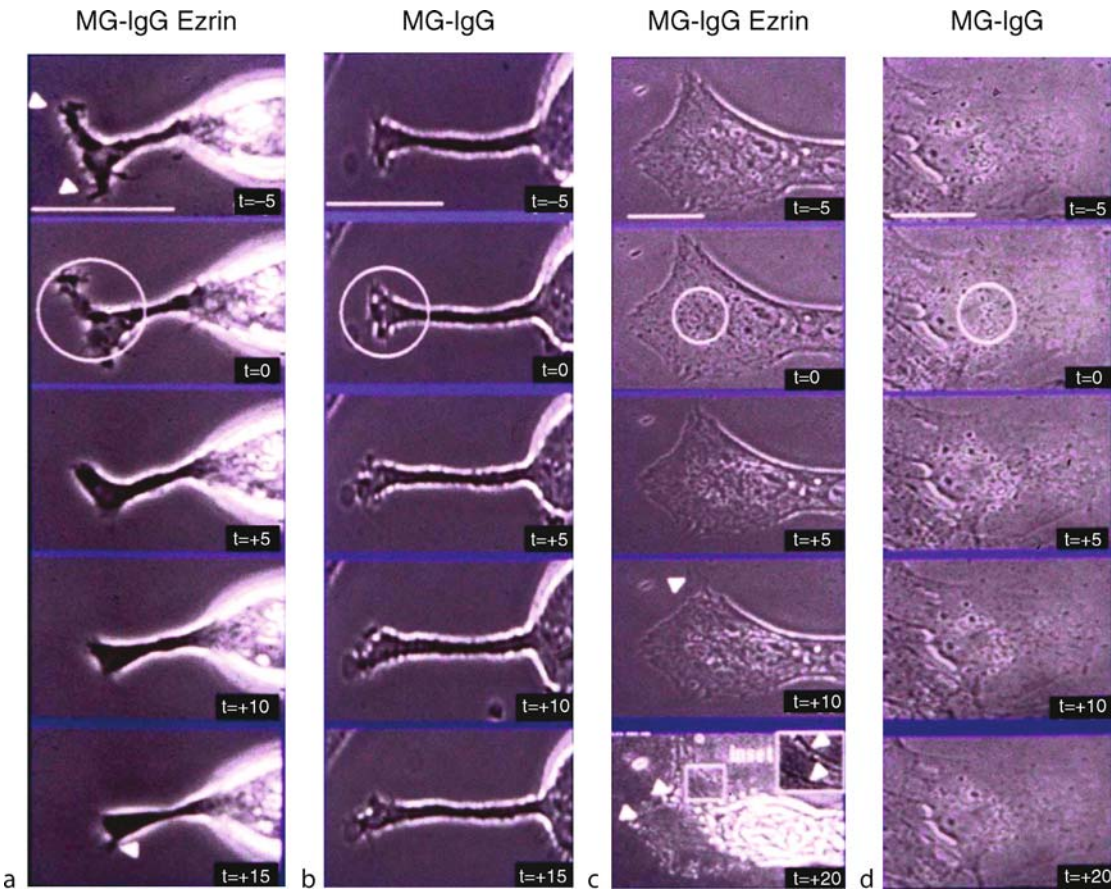
As with any technology, CALI has its limitations, and a clear understanding of these is required for its judicious application. Inactivation is dependent on quality, specificity and site of antibody binding and also on the susceptibility of the targeted protein to free radical damage. It should be noted that only the protein (not the gene) is inactivated and hence recovery is dependent on de novo synthesis. This usually allows a loss of function of hours to perhaps a day. The loss of function may not be complete so that activity is "knocked down" as opposed to "knocked out." As such, residual activity may obscure a potential phenotype. In general, a negative result is difficult to interpret for CALI as with most other inactivation approaches.

Application

Current Applications

CALI has been used for over 50 proteins and been successful in ~90% of these cases. CALI has precisely mimicked Drosophila genetic loss of function mutations in several direct comparisons. The proteins studied in many cell and animal systems span a diverse array that include membrane receptors, cytoskeletal proteins, signal transduction molecules and transcription factors. The understanding of how proteins function in the nerve growth cone has been a major area of study that has utilized CALI. The functional roles of proteins such as NCAM, L1, calcineurin, talin, vinculin, myosin V and Ib, radixin and tau have been recently addressed. For these studies, methods for introducing antibodies into living cells have been optimized including electroporation, trituration and microinjection.

Of particular relevance to cancer research is the application of CALI to proteins that have roles in cancer cell migration. One example of the application of CALI to a protein of cancer relevance is the prototypic ERM-family (►ERM proteins) member, ezrin. Ezrin is an actin-associated protein that shows increased expression and phosphorylation upon fos-mediated transformation of fibroblasts that is correlated with a change in cell shape (from flat to rounded) and motility (from lamellipodial to pseudopodial). CALI of ezrin in transformed fibroblasts causes a decrease in membrane ruffling and pseudopodial retraction. CALI of ezrin in normal fibroblasts causes a marked collapse of the leading edge lamellipodia (Fig. 2). These studies implicate ezrin in cell shape and motility and suggest that ezrin has a critical role in the shape and motility changes associated with oncogenic transformation. A second protein of interest is the tumor supressor ►hamartin. Hamartin binds to ERM proteins and its function is regulated by the small GTPase, Rho. CALI was used to show a role for hamartin in cell adhesion and suggests it might be involved in a rate-limiting step in tumor formation.



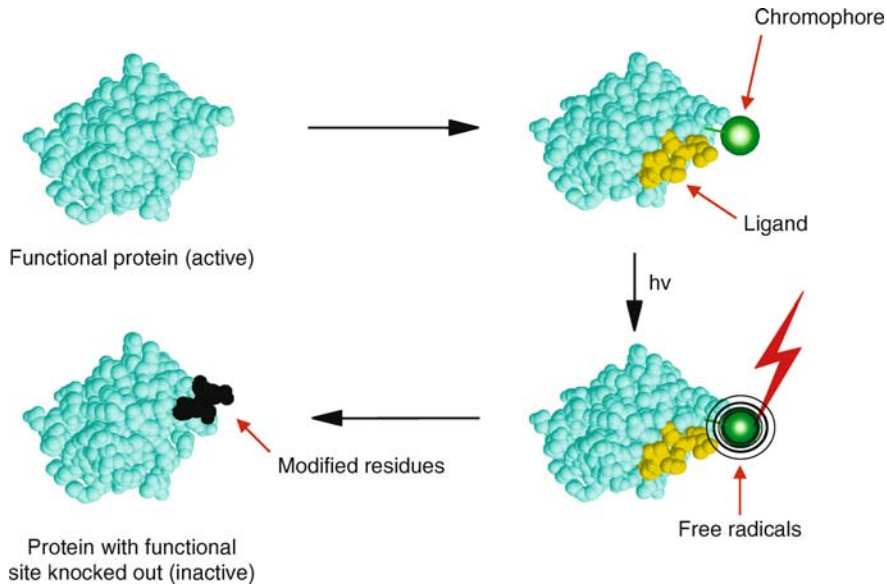
Chromophore-Assisted Laser Inactivation. Figure 2 Micro-CALI of Ezrin affects fibroblast shape and motility. Fibroblasts transformed with v-fos, change their shape and motile behavior and show an increase in the expression and phosphorylation of the actin-associated ERM protein, Ezrin. We applied micro-CALI of Ezrin within the circled areas to v-fos-transformed fibroblasts (A and B) and normal fibroblasts (C and D). Micro-CALI of Ezrin in v-fos transformed cells caused a loss of membrane ruffling (arrowheads) and pseudopodial retraction (a) while laser irradiation of cells injected with Malachite Green-labeled non-immune IgG had no effect on motility (b). Micro-CALI of Ezrin in normal fibroblasts caused a marked collapse of the leading edge (c) with filaments remaining attached to the substratum (arrowheads in inset of panel labeled t = +20). Irradiation of cells, injected with Malachite Green-labeled non-immune IgG had no effect on cell shape (d). Scale bars = 10μm; time is in minutes.

Future Applications

CALI is currently being combined with advances in dynamic imaging to visualize subcellular changes in response to the loss of function of specific proteins. We view that a major application of CALI for cancer research will be in target validation. As CALI lends itself well to combinatorial approaches and high throughput methods, it may be a powerful tool in addressing function in a proteome wide manner. A new use for CALI is in refining drug discovery screens to direct them against binders of a single domain on the target protein. CALI causes localized oxidative damage to modify residues of the protein near the antibody-binding site. By combining CALI with high resolution mass spectrometry to map those sites of damage, it may be possible to correlate loss of function with particular domains on a protein (Fig. 3).

Conclusions

CALI is a means for the inactivation of specific proteins in situ with a high degree of spatial and temporal resolution. CALI converts a binding reagent (such as an antibody) into an functional inhibitor. A large number of studies has demonstrated the potential of CALI in addressing cellular processes. It has recently been employed to address cellular mechanisms of cancer, and we believe that this technology is poised to contribute significantly to target validation and drug discovery for cancer-relevant processes.



Chromophore-Assisted Laser Inactivation. Figure 3 Principle of Xplore. Xplore uses CALI and high resolution mass spectroscopy to map regions of functional importance on proteins. After CALI inactivation, sites of oxidative damage are mapped by high resolution mass spectroscopy, providing a correlation of a protein function with specific domains of the targeted protein.

Chromosomal Aberrations

Definition

Damage to the chromosomes of a cell by a chemical carcinogen or other genotoxic agent, such that the shape of the chromosome is changed. Examples include gaps in chromosomes, breaks in chromosomes, fragmentation of chromosomes, dicentric chromosome formation, chromosome translocations, and satellite associations.

►Nickel Carcinogenesis
►Chromium Carcinogenesis

Chromosomal Imbalance

Definition

Loss or gain of chromosome copy number.

►ArrayCGH

Chromosomal Instability

Susanne M. Gollin
Department of Human Genetics, Public Health and the University of Pittsburg Cancer institute, Pittsburgh, PA, USA

Synonyms

Genetic instability; CIN

Definition

Chromosomal instability is the gain and/or loss of whole chromosomes or chromosomal segments at a higher rate in a population of cells, such as cancer cells, compared to their normal counterparts (normal cells). In some cancers, each cell within the tumor has a different chromosomal constitution (karyotype) due to chromosomal instability, which may be defined in practical terms as numerical and/or structural chromosomal alterations that vary from cell to cell. Although the terms chromosomal instability and genomic instability have been used interchangeably, this is technically incorrect, as they refer to different forms of genetic instability.

Characteristics

Chromosomal instability is a characteristic of cancer cells, especially solid tumors (rather than most hematologic (blood cell) malignancies). Several cellular mechanisms lead to numerical and structural chromosomal instability in cancer cells, including defects in (i) chromosomal distribution to the daughter cells (chromosome segregation), (ii) cell cycle checkpoints that protect against proliferation of abnormal cells, (iii) telomere (specialized structures that cap the ends of chromosomes) stability, and (iv) the DNA damage response. Although in the past, these mechanisms were thought to be unrelated, it has become clear that they are intimately intertwined, connecting the complex network of cellular pathways. Human papillomavirus and other oncogenic viruses interfere with these processes, causing chromosomal instability and tumor formation in the cells that they infect. Chromosomal instability plays an important role in cancer by creating large-scale genetic changes in as little as one cell generation, leading to rapid cancer cell evolution. The rate of discoveries about the mechanisms leading to chromosomal instability in cancer cells is accelerating, improving our understanding of how cells become cancer cells and how cancer cells become more dangerous to the patient by progressing and/or metastasizing.

Both clonal numerical and structural chromosomal alterations and chromosomal instability are common features of human cancers. Aneuploidy is the condition in which the chromosome number in a cell, population of cells, or person is not an exact multiple of the usual haploid chromosome number ($N = 23$ for humans). Aneuploidy results from numerical chromosomal alterations. Cancers with chromosomal instability are characterized by aneusomy, a condition in which a population of cells contain different numbers of chromosomes. In tumor cells, gains and losses of chromosomal segments arise as a result of structural chromosomal alterations, including reciprocal and non-reciprocal chromosomal translocations, homogeneously staining regions (in which a cassette of contiguous genes, including at least one oncogene or growth-related gene, is tandemly repeated (amplified) at least five times on a diploid background), other forms of gene amplification (e.g., double minute chromosomes), insertions, and deletions. Structural alterations may result in a further imbalance in gene expression, resulting in chromosomal instability. In some tumors, each cell within the tumor has a different karyotype due to chromosomal instability.

Historical Background

Chromosomal instability is thought to be the means by which cells develop the features that enable them to become cancer cells. In spite of the presence of cell-to-cell chromosomal instability, the tumor karyotype is thought to be quite stable over time, probably because advanced tumors have evolved a genetic makeup (genotype) optimized for growth, making it less likely that additional genetic alterations will confer an additional growth advantage. Chromosomal alterations and karyotypic instability in human tumor cells have been investigated for nearly a century. David von Hansemann first identified abnormal dividing cells is tissue sections of tumors, including cell divisions that appeared to have asymmetric spindles or multiple spindle poles (multipolar spindles) that would lead to unequal distribution of the chromosomes to the daughter cells, and chromosomes stretched between the two spindle poles late in cell division (anaphase bridges). Theodor Boveri [2], while studying chromosomal segregation in *Ascaris* worms and *Paracentrotus* sea urchins in the early 1900s suggested that malignant tumors arise from a single cell with an abnormal genetic constitution acquired as a result of defects in the mitotic spindle apparatus. Today we know that numerical chromosomal instability arises as a result of chromosome segregational defects, most frequently resulting from multipolar spindles. Structural chromosomal instability results from chromosome breakage and rearrangement due to defects in cell cycle checkpoints, the DNA damage response, and/or loss of telomere integrity. Structural chromosomal instability frequently results from breakage-fusion-bridge (BFB) cycles, first described in maize by geneticist Barbara McClintock in 1938. In this process, a chromatid break occurs, exposing an unprotected chromosomal end which, after replication, is thought to fuse with either another broken chromatid or its sister chromatid to produce a dicentric chromosome. During the anaphase stage of mitosis, the two centromeres are pulled to opposite poles, forming a bridge which breaks, resulting in more unprotected chromosomal ends, and thus the cycle continues. Our studies of cancer cells suggest that structural chromosomal instability, including gene amplification, occurs by BFB cycles. The basis for these BFB cycles is not entirely clear, although recent studies of chromosomal

fragile site breakage, some of which occurs as a result of cigarette smoking and leads to induction of BFB cycles, telomere dynamics, and the DNA damage response, suggest that these critical cellular processes play major roles in the development of structural chromosomal instability. In this contribution, defects in chromosomal segregation, cell cycle checkpoints, telomere function, and the DNA damage response and their role in mechanisms leading to chromosomal instability are introduced and literature citations (References) are provided for the interested reader.

Chromosome Segregational Defects Lead to Chromosomal Instability

One of the fundamental processes required in the life of a cell, whether from a unicellular or multicellular organism, is chromosome segregation. Fidelity of chromosome segregation, whether in meiosis or mitosis, is necessary for genomic stability and the continuation of life as we know it. Abnormal chromosome segregation results in aneuploidy, abnormal numbers of chromosomes being distributed to daughter cells, such that the daughter cells don't match each other or their mother cell. This is the essence of chromosomal instability. Recent studies have shown that several factors can result in segregation defects, including abnormal chromosome-spindle interactions, premature chromatid separation, centrosome amplification, multipolar spindles, and abnormal cytokinesis (cell division). Chromosomal segregational defects (multipolar spindles, lagging chromosomes at metaphase and anaphase, and anaphase bridges) in cancer cell lines are an intrinsic, heritable trait in the general tumor cell population. Tumor cells expressing chromosomal instability cannot be "cloned," as they continue to express numerical and structural chromosomal instability generation after generation. In some cancers ongoing chromosomal instability is a feature of both primary tumors in the patient and cell lines cultured in the laboratory from biopsies removed from those tumors. Many studies of proteins involved in the process of chromosome segregation, spindle function, and cytokinesis are in progress in numerous laboratories. The role of these proteins in chromosomal instability and implications in the diagnosis, prognosis, and therapy of human tumors will be revealed in the next few years.

A Defective Response to DNA Damage Leads to Chromosomal Instability

For many years, cytogeneticists (scientists who examine chromosomes) have known that patients with "chromosome breakage" syndromes express chromosomal instability. Yet, until recently, features of these syndromes have not been utilized to define defects in the DNA damage response in cancer cells. Causes of DNA damage include attack by ultraviolet light, ionizing radiation (X-rays), or environmental chemicals, and cellular errors, such as "spelling errors" (base pair mismatch) during DNA replication, replication fork collapse, or defects caused by naturally occurring reactive oxygen species. One type of DNA damage is the double strand break, which leads to a cascade of cellular events (the DNA damage response) that usually results in repair of the damage or cell death. Failure in the DNA damage response and double strand break repair can lead to genetic alteration or chromosomal instability, which can result in transformation from a normal cell to a cancer cell.

The DNA damage response involves the sensing of DNA damage followed by transduction of the damage signal to a network of cellular pathways, from those involved in the cellular survival response, including cell cycle checkpoints, DNA repair, and stress responses to telomere maintenance, and the apoptotic pathway. To make a simple analogy in an effort to describe the complex DNA damage response to double strand breaks, we can say that our cellular instruction book for all of the activities that go on in our cells and in our bodies is made up of 23 chapters, the chromosomes, and for safety's sake, we have two copies of the book, one from our mother and one from our father, although they aren't exact copies (e.g., the set of eye color genes from your mother may code for blue eyes and the one from your father, brown). The genes are like sentences in a chapter, made up of three letter words composed of the four letters of DNA, A, T, C, and G. The 23 different chromosomes in the cells, composed of many genes, are equivalent to the 23 chapters in the book, made up of many sentences. The total genome is equivalent to the whole instruction book for the cells, and the instructions code for proteins, the molecules that do the work in our bodies. So in total, we have 46 chromosomes, two copies of each one. Sometimes, this very long set of DNA instructions becomes damaged (like the pages in the book can become torn or fall out) from smoking, chemicals, X-rays, oxidants that occur naturally in our bodies (why some of us take "antioxidant" vitamins), or other insults. Although our DNA is a code of letters like words in a book, it really looks like a ladder or even like railroad tracks. To more easily think about DNA repair, we need to visualize it as railroad tracks. Like the railroad company, which has special vehicles that check the integrity of the tracks, we have proteins that check our DNA (sensor proteins and checkpoint proteins). If the sensor protein spots a double strand break or another defect that might derail the train or cause a defect in the cellular instructions (mutation), she then tells the communications officer (signal transducer) to call headquarters which in turn, calls the repair team. This happens in our cells, in which case the repair team is a series of proteins that carry out sequential multistep assessment and repair of the damage (the DNA damage response).

If they find that a cargo train has already been instructed by the defect to race out of control, analogous to a cell proliferating in an uncontrolled fashion, making more and more copies of itself, on the way to making a cancer, they kill that cell. But, what if the protein that has the job of pushing the kill switch is sick that day, the cell cannot be killed and a cancer ensues. In our cells, this DNA damage response pathway is carried out by about 50 proteins in a carefully choreographed process. With the advances in the human genome project, we are learning more about the proteins in this pathway and how defects (mutations) in them can cause predisposition to cancer.

Loss, mutation, or altered function of the genes that code for some of the DNA damage response proteins cause familial cancer syndromes and in some cases, chromosomal breakage syndromes, which may affect heterozygous gene carriers or affected (homozygous) individuals. Although not clear at this time, the role of these critical DNA damage response genes in chromosomal instability merits further investigation. The DNA damage response genes involved in known familial cancer syndromes include ►*ATM*, *TP53*, *BRCA1*, *BRCA2*, *FANC*, *CHEK2*, *BLM*, and *MRE11A*. The involvement of the DNA damage response genes, *BRCA1* and *BRCA2* in familial breast and ovarian cancer is well known. Both genes also appear to be associated with an increased risk of prostate cancer, and *BRCA2* is involved in familial pancreatic cancer. Germline *TP53* mutation carriers have Li-Fraumeni syndrome which is associated with a high risk of breast and brain tumors, sarcomas (muscle tumors), leukemia (blood cell tumors), laryngeal (voice box) and lung cancer, and other tumors. Germline *CHEK2* mutation carriers may present with a Li-Fraumeni-like syndrome and may have an increased risk for a wide range of tumors including breast, prostate, and colorectal (intestinal) cancer. Patients with ataxia telangiectasia, the autosomal recessive genetic disorder characterized by a defective *ATM* gene, manifest progressive cerebellar ataxia (staggering gait), telangiectases ("blood shot" eyes and skin), immune dysfunction, chromosomal instability, increased sensitivity to ionizing radiation (X-rays), and predisposition to cancer, especially leukemia. Heterozygous *ATM* carriers (both human and mouse) of dominant-negative (interfering) missense mutations are at increased risk for solid tumors, including breast cancer. Fanconi anemia (FA) is a rare genetic cancer susceptibility syndrome characterized by skeletal abnormalities, skin pigmentation abnormalities, bone marrow failure, chromosomal instability in the form of rearrangements between non-homologous chromosomes, and sensitivity to DNA crosslinking agents. FA patients are predisposed to developing cancer, primarily leukemia and epithelial tumors, especially squamous cell carcinoma of the mouth and throat (called head and neck cancer) or cervical cancer. The risk of solid tumors in FA patients is ~50-fold higher for all solid tumors compared to the general population, but about 700-fold higher for head and neck cancers. Bloom syndrome is an autosomal recessive disorder characterized by growth deficiency, sun-sensitive facial redness, hypo- and hyper-pigmented skin, sterility in males, reduced fertility in females, predisposition to a variety of malignancies, and chromosomal instability. Thus, patients with cancer predisposition and "chromosomal breakage" syndromes will continue to educate us about the cellular processes that lead to chromosomal instability and cancer.

Telomere Dysfunction May Lead to Chromosomal Instability

Telomere loss or dysfunction is a cause of chromosomal instability in the laboratory mouse. Telomere loss can result from DNA damage or occur spontaneously in cancer cells which often have a high rate of telomere loss due to telomere shortening with each cell division. Telomere alterations in certain genetically engineered mice mirror those in human epithelial tumors, lending support to the hypothesis that telomere defects drive chromosomal instability in cancer cells and age-related epithelial carcinogenesis. Thus, in mouse and man, telomere dysfunction leads to chromosomal instability, as shown by studies of telomere dysfunction in the mouse, chromosomal breakage patterns in human tumors, and the observation that cancer predisposition syndromes can lead to both telomere dysfunction and chromosomal instability. Consistent with this hypothesis, both telomere shortening and cancer incidence increase with age. Telomeres play an important role in chromosomal instability, but the exact details remain under active investigation.

Cell Cycle Disturbances Result in Chromosomal Instability

Oncogenic (cancer causing) viruses, such as human papillomavirus (a sexually transmitted disease which causes cervical cancer in women, penile cancer in men, and oral and anal cancer in both men and women), recapitulate the abnormalities, including defects in chromosome segregation, centrosome dynamics, telomere mechanics, the DNA damage response, cell cycle regulation, and cell cycle checkpoints, that appear to play important roles in the development and maintenance of chromosomal instability. The primary impact of chromosomal instability is cancer. In addition, chromosomal instability is a major cause of tumor evasion of or resistance to therapy. Therefore, a complete understanding of the biological basis of chromosomal instability is essential for developing therapies targeted against the defects in cancer cells.

Definition

The ►chromosomal translocation t(8;21) is associated with ►acute myeloid leukemia. The resultant fusion gene AML1/MTG8 (AML1/ETO, RUNX1/CBFA2T1, RUNX1/RUNX1T1) is a repressor of gene transcription. In this chapter, the fusion gene is named *AML1/MTG8*, and the corresponding fusion protein AML1/MTG8.

Characteristics

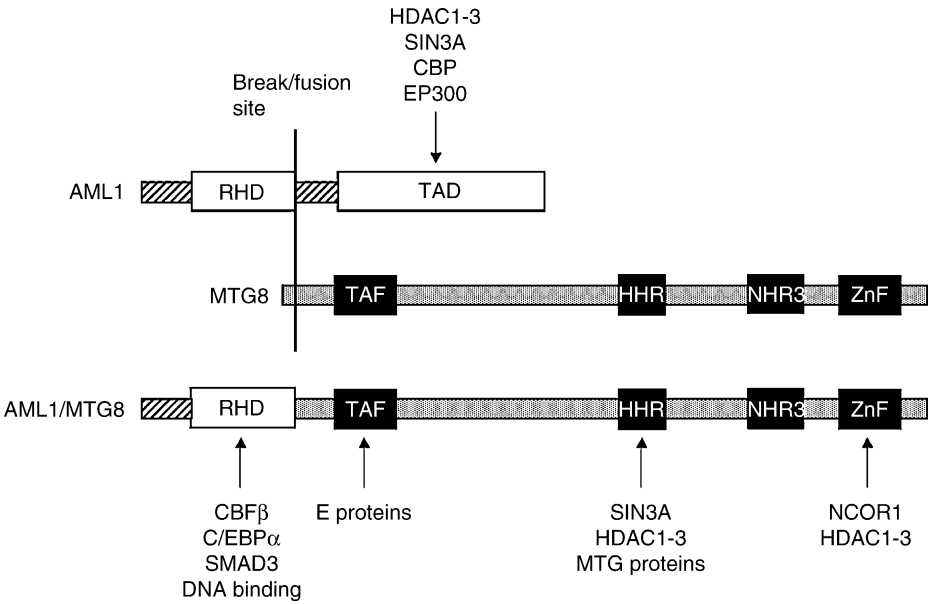
Cytogenetics and Morphology

Almost 50% of all cases of acute leukemia are associated with recurrent chromosomal changes such as inversions or translocations of material from one chromosome to the other. t(8;21)(q22;q22) marks a chromosomal translocation, where the chromosomes 8 and 21 exchanged their long arms (the q arms) from band 22 till the telomere. This translocation is exclusively associated with acute myeloid leukemia (AML). Most commonly, standard cytogenetic analysis is used to detect the t(8;21). In addition, molecular techniques such as ►FISH (fluorescence in situ hybridization) or reverse transcriptase polymerase chain reaction (RT-PCR) are increasingly used for the identification of t(8;21) positive patients. Several studies comparing the sensitivity of PCR techniques and standard cytogenetics for the detection of t(8;21) have found AML1/MTG8 transcripts also in patients with no cytogenetic evidence of this aberration. These findings indicate, that the sensitivity for the detection of a t(8;21) can be increased by molecular screening of all AML patients.

The leukemic blasts of t(8;21)-positive AML patients are often large and display characteristic morphological features such as abundant cytoplasm, numerous granules, and single needle-like Auer rods. In most cases, the leukemic cells express the ►stem cell marker antigen CD34 on their surface. In contrast to most solid tumors, the amount of additional chromosomal changes is rather limited in t(8;21)-positive leukemia. The t(8;21) is significantly associated with the loss of a sex chromosome. Other additional chromosomal changes include a trisomy of chromosome 8 and a deletion of chromosome 9q.

AML1/MTG8

The translocation t(8;21) affects two genes. The *AML1* (►*RUNX*1) gene located on chromosome 21 codes for a transcription factor which is essential for hematopoiesis. The *MTG8* gene on chromosome 8 encodes a corepressor able to interact with several histone deacetylases (HDACs). Because of its reciprocal



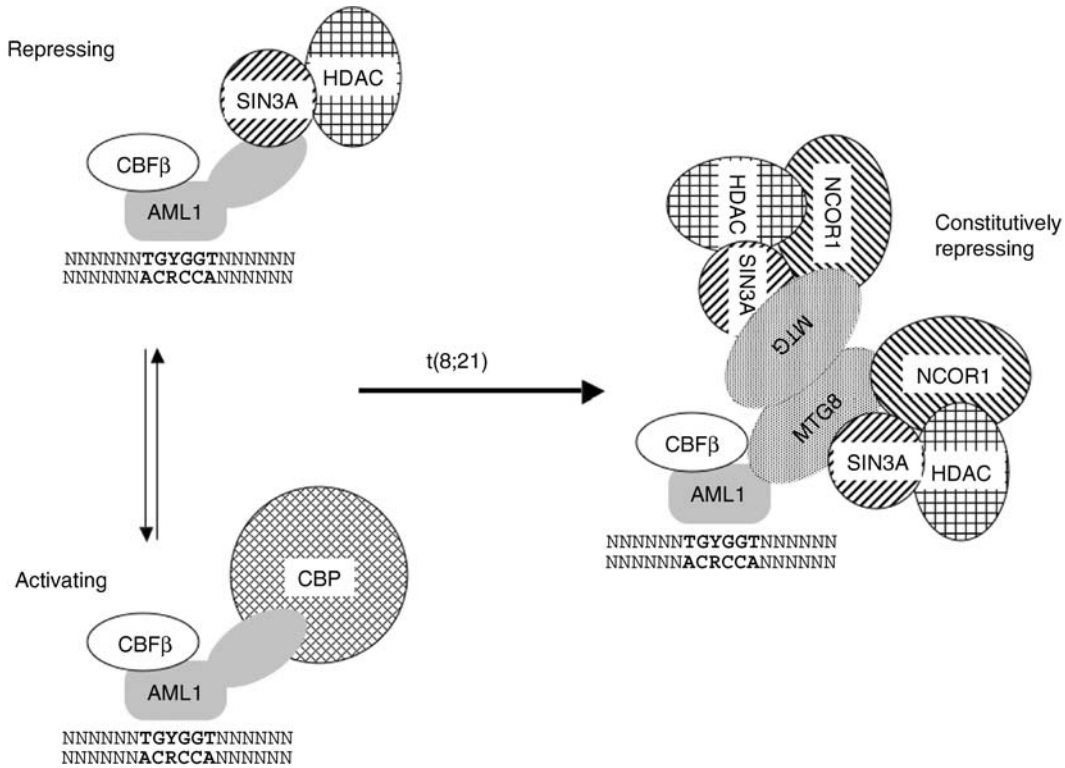
Chromosomal Translocation t(8;21). Figure 1 Primary structure of AML1/MTG8, AML1b, and MTG8. The translocation t(8;21) fuses the N-terminal part of AML1 to the almost complete MTG8 protein. Functions and interacting proteins for the different domains are indicated. A line marks the fusion site. RHD, runt homology domain; TAD, transactivation domain; TAF, TATA box binding protein-associated factor homology domain; HHR, hydrophobic heptad repeat; NHR3, nervy homology region 3; ZnF, zinc-finger region.

nature, the translocation t(8;21) generates two fusion genes, the derivative 8, *MTG8/AML1*, and the derivative 21, *AML1/MTG8*. However, leukemic cells express only *AML1/MTG8*; MTG8/AML1 protein has not been identified yet. In the case of the AML1/MTG8 fusion protein, the DNA-binding domain of AML1 (the runt homology domain, RHD) is linked to the almost complete MTG8 (Fig. 1). As a consequence, the transcriptional modulator AML1 is converted into a constitutive repressor. However, since only one of the two copies of chromosome 8 and 21 are affected by the translocation, each t(8;21)-positive cell still contains one intact copy of these chromosomes and, thus, expresses nonfused wild-type AML1 in addition to AML1/MTG8.

AML1/MTG8 acts as a transcriptional repressor. Via the ►SIN3A and ►NCOR1 (N-CoR) bridging proteins, AML1/MTG8 recruits HDACs to genes, which contain AML1-binding sites in their promoters, thus leading to the deacetylation of histones and, consequently, silencing of the target gene (Fig. 2). Established target genes include cytokine and growth factor receptors such as the gene for M-CSF receptor (*CSF1R)* or cell cycle control genes such as $p14^{ARF}$ (*CDKN2A*). Moreover, AML1/MTG8 interferes with hemopoietic differentiation by sequestering factors essential for these processes such as ►C/EBPα (CEBPA), ►SMADs, or Vitamin D receptor (VDR).

AML1/MTG8 in Leukemogenesis

The translocation t(8;21) is most likely an initiating event in the development of leukemia. AML1/MTG8 expression has been found in blood samples of newborn children at a much higher incidence than the probability to develop leukemia. Furthermore, some of the cured AML patients remain positive for AML1/MTG8. Moreover, AML1/MTG8 supports the expansion of hemopoietic stem cells both in cell culture and in animal models. In conclusion, AML1/MTG8 generates and maintains a pool of preleukemic cells, but is not sufficient to induce leukemia. Additional genetic changes such as mutations in growth factor receptors (e.g., c-kit) or in ►p53 are required for full leukemic transformation. Nevertheless, leukemic persistence requires the continuous expression of AML1/MTG8 as shown by RNA interference experiments. Notably, a C-terminally truncated version lacking a binding domain for NCOR-HDAC complexes has a much higher transforming capacity in a leukemia mouse model than the full-length AML1/MTG8 protein. Interestingly, similar splice variants of *AML1/MTG8* have been identified in patients suffering of t(8;21)-positive leukemia. Because of



Chromosomal Translocation t(8;21). Figure 2 AML1 and AML1/MTG8. Dependent on cellular signaling events, AML1 can switch from a repressive mode (complexed with SIN3A and HDACs) to an activating mode (complexed with the transcriptional activators CBP or EP300). Replacement of the transactivation domain by MTG8 results in oligomerisation with other MTG proteins, recruitment of histone deacetylases and, consequently, in a constitutive repression of AML1 target genes. The DNA binding site is indicated in bold. CBFβ, Core binding factor β (Cofactor of AML1).

its essential role in maintaining leukemia, and due to its exclusive expression in preleukemic and leukemic cells, *AML1/MTG8* might provide a promising target for leukemia-specific therapeutic approaches.

Clinical Relevance and Therapy

The translocation t(8;21) is found in about 10% of adult acute myeloid leukemia (AML) patients. Patients with t(8;21) are generally younger than 60 years. Most cases of t(8;21) positive AML show a ►FAB M2 or, less often, a M1 subtype, that is with (M2) or with minimal (M1) signs of maturation. This translocation marks a subgroup of patients, which responds well to standard chemotherapy and, thus, has a rather good prognosis. Standard induction chemotherapy consisting of ►cytarabine (5-azacytidine) and an anthracycline achieves a very high complete remission (CR) rate of approximately 90% in patients with t(8;21). Moreover, an intensive consolidation with high dose cytarabine or autologous stem cell transplantation yields an overall survival of approximately 50–70%. A low white blood cell count and high platelets at diagnosis are favorable prognostic factors, whereas the loss of the Y-chromosome in male patients has an adverse prognostic effect. In t(8;21)-positive patients in CR, minimal residual disease can be detected by RT-PCR for AML/MTG8 fusion transcripts. As mentioned earlier, some of the patients remain positive for AML1/MTG8 even in long-term CR or after ►allogeneic stem cell transplantation most probably due to the persistence of nonleukemic t(8;21)-positive multipotent progenitors. However, it has been shown that serial quantification of *AML1/MTG8* transcript levels by quantitative RT-PCR might identify patients at high risk for relapse.

Chromosomal Translocations

Francisco J. Novo
Department of Genetics, University of Navarra, Pamplona, Spain

Definition

A chromosomal translocation is a type of chromosomal rearrangement in which two non-homologous chromosomes exchange genetic material. The exchange process involves breakage of each chromosome at a specific point called ►breakpoint, followed by fusion of the fragments generated by these breaks. A causative role has been demonstrated for some chromosomal translocations in various cancer types.

Characteristics

Instability of the genome, ►chromosomal instability in particular, is one of the hallmarks of cancer. Therefore, chromosomal rearrangements are very common in cancer cells. A frequent type of rearrangement is the translocation of genomic fragments between different chromosomal regions. The simplest case is a reciprocal translocation between two chromosomes, but translocations can also involve three or more chromosomes. If no genetic material is lost in the process, translocations are said to be "balanced." A well-known example of a reciprocal chromosomal translocation in cancer is the t(9;22) implicating the *ABL1* gene on chromosome 9 and the *BCR* gene on chromosome 22. This BCR-ABL1 translocation is found in most patients with ►chronic myeloid leukemia.

Chromosome translocations are found both in solid and hematological malignancies. Solid tumors usually display complex ►karyotypes with many different translocations and other types of chromosomal rearrangements such as deletions, amplifications, inversions, etc. In contrast, a frequent feature of most types of leukemias and lymphomas is the presence of a single or a few translocations, many of which are recurrent (i.e., found in different patients with the same type of cancer, or even in different tumor types). For this reason, chromosomal translocations have been best characterized in hematological cancers.

Biology

The mechanism underlying the presence of chromosomal translocations in cancer cells is the subject of active research. Various lines of evidence over the past years have identified several requirements for the generation of chromosome translocations. First of all, two breaks must be created in different chromosomes at the same time. Also, the free ends must be close to each other within the cell nucleus. Finally, some repair pathway must join the broken ends together, and the resulting molecule must provide some proliferative advantage to the cell.

With respect to the initial step, it is now generally accepted that chromosomal translocations are the result of DNA ►double-strand breaks, a type of ►DNA damage in which both strands of the double-helix are broken. Double-strand breaks are created throughout the genome by ►oxidative damage, radiation, replication over a single-strand break, genotoxic chemicals or physiological processes such as the assembly of active immunoglobulin and T-cell receptor genes during lymphocyte development through ►V(D)J recombination. There are three main pathways that repair double-strand breaks in mammalian somatic cells: i) ►homologous recombination repair, which relies on the presence of an intact homologous template in order to repair the DNA lesion; ii) single-strand annealing, which requires some homology at both sides of the break, usually in the form of ►direct repeats; iii) ►non-homologous end-joining, which results in the religation of the ends without the requirement for a template. The general consensus is that, in cancer cells, chromosomal translocations are the result of the repair of double-strand breaks via non-homologous end-joining.

Recent work in the field of chromosome localization has shown that chromosomes occupy specific ►chromosomal territories inside the cell nucleus, and that a substantial amount of intermingling takes place between chromatin loops from neighboring territories. For example, loops from different territories can co-localize if genes present in those loops are transcribed at the same time and utilize the same ►transcription factory. Thus, two chromatin loops (from different chromosomes) that sustain a double-strand break simultaneously and are localized in close proximity are more likely to be involved in a translocation event. This could explain the recurrence of certain chromosomal translocations in specific cancer types.

However, it is possible that many of the translocations generated in a cell never lead to development of cancer. Chromosomal translocations are associated with cancer only when the resulting fusion products possess some oncogenic property that favors the clonal expansion of those cells. In this regard, there are two main mechanisms by which chromosomal translocations disrupt normal cellular processes. In one type of translocations, a gene is separated from its regulatory elements (promoter, enhancers) and juxtaposed to the regulatory elements of a different gene. As a result, the pattern of expression of the gene is altered and this leads to the acquisition of growth or survival advantage to those cells. Translocations involving immunoglobulin genes are the best example of this mechanism. For example, the t(8;14) found in Burkitt lymphoma fuses the ►*MYC oncogene* to the regulatory elements of the gene coding

for immunoglobulin heavy chains, resulting in deregulated and constitutive expression of *MYC* in lymphoid cells. The other type of translocations lead to the acquisition of an oncogenic phenotype because they create a ►fusion gene that is translated into a ►chimeric oncoproteins. This hybrid fusion protein brings together functional domains that were present in both original proteins, and this results in some gain of function which helps the cell to escape normal control mechanisms. For example, the t(15;17) found in patients with ►acute promyelocytic leukemia fuses part of the *PML* gene on chromosome 15 to part of ►retinoic acid receptor A (*RARA*) gene on chromosome 17. The chimeric fusion protein lacks RARA's responsiveness to retinoic acid, a consequence of which is that some bone marrow progenitor cells cannot undergo the normal process of differentiation.

Breakpoints are sometimes clustered non-randomly in specific regions of the genes involved in a translocation. This has prompted an active search for structural DNA elements or sequence motifs that could be associated with chromosomal translocations in cancer. Although some chromatin features have been proposed to promote the appearance of a double-strand break in their vicinity, it is unclear at present whether the localization of a breakpoint is determined primarily by the presence of such elements. Alternatively, double-strand breaks might be generated randomly throughout the genome and the clustering of translocation breakpoints seen in some tumors would result from functional selective pressures, as only those fusion products that confer a proliferative advantage to the cell will eventually initiate or promote tumor progression and be found in cancer cells. These two mechanisms are not mutually exclusive, and it is likely that the non-random clustering of translocation breakpoints that is seen in some cancers is the result of both processes.

Clinical Relevance

The fact that some chromosomal translocations are associated with specific malignancies is also important from the clinical point of view. A complete collection of published chromosomal translocations and the cancer types in which they were detected can be found in the Mitelman Database of Chromosome Aberrations in Cancer (http://cgap.nci.nih.gov/Chromosomes/Mitelman).

In some cases, especially in ►hematological malignancies, the diagnosis of the disease relies on the detection of a particular chromosomal translocation.The laboratory tools most frequently used in the diagnostic setting are conventional karyotyping (G-banding), ►fluorescence in situ hybridization (FISH) and ►PCR-based molecular techniques. Analysis of cancer patients has also shown that the clinical course of the disease sometimes depends on the presence of specific translocations. Therefore, detection of chromosomal translocations is also important to estimate the probability of response to therapy or the risk that the cancer will recur after treatment. For this reason, specific translocations are part of the international classification system proposed by the World Health Organization for various types of malignancies. Importantly, the detection of specific chromosomal translocations is also used to assess the efficacy of treatment, since it provides a rational way to follow the evolution of the tumor clone and to confirm (or rule out) the presence of ►minimal residual disease.

Finally, the identification of chromosomal translocations has been instrumental in designing new effective therapies against some types of cancer. The best example of this is the new generation of drugs, like ►ST1-SH against ►chronic myeloid leukemia, and other malignancies characterized by the presence of chromosomal translocations involving ►tyrosine kinase genes. The finding that these tumors are the result of deregulated tyrosine kinase activity has led to the development of specific inhibitors and a dramatic increase in response to therapy and in survival rates in those patients.

Chromosome

Definition

Structures in the nucleus, classified according to size, the location of the centromere, and the banding pattern along each arm. The autosomes are numbered from 1 to 22 in descending order of length; the sex chromosomes are referred to as X and Y. Both the long and short chromosome arms consist of one or more regions.

Chromosome Abnormality

Definition

Changes can be either structural, implying that the banding pattern or size of a chromosome is altered, or numerical, which means additional or missing whole chromosomes. Loss or gain of whole chromosomes are indicated by a plus " + " or minus "*" sign before a chromosome number.

Chromosome Band

Definition

Chromosomal area distinguishable from adjacent segments by its lighter or darker staining intensity. Bands are numbered consecutively from the centromere outward along each chromosome arm. Each band can be individually designated by first listing the chromosome number, then the chromosome arm, the region, and band number with the region. For example, 12q13 means chromosome 12, the long arm, region 1, band 3.

Chromosome Condensation

Definition

Chromosome changes occur throughout the cell cycle, however, chromosome condensation is first visible at the G2/M transition. Human naked DNA must be compacted ~10,000 fold to allow it to resolve into pairs of sister chromatids that can be separated from one another during the middle stage of mitosis. The binding of multisubunit phosphoprotein complexes, known as condensins, tightly regulates chromosome condensation. Topoisomerase II, an enzyme that regulates DNA topology, by breaking one DNA duplex and passing another through the gap, is required for complete chromosome condensation. Inhibitors of this enzyme stop complete chromosome condensation.

►G_2/M Transition
►Topoisomerases

Chronic Bronchitis

Definition

A daily, productive cough for at least 3 months in two successive years with no other cause for cough elucidated.

►Chronic Obstructive Pulmonary Disease and Lung Cancer

Chronic Granulomatous Disease (CGD)

Definition

Is a genetically heterogeneous immunodeficiency disorder resulting from the inability of phagocytes to kill microbes they have ingested. This impairment in killing is caused by any of several defects in the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase enzyme complex, which generates the microbicidal respiratory burst. In CGD, phagocytes ingest bacteria normally, but they cannot kill them. It is a primary immunodeficiency that affects phagocytes of the innate immune system and leads to recurrent or persistent intracellular bacterial and fungal infections and to granuloma formation. CGD is a syndrome that typically manifests as pneumonia, infectious dermatitis, and recurrent or severe subcutaneous abscess formation. In addition to increased susceptibility to infections, patients have a higher prevalence of mucosal inflammatory disorders such as colitis, enteritis, and gastric outlet obstruction. Cutaneous disease occurs in 60–70% of patients.

►Primary Myelofibrosis

Chronic Liver Disease

Definition

CLD, is the process that involves the immunologically mediated damage or destruction of various cell types

within the liver. CLD encompasses hepatitis (►inflammation of the liver), fibrosis (scarring, which involves the accumulation of connective tissue in the place of liver tissue) and cirrhosis (extensive scarring in which connective tissues completely surrounds islands of remaining liver tissue)

►Hepatitis Virus Associated Hepatocellular Carcinoma

Chronic Lymphocytic Leukemia

Jesper Jurlander
Department of Hematology, Rigshospitalet, Copenhagen, Denmark

Synonyms

CLL

Definition

CLL is a chronic form of leukemia with accumulation of small mature B-lymphocytes that express the surface membrane proteins CD5, CD19 and CD23.

Characteristics

Diagnosis

A diagnosis of CLL requires persistent absolute lymphocytosis of 5×10^9/l or more, with a characteristic immunephenotype and cytomorphology. Usually the diagnosis can be made based on a blood sample. In the identical lymphoma disorder, small lymphocytic lymphoma, the level of circulating tumor cells in the blood and bone marrow may be very low or absent. The diagnosis of SLL therefore may require a lymph node biopsy.

Epidemiology

CLL is the most common leukemia in the western world, with an incidence of ~5 new cases per 100,000 persons per year. The median age at diagnosis is 70 years, and the incidence increases with age. CLL may be seen in younger adults, but never in children.

Etiology

The causes of CLL are largely unknown. Unlike other leukemias, there is no relation to exposure to chemotherapy or ionizing radiation.

Pathogenesis

The forces that drive the relentless expansion of the CLL clone are unknown. Models of the pathogenesis of CLL have focused on the B-cell receptor. Like other mature B-cells, CLL cells express immunoglobulin in the cell membrane, structurally ordered inside the B-cell receptor (BCR) complex. The immunoglobulin molecules in the CLL BCR-complex are unique in several ways: (i) The repertoire of Ig-genes used by CLL cells is skewed, compared to normal B-cells (ii) The genes encoding the heavy chain variable segments only show signs of somatic hypermutation in about half of cases. (iii) The BCR-complex is expressed at much lower densities, than on normal or other malignant B-cells. (iv) The three-dimensional structure of the immunoglobulin molecules encoded by B-cells are remarkably stereotypic. Taken together, these observations suggest that the BCRs of CLL cells may be activated and transduce signals, by a limited and restricted set of (auto)-antigens, that drive the expansion and survival of the CLL clone. Abnormal expression of certain molecules involved in signal transduction from the BCR, for example overexpression of ZAP-70 or CD38, or low expression of $p72^{syk}$, may further modify the signaling capacity of the BCR in CLL cells. The result of this altered signaling is extended survival of B-CLL cells, and perhaps even increased proliferation. Furthermore, the most common cytogenetic lesion in CLL cells, result in deletion of a segment on chromosome 13q14 encoding the two ►micro-RNA's miR-15 and miR-16. These miR's can target and destroy Bcl-2 mRNA transcripts, leading to abandoned expression of Bcl-2 protein. When miR-15 and miR-16 are lost, due to the 13q14 deletion, the absence of the negative regulation of Bcl-2 may extend the longevity of CLL cells. Given the extended life cycle of a CLL cell, the risk of acquiring additional chromosomal aberrations is increased, and may for example result in losses at 11q22 (the ►*ATM* gene) or 17p (the *p53* gene). Both of these aberrations will further destabilize the negative regulation of Bcl-2, and furthermore, decrease the DNA damage response. In particular, the ability of p53 to induce cell cycle arrest upon DNA damage. In this way, the loss of control over apoptosis, induced by Bcl-2 overexpression, becomes linked to loss of control the G1-restriction point of the cell cycle, resulting in increased proliferation and transformation to the truly malignant and aggressive form of leukemia, seen in the end stages of advanced chemotherapy refractory CLL.

Thus, the highly variable clinical course observed for many years in CLL, is reflected by an equally variable spectrum of molecular aberrations detected in CLL cells. About half the cases of CLL have few molecular aberrations, and are characterized by very slow expansion of the clone, resulting in an indolent form of leukemia that may not affect the mortality or morbidity of the patient. The other half of the patients, show molecular features of aggressive disease, and follows a clinical course that sooner or later develops into aggressive, refractory and lethal leukemia.

Risk Prediction in CLL

Traditionally, the estimation of prognosis in CLL patients has relied on clinical staging systems, the two most widely used systems being those of Rai and Binet. Both systems use practical measurements of tumor size and bone marrow failure for prognostic estimation in CLL. Patients presenting with lymphocytosis alone generally have a favorable prognosis. Patients with lymphocytosis and enlarged lymph nodes, liver or spleen have an intermediate prognosis. Patients presenting with signs of bone failure, i.e. anemia or thrombocytopenia not caused by autoimmunity, have a poor prognosis. However, the clinical staging systems are static, and can only describe the patient status at presentation. The increased usage of standard blood tests in the clinic, results in identification of CLL patients at earlier stages of the disease, thereby eroding the informativeness of clinical staging systems. Today, more than 75% of patients are diagnosed by chance, usually because of examination for a non-CLL related condition, at a stage where lymphocytosis is the only manifestation of the disease.

The identification of biological risk predictors now allows definition of low-risk and high-risk cases, based on molecular features at the time of diagnosis. The major risk predictors are (Table 1).

Patients with no high-risk features have an expected median survival of more than 15 years. Patients with some high-risk features have an expected median survival around 10 years. Patients with many high-risk features have an expected median survival of 5 years or less.

Symptoms and Signs of Active CLL

There is no chemotherapy treatment that can cure CLL at present. ►Non-myeloablative allogeneic hematopoietic cell transplantation may do so, but the considerable morbidity and mortality associated with this treatment, makes it an option only for patients in advanced FC refractory stages. Therefore the treatment strategy is to await signs of active disease, before treatment is initiated. The signs of active CLL was defined by the NCI working group on CLL, also known as the Cheson criteria:

- Progressive bone marrow failure:
  - Development or worsening of non-immune mediated anemia
  - Development or worsening of non-immune mediated ►thrombocytopenia
- Massive or progressive lymph node enlargement
- Massive or progressive enlargement of the spleen
- Progressive lymphocytosis:
  - More than 50% increase in lymphocyte count in less than 2 months
  - Lymphocyte doubling time of less than 6 months
- Disease symptoms:
  - Weightloss (>10%) in less than 6 months
  - Fever of unknown origin for more than 2 weeks
  - Extreme fatigue
  - Night sweats
- Steroid resistant autoimmune cytopenia

Treatment Strategies in CLL

Once the patient has developed active CLL, it is necessary to prepare a long-term treatment strategy, ensuring that the relevant options are available for the patient at the inevitable subsequent relapses. The goal of the treatment must be accessed, i.e. tumor reduction, tumor control or tumor eradication, and developed in the context of patient age, co-morbidity and biological risk prediction. Elderly patients, or patients with significant co-morbidity, may not benefit from aggressive treatment, not at least due to toxicity. Tumor control, using single agent alkylating regimens, such as chlorambucil, may be sufficient. Standard treatment, aiming at tumor control, for patients younger

Chronic Lymphocytic Leukemia. Table 1 Risk prediction in CLL

Predictor	Low-risk CLL	High-risk CLL
►Immunoglobulin heavy chain gene mutations or usage	Mutated. (Less than 98% homology to the germ-line sequence)	Unmutated. (More than 98% homology to the germ-line sequence). H3-21 gene, regardless of mutational status
►Cytogenetics by FISH	Del13q14 as sole abnormality	Del17p and/or Del11q22 and/or Trisomy 12
►Clinical stage	Lymphocytosis only	Bone marrow failure (non-immune mediated anemia/ thrombocytopenia)
►ZAP-70 protein expression	<20% positive cells by flowcytometry	>20% positive cells by flowcytometry
►CD38 protein expression	<30% positive cells by flowcytometry	>30% positive cells by flowcytometry
►CLLU1 mRNA expression	<40-fold upregulation by quantitative RT-PCR	>40-fold upregulation by quantitative RT-PCR

than 70 years of age is the combination of (oral) ►fludarabine and ►cyclophosfamide (FC). The initiation of FC therapy in younger patients is also the evaluation of an ultimative risk predictor. FC non-responders, or early (<1 year) relapses, have a particularly unfavorable clinical course, with a median overall survival of less than 2 years. Therefore, patients younger than 70 years of age, started on treatment with a ►fludarabine containing regimen, should have their options for allogeneic hematopoietic cell transplantation (allo-HCT ►allogenic cell therapy) accessed at start of the treatment, primarily by tissue typing and identification of potential sibling allo-HCT donors. The expected median event free survival, is 1-year for alkylating agents, 2 years for fludarabine monotherapy and 3 years or more for fludarabine combination regimens. None of these strategies will cure CLL, and relapses are inevitable. If the recurrence of active CLL occurs later than the expected time point, the initial treatment may successfully be repeated. If not, it may be considered to escalate to a more aggressive regimen, again considering the age and co-morbidity of the patient.

Given the incurable nature of the disease, the described treatment strategy will eventually select for patients who are resistant to fludarabine containing regimens. These patients constitute a growing and very significant challenge in CLL centers. First of all, their disease at this points have every sign of aggressive leukemia, with bone marrow failure and constitutional symptoms being the most important signs of disease. Secondly, fludarabine refractory patients more often than not, present with a very severe immunodeficiency. It is opportunistic infections, more than the leukemia, that is threatening in advanced stages of CLL. Treatment options at this point, for example monoclonal anti-►CD52 antibodies (►alemtuzumab), may reduce and control the tumor, but will inevitably worsen the immunodeficiency. The only way out of this situation, with aggressive leukemia, and disabled immune function, is allo-HCT.

Allo-HCT in CLL

The effectiveness of allogeneic-HCT relies on two principles, with the aim to eradicate the tumor: (i) To deliver disease effective high dose chemo- or radiotherapy that can eradicate the tumor, and will eradicate normal bone marrow function, which however can be restored by reinfusion of normal bone marrow precursors. (ii) To develop allo-reactivity, that will target and destroy the leukemia, without targeting the patient. Standard transplantation evokes both principles. Non-myeloablative, or reduced intensity transplantation, using modern immunosupression to allow the new immune system to develop, is focused on the second principle. This second form of allo-HCT appears to be particularly effective in CLL. However, at a certain cost. The introduction of a new immune system, will create the risk that the new graft (immune system) will not only target the leukemia, but several tissues in the engrafted recipient. The risk is development of ►graft-versus-host disease (GVHD). The GVH-disease follows an acute and a chronic phase. The acute phase is responsible for a treatment related mortality of ~10%. The deaths caused by chronic GVH occurs at the same frequency, and living with chronic GVH-disease causes severe reduction in life quality. Therefore, allo-HCT cannot be considered an option for the general CLL-population. However, in younger patients, with FC-refractory disease, or deletions at 17p, allo-HCT may be the only way to survive the disease.

In summary, the development of biological risk predictors, new effetive chemo- immunotherapy combinations and the possibility for allo-HCT for at least some patients, has changed the management of CLL considerably since, and will continue to do so over the next years.

Chronic Lymphocytic Thyroiditis

Definition

Hashimoto Thyroiditis.

Chronic Lymphoproliferative Disorders

Definition

Malignancies of the lymphocytes and lymphoid tissue in the body, chronic.

►Mastocytosis

Chronic Myeloid Leukemia (CML)

Definition

Synonym myelocytic leukemia, also chronic myelogenous leukemia a myeloproliferative disorder associated with clonal proliferation of cells of bone marrow stem cell origin with excessive production of mature-appearing granulocytes. It is associated with a reciprocal translocation (t(9;22)(q34;911) leading to the

appearance of the Philadelphia (Ph1) chromosome and the ►BCR-ABL1 fusion protein. Therapy using tyrosine kinase inhibitors targeting ABL has proved very effective in achieving remission.

Chronic Obstructive Pulmonary Disease and Lung Cancer

Juhayna Kassem[1], Ronald G. Crystal[1,2]
[1]Division of Pulmonary and Critical Care Medicine, Weill Cornell Medical College, New York, NY, USA
[2]Department of Genetic Medicine, Weill Cornell Medical College, New York, NY, USA

Definition

►Chronic obstructive pulmonary disease (COPD) and ►lung cancer have rising prevalence worldwide with estimates of significant increases in mortality over the next few decades. Both diseases are directly linked to cigarette smoking, environmental exposures and old age, and both cluster in families, suggesting genetic links (►genetic disorders associated with cancer predisposition and chromosomal instability) to disease susceptibility. But irrespective of tobacco history (►tobacco carcinogenesis; tobacco-related cancers) and environment, there is growing evidence supporting an increased incidence of lung cancer in individuals with COPD.

Primary lung cancer is usually divided into two broad classes, small cell lung cancer and non-small cell lung cancer (tobacco carcinogenesis; ►cancer causes and control; ►tobacco-related cancer), which includes adenocarcinoma, squamous cell carcinoma and large cell carcinoma.

Characteristics

COPD

COPD is a chronic disorder characterized by airflow limitation that may be accompanied by hyperreactivity but is not fully reversible and is usually progressive. The disease is primarily caused by cigarette smoking, and to a lesser extent, by other noxious particles and gases. Despite smoking cessation, once COPD is established, the disorder continues to progress, albeit at a slower rate. Although COPD is a lung disorder, it is also associated with significant systemic abnormalities.

COPD is a general category that includes ►chronic bronchitis, an inflammatory airway disorder characterized by a daily, productive cough for at least 3 months in two successive years, and ►emphysema, an abnormal, permanent airspace dilation with destruction of the alveolar walls without evidence of fibrosis. Most patients with COPD have components of both chronic bronchitis and emphysema, and some have superimposed asthma, with airway hyperactivity and reversible limitation to expiratory airflow.

Most cases of COPD start with abnormalities in the small airways, with epithelial changes, ►inflammation in the airway walls, and narrowing of the airway lumen, limiting airflow. As the disease progresses, the airflow limitation is manifest by abnormalities in ►spirometry, a physiologic test that measures inhaled and exhaled volumes of air independently and as a function of time. The most commonly used parameters relevant to COPD are the forced vital capacity (►FVC, the volume of air that can be forcibly exhaled following maximal inspiration) and the forced expiratory volume in one second (►FEV1, the volume of air that is exhaled in the first second of that same maneuver). A reduction in FEV1 directly correlates with the degree of airways disease from inflammation, fibrosis or intraluminal exudates that characterize COPD. Following the use of inhaled bronchodilators, if the FEV1/FVC is <70% and the FEV1 is <80% of expected values, airflow limitation is present. The airflow limitation that characterizes COPD results from the intrinsic airway disease *per se*, as well as the loss of airway structural support from the destruction of the alveolar walls. The alveolar wall destruction also results in a reduction in the diffusing capacity for carbon monoxide, and can be visualized by computerized tomography of the chest.

Lung Cancer

Lung cancer is the leading cause of cancer related deaths worldwide. Like COPD, most (85–90%) of all lung cancers are a result of exposure to smoking. The risk of developing lung cancer, even after smoking cessation, persists for years. In the United States, the rate of lung cancer in former smokers is now equal to the rate in current smokers and is expected to increase even more in the next decades.

Link to Decline in FEV1

The incidence of both lung cancer and COPD increases with >20 pack-year smoking exposure. Smoking one pack of cigarettes per day can increase the normal decline in FEV1 from an expected 30 to 50–60 ml/year. Overall increases in mortality associated with COPD are directly associated with declining FEV1. The decrease in FEV1 associated with COPD is also directly linked to lung cancer, as well as to an increased risk of cardiovascular disease, including coronary heart disease and stroke.

COPD and Lung Cancer Associations

While COPD and lung cancer are both related to smoking, there is data from as early as the mid-1960s to support that the two diseases are even more closely related. Van Der Wal et al were the first to demonstrate a high incidence of lung cancer in patients with "chronic nonspecific lung disease," now recognized as COPD. Goldstein et al in 1968 reported a 32 times higher rate of lung cancer in patients with radiographic evidence of bullous emphysema in hospitalized patients with cancer as compared to other hospitalized patients who were used as controls. These data were supported by several subsequent studies in the 1970s and 1980s.

In 1976, Davis et al suggested that a reduced FEV1 itself might be an independent risk factor for the development of lung cancer, demonstrating a 4–5-fold increase in lung cancer in their patients with COPD as compared to lung cancer rates in previously reported series of smokers without COPD. A prospective study by Skillrud et al comparing 113 people with COPD to 113 matched controls without COPD followed over a 10 year period, found that all cause mortality increased with COPD, a decreased FEV1 was directly linked to a decreased time to death from any cause, and, that despite shorter survival data for patients with COPD, there was a clear, increased risk for the development of lung cancer in the COPD population. Overall, the risk of developing lung cancer in patients with airway obstruction is 4.4 times greater than in those without obstruction to expiratory airflow.

In 1997, a retrospective review of data collected from two large prospective study groups, The Intermittent Positive Pressure Breathing Trial sponsored by the National Heart, Lung and Blood Institute and the Johns Hopkins Lung Project, was conducted by the National Cancer Institute's Cooperative Early Lung Cancer Detection Program. The goal was to evaluate the association between the degree of airway obstruction and the development of lung cancer. This study demonstrated that the frequency of lung cancer was proportional to the degree of airflow obstruction, and that the risk of lung cancer was more closely linked to a decline in FEV1 than to older age or degree of tobacco use.

The 1994 study by Islam et al reviewed prospectively data collected over a 28 year period in a community-based study in Tecumseh, Michigan in 3,900 subjects. They determined that the initial FEV1 and the rate of decline in FEV1 were each independent predictors of lung cancer development. When loss of FEV1 reached 100 ml/year, the risk of lung cancer reached as high as 30 times the rate seen in matched controls.

A study by Mannino, published in 1993, reviewed patients in the First National Health and Nutrition Examination Survey database who had at least a 22 year follow up. They demonstrated that moderate to severe obstructive disease was associated with a higher incidence of lung cancer and that there was no difference in rates of lung cancer when comparing current to former smokers.

Possible Mechanisms of the COPD - Lung Cancer Risk

The relationship between reduced FEV1 and the development of primary lung cancer is not clear, although many theories have been advanced. It is generally accepted that both disorders result from a combination of genetic and environmental factors (cancer causes and control; ►cancer epidemiology). However, while the link to smoking is clear, the commonalities of the smoke components that cause COPD and lung cancer are not clear (genetic disorders associated with cancer predisposition and chromosomal instability), nor are the genetic differences linking a susceptibility to both diseases.

One gene of common interest is ►vascular endothelial growth factor (VEGF). While COPD has been theorized to be associated with decreased availability of VEGF leading to capillary apoptosis in the lung, lung cancer, as with other cancers, is associated with an increased expression of VEGF supporting ingrowth of capillaries into the developing tumor. Linkage studies in both humans and mice have suggested that allelic loss in some regions of chromosome 6q and 12q are associated with lung cancers as well as with COPD. Finally, excess amounts of matrix metalloproteinases (MMPs), enzymes that degrade extracellular membranes are associated with a decline in lung function, as well as an increased risk of lung cancer.

Chronic inflammation (►inflammation in cancer) has long been linked to cancer in many organs, as evidenced by the development of esophageal adenocarcinoma (►esophageal cancer) following chronic gastric reflux. This concept has led to the theory that COPD and lung cancer risks increase in the face of chronic inflammation. Consistent with that concept, cigarette smoking (tobacco carcinogenesis; tobacco-related cancer) has been shown to cause sustained changes in gene expression of respiratory epithelial cells. Some of these changes have been noted to persist, regardless of smoking cessation, for decades. Some of the inflammatory changes are likely associated with the development of both COPD and lung cancer. One example is the loss of the tumor suppressor gene, p53 (►p53 protein, biological and clinical aspects) which generally inhibits inflammation. Allelic loss of p53 is known to lead to inflammatory responses including increases in nuclear factor-κB, a transcription factor linked to both COPD and cancer, via inflammatory pathways. Other genes, including antioxidants, oncogenes and other ►tumor suppressor genes have also been suggested as key risk factors to the development of COPD and lung cancer.

Summary
The reasons why only a minority of smokers develop smoking related lung disease are still not clear and many challenging questions remain unanswered regarding COPD, lung cancer and the relationships between them. More information on their associations with environmental exposures (including but not limited to tobacco), genetic susceptibility, and inflammatory processes is still needed. It is evident that these connections are not simply based on tobacco use and that there is a genetic predisposition to the development of each. While smoking cessation will clearly reduce the incidence of COPD and lung cancer, it will not eliminate either disease for many decades to come. Further well-formulated studies are required to continue to evaluate the connections between environmental exposures, inflammation, genetic expression and the development of COPD and lung cancer, which remain two pulmonary diseases with the highest morbidity and mortality in the world.

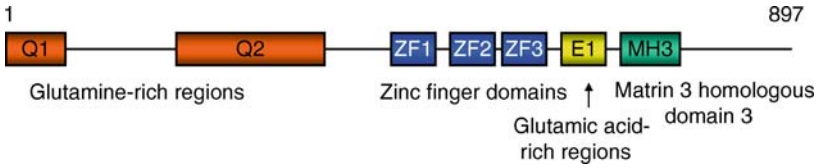
Cip-Interacting Zinc Finger Protein 1 Ciz1

Petra Den Hollander, Rakesh Kumar
Molecular and Cellular Oncology, The University of Texas MD Anderson Cancer Center, Houston, TX, USA

Definition

Ciz1 is a member of the Matrin 3 protein family and also called NP94 (Nuclear Protein 94). At the N-terminal



Cip-Interacting Zinc Finger Protein 1 Ciz1. Figure 1 Schematic representation of protein domains in Ciz1.

region, Ciz1 contains poly-glutamine repeats and glutamine rich regions. Additionally, the C-terminus contains three zinc-finger motifs, an acidic region and a matrin 3-homologous domain 3 (MH3 domain), which shows 40.4 and 37.7% identity (55.8 and 64.2% similarity) to NP220 and matrin 3 (two other members of the Matrin 3 family), respectively (Fig. 1). Ciz1 is expressed in a wide variety of tissues, with highest expression in pancreas, testis, kidney and brain, with the highest expression in cerebellum, and is mainly localized in the nucleus. Ciz1 is expressed in a number of cell lines from multiple organ systems. None of the genes of Yeast, *C. elegans* or *Drosophila* showed any overall structural similarities to Ciz1, suggesting that Ciz1 is a unique protein only found in vertebrates.

Characteristics

Ciz1 directly interacts with ►p21^{WAF1} and is predominantly located in the nucleus. However, upon co-overexpression of Ciz1 and p21^{WAF1}, an enhanced cytoplasmic localization of both proteins was detected. Ciz1 is a DNA binding protein, and its DNA consensus sequence was determined by a modified selected and amplified binding (SAAB) sequence method (ARYSR (0–2)YYAC). Ciz1 is a binding partner of Dynein Light Chain 1 (DLC1), shown by using a modified ►proteomics technique. Ciz1 influences the ►cell cycle progression at the G_1-S transition by affecting the kinase activity of Cdk2. A reduced localization of p21^{WAF1} in nuclei of DLC1 overexpressing cells strengthened the hypothesis that Ciz1 (together with DLC1) in important for the sequestration of p21^{WAF1} in the cytoplasm, which will then release the repression of the Cdk2 kinase complex and induce the G_1-S transition. Also, cell-free experiments have demonstrated that Ciz1 has a role in mammalian DNA replication. The addition of Ciz1 protein increases the number of nuclei that initiate DNA replication, and when mutating the potential ►cyclin-dependent kinase (Cdk) phosphorylation sites, Ciz1 functions were compromised in vitro. Ciz1 co-localizes with PCNA in foci in the nucleus, and Ciz1-depleted cells are unable to replicate their DNA.

Besides significant role in the cell cycle progression, Ciz1 is responsible for potentiating the transactivation activity of the ►Estrogen Receptor alpha (ER). Ciz1 is a coregulator of ER by enhancing ER transactivation activity and recruitment to target gene chromatin. Ciz1 induces the hypersensitivity of ►breast cancer cells to ►estradiol and induces the expression of ER target gene ►cyclin D1 at a femto-molar dose of estrogen, with likely downstream effects on G1 progression and DNA replication. In addition, overexpression of Ciz1 promotes the growth-rate, anchorage-independence and tumorigenesis of breast cancer cells in a xenograft model. Interestingly, Ciz1 is also an estrogen-inducible gene, suggesting that overexpression of Ciz1 in breast cancer cells may support hormone hypersensitivity.

Ciz1 has a functional MH3 domain since its C-terminal region essential for the anchoring of Ciz1 to the nuclear matrix, and this immobilization is cell-cycle dependent and occurs probably during late G1 or early S phase. Although the C-terminus is sufficient for the immobilization of the Ciz1 protein to the nuclear matrix, the N-terminal region is required for the focal localization of Ciz1 in the nucleus. Using biotinylated-dUTP and GFP-tagged Ciz1, Ciz1 was shown to be co-localized with the newly synthesized DNA. Thus, Ciz1 has multiple functions in cell cycle progression and cell proliferation control and has a potential role in tumorigenesis.

C

Circadian

Definition

Rhythms with a period (cycle duration) of about 24 h (circa, about; dies, day) characterize many biological functions in unicellular organisms, plants, as well as all kinds of animals, ranging from insects to rodents, wildlife, and humanisms. In mammals, rhythms in locomotor activity, body temperature, hormonal secretions, etc. persist in constant environmental conditions. Yet the period of these endogenous rhythms slightly differs from precisely 24 h, being close to 24.8 h on the average in humans.

►Circadian Clock Induction

Circadian Clock

Definition

Most cells in the brain and peripheral tissues contain a molecular clock consisting of at least 12 specific clock genes in mammals. Interacting transcriptional and post (transcriptional loops constitute this molecular clock which rhythmically control many metabolic and proliferation functions in most living cells.

Definition

The ►circadian timing system efficiently orchestrates the physiology of living organisms to match environmental or imposed 24-h cycles. Most cells in the brain and peripheral tissues contain a molecular clock consisting of at least 12 specific clock genes in mammals. This molecular clock rhythmically controls the transcriptional activity of nearly 10% of the genome, ~10% of which are proliferation-related genes, over the 24 h. Among the 12 genes which constitute the molecular clock, *Per2*, *Bmal1*, and *Rev-erbα* play a central role. Thus, a null mutation in these genes results in profound alterations of the circadian phenotype. The intracellular clock mechanisms involve interacting positive and negative transcriptional feedback loops that drive recurrent rhythms in the RNA levels of these key components. High levels of Bmal1 mRNA and protein promote the formation of BMAL1:CLOCK heterodimers that bind to the ►E-box sequences in the promoter of clock genes *Per2* and *Rev-erbα* and activate their transcription. In turn, Rev-erbα negatively regulates Bmal1 transcription, while PER2:CRY1 complexes inhibit the transcription of their own genes by interfering with CLOCK:BMAL1. Phosphorylation of PER and CRY proteins through casein kinase (CK) Iδ/ε activity plays a key role in the regulation of clock proteins degradation and length of precise circadian period.

The circadian organization of drug metabolism pathways as well as ►cell cycle, ►DNA repair, and ►apoptosis is responsible for dosing time dependencies in drug ►pharmacokinetics and pharmacodynamics. As a result, about 24-h changes in anticancer drug tolerability and efficacy call for ►chronotherapeutics, i.e., the delivery of anticancer treatments according to circadian (and other) rhythms. Dedicated ►drug delivery systems can actually administer chemotherapeutic drugs at specific optimal times and/or according to an optimal circadian pattern to cancer patients.

Conversely, destruction of the ►circadian pacemaker in the brain, iterative alterations of the environmental cycles, or clock gene mutations usually produce severe modifications within the ►circadian timing system that result in the uncoupling of coordinated biological functions. Such ►circadian disruptions can influence cancer processes.

Characteristics

Relevance of Circadian Disruption for Cancer Processes

The relative risk of developing breast, colorectal, or prostate cancer is enhanced 50–300% in populations exposed to prolonged shift work, frequent transmeridian flights, or chronic light exposure at night. These latter conditions profoundly alter the circadian timing system and the downstream control it exerts on cellular proliferation, DNA repair, apoptosis, and metabolism. These circadian alterations can consist of a decrease in rhythm amplitude, a phase shift and/or a modification, or a suppression of the circadian period. Circadian

physiology monitoring reveals relevant rhythm alterations in nearly one third of patients with metastatic cancer. In patients with advanced or metastatic cancer, disrupted circadian rhythms in rest-activity or cortisol secretion are associated with poor quality of life and increased risk of an earlier death. In experimental models, the growth rate of transplanted tumors is accelerated with the disruption of the circadian timing system through ablation of the hypothalamic circadian pacemaker or chronic jet lag produced by 8-h advances of light onset every 2 days.

Circadian Clock Control of Cell Cycle

At least three molecular mechanisms link molecular ►circadian clock with the cycling of cell division. The molecular clock controls Wee1 transcription through an E-box-mediated mechanism. WEE1 negatively controls the activity of CDK1/Cyclin B1, which facilitates the ►G2/M transition (Fig. 1). In addition, the BMAL1: CLOCK heterodimers repress ►c-Myc transcription through E-box-mediated reactions in the *c-Myc* gene P1 promoter and PER 2 can suppress c-Myc expression indirectly. In general, knocking down the molecular clock modifies transcription patterns of genes involved in the cell cycle regulation. This can translate into genomic instability, thus favor malignant ►progression or growth. Both *Per1* and *Per2* as well as possibly other clock genes also control DNA repair through interactions with ►*ATM* and *mdm2*.

Circadian Disruption in Cancer Tissues

The circadian expression pattern of core clock genes *Per2*, *Bmal1,* and *Rev-erbα* can be severely altered in experimental tumors in mice. In experimental Glasgow osteosarcoma, a transplantable mouse tumor with a doubling time of 2–3 days, the transcriptional rhythms in these three clock genes displayed altered amplitudes and phase at an early stage of growth that subsequently evolved toward arhythmicity (Fig. 2).

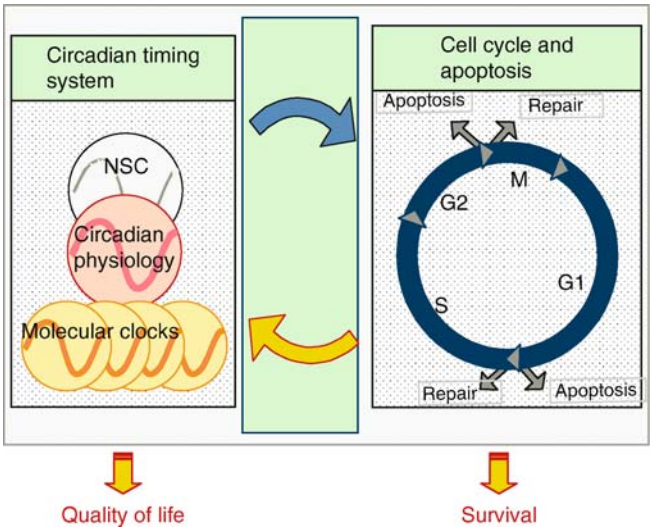
Physiologic Clock

The adjustment of a cosine curve with a 24-h period to mRNA expression of Rev-erbα (blue line), Per2 (red line), and Bmal1 (green line) allows to build a model of the circadian clock in healthy liver of $B6D2F_1$ mice. This model establishes physiological dynamic relations with maxima occurring near Circadian time 6 (CT6) for Rev-erbα, CT15 for Per2, and CT23 for Bmal1.

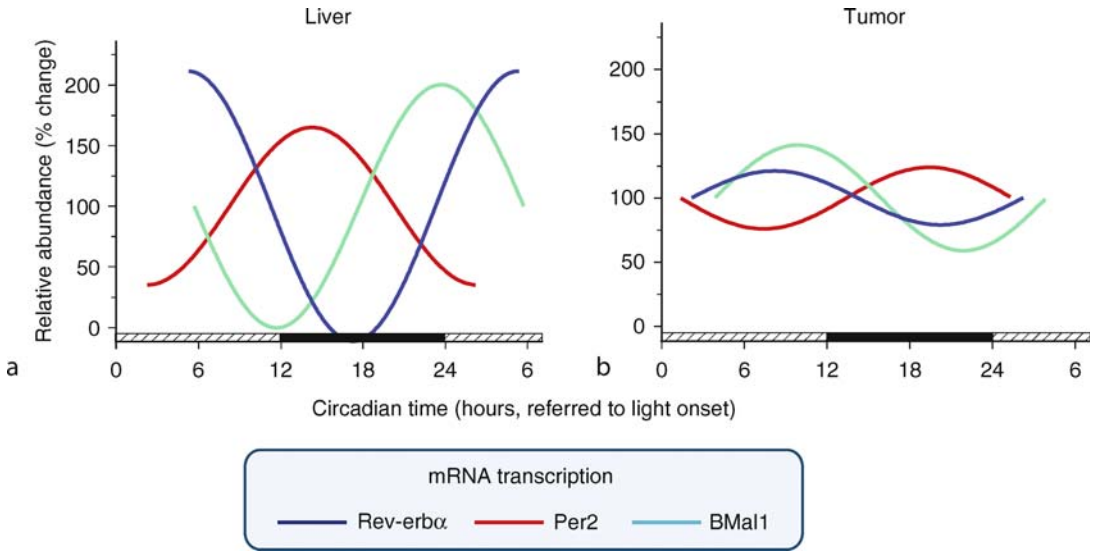
Tumor Clock

The same method is applied to clock genes data for control tumors. No clock gene transcription rhythm is validated.

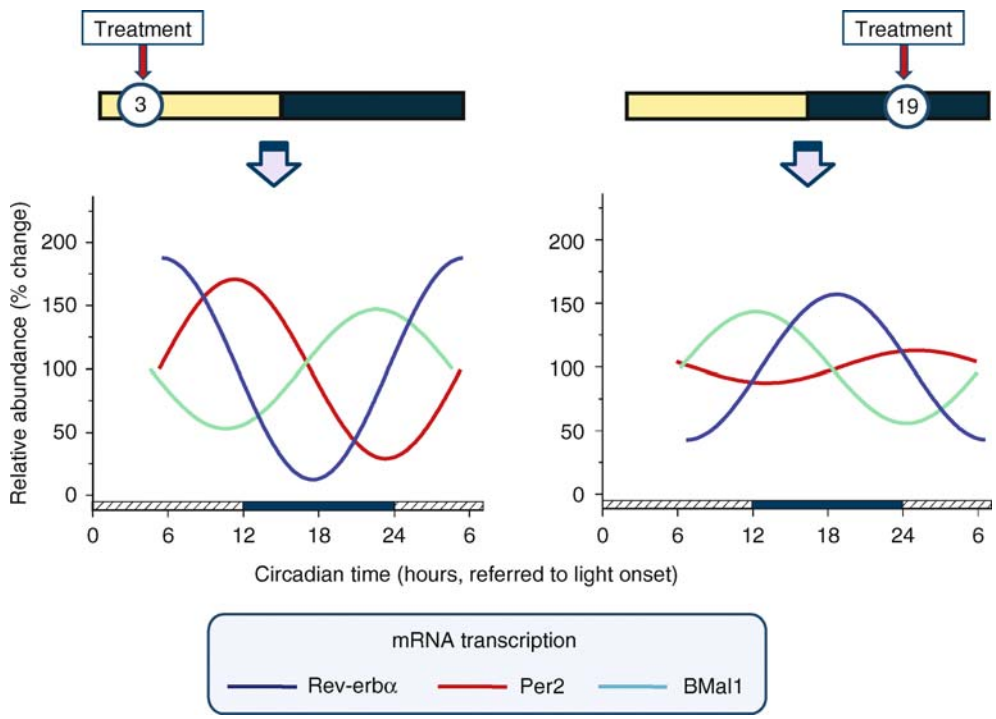
The ablated rhythms in clock gene expression in tumor tissue could result from an altered synchronization of the molecular clocks in each malignant cell or from an impairment of the molecular clock within each individual cancer cell. The first possibility would happen, for instance, if the internal rhythm in each cell beats with a period that differs by minutes or hours from those of its neighbors. Alternatively, clock genes defects could result in nonfunctional molecular clocks through deletions, mutations, or ►methylation of promoter region. In several human cancers, decreased expressions of the Per1, Per2, or Per3 genes were found at a single time-point, in comparison with reference tissues.



Circadian Clock Induction. Figure 1 Schematic representation of the interactions between the circadian timing system and the cell division cycle. SCN: suprachiasmatic nuclei, the main circadian pacemaker in the hypothalamus.



Circadian Clock Induction. Figure 2 ►Cosinor-based model of molecular clock in mouse healthy liver (a) or tumor Glasgow osteosarcoma (b).



Circadian Clock Induction. Figure 3 Example of tumor circadian clock induction with CDKI seliciclib as illustrated with cosinor-based model of molecular clock. Physiologic phase relations between expression patterns of the three core clock genes, similar to those in healthy liver, are induced with seliciclib treatment in the early rest span (at Zeitgeber Time 3, ZT3), but not if the drug is given during darkness (at ZT19).

Circadian Clock Induction

Peripheral ►synchronizers, such as feeding schedules, and drugs, such as ►cyclin-dependent kinase inhibitor (CDKI) seliciclib, can induce rhythmic clock gene expression patterns in malignant tumors with otherwise disrupted or uncoordinated molecular clocks. Indeed, exposure of tumor-bearing mice to chronic jet lag severely disrupts the already altered temporal patterns

of core clock gene expressions in tumor. Programming food availability to 6 h daily induces near normal molecular clock in the tumor and slows down malignant growth. The administration of seliciclib also induces near normal molecular clock in mice dosed in the early light span, but has no such effect if treatment is applied during darkness (Fig. 3). Feeding or pharmacologic induction of the tumor clock is associated with antitumor effect. Both clock induction and antitumor effects depend upon the circadian time of application.

Circadian clock induction improves control of ►G2/M gating through an enhancement of Wee1 transcription, a gene that is unidirectionally controlled by CLOCK-BMAL1. In the case of seliciclib, the induction of the molecular clock involves inhibition of CK1δ/ε, a key determinant of circadian period. In turn, inhibition of CK1δ/ε impairs PER2 degradation and nuclear translocation and results in increased *Bmal1* transcription. Since highly coordinated sequential transcription is a major mechanism of circadian rhythms, programmed food availability or daily seliciclib act as strong resetters of tumor cells that have lost synchrony in functional clocks, through transient inhibition of CK1δ/ε or other pathways within permissive time windows.

In conclusion, while malignant tumors tend to display disrupted molecular clocks and to lose circadian coordination, feeding schedules and drugs like CDKI seliciclib can slow down tumor growth through circadian clock induction. The mechanisms underlying these favorable effects involve the cross talk between the circadian clock and the cell cycle, two biological oscillators whose interactions represent a new relevant dynamic target for cancer therapeutics. Furthermore, the extent of circadian clock induction and that of antitumor activity depend upon the circadian time of drug administration, revealing the relevance of chronotherapeutics of CDKI for improving cancer control.

Circadian Disruption

Definition

Modifications within the circadian timing system that result in the uncoupling of coordinated biological functions.

►Circadian Clock Induction

Circadian Pacemaker

Definition

The circadian clocks that reside in nearly all mammalian cells are coordinated mainly by the suprachiasmatic nuclei (SCN), a pair of neuronal nuclei located at the floor of the third ventricle in the hypothalamus. This coordination is exerted through known neuroanatomic circuitry and diffusible signals. The SCN also receives direct input pathways from the retina and other brain areas so that it adjusts the phasing of the circadian timing system to the light–dark and social synchronizers.

►Circadian Clock Induction

Circadian Rhythm

Definition

A self-sustained biological rhythm or oscillation of behavior, metabolism, biochemistry and/or physiology that repeats with a cycle of approximately 24 h; literally means a rhythm of about (circa) a day (dian).

►Melatonin

Circular Dorsal Ruffles

Definition

Transient regions of cell membrane that extend from the surface of cells as they initially respond to growth factor

stimulation. They are thought to supply membrane and protein components required for sustained lamellipodia formation, as well as regulating growth factor receptor internalization.

►Cortactin

Circulating Endothelial Cells (CECs)

Definition

Are cell populations circulating in the peripheral blood that exhibit an endothelial cell-specific surface marker phenotype (e.g., positive for CD31, but not for CD45, a pan-hematopoietic marker).

►Antiangiogenesis

Circulating Nucleic Acids

Michael Fleischhacker
Charité-Universitätsmedizin Berlin, CCM, Berlin, Germany

Synonyms

Cell-free circulating nucleic acids; Extracellular nucleic acids; CNAs

Definition

Circulating nucleic acids (CNAs) are nucleic acids, i.e., DNA, and RNA, isolated from cell-free plasma/serum and other "circulating" body fluids like lymphatic fluid. For nucleic acids obtained from body fluids like liquor, ascites, milk, bronchial lavage fluids, urine, stool, or isolated from cell-free supernatants of in vitro cultivated cells, the terms extracellular or cell-free nucleic acids are better suited. CNAs are found in the animal kingdom, in plants, and in the microbial world as well. In humans and in animals, most of these nucleic acids seem to derive from dead cells (apoptosis, necrosis), but there are probably also mechanisms leading to an active release. The majority of cell-free circulating DNA molecules are of low molecular weight (up to ~300–500 bp). The amount of CNAs in healthy subjects is very low (~1–20 ng DNA/ml plasma), while in patients with a tumor (but with a benign disease as well) a much higher quantity can be found (up to several orders of magnitude).

Characteristics

Biological Aspects

The presence of CNAs in plasma samples of humans was reported by Mandel and Metais in 1948. Leon et al were the first to describe a relationship between CNAs in cancer patients and their clinical parameters, and the group of Drs. Stroun and Anker clearly demonstrated that at least part of CNAs in cancer patients is derived from the tumor itself [1].

Healthy subjects contain a few ng DNA/ml plasma, while patients with a malignant or benign disease may contain an increased quantity of CNAs (up to 2–3 orders of magnitude more), but there is a wide range. The increase in the amount of CNAs in diseased patients is very unspecific, not related to any malignancy in particular, and can be observed in trauma patients as well as in patients with inflammatory conditions (like chronic inflammations in patients with ulcerative colitis).

CNAs are not naked but are released in complexes that make them resistant against attacks of nucleolytic enzymes. So far all known cellular nucleotide sequences analyzed in CNAs (i.e., DNA, and RNA) were also found in plasma/serum and other body fluids. Therefore CNAs are probably a mirror of all cellular nucleic acids, but whether the quantitative ratios are the same in both compartments is unknown so far. The half-life of CNAs seems to be very short (in the range of minutes). The clearance mechanisms in animals, including the human species, are probably an excretion in urine and stool or an uptake by the liver. In plants the traffic of nucleic acids, i.e., DNA, and RNA, plays an important role in cell–cell communication (like spreading of a primary crown gall, which is considered a plant tumor, to "metastatic sites"), and in the animal kingdom CNAs might be involved in ►horizontal gene transfer (HGT).

Clinical Aspects

CNAs isolated from cancer patients may contain all the genetic alterations found in the tumor cells themselves. These include DNA ►amplifications, inversions, point mutations (►Oncogenes), deletion of a ►tumor suppressor gene, ►microsatellite alterations, hypermethylation (►Methylation) of ►CpG islands in promoter regions, mutations in ►mitochondrial DNA, the presence of viral nucleic acids, and the possibility to detect a larger quantity of mRNA for genes that are overexpressed in tumors. While there does not seem to be a well-defined relationship between an increased quantity of CNAs in plasma/serum and the presence of a malignancy or any other clinical parameters (►Tumor staging, ►tumor grading, size of the tumor, presence/absence of ►metastases, etc.), the amount of CNAs in plasma/serum is frequently higher in tumor patients

than in the control populations. The detection of mutations, frequently found in tumor cells (such as in ►*p53* gene family, ►*K-ras*, ►*N-ras*, ►*APC*, ►*BRAF*), has also been possible in CNAs. The detection of microsatellite alterations (i.e., the ►loss of heterozygosity (LOH) or band shifts) in CNAs from tumor patients is one of the most frequent genetic changes found in DNA from plasma/serum. Almost all solid tumors and many ►hematological malignancies harbor microsatellite alterations detectable in CNAs. One of the main problems with assays detecting these alterations is their low sensitivity. Since CNAs are a mix of nucleic acids derived from normal, i.e., healthy, and tumor cells and most often the fraction of the tumor-derived DNA is much smaller than the one derived from normal cells, it can be very difficult or impossible to detect these changes (the sensitivity for methods detecting an LOH is ~1:200). In contrast, the detection of point mutations or hypermethylated sequences as a positive detectable marker is more straightforward and yields higher assay sensitivity. The CpG dinucleotides are found in small stretches of DNA termed CpG islands that are frequently located around the transcription start sites of human genes (promoter regions). Such a promoter hypermethylation is commonly found in so-called ►tumor suppressor genes, leading to a shutdown of these genes (►Epigenetic gene silencing). Recently developed methods (mostly based on PCR (►Real-time PCR)) yield a high test sensitivity (one single hypermethylated allele can be detected against a background of up to 10,000 unmethylated alleles) and also allow a ►real-time quantification of methylated alleles. The presence of cell-free viral nucleic acids had been described before CNAs became popular as new tumor markers, and the strong association of a virus infection and the development of certain types of cancer makes the detection of viral nucleic acids an interesting field. There are strong correlations between the development of a nonnasopharyngeal head and neck carcinoma (NNHNC) and an infection with the Epstein-Barr virus (EBV); between cervical cancer and an infection with the ►human papilloma virus (HPV), especially types 16 and 18; between Hodgkin's disease and other lymphoproliferative diseases and EBV. While DNA is a rather stable molecule, RNA is much more fragile and prone to degradation by the ubiquitous presence of RNA degrading enzymes. Since it is known that the serum RNAse concentration is elevated in cancer patients, it was quite a surprise when EBV-associated RNA was detected in the plasma of nasopharyngeal carcinoma patients and tyrosinase *mRNA*, a gene overexpressed in melanoma cells, was found in the serum of melanoma patients.

The reasons for the observation that frequently there is no complete concordance between alterations found in the primary tumor and in CNAs are based on the facts that extracellular nucleic acids are a mix of normal and tumor-derived nucleic acids, that most solid tumors are heterogeneous and contain subclones that are genetically heterogeneous, and that primary tumors, their subclones, and metastases may differ in the ability to shed nucleic acids into their environment. This makes it even more difficult to establish a marker panel that can be useful in a clinical setting. There are quite a few reports in which a correlation between the presence of genetic alterations in CNAs and clinical parameters was found. It has been shown that the determination of the quantity of circulating viral nucleic acids before and/or after therapy might be a good marker to evaluate the response to a therapy or an overall and disease-free survival. Similar observations were made for the detection of methylated sequences in CNAs (APC, RASSF1A, p15, and p16INK4A) and some clinical parameters. In addition, there might be a correlation between the presence of *K-ras* and *p53* mutations in CNAs and the survival of the affected patients. In any case (and this holds true for all methods and genetic alterations mentioned above) a thorough validation of the potential markers is a conditio sine qua non, since some of the tumor-associated genetic alterations are not only found in the tumor itself, but have also been detected in histologically normal tissue of cancer patients, in people having a certain risk for the development of a tumor, or even in cells obtained from obviously healthy subjects. This was demonstrated for the *p53* tumor suppressor gene whose alterations are found in progenitor lesions of the lung, esophagus, head, and neck, and colon. Some of the tumor-associated changes seen in cellular DNA were also detected in plasma DNA of nontumor patients, like microsatellite alterations in plasma DNA from patients with benign respiratory diseases and a tumor-associated gene promoter methylation in plasma from women who have never smoked. In addition, patients with long-standing ulcerative colitis are frequently tested positive for mutations of the *Ki-ras* and *p53* genes even if there are no signs of a tumor. Finally a couple of important technical issues need to be resolved (like determination of the influence of preanalytical factors on the result, standardization of the different methods, choice of an optimal marker panel, etc.) before the analysis of CNAs can be a useful and clinically meaningful tool.

Circulating Progenitor Cells (CPCs)

Definition

Are cell populations circulating in the peripheral blood that express progenitor/stem cell-specific surface markers (e.g., CD34, CD133).

►Antiangiogenesis

Circulating Tumor Cells

Patrizia Paterlini-Bréchot
INSERM Unit 807, Faculté de Médecine Necker Enfants Malades, 75015 Paris, France

Definition

Circulating tumor cells (CTC) are tumor cells spread in blood and/or lymphatic vessels from solid tumors, thus including all types of tumor cells except those derived from leukemia and lymphoma. CTC may circulate as aggregated tumor cells, which are defined as ►circulating tumor microemboli or "►collective tumor cells migration (CTM)."

Characteristics

Tumor cells may circulate in blood spontaneously, i.e., because of their invasive capabilities, or for other causes of cell spreading. Spontaneous circulation of tumor cells represents the early hallmark of the invasive behavior of a proportion of cancer cells and the first step of the process leading to the formation of ►metastases. Nonspontaneous circulation of tumor cells may derive from iatrogenic invasive procedures (biopsy, surgical intervention, etc.), tumor compression and tumor inflammation.

The process by which tumor cells spreading from solid tumors gives rise to metastases includes the following steps: tumor growth, ►angiogenesis, tumor cell detachment, ►epithelial to mesenchymal transition (EMT), motility, ►intravasation, survival in vessels and embolization, collective tumor cells migration (CTM), possible ►extravasation, mesenchymal to epithelial transition (MET), formation of ►micrometastases and growth of ►macrometastases (Figs. 1 and 2).

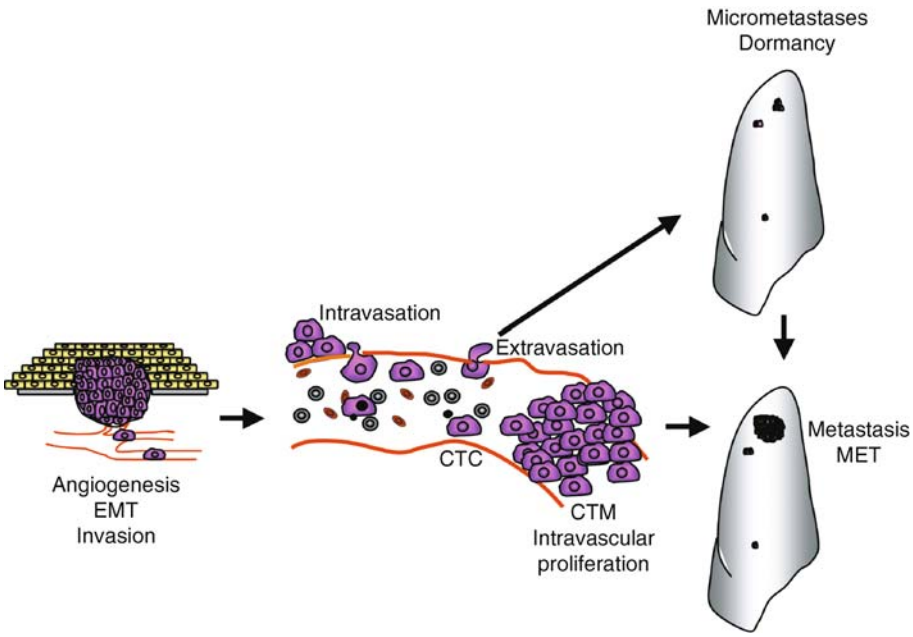
Growing cells rapidly outstrip the supply of nutrients and oxygen and suffer from hypoxia. Hypoxia inducing factor (HIF), which mediates the transcriptional response to hypoxia, is a strong promoter of tumor growth and ►invasion and controls angiogenesis via two key angiogenic factors (VEGF-A and angiopoietin-2). Hypoxia determines cell necrosis and release of inflammatory mediators such as cytokines and ►chemokines which recruit, among other cells, leukocytes and ►macrophages. These, in turn, stimulate angiogenesis, extracellular matrix breakdown, and tumor cells motility. Local production of basic fibroblast growth factor (bFGF), epidermal growth factor (EGF), hepatocyte growth factor (HGF), and transforming growth factor beta (TGF-beta) mediate the control of tumor cell survival/►apoptosis balance and of E-cadherin down-regulation leading to reduced cell adhesion and increased tumor cell invasiveness.

Furthermore, hypoxia, acting through LOX induction and Snail activation, leads to E-cadherin repression, a crucial feature of the EMT. During EMT, Twist may need to activate antiapoptotic programs in order to allow epithelial cells to convert to a mesenchymal fate while avoiding ►anoikis.

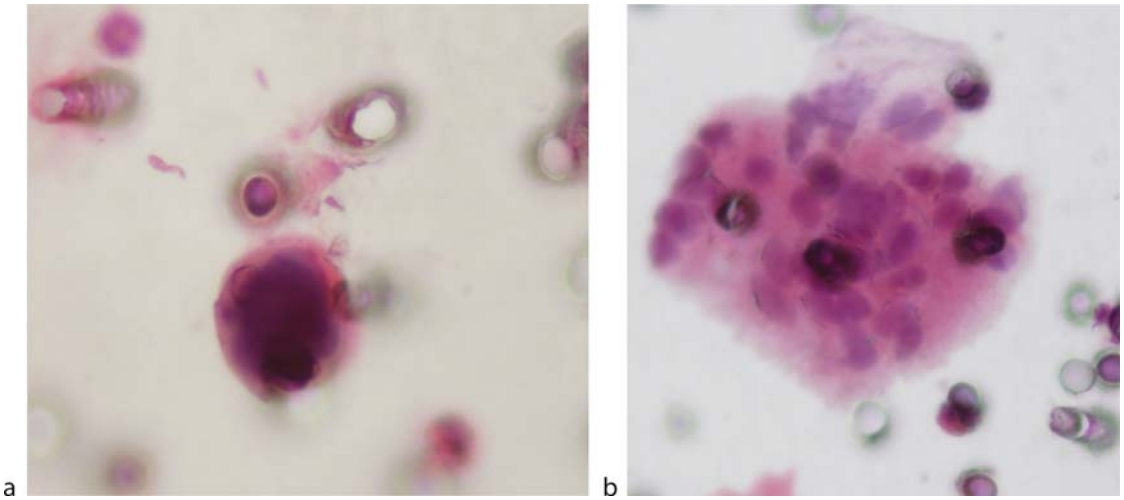
Tumor cells can also invade as multicellular aggregates or clusters (a process known as "collective tumor cells migration." Multicellular aggregates of tumor cells, also called circulating tumor microemboli (CTM), are thought to have potential advantages for survival, proliferation and establishment of micrometastatic lesions in distant organs. Actually, it has been shown that CTM may give rise to metastasis without extravasation, by attaching to vessel walls of arterioles and capillaries, and proceeding to cell proliferation within the vasculature, rupture of capillary walls, and formation of metastases (Fig. 2). Thus, it is generally accepted that the presence of CTM in blood is a marker of highly metastatic potential.

Once the target organ is reached, mesenchymal-like CTC may need to reverse to epithelial-like tumor cells via MET in order to regain the ability to proliferate.

The mechanisms involved in the preferential choice of a target organ for metastatic tumor cell proliferation (►"seed and soil" theory) are still not completely understood. Organ-specific attractant molecules (chemokines) can stimulate migrating tumor cells to invade the walls of blood vessels and enter specific organs.



Circulating Tumor Cells. Figure 1 Main steps leading to development of metastases. Growing tumor cells outstrip oxygen supply and activate angiogenesis. Invading tumor cells undergo the phenotype switch "epithelial to mesenchymal transition (EMT)": they progressively lose epithelial antigens, acquire mesenchymal antigens, and motile propensities (like fibroblasts). After entering blood vessels (intravasation), circulating tumor cells (CTC) undergo apoptosis or circulate as isolated CTC. After extravasation to distant organs, CTC remain as dormant solitary cells or undergo limited proliferation (micrometastases). Unrestrained CTC proliferation gives rise to metastases, via phenotype reversion "mesenchymal to epithelial transition (MET)" and angiogenesis. Circulating tumor microemboli (CTM) represent "collective tumor cell migration" of tumor cells. They cannot extravasate, but arrest in capillaries and proliferate, rupturing the capillary walls and giving rise to metastases.



Circulating Tumor Cells. Figure 2 CTC and CTM enriched by ISET. A CTC (a) from a patient with prostate cancer (hematoxylin and eosin staining, 100×), and a CTM (b) from a patient with kidney cancer (hematoxylin and eosin staining, 83×), enriched by ISET and detected by cytopathological analysis.

Tumor–endothelial interaction, appropriate adhesion molecules expressed by endothelial cells in distant organs, and local growth factors can drive matastatic tumor cell proliferation.

Convergent recent results have led to the present knowledge that invasion can be early and sometimes clinically dormant. Tumor cell dissemination may precede evident primary tumor outgrowth by many

years. The capacity to metastasize may be preordained by the spectrum of mutations acquired early in tumorigenesis, which means that some cancers start out "on the wrong foot." In fact, it has been demonstrated that cancer cells in the primary tumor may harbor a gene-expression signature matching that observed in the metastatic colony and that this signature can be used to predict, with high accuracy, whether the tumor will remain localized or whether the patient will experience metastases and disease relapse.

Epithelial cancer cells have very low survival rates in circulation. The fate of intravasated tumor cells includes a rapid phase of intravascular cancer cell disappearance. This process has been related to "anoikis." Many cancer cell types with increased metastatic potential are resistant to anoikis compared with the parental cells, a tumor cell behavior related to the expression of apoptosis inhibitors.

Animal studies, in which tumor cells are directly introduced into the systemic circulation, have established that around 1/40 CTC give rise to micrometastases and only approximately 0.01% proliferate into macrometastasis. This metastatic inefficiency is principally determined by CTC susceptibility to apoptosis, failure of solitary cells extravasated in distant organs to initiate growth, and failure of early micrometastases in distant organs to stimulate angiogenesis and continue growth into macromatastases. Both solitary cells and micrometastases may remain in "►dormancy" for years. The immune system and angiogenesis have been shown to play a role in tumor cell dormancy, although the mechanisms may be variable in different tumors and are not completely understood. Finally, it has been suggested that any factor that tips the balance between proliferation and apoptosis may result in tumor progression or regression.

CTC Detection and Characterization

The challenge of CTC/CTM detection is related to the requirement of high sensitivity combined with high specificity. Since invasion can start very early during tumor development, identification and counting of CTC when they are very rare (few CTC/CTM per 10 ml of blood, which means few CTC/CTM mixed with approximately 100 million leukocytes and 50 billion erythrocytes) could alert the oncologist about a developing tumor invasion process.

Specificity is also an absolute requirement in this field. In fact, a wrong identification of "nontumor cells" (like epithelial non tumor cells, for instance) as "tumor cells," could generate poor clinical and therapeutical choices having a negative impact on the quality and/or expectancy of life in patients with cancer.

Indirect methods to detect CTC do not provide a diagnostic identification of CTC. They target epithelial cells and/or use organ-specific markers which identify cells from organs but do not demonstrate their tumorous nature. These include immuno-mediated methods and RT-PCR (reverse transcriptase-polymerase chain reaction) methods. Since specific antigens or transcripts characterizing CTC are not known at present (antigens or transcripts which are expressed by all the tumor cells from a solid tumor type and not expressed by leukocytes or by other circulating nontumor cells), authors have used antibodies or transcripts specific to epithelial antigens or organ-specific antigens to identify CTC [for instance, EpCAM, BerEP4, Cytokeratins (CK)]. Epithelial-specific antibodies and transcripts can specifically detect nontumor circulating epithelial cells, or they can nonspecifically detect nontumor, nonepithelial circulating cells, thus giving false positive results. Invasive tumor cells tend to loose their epithelial antigens due to EMT process, and nontumor epithelial cells can also be present in blood. Finally, CTM cannot be reliably detected by immuno-mediated and RT-PCR approaches (as multiple cell labeling tend to dissociate tumor cell aggregates and RT-PCR methods destroy cell membranes). Thus, it appears that a reliable diagnostic identification of CTC and CTM cannot be based on the expression of epithelial-specific transcripts or antigens.

Direct methods, in particular density-gradient isolation and ISET (isolation by size of epithalial tumor cells), followed by cytopathological analysis, are meant to provide a diagnostic identification of CTC [1].

Given the important limitations of immune-labeling and RT-PCR assays, direct diagnosis of CTC/CTM can only be obtained, in a routine manner, by cytopathological analysis of the isolated cells. CTC characterization showing genetic abnormalities can provide clues to the tumorous nature of the cells detected by direct or by indirect methods. However, this approach is not feasible in a routine manner. Genotyping of CTC can be performed by FISH (fluorescence in situ hybridization) or by CGH (comparative genomic hybridization) directed to single tumor cells or pools of tumor cells. Analyses of oncogene amplifications (ex HER2) can be performed by FISH and/or by quantitative PCR after laser microdissection of CTC. Oncogene mutations can be recognized in cytopathologically validated CTC after laser microdissection. Immunolabeling is an interesting approach to characterize the invasive potential of CTC by assessing the expression of tumor markers (for instance HER-2, metalloproteinases, EGF-R, uPAR, alpha-fetoprotein) on enriched cells. However, FISH and immunological staining may have a certain rate of nonspecific labeling.

Detection of apoptotic cells [for instance by TUNEL (TdT-uridine nick end labeling) analysis] may be relevant before and after anticancer therapy, in order to assess the proapoptotic effect of therapeutic

programs. However, the method used to prepare the cells for analysis may induce apoptotic cell death in cells made fragile by blood storage, multiple manipulations, and magnetic particles.

Clinical Impact of CTC Detection

Several studies have shown the potential of CTC/CTM detection and counting in cancer prognosis and follow up. However, the clinical impact of CTC detection is not completely established because a substantial number of studies do not meet essential criteria for quality assurance, stressing the need for a gold standard assay. The definition of a standardized, uniform, cytopathologic method to specifically and sensitively detect CTC/CTM is crucial to perform large clinical trials focused on patients with different types of solid cancers at different clinical stage. These trials are expected to generate reliable results and provide guidelines to use the new marker in clinical oncology.

These assays are also expected to expand the knowledge of the invasion process and to generate new CTC data aimed at improving the patient's quality and expectancy of life.

Circulating Tumor Microemboli (CTM)

Definition

Synonym "collective tumor cells migration"; are multicellular aggregates or clusters of tumor cells. They have potential advantages for survival, proliferation, and establishment of micrometastatic lesions in distant organs.

►Circulating Tumor Cells
►Micrometastasis

Cirrhosis

Definition

Cirrhosis is a consequence of chronic liver disease characterized by replacement of liver parenchyma by fibrotic tissue and regenerative nodules, leading to progressive loss of liver function. Cirrhosis is most commonly caused by excessive consumption of alcohol and viral infections but has many other possible causes. Cirrhosis has a high mortality due to various complications.

CDDP; cis-Diamminedichloroplatinum; cis-dichlorodiammineplatinum(II); cis-Platinum II; DDP

Definition

Cisplatin is classified as a platinum compound and an alkylating cytotoxic agent. Much of our current understanding of the unique properties of ►platinum drugs has come from studies of cisplatin, especially its antitumor activity. The antitumor activity of platinum (II) complexes requires several unique chemical properties including the presence of chloride, bromide, oxalate, or malonate as leaving group and the neutral complex with inert carrier ligands such as NH_3 groups. Minor variations in the structure of these ligands may have a profound effect on the antitumor activity and toxicity of platinum compounds. The cis conformation is required for a complex to be a biologically effective agent and has significant cytotoxic properties while the trans isomer does not.

Characteristics

Since the discovery of the antitumor potential of cisplatin by Rosenberg and coworkers, therapeutic efficacy of cisplatin as an anticancer agent has been established in a variety of preclinical animal tumor models and in clinical human cancers. Cisplatin has now been one of the most widely used chemotherapeutic agents for treatment of many human cancers. The success of cisplatin in cancer treatment has been due to its many unique properties: a wide spectrum of antitumor activity against drug-sensitive as well as drug-resistant human tumors; a potent inhibition against tumors with varied proliferation and growth characters; effectiveness on both solid and disseminated tumors; and broad cytotoxic activity against viral-induced, chemical-induced, and transplantable tumors with no strain or species specificity.

Mechanisms of Action

The biochemical and biological properties of cisplatin rely on the relative ease of substitution of the chlorine ligands with nucleophilic species such as nucleic acid bases of a DNA strand. It is now widely accepted that cisplatin is similar to the bifunctional alkylating agents and its primary target is DNA. After cisplatin enters the cells, the chloride ligands are replaced by water molecules. This reaction results in the formation of positively charged platinum complexes that form covalent bounds with nucleopholic sites on guanine bases in a DNA strand using intrastrand and interstrand cross-links and create cisplatin–DNA adducts. The most prevalent and unique form of cisplatin–DNA adducts is the 1,2-intrastrand cross-link that cannot form with the inactive isomer of ciaplatin, trans-DDP, suggesting that such an adduct might be responsible for the biological activity of cisplatin. Other platinum–DNA adducts form a distinct structural element that interacts with DNA differently. The formation of these DNA adducts disrupts DNA function and prevents DNA, RNA, and protein synthesis. Regulatory mechanisms that detect the abnormal DNA activate a chain of cellular response to correct or repair the faulty DNA and this ultimately leads to programmed cell death (►apoptosis). Cisplatin-mediated cell killing is believed to be cell cycle phase nonspecific, although there is now much evidence that it may be most effective in G1 phase. Cisplatin also has immunosuppressive, radiosensitizing, and antimicrobial properties.

Cisplatin and Cancer Treatment

Cisplatin is an effective chemotherapeutic drug against a wide spectrum of human cancers. It has been primarily used in the treatment of epidermoid carcinomas of the head and neck, lymphoma, nonHodgkin and Hodgkin disease sarcoma, mesothelioma, osteosarcoma, and adrenal carcinoma and of bladder, brain, and cervical, esophageal, gastric, lung, nasopharyngeal, ovarian, prostate, and testicular cancers. It has also proved to be of benefit in the treatment of other cancers of anal, kidney, liver, breast, penile, and thyroid and of choriocarcinoma, lymphomas, and melanoma. The effectiveness of ciaplatin is however mostly due to the inclusion of other antineoplastic agents into the chemotherapy regimens. For example, such combination therapy of cisplatin along with vinblastine and bleomycin produces complete remission in more than 70% of patients with testicular cancers and substantially improves the survival rate of patients with ovarian cancer. This high success rate is mostly due to synergistic effects, where multidrug combination prevents the drug-induced resistance in tumor cells and, in addition, to the reduced toxic effects of the combination therapy with respect to the total toxicity of each equivalent single

agent. A marked therapeutic synergy has been shown in combination of cisplatin with a wide variety of other chemotherapeutic agents, such as 5-fluorouracil and cytarabine.

Cisplatin is supplied for clinical use as a lyophilized powder in vials that contain 10 mg of the drug, a diuretic, usually mannitol, and salt, or as a 1 mg mL^{-1} aqueous solution. The powder is reconstituted with sterile water to a concentration of 1 mg mL^{-1} and followed by further dilution with saline for intravenous (i.v.) administration. The standard method of administration of cisplatin is as a single slow i.v. injection or infusion every 3–4 weeks. Recently, cisplatin has been shown to be more effective when given locally to the site of the tumors. The most common method is intraperitoneal (i.p.) administration and this type of therapy is most effective for ovarian cancers. The specific dose of cisplatin will vary from patient to patient and depends on a number of criteria.

Cisplatin-Induced Resistance

Even though cisplatin has proven to be a highly effective chemotherapeutic agent for treating various types of cancers, one of the significant limitations toward the successful treatment of malignant cancers with cisplatin and other platinum-based drugs is the emergency of drug resistance. Drug resistance has significant clinical implications and accounts for the failure of a single platinum agent-mediated chemotherapy in curing the majority of cancer patients. When cells become resistant to cisplatin, a large dose escalation has to be applied, which can lead to severe multiorgan toxicities such as failures of the kidneys and bone marrow, intractable vomiting, and deafness. Cellular resistance to these drugs consists of complex mechanisms involving multiple biological pathways. The acquisition or intrinsic presence of resistance significantly undermines the curative potential of these drugs against many human malignant cancers. Although the precise mechanisms by which cells develop resistance to cisplatin are still not well known, several cellular processes have been identified or suggested attributing to invulnerability to cisplatin-induced cytotoxicicty.

Inhibition of Drug Uptake and Decreased Intracellular Accumulation

In order for cisplatin to exercise its cytotoxic effect on tumor cell, it must be taken and accumulated inside of cancer cells to reach and bind to the DNA and cause cell death. The cancer cell, however, has to develop mechanisms either to keep cisplatin out of the cell or to remove cisplatin from the cell to survive. Alterations in cellular pharmacology, including inhibition of cisplatin uptake and reduced cisplatin accumulation by cancer cells, have been observed in numerous model systems and appear to be a major form of acquired resistance. An increase in the production of cellular thiols such as metallothione and glutathione has been shown to block the formation of cisplatin–DNA adducts and sequester cisplatin and remove it from the cell.

Increased DNA Repair

Cancer cells can also become resistant to cisplatin by an enhanced ability to remove cisplatin-DNA adducts and to repair cisplatin-induced ►DNA damages through an upregulated expression and activity of certain DNA repair proteins. For example, a nuclear protein called XPE-BF (xeroderma pigmentosum group E binding factor) has been shown to be upregulated early in the development of cisplatin resistance and be able to repair cisplatin damaging. Another example of a DNA repair protein that may be involved in the recognition of cisplatin damage is ERCC1, one of the essential components of the mammalian nucleotide excision repair (NER) pathway. A higher level of ERCC1gene expression is observed in cisplatin-resistant cells than in cells that are sensitive to cisplatin and in tumor tissues from patients who were clinically resistant to cisplatin therapy than those who responded favorably to the treatment. In addition, an increased level of ERCC1 expression was also found in patients who developed resistance after initial cisplatin treatment. More recently, it has been shown that an enhanced capacity to tolerate cisplatin-induced damage may also contribute to cisplatin resistance. Alterations in proteins that recognize cisplatin–DNA damage (mismatch repair and high-mobility group (HMG) family proteins) and in pathways that determine sensitivity to apoptosis may contribute to damage tolerance. Furthermore, tumor suppressor genes have also been linked to the ability of DNA repair to confer cisplatin sensitivity. Interruption of p53 ►tumor suppressor gene by dysfunctional mutations found in breast, ovarian, and lung cancer cells may increase tumor cells' sensitivity to cisplatin, possibly by a decrease in p53-mediated DNA repair. Recently, NPRL2, a novel tumor suppressor gene identified in human chromosome 3p21.3 region, has been suggested to be involved in DNA mismatch repair, cell cycle checkpoint signaling, and regulation of the apoptotic pathway. The loss of NPRL2 protein expression was significantly correlated to cisplatin resistance in human nonsmall cell lung cancer cells. However, it remains to be determined whether any of these mechanisms contribute significantly to resistance in the clinical setting. Ongoing biochemical modulation and translational correlative trials should clarify which specific mechanisms are most relevant to clinical cisplatin resistance. Such investigations have the potential to improve the ability to predict likelihood of response and should identify potential targets for pharmacological or molecular intervention.

Development of Cisplatin Analogs

Besides a remarkable therapeutic efficacy in a series of solid tumors and outstanding activity of cisplatin the platinum-based therapy is in part accompanied by a set of severe toxic side effects. Analogs or second-generation platinum drugs have being designed and developed to exhibit an exclusive tumor selectivity, enhance the efficacy, improve the toxicity profile, overcome resistance of the original drug, and to be able to be taken orally. Many second-generation analogs of cisplatin have been made. Some have been found to produce the same therapeutic effects as cisplatin but with lower required doses and reduced side effects. Three of these analogs are carboplatin, spiroplatin, and iproplatin. Carboplatin has proven to be the most useful of these three analogs and was approved by the FDA for the treatment of ovarian cancers and for first line lung cancer treatment. Carboplatin and cisplatin have been shown to form an identical type of adduct with DNA and have similar activities against ovarian and lung tumors but is less toxic to the peripheral nervous system and the kidneys. Carboplatin works in some cases when cisplatin has failed. The decreased toxicity of carboplatin and the activity of carboplatin against cisplatin-resistant tumors have led to greater use of carboplatin which has resulted in carboplatin becoming the greater moneymaker of the two drugs. In addition to carboplatin and other second-generation cisplatin analogs, several third-generation drugs have been synthesized and tested, such as platinum (IV) dicarboxylates. These analogs can be taken orally, a significant improvement over cisplatin which can only be administered intravenously. These new platinum complexes and their promising therapeutic strategies in terms improved accumulation and activation at the tumor site are demonstrating a stepwise approach toward the "magic bullet" to human cancer therapy.

c-Jun N-terminal Kinase (JNK)

Definition

JNK, also known as stress-activated protein kinase (SAPK), belongs to the mitogen-activated protein kinase (MAPK) superfamily, which transmits extracellular signals into the nucleus. In response to various environmental stresses, JNK is activated by dual phosphorylation on Thr183 and Tyr185 and in turn phosphorylates Ser63 and Ser73 in the amino terminal activation domain of c-Jun protein. The resultant phosphorylation enhances the transcriptional activity of c-Jun and its heterodimer ►AP-1.

Cladribine. Figure 1 Chemical structure of cladribine.

Definition

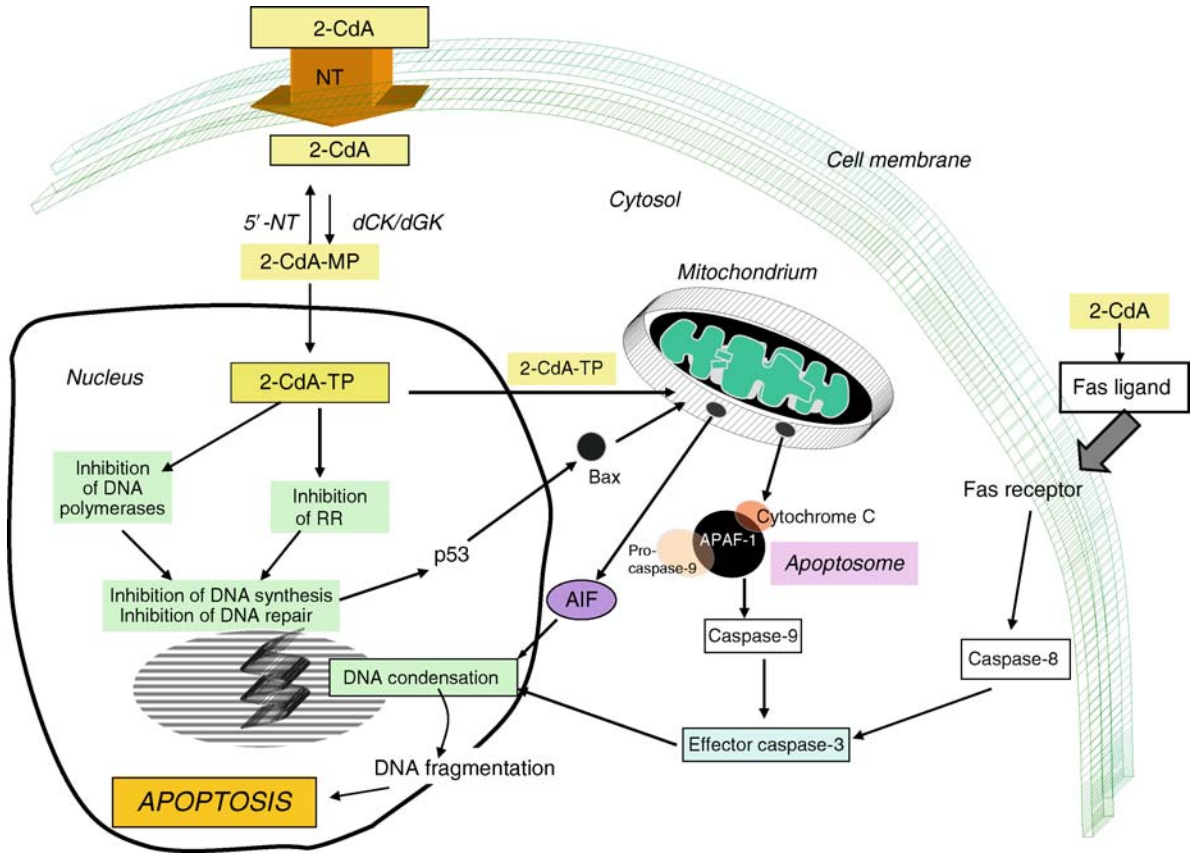
Cladribine is a purine nucleoside analog (PNA) synthesized by a simple substitution of a chlorine atom with a hydrogen atom at the position 2 of the purine ring of deoxyadenosine and resistant to deamination by adenosine deaminase (ADA) (Fig. 1).

Characteristics

2-CdA is a prodrug and its intracellular phosphorylation is necessary for cytotoxic effect to occur. It is phosphorylated by deoxycytidine kinase (dCK) and accumulates as 2-chlorodeoxyadenosine triphopsphate (2-CdATP). High activity of this enzyme in lymphocytes along with their low 5 nucleotidase (5′-NT) activity explains its relatively high selectivity for lymphoid cells. The nucleoside that is formed does not readily exit from the cells through the cell membrane and therefore is accumulated inside the cell. This metabolite disrupts cell metabolism by incorporating into the DNA of the actively dividing cells and freezes cell cycles at S phase. In contrast to other antineoplastic drugs, 2-CdA is cytotoxic to both proliferating and quiescent cells. In quiescent cells 2-CdATP interferes with proper repair of DNA and leads to a total disruption of cellular metabolism via accumulation of breaks in DNA strand, which in turn lead to p53 expression and consequently to induction of apoptosis. Apoptosis induced by 2-CdA can be mediated either via DNA damage and p53 protein expression or directly via mitochondrial permeability transition pore. Inhibition of DNA repair and accumulation of DNA breaks lead to p53 expression, which plays a key role in control of apoptosis and cell cycle and influences the bcl-2 protein family with antineoplastic properties ,as well as bcl-2 like proteins such as bax, bcl-xs and bak, which have proapoptotic action (Fig. 2).

Administration and pharmacokinetics

Clinical pharmacokinetics of 2-CdA have been evaluated in patients with lymphoproliferative diseases and acute leukemia. The drug is usually administrated



Cladribine. Figure 2 -Schematic presentation of cladribine (2-CdA) pathways. (2-CdA-MP-cladribine monophosphate; 2-CdA-DP-cladribine diphosphate; 2-CdA-TP cladribine triphosphate; dCK- deoxycytidine kinase; dGk-deoxyguanine kinase; 5′-NT - 5′- nucleotidase.

i.v. in a dose of 0.12–0.14 mg/kg/day for 5–7 days in continuous infusion or 2-hour infusion. Oral and subcutaneous method of administration can be also used. This routes result in substantial improvement of the quality of life in disorders that require repeated courses of treatment.

After administration of 2-CdA at a dose 0.14 mg/kg as a 2-hour i.v. infusion the mean maximum plasma concentration of the drug is 198 mol/L (range 70–381 mol/L). The steady-stage drug concentration during 24-h continuous infusion of 2-CdA at a dose of 0.14 mg/kg is 23 mol/L. The areas under the concentration time curves (AUC) are similar for both the 2-h (588 mol/L) and 24-h (552 mol/L) infusion. Following administration of 2-CdA at a dose of 0.12 mg/kg as a 2-h i.v. infusion or continous 2-hour infusion the mean cellular concentration of 2-CdA nucleotides are 12.2 mol/L and 10.8 mol/L, respectively. Cellular concentration of the drug exceeded plasma concentration 128 to 373 times. There is a linear dose relationship for 2-CdA between 0.2 and 2.5 mg/m^2/h and elimination followed by two compartment model. The two compartment model showed a half life (T1/2α) of 35 ±12 minutes and T1/2β of 6.7±2.5 h. The mean apparent volume of distribution (Vdr) is 9.2 ±5.4 L/kg.

Clinical activity

2-CdA was approved by the FDA for the treatment of hairy cell leukemia (HCL) and in some European countries for the treatment of refractory/relapsed chronic lymphocytic leukemia (CLL). Moreover several clinical trials continued the value of this agent in low-grade non-Hodgkin lymphoma (LG-NHL), Waldenström macroglobulinemia (WM), cutaneous T-cell lymphoma (CTCL), Langerhans cell histiocytosis (LCH) and systemic mastocytosis. 2-CdA has also some activity in acute myeloid leukemia (AML) and idiopathic myelofibrosis (IM).

1. *Hairy cell leukemia*. 2-CdA induces durable and unmaintained complete response (CR) in about 80% of patients with HCL after a single course

of therapy. However, patients in an apparent clinical and hematological remission following a single course of 2-CdA may have residual disease and 20–30% of them relapse at 10 years follow-up. However, 2-CdA may be equally effective in the reinduction therapy. Moreover, this agent may be also effective in patients with HCL who did not enter remission after splenectomy, interferon-α or even pentostatin.

2. *Chronic lymphocytic leukemia.* 2-CdA used alone or in combination with other cytotoxic drugs showed good efficacy and acceptable toxicity profile in CLL. The drug is more effective in the previously untreated patients than in the patients refractory to or relapsed after conventional therapy with alkylating agents. The overall response (OR) rate ranges from 75 to 85% and CR from 10 to 47% when 2-CdA is used in first line therapy. In the pretreated patients OR rate ranges first 30 to 70% and CR from 0 to 30%. The combination of 2-CdA with cyclophosphamide (CC), cyclophosphamide and mitoxntrone (CMC) or rituximab (RC) can be more effective than 2-CdA alone. ►Randomized studies indicate that 2-CdA alone and CC used as the first-line therapy give similar OR and CR and are of comparable toxicity as fludarabine alone or fludarabine combined with cyclophosphamide, respectively.
3. *Waldenström's macroglobulinemia.* 2-CdA is a reasonable choice for the first line treatment of WM patients. In this disease, 2-CdA has been shown to be active in 64% to 100% of the the previously untreated patients and 14% to 78% of the refractory or relapsed patients. The median time of response to this agent in the previously untreated patients varied between 13 and 28 months. The response rate is higher and the duration of response is longer when 2-CdA is given to the patients with primary refractory disease or to the patients relapsing of therapy rather than to the patients with the disease in resistant relapse.
4. *Cutaneous T-cell lymphoma.* 2-CdA showed some activity in advanced CTCL patients, including Sezary syndrome, and *mycosis fungoides*. This drug produces 25% OR in CTCL. However, high incidence of septic complications and significant treatment related mortality was observed.
5. *Other lymphoid malignancies.* 2-CdA showed remarkable activity in both previously treated and untreated patients with low grade non Hodgkin's lymphoma (LG-NHL). In relapsed/refractory LG-NHL the drug induced durable response with OR rates ranging from 36% to 56% and CR rates between 10% and 20%. 2-CdA is also effective in combination with alkylating agents and/or mitoxantrone in the treatment of refractory or relapsed advanced stage LG-NHL. High activity and low toxicity was reported in the patients with LG-NHL and mantle cell lymphoma treated with 2-CdA combined with rituximab (RC regimen) or rituximab and cyclophosphamide (RCC).
6. *Langerhans cell histiocytosis.* 2-CdA has a major clinical activity in both pediatric and adult patients with LCH. Clinical response was observed in 60–100% patients with a median disease free survival of 33–50 months. Combination with cyclophosphamide may be even more effective in the treatment of LCH.
7. *Systemic mastocytosis.* 2-CdA exerts cytotoxic and anti-apoptotic effect on mast cell leukemia derived cell line HMC-1 cells. Efficacy of 2-CdA in pretreated systemic mastocytosis patients has been reported, with partial response achieved in up to 75% of patients. This agent has a role in the treatment of symptomatic mastocytosis which is unresponsive to conventional therapy with interferon-α.
8. *Acute myeloid leukemia.* 2-CdA as a single agent is more active in pediatric AML than in adults. 2-CdA increases cell concentration of Ara-CTP which is active metabolite of cytarabine (Ara-C). The combined use of both agents is active regimen in the patients with AML. The addition of G-CSF may further improve the effects of 2-CdA and Ara-C (CLAG regimen). Even better results (50% CR) have been achieved in the refractory/relapsed patients when CLAG was combined with mitoxantrone (CLAG-M). Encouraging results with combination of 2-CdA, Ara-C and idarubicin have been also observed in previously untreated elderly AML patients (62% CR).
9. *Idiopathic myelofibrosis*. 2-CdA used alone was investigated in idiopathic myelofibrosis. Clinical and hematological response was seen in about 50% of patients with median response duration of 6 months.

Toxicity and adverse effects

The tolerability profile of 2-CdA is distinguishable from that of other cytotoxic agents. However, bone marrow suppression with prolonged thrombocytopenia, neutropenia and anemia is a common complication of this drug. Moreover the treatment with 2-CdA leads to a decrease in the CD4+/CD8+ ratio for an extensive period of time exceeding even 24 months. In consequence, infections, including opportunistic ones, are frequent events and infections with fatal outcome are reported. The most common infection complications arising from 2-CdA toxicity are respiratory tract infections with bacterial pathogenes and unexplained fever. Oportunistic infections caused by *Pneumocystic carini*, cytomegalovirus, herpes simplex virus, zoster

virus and mycobacteria are also observed. Some reports suggest that 2-CdA may induce autoimmune hemolytic anemia, especially in the patients with CLL. Prolonged immunosuppression related to 2-CdA treatment may increase the risk of the second malignancies.

Clark Level

Definition

Referring to the level of melanoma invasion, describing the maximal depth of melanoma cell penetration using the anatomical structures of the skin.

Clark Level I: melanoma cells are confined to the epidermis (and appendages); equivalent to melanoma in situ

Clark Level II: melanoma cells extending to the papillary dermis

Clark Level III: extension of the tumor cells filling and expanding the papillary dermis

Clark Level IV: invasion of the reticular dermis

Clark Level V: invasion of the subcutaneous fat

Although level of invasion has historically been shown to correlate with prognosis, its utility in staging primary cutaneous melanoma has been supplanted by Breslow depth, except for thin primary melanomas (i.e. up to 1 mm Breslow depth; AJCC/UICC T1) where both Clark level and Breslow depth are included.

Class II Tumor Suppressor Genes

Christine Sers
Institute of Pathology, University Medicine Charité, Berlin, Germany

Definition

Class II tumor suppressor genes encode proteins that function in the negative regulation of cell growth. The genes are downregulated in cancer without mutations or deletions in their coding regions. Downregulation is reversible indicating that gene and protein function can be reconstituted upon appropriate treatment.

Characteristics

The term "class II tumor suppressor gene" was invented in 1997 by Ruth Sager, who was the first to realize during the upcoming age of ►gene expression profiling that in human cancers many genes show reduced expression in tumors without being deleted or mutated. Accordingly, two classes of tumor suppressor genes were suggested: Class I tumor suppressor genes (►tumor suppressor genes, TGS) that are lost in cancer due to mutation or deletion and class II tumor suppressor genes that are not altered at the ►DNA level, but rather exhibit strongly reduced expression in tumors as compared with normal tissue.

Examples for classical, bona fide class I tumor suppressor genes are *Rb, p53,* or *WT1*. These genes are found frequently deleted or mutated in the large majority of human cancers. A list of class II tumor suppressor genes that have been identified today are summarized in Table 1 and harbor well-defined genes such as *Thrombospondin* (*THBS*), *H-REV107-1*, and ►*maspin*.

Evidence for a Class II Tumor Suppressive Activity

Due to the reversible nature of class II tumor suppressor gene regulation, their expression levels may vary during tumor development. This is in sharp contrast to class I tumor suppressors and renders the functional characterization of class II genes challenging. The suppressive impact of a given class II tumor suppressor gene might depend on the tumor type and even more on tumor stage and on the underlying genetic alterations. *H-REV107-1* and *maspin* are two class II tumor suppressors, which have been characterized extensively. *H-REV107-1* is downregulated in ovarian cancer and acts as a growth suppressor in vitro and in vivo by inducing ►apoptosis in ►ovarian carcinoma cells. No mutations with the *H-REV107-1* gene have been detected in ovarian tumor samples and overexpression or induction of the gene by interferon γ stimulates apoptosis. Also the mechanism

Class II Tumor Suppressor Genes. Table 1 List of characterized class II tumor supppresser genes involved in negative growth regulation in human tumors

Tumor suppressor gene	Gene function	Cancer type	Mechanism of inactivation
Maspin	Serine protease inhibitor	Breast	Transcriptional repression P53 loss
ING1-4	HDAC/HAT cofactor	NSCLC, breast	Unknown
RNASet2	Secreted glycoprotein	Ovary	Unknown
RARRES3 (TIG3)	Signaling regulator	Colon, ovary	Unknown
H-REV107-1 (HRSL3)	Signaling regulator	ovary	Loss of IRF1
THBS1	Angiogenesis inhibitor	Prostate, ovary	Transcriptional repression by ATF1 or Id1
Tropomyosin	Microfilament compo-nent	Breast	Methylation
Gelsolin	Actin binding	Ovary, breast	Chromatin modification lack of ATF1 binding
CAV1	scaffold protein	Ovary	Unknown
RASSF1	Negative RAS effector	Various	methylation
LOX	Extracelullar cross-linker	Skin, breast	Loss of IRF1, methylation
RARRES1 (TIG1)	Unknown	Prostate, lung	Methylation
PRSS11 (HtrA)	serine protease	Melanoma, ovary	Unknown
KLK10	Secreted serine protease	Breast, testis, ovary	Methylation

of H-REV107-1 action as a signaling regulator indicates that its downregulation is necessary to enable antiapoptotic signaling in ovarian carcinoma. Thus, for the *H-REV107-1* gene, evidence for its class II tumor suppressive nature comes from several studies investigating expression and regulation in vitro an in vivo, as well as mutational and functional analysis. In a similar way, the ►serine protease inhibitor (serpin) *maspin,* originally identified as being downregulated in human breast carcinomas, was characterized. Maspin exerts a number of different functions inside and outside the cell and downregulation of the gene is achieved by various mechanisms in human carcinomas. Maspin inhibits invasion and ►angiogenesis probably by interfering with cytoskeletal signaling thereby altering components of the cytoskeleton. Maspin was also shown to hamper the migration of cultured endothelial cells upon VEGF chemoattraction and to sensitize both tumor and endothelial cells for drug-induced apoptosis.

Class II Tumor Suppressor Identification

Different paths of identification have been used for class I and class II tumor suppressor genes. Class I tumor suppressors are usually localized in critical chromosomal regions often found deleted in cancer. In contrast, most class II tumor suppressors were recognized during large-scale expression profiling as being downregulated in tumor cells and tissues. They light up in approaches such as ►differential display, ►subtractive hybridization, and ►DNA microarray analysis. In addition, some class II tumor suppressors where identified as being encoded in mutational hotspots without directly comprising a target for deletions and mutations in a given tumor. Further proof that an individual gene identified during such an approach is a true class II tumor suppressor requires careful analysis of the genomic sequence and functional analysis of the mechanisms of suppression and function of the protein. Interestingly, high-throughput screening also revealed that the transition between class I and class II tumor suppressors is a smooth one. Canonical tumor suppressor genes such as *BRCA1* and *WT1*, frequently inactivated by mutation in hereditary breast cancer and Wilms' tumor, respectively, can be suppressed by nonmutational mechanisms in sporadic carcinomas and thus turn into class II tumor suppressors in these cancer types. Distinct class II tumor genes, e.g., ING-family members, are inactivated by missense mutations in one cancer type, but lost by downregulation in another cancer type. Therefore, it will be more precise in the future to define a class I mechanism (mutation, deletion) or a class II mechanism (transcriptional or functional inactivation) for an individual tumor suppressor gene in a defined tumor type.

Mechanisms of Inactivation

For the majority of class II tumor suppressors the precise mechanism of downregulation has not been elucidated. However, it has become clear that often alterations in upstream ►signaling cascades and transcriptional regulatory complexes can finally result in the loss of downstream gene expression. Oncogenic signaling pathways emerging from overexpressed ►receptor tyrosine kinases like ►*HER2* and from cytoplasmic oncoproteins such as ►RAS have been shown to suppress class II tumor suppressors in a

reversible manner. Differentiation signals emerging from hormone and vitamin receptors can normally stimulate the expression of class II tumor suppressors such as *RARRES3* and *TIG1* but are lost in cancer cells. Also, deregulation of ►microRNAs might be one mechanism for class II tumor suppressor inactivation. Several class II tumor suppressors, e.g., *CAV1, maspin, THBS1*, have been identified as p53 target genes. *P53*, a bona fide class I tumor suppressor, acts as a transcriptional regulator and belongs to the most frequently lost suppressor genes in human carcinomas. It is evident that loss of p53 entails a loss of targets genes, some of which act themselves as tumor suppressors. For the *maspin* gene, active suppression through a ►hormone-responsive element and lack of transactivation have also been detected. Likewise inactivation of the interferon-responsive transcription factor 1 (►IRF1) was found to determine loss of the *H-REV107-1* class II tumor suppressor involved in the induction of apoptosis in human ovarian carcinomas. In addition, aberrant localization of the maspin protein was found to account for altered function. In ovarian carcinoma, only cytoplasmic maspin localization is associated with poor prognosis, while nuclear maspin was found in less aggressive carcinomas, suggesting a tumor suppressive role of only nuclear maspin. A frequent class II mechanism for gene inactivation is chromatin modification such as ►histone methylation, ►histone acetylation, and DNA ►methylation and a number of class II tumor suppressors, e.g., *RASSF1*, *tropomyosin,* or *TIG1* are suppressed via DNA methylation.

Clinical Relevance

Class II tumor suppressors offer novel therapeutic opportunities because they are present as wild-type alleles in cancer cells. Like class I tumor suppressors, class II tumor suppressor genes are involved in the regulation of apoptosis, cell signaling, differentiation, invasion, and metastasis. As one example, the serine protease inhibitor maspin could be induced by the breast cancer drug Tamoxifen, thereby contributing to the metastasis suppressing effects of the drug. Due to the variety of different mechanisms involved in class II tumor suppressor gene inactivation, therapeutic importance is currently under investigation for most of the class II tumor suppressors. However, the reconstitution of proapoptotic or immune-modulatory properties through interference with chromatin modification and DNA methylation in tumors has already entered clinical trials and will be improved in the near future.

Class III Histone Deacetylases

►Sirtuins

Class Switching

Definition

Class switching is a process by which the rearranged variable region from an immunoglobulin heavy chain gene is brought into the vicinity of a constant region gene other than IgM or IgD. Typically the intervening DNA between the variable region and the downstream constant region is lost during this recombination.

►B-cell Tumors

Classifier

Definition

Artificial predictive model utilized to assign samples to different categories (classes).

►Supervised Classification

Clastogen

Definition

Is a material which is capable of causing breaks in chromosomes leading to deletions or rearrangements of the chromosomes. This is one of the forms of mutagenesis and can lead to tumorigenesis.

►Micronucleus Assay

Clastogenesis

Definition

Any process that leads to breaks in chromosomal material, or rearrangement, gain or loss of pieces of chromosome.

►Genetic Toxicology

Clathrin

Definition

The major structural component of coated pits constituted by a larger, ~190 KDa protein, the clathrin heavy chain, which is complex to a smaller (~25 KDa) subunit, the clathrin light chain. Heavy–light chain dimers can further assemble into complexes called triskelions, which represent the building blocks of the polygonal array that constitutes the organizing scaffold of a pit.

►Endocytosis
►Huntingtin Interacting Protein 1 (HIP1)

Clathrin-mediated Endocytosis

►Endocytosis

Clear Cell Sarcoma of Soft Tissue

Definition

Sarcoma occurring in young adults, showing melanocytic differentiation and typically affecting the tendons and aponeuroses. It has a nested to fascicular growth pattern, with epithelioid or spindle cells positive for melanoma markers.

►Uncertain or Unknown Histogenesis Tumors

Clear Cell Sarcoma of the Kidney (CCSK)

Definition

Highly malignant childhood renal tumor, often with a polymorphic and challenging histology. Untreated CCSK metastasizes to the bones and lung, recently brain metastases have been reported in patients treated with chemotherapy. Since the introduction of new drugs in the standard treatment, such as cyclophosphamide, doxorubicin, etoposide, and carboplatin, prognosis is improving.

►Mesoblastic Nephroma

Clearance

Definition

The volume of a specific compartment (such as plasma) completely cleared of a specific compound per unit time. Renal clearance refers to the volume of plasma cleared via the kidneys and is measured as a test of kidney function. After intravenous infusion, the clearance of a drug is calculated.

►Irinotecan

Cleavable Complex

Definition

Is the covalent interaction between DNA and the nuclear enzyme topoisomerase I.

►Irinotecan
►Topoisomerases

Clinical Cancer Biomarkers

Martin Tobi
Section of Gastroenterology, Detroit VAMC, Detroit MI, USA

Synonyms

Tumor markers; Biological markers; Surrogate endpoints

Definition

A biological analyte that serves as a tool to answer clinically relevant management issues regarding a specific cancer disease.

Characteristics

The analytes must be measurable qualitatively or quantitatively and they may be a biological substance or a process that is dynamically based on a specific tumorigenic pathway. They may occur at the molecular, cellular, or somatic level and should have the ability to detect and thereby reveal sentinel events impacting health outcome with respect to carcinogenesis. They may emanate from the cancerous process itself or the host reaction to the various processes involved in the cancer pathway. The analytes can be measured in a variety of bodily fluids such as blood, saliva, urine, breast fluid, colonic effluent (stool or washings), and sputum or other fluids relevant to the specific cancer disease. There is a current attempt worldwide at standardization of objective assays by criteria such as levels of evidence that attempt validation for innumerable marker candidates.

Diagnostic Tumor Markers

These markers can be applied over the continuum of carcinogenesis from premalignancy to metastatic cancer. While risk markers such as carcinogen-►adducts to DNA are classical risk biomarkers, for example, in ►smokers at risk for ►lung cancer, none have been conclusively validated for utility in individuals at risk while others such as ►adenomatous colonic polyps have been well established in ►hereditary cancer syndromes as well as in sporadic ►colon cancer carcinogenesis. Risk markers and early detection screening markers share the same endpoint for cancer detection but the expectation for accuracy (see formula) differs in that risk markers are not expected to be as accurate as screening markers.

$$\text{Sensitivity} = \frac{\text{True positive}}{\text{True positive} + \text{false negative}} \times 100$$

However both are dependent on the prevalence of the disease in the population being tested. Only two markers are approved for clinical screening in asymptomatic individuals, having been validated using criteria for sensitivity, specificity, accuracy, positive and negative predictive value (see formula) in a prospective manner in multiple clinical trials internationally; the stool-based ►fecal occult blood test (FOBT*)* and the serum-based ►prostate specific antigen (PSA).

$$\text{PPV} = \frac{\text{Prevalence} \times \text{sensitivity}}{(\text{Prevalence} \times \text{sensitivity}) + ([1 - \text{prevalence}] \times [1 - \text{specificity}])}$$

Though neither fulfills the ultimate optimal screening test criteria for cost-effective reduction of overall mortality, FOBT has been shown to reduce disease-specific mortality significantly. FOBT is a qualitative test performed on guaiac-impregnated paper that utilizes the peroxidase activity of hemoglobin to effect a resultant blue color change when an appropriate reaction solution is applied. The hemoglobin in the stool is derived from tumors where a tendency to bleed raises the baseline gastrointestinal blood loss tenfold but clearly cannot differentiate from other endogenous or exogenous dietary sources of hemoglobin. The chance of cancer being discovered on a follow-up ►colonoscopy in the individual patient with any one positive result from two smears each from three consecutive stools is 2–5%. PSA is a serine protease ►kallikrein and is measured by a quantitative immunoassay performed on serum from the blood circulation containing PSA that is secreted by prostatic ductal and acinar cells. PSA functions as a liquefying agent in ►prostate cancer tissue. It is mostly complexed to ►serum proteases or as a minority free PSA form (5–35%). Although the prostate is the major source, other tissues may also secrete PSA such as endometrial, breast, adrenal, or renal tissues. In the individual patient with a test result of >4 ng/ml the chance of cancer as detected by prostatic transrectal, ►ultrasound-guided biopsy is 25–30%. A variety of diagnostic cancer markers are commonly used to complement other clinical diagnostic modalities and some of these may also have prognostic utility, and are available for different cancer types. The ultimate goal of screening is to detect early disease that is amenable to effective treatment ideally demonstrated by efficacy in prospective, randomized trials.

Prognostic/Predictive/Markers

►Prognostic markers are expected to discriminate between patients in predicting a variety of better or worse prognostic outcomes (overall or disease-specific mortality, time to recurrence of disease) independent of treatment and are usually arrived at because of an association with the tumorigenic process under consideration. Predictive markers relate directly to the outcomes of specific therapeutic interventions but many markers may share prognostic and predictive qualities. The optimal marker is one that influences the disease management to improve the clinical outcome although other outcomes such as cost benefit or quality of life may also be evaluated. Prognostic markers are usually compared to traditional clinical prognosticators such as pathologic stage of the disease and ►grade

of tumor. In order to broaden the application of a marker the measurement assay should be simple and reproducible. ►Multivariate analysis statistical analysis of data from retrospective or prospectively trials is the standard for identifying markers as independent prognostic/predictive indicators. The best studied examples of such markers are in the field of ►breast cancer.

Examples of prognostic makers in this clinical scenario are ►estrogen receptors (ER +), ►progesterone receptors (PgR +), and the two components of the ►urokinase-type activation system, the activator (uPA) and activator inhibitor type-1 (PAI-1). The presence of the former two are associated with a better prognosis while patients with low levels of the two latter markers have significantly better survival than the patients with the converse pattern. All these markers are currently in clinical use but the models used to stratify risk differ in that some professional bodies such as the International Consensus Panel on the Treatment of Primary Breast Cancer as of 2003 were using ER + and PgR + status as part of their strategy to designate low risk patients as opposed to the Eastern Cooperative Oncology Group which uses ER + but not PgR +. These models contrast with the expert panel of the American Society of Clinical Oncology which uses neither in their model. The widely used ►Nottingham prognostic index, a model based mainly on pathological parameters, has been validated. Much effort has been invested to complement this system with other markers such as ►*Her-2* and markers of ►angiogenesis. With respect to predictive markers, those that display a treatment by marker interaction quality in predicting response to a specific treatment are likely to be adopted into clinical practice. The ►c-erbB2 marker may be predictive in selection of specific ►adjuvant therapy strategies. Statistical analyses used to evaluate any model also have limitations as significance may not necessarily translate into clinical utility. Lactate dehydrogenase serves as one of the important prognostic marker for ►lymphomas and is a surrogate of tumor burden. Cytogenetic analysis and/or fluorescent in situ hybridization is prognostic of outcome in acute leukemias and other ►hematologic malignancies.

Surrogate/Monitoring Markers

►Surrogate markers are technically surrogate endpoint markers and confer a reasonable likelihood of predicting clinical benefit for a particular therapeutic intervention. The validation measures are accuracy and reproducibility within a controlled study design. Classically, these markers are used to provisionally evaluate a new intervention. A successful outcome in the measured marker favoring the said intervention confers an expectation that future supporting evidence for positive clinical risk:benefit ratio will evolve. Often, a single marker may not account for all observed treatment effects and a battery of markers directed at various components in the tumorigenic pathway may be required. The major advantage of this category of markers is that measuring the effect of an interventional agent with a final conventional endpoint may involve a very large population and many years of follow-up. An example is the use of the chemopreventive effect of acetyl salicylic acid (►aspirin) on ►colorectal cancer. Most studies employ a surrogate endpoint marker represented by a reduction of colorectal adenomatous polyps at the end of a designated follow-up period. In this setting, the adenomas substitute for the ultimate hard endpoint of invasive cancer. Monitoring markers gauge the response to a specific therapy by a parallel change in marker levels with measurable tumor volumes. Alternatively, these monitoring markers may detect occurrence and extent of recurrent disease after primary treatment that may allow for timely institution of secondary treatment modalities but may also be used as surrogate endpoint markers with the same therapeutic intent. Examples are alpha-►fetoprotein and human chorionic ►gonadotropin-beta in ►germ cell tumors (pretreatment levels of which also serve as prognostic markers); ►carcinoembryonic antigen (CEA) and ►CA19-9 in gastrointestinal cancers; and CA125 in ovarian tumors. However, despite their popular use, little actual objective survival benefit has been demonstrated.

Miscellaneous Markers

Emerging markers of tumor metabolism have emerged that utilize ►stable epitope-based dynamic metabolic profiles (SIDMAP). These strategies take advantage of unique anabolic changes induced by protein kinase activation resulting in the preferential nonoxidative utilization of glucose in the pentose cycle for nucleic acid synthesis. This can be used in the development of drugs that impact on protein kinases and effector targets. The most practical expression in clinical practice is the use of the ►positron emission tomography (PET) scan for the monitoring of response to cancer chemotherapy. Assays of tumor ►hypoxia have shown an adverse effect on response to radiotherapy. Oxygenation can be measured directly or by endogenous markers such as ►hypoxia-inducible factor 1 alpha (HIF-1alpha) where overexpression has been shown to confer an adverse outcome suggesting a role for specific hypoxia related treatment.

Clinical Pathology

Definition

The study by laboratory techniques of body fluids or tissue extracts in disease diagnosis.

►Molecular Pathology

Clinical Studies

Definition

Describe the three phases of clinical study in humans: phase I safety/toleration; phase II early efficacy and phase II definitive efficacy studies.

►ADMET Screen

Clinical Trial

Definition

Refers to the administration of a prospective new drug or therapy to human subjects in a controlled fashion to determine whether the drug or therapy is sufficiently safe and effective to warrant its approval for general medical practice. Typically, clinical drug trials are conducted in three successive phases with increasingly larger test populations: a phase I trial to determine the safe limits of a new drug, a phase II trial to determine whether a new drug is therapeutically effective and to establish its effective dose, and a phase III trial to determine how the effectiveness of the new therapy compares to the existing standard of care and to assess any unexpected adverse effects in the general population.

CLL

►Chronic Lymphocytic Leukemia

CLN

►Conjugated Linolenic Acids

Clonal

Definition

Clonal is an adjective used to describe a group of cells, or an organism that is descended from and genetically identical to a single common ancestor. Malignancies or cancers are usually clonal diseases.

Clonal Proliferation

Definition

Clonal proliferation describes the selection and reproduction of only one type of cell.

►Acute Myeloid Leukemia

Clone

Definition

Cell population derived from a single progenitor. It is common practice in tumor cytogenetics to infer a clonal

origin when a number of cells have the same or closely related karyotypic characteristics. Since subclones may evolve during the development of a neoplasm, clones are not necessarily completely homogeneous.

►Laryngeal Carcinoma

Clonogenic Survival Assay (CSA)

Definition

An assay used to determine the number of cancer cells that retain the ability to divide a sufficient number of times to form a macroscopic colony (typically >50 cells) after treatment or experimental manipulation. Cells are plated in culture dishes and stained colonies are counted ~1–2 weeks later. Clonogenic capacity is usually expressed as the surviving fraction which is the plating efficiency of treated cells divided by the plating efficiency of untreated control cells subjected to the same assay. Plating efficiency is defined as the number of cells counted/number of cells originally plated. The clonogenic assay is particularly useful in cancer research as it integrates many forms of cell death (necrosis, mitotic catastrophe, apoptosis) into one end point critical for cancer therapy – that of continued reproductive capacity.

►Three-Dimensional Tissue Cultures

Clonorchis Sinensis

Definition

Is a human liver fluke in the class Trematoda, Phylum Platyhelminthes. This parasite is found mainly in the common bile duct and gall bladder and feeds on bile. The parasite is endemic to Japan, China, Taiwan, and Southeast Asia.

►Bile Duct Neoplasms

Cluster of Differentiation 44

►Adipose Tumors

Cluster of Differentiation (CD) Molecules

Definition

Cluster of differentiation molecules are cell surface targets on leukocytes (and other cells) recognized by specific sets of antibodies (designated CD-plus a number).

►CD Antigens

Clustering

Definition

A statistical method for identification of patterns that may be similar.

►CD Antigens

CMC

Definition

Complement-mediated cytotoxicity.

►Immunoprevention of Cancer

CMF

Definition

Combination of three cytotoxic drugs: Cyclophosphamide, methotrexate, and fluorouracil.

Coagulation Pathway

Definition

(i) Extrinsic pathway. During coagulation, tissue factor (TF) binds factor VIIa (FVIIa), and the TF-FVIIa complex interacts with factor X (FX) to form active factor Xa (FXa). FXa then interacts with factor Va (FVa), a cofactor for FXa-mediated conversion of prothrombin to thrombin. Thrombin in turn is able to cleave fibrinogen, resulting in fibrin clot formation. (ii) Intrinsic pathway. The intrinsic pathway is triggered by exposure of blood to collagen underlying damaged vessels, and begins with the conversion of FXII to FXIIa, which is catalyzed by kallikrein and kininogen. This conversion then initiates a cascade of events involving activation of FXI, FX and converging with the extrinsic pathway and the FXa-dependent conversion of prothrombin to thrombin.

►Proteinase-Activated Receptors

Coagulopathy

Leo R. Zacharski[1,2], Cocav A. Engman[2]
[1]VA Hospital, White River Junction, VT, USA
[2]Department of Medicine, Dartmouth Hitchcock Medical Center, Lebanon, NH, USA

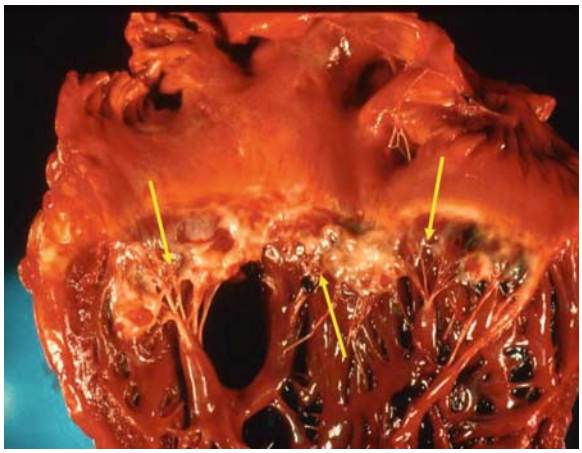
Definition

The changes in pathways of clot formation and lysis, and their interactions with cells and tissues that precede or accompany cancer.

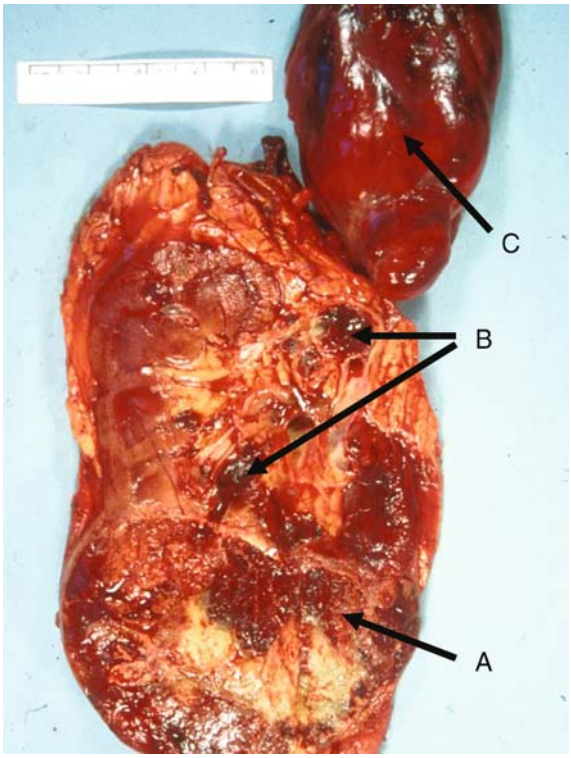
Characteristics

Blood coagulation dyscrasias have been linked to cancer for centuries. Tumor regression with leeching, and bleeding and thrombosis complicating malignancy were among the early cues to an elegant but ruinous cybernetics. In 1867, Trousseau described "painful edema" (deep vein thrombosis, DVT) with both established and as yet undiscovered malignancies. The common occurrence of venous thromboembolism (VTE) with cancer signals poor survival and is a common cause of death in cancer patients. Compression of veins and organ damage by tumor masses, superimposed infection, surgery, radiation therapy, chemotherapy, hormonal therapy, growth factor/cytokine administration and anti-angiogenic therapy predispose to cancer-related thrombosis. Cancer-related thrombotic syndromes besides VTE include non-bacterial thrombotic (marantic; pertaining to wasting disease) endocarditis (Fig. 1), microangiopathy, migratory superficial phlebitis, arterial thromboembolism and Raynaud's phenomenon. Renal cell carcinoma is famous for thriving in a clot in the renal vein and inferior vena cava (Fig. 2). Tumor cells having procoagulant properties may activate coagulation in the adjacent pericellular matrix (►Fibrinogen). More often, heightened cytokine and growth factor expression that mediates malignant growth also triggers host macrophage- or endothelial cell-initiated coagulation activation locally and systemically. In contrast to the physiologic hemostatic response to injury, coagulation activation with malignancy is inexorable (in the absence of intervention) and incapable of self-attenuation; Dvorak's "wound that does not heal."

Laboratory tests of coagulation activation are a sensitive indicator of future cancer risk; abnormalities are virtually universal in established malignancy and signal poor prognosis. Systemic coagulation activation is typically triggered extravascularly by the ►tissue factor-initiated or "extrinsic" (the inciting agent resides on cells and tissues apart from plasma protein coagulation factors) pathway. The more sensitive the test in an up-stream direction in the coagulation pathway, the more likely the test will be abnormal.



Coagulopathy. Figure 1 Non-bacterial thrombotic (marantic) endocarditis of the mitral valve in a patient with gastric carcinoma. Arrows indicate pearly white fibrin vegetations on valve edges.



Coagulopathy. Figure 2 Resected kidney showing: (a) renal cell carcinoma originating in the lower pole; (b) growth of the tumor into the venous drainage to become (c) a tumor thrombus extracted from the inferior vena cava.

Triggering of systemic coagulation activation leads to increased turnover of platelets and fibrinogen (disseminated intravascular coagulation, DIC) in malignancy (Fibrinogen, ►plasminogen-activating system). Early subliminal DIC may be "compensated" when production equals destruction leading to normal levels of both. Worsening DIC becomes "over compensated" and elevated levels of platelets and fibrinogen are common with cancer. The physiologic attempt to resolve injury is subverted resulting in paradoxical promotion of the "wound." Severe DIC may "decompensate" when production no longer meets demand resulting in low platelet and fibrinogen levels (the defibrination syndrome). Bleeding and/or multi-organ failure may follow. Symptomatic DIC may be the first manifestation of a small, as yet undiscovered tumor because of systemic effects of thrombogenic cytokines (eg, IL-1, TNF alpha).

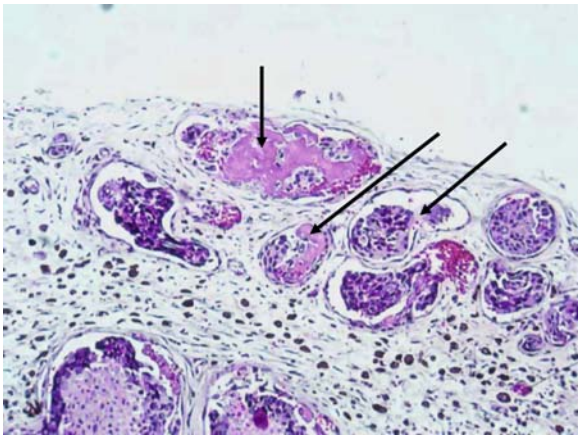
Cancer-related bleeding can occur because of consumption of coagulation factors and platelets due to DIC, but also because of hyperviscosity syndrome, inhibitors of specific clotting factors, and ITP-like thrombocytopenia. Notable changes in coagulation tests include thrombocytosis, the "lupus anticoagulant," heparin-like anticoagulants, and the presence of ►cryofibrinogen. Levels of ►d-dimer predict more advanced disease and reduced cancer survival (Plasminogen-activating system). The ability of low molecular weight heparin (LMWH) treatment to suppress d-dimer levels in advanced malignancy may mark the anti-tumor activity of this class of drugs (►Heparanase, ►heparanase inhibitors).

The inciting force for coagulation activation can exist long before cancer is evident (►Cancer causes and control). Evaluation of patients with DVT for occult malignancy is indicated when no obvious hereditary or acquired (for example, recent surgery, trauma, pregnancy, etc) cause exists. The probability of malignancy within two years of an episode of unexplained (idiopathic) DVT approaches 10% and is higher when DVT is bilateral or recurrent. The history, physical examination (including pelvic examination) and routine laboratory testing with chest X-ray are crucial for evaluating DVT patients at risk for occult malignancy, and re-examination at 6-month intervals for at least two years is appropriate. Tumor markers, abdomino-pelvic scanning, and sometimes cytologic and endoscopic procedures aid discovery of occult disease. Chances of detecting cancer increase with patient age (►Aging and cancer), and a variety of tumor types may be discovered. The old dictum that malignancy discovered on evaluation of a sentinel DVT is untreatable or inoperable is false.

Heparin followed by maintenance warfarin is standard of care for cancer-associated VTE but thrombosis may recur despite "adequate" warfarin anticoagulation. Warfarin control may be precarious due to drug interactions, poor nutrition, compromised liver function due to metastatic disease and other factors. LMWHs that can be self-injected at home allow dose adjustment and more stable anticoagulation in difficult patients, and reduce the risk of DVT recurrence. Use of LMWHs is expected to increase as more clinical trials show they improve cancer survival.

The coagulation mechanism and cancer share metabolic traffic patterns that regulate not only clot formation and dissolution (Plasminogen-activating system) but also tumor growth. Many molecules that participate in coagulation reactions also support tumor cell proliferation, angiogenesis, invasion of extracellular matrix, and metastatic dissemination (Fig. 3) (►Metastasis). A half-century of studies in animal models of malignancy have shown that virtually any manipulation of the coagulation mechanism will alter tumor behavior. However, perplexing variability in response to such interventions signals important differences in mechanisms between tumor models.

Viewing malignancy as a "solid phase coagulopathy" provides insights into regulation of malignant transformation and the aberrant behavior of transformed



Coagulopathy. Figure 3 Tumor cell thrombi in the meningeal microvasculature (arrows) of a patient with metastatic carcinoma.

cells. Platelets are traveling packets of growth factors that "deliver the goods" to sites of vascular invasion by tumor and that enhance metastasis by linking tumor cells to endothelium. Fibrinogen and fibrin in the tumor matrix impart cohesion and induration to tumor masses and provide a scaffolding for tumor cell growth and angiogenesis (Fibrinogen). Thrombin and activated factors VII, X and XII are tumor cell mitogens. Numerous proteins and protein fragments from coagulation and fibrinolytic pathways regulate angiogenesis. Pathologic production of ►urokinase-type plasminogen activator contributes to expression of many features of the transformed phenotype (Plasminogen-activating system).

Molecular participants in coagulation pathways have been mapped in tumor tissue *in situ* and two dominant patterns found. Type I tumors express coagulation factor intermediates with generation of enzymatically active factor X and thrombin on the tumor cells with conversion of fibrinogen to fibrin adjacent to the cells (Fibrinogen). Examples include small cell carcinoma of the lung (SCCL), renal cell carcinoma and melanoma. Type II tumors express a pathway of proteolysis initiated by urokinase-type plasminogen activator but lack a tumor cell coagulation pathway (that may be present on activated macrophages in the tumor matrix). This mechanism has been observed in breast, colon, prostate and non-small cell lung cancers. Other tumor types may have neither of these or an alternative mechanism (lymphomas, mesothelioma). Such information provides a framework for developing hypotheses about how these heterogeneous pathways contribute to tumor growth and dissemination. For example, warfarin and heparins have been shown in randomized trials to improve response rates and survival in SCCL. Aprotinin, an inhibitor of the plasminogen activator-plasmin pathway, has a similar effect in colon cancer. The heparins have attracted attention for cancer clinical trials because they limit coagulation activation and block tumor growth factors, angiogenesis and metastasis (Heparanase, heparanase inhibitors). They might be effective in certain type I and type II tumors (for example, SCCL and colon cancer).

Current research seeks more precise prediction of thrombosis risk, definition of upstream initiators of thrombosis, the identity of common denominators of coagulation activation and carcinogenesis (►Oxidative DNA damage, ►oxidative stress), and clarification of how the coagulation mechanism regulates tumor growth. Cause-and-effect relationships can be defined based on current knowledge of molecular heterogeneity among human tumor types and the availability of drugs that target corresponding components of coagulation and fibrinolysis pathways. For example, evidence from randomized clinical trials showing improvement of cancer outcome upon treatment with anticoagulant heparins should point the way to trials of heparins engineered to block tumor growth but not coagulation that can be tested in increasing doses and combined with interventions targeting other pathways.

Coagulation biology has broadened and deepened our understanding of cancer biology, and suggested testable new and relatively non-toxic strategies for the prevention and treatment of neoplasia. Viewing the coagulation-cancer interaction as an inappropriate "response to injury" invites enquiry into common denominators of coagulation activation and carcinogenesis that stand to disclose the cause(s) of both (Oxidative DNA damage, oxidative stress).

Co-chaperone

Definition
A protein which interacts with a chaperone and modulates its activity.

►Methylation-Controlled J Protein (MCJ)
►Molecular Chaperones

Cockayne Syndrome

Definition
CS; Have a defect in transcription-coupled repair, which is type of ►nucleotide excision repair. Clinical phenotype include growth failure, progressive neurological degeneration, retinal degeneration, photosensitive skin and deafness. Most CS patients die at an early age.

►Xeroderma pigmentosum

Coding Region

Definition
Region of DNA that encodes the amino acid sequence of a polypeptide (or occasionally a functional mature RNA that does not specify a polypeptide).

Codon

Definition
A nucleotide triplet that specifies an amino acid or a translation stop signal.

Codon-Optimization

Definition
Based upon biases in codon usage between species, a DNA mutagenesis technique that is used to maximize the expression of a transgene in the cells of a foreign species relative to the species that the gene originated.

►Bioluminescence Imaging

COE

►Early B-cell Factors

Cofactor

Definition
A cofactor can be considered a helper or assistant in protein-regulated processes. In general it indicates enzymes, such as kinases or acetylases that enforce transcription factor-mediated transcription.

►Isoflavones

Coffee Consumption

Susanna C. Larsson
Division of Nutritional Epidemiology, Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden

Definition
Coffee is a beverage made from coffee beans, which have been cleaned, dried, roasted, ground, and brewed with hot water to extract their flavor.

Characteristics
Coffee, along with tea and water, is one of the most frequently consumed beverages in the world. The popularity of coffee is likely related not only to its taste but also to its content of caffeine, which stimulates the central nervous system. Associations between coffee consumption and risk of cancer and other chronic diseases have been studied extensively. Concerns about potential health risks of coffee drinking raised by ►epidemiologic studies in the past were likely

exaggerated by associations between high coffee consumption and unhealthy behaviors, such as smoking and excessive alcohol consumption. More recent knowledge has put coffee in a more optimistic light, and to date there is evidence that coffee consumption may reduce the risk of some chronic diseases, including liver cancer, type 2 diabetes mellitus, and Parkinson disease.

Coffee Constituents

Roasted coffee is a complex mixture of more than a thousand different substances, including lipids, carbohydrates, nitrogenous compounds, alkaloids, phenolic compounds, vitamins, and minerals. Coffee is a major source of caffeine, an alkaloid that occurs naturally in coffee beans, tea leaves, cocoa beans, and other plants. The caffeine content of coffee can be quite variable. A cup of coffee is usually assumed to provide 100 mg of caffeine, but the amount of caffeine in a standard cup (150 ml) of brewed coffee can range from 40–220 mg. Caffeine has been shown to be ►mutagenic. Conversely, caffeine has also been reported to inhibit chemical ►carcinogenesis and UVB light-induced carcinogenesis in animal models.

Two diterpenes, cafestol and kahweol, are found at significant levels in unfiltered coffee. These diterpenes are released from roast and ground coffee beans by hot water, but are largely removed from brewed coffee by paper filters. The amount of cafestol and kahweol in coffee depends on the brewing method. Scandinavian boiled coffee, Turkish coffee, and French press coffee contain relatively high levels of cafestol and kahweol (6–12 mg/cup), whereas filtered coffee, espresso coffee, and instant coffee contain low levels of cafestol and kahweol (0.2–0.6 mg/cup). The coffee diterpenes have been reported to possess anti-inflammatory and anti-carcinogenic properties.

Coffee contains several different chlorogenic acids, and it has been estimated that chlorogenic acid intake is several times higher for persons who regularly drink coffee as compared with non- drinkers. The chlorogenic acid content of a cup of brewed coffee (150 ml) has been reported to range from 15–325 mg. Data obtained from *in vitro* and *in vivo* studies indicate that chlorogenic acid mostly presents ►antioxidant and anti-carcinogenic activities.

Coffee contains significant amounts of ►lignans, which are biphenolic compounds present in plant foods. Lignans can be converted by intestinal bacteria into enterolignans (enterodiol and enterolactone) that possess antioxidant and weak estrogen-like activities. Coffee also contains several micronutrients, in particular magnesium, potassium, niacin, and vitamin E.

Coffee Association with Cancer

Numerous epidemiologic studies have examined the association between coffee consumption and risk of cancer at various sites, particularly the bladder, pancreas, colorectum, stomach, breast, and ovary. Associations between coffee consumption and cancer risk have been reviewed at regular intervals. The literature was extensively reviewed in 1990 by a Working Group of the International Agency for Research on Cancer (IARC). The Working Group concluded that, in humans, there is limited evidence that coffee drinking is carcinogenic in the urinary bladder, lack of evidence of carcinogenicity in the breast and large bowel, and inadequate evidence of carcinogenicity in the pancreas, ovary, and other sites. In 1997, the World Cancer Research Fund in association with the American Institute for Cancer Research concluded that "Most evidence on coffee suggests that coffee drinking has no relationship with cancer risk." The authors of a 2000 review of the epidemiologic literature from 1990 through 1999 wrote that "This updated and comprehensive overview of coffee and cancer epidemiology provides further reassuring information on the absence of any appreciable association between coffee intake and most common cancers, including cancer of the genital tract, digestive tract, and of the breast." Taken together, there is no scientific evidence that moderate consumption of coffee increases the risk of developing cancer. In contrast, emerging evidence suggests that coffee drinking may lower the risk of liver cancer.

Bladder and Lower Urinary Tract Cancer. The association between coffee consumption and risk of ►bladder cancer remains controversial, despite a large amount of epidemiologic data. In general, coffee consumption has been associated with an increased risk of bladder cancer, but the excess risk is generally modest and not dose-related. A 2001 review and ►meta-analysis identified 34 ►case-control studies and three prospective ►cohort studies. The authors found that coffee consumption might increase the risk of lower urinary tract cancer by approximately 20%. In a large ►cohort study in the Netherlands (based on 569 bladder cancer cases) published after that review, coffee consumption was associated with a small increase in risk for bladder cancer in men but was inversely associated with risk in women. A combined analysis of ten European case-control studies published in 2000 attempted to eliminate potential ►confounding by smoking by considering nonsmokers only. In this study, the risk of bladder cancer was not found to be higher in coffee drinkers than in non-coffee drinkers, unless consumption was ten or more cups per day. Hence, overall evidence indicates that coffee drinking is unlikely to have any major influence on bladder cancer risk. The possibility that the relation between coffee consumption and bladder cancer observed in some studies is due to ►bias or confounding is tenable.

Pancreatic Cancer. A possible association between coffee consumption and pancreatic cancer was raised in

the early 1980s when a ►case-control study suggested an almost threefold increased risk of pancreatic cancer associated with drinking three or more cups of coffee per day. However, most subsequent studies have not confirmed a significant relation between coffee consumption and risk of pancreatic cancer. Based on the existing literature in 1990, a Working Group of the International Agency for Research on Cancer concluded that there was little evidence to support a causal relationship between coffee consumption and pancreatic cancer risk. Out of nine cohort studies of coffee consumption and pancreatic cancer conducted since then, two showed increased risks associated with higher coffee consumption and seven observed no association. Overall, the evidence indicates that coffee consumption is unlikely to have any major impact on pancreatic cancer risk.

Colorectal Cancer. ►Case-control and cohort studies have provided different messages about the relation between coffee consumption and risk of colorectal cancer. While most case-control studies have reported an inverse association between coffee drinking and risk of ►colon cancer or colorectal cancer, no association has been found in large prospective cohort studies. However, results of two large cohort studies in the United States showed that men and women who drank two or more cups of decaffeinated coffee per day had approximately half the risk of rectal cancer than those who did not drink decaffeinated coffee. Overall, despite convincing findings in ►case-control studies, it remains unclear whether coffee consumption reduces the risk of colon or rectal cancer.

Gastric Cancer. In the literature to date, there are at least sixteen case-control studies on coffee consumption and risk of ►gastric cancer; a significant association (inverse) was reported in only two of these studies. Of seven prospective cohort studies, a significant increase in risk of gastric cancer associated with higher coffee consumption was found in two studies, including a cohort of Hawaiian-Japanese and a cohort of Swedish women. The remaining five cohort studies observed no substantial association. Thus, it appears unlikely that coffee plays a major role in gastric carcinogenesis.

Breast Cancer. Out of fourteen case-control studies on coffee consumption and risk of breast cancer, three reported an inverse association and eleven observed no association. A Finish case-control study found that coffee consumption was inversely associated with breast cancer risk in postmenopausal (but not in premenopausal) women. A large case-control study in the United States also reported a decreased risk with higher coffee consumption, but the association was limited to premenopausal breast cancer. In a multicenter case-control study of women at high risk for breast cancer due to BRCA gene mutations, breast cancer risk was significantly lower among women who habitually drank six or more cups of coffee per day than among non-coffee drinkers. None of at least eight prospective cohort studies have found any significant association between coffee consumption and risk of breast cancer. Taken as a whole, there is no consistent evidence for a link between coffee drinking and breast cancer risk.

Ovarian Cancer. Of thirteen case-control studies on coffee consumption and risk of ►ovarian cancer, a significant association was found in five studies, with four reporting an increased risk and one a decreased risk with higher coffee consumption. No significant relation between coffee consumption and ovarian cancer was observed in three prospective cohort studies, including a cohort of Seventh-day Adventists based on 51 fatal cases, a Norwegian cohort based on 93 incident cases, and a Swedish cohort based on 301 incident cases. Overall, it appears unlikely that coffee consumption has a major impact on the risk of ovarian cancer.

Prostate Cancer. Of five ►case-control and six prospective cohort studies, none has reported any significant relation between coffee consumption and the risk of ►prostate cancer. Thus, it can be concluded that coffee consumption probably has no relationship with prostate cancer risk.

Kidney Cancer. Seven of eight case-control studies have found no association between coffee consumption and risk of kidney cancer (specifically, renal cell carcinoma). A case-control study in Los Angeles reported a significant increase in risk among women (but not men) who drank more than five cups of coffee per day. A Norwegian cohort study observed no significant association. Likewise, coffee consumption was not associated with risk of renal cell carcinoma in a study consisting of two large prospective cohorts of about 90,000 women and 48,000 men in the United States. Thus, it can be concluded that coffee consumption probably has no relationship with the risk of renal cell carcinoma.

Liver Cancer. To date, there are nine published epidemiologic studies on coffee consumption and risk of primary liver cancer or ►hepatocellular carcinoma, the major type of primary liver cancer. In a prospective cohort study of more than 90,000 Japanese men and women, those who consumed coffee on a daily or almost daily basis had half the risk of developing hepatocellular carcinoma than those who almost never drank coffee. The risk decreased with increasing amounts of coffee consumed; compared with non-coffee drinkers, those who consumed five or more cups per day had a 76% lower risk of hepatocellular carcinoma. Likewise, in a cohort study consisting of approximately 111,000 Japanese men and women, the risk of death due to hepatocellular carcinoma was 50% lower among drinkers of one or more cups of coffee per day than among non-coffee drinkers. Two smaller cohort studies in Japan and five case-control studies (two in Japan and three in

Europe) have confirmed an inverse association between coffee consumption and risk of primary liver cancer or hepatocellular carcinoma. Furthermore, coffee consumption has been associated with a decreased risk of chronic liver disease and hepatic cirrhosis. Compounds in coffee, including caffeine and chlorogenic acid, have been found to inhibit chemically induced hepatic carcinogenesis in animal models. Overall, the evidence suggests that coffee drinking may reduce the risk of liver cancer.

►Coffee Consumption
►Obesity and Cancer Risk
►Uranium Miners

Coiled Bodies

►Cajal Bodies

Coiled-Coil Domain

Definition

Is an α-helix protein structure coiled together like the strands of a rope. The most common types are dimers and trimers. Many proteins with coiled-coil domains are involved in important biological functions such as the regulation of gene expression, for example, transcription factors.

►Doublecortin

Colchicine

Definition

Inhibits microtubule polymerization by binding to tubulin, one of the main constituents of microtubules. Availability of tubulin is essential to ►mitosis, and therefore colchicine effectively functions as a “mitotic poison.” Since one of the defining characteristics of cancer cells is a significantly increased rate of mitosis, this means that cancer cells are significantly more vulnerable to colchicine poisoning than are normal cells. The therapeutic value of colchicine against cancer is (as is typical with chemotherapy agents) limited by its toxicity against normal cells.

►Vascular Disrupting Agents

Cold Surgery

►Cryosurgery in Bone Tumors

Coley Toxin

Definition

Is a bacterial mixture consisting of the killed species *Borrelia burgdorferi*, *Streptococcus pyogenes* and *Serratia marcescens*, which was used historically as a vaccine for tumor therapy. William Coley noted spontaneous tumor regression in some patients after an episode of septicemia. He showed that cancer can be controlled by injections of bacterial products. The immunological basis of protection reflects properties of the bacterial oligonucleotides.

►Immunotherapy

Collagen

Definition

A fibrous structural protein found in large quantities in the connective tissues. Twenty eight different types of collagen have been characterized. A number of ►angiogenesis inhibitors (e.g. Tumstatin, Canstatin and ►Endostatin) are generated by the proteolytic fragmentation of the carboxyterminal non-collagenous domain (NC1) of collagen.

Collapsin

►Semaphorin

Collective Cell Invasion

Definition

Cell-cell adherence is maintained and the cells migrate as a sheet. This invasion pattern is usually seen in the absence of epithelial-mesenchymal-transition and requires the expression of β1-integrin and surface proteases. Collective cell invasion can be induced by podoplanin.

Colon Cancer

Gabriela Möslein
Helios klinik, Allgemein- und Viszeralchirurgie, Bochum, Germany

Synonyms

Cancer of the large intestine; Malignant neoplastic changes of the colon

Definition

Colon cancer refers to malignant neoplasia of the large intestine. The demarcation line to the more distal rectal cancer is defined as being proximal to 16 cm of the anocutaneous line.

Characteristics

Due to the slow development of precursor lesions in the form of adenomatous polyps or dysplastic lesions, no other tumor offers as many possibilities and as much time for preventive measures. Diagnosis of colon cancer in early stages highly increases the probability of curative resection. A 5-year survival rate of patients diagnosed with stage one colon cancer (limited to the bowel wall) is 90%, which is decreased to 35–60%

in patients with a positive nodal status (stage III) and drops to less than 10% in the metastatic disease (stage IV).

Screening Strategies for the Average Risk Population

Early colon cancer detection programs have been suggested to asymptomatic population of a certain age. The World Health Organisation (WHO), the American Cancer Society and the Agency for Health Care Policy and Research (AHCPR) recommended an annual ►fecal occult blood test (FOBT) and a 5-yearly sigmoidoscopy for the asymptomatic population older than 50. In Germany this proposal has been extended to annual FOBT and rectal-digital examination beginning at the age of 45. In 1994 however, this was followed by only 44.1% of women and 14.4% of men. To date it has not been demonstrated that the rectal digital examination by itself is an efficient means for the early detection of rectal cancer. It therefore seems unreasonable to replace the sigmoidoscopic examination by the rectal digital examination, although it is an essential part of every physical examination in patients older than 50.

FOBT (Fecal Occult Blood Test)

Three large randomized studies carried out in USA, Denmark and Great Britain in a period of 8–13 years, have demonstrated the benefits of FOBT in early colon cancer detection and in the reduction of mortality by 15–33%. Although FOBT is more specific without rehydration, best results were achieved when the test was carried out once a year and included rehydration. FOBT is an adequate screening modality for early cancer detection, reducing mortality rates as well as treatment costs. It is in itself, however, not the appropriate means in cancer prevention since it implies the removal of neoplastic changes even before the event of malignant transformation.

Sigmoidoscopy

Periodic sigmoidoscopy from age 50 onwards, reduces the mortality of rectosigmoidal cancers by 60% and usually a control interval of 5 years is sufficient. The risk of developing colon cancer proximal to the splenic flexure, however, remains unaffected. Compared to FOBT alone, the combination of the two procedures increases the cancer-preventive effect by a factor of 2.2.

Colonoscopy

In the age group of 55- to 64-year-old asymptomatic persons, the combination of FOBT and sigmoidoscopy result will, in the case of positive test results, lead to the recommendation of performing colonoscopy. The question may therefore be raised, if a base-line colonoscopy is a suitable alternative for this age-group. In approximately one third of all patients, polyps will be detected (and removed) such that this strategy would imply a true cancer-prevention. On the other hand, 70% of persons with a negative colonoscopy would not require any further screening modalities for a period of 5 years.

Double Contrast Barium Enema

This radiologic examination cannot replace colonoscopy since the sensitivity is significantly lower (83% versus 95%). The probability of overlooking a small cancer is increased fourfold compared to the endoscopic procedure. Small polyps, however, are also frequently not recognized during the endoscopic examination. In a prospective study, every fourth adenoma under the size of 5 mm was overlooked. The detection of adenomas larger than 1 cm in diameter was reproducible in 94% of the cases. The reliability of colonoscopy depends much on the experience of the person performing the examination.

Preoperative Diagnosis of Colon Cancer

Required examinations:

- History (including family history).
- Physical examination (including rectal-digital examination).
- Colonoscopy with biopsy or double-contrast barium enema with subsequent biopsy of a pathological alteration. If the barium enema does not show a pathological lesion, it may entirely replace endoscopy.
- If a stenosis cannot be surpassed preoperatively, colonoscopic examination in the first 3 months after operation is warranted.
- Ultrasound sonography of the abdomen.
- Radiologic thorax examination.
- Tumormarker ►CEA (carcino embryonal antigen).
- MRI (as an alternative or extended examination).
- CT scan of the thorax if in doubt about lung metastases.
- In case of sigmoid cancers: urine sedimentation, CT scan. If ultrasound examination suggests infiltration of the urinary tract or if red blood cells are demonstrated in the urine sedimentation, cystoscopy is recommended to investigate bladder infiltration. Gynecological examination, if infiltration of the uterus or the ovaries is suspected.

Preoperative (Neoadjuvant) Therapy

To date no benefits have been shown in using ►neodajuvant therapy in colon cancer.

Surgical Therapy (with the Aim to Cure)

Surgery aims at the curative resection of the tumor-bearing segment of the colon together with the regional lymph nodes. In addition, the (partial) resection of

adjacent organs, if these are infiltrated by tumor (multivisceral resection) may be necessary. Colon cancers usually have a circular growth pattern. In order to remove the intramural tumor cell spread, a minimal margin of 2 cm suffices. A regional lymphnode involvement is more widespread. Lymphnodes show a tangential metastatic involvement (up to 10 cm away from the macroscopic tumor), their preferred distribution being towards the center.

Cancers of the Cecum and Ascending Colon

Generally, a right-sided hemicolectomy is the treatment of choice in such patients, including the radicular removal of the lymphnodes of the right colic artery and the ileocolic vessels. The large omentum of the colon is removed together with the colon segment. If the dissection of the gastrocolic ligament is considered, one might be confronted with contrasting opinions regarding the right gastroepiploic artery. Some authors recommend the preservation of the vessel, others do not.

Cancers of the Right Flexure and the Proximal Transverse Colon

As a rule of thumb, extended right-sided hemicolectomy is warranted if the right colic artery is dissected at its origin, out of the superior mesenteric artery. The distal resection lies close to the splenic flexure, allowing circulation. If the blood supply of the distal transverse segment appears insufficient, the additional resection of this segment becomes necessary. The large omentum is completely removed, together with the gastroepiploic ligament and the right gastroepiploic vessels (resection of potentially involved lymphnodes above the pancreas).

Cancers of the Transverse Colon

Cancers in the mid-transverse colon are treated with an entire resection of the segment, including the flexures. The omentum as well as the gastroepiploic ligament and arcade are removed together with the colonic specimen. If the cancers are close to the flexures, hemicolectomy extended to the right and the left is the procedure of choice.

Tumors of the Left Colonic Flexure

Suggested is an extended left-sided hemicolectomy, together with the removal of the lymphnodes of the medial colic vessel and the inferior mesenteric vessels. Equally radical is the central ligature of the left colic artery at its origin, leaving the central part of the inferior mesenteric vessels intact. Under these circumstances the superior rectal vessels remain unaffected, such that the circulation in the remaining sigmoid colon is not impaired. Depending on the exact tumor localization and blood supply, the right colonic flexure may be preserved. Lymphnodes along the central portion of the superior mesenteric vessels should always be removed for diagnostic evaluation.

Tumors of the Descending Colon and Proximal Sigmoid Colon

Generally, left-sided hemicolectomy is recommended, with radicular ligation of the inferior mesenteric vessel. The distal margin of resection lies in the upper part of the rectum and usually the left flexure has to be removed. In order to obtain a tension-free anastomosis, sometimes the medial colic artery has to be sacrificed.

Tumors of the Middle and Distant Sigmoid Colon

In this case, radicular segmental sigmoid resection is the preferred option. The inferior mesenteric artery is ligated either centrally or distal, relative to the origin of the left colic artery. The inferior mesenteric vein should be ligated at the lower edge of the pancreas.

Further Constellations Influencing Surgical Strategy

Multivisceral resections: If adjacent structures are inherent to the tumor, these should, in addition to the lymphnode resection, be resected “en bloc.” In contrast, biopsies to confirm tumor infiltration of adjacent organs are to be avoided since cell dissemination might be initiated. Distant metastases: The resection of synchronous or metachronous metastases of the liver, lung etc. is indicated only, if this resection has curative intent and complies with the oncological principles. If the metastases are unresectable, “palliative measures” apply. Multiple colonic primaries: The extent of resectional surgery depends on additional lymphnode dissections recommended for each tumor. As a result colectomy with ileorectal anastomosis may be indicated. Synchronous occurrence of colonic polyps: Adenomas that are not removable endoscopically should be resected during colon cancer surgery. In this case a margin of 2 cm applies. Extended resection to the segmental lymphnode is not necessary. Cancer diagnosis in endoscopically removed polyps: If, unexpectedly, the histological examination reveals malignancy, oncological resection of the colonic segment is indicated. This may be neglected only in the case of a polyp with tumor-free stem which is confined to the submucosa with “low risk” (pT1, G1–2, no lymph vessel involvement). Segmental resection: In patients with metastatic disease, radical resection of the colonic segment with lymph node removal may not be indicated. Very poor physical condition or the high age of some patients may justify colonic surgery which does not follow oncological principles. Emergency operation: Nevertheless, high-urgency surgery, unavoidable due to bowel obstruction, tumor or colon perforation should comply with oncological principles. Laparoscopic surgery: To date, no data are available

that document the operative outcome in patients that underwent laparoscopic colon cancer surgery. Future consideration of ongoing studies with long follow-up periods is therefore necessary for the optimal treatment of colon cancer. Nevertheless, there are no objections to carry out laparoscopic colon cancer surgery in a palliative setting. Ulcerative colitis and familial adenomatous polyposis (FAP (►APC gene in Familial Adenomatous Polyposis)): Cancers of this type require proctocolectomy, if possible continence-preserving. Especially in an early stage, cancer in the proximal two thirds of the rectum is not a contraindication for ileoanal pouch surgery. ►HNPCC (hereditary nonpolyposis colorectal surgery): In the event of this autosomal-dominant syndrome, many authors suggest extended cancer surgery in the form of prophylactic bowel removal (colectomy and ileorectal anastomosis or restorative proctocolectomy). Occurrence of metachronous colorectal cancer and the observation of so-called interval cancers is significant. However, the benefit of prophylactic colon removal (without the evidence of neoplasia) remains uncertain, especially if considering a reduced penetrance of ~80%.

Intra- and Postoperative Histopathological Diagnosis

Due to technical complications the immediate pathological classification of a tumor/polyp in a frozen section is not an option. Pathological evaluation after oncological surgery is, however, of prognostic significance in the locoregional resection (R-classification), the depth of invasion (pT classification) and the grading and lymphnodal status (pN classification) and forms the basis in the decision process concerning ►adjuvant therapy. The total number of resected lymph nodes and metastatic lymphnode occurrence is therefore of essential relevance. Perforation of the tumor during surgery is of prognostic significance and must be documented.

►Microsatellite tumor instability is of special relevance in the setting of HNPCC, and of increasing interest since response rates to adjuvant therapy have shown that stable and instable tumors differ in their biological response to chemotherapeutic agents. Although the natural course of unstable tumors is more benign, than the natural course of stable tumors, the biological response to conventional chemotherapy in stable tumors is better.

Classification of Colorectal Cancers

There are two classifications that are used separately, the Dukes and the TNM (tumor, lymphnodes, metastases) classification.

The Dukes-Classification (Table 1) is preferred in the US and UK and describes the following stages:

The TNM-staging (suggested by the Union internationale contre le cancer, UICC) (Table 2) is preferred in European countries and distinguishes between the stages listed below. T stands for the expansion of the primary tumor; N for the lack or the presence of metastases of the lymphnodes; M for the lack or the presence of distant metastases. Numbers indicate the extent of malignant processes; p, post-operative.

Colon Cancer. Table 1 Dukes-classification

Dukes A	Growth limited to wall, nodes negative
Dukes B	Growth beyond muscularis propia, nodes negative
Dukes C1	Nodes positive and apical negative
Dukes C2	Apical node positive
Dukes D	Growth beyond originating organ

Colon Cancer. Table 2 TNM-staging

pT1	Local invasion of submucosa
pT2	Local invasion of the muscularis propia
pT3	Local invasion beyond the muscularis propia
pT4	Tumor cells have reached peritoneal surface or invaded adjacent organs
pN0	No lymphnodes affected by metastases
pN1	One to three lymphnodes affected by metastases
pN2	Four or more lymphnodes affected by metastases
pM0	No distant metastasis
pM1	Distant metastasis

Adjuvant Therapy

- In order to recommend adjuvant therapy, complete removal of all regional and metastatic lesions (R0 resection) in addition to the tumor removal is necessary. Recommending adjuvant therapy is based on the pathohistological classification of the tumor, specifically of the pN status. In order to define the lymphnode status, a minimum of twelve regional lymphnodes should be examined. Immunocytological studies of isolated tumor cells in either bone marrow aspiration biopsies or in the peritoneal fluid should not, at least at this point, be referred to in the decision for or against adjuvant therapy since the impact of "minimal residual disease" remains to be established.
- Patients with early-stage colorectal cancer (stage I or II) and patients after R0 resection of distant metastases should receive adjuvant therapy in the setting of controlled studies only.
- The benefits of adjuvant therapy in UICC stage III cancers (all pT stages, pN1-2, M0) remain to be established. A quality-controlled surgical treatment with and without adjuvant therapy is currently under evaluation. Outside these studies, adjuvant therapy is recommended for stage III cancers.
- Adjuvant chemotherapy for stage III colon cancers: One year administration of 5-FU (fluouracil) and levamisol proved to be as effective as a 6-monthly administration of 5-FU and folinic acid. Although there is variation between different adjuvant protocols, general contraindications for adjuvant therapy are listed below:
  - General physical condition under the score of 2 (WHO)
  - Uncontrolled infection
  - Liver cirrhosis
  - Severe coronary heart disease, cardiac insufficiency (NYHA III and IV)
  - Preterminal and terminal renal insufficiency
  - Limited bone marrow function
  - Unavailability for regular control check-ups

To date there appears to be no benefit in the administration of monoclonal antibody treatment (17 1A) in addition to conventional chemotherapy.

Follow-Up

Due to the low rate recurrence rate, no major prognostic advantage from follow-ups is expected for patients with early cancer (UICC I) and R0 resection. The advice to perform two colonoscopies, 2 and 5 years post colon cancer surgery, is aimed towards an early identification of second primaries. An intensified surveillance of individual cases is justified in circumstances that lead to suspect a higher recurrence rate, i.e. tumor perforation, G3 and G4 tumors or histologically verified pericolic vessel infiltration. After palliative tumor resection (R2) a symptomatic follow-up is recommended.

Following R0 resections of tumor stages II and III, the main benefits of follow-up strategies can be expected, if the general physical condition of the patient does not object to recurrent surgical intervention. Two specific follow-ups are recommended within 5 years of primary surgery (year 2 and year 5) and include physical examination, CEA-level, abdominal ultrasound, X-ray of the thorax and colonoscopy. Intensified follow-up is recommended for patients with an increased hereditary risk.

Cellular and Molecular Features

Colorectal tumors provide an excellent system in which to search for and study genetic alterations involved in the development of neoplasia. It appears that most if not all malignant colorectal tumors arise from preexisting benign adenomas. These precursor lesions can be removed and studied at various stages of development. Colorectal tumors develop as a result of oncogene mutations in combination with the mutated tumor suppressor genes, the latter being predominant.

Human colorectal tumors, including very small adenomas, have a monoclonal composition. Adenomas therefore arise from a single or a small number of cells which initiate the process of neoplasia by clonal expansion. Genetic alterations within the majority of neoplastic cells studied so far, suggest an impaired regulation of cell growth that enables those cells to become the predominant cell type, eventually constituting the neoplasm.

The development process in patients with sporadic cancer (as opposed to ►familial cancer) occurs over a period of decades. The series of genetic alterations involves oncogenes such as ►RAS as well as tumor suppressor genes (particularly those on chromosome 5q, 17p and 18q). In general, the three stages are represented by increasing tumor size, dysplasia and villous content. The mutation of the Ras gene (usually K-Ras), appears to occur within a single cell of a preexisting small adenoma followed by clonal expansion which produces a larger and more dysplastic tumor. Deletions of chromosome 17p and 18q generally arise at a later stage of tumorigenesis, than deletions of chromosome 5q or Ras gene mutations. In this ►multistep development the total number of genetic alterations rather than their order of occurrence, determines the biological properties of neoplasia.

Tumors continue to progress once cancers have formed and the cumulative loss of tumor suppressor genes on different chromosomes correlates with the ability of the tumor to metastasize and to cause death.

Recent investigations have shown that ~25% of randomly selected colorectal cancers are unstable, a phenomenon used as an independent prognostic factor in colorectal cancer. In addition, the loss of heterozygosity (►LOH) at a chromosome 8p marker (termed ►allelic imbalance) has, as recently reported, been related with a poor patient outcome. It may therefore be expected, that the molecular characterization of colorectal tumors will increasingly affect the individual risk assessment and the suitable intervention strategies.

The identification and characterization of molecular mechanisms underlying tumor development and tumor growth offer new opportunities in cancer treatment. An intricate genetic scenario is responsible for a complex human neoplastic condition. The relevance of individual steps within, might open doors for therapeuticals that specifically target essential, although malfunctioning, check-points.

Perspective

In developing countries, especially Asia, incidences of colon cancer are rapidly rising. In the United States and in Germany, ~130,000 and 50,000 patients, respectively, are diagnosed with colorectal cancer every year. Colorectal cancer comes second in the group of tumor-related deaths. The life-time risk of developing colorectal cancer in Germany is 4–6%; with the majority of these cancers occurring in people aged 50 and above. Gaining new insight into the molecular pathogenesis of colorectal cancer will allow progress in many facets of disease control. They include the identification of genetically predisposed groups for targeted surveillance and/or chemo-prevention, prognosis for patients with established cancer, predictions of treatment efficacy and the development of novel treatment strategies.

Colorectal Premalignant Lesions

Luca Roncucci
Department of Medicine, University of Modena and Reggio Emilia, Modena, Italy

Synonyms

Adenomas; Adenomatous polyps; Microadenomas

Definition

Colorectal premalignant lesions are focal lesions which precede cancer development. They include different entities: adenoma is the only one for which the available scientific evidence of its premalignant nature is more convincing.

Colorectal adenomas are polypoid, flat or depressed lumps of epithelial origin, which can be found throughout the large bowel, whose main histological feature is ►dysplasia. They may be single or multiple, rarely hundreds or even thousands, as in patients with ►familial adenomatous polyposis (FAP). Adenomas, if left untreated, grow and finally may become malignant. However, only a fraction of colorectal adenomas acquire malignant features, and sometimes may also regress. Polypoid adenomas are the most frequent and can be sessile (with a large base) or pedunculated (with a stalk attached by a narrow base on the colorectal mucosal surface).

Other kinds of colorectal lesions may be premalignant; they are hyperplastic polyps, hamartomatous polyps, aberrant crypt foci, and dysplasia in inflammatory bowel diseases (IBD).

Hyperplastic polyps are round, sessile, and pale lesions usually with a diameter of less than 1 cm. Histology shows elongated, dilated, and typically saw-like crypts, lined by a single layer of colonic epithelium, and usually no feature of dysplasia. Thus, hyperplastic polyps are not considered premalignant. However, a variant of hyperplastic polyps showing areas of both dysplasia and hyperplasia in the same lesion (referred to as mixed polyps) or others where, in a hyperplastic architecture, cytological signs of dysplasia are present (referred to as serrated adenomas), can be considered premalignant.

Hamartomatous polyps are rare colorectal polypoid lesions whose main histological feature is the presence in the same lesion of different normal colorectal tissues (mainly epithelial glands, connective tissue, and smooth muscle) showing marked alteration of the whole architecture.

Aberrant crypt foci are microscopic focal lesions which can be observed under a light or a dissecting microscope at 30–40× magnification, or even during magnifying colonoscopy, on the colorectal mucosal surface after staining with a vital dye, methylene blue, in patients with FAP, cancer, or benign diseases of the large bowel. They were originally described in mice exposed to colonic carcinogens and then identified also in humans. They appear as clusters of altered colonic crypts, enlarged, and deeply stained than normal at topological view, often showing abnormal-shaped lumens and slightly bulging on the level of the normal mucosal surface.

In patients with IBD (ulcerative colitis and Crohn's disease) dyplasia may be observed in biopsies taken during colonoscopy as flat lesions or polypoid masses. Dysplasia in IBD is a premalignant feature, which deserves further clinical management.

Characteristics

Adenomas

Adenomas are rare in Africa and in most Asian countries, while they are very frequent in many developed countries, where 30–40% of individuals over 50 years harbor an adenoma of any size in the colon. The widespread use of colonoscopy contributed to the increased prevalence of adenomas in these populations. The geographical distribution of adenomas lends support to the contention that dietary and lifestyle factors in western countries play some role in their etiology. Among them, a high intake of meat (expecially red meat), a low intake of vegetables and fiber, a low physical activity, and insulin resistance are the most consistent. It is well-established that their prevalence increases with age. Adenomas are more frequent in the left colon (distal to the splenic flexure) and in the rectum, reflecting the anatomical distribution of carcinoma, though recently an increased prevalence in the right colon due to the use of pancolonoscopy has been reported. Adenomas are usually less than 1 cm in diameter, sometimes less than or equal to 0.5 cm (diminutive polyps). When larger, more often they show a villous architecture (see later) and proclivity to malignant transformation. Adenomas are single in most cases. In about half of the individuals, two or more lesions can be observed at endoscopy. The number of adenomas is strictly related to the risk of developing cancer; in ►FAP cancer incidence approaches 100%. According to the main architecture of the lesion, adenomas may be divided into three histological types: tubular, tubulovillous, and villous, the latter having the highest probability of becoming malignant. Tubular adenomas show a prevalent glandular architecture in more than 80% of the whole lesion. Villous adenomas have more than 80% of villous architecture, characterized by long fronds of papillary epithelium arising from the mucosal surface of the colon (Fig. 1). Tubulovillous adenomas show both components, each less than 80%. In all colorectal adenomas, dysplasia is graded into three different levels of severity, i.e., mild, moderate, and severe. The current grouping of grades into two categories: "low-grade" (mild and moderate) and "high-grade" (severe) is justified by the poor reproducibility in the separation between mild and moderate grades. This uncertainty stems from the definition of dysplasia, term with a high level of subjectivity. More advanced is the overall grade, higher is the risk of cancer development, which is evident when malignant cells pass through the muscularis mucosae and invade the submucosal layer of the bowel wall, identifying a malignant polyp. This is the earliest form of carcinoma with metastatic

Colorectal Premalignant Lesions. Figure 1
Histological section of a villous adenoma with typical papillary epithelium.

potential; the risk of lymph node metastasis has been estimated around 10% overall.

Flat adenomas are short lumps of mucosa with a reddish surface, sometimes with a central area of depression. At histology these adenomas show the same three types of architecture described for polypoid adenomas, but they progress to cancer with a higher frequency, providing further evidence for the adenoma–carcinoma sequence.

Sometimes adenomas bleed, but most remain asymptomatic, and are discovered by chance during colonoscopy. Flat and depressed adenomas are not easily seen during endoscopy, but it is important to identify and remove them, due to their higher malignant potential. Indeed, the optimal treatment for adenomas (and for colorectal polyps in general) is its removal, usually during colonoscopy, or seldom by surgical operation, expecially large adenomas of the rectum. The pathologic diagnosis is then mandatory for planning the future endoscopic follow-up of the patient. Estimating the risk of developing other lesions after removal of adenomas is not an easy task. The current evidence suggests that larger, multiple, and villous adenomas do recur more frequently and require a closer endoscopic follow-up.

Adenoma–Carcinoma Sequence

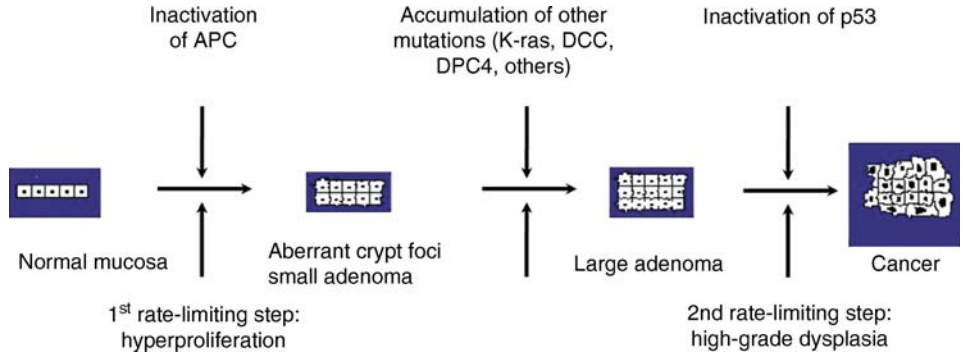
Overwhelming evidence suggests that colorectal carcinomas develop from preexisting adenomas, which is referred to as the so-called adenoma–carcinoma sequence hypothesis based upon the following observations:

1. Focal adenomatous areas have been frequently observed in colorectal carcinomas; on the other hand, focal infiltration by carcinomatous tissue (beyond the muscularis mucosae) can be observed in adenomas;
2. If adenomas are not removed, cancer may develop at the polyp site, and accurate surveillance with removal of polyps leads to a reduction of the expected number of invasive carcinomas;
3. Adenomas and carcinomas share a similar distribution along the large bowel, being more frequent in the descending and sigmoid colon, and in the rectum;
4. Age-specific incidence rate of colorectal adenomas shows a peak that precedes that of cancer by about 5 years, in keeping with the estimated time lag required for malignant transformation;
5. Adenomas have an hyperproliferative epithelium, as carcinomas;
6. Similar patterns of genetic and epigenetic alterations have been reported for adenomas and carcinomas, though usually they are less frequent and severe in adenomas than in carcinomas.

The adenoma–carcinoma sequence has been revisited by a genetic point of view, and definite steps of activation of oncogenes and inactivation by allelic loss of tumor suppressor genes, which underlies colorectal carcinogenesis, have been identified (Fig. 2). In particular APC inactivation seems one of the earliest events causing hyperproliferation of epithelial cells and microadenoma formation, then accumulation of mutations in other genes [K-*ras* (►ras), DCC, and others] are responsible of adenoma growing. Finally, later inactivation of the tumor suppressor gene *p53* [*p53* gene family] seems the key event for malignant transformation. Moreover, in some cases ►microsatellite instability (MSI) (expecially in tumors from patients with ►Lynch syndrome) and hypermethylation of ►CpG islands in the promoter region of several genes, causing gene silencing, has been demonstrated in adenomas.

Hyperplastic Polyps

The premalignant potential of hyperplastic polyps is not supported by most evidence. However, some observations seem to point to the contrary. Polyps with mixed but distinct features of hyperplasia and dysplasia may become malignant. Their nature is not yet understood. It is possible that adenomatous tissue develops within a hyperplastic polyp. Also serrated adenomas have premalignant potential because of some cytological features of epithelial cells lining the crypts; evident



Colorectal Premalignant Lesions. Figure 2 Genetic model of colorectal carcinogenesis, including the main molecular alterations underlying the development of colorectal lesions.

signs of dysplasia have been identified in 30–40% of serrated adenomas. Moreover, it should be mentioned the rare hyperplastic polyposis, a syndrome which seems to have malignant potential, acquired through mutator pathways. Some biomolecular alterations similar to those found in adenomas, have been reported in hyperplastic polyps, including K-*ras*, and p53 mutations, and MSI.

Hamartomatous Polyps

Hamartomatous polyps are observed in two diseases: ►Peutz–Jeghers syndrome and juvenile polyposis. They are not considered precancerous lesions, although some authors have reported the development of adenocarcinoma in hamartomatous polyps, and others the coexistence of adenomatous and carcinomatous tissues in these polyps. Finally, in Peutz–Jeghers syndrome a frequent occurrence of gastrointestinal as well as extradigestive cancers has been observed.

Aberrant Crypt Foci

Aberrant crypt foci are smaller than adenomas, and usually not visible to the naked eye. Luminal openings of aberrant crypts show various shapes, each corresponding to definite histological alterations. Indeed, histologically ACF are rather heterogeneous. They may show various alterations, from hypertrophy (only dilated crypt with no cell alteration), to hyperplasia, to severe dysplasia. Only a minor fraction (10–30%) of the ACF examined is defined as dysplastic (referred to as microadenomas). Dysplasia may be focal in an aberrant crypt focus, and even in a single aberrant crypt, suggesting that a transition from hyperplasia to dysplasia in aberrant crypts is possible. Dysplasia seems more frequent in larger and in proximal colonic ACF. ACF with dysplasia can be considered true premalignant lesions, whereas for ACF with other histological features the matter is questionable, and the mechanisms and steps of the progression remain unclear. The main points in favor of their premalignat potential are as follows. The density of ACF is higher in patients with FAP. In these patients the ACF examined show definite dysplasia at histology in 75–100% of cases. In patients with cancer and benign diseases of the large bowel the density of ACF is lower, but higher in the distal colon and rectum. Older individuals harbor a higher number of ACF in their colon. Epidemiological evidence suggests that density of ACF in patients with colon cancer is related to environmental factors as it happens for adenomas and carcinomas. ACF have a hyperproliferative epithelium. In particular an extension of the proliferative compartment to the upper portion of aberrant crypts is evident in dysplastic ACF. The premalignant potential of ACF is further supported by the finding of several genetic and epigenetic alterations (►epigenetics), similar to those reported in adenomas and sometimes in hyperplastic polyps, including DNA MSI and DNA hypermethylation.

Inflammatory Bowel Diseases

Patients with ulcerative colitis or Crohn's disease may have an increased risk of developing colorectal cancer, depending on the duration of the disease and the extent of the involved mucosa. The risk is related to dysplasia which may be documented in the colorectal mucosa of these patients as flat areas or dysplasia-associated lesions or masses which resembles an adenoma. Dysplasia is the consequence of chronic inflammation typical of these diseases. The lesions are at high-risk of becoming malignant and their presence requires close follow-up and should guide surgical treatment.

Combination Therapy

Definition

An approach to the treatment of cancer and other diseases in which several different drugs, each with different mechanisms of action, are simultaneously administered to the patient so as to improve the probability of clinical success.

►Drug Design

Combinatorial Chemistry

Definition

The synthesis of a large number of new chemical compounds by combining various sets of compound "building blocks."

►Small Molecule Screens

Combinatorial Libraries

Definition

A collection of candidate drugs which has been systematically expanded by incorporating a range of substituents at various sites on a molecular scaffold, then reiteratively expanded by further modifications of those substituents. Combinatorial libraries are typically created by automated synthetic schemes and analyzed by robotic high-throughput screening assays.

Combinatorial Selection Methods

Michael W. Van Dyke
Department of Molecular and Cellular Oncology, The University of Texas M. D. Anderson Cancer Center, Houston, TX, USA

C

Synonyms

CASTing; *In vitro* genetics; REPSA; SAAB; SELEX; TDA

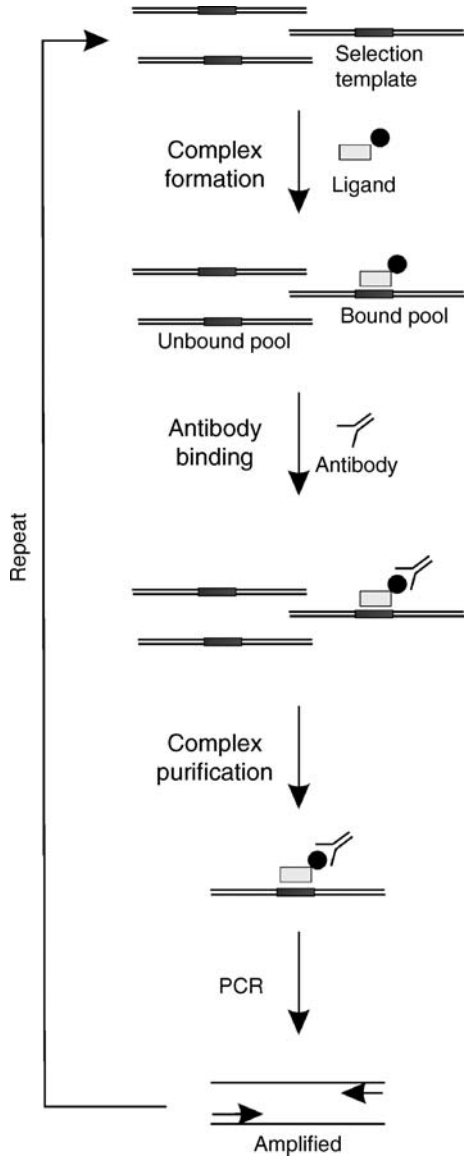
Definition

Combinatorial selection methods refer to a series of reiterative approaches involving large pools of randomized oligonucleotides, a selection process, and PCR amplification for identifying preferred ligand-binding sites on nucleic acid receptors.

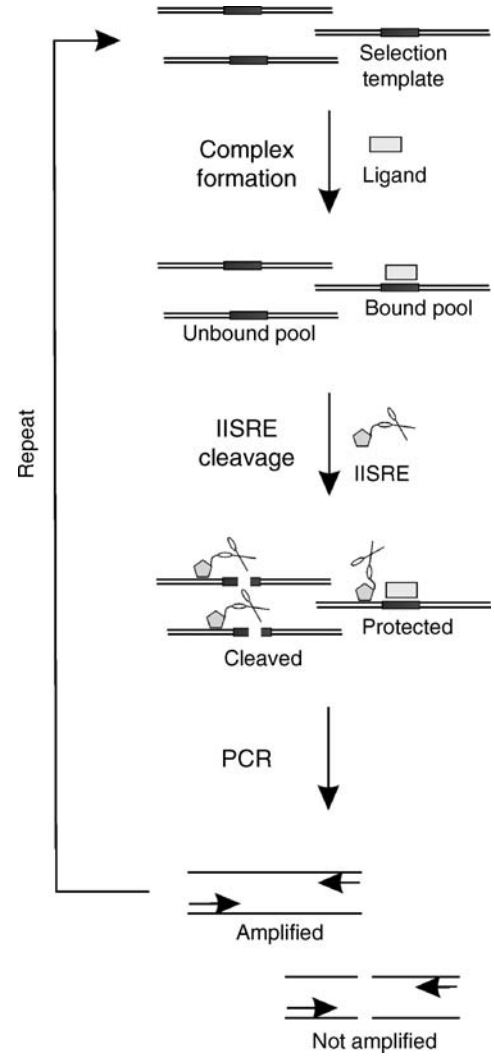
Characteristics

Combinatorial selection methods are reiterative *in vitro* methods used to find the preferred nucleic acid–binding sequences of many ligand types. Examples of combinatorial selection methods include cyclic amplification and selection of targets (►CASTing), ►*in vitro* genetics, restriction endonuclease protection, selection, and amplification (►REPSA), and systematic evolution of ligands by exponential enrichment (►SELEX). Typically these combinatorial methods involve large populations of nucleic acids containing a region of randomized sequence, a selection process, a means of amplifying the selected subpopulation, and the ability to cyclically repeat selection and amplification steps to obtain sequences that bind with high affinity to the selecting ligand. Figures 1–3 show the basics of these combinatorial selection methods. Note: ►phage display, which uses randomized sequences within a bacteriophage genome to allow the expression of a variety of viral coat fusion proteins for use in the selection of peptides that interact with particular ligands, may also be formally considered a combinatorial selection method.

Ligands investigated by combinatorial selection methods include proteins, peptides, nucleic acids, and various small molecules (molecular mass <1000 Da). Receptors are usually DNA or RNA oligonucleotides. Selections are typically performed *in vitro* and require the physical separation of ligand-bound from unbound nucleic acids. Under optimal selection conditions, the selected subpopulation constitutes only a tiny fraction of the input nucleic acid. Thus, amplification of the selected nucleic acid, typically by a polymerase chain reaction (PCR) method, is necessary to acquire workable quantities of material. Amplifications can

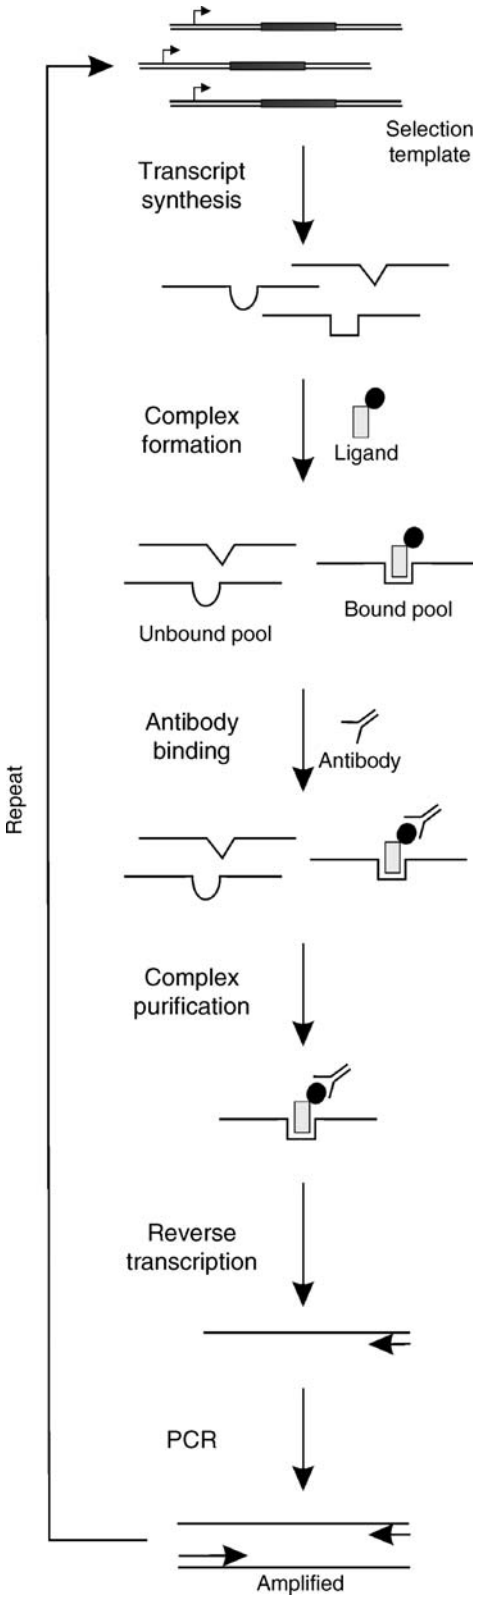


Combinatorial Selection Methods. Figure 1 Steps within a cycle of CASTing. (1) Primary complex formation between ligand and selection template mixture, (2) Secondary complex formation following antibody binding, (3) Secondary complex purification by immunoprecipitation, and (4) PCR amplification of selected DNAs. Steps 1–4 are repeated until a population of selection templates with desired properties is isolated. Open and filled regions on selection templates refer to defined and randomized sequences, respectively.



Combinatorial Selection Methods. Figure 2 Steps within a cycle of REPSA. (1) Primary complex formation between ligand and selection template mixture, (2) IISRE binding and selection template cleavage, and (3) PCR amplification of selected DNAs. Steps 1–3 are repeated until a population of cleavage-resistant selection templates emerges. Open and filled regions on selection templates refer to defined and randomized sequences, respectively.

be performed under highly stringent conditions, to maintain nucleic acid sequence integrity. Alternatively, amplifications may be performed under less stringent conditions (e.g. through the use of a low-fidelity reverse transcriptase), thereby allowing the introduction of mutations that could provide even higher affinity in subsequent selection rounds. Finally, because of limitations in the selection process, often a single round of selection does not yield the highest possible affinity species. Thus, multiple cycles of selection and amplification are often used to obtain the desired results. Progress toward isolating the highest affinity species can be determined after each cycle. Alternatively, many investigators proceed *sola fide*, with the hope that after a certain numbers of cycles, useful material will be obtained.



Combinatorial Selection Methods. Figure 3 Steps within a cycle of SELEX. (1) Preparation of RNA transcript mixture from template DNA, (2) Primary complex formation between ligand and selection transcript mixture, (3) Secondary complex formation following antibody binding, (4) Secondary complex purification by immunoprecipitation, (5) Reverse transcription of selected RNAs, and (6) PCR amplification of selected cDNAs. Steps 1–6 are repeated until a population of selection templates with desired properties is isolated. Open and filled regions on selection templates refer to defined and randomized sequences, respectively. Raised, rightward pointing arrows on SELEX selection templates indicate transcription start sites.

Combinatorial selection methods have been used to identify consensus DNA-binding sequences for specific transcription factors, isolate RNA ▶aptamers for high-throughput proteomic applications, and identify preferred DNA-binding sequences for antineoplastic agents. They have become standard tools in biochemical and molecular biology research, as well as in the development of new drugs and diagnostics, especially in the cancer field. Descriptions of some of the more commonly used combinatorial selection methods and their applications in cancer research and treatment are provided below.

CASTing

CASTing is an archetype for several related combinatorial selection methods, including selected and amplification binding (▶SAAB) and target detection assay (▶TDA). The steps involved in CASTing are shown in Fig. 1. Typically, these methods use randomized double-stranded DNA oligonucleotides as the receptor or ▶selection template and proteins as ligands, although other ligands including small molecules and nucleic acids have also been used successfully. Selection templates include a central element (often 6–20 bp in length) containing a degenerate or randomized sequence flanked by two defined sequences of suitable length and base composition to allow for efficient amplification by PCR. Binding reactions are performed *in vitro* between a ligand and a population of selection templates sufficient for a good representation of all possible sequences. Ligand-bound oligonucleotides are then physically separated from unbound oligonucleotides by various methods, either through capitalizing on the different physical properties of ligand-DNA complexes compared with free oligonucleotides and standard biochemical techniques (e.g. reduced electrophoretic mobility and electrophoretic mobility shift assays (EMSA), increased hydrophobicity and nitrocellulose filter binding) or through affinity methods (e.g. immunoprecipitation, affinity chromatography). Of course, application of these separation methods requires *a priori* knowledge of the ligand and its DNA complex and/or

physical modification of the ligand (e.g. epitope-tagged proteins, biotinylated small molecules). Amplification of the selected oligonucleotides is achieved through direct PCR. Cycles of binding, separation, and amplification are often repeated four to eight times, depending on the length of the randomized region within the selection template and the efficiency of the selection process. The resulting selected oligonucleotides can then be individually subcloned and sequenced or the entire pool directly sequenced, and the resulting information can be used to derive a consensus.

Combinatorial selection methods such as CASTing have been used primarily to determine the specific DNA-binding sites of proteins such as eukaryotic transcription factors. Many of these proteins play important roles in cancer as ►oncogenes or as ►tumor suppressors (e.g. ►c-myc, ►p53).

REPSA

REPSA is a combinatorial selection method similar to CASTing in that it identifies preferred ligand-binding sites on double-stranded DNAs. The steps involved in REPSA are shown in Fig. 2. As in CASTing, a REPSA selection template also contains an element of randomized sequence flanked by two defined sequences. However, in REPSA selection templates, the defined flanking sequences also contain type IIS restriction endonuclease (►IISRE) binding sites oriented so that the IISREs cleave sites within the randomized cassette. Type IISREs differ from conventional type II restriction endonucleases in that they do not cleave DNA directly at their binding site but rather at a fixed distance from their binding site. They also cleave duplex DNA without regard to sequence specificity; thus, they are powerful probes of ligand binding in the randomized cassette. After binding reactions are performed, the mixture of ligand, selection templates, and their complexes is subjected to cleavage by an IISRE. Unbound selection templates are preferentially cleaved, rendering them incapable of serving as templates in subsequent PCR amplifications. Intact templates are amplified, however, and serve as the input of reiterative rounds of selection, cleavage, and amplification. Subcloning, sequencing, and analysis are identical to those in CASTing.

Because REPSA does not require physical separation between ligand-bound and unbound selection templates, it is more versatile than many other combinatorial selection methods. Almost any ligand that can inhibit IISRE cleavage is suitable for use with REPSA. Ligands including proteins, nucleic acids, and both noncovalent- and covalent-binding small molecules have had their preferred duplex DNA-binding sequences successfully determined by REPSA. REPSA can also be used with mixtures of ligands, with unknown and uncharacterized ligands, and with native, unmodified ligands. Given the limitations of alternative methods, REPSA has been proven most effective in determining small molecule binding specificity, especially for those modular DNA-binding small molecules used to target specific genes (e.g. hairpin polyamides). In addition, REPSA has been proven highly effective in determining the binding specificity of several ►small molecule drugs, including ►alkylating agents and ►topoisomerase poisons (e.g. ►adriamycin and ►irinotecan). REPSA can also be used to identify the preferred sites of antineoplastic agent (e.g. ►cisplatin and other ►platinum drugs) and ►carcinogen-macromolecular ►adducts to DNA. It is envisioned that REPSA should be useful in the development of new anticancer drugs that target specific DNA sequences and genes and in better understanding chemical carcinogenesis.

SELEX

SELEX differs from CASTing and REPSA in that it primarily uses single-stranded RNA and DNA oligonucleotides as the receptor for various ligands. These single-stranded oligonucleotides adopt sequence-dependent three-dimensional structures in solution on the basis of base pairing (both through Watson-Crick and noncanonical hydrogen bonding schemes), base stacking, and other interactions. These structures then have the potential to interact with a variety of ligands, including proteins and small molecules. Thus, SELEX affords the possibility of identifying potential receptors within a larger conformational space than usually explored by other combinatorial approaches.

The steps involved in SELEX are shown in Fig. 3. The nucleic acids used in SELEX binding reactions are usually derivatives of double-stranded DNA templates (e.g. single-stranded RNA transcripts). Thus, whereas the flanking regions of the selecting transcripts need to be of sufficient length to allow PCR amplification, the complete templates are often longer to provide information for transcript generation (e.g. a bacteriophage promoter region). In addition, since the single-stranded nucleic acids need to be of sufficient length to adopt a stable three-dimensional structure, the randomized region of SELEX templates tends to be considerably longer (20–100 nucleotides) than that of other combinatorial selection methods. An initial step in SELEX involves the production of selection transcripts from the parent template. The binding and separation steps are comparable to those in CASTing. After selection, RNA transcripts need to be converted into complementary DNA strands by reverse transcription before amplification by PCR. As with other combinatorial selection methods, cycles of transcription, binding, separation, reverse transcription, and amplification can be repeated until desired results are obtained. Note that the long length of some SELEX

randomized regions makes it highly unlikely that all possible sequences are well represented in the initial selection. Thus, either the reverse transcription or PCR amplification steps are performed with enzymes having relatively low fidelity. This allows the introduction of mutations into the selection templates, which provides the opportunity to identify even higher-affinity oligonucleotides than were present in the initial selection. Subcloning, sequencing, and analysis are comparable to those in other combinatorial selection methods.

SELEX, being a combinatorial method that uses single-stranded nucleic acids, has the unique ability to present a large variety of different conformational shapes for selection, rather than just different duplex DNA sequences. This allows SELEX to identify linear nucleic acid sequences that adopt structures capable of interacting with a variety of ligands, including those not normally believed to interact with natural nucleic acids. Oligonucleotides containing these SELEX-selected sequences are known as aptamers, and aptamers have been identified that bind to a variety of proteins and small molecule ligands with specificities and affinities rivaling those of antibodies. Thus, a considerable number of uses for aptamers have been found in microarray-based proteomic analyses, especially in medical diagnostics. In addition, although unmodified nucleic acids have a relatively short half-life *in vivo*, chemically modified oligonucleotides can persist for several days. Thus, modified aptamers (e.g. ►aptamer bioconjugates) are being developed as targeted therapeutic agents for both acute and chronic diseases, including cancer.

Comet Assay

Peter Schmezer
Division of Toxicology and Cancer Risk Factors, German Cancer Research Center (DKFZ), Heidelberg, Germany

C

Synonyms

Single cell gel electrophoresis assay (SCGE); Single cell microgel electrophoresis assay

Definition

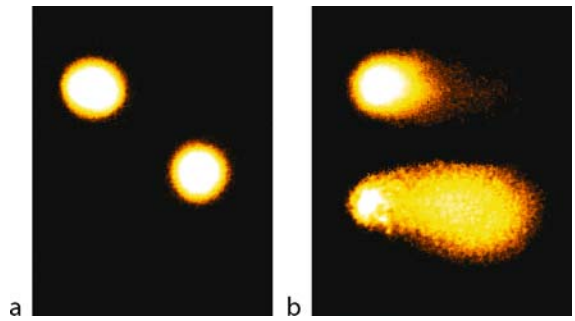
The comet assay is a sensitive electrophoresis technique for studying ►DNA damage and ►repair of DNA in individual cells. It has become one of the standard methods for testing of ►genotoxic stress and it is also frequently utilized in environmental and human ►biomonitoring, molecular ►cancer epidemiology as well as in fundamental cancer research.

Characteristics

The assay can be applied to all cell types including human, animal or plant cells, whether in culture or isolated from organs or tissues. In general, single cell suspensions are prepared, and cells are subsequently embedded in a thin agarose gel on microscope slides. Consecutive cell lysis with detergent and high salt removes cellular and nuclear membranes and proteins, and liberates DNA in the form of a compact, nucleus-like structure which is also called nucleoid. The gel-embedded DNA is then subjected to electrophoresis. DNA migrates toward the anode in a way that is dependent on its size. Thereby, DNA migration corresponds to the number of DNA lesions, i.e. increased electrophoretic migration is correlated with an increased amount of DNA damage present in the cell. DNA is stained by a fluorescent DNA-binding dye and so visualized by fluorescence microscopy as to show DNA migration. Several imaging software programs are commercially available to analyze the microscopic pictures and to quantify DNA migration (Fig. 1).

Modifications

Different modifications of the assay have been developed. The most common version applies alkaline electrophoretic conditions in concert with an alkaline pre-treatment of DNA. This leads to the conversion of so-called alkaline labile sites to strand breaks, and increases the spectrum of DNA lesions that can be detected. Before electrophoresis, additional incubation of DNA with damage-specific DNA repair enzymes,



Comet Assay. Figure 1 Comet assay micrographs of (a) undamaged cells, and (b) cells with DNA damage; DNA stained with SYBR® Green; observation at 250× magnification using a fluorescence microscope; the term comet assay refers to the comet-like structure present in damaged cells after lysis and gel electrophoresis.

such as DNA glycosylases or endonucleases, can enhance both sensitivity and specificity of the assay. These enzymes recognize DNA lesions with high specificity and convert them to strand breaks which increase DNA migration. Examples are endonuclease III to detect oxidized pyrimidines, formamidopyrimidine DNA glycosylase to detect 8-oxoguanine and other altered purines, and T4 endonuclease V to detect ►UV radiation-induced pyrimidine dimers. Neutral electrophoresis conditions facilitate the detection of DNA double strand breaks.

Areas of Application

Genotoxicity Testing

International guidelines have been published for the application of the comet assay in genotoxicity testing and biomonitoring. The assay is widely used in this research area due to several advantages such as (i) sensitivity to detect low levels of DNA damage, (ii) requirement for relatively small amounts of cells and test substances, and (iii) possibility to perform high-throughput analyses implying automated imaging. The technique is able to detect a broad spectrum of DNA damaging agents including both ionizing and UV radiation, ►alkylating agents, chemicals that form free radicals or ►adducts to DNA, and various metal compounds. Modified versions of the assay have been developed to measure the genotoxic effects of DNA–DNA or DNA–protein cross-linking agents such as ►cisplatin. Agents that directly induce DNA strand breaks are readily detectable. Other DNA lesions such as bulky DNA adducts, e.g. formed by ►polycyclic aromatic hydrocarbons do not increase DNA migration by itself. Here, DNA breaks occur only as intermediates during their repair process when these adducts are eliminated from cellular DNA by ►nucleotide excision repair. These intermediate breaks are normally short-lived, especially in dividing cells. They are however effectively detectable by the comet assay when the breaks are accumulated by delaying DNA synthesis with specific inhibitors.

DNA Repair

The comet assay is increasingly used to measure DNA repair. Here, the removal of afore induced DNA lesions is monitored over time, and both clearance of alkaline labile sites and repair-mediated rejoining of strand breaks can be observed as a decrease in DNA migration. The repair activity of intact cells as well as of cell extracts has been successfully analyzed. The repair of specific DNA lesions can be followed (i) by utilizing agents that induce a well characterized type of DNA damage, and (ii) by pre-treatment of the gel-embedded nucleoids with lesion-specific enzymes. An important and prominent example is the detection of 8-oxoguanine, a mutagenic base byproduct which occurs as a result of exposure to reactive oxygen. Studying repair of oxidized bases by pre-teatment of nucleoids with the enzyme Ogg1 (8-oxoguanine DNA N-glycosylase 1) or its bacterial counterpart Fpg (formamidopyrimidine DNA glycosylase) has revealed considerable variation among subjects. Furthermore, the application of the comet assay in human intervention trials showed that the level of oxidative DNA damage can be modulated, e.g. the supplementation of diet with antioxidant-rich fruit increased the antioxidant status of lymphocytes and enhanced DNA repair activity. The comet assay as described provides evidence of DNA damage and repair in the whole genome of the analyzed cell. These measurements can also be focused on specific genomic regions when the analysis is combined with fluorescence in situ hybridization (FISH).

Biomonitoring

The induction of DNA lesions is considered to be a crucial event in ►carcinogenesis and, in the case of absent or imperfect DNA repair, might lead to mutations, a key driving force in cancer development. The comet assay is applied in human biomonitoring studies, e.g. to detect genotoxic environmental or occupational exposures in human white blood cells, and it can be used as a tool to characterize hazards in risk assessment studies. The potential of the assay to detect DNA lesions in peripheral blood lymphocytes has also been exploited in cancer patients receiving antineoplastic chemo- or radiotherapy. It is however important to note that the level of DNA damage that is detected in these studies was shown to be – at least in some studies – influenced by age, gender and a variety of additional environmental or lifestyle factors such as

exposure of subjects to air pollution, sunlight, dietary components, smoking or excessive physical exercise.

Cancer Susceptibility

In addition to its use as a ►biomarker of exposure to genotoxic carcinogens, it can also serve as a biomarker for cancer susceptibility. By analyzing human cell samples, e.g. peripheral blood lymphocytes, it allows estimation of inter-individual differences in response to genotoxic carcinogens and facilitates the identification of susceptible subjects. When applied in molecular epidemiological studies, individual differences both in the extent of induced DNA damage (mutagen sensitivity) and in the ability to repair DNA lesions (DNA repair capacity) can be monitored. The assay was successfully utilized in such studies, e.g. to demonstrate that cells from lung cancer patients showed significantly increased mutagen sensitivity and reduced DNA repair capacity as compared to cells from control subjects. These data, and further results from studies using comparable assays, emphasize the importance of mutagen sensitivity and DNA repair capacity as host factors which are strongly associated with the risk of developing cancer and other diseases. Furthermore, family studies and studies in monozygotic and dizygotic twins provide strong and direct evidence that mutagen sensitivity is highly heritable. Overall, epidemiological studies revealed a positive and consistent association between these at risk phenotypes and cancer occurrence with an increased risk ranging from 2 to 10. Application of the comet assay, e.g. in prospective cohort studies and multi-laboratory trials will further contribute to its validation and, if successful, will offer new possibilities to improve cancer screening programs, to prevent tumor initiation, and to intervene in tumor progression in a patient-tailored manner.

Committed

Definition

Used to describe cells whose fate is already determined along a particular path of differentiation – at least within the bounds of the experimental assay.

Common Bile Duct

Definition

The duct formed by the junction of the gallbladder duct (cystic duct) and the common hepatic duct from the liver which carries bile to the gut (duodenum).

►Hepatic Epithelioid Hemangioendothelioma

Common Fragile Sites

Definition

Specific chromosomal loci that are especially prone to forming gaps and break as seen on metaphase chromosomes under conditions of replication stress. Found in all individuals, common fragile sites are considered a normal component of human chromosomes.

►Fragile Site

Common Melanocytic Nevi

Definition

Moles composed of ►nevus cells (melanocytes) grouped in collections within the first and/or second layers of the skin. The tendency to develop nevi is influenced by familial factors and sun exposure. Most nevi have a very low malignant potential.

►Protease Activated Recept Family
►Melanocytic Tumors

Comorbidity

Definition

Comorbidity describes any distinct additional clinical entity that has existed or may occur during the clinical course of a patient with a primary (index) disease. There is currently no consensus on how to quantify comorbidities but several scales and indices are available.

►Acute Myeloid Leukemia

Comparative Genomic Hybridization (CGH)

Definition

Is a molecular-cytogenetic method for the analysis of copy number changes (gains /losses) in the DNA content of tumor cells.

►Array (CGH)

Comparative Genomics

Definition

The analysis and comparison of genomes from different species.

Comparative Oncology

Melissa C. Paoloni, Chand Khanna
National Cancer Institute, Center for Cancer Research, Comparative Oncology Program, Bethesda, MD, USA

Definition

Comparative oncology is the discipline that includes spontaneous, naturally occurring cancers seen in companion (pet) animals into studies of cancer biology and therapy.

Characteristics

An under-utilized group of animal models in the study of cancer biology and therapy include companion animals, primarily dogs, which naturally develop cancer. In the United States, there are ~60–70 million pet dogs. Based on crude incidence rates, it is estimated that over one million new cases of cancer are diagnosed in pet dogs each year. Due to increasing emphasis on the human-animal bond, the pet owning public is motivated to seek out new and effective treatment options for their pet animals with cancer. This population provides a platform to study cancer biology and therapy in a natural system that can serve as an intermediary step between ►mouse models and human patients. Naturally occurring cancers in pet dogs and humans share many features, including histological appearance, tumor genetics, biological behavior and response to conventional therapies. Tumor initiation and progression are influenced by the same factors for both human and canine cancer, including age, nutrition, sex, reproductive status, and environmental exposures. Several genetic alterations and molecular signaling pathways known to be important in human cancers have been defined and shown to be relevant in cancers of pet dogs.

Some malignant histologies of comparative interest include:

- Canine ►Osteosarcoma
- Canine NH Lymphoma
- Canine Prostate Carcinoma
- Canine Mammary Carcinoma
- Canine Melanoma
- Canine Lung Carcinoma
- Canine Head and Neck Carcinoma
- Canine Soft tissue Sarcoma
- Canine Bladder Carcinoma
- Canine Renal Cystadenocarcinoma

History

The value of naturally occurring cancers seen in companion animals, as models of human cancer has been recognized for over 30 years. Early studies in the field of bone marrow transplantation utilized dogs with non-Hodgkin's lymphoma (►Malignant Lymphoma, Hallmarks and Concepts) to define optimal preparatory regimens for bone marrow transplant. Since then, the activity and optimal use of a wide variety of anticancer agents have benefited from information derived from studies in these large animal naturally occurring cancer models. These have included:

- Limb sparing techniques for osteosarcoma
- Cytotoxic chemotherapy
- Inhalation therapy for pulmonary malignancies
- Immunotherapy

- Peptide vaccine (►Peptide Vaccines for Cancer)
- DNA vaccine
- Cell based immunotherapy

- ►Anti-angiogenic therapy
- Isolated perfusion techniques
- Small molecule inhibitors (►Small Molecule Drugs)

Scientific Advancements

A recognized and long standing weakness of comparative models was a limited opportunity to investigate the biological basis of an anticancer agent's activity or lack of activity. However with the public release of a high-quality draft sequence covering 99% of the canine genome (2.5 billion base pairs) it is now possible to apply many of the same methodologies used to interrogate human cancer, in the dog. The genome sequencing suggests that all ~19,000 genes in the dog have a similar gene in the human genome. The dog and human lineages are more similar than the rodent lineage both in terms of nucleotide divergence and rearrangements. Also the single nucleotide polymorphism (SNP) frequency in dogs is similar to SNP frequency in the human population, even with the diversity of breed phenotypes. Thus, the genomes of dog and human are similar enough to suggest that genomic information learnt about one species can be easily transferred to and be applicable for the other.

Coupled with this more available genomic data, reductions in the cost of generating biological reagents have contributed to the development of novel investigative platforms for the study of canine tissues. Evidence of this includes the availability of commercially available canine oligonucleotide microarray, optimized conditions for proteomic studies, validated canine specific antibodies and characterization of human antibodies that cross react with canine epitopes. Collectively, the opportunity now exists to conduct detailed and biologically intensive studies in dogs that have cancer, that can evaluate cancer associated target genes/proteins and pathways important in cancer biology and therapy.

Need for New Models of Drug Development

Cancer drug development (►Drug Design) is costly, linear, and inefficient. Costs associated with development incrementally rise as the path proceeds. The two most common causes of drug failure are toxicity or lack of efficacy. These failures are most costly once a drug enters phase I human trials but are even more costly if they occur after phase II trials, and beyond (►Clinical Trial). It is therefore essential that "go-no-go" decisions focus on the issue of toxicity and efficacy as early in the development path as possible. An information gap has historically existed between preclinical studies and phase I human trials; however, with the development of novel non-cytotoxic anti-cancer agents, this gap is now equally evident later in the drug development path. After successful completion of phase I human clinical trials, the design of phase II trials often has to take place without sufficient information including biological dose, schedule, and regimen for many of these novel agents. For both cytotoxic and, more importantly novel non-cytotoxic agents, additional model systems are needed. The "model" advantages of companion animal cancers provide an opportunity to integrate studies that include companion animals into the development paths of new cancer drugs. The outcome will include earlier assessment of agent activity and toxicity and the validation of biological endpoints and surrogate markers critical to the design of more informed phase I and phase II human clinical trials.

Comparative oncology models are well-suited for integration into preclinical cancer drug development efforts for several reasons. By their nature, companion animal cancers are characterized by inter-patient and intra-tumoral heterogeneity, the development of recurrent or resistant disease, and metastasis to relevant distant sites. In these ways, companion animal cancers capture the "essence" of the problem of cancer in ways not seen in other animal model systems. The lack of gold standard treatments for canine cancer patients allow for the early and humane testing of novel therapies. The shortened life span of companion animal patients and their early metastatic failure allow rapid completion of clinical trials of novel agents. A further rationale for the use of these models in non-clinical efficacy studies is the immune competence of the host, relevant and species-concordant tumor-microenvironment interactions, spontaneous development of tumors, and more importantly spontaneous development of resistance patterns to standard therapies within an individual animal. Additional attributes of comparative oncology include the opportunity to gather serial biopsies from target and non-target lesions and repeated body fluid collection (serum, whole blood, urine) from the same animal during exposure to an investigational agent. This serial sampling allows for the identification of tumoral and surrogate pharmacodynamics endpoints that can be uniquely correlated to response in ways that are often deemed unacceptable in human trails (►Preclinical Testing).

Clinical Applications

Efforts to perform co-ordinated, multi-center preclinical cancer trails in companion (pet) dogs exist in a number of different formats allowing for the rapid evaluation of cancer drugs in biologically intensive trials. Hallmarks of comparative oncology trials include good clinical practice (GCP) trial conduct, computer-based data management and reporting and multiple study endpoints. The ability to capture data contemporaneously in preclinical dog trials allows for the reporting of

toxicities, if they are to occur, in a rapid and systemic fashion.

Mechanisms and procedures for integration of data from preclinical trials in tumor bearing dogs into the regulatory pathway are currently being defined. However, the use of clinical trials using pet dogs will not only provide information important to the initiation of early human clinical trials (Phase I) but also will inform the appropriate design of later development trials (Phase II/Phase III). It is expected, through the integration of comparative oncology modeling, that the cancer drug development path will become more informed, efficient, and less costly.

Complement

Definition

The complement system is part of the immune system's defense mechanism against microbes and foreign cells. When initiated, the complement cascade activates a series of complement components, which interact to form a membrane attack complex. The formation of this complex at the surface of the foreign cell/microbe leads to its lysis and killing

►Cystatins

Complement Cascade

Definition

A precise sequence of events usually triggered by an antigen-antibody complex, in which each component of the complement system is activated in turn.

Complement-Dependent Cytotoxicity

Definition

(CDC) refers to the lysis of a target cell in the presence of ►complement system proteins. The complement activation pathway is initiated by the binding and fixation of the first component of the complement system (CIq) to the fragment crystalline (Fc) region of a (therapeutic) antibody complexed with a cognate antigen. The end result is a membrane attack complex that generates a hole in the cell membrane, ultimately causing cell lysis and death.

►Immunotherapy
►Diabody
►Interferon-α

Complement-Mediated Cell Death

Definition

A process used by the immune system whereby members of the complement factor family (comprised of at least 20 distinct proteins) recognize antibody-coated cells and facilitate cell lysis resulting in cell death.

►Osteopontin
►Immunoprevention of Cancer

Complementarity Determining Region

Definition

CDR; Is a short amino acid sequence found in the variable domains of immunoglobulin and T cell receptor proteins that complements an antigen and therefore provides the receptor with its specificity for that particular antigen.

►Anti-HER2/Neu Peptide Mimetic (AHNP)
►Hypervariable Region

Complementation Groups

Definition

Complementation groups are subgroups of DNA repair-deficiency syndromes, each representing a separate (defective) DNA repair gene; xeroderma pigmentosum.

►Xeroderma Pigmentosum
►Fanconi Anemia

Complete Cytoreduction

Definition

Visceral resections and peritonectomy procedures whose goal is to remove malignancy to the extent that subsequent intraperitoneal chemotherapy will result in a complete eradication of the abdominal and pelvic disease.

►Appendiceal Epithelial Neoplasms

Complete Hematologic Remissions

Definition

Achievement of a normal white blood cell (WBC) and platelet count, normal differential, and no signs and symptoms of leukemia cells.

►Nilotinib

Complex Karyotypic Changes

Definition

more than three numerical and/or structural aberrations in a clone.

Compound Screen

►Small Molecule Screens

Compounds from Organisms

►Natural Products

Computed Tomography

Definition

Computed tomography (CT), also known as computerized tomography or computed axial tomography (CAT), is medical technology that uses special X-ray equipment to obtain image data from different angles around the body, and computer processing of the information to produce three-dimensional images. While conventional X-rays provide flat two-dimensional images, CT images show a detailed views of cross-sections of body tissues and organs.

►Radiation Oncology

Concatamerization

Definition

Formation of large molecules consisting of tandem copies of a nucleic acid.

Concomitant

Definition

Given at the same time, e.g. radiotherapy combined with chemotherapy.

►Ionizing Radiation Therapy

Conditionally Replicating Adenovirus

►Oncolytic Adenovirus

Conditionally Replicative Adenovirus

►Oncolytic Adenovirus

Conduit

Definition

A channel, pipe or pore that allows liquids or substances to pass.

►Connexins

Confidence Interval

Definition

CI defines the uncertainty of the risk estimate and is confounded by sample size. The probability that the unknown true risk lies within a 95% confidence interval (before drawing the sample) is 95%. After drawing the sample and calculating the risk estimate, there is considerable assurance that the confidence interval covers the true estimate.

Confocal Laser-Scanning Microscopy In Vivo

Armin Gerger[1], Josef Smolle[2]
[1]Department of Internal Medicine, Division of Oncology, Medical University Graz, Graz, Austria
[2]Department of Dermatology, Medical University Graz, Graz, Austria

Definition

Confocal laser-scanning microscopy (CLSM) in vivo represents a novel imaging tool that allows the noninvasive examination of skin cancer morphology in real time at a resolution for viewing microanatomic structures and individual cells.

Characteristics

In recent decades, enormous strides have been made in noninvasive imaging of cancer tissues with the development and refinement of computerized axial tomography, magnetic resonance imaging, and positron emission tomography, to name a few. Progress in noninvasive skin cancer imaging, however, has been slower than in other specialities due in part to the ease with which skin is visually examined and biopsied. Early detection of malignant skin tumors is essential, and still one of the most challenging problems in clinical oncology. Although surgical excision in early stages of tumor development is almost always curative, delayed recognition of skin malignancies puts the patient at risk for destructive growth and death from disease once the tumor has progressed to competence for metastasis. The early diagnosis of malignant skin tumors by naked-eye examination, however, is still rather poor. Technological advancements have led to the development and investigation of imaging tools to provide information to the clinician that can improve the diagnostic performance for early diagnosis and assist in the management of cutaneous malignancies. Among novel noninvasive imaging techniques, CLSM stands out because of its high resolution. CLSM provides for the first time in vivo imaging of individual cancer cells and offers windows on living tissue. Investigations of CLSM for in vivo examination of human skin was first published in 1995, 2 years later the first commercially available in vivo confocal reflectance microscope was introduced to the research community. Since then, valuable experience has been gained from research labs and hospitals around the world. Imaging is based on the detection of back scattered light with contrast due to naturally occurring refractive index variations of tissue microstructures. A confocal digital imager consists of a point source of light that illuminates a small spot within the biological specimen. The illuminated spot is then imaged onto a detector through a pinhole aperture. This aperture acts as a spatial filter, rejecting light that is reflected from the out-of-focus portions of the object, so the resultant image has the high contrast of a thin-section image. The light source, illuminated spot, and detector have the same foci, or are placed in conjugate focal planes, and are therefore confocal to each other. The diameter of the detector aperture is matched to the illuminated spot through the intermediate optics. Because a small spot is illuminated and then detected through a small aperture, only the plane in focus within the specimen is imaged. Light originating from out-of-focus planes is prevented from entering the detector. A confocal digital imager thus allows imaging of thin

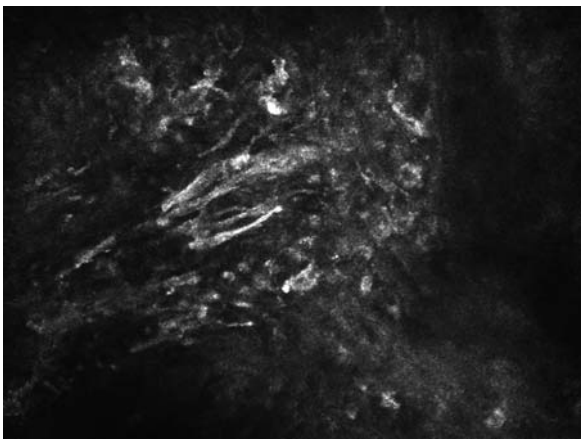
slices of tissue, or optical sectioning, with high axial resolution and contrast. The confocal digital imager illuminates and images only a small spot at a time. To view the whole specimen, the illumination spot is scanned over the desired field of view. The illumination spot is raster-scanned optomechanically to sweep the entire area. The specimen is illuminated point by point, and then the image is created in the corresponding manner. Real-time confocal imaging of human skin involves laser scanning rather than white-light tandem scanning. Laser scanning has the benefits of bright, higher contrast imaging, higher magnifications, and deeper penetration. Infrared lasers coupled to a fast scanner allow video rate imaging of skin to maximum depths of 300 μm. The thickness of the in vivo optical slice obtained is 2–5 μm. To minimize blurring, a skin-to-microscope contact device stabilizes the skin to within ±2 cells. Live images are displayed on a video monitor. With in vivo imaging, the virtual sectioning occurs in the horizontal plane, which correlates to en face sections as opposed to the vertical sections of routine histology. Contrast in the image correlates to naturally occurring variations in refractive index of organelles and microstructures within the skin. Epidermal keratin, for example, varies in refractive index depending on the state of differentiation of the keratinocyte. As the keratinocytes mature within the epidermis and the molecular weight of the keratins within an epidermal keratinocyte increases, the keratinocytes become more refractile, thus causing an increase in refractive index. As a result, the confocal images become brighter and the keratinocytes within the epidermis are well defined. The pigment melanin within the epidermis also has a high refractive index, in fact higher than keratin. Visually, melanin has a characteristic brown-black appearance because of the absorption of visible light. When illuminated with infrared light, however, the absorption is greatly reduced. This reduced absorption, combined with the intrinsic high refractive index, causes enhanced back scattering of reflected light that is collected by the confocal microscope. Higher concentrations of melanin cause an increase of back scattering to occur. Consequently, what appears as brown-black to the naked eye will appear white or bright in a confocal image.

The main advantage of CLSM is the unique opportunity to image thin sections of living tissue at a resolution equal to that of conventional microscopes used to view histology slides. Cellular and architectural details can be examined without having to excise and process the tissue as in standard histology. When the objective lens is placed onto an adapter ring, which is fixed on the tumor, real-time images can be obtained in seconds at the bedside. As a limitation in the current state of technological confocal microscopy development it has to be addressed that assessment of microanatomic structures can only be done to a depth of 300 μm, which corresponds to the papillary dermis. Thus, processes in the reticular dermis and tumor invasion depth cannot be reliable evaluated at the present state of confocal imaging technology.

Clinical Relevance

Initial research has concentrated on the most clinically relevant cutaneous malignancies. Tumors that have been imaged and characterized include ►melanocytic skin tumors and nonmelanoma skin cancer. Confocal images have been qualitatively and quantitatively correlated to corresponding horizontal histology sections. The primary goal was to define and understand skin cancer morphology as seen with a confocal microscope in vivo. These preliminary studies were helping to develop an ability to understand and interpret confocal images of skin cancer. In the present state of investigations, the focus lies on the diagnostic accuracy of the method and consequently the integration into clinically routine procedures. Of all the cancers, ►melanoma of the skin represents one of the greatest challenges in early or preventative detection. Using CLSM, distinct morphologic features can be described for the differentiation of benign common nevi and malignant melanoma (Fig. 1). For example, in general, progression from monomorphic features in benign common nevi to increasing pleomorphism and architectural disarray in dysplastic nevi and melanomas was found.

Melanocyte cytology shows round to oval, bright and monomorphic cells in benign nevi whereas melanomas tend to present polymorphic and irregularly shaped cells. Nevus cell nests can be clearly seen in benign common nevi, but are less defined in dysplastic nevi. Disarray of architecture can be found in melanoma.



Confocal Laser-Scanning Microscopy In Vivo. Figure 1 Confocal in vivo image of malignant melanoma.

Keratinocyte cell borders can be readily detected in benign common nevi, show focal absence in dysplastic nevi and are poorly defined or absent in melanoma. Dendrite-like structures with a complex branching pattern are frequently seen in melanoma, but less frequently in benign nevi, where they are smaller and more delicate. In a recently published study, excellent sensitivity and specificity achieved for the diagnosis of melanoma using confocal microscopy in vivo, based on distinct morphologic features, has been described. Of note, the independent observer received only a 30 min presentation that instructed them in the confocal morphologic features of melanocytic skin tumors. Moreover, statistical analysis showed excellent to perfect inter and intraobserver agreement for the confocal morphologic attributed studied. Nonmelanoma skin cancers are the most common malignancies among the Caucasian population. The most frequent of these are ►basal cell carcinomas and squamous cell carcinomas. Based on several studies, confocal images of both basal cell carcinomas and squamous cell carcinomas show relevant cellular and architectural features comparable to standard pathology. Moreover, a high diagnostic accuracy, prior to naked-eye and other noninvasive imaging techniques, could be achieved by the confocal microscope. Another potential use of CLSM in vivo is presurgical margin detection for skin cancer surgery. Surgical management of amelanotic melanomas as well as melanomas, basal cell carcinomas, and squamous cell carcinomas with ill-defined borders present a significant clinical challenge currently addressed by serial excisions. In these settings, CLSM provides a much improved first approximation of the lateral borders between the tumor and normal skin. The cumulative experience with CLSM by different investigators clearly holds promise for this technology in the future. The results of several studies indicate that in vivo examination of skin tumors by CLSM can provide useful diagnostic information. CLSM represents an opportunity for clinicians to add useful and reliable information in their diagnostic decisions and therefore may spare some patients a biopsy or excision procedure and save time and costs.

Conjugated Double Bonds

Definition
Are double bonds that are separated from each other by one single bond (–C=C–C=C–); conjugated systems with alternating single and double bonds result in a general delocalization of electrons across adjacent atoms allowing for resonance-stabilized structures that impart both capacity to act as biological antioxidants and the ability to absorb and give off certain wavelengths of light that cause a compound to appear colored (e.g. β-carotene is responsible for the orange color of carrots, lycopene for the red color of tomatoes).

►Carotenoids

Conjugated Linoleic Acid (CLA)

Definition
Conjugated linoleic acid (CLA) refers to a family of at least 13 geometric isomers of linoleic acid, which is found preferentially in dairy products and meat of ruminants.

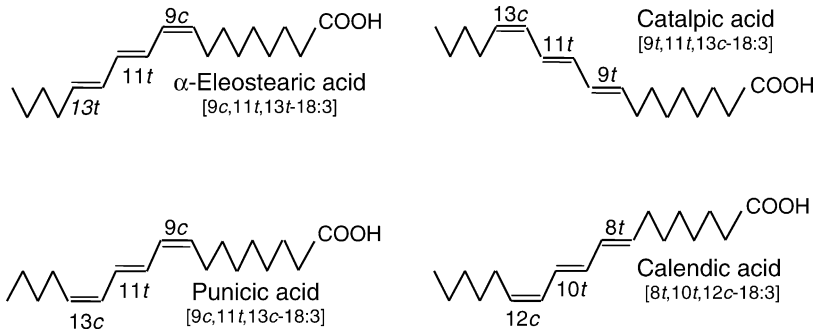
►Lipid Mediators

Conjugated Linolenic Acids

Kazuo Miyashita
Department of Bioresources Chemistry, Faculty of Fisheries Sciences, Hokkaido University, Hakodate, Hokkaido, Japan

Synonyms
CLN

Definition
Conjugated linolenic acid (CLN) is a general term for the geometrical and positional isomers of octadecatrienoic (18:3) acid with three conjugated double bonds. Conjugated linolenic acids occur in several terrestrial plants (mainly seed oils). They include α-eleostearic acid (9*cis*(c),11*trans*(t),13t-18:3), catalpic acid (9t,11t,13c-18:3), punicic acid (9c,11t,13c-18:3),



Conjugated Linolenic Acids. Figure 1 Structure of conjugated linolenic acids (CLN).

calendic acid (8t,10t,12c-18:3) and jacaric acid (8c,10t,12c-18:3) (Fig. 1). High contents of calendic acid, punicic acid and α-eleostearic acid are found in seed oils of pot marigold, pomegranate and tung/bitter gourd respectively.

Characteristics

In-Vitro Studies

Conjugated linolenic acid (CLN) shows cytotoxic effect on mouse tumor cell (SV-T2). However, there is a difference in the toxicity between CLN isomers. Fatty acid from pot marigold (8t,10t,12c-18:3; 33.4%) has no effect on the cell line up to 250 μM, but other kinds of fatty acids from seed oils are cytotoxic to SV-T2 cells below 20 μM. The same effect is observed in the case of human monocytic leukemia cell (U-937). Generally, 9,11,13-CLN and all trans-CLN are more cytotoxic than 8,10,12-CLN and CLN containing cis configuration, respectively. The higher cytotoxicity of 9,11,13-CLN or all trans CLN isomers is partly due to the different susceptibilities of these CLN isomers to lipid peroxidation. On the other hand, the inhibitory effect of CLN on the growth of colon cancel cells is related to the regulation of peroxisome proliferator-activated receptor (PPAR)γ. ►PPARγ ligands such as troglitazone and 15-d-prostaglandin (PG) J_2 cause growth inhibition and induce ►apoptosis in cancer cells. CLN shows a higher ligand activity on PPARγ than troglitazone. ►Bcl-2, ►GADD45, and ►p53 are known as an important molecular target in apoptosis-inducing pathways. In Caco-2 cell treated with 9c,11t,13t-CLN, Bcl-2 expression is down-regulated, while GADD45 and p53 expressions are up-regulated. Therefore, two possible mechanisms of the anticarcinogenic activity of CLN can be hypothesized *viz.*, induction of apoptosis *via* lipid peroxidation and regulation of target gene and protein.

In-Vivo Studies

CLN from bitter gourd seed oil (BGO) significantly reduces the frequency of colonic aberrant crypt foci (►ACF) in rat as a precursor of colon carcinogenesis. In this case, the proliferating cell nuclear antigen (►PCNA)-labeling indices in ACF and normal-appearing crypts also decreases by dietary feeding of CLN. Furthermore, feeding of CLN enhances apoptotic cells in ACF without affecting the surrounding normal-appearing crypts. ►Chemopreventive ability of BGO on rat colon cancer can be found in a long-term *in vivo* assay. Dietary administration of BGO rich in CLN (9c,11t,13t-18:3) significantly inhibits the development of colonic adenocarcinoma induced by ►azoxymethane (AOM) in male F344 rats without causing any adverse effects. In addition, BGO intake significantly reduces the multiplicities of colorectal carcinoma (number of carcinomas/rats) in rats. Other CLN isomer (9c,11t,13c-18:3) from pomegranate seed oil (PGO) also shows the chemopreventive effect on rat colon cancer induced by AOM. Dietary feeding of PGO suppresses progression of adenoma to malignant neoplasm in post-initiation phase of colon cancer. Dietary feeding of BGO and PGO enhances PPARγ expression in non-lesional colonic mucosa. Synthetic ligands for PPARα and PPARγ effectively inhibit AOM-induced ACF in rats. Therefore, it may be possible that BGO and PGO suppress colon carcinogenesis by means of altering PPARγ expression in colonic mucosa.

Conjugation

Definition

The joining together of two chemicals (by an enzyme).

►Carcinogen Metabolism

Conn Syndrome

Definition

Conn syndrome, first reported by Jerome W. Conn, is a result of an increased production of aldosterone, a hormone produced by the zona glomerulosa of the adrenal cortex. This hormone causes the retention of water and sodium and excretion of potassium. The clinical manifestations include high blood pressure, headaches, and muscle cramps. A small proportion of children with adrenocortical cancer overproduce aldosterone.

►Childhood Adrenocortical Carcinoma

Connexins

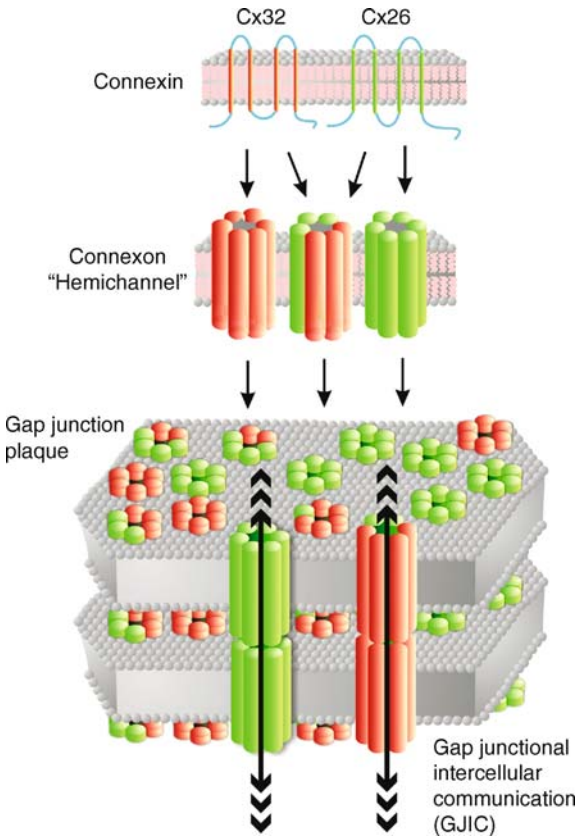
Dale W. Laird
Department of Anatomy and Cell Biology, University of Western Ontario, London, ON, Canada

Definition

Connexins are proteins which assemble into channels that allow for small molecules to pass directly from one cell to another.

Characteristics

The family of connexin (Cx) proteins is composed of 21 members in humans. All connexins (►Cx32 and ►Cx26) share common features of assembling into ►connexons also called "hemichannels" consisting of six subunits of the same or different connexins (Fig. 1). Hemichannels from apposing cells dock and the resulting channels cluster into a junctional complex known as a ►gap junction or often referred to as a gap junction plaque. Gap junctions allow for the direct intercellular exchange of secondary messengers and other small molecules, a process termed gap junctional intercellular communication (GJIC) (Fig. 1). Gap junctions have a ubiquitous distribution in human tissues, and these specialized intercellular channels are essential for normal cell function, proper cell differentiation, tissue development, metabolic transport, ion transfer and cell growth control. Importantly, each connexin is assembled into a channel with unique



Connexins. Figure 1 Connexins (e.g. Cx32 or Cx26) are gap junction proteins that thread through the lipid bilayer of cell membranes four times. Connexins of the same type (orange or green rods) or different types (mixtures of orange and green rods) assemble into hexameric arrangements with a central pore known as connexons or "hemichannels." Connexons from opposing cells dock and tightly cluster into gap junction plaques allowing for bidirectional exchange of small molecules a process known as gap junctional intercellular communication (GJIC).

properties that are thought to reflect distinct physiological roles for the different gap junction channel types. In numerous diseases connexins are either not produced or mislocalized (e.g. many cancers) or contain mutations that inhibit the normal function of the resulting channels. Mutations of connexin genes are linked with human diseases including neurodegeneration, skeletal abnormalities, ►keratodermas, and hereditary ►sensorineural deafness. For example, mutations in the gene encoding Cx26 are the most common cause of ►congenital hearing loss.

Connexins as Tumor Suppressors

The evidence that connexins play a role in cell growth control and early tumorigenesis ranges from circumstantial to direct linkages. First, most soft tissue tumors typically have reduced gap junctions due to either decreased connexin expression or an inability to efficiently assemble connexins into gap junctions. Second, tumor promoters, ►mitogens and ►oncogenes are known to reduce GJIC. Third, re-expression of connexins in tumor cells frequently revert cancer cells to a less aggressive cell type and slows cell growth, highlighting the tumor suppressive behavior of connexins. Fourth, mice lacking one member of the connexin family (Cx32) are 10–25 times more at risk of developing chemically or radiation-induced liver or lung tumors. The evidence that mutations in the genes encoding connexins lead to increased susceptibility to cancer is sparse and thus connexins are more commonly thought of as ►Class II tumor suppressors reflecting the consequence of reduced expression or ability to make gap junctions. Collectively, convincing data suggest that connexins play a role in ►carcinogenesis particularly at disease onset, progression and early events associated with ►metastasis. The role of connexins in cancer cells that enter the blood stream and proceed to break through the endothelial wall in later stage metastasis is less clear. In fact, considerable evidence would support the position that connexin expression in later stage disease favors the ability of cancer cells to enter and propagate at new tissue sites. Consequently, a working paradigm is that connexins protect cells from becoming cancerous, act to suppress the growth of primary tumors and play an inhibitory role in cells breaking away from the primary tumor. However, in advanced disease where tumor cells were successful in escaping the primary tumor, connexin re-expression may facilitate the cancer cells exiting the blood system to enter and populate a second tissue site.

Connexins as a Therapeutic Target

The likelihood of connexins being a good target for ►combination therapy for primary tumors remains promising. Considerable evidence supports the notion that upregulation of connexins alone with only minimal increases in GJIC may be sufficient to suppress the growth and expansion of the primary tumor. However, it is likely that such a putative treatment would need to be combined with drugs designed to induce cell death. Unfortunately, there are no drugs in clinical cancer trials that specifically target the regulation of connexins. The reason for this is primarily due to the lack of a non-toxic drug that will specifically up-regulate connexins within the tumor. The need for a tumor specific drug is critical as many studies indicate that a system wide up-regulation of connexins and gap junctions in non-diseased organs would likely lead to pathological side effects. Consequently, any drug or gene therapy development would need to target the cancer cells only to avoid detrimental side effects. In addition to increasing connexin content in tumor cells, it is almost a certainty that any curative strategy would require combinational therapy where connexin up-regulation and increases in GJIC would be accompanied with a second therapeutic strategy. Evidence has suggested that gap junctions could act as ►conduits for delivery of ►pro-drugs deep into the tumor allowing for a more effective cell kill throughout the tumor. Again, such treatment strategies would necessitate good gene targeting or specific drug treatments that restrict their effects to the primary tumor. At a minimum, the increase presence of connexins and gap junctions would be expected to provide a decrease in tumor expansion while a patient is exposed to repeated treatment protocols designed to kill the tumor cells. The importance of connexins as a possible target in the treatment of metastatic disease is relatively unknown. Based on findings in animal models, additional precautions must be considered as connexins have been reported to enhance the movement of tumor cells from the blood to vital organ tissues. Additional research is also necessary to determine what role connexins play in facilitating or inhibiting the interaction of the tumor cell with the surrounding ►milieu of cells and the extracellular matrix that become the "soil" for metastatic tumor cell growth.

In summary, the role of connexins in carcinogenesis and metastatic disease may in fact be two fold. First, the bulk of the evidence would support members of the connexin family as acting as inhibitors of cancer onset, primary tumor growth and early stage events associated with metastasis. As such, this highlights connexins as a viable target for cancer prevention and treatment of primary disease. Second, a paradigm is developing where connexin expression may favor later stage metastatic properties of at least some tumor cell types. Consequently, interventions where connexins are targeted and downregulated only in tumor cells circulating in the blood may serve as an advantage

in treatment strategies of more advanced disease. Clearly more information involving better experimental models is necessary to resolve the full function of connexins in carcinogenesis and disease progression.

Connexon

Definition

A hexameric arrangement of six connexin family members resulting in a structure with a distinct central pore.

►Connexins

Conservative Surgery

Definition

Surgery that completely removes cancer and leaves as much healthy tissue as possible.

►Adjuvant Chemoendocrine Therapy

Conserved Region

Definition

A conserved region is a region within a gene or protein that remains identical or near-identical between species and through evolution.

►*Myc* Oncogene

Constant Region

Definition

That part of an ►antibody structure that is characteristic for each antibody class.

Constitutive

Definition

Describing a state of activity that occurs at a constant level and is therefore not responsive to modulation by physiologic regulators, or a type of control that yields such a constant output.

Contact Inhibition

Definition

When grown in monolayer, cells arrest growth when they contact each other and reach confluency. Under these circumstances, cancer cells usually continue growth and pile up on top of one another.

►Cell Adhesion Molecules
►Ether à-go-go Potassium Channels

Contact Inhibition of Cell Division

Definition

The process by which cells touch, and then send biochemical signals from the membranes through the microtubules and microfilaments to the nucleus, signaling that they have touched, leading to negative signals which stop further cell growth.

►Chemically Induced Cell Transformation

Contact Normalization

Gary S Goldberg
Molecular Biology, University of Medicine and Dentistry of New Jersey, Stratford, NJ, USA

Synonyms

Heterologous growth control

Definition

The process by which nontransformed cells force tumor cells to assume a normal morphology and phenotype.

Characteristics

Transformed cells often survive medical treatment and lay dormant for many years before they emerge to cause relapse in a patient. Nontransformed cells can force tumor cells to assume a normal morphology and phenotype by a process called "Contact Normalization" (Fig. 1).

Contact Normalization is a powerful global phenomenon. Cells transformed by a variety of chemicals, viral agents, and oncogenes can be normalized by contact with nontransformed cells. This process is dramatically exemplified by malignant tumor cells that form normal adult organs when injected into mouse blastocysts.

Contact Normalization is an important process in vivo. Genetically transformed cells can assume a normal morphology and reside in many organs including skin, breast, and intestine. Moreover, since these "occult tumor" cells are phenotypically normal, they tend to resist chemotherapy. As stated above, Contact Normalization is a powerful process; transformed keratinocytes that comprise up to 4% of epidermal volume can be controlled in human skin for decades.

In at least in some cell systems, Contact Normalization requires direct contact between transformed cells and nontransformed cells. Thus, intercellular junctional proteins such as ►connexins and ►cadherins may augment the ability of nontransformed cells to normalize the growth of adjacent tumor cells. Since these junctions are often disrupted in malignant and metastatic tumor cells, they should be stabilized in tumor cells undergoing Contact Normalization in the microenvironment.

Contact Normalization. Figure 1 Contact normalization. Tumor cells are normalized by contact with nontransformed cells. Cancer arises when this process is unsuccessful. Intercellular junctions are disrupted in invasive and metastatic tumor cells, but should be stabilized during Contact Normalization.

Contralateral

Definition

Contralateral referring to the opposite side.

Contralateral Breast Cancer

Bilateral primary breast cancer; increasing breast cancer incidence rates, improved prognosis, and growing life expectancy have resulted in an increasing number of women at risk of developing bilateral primary breast cancer. In the US alone, there are ~2.2 million living diagnosed at sometime with breast cancer.

Contra-lateral breast cancers are divided in those that are synchronous, that is when breast cancers are diagnosed in both breasts simultaneously, and metachronous, normally defined as diagnosed more than 6 months from the first cancer. The age specific incidence of synchronous breast cancer mimics that of unilateral breast cancer. In contrast, the risk of being diagnosed with a metachronous bilateral cancer is higher among women diagnosed before the age of 45 compared to those older at time of diagnoses of the first breast cancer. The risk of metachronous bilateral breast cancer is elevated throughout the entire life of a woman, and is ~0.5–1% annually.

The incidence of synchronous bilateral breast cancer has shown a steady increase in the last 30 years, although somewhat leveling off the last years. This is in sharp contrast to the metachronous contra-lateral breast cancers where the incidence has decreased by ~30% over the last 30 years. This is most likely a function of the increasing use of postoperative adjuvant therapy.

A woman with a synchronous bilateral breast cancer has a higher mortality rate compared to women with unilateral cancer, this is particularly evident before the age of 50 where a synchronous cancer entails about a two time higher mortality rate. Women who develop a metachronous bilateral cancer within 5 years of the first cancer and before the age of 50 are at a four times higher risk of dying from breast cancer compared to an age-matched woman with unilateral cancer. Time since diagnoses of first cancer also influences the prognosis of the second cancer. Young women with an early metachronous cancer have a particularly bad prognosis, while women who were diagnosed more than 10 years after the first cancer has a prognosis similar of that of a unilateral breast cancer.

Contrast Agents

Definition

Compounds or small particles that are injected into circulation to enhance the ability of a medical image system to detect blood vessels or display differences in blood flow to different tissues. The formulation of a contrast agent depends on the physics of the imaging technology with which the agent will be used.

High-flow microinfusion; Interstitual microinfusion; Intracerebral microinfusion; Intracerebral clysis; CED.

Definition

Convection-enhanced delivery (CED) is a novel delivery method that allows direct drug infusion into the brain in a ►locoregional manner. The delivery is accomplished through surgically implanted catheters in the brain that are connected to external drug infusion pumps that generate a positive infusion pressure. This positive pressure begins the process of convection, which is the augmentation and maintenance of the brain's normal physiologic bulk flow of interstitial fluid. The enhanced bulk flow through the ►interstitial space acts as the carrier of the desired agent.

Characteristics

High-grade primary ►brain tumors, such as ►glioblastoma multiforme, remain one of the most challenging diagnoses to treat effectively. Despite a range of therapeutic options and their combinations, including surgical resection, external beam radiation therapy, and ►chemotherapy, the median survival remains an astounding 12–14 months. Due to the compartmentalized distribution of functional areas within the brain and the consequence to the patient's independence with compromise of these functions, surgical resection must

be tempered. Radiation therapy has proven benefit; however, there is a finite limit to the brain's tolerance to radiation effects. Therefore, focus has shifted toward maximizing the role of chemotherapeutic agents in the treatment of primary brain tumors.

Several factors have contributed to the failure to substantially improve survival among patients with primary brain tumors. While some are attributable to the biology of the disease, others are due to the limited activity of many agents, and the obstacles to effective delivery of therapeutic agents within the brain. Recent advances in the understanding of the pathogenesis of primary brain tumors have also resulted in the development of novel therapeutic ►drug designs, many with high specificity, due to the incorporation of structures such as ►monoclonal antibodies to their structures. Although highly specific in their targeting and activity, these new agents also possess characteristics such as high molecular weight and polarity, and therefore may not be suitable for traditional routes of drug delivery.

One physiological barrier that must be overcome is the ►blood-brain barrier (BBB). The BBB is both a physical and a metabolic barrier that allows entry of selected substance from the circulation into the brain. Specifically, substances with lipid solubility cross the cell membrane, as well as those with specific transport systems. Substances with a molecular weight >500 Da cannot cross through the BBB. This limitation may exclude the use of otherwise highly bioactive chemotherapeutic agents currently in development; in other words, anti-tumor agents must be small is size and lipophilic in nature in order to reach the brain following enteral or parenteral administration.

Free concentration gradients of substances are the driving force for ►diffusion as a passive transport mechanism. Diffusion of substances in the interstitial space of the brain is largely dependent on the molecular weight of the compound, with higher molecular weight compounds resulting in less diffusion than of smaller molecular weight compounds. Diffusion is also a very slow process and the desired agent is subject to many forces that may limit its diffusive capacity, such as capillary uptake and metabolism. Due to these physical limitations, in order to achieve a therapeutically meaningful concentration of a drug, very high concentrations, often supratherapeutic, must be delivered to ensure passage of meaningful concentrations of drug beyond the immediate delivery site. Realization that diffusion results in only millimeter distances of drug penetration through the interstitial space, when the biology of primary brain tumors dictates that regions an order of magnitude greater needs to be covered with the desired agent, led to interest in utilizing the brain's physiology, interstitial bulk flow, as a mechanism for drug delivery to the brain.

Although the brain itself lacks a lymphatic system, the interstitial space is a dynamic compartment where bulk flow of fluid occurs under normal physiologic conditions. Augmenting this bulk flow, by the initiation of a point-source of positive iatrogenic pressure generated by a pump connected to a surgically implanted catheter in the brain, results in fluid convection. When desired agents are dissolved in the diluents and delivered through the catheter, the positive hydrostatic pressure results in distribution of the agents through the interstitial space in a radial, thus spherical, direction. CED has consistently resulted in centimeter-radius volumes of distribution and is able to distribute these agents, independent of their molecular weight, polarity, and concentration. In fact, CED results in a less than one-log decrease in concentration of the delivered agent at the "leading edge" compared to its concentration at the catheter site, unlike the distribution achieved by using diffusion. With the direct infusion of the desired agent into the interstitial space, the BBB is circumvented and theoretically acts as a barrier to keep agents from entering the circulation, which decreases systemic toxicity. To that end, small, lipophilic agents are not deemed favorable agents for CED application.

Clinical Application

CED is a novel technique that allows locoregional drug distribution for the treatment of a locoregional disease such as primary brain tumors; however, CED is not yet considered a clinical standard of care and is practiced only in research settings. However, ►preclinical, Phase I, Phase II, and now Phase III clinical trials have demonstrated CED to be well-tolerated and safe for drug delivery into the brain. Adverse effects, seen in ~30% of patients undergoing CED, appear to be related to the increased ►cerebral edema following drug infusion. Neurological deficits often respond to medical techniques aimed at reducing cerebral edema and thus are transient.

While the volume of distribution achieved by CED increases linearly with the volume of infusion, several technical factors have also been found to influence the efficacy of CED. As the delivery device situated within the brain, the catheter has received particular attention. One of the difficulties encountered with CED is the phenomenon of reflux, or leak back, of the agent along the catheter. This is encountered with high infusion rates, and large catheter diameters. To combat reflux, research has focused on catheter design in an effort to create a reflux-proof catheter.

With regard to infusion rates, one of the disadvantages of CED is the need to infuse the desired agent over a protracted period of time, often lasting several days in duration. This necessity stems from the reflux problem mentioned above which, should it occur, limits the volume of distribution of the agent. Therefore, a rate of infusion is chosen which exceeds the rate at which the

brain can remove fluid from the interstitial space but is less than the rate at which leak back may occur.

The anatomic complexity of the brain and of the region afflicted by a primary brain tumor also affects the efficacy of CED. Due to the presence of tumor tissue, white matter, and gray matter, the intersititial space is not uniform. Furthermore, the pattern of ►gyri and ►sulci, and therefore the ►subarachnoid space, the proximity of the ►ependymal layer that lines the ventricle space, and the presence of tumor necrosis complicate catheter positioning, which must be accomplished after thorough presurgical planning. The subarachnoid space, ependymal layer, and tumor necrosis all represent low-resistance areas that would lead to the potential loss of convection. Radiographic correlate of effective convection is detected on T2-weighted magnetic resonance imaging sequence as an increase in the fluid signal within the targeted region.

Currently, there are several targeted therapeutic agents in advanced clinical development. The most advanced along its development is the agent IL13-PE38QQR, which is a chimeric protein based on the fusion of IL-13 as a ligand and the *Pseudomonas aeruginosa* exotoxin as the cytotoxic agent. The IL-13 receptor is known to be over-expressed in high-grade primary brain tumors, while the exotoxin is a potent inducer of cell death by arresting cellular protein synthesis.

IL13-PE38QQR has undergone rigorous testing thus far, and the results of three Phase I/II trials were recently presented. In aggregate, 74 patients were enrolled in these trials, which determined the maximally tolerated dose of the agent. In addition, patient outcomes were compared when CED was conducted with the delivery catheters located in the peritumoral region compared to the intratumoral space. Improved survival was seen among patients undergoing peritumoral infusions; within this group of patients receiving peritumoral infusions, those who had more than two "optimally" placed catheters had a significantly improved median survival.

A Phase III trial was initiated in 2004 which compared IL13-PE38QQR, delivered by CED, to another local drug delivery technique that relied on diffusion for drug dispersion. Three hundred patients were randomized to this trial and the final results remain to be reported.

Future Directions

While CED represents a novel drug delivery technique, it also remains a field in evolution. Several lines of research are currently focusing on areas for continued improvement. Questions remain regarding the optimal placement and number of CED catheters. In Phase I/II trials of IL13-PE38QQR, patients with "optimally" placed catheters had better outcomes. Whether this will be confirmed in the Phase III trial will be of great interest.

With regard to ►pharmacokinetic parameters, efforts are underway to increase the half-life of therapeutic agents, allowing the agents to remain available long after CED is halted. Investigators have demonstrated that encapsulation of their agents in ►liposomes is one such strategy. Another consideration is that, depending on the pharmacokinetic characteristics of the therapeutic agent, prolonged infusions may yield greater clinical efficacy. In that situation, alternative delivery methods of CED, such as implanted pumps housed entirely under the skin, may provide protection from infectious complications yet retain the drug delivery advantage.

Synonyms
Src8; Amplaxin; EMS1

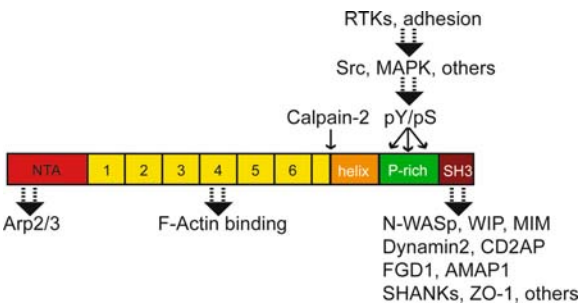
Definition
Cortactin is a protein that is a component of the cortical actin cytoskeleton, where it participates in regulating the assembly and organization of filamentous actin in protrusive structures generated during cellular movement. Cortactin gene ►amplification and overexpression is found in several cancer types, where it contributes to enhanced tumor cell ►motility, ►invasion and ►metastasis.

Characteristics
Cortactin is an actin-binding protein and kinase substrate that is intimately associated with the microfilament network underlying the plasma membrane in most cells. It plays an important role in ►signal transduction pathways that mediate chemotactic cues from the extracellular environment that initiate and maintain cell ►migration. Activation of growth factor receptors or ►adhesion molecules results in the phosphorylation of cortactin at several tyrosine and serine residues. Cortactin phosphorylation is coincident with

changes in plasma membrane architecture that occur during the initial phases of cellular movement, including the formation of ►lamellipodia and ►circular dorsal ruffles that are required for the extension of a cell's leading edge. Cortactin is also enriched in ►invadopodia, ventral protrusive structures that contain membrane-bound proteases and enhance cellular invasion by facilitating the focal degradation of extracellular matrix. In addition to its role in cell motility, cortactin is also associated with various intracellular membrane compartments, including endosomal vesicles and the Golgi apparatus, and plays an important role in the early events of ►endocytosis and in vesicle trafficking.

Structure and Binding Partners

Cortactin is expressed in all tissues except cells of myeloid lineage, where it is functionally replaced by the related protein ►HS1. Based on primary sequence analysis cortactin is subdivided into several distinct domains (Fig. 1). The amino-terminal domain (NTA) contains a series of acidic residues and a binding motif that interacts with the ►Arp2/3 complex. The NTA domain is followed by a series of 37 amino acid tandem repeats, six complete and one incomplete in the predominant isoform. The repeat region interacts with F-actin, with binding activity centered around the fourth repeat. Alternative splicing in some cells is responsible for two additional isoforms that lack either the sixth complete or fifth and sixth complete repeat segments. These forms bind F-actin at reduced affinities. Following the repeats region is an alpha helical domain that is the site of cleavage by the protease ►calpain 2. This is followed by a proline-rich region that harbors serine, threonine and tyrosine residues that serve as the primary sites of phosphorylation. An ►SH3 domain is found at the extreme carboxyl terminus that binds to proline-rich sequences on a variety of proteins including the actin regulatory proteins ►N-WASp, WASp interacting protein and the missing in metastasis protein, the endocytic proteins ►dynamin 2 and ►CD2AP, the small ►GTPase regulatory proteins ►FGD1 and ►AMAP1, scaffolding proteins of the ►SHANK family and the ►tight junction protein ►ZO-1. These structural parameters and binding partners allow cortactin to function as a molecular scaffold by linking a wide variety of diverse regulatory molecules to sites of Arp2/3-mediated actin assembly.



Cortactin. Figure 1 Domain structure of cortactin and associated binding proteins. This is a simplified representation showing domain organization, binding proteins and regulatory signaling pathways. See text for details.

Function

The function of cortactin has been best defined in regards to cell motility. Downregulation of cortactin protein expression reduces cellular movement while overexpression of cortactin enhances this process. Biochemical studies have determined that cortactin activates Arp2/3 complex actin nucleation activity through the NTA domain, and its localization within lamellipodia indicates that cortactin contributes to the formation of the dendritic cortical actin network responsible for lamellipodia protrusion. Important in this aspect is the ability of cortactin to stabilize Arp2/3-produced actin networks, a feature unique among Arp2/3 activating proteins that serves to prolong the half-life of branched F-actin filaments at the cell periphery. Accordingly, cortactin depletion reduces the ability of extended lamellipodia to persist and inhibits efficient leading edge dynamics. Cortactin can effect Arp2/3 mediated actin polymerization by additional alternative mechanisms, most notably by activation of the Arp2/3 regulatory protein N-WASp through association with the cortactin SH3 domain. Cortactin fragments lacking the NTA but containing the SH3 domain are capable of stimulating motility, suggesting that the NTA and SH3 domains can function independently with regards to promoting actin-based cell movement. The interaction of cortactin with dynamin 2 is also noteworthy in that cortactin is recruited to subpopulations of clathrin-coated pits by dynamin 2 and is important for driving the scission of invaginating pits to produce intracellular endocytic vesicles. The cortactin-dynamin complex is also important in regulating cell morphology, invadopodia function and the genesis of vesicles from the trans-Golgi network.

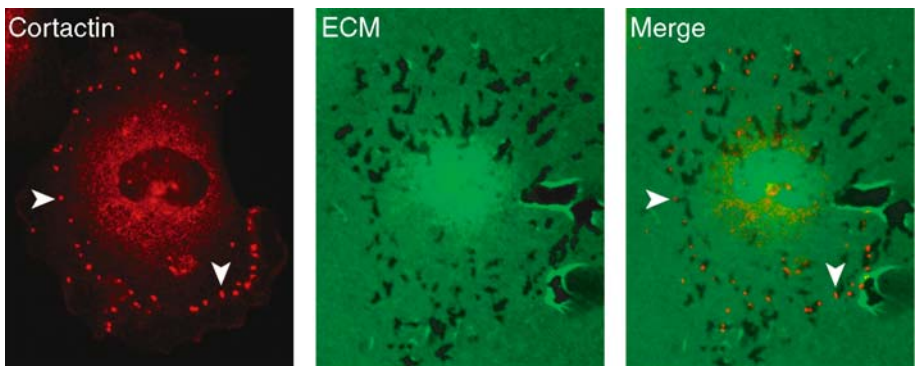
Regulation

Evidence to date indicates that phosphorylation on tyrosine and serine resides are the main factors involved in regulating cortactin function, although the precise mechanisms are unclear. Activation of ►receptor tyrosine kinases or adhesion molecules leads to phosphorylation of three tyrosine sites in the proline-rich domain that are required for efficient cell migration. These sites are direct targets of ►Src and related

non-receptor tyrosine kinases, and are hyperphosphorylated by oncogenic variants (i.e, v-Src). Tyrosine phosphorylated cortactin is enriched within lamellipodia and invadopodia, indicating a potential role in regulating cortical actin dynamics and has been shown to influence F-actin architecture. Cortactin is also phosphorylated on two serine residues by ►MAP kinase in the proline-rich domain, and dual phosphorylation of cortactin by Src and MAP kinase has opposing effects on the ability of the cortactin SH3 domain to interact with and activate N-WASp. This has led to the proposal of a regulatory phosphorylation switch mechanism predicated by cortactin initially existing in an autoinhibited closed conformation, with the SH3 domain binding back and interacting with motifs in the proline-rich domain. Phosphorylation of cortactin by MAP kinase induces a conformation change that renders the SH3 domain accessible for binding and activating N-WASp, whereas phosphorylation of cortactin by Src causes disassociation of N-WASp from the SH3 domain and subsequent downregulation of N-WASp activity. This proposal remains theoretical in part since it is derived primarily from biochemical analysis and evidence for an intramolecular cortactin interaction is lacking. In addition to phosphorylation indirectly regulating N-WASp activity, the serine/threonine kinase ►PAK1 phosphorylates cortactin within the first tandem repeat, resulting in reduced F-actin binding. Subsequent work has identified over 17 additional phosphorylation sites in every domain except the SH3, but the responsible signaling pathways and functional significance of these modifications are currently unknown. Besides phosphorylation, cortactin is also regulated by the calcium dependent protease calpain 2, which cleaves cortactin between the repeats and alpha helical domain and is important in limiting the extent of lamellipodia protrusion.

Role in Cancer

The cortactin gene (*CTTN*, formerly *EMS1*) maps to chromosome 11q13.3, a region that is frequently amplified in a number of cancers with inherently high invasive and metastatic potential, including ►breast, ►head and ►neck, ►ovarian, ►bladder and ►hepatocellular carcinomas. 11q13 and *CTTN* amplification is associated with poor pathological outcome parameters including increased tumor recurrence, advanced disease stage, poor histological differentiation, increased lymph node metastasis and reduced disease specific survival. Mechanistically, cortactin overexpression as a result of *CTTN* amplification increases tumor cell motility and invasion as well as preventing the internalization and ubiquitylation-mediated degradation of ►EGF receptor, a receptor tyrosine kinase often overexpressed in carcinomas that is a potent activator of Src and MAPK. Sustained EGF receptor activity as a result of *CTTN* amplification and cortactin overexpression promotes increased cortactin tyrosine phosphorylation, which has been shown to enhance distant metastasis of breast carcinoma cells in ►mouse models. ►EGF receptor inhibitors suppress tumor cell invasion and cortactin tyrosine phosphorylation, providing further support for the clinical relevance of cortactin phosphorylation in human cancer. Specific functions for cortactin in tumor cell invasion have been identified, most notable being its absolute role in the signaling and structural requirements governing the formation and function of invadopodia (Fig. 2). Cortactin is



Cortactin. Figure 2 Cortactin localization in invadopodia corresponds to sites of extracellular matrix degradation. Shown is a cell from a head and neck squamous cell carcinoma tumor containing invadopodia, visualized by immunofluorescent staining for cortactin in red as focal dots within the cell cytoplasm. The cell was grown on a green fluorescent extracellular matrix (ECM), and sites of matrix degradation are visualized as cleared dark regions against the green background. When merged, these areas correspond with cortactin-labeled invadopodia and are highlighted with arrowheads.

required to recruit and sequester the main invadopodial ►matrix metalloproteinase MT1-MMP into sites of newly initiated invadopodia. Cortactin tyrosine phosphorylation levels within invadopodia correlate to the degree of extracellular matrix degradation activity, but the functional significance of cortactin phosphorylation in invadopodia is currently undefined. Cortactin in invadopodia forms a complex with the focal adhesion protein ►paxillin and other signaling proteins. Often present in invasive carcinomas is amplification and overexpression of AMAP1, which physically links paxillin and cortactin together in promoting tumor invasion. Targeting of the trimeric paxillin-AMAP1-cortactin complex with competitive peptides mimicking the AMAP1 binding site for the cortactin SH3 domain suppresses carcinoma invasion and may show potential value in ►anti-metastatic therapy. In addition to its role in promoting tumor cell invasion and metastasis, cortactin has been shown to be a prominent tumor antigen and is present at high levels in the sera of subsets of breast cancer patients. Recent work has determined that cortactin is an extracellular ligand for ►TEM7, a transmembrane receptor expressed primarily on the surface of tumor endothelial cells. While the function of TEM7 is currently unknown, related TEM proteins promote endothelial cell growth and survival, raising the possibility that cortactin released into the circulation from necrotic or damaged tumor cells, especially tumors with *CTTN* amplification, may serve an unexpected role by promoting or maintaining tumor ►angiogenesis.

Corticosteroids

Definition

Are a family of drugs related to steroids that are naturally produced in the adrenal cortex, such as cortisone. Corticosteroids can kill lymphocytes, especially developing thymocytes, inducing apoptotic cell death. They are useful antiinflammatory, antilymphoid tumor, and immunosuppressive agents. Natural and synthetic analogs of the hormones secreted by the pituitary gland. These analogs include glucocorticoids, mineralocorticoids, and corticotropins.

►Rituximab
►Sjögren Syndrome

Corticotrophin

Definition

A hormone produced by the anterior lobe of the pituitary gland that stimulates the secretion of cortisone and other hormones by the adrenal cortex.

►Adrencorticotropic Hormone
►ACTH

Corticotrophin-Releasing Hormone

Definition

CRH; A hormone made by the hypothalamus that stimulates the release of ►corticotrophin by the anterior pituitary gland.

Cortisol

Definition

Cortisol is an important hormone in the body, secreted by the adrenal glands and involved in the following functions and more: Proper glucose metabolism, Regulation of blood pressure Inflammatory response, Insulin release for blood sugar maintenance, and Immune function.

Corynebacterium Diphtheriae

Definition

A bacteria causing Diphtheria that is a contagious disease of the throat.

►Cytokine Receptor as the Target for Immunotherapy and Immunotoxin Therapy

Cosinor

Definition

Statistical method used to compute rhythm parameters and their 95% confidence limits through the adjustment of the best fitting cosine function with an a priori chosen period (usually, τ = 24 h for circadian rhythms). The main parameters are the amplitude, half the difference between maximum and minimum of cosine function, and acrophase, location of maximum, usually referred to light onset.

►Circadian Clock Induction

Costello Syndrome

Definition

A developmental defect characterized by a complex disorder involving characteristic craniofacial features, failure to thrive, developmental delay, cardiac and skeletal anomalies and a predisposition to develop neoplasia.

Costimulation

Definition

A process that is necessary for full activation of T cells via antigen-specific signaling pathways. Signals during costimulation are provided by the interaction of molecules other than T cell antigen receptor.

►T-Cell Response

Costimulatory Signal

Definition

The proliferation of lymphocytes, requires both antigen binding and the receipt of a costimulatory signal. Costimulatory signals are delivered to T cells by the costimulatory molecules B7.1 and B7.2, related molecules that are expressed on the surface of the cell presenting antigen, and which bind the T-cell surface molecule CD28. B cells may receive costimulatory signals from common pathogen components such as LPS, from complement fragments, or from CD40 ligand expressed on the surface of an activated antigen-specific helper T cell.

►Sjögren Syndrome

Coumestans

Definition

A class of phytoestrogens.

►Phytoestrogens

γ-Counter

Definition

Detection unit for ►γ-irradiation.

Cowden Disease

►Cowden Syndrome

Cowden Syndrome

Deborah J. Marsh[1], Roberto T. Zori[2]
[1]Kolling Institute of Medical Research and Royal North Shore Hospital, University of Sydney, NSW, Australia
[2]University of Florida, Gainesville, FL, USA

Synonyms

Cowden disease; Multiple hamartoma syndrome; PTEN hamartoma tumor syndrome

Definition

Cowden syndrome (CS, OMIM#158350), along with Bannayan-Riley-Ruvalcaba syndrome (BRR, OMIM# 153480), Peutz-Jeghers syndrome (PJS, OMIM#175200) and juvenile polyposis syndrome (JPS, OMIM#174900), is a member of a group of rare autosomally dominant inherited conditions classified as the ►hamartoma syndromes. Proteus syndrome (PS, OMIM#176920), although most frequently of sporadic presentation, has also been classified as part of this hamartoma-tumor syndrome spectrum. CS takes its name from the proposita of the first family described. It is characterized by an increased risk of developing breast, thyroid and endometrial cancer along with the presence of hamartomas in multiple organ systems. The susceptibility gene for both CS and BRR is the tumor suppressor ►*PTEN* (alternatively named ►*MMAC1* or ►*TEP1*).

Characteristics

CS displays variable expressivity within families, however usually presents in the third decade. CS hamartomas are present in tissues derived from all three ►germ cell layers, specifically the breast, thyroid, skin, central nervous system and gastrointestinal tract. The incidence of CS has been estimated to be 1 in 200,000 individuals. Ninety-nine percent of CS patients display the hallmark CS hamartoma known as ►trichilemmomas in addition to mucocutaneous papules. Seventy percent of female CS patients develop breast ►fibroadenomas, 40–60% have thyroid adenomas, whilst gastrointestinal polyps occur in 35–40% of CS patients. Breast cancer develops in 25–50% of female CS patients and on occasion also in males, whilst thyroid cancer develops in 3–10% of all affected individuals. Disease of the central nervous system, most often benign but in some cases malignant, occurs in 40% of cases. Lhermitte-Duclos disease, a condition of dysplastic gangliocytoma of the cerebellum manifesting as seizures, tremors and poor co-ordination, has been reported in conjunction with CS. Megencephaly or macrocephaly occur in approximately 38% of CS patients. Other abnormalities including those of the genitourinary tract may also be present. Given the subtle and poorly recognized physical findings in individuals with CS, it is thought that this condition may often be underdiagnosed. The International CS Consortium has developed and recently revised diagnostic criteria to aid in the identification of this syndrome.

CS shows partial clinical overlap with BRR as patients with either syndrome may develop intestinal hamartomatous polyps, macrocephaly (in nearly 100% of cases of BRR) and ►lipomas (occurring frequently in BRR but in a minority of patients with CS). Other features of BRR include very early age of onset, pigmented macules of the glans penis ("speckled penis") in males, ►hemangiomas, mild mental retardation and developmental delay. Both the unique and overlapping clinical features of CS and BRR are described in the Table 1. A number of anecdotal cases of malignancy affecting the thyroid and brain have been reported in BRR, however whilst malignancy is well described in CS, it is not part of the classic BRR phenotype. Nevertheless, because of the apparent increased risk of developing cancer in BRR recommendations for cancer screening have been made. In addition, a number of families have been reported in which both CS and BRR are present. In these families, CS is generally present in the parental generation, whilst BRR appears in the younger generation, suggesting a form of ►anticipation (Fig. 1 and Fig. 2).

Molecular Features

PTEN, the first protein tyrosine phosphatase shown to function as a tumor suppressor, is the susceptibility gene for both CS and BRR. A processed ►pseudogene is located on chromosome band 9p21, missing the initiating methionine present in PTEN but sharing greater than 98% homology with the *PTEN* coding region.

PTEN contains nine exons encoding a dual-specificity ►phosphatase mapped to 10q23.3, with

Cowden Syndrome. Table 1 Clinical features seen in Cowden syndrome and Bannayan-Riley-Ruvalcaba syndrome

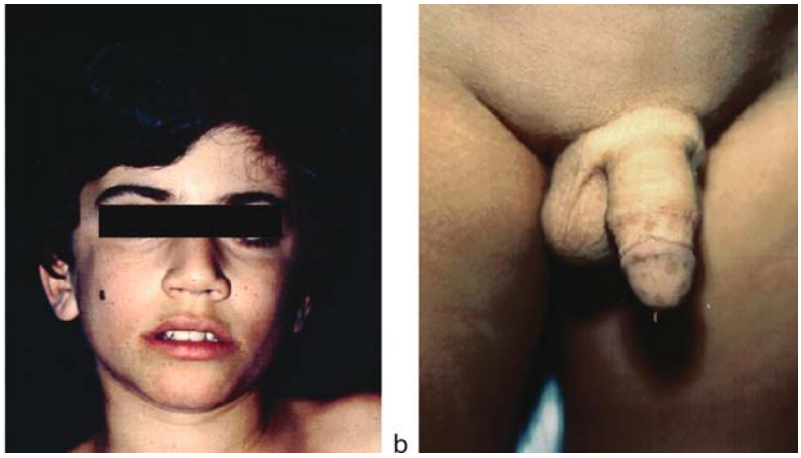
	Cowden syndrome	Bannayan-Riley-Ruvalcaba
CNS	Lhermitte-Duclos disease	Developmental delay[a], seizures, myopathy
Endocrine	Multinodular goitre, adenoma, thyroid anomalies, thyroiditis, hypothyroidism	Hashimoto's thyroiditis[a], diabetes mellitus
►Growth disturbances:		
Generalized	Macrocephaly	Macrosomia at birth, enlarged penis and testes, localized overgrowth, macrocephaly
Skin	Facial trichilemmoma[b], acral keratoses, hemangioma, mucosal lesions, papillomatous papules[b], hypertrichchosis, vitiligo, pseudo-acanthosis nigricans, skin cancers (basal cell, squamous cell and melanoma)	Penile lentigines, acanthosis nigricans, verruca vulgaris type facial changes, tongue polyps, Café au lait spots, angiokeratoma, lipoma/ lipomatosis[a]
Gastrointestinal	Polyps in entire gastrointestinal tract, gastrointestinal cancers	Polyps in distal gastrointestinal tract
Breast	Fibrocystic breast disease, adenocarcinoma	–
Other benign tumor	Uterine leiomyoma, ovarian cysts, fibroma, meningioma, glioma, neuroma	Meningioma, angiolipoma, hemangioma[a] (especially intracerebral and bony) lymphangioma
Other malignant tumors	Thyroid (non-medullary)[b], cervix, uterus, bladder, liver, renal, acute myelogenous leukemia, non-Hodgkin lymphoma, liposarcoma, trichilemmomal carcinoma, renal cell carcinoma	–

[a]Common in BRR, occasionally seen in CS.
[b]Reported in CS, occasionally seen in BRR.

Cowden Syndrome. Figure 1 Female with Cowden syndrome. (a) Macrocephaly (head circumference of 59½ cm, greater than the 97th percentile). (b) Multiple small papules of the tongue and mouth.

homology to the cytoskeletal proteins tensin and auxillin. Residues 122–132 located in exon 5 encode the classic phosphatase core motif (I/V)HCXXGXXR (S/T)G. The COOH-terminus contains three potential tyrosine phosphorylation sites at residues 240, 315 and 336, as well as two potential serine phosphorylation sites at residues 335 and 338. It also contains a potential ►PDZ binding domain encoded by the last four amino acids (ITKV) that may have a role in its subcellular localization and/or substrate interactions.

PTEN has been shown to reduce tyrosine phosphorylation of focal adhesion kinase (FAK) *in vitro* suggesting a role in cell migration and invasion. However, the major endogenous substrate of PTEN would seem to be phosphatidylinositol 3,4,5-trisphosphate (Ptd-Ins $(3,4,5)P_3$), a phospholipid in the phosphatidylinositol 3-kinase (PI-3 kinase) pathway and an important second messenger in cell growth regulation. In this pathway growth factors such as insulin, platelet derived growth factor and fibroblast growth factor stimulate the enzyme



Cowden Syndrome. Figure 2 Male with Bannayan-Riley-Ruvalcaba Syndrome (son of female in Fig.1). (a) Macrocephaly (head circumference of 59 cm, greater than the 97th percentile). (b) Multiple hyperpigmented macules of the penis.

PI3-kinase to phosphorylate Ptd-Ins(4,5)P_2 to produce Ptd-Ins(3,4,5)P_3. PTEN acts as a 3-phosphatase to dephosphorylate Ptd-Ins(3,4,5)P_3 to Ptd-Ins(4,5)P_2. When PTEN is mutant, Ptd-Ins(3,4,5)P_3 accumulates and activates protein kinase B (PKB)/►AKT to function as an oncogene, thus causing the tumorigenic state. AKT is a ►serine-threonine kinase and a known cell survival (anti-apoptotic) factor. Thus, apoptosis is a likely mechanism for PTEN-induced growth suppression. However, PTEN is also able to cause cell cycle arrest in cells in the G_1 phase, possibly via modulation of levels of RB phosphorylation.

Elucidation of the crystal structure of PTEN has revealed a wider and deeper phosphatase active site than is usually described in other dual-specificity phosphatases that allows the accommodation of Ptd-Ins (3,4,5)P_3. Further, the make up of the residues in this pocket cause it to have a positive charge consistent with the negative charge of Ptd-Ins (3,4,5)P_3 and with the preference displayed by PTEN for highly acidic polypeptide substrates. One particular germline mutant found only in CS, G129E, has been shown to have normal phosphatase activity against non-phospholipid substrates *in vitro* and in cell lines but has no phosphatase activity against Ptd-Ins(3,4,5)P_3. It is believed that mutation of this residue reduces the size of the active pocket so that it can no longer accommodate the phospholipid substrate Ptd-Ins(3,4,5)P_3. However, catalysis of the smaller substrates of phospho-tyrosine, serine and threonine are not disrupted. Furthermore, a C2 domain is present in the C-terminal domain and associates over an extensive interface with the phosphatase domain creating interdomain hydrogen bonds between conserved residues. This interphase region provides strong evidence that the C2 domain not only functions to recruit substrate, but also optimally positions it available to the phosphatase catalytic domain. Germline mutations of conserved residues involved in the creation of this interphase, including serine at position 170, have been reported in BRR. Thus, there is strong evidence that the lipid phosphatase activity of PTEN is essential for its tumor suppressor activity.

Clinical Aspects

PTEN is mutated in the germline of up to 80% of patients with CS and up to 60% of patients with BRR. Mutations are scattered largely along the entire gene with the exception of exon 1, including point mutations, insertions, deletions, deletion-insertions and splice site mutations. Germline mutations and deletions have also been reported in the promoter region of *PTEN* in patients with CS and BRR. In BRR alone, gross ►hemizygous deletions and also a balanced translocation likely affecting the PTEN gene have been reported. Further, loss of the wild type allele has been identified in hamartomas from a subset of CS individuals with *PTEN* mutation, providing additional evidence that PTEN is functioning as a classic tumor suppressor according to Knudson's two-mutation model. However, there are many cases where loss of the wild-type allele is not observed in affected CS tissue. As is suggested by one of the $Pten^{+/-}$ mouse models, PTEN haploinsufficiency may be all that is required for the presence of the characteristic developmental defects and tumor formation seen in CS and BRR. It was first thought that none of the 3 $Pten^{+/-}$ mouse models described developed the classic benign and malignant tumors of CS and BRR, although the presence of colonic microscopic hamartomatous polyps not dissimilar to what is seen in CS and BRR was reported. However, a

study of Pten$^{+/-}$ mice older than 6 months reported the development of a range of tumours more similar to the spectrum of tumors observed in CS patients, specifically breast tumours in 50% of females, 100% of females with endometrial hyperplasia and a high incidence of endometrial cancer, prostate and adrenal neoplasia and tumors of the gastrointestinal tract.

PTEN germline mutations in CS and BRR have been found to cluster in exons 5, 7 and 8, with the great majority occurring in exon 5. This may be a function of the fact that exon 5 is the largest exon of this gene, constituting 20% of the coding region, but this exon also contains the protein tyrosine phosphatase (PTPase) core motif. Of note in CS, most mutations that occur in the core motif are non-truncating, suggesting the importance of this functional domain.

Identical mutations, including Q110X, R130X, R233X and R335X have been reported in both CS and BRR, making the presence of other genetic and/or epigenetic factors such as modifier loci highly likely in the determination of phenotype. Furthermore, a number of families have been reported with CS diagnosed in the older generation and BRR present in the younger generation suggesting some form of anticipation that is currently not well understood. From this, it could be concluded that BRR and CS are different presentations of a single syndrome with broad clinical expression. In fact, it has been suggested that *PTEN* mutation positive CS and BRR patients should be clinically grouped as a single entity and classified as the "PTEN hamartoma-tumor syndrome" (PHTS).

DNA based predictive testing programs can now be incorporated as part of the clinical management of CS and BRR individuals. At the level of clinical management, cancer surveillance coupled with genetic counseling becomes important for CS and BRR patients as well as their first degree relatives.

Preliminary genotype-phenotype correlations have been reported for both CS and BRR and a number of trends observed. Firstly in a study of BRR and CS/BRR overlap families, the correlation of a germline *PTEN* mutation with the presence of lipomas and also with any cancer or breast fibroadenoma was determined. In CS families a number of correlations were observed including an association between the presence of a *PTEN* mutation and breast involvement, as well as the presence of a missense mutation and the involvement of all five organ systems (ie. breast, thyroid, gastrointestinal tract, central nervous system and skin). It is possible that this latter trend may in fact be a positional effect given that the majority of missense mutations occur in the PTPase core motif. One study states that the presence of a *PTEN* mutation in either CS alone, BRR alone or CS/BRR overlap families predisposes individuals to the presence of tumors, whether they be benign such as the lipomas seen predominantly in BRR, or malignant such as the breast, thyroid and uterine carcinomas seen in CS or CS/BRR overlap families. Confirmation of these preliminary findings requires analysis of a larger number of families before they can be directly transferred to the clinic.

Clinical cancer surveillance of patients with CS is recommended. All patients with a *PTEN* mutation should undergo careful annual physical examinations with special attention to the skin and thyroid from the teens. For females, breast self examination from 18 years, annual clinical breast examination from age 25 and annual mammography/MRI at age 30–35 years is recommended. Thyroid ultrasound is recommended at 18 years with annual thyroid ultrasounds thereafter. Annual surveillance of the endometrium, with biopsies of the endometrium from the thirties and annual transvaginal ultrasound examination with biopsy of suspicious areas after menopause should be performed. Urine should be checked annually for blood. All specific cancer screening should be started at least 5–10 years earlier than the earliest appearance of the specific cancer in the family.

In addition to being mutated in the germline of patients with CS and BRR, PTEN has been described as "…the most highly mutated tumor-suppressor gene in the post-p53 era… ." It is mutated in a spectrum of human malignancies including glioblastoma (where *PTEN* mutation would seem to be a late event in tumor progression), endometrial hyperplasias (likely an early event) and carcinomas, prostate cancer and malignant melanoma and less commonly in thyroid neoplasias, breast and colon cancer. Thus, it is likely that syndromic hamartomas and cancers in CS and BRR develop on a background created by loss of the tumor suppressor function of PTEN. Furthermore, *PTEN* is a highly significant gene in the development of a wide range of sporadic human cancers.

CpG

Definition

Bacterially derived DNA triggers innate immune defense mechanisms, the activation of dendritic cells, and the production of TH1 cytokines. This is due to recognition of certain CpG dinucleotide sequences which are immunostimulatory. CpG stimulatory (CpG-S) sequences are hypomethylated. The optimal immunostimulatory sequence is an unmethylated CpG dinucleotide flanked by two 5′ purines and two 3′ pyrimidines. Additionally, flanking regions outside this immunostimulatory hexamer must be guanine-rich to ensure binding and uptake into target cells. CpG-S sequences induce polyclonal B-cell activation and the upregulation of cytokine expression and secretion mediated by Toll-like receptor 9. Stimulated macrophages secrete IL-12, IL-18, TNF-α, IFN-α, IFN-β and IFN-γ, while stimulated B-cells secrete IL-6 and some IL-12 and drive the immune response toward a Th1 phenotype.

CpG Islands

Christoph Plass
German Cancer Research Center (DKFZ), Heidelberg, Germany

Synonyms

*Hpa*II tiny fragments (HTF) islands

Definition

CpG islands are short stretches of DNA sequences with an unusually high GC content and a higher frequency

of CpG dinucleotides as compared to the rest of the genome. Together CpG islands account for about 1–2% of the genome and their location is mainly in the 5′ regulatory regions of all housekeeping genes as well as up to 40% tissue specifically expressed genes.

Characteristics

With the rapid accumulation of sequencing data it became obvious that the distribution of the four bases, adenine (A), cytosine (C), guanine (G), and thymine (T), in the genomic sequence is not even. Normal DNA has an average GC content of 40% and an AT content of 60%. Early work by Bird et al [1] identified stretches of genomic sequence characterized by an unusual high number of HpaII restriction sites (restriction site: C^CGG). These sequences were initially called "HpaII tiny fragments (HTF) islands." Careful inspection of those sequences indicated that the ratio of CpG dinucleotides is higher than in the rest of the genome. Normal DNA sequence contains only 25% of the CpG dinucleotides expected from the base composition. These stretches of DNA sequence, with a high GC content and a frequency of CpG dinucleotides that is close to the expected value, are now called CpG islands.

The following three criteria, established by Gardiner-Garden and Frommer [2], are commonly used to define CpG islands: First, the sequence is longer than 200 bp but can be up to several kilo basepairs in size. Second, the GC content is above 50% while the rest of the genome is at about 40%. Third, the CpG ratio (observed/expected) is above 0.6 while the rest of the genome is 0.2. Changes to this definition have been proposed using slightly modified criteria.

The human genome contains about 29,000 CpG islands and the estimated number in the mouse genome is slightly less. The majority of these sequences are located in the 5′ region (promoter and or exon 1) of all housekeeping genes and a large number of tissue specifically regulated genes. However, CpG islands in the 3′ end of genes or in intronic sequences have been found. The preferential location of CpG islands in 5′ regions of genes can be used for the identification of novel genes. Rare cutting restriction enzymes with GC rich recognition sequences such as NotI (GC^GGCCGC), AscI (GG^CGCGCC), BssHII (G^CGCGC) and EagI (C^GGCCG) can be used for the restriction mapping of large genomic clones. Clusters of those restriction enzyme cutting sites would indicate the presence of a CpG island. It is unknown why the mouse genome has fewer CpG islands than the human genome, when the estimated number of genes in both genomes is expected to be very similar. One possible explanation is that the rate of CpG dinucleotide loss due to deamination (see below) is higher in the mouse than it is in the human genome. The location of CpG islands is in the early replicating, less condensed and GC-rich R-bands of chromosomes.

Preservation of CpG Islands

The origin of CpG islands in the vertebrate genomes is closely associated with DNA ►methylation and a process called deamination. DNA methylation in the vertebrate genomes is found mainly in CpG dinucleotides. Those CpG dinucleotides that are located within CpG islands are usually unmethylated. However, CpG dinucleotides located outside of CpG islands are methylated at the 5′ position of the cytosine. Methylation of CpG dinucleotides makes these sites vulnerable to spontaneous deamination leading to a transition of the 5-methylcytosine to thymine, a process that is believed to be the cause for depletion of CpG dinucleotides from the genome.

Clinical Relevance

Although CpG islands are usually unmethylated there are a few important exceptions. Methylation in CpG islands has been correlated with the transcriptional silencing of the adjacent genes. The detailed molecular process controlling this inactivation, however, is not known. Protein complexes, containing the methyl CpG-binding protein and co-repressor enzymes modifying histone tails as major components, are able to bind to methylated promoters. These protein complexes induce histone deacetylation, which mediates the formation of transcription-repressing chromatin. In *in vitro* experiments, re-expression could be achieved by adding trichostatin A (TSA), a specific inhibitor of histone deacetylases. Two general methylation events in CpG islands can be distinguished: First, the developmentally regulated process of CpG island methylation found in the inactive X-chromosomes, in promoter regions of genes that are regulated in a tissue specific manner and in imprinted genes. Second, the aberrant CpG island methylation in cancer.

Normal, Developmentally Regulated, CpG Island Methylation

- Most CpG islands in the inactive X-chromosome of females are densely methylated. This process of X-chromosome inactivation is linked to the transcriptional silencing of genes on the inactive X-chromosome (phosphoglycerate kinase 1 (PGK1), glucose 6-phosphate dehydrogenase (G6PD) or androgen receptor (AR). Exceptions are found in a few number of CpG islands in genes that escape X inactivation (e.g. STS, ZFX or UBE1).
- Some CpG islands become methylated in other normal developmental processes including cell differentiation and aging. The result of this methylation is the selective inactivation of genes in specific

tissues or at certain developmental stages (e.g. estrogen receptor).
- Genes that are expressed from either the paternal or the maternal allele are called imprinted genes. These genes are found to have CpG island methylation of one allele. While methylation usually occurs in the inactive allele, CpG island methylation was found in some instances in the active allele. This feature of allele specific methylation in a CpG island was used as a tag for the identification of novel imprinted genes in the mouse using the ►restriction landmark genomic scanning (RLGS) technique for a genome wide scan for patterns of allele specific methylation.

Aberrant CpG Island Methylation in Cancer

Hypermethylation of CpG islands in various cancers has been observed and is correlated with the transcriptional inactivation of tumor suppressor genes and other cancer related genes. It was shown that methylation in a CpG island can serve as one of the two "hits" needed for the inactivation of a tumor suppressor gene. While CpG island methylation in some tumors is restricted to a small number of CpG islands, other tumors show a methylation phenotype with up to 10% methylated CpG islands. A subset of CpG islands is methylated in a tumor type specific matter, while other CpG islands can be methylated in different tumor types. It was also shown that many of the genes associated with methylated CpG islands could be reactivated in cell lines by experimental demethylation using 5′-aza-2′deoxycytidine.

Cre-Lox Recombination

Definition

The Cre/lox system is used as a genetic tool to control site specific recombination events in genomic DNA. The system begins with the Cre protein, a site-specific DNA recombinase. Cre can catalyze the recombination of DNA between specific sites in a DNA molecule. These sites, known as *loxP* sequences, contain specific binding sites for Cre that surround a directional core sequence where recombination can occur.

When cells that have *loxP* sites in their genome express Cre, a reciprocal recombination event will occur between the *loxP* sites. The double stranded DNA is cut at both *loxP* sites by the Cre protein and then ligated (glued) back together. It is a quick and efficient process. The effect of recombination depends on the orientation of the *loxP* sites. For two lox sites on the same chromosome arm, inverted *loxP* sites will cause an inversion, while a direct repeat of *loxP* sites will cause a deletion event. If *loxP* sites are on different chromosomes it is possible for translocation events to be catalyzed by Cre induced recombination.

Cripto-1

Caterina Bianco
Mammary Biology and Tumorigenesis Laboratory, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA

Synonyms

Teratocarcinoma-derived growth factor-1; TDGF-1

Definition

Human Cripto-1 is a cell membrane associated protein important for embryonic development, stem cell renewal and tumorigenesis.

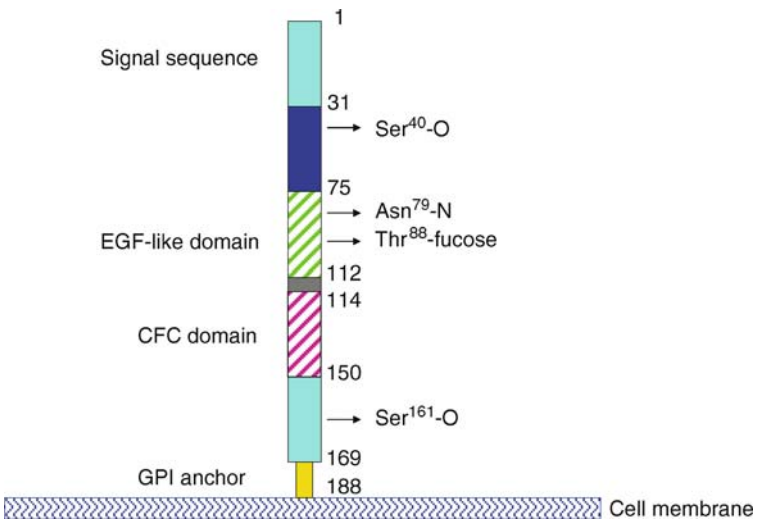
Characteristics

Structure of Cripto-1, a Member of the EGF-CFC Protein Family

Human Cripto-1 (CR-1), originally identified from a human embryonal carcinoma cDNA library, is the founding member of the Epidermal Growth Factor ►(EGF)-CFC (Cripto in humans, FRL1 in *Xenopus* and Cryptic in mice) family of proteins identified only in vertebrates. The ►EGF-CFC protein family includes monkey Cripto-1, mouse Cripto-1 (Cr-1), chicken Cripto-1, zebrafish *one-eyed pinhead* (*oep*), *Xenopus* FRL1 and mouse and human Cryptic. EGF-CFC proteins contain multiple domains consisting of an amino-terminal signal peptide, a modified EGF-like domain, a cystein-rich CFC motif and a short hydrophobic carboxy-terminus containing, in some cases, consensus sequences for a ►glycosylphosphatidylinositol (GPI) anchorage site that serves to attach the protein to the cell membrane (Fig. 1). EGF-CFC proteins are mostly found to be cell membrane-associated. However, human CR-1 can also be detected in the conditioned medium of several cancer cell lines and in the plasma of colon and breast cancer patients, probably by cleavage of the ►glycosylphosphatidylinositol (GPI) linkage by GPI-specific enzymes. An overall sequence identity of approximately 30% exists between the EGF-CFC members across different species. Within the EGF-like domain there is a 60–70% sequence similarity, whereas in the CFC-motif the similarity ranges from 35 to 48%. The modified EGF-like domain corresponds to a region of approximately 40 amino acids containing six cysteine residues. Whereas the canonical EGF-like domain that is present in the EGF family of growth factors (►Epidermal Growth Factor Receptor Ligands) such as EGF, transforming growth factor α (TGFα) and heregulins, contains three loops (A, B and C) due to the presence of three intramolecular disulfide bonds, the variant EGF-like domain in the EGF-CFC proteins lacks the A loop, has a truncated B loop and possess a complete C loop. The presence of this unusual EGF-like domain explains the observation that CR-1 does not directly bind to any of the known *erb*B type I tyrosine kinase receptors including the EGF receptor, *erb*B2, *erb*B3 and *erb*B4. EGF-CFC proteins are glycoproteins that range from 171 to 202 amino acids with an unmodified core protein of 18–21 kDa in size. The native mouse and human Cripto-1 proteins are 24, 28 and 36 kDa in size, although proteins ranging in size from 14 to 60 kDa have been identified in mouse and human normal tissues. This variation in size could be due to the removal of the hydrophobic signal peptide and to posttranslational modifications of the core protein. In fact, all the members of the EGF-CFC family, except for *oep*, are glycoproteins that contain a single N-►glycosylation site and potential O-glycosylation sites (Fig. 1). A single O-linked ►fucosylation site (Fig. 1) has been identified within the EGF-like domain of human CR-1 and a single point mutation in the fucosylation consensus sequence results in the loss of Cripto-1-dependent Nodal signaling (see below).

Cripto-1 During Embryonic Development and in Embryonic Stem (ES) Cells

Cripto-1 functions as a co-receptor for the TGFβ family ligands, Nodal and Vg1/growth and differentiation factor 1 and 3 (GDF1 and 3), during early vertebrate embryogenesis. Genetic studies in zebrafish and mice have defined an essential role for Nodal that functions through Cripto-1 in the formation of the primitive streak,



Cripto-1. Figure 1 Schematic diagram of the human Cripto-1 protein domains. Sites of glycosylations are indicated by *arrows*.

patterning of the Anterior/Posterior axis, specification of the mesoderm and endoderm during gastrulation and establishment of Left/Right asymmetry of developing organs. Cripto-1-dependent Nodal signaling depends upon the Activin type II (Act RII) and type I (Alk4) serine/threonine kinase receptors that activate the Smad-2/Smad-3 intracellular signaling pathway (►Smad Proteins in TGFβ Signaling). Evidence from several studies suggests that Cripto-1 recruits Nodal to the Act RII/Alk4 receptor complex by interacting with Nodal through the EGF-like domain and with Alk4 through the CFC domain. Cr-1 null mice die at day 7.5 due to their inability to gastrulate and form appropriate germ layers. Disruption of Cr-1 in Cr-1$^{-/-}$ embryos results in the formation of embryos that possess a head without a trunk, demonstrating that there is a severe deficiency in mesoderm and endoderm without a loss of anterior neuroectoderm formation. Homozygous knock out of the Cr-1 gene in pluripotential ►embryonic stem cells (ES cells) impairs their ability to differentiate *in vitro* into cardiomyocytes without affecting the ability of ES cells to differentiate in other cell types. In fact, Cr-1$^{-/-}$ ES cells show extensive neuronal differentiation *in vitro* and *in vivo*, suggesting that Cripto-1 could represent a key molecule required for both induction of cardiomyocyte differentiation and repression of neural differentiation. In this regard, Cr-1$^{-/-}$ ES cells, when transplanted *in vivo* at low doses, generate a pool of dopaminergic cells that are able to induce behavioral and anatomical recovery in animal models of Parkinson's disease. It has recently been established that Cripto-1 is a ►stem cell marker in mouse and human ES cells and in conjunction with Nanog, Nodal, Oct3/4 and GDF3 is involved in maintaining self-renewal and pluripotentiality of ES cells. Since malignant ES cells are probably the most appropriate targets for therapy in cancer, stem cell markers could be used as a signature to identify adult tissue cancer stem cells (►Stem Cells and Cancer).

Cripto-1 in Mammary Gland Development

Ovarian hormones and several growth factors, such as TGFβ, TGFα, EGF and insulin ►like growth factor, have been shown to play a crucial role in the regulation of the development and maturation of the mammary gland. In the mouse mammary gland, Cr-1 is detected during different stages of postnatal mammary gland development. In fact, Cr-1 protein has been detected in 4–12-week-old virgin, midpregnant and lactating mouse mammary gland. In the virgin pubescent mammary gland Cr-1 expression is observed in the cap stem cells of the growing terminal end buds and in the ductal epithelial cells from pregnant and lactating mice. Expression of Cr-1 in ductal epithelial cells is enhanced by approximately 3- to 5-fold during pregnancy and lactation. Further support for CR-1 regulation of mammary epithelial cells derives from data showing that CR-1 can modulate milk protein expression in ►HC-11 mouse mammary epithelial cells. HC-11 mouse mammary epithelial cells express the milk protein β-casein after exposure to the lactogenic hormones dexamethasone, insulin and prolactin (DIP). Prior treatment of ►HC-11 cells with exogenous CR-1 during logarithmic growth induces a competency response to DIP with respect to the induction of the milk protein β-casein. In contrast, simultaneous treatment of HC-11 cells with CR-1 in the presence of DIP inhibits β-casein expression. This inhibitory effect of CR-1 on milk protein expression may be biologically significant since soluble CR-1 protein can be found in human milk.

Cripto-1 in Transformation, Tumorigenesis and Angiogenesis

A first clue to the biological activity of Cripto-1 derives from studies demonstrating the ability of human CR-1 to transform mouse NIH-3T3 fibroblasts, mouse NOG-8 and mouse CID-9 mammary epithelial cells *in vitro*. However, NOG-8 and CID-9 cells transformed cells are unable to form tumors in nude mice, suggesting that additional genetic alterations are necessary to complete the tumorigenic phenotype *in vivo*. Further support for the transforming potential of Cripto-1 derives from studies showing increased expression of Cripto-1 in cells transformed by different oncogenes. In this regard, Ha-*ras* (►Ras) has been shown to upregulate Cr-1 expression in rat CREF embryo fibroblasts or rat FRLT-5 thyroid epithelial cells. Also, v-*ras*/Smad-7 transformed keratinocytes develop skin tumors that overexpress CR-1 and TGFα, suggesting that Smad-7 induces tumor formation through upregulation of CR-1 and other EGF-related peptides. Overexpression of Cr-1 in EpH4 mouse mammary epithelial cells increases cell proliferation, anchorage-independent growth in soft agar and the formation of branching structures when the cells are cultured in a three-dimensional type I collagen gel matrix. Furthermore, EpH4 Cr-1 cells show an increase in their migratory behavior in ►Boyden chamber studies and in ►wound healing assay. Exogenous CR-1 protein is also able to stimulate chemotaxis of wild-type EpH4 cells and can induce scattering of NOG-8 mouse mammary epithelial cells grown at low density as colonies on plastic. The scattering effect is characterized by a change in morphology of the epithelial cells to a more fibroblastic-like phenotype and by a decrease in cell-cell adhesion due to reduction in ►E-cadherin expression. These findings suggest that Cripto-1 may play a role in inducing ►epithelial to mesenchymal transition (EMT) of mammary epithelial cells. In fact, MCF7 breast cancer cells overexpressing CR-1 show increased invasion through matrix-coated membranes and mammary hyperplasias and tumors from MMTV-CR-1 ►transgenic mice (see below) show a

dramatic reduction in the levels of expression of the adhesion molecule E-chaderin, whereas the mesenchyme cell cytoskeleton component, vimentin, is significantly increased. Regulation of cell proliferation, cell motility and survival by CR-1 is dependent upon activation of two major intracellular signaling pathways, the *ras*/*raf*/mitogen-activated protein kinase (MAPK) (►Map Kinase) and phopshatidylinositol 3′ kinase (PI3K)/Akt (►AKT Signal Transduction Pathway in Oncogenesis) signaling pathways. Activation of these two intracellular signaling pathways is independent of Nodal and Alk4, since CR-1 can activate MAPK and Akt in EpH4 mammary epithelial cells and MC3T3-E1 osteoblast cells that lack Nodal and Alk4 expression, respectively. Activation of these two signaling pathways is mediated by binding of CR-1 to the GPI-linked heparan sulfate proteoglycan Glypican-1, which can then activate the cytoplasmic tyrosine kinase c-src triggering activation of MAPK and Akt. Finally, an intact c-src kinase is required by CR-1 to induce *in vitro* transformation and enhance migration in mammary epithelial cells.

In addition to regulating cell proliferation and transformation, CR-1 plays an essential role in tumor ►angiogenesis. In fact, CR-1 has a strong angiogenic activity *in vitro* in cultured ►human umbilical vein endothelial cells (HUVECs), stimulating proliferation, migration, invasion and differentiation of HUVECs into vascular-like structures when the cells are grown in ►Matrigel. Furthermore, recombinant CR-1 protein stimulates new blood vessel formation in silicone cylinders filled with Matrigel implanted under the skin of nude mice and microvessel formation in response to CR-1 is significantly inhibited *in vivo* by an anti-CR-1 blocking mouse monoclonal antibody. Finally, tumor xenografts that develop from CR-1 overexpressing MCF-7 breast cancer cells in the cleared mammary fat pad of nude mice have a significantly higher microvessel density than tumor xenografts that form from control MCF7 cells.

Transgenic Mouse Models Overexpressing CR-1 in the Mammary Gland

Transgenic mouse models have shown that overexpression of a human CR-1 transgene in the mouse mammary gland under the control of the ►mouse mammary tumor virus (MMTV) or ►whey acidic protein (WAP) promoter results in mammary hyperplasias and adenocarcinomas. Virgin MMTV-CR-1 transgenic mice exhibit enhanced ductal branching, intraductal hyperplasias and hyperplastic alveolar nodules. Approximately 30–40% of multiparous female mice develop papillary adenocarcinomas. The relatively long latency period suggests that additional genetic or regulatory alterations are required to facilitate mammary tumor formation in conjunction with CR-1. Unlike the MMTV promoter that starts to be active in the virgin mammary gland, the WAP promoter is maximally expressed at mid-pregnancy and lactation. Approximately 50% of old nulliparous WAP-CR-1 mice develop multifocal intraductal hyperplasias and more than half of multiparous WAP-CR-1 female mice develop multifocal mammary tumors of mixed histological subtypes. These tumors are a mixture of regions containing glandular, papillary and undifferentiated carcinoma, as well as myoepithelioma and adenosquamous carcinoma. Mammary tumors of mixed histology are normally phenotypes that are associated with transgenic mice that have alterations in the canonical Wnt/β-catenin pathway (►Wnt Signaling). In fact, increased expression of an activated β-catenin has been found in the mammary tumors of WAP-CR-1 transgenic mice, suggesting that a canonical Wnt pathway may be activated in these tumors.

Expression of CR-1 in Human Carcinomas and Premalignant Lesions

CR-1 is overexpressed, relative to noninvolved adjacent tissue, in ∼50–90% of carcinomas that arise in the colon, breast, stomach, pancreas, lung, gall bladder, testis, bladder, ovary, endometrium and cervix. Furthermore, enhanced expression of CR-1 has also been detected in premalignant lesions, such as colon adenomas, intestinal metaplasia of the gastric mucosa and ductal carcinoma *in situ* of the breast. In this respect, the frequency and level of CR-1 expression in colon adenomas and intestinal metaplasia in the stomach are directly correlated with the size, histological subtype and degree of dysplasia in these lesions, suggesting that CR-1 might be an early marker for malignant transformation in these tissues. CR-1 expression has also been detected in approximately 60% of normal colon mucosa specimens from individuals with a high incidence of colon carcinomas, but only in 20% of colon mucosa from low-risk individuals. In addition, expression of CR-1 in the adjacent noninvolved colon epithelium surrounding colon tumors is significantly correlated with increased lymph node involvement and with a higher rate of recurrence of colorectal tumors. Although no significant correlations have been found between CR-1 expression and prognosis, a recent study suggests that CR-1 is an independent prognostic factor in breast cancer. In fact, in more than 100 invasive breast cancers, overexpression of CR-1 has been found more often in high grade and poor prognosis tumors compared to low grade and good prognosis breast cancers and is significantly associated with decreased patient survival. Another study has also demonstrated a significant increase in the plasma levels of CR-1 protein in patients affected by colon and breast carcinomas, suggesting that CR-1 might represent a novel serological marker for breast and colon cancer.

Cripto-1 (Cr-1)

Definition

Is a glycoprotein member of 188 aa. Cr-l has been implicated in development. Expression of Cr-l was reported in trophoblast and embryoblast of 4-day old mouse blastocysts, and the myocardium of developing heart tubes in 8.5 old mice embryos. Transgenic murine embryos lacking Cr-l are devoid of cardiac specific gene expression (α and β- myosin heavy chain, myosin light chains 2A and 2V). Antisense RNA silencing studies showed that inhibition of Cr-1 expression inhibits the growth of human colon carcinoma cell lines expressing this factor.

►Epidermal Growth Factor (EGF)-Like Ligands

Crk

Definition

Adaptor protein with one SH2-domain and two SH3-domains. It is homolog to v-Crk oncogene. Crk is involved in regulation of cell growth, cell motility, and apoptosis.

►Focal Adhesion Kinase

CRLR

Definition

Calcitonin receptor-like receptor, distinct from CTR. Although it has affinity for calcitonin, it generally binds to other CT family of peptides. It requires association with RAMPs for translocation at the membrane, for ligand binding and generation of biological response. Its ligand specificity can be altered by changing the complexed RAMP molecule

►Calcitonin

Crocidolite

Definition

Is an amphibole form of ►asbestos. Iron predominates over magnesium in its composition. Following inhalation, it is strongly carcinogenic.

Crohn Disease

Gerard Dijkstra, Maikel P. Peppelenbosch
University Medical Center Groningen, University of Groningen, Groningen, The Netherlands

Synonyms

Inflammatory bowel disease (also includes ulcerative colitis)-related cancer; Nonprimary APC mutation colorectal cancer

Definition

Crohn disease (also: regional enteritis) is a chronic, inflammatory condition of the gastrointestinal tract, usually episodic in nature. Like ulcerative colitis, the other main entity of ►inflammatory bowel disease (IBD), it is linked to the development of colorectal cancer (CRC), patients suffering from Crohn disease having an approximately six times higher change of contracting the disease.

Characteristics

IBD patients, which include the two related conditions of Crohn disease and Ulcerative Colitis, have an increased risk of developing CRC. The risk depends on disease duration, extent of inflammation, presence of primary sclerosing cholangitis, a positive family history of CRC, age of onset, and the degree of endoscopic and histologic activity (►Inflammation in cancer). Furthermore, CRC accounts for about 15% of deaths related to IBD, however, IBD-related colorectal

carcinoma accounts for only 1–2% of all cases of CRC. Although, the number of IBD-related CRC of the total cases of CRC is low, the mortality rate in patients with a diagnosis of CRCs in the setting of IBD is higher than for those afflicted with sporadic cases of CRC (►Cancer epidemiology). Additionally, the risk for CRC is not related to disease activity, patients who are clinically quiescent do not have a lower risk for developing CRC compared to patients who suffer from a more active disease history. Moreover, during the last decades the incidence of IBD has continued to rise worldwide, reaching incidence rates of 16.6/100,000 in North America and 9.8/100,000 in Europe. IBD, the hereditary syndromes of familial adenomatous polyposis (FAP), and hereditary nonpolyposis colorectal cancer (HNPCC) are together the top three of high-risk conditions for CRC (►Colon cancer; ►Gastrointestinal tumors; ►Peutz-Jeghers-syndrome).

Chemoprevention of IBD-Related CRC

Cancer chemoprevention is based on the arrest of one or several steps in the multistep carcinogenesis process, which attempts to block, reverse, or delay carcinogenesis before the development of invasive disease (►Chemoprotectants). Mesalazine (5-aminosalicylic acid (5-ASA)), for which there is long-term clinical experience in the treatment of patients with IBD, is well tolerated, has limited systemic side effects, and has no gastrointestinal toxicity (►Antiinflammatory drugs). In a rodent model of CRC, mesalazine inhibits tumor growth and reduces the number of aberrant crypt foci colorectal ►premalignant lesions, whereas in patients with sporadic polyps or cancer of the large bowel, mesalazine induces apoptosis and decreases proliferation in the colorectal mucosa. Epidemiological data strongly support a chemopreventive role for mesalazine in ulcerative colitis-associated CRC and especially the data published by Eaden et al. show compelling evidence for a protective effect of long-term mesalazine use in patients with ulcerative colitis [1]. Together, these data suggest a chemopreventive role for mesalazine in CRC development.

Wnt/β-Catenin Pathway (Wnt Signaling)

The most important pathway in CRC is the Wnt/β-catenin pathway. Aberrant activation of this pathway by *Apc* or *β-catenin* mutation occurs in FAP (►*APC* gene in familial adenomatous polyposis) and most sporadic CRCs already early in carcinogenesis. In this pathway, Wnt binds to the transmembrane Frizzled receptor, which leads to activation of the cytoplasmic Disheveled (Dsh) protein. Dsh forms a complex with the β-catenin degradation complex, which consists of the adenomatous polyposis coli gene product (*APC*), glycogen synthase kinase-3β (GSK-3β), axin, and β-catenin. In the absence of ►Wnt signaling, β-catenin within this complex is phosphorylated by GSK-3β, and this leads to its rapid degradation via the ubiquitin pathway (►Ubiquitination). In response to Wnt signals, β-catenin is no longer targeted for degradation and accumulates to high levels in the cytoplasm. This stabilized β-catenin translocates to the nucleus where it binds with members of the T-cell factor (Tcf)/lymphoid enhancer factor (Lef) family of transcription factors, and activates the transcription of Wnt target gene expression (►APC/β-catenin pathway). Constitutive activation of this pathway is seen in almost all CRCs, mostly due to a mutation in the *Apc* gene. However, IBD-associated CRC is usually not associated with *Apc* mutations. Low prevalence of truncating mutations in the *Apc* gene is also seen in esophageal cancers, which is as IBD-associated carcinoma also an inflammatory-related carcinogenesis. Nonetheless, the function of the *Apc* gene is commonly repressed in esophageal carcinomas because the majority of the primary tumors have hypermethylated *Apc* promoter regions. Data on methylation status of *Apc* promoter regions of IBD-associated tumors are not published yet (►Methylation).

This opens a window for drug intervention. We have shown that that using concentrations of mesalazine identical to concentrations seen in patients with IBD, mesalazine inhibits the Wnt/β-catenin pathway via inhibition of protein phosphatase 2A. However, little is known about aminosalicylic acids and Wnt/β-catenin pathway. Hence, much more research should be conducted investigating the effect of NSAIDs on this important pathway in colon cancer.

Conclusions

Chronic inflammation of the Colon, as observed in Crohn disease and ulcerative colitis is closely linked to the development of CRC. The pathogenesis of this disease is different from the classical pathway, involving loss of APC function. Chemoprevention of CRC-development, using mesalazine is essential in this patient group.

Cold surgery; Freeze surgery

Definition

Operative cutting of tissue or the targeted destruction of pathological tissue by induced cold necrosis at temperatures down to –196°C.

Characteristics

Cryobiology

Cryobiology deals with the physical effects of low temperatures and the changing of temperatures in living tissues. The state or phase (vapor, liquid or solid) of water depends on temperature, pressure and volume. The liquid and solid phase of pure water are in equilibrium at atmospheric pressure and 0°C. By increasing the pressure this temperature (0°C) or freezing point can be lowered. This phenomenon is known as ►supercooling.

When its temperature is lowered, water will show ►vitrification or ►crystallization. Very rapid cooling of pure water will induce vitrification that entails the formation of amorphous, transparent, glasslike structures rather than crystals. Crystallization requires initiating nuclei, for instance an insoluble crystalline impurity). Slow cooling rates of water (<1°C/min) will induce large crystals around a few nuclei. During fast cooling rates many small crystals are formed which are thermodynamically unstable and tend to join each other by recrystallization to minimize their surface energies.

During freezing of solutions, ice crystals remove more and more pure water from the solution, elevating the dissolved solute concentration and lowering the vapor pressure of water to that of ice at the same temperature. In this situation solid and liquid phase coexist and this ►supercooled phase ends with a sudden rise of the temperature due to dissipation of latent heat generated by the recrystallization of the thermodynamically unstable small crystals. This phenomenon takes place at a ►eutectic temperature.

The nature of the tissue responding to low temperatures varies with the intensity of the induced cold. A minor cryogenic injury produces only an inflammatory response; a greater injury will produce tissue destruction. The effects of every physical state on living tissue can be divided in immediate and delayed effects. Immediate destructive properties of ►cryosurgery are the result of mechanical damage due to the formation of ice, whereas the delayed effects are due to progressive failure of the microcirculation (vascular stasis), tissue ischemia and ultimately cell death. When tissue temperature is lowered without reaching subzero temperatures cell metabolism is reduced. This is a reversible process and used to its benefit in cardiac surgery. However, if living tissue is continuously subjected to low, but non-freezing temperatures, cell death will occur.

The freezing of tissue is more complicated since its solvent (water) is divided by cell membranes into extracellular and intracellular compartments. Cell membranes in general easily allow the passage of water, but far less readily allow passage of other solutes. When tissue is subjected to a constant slow lowering of temperature it first enters a supercooled phase. Temperatures of 10–15°C below zero will initiate ice formation in the extracellular compartment. The intracellular compartment remains unfrozen because it contains substances with high and low molecular weight, which lower freezing temperatures. Due to the freezing of water in the extracellular compartment concentration of solutes will rise, creating an osmotic pressure induced transport of water from the intra- to the extracellular compartment. This loss of water will lead to shrinkage of the cell, accompanied by higher concentrations of the solutes, which further prevent the formation of ice in the intracellular compartment.

The shrinkage and high concentration of solutes, especially of salts, may be responsible for cell injury. This phenomenon seems especially of importance

during slow freezing rates. Very rapid cooling induces intracellular ice formation, because there is insufficient time for water leaving the cell to maintain osmotic equilibrium across the cell membrane. Intracellular ice formation is believed to be lethal to the cell. Based on histological investigations it has been shown that intracellular ice causes mechanical damage to the membrane, and disturbs the function of mitochondria and other cell organelles and membranes.

Furthermore masses of frozen cells, closely packed will be subjected to shearing forces of ice formation that will injure the tissue structure. Propagating ice will induce cell damage, regardless of the fact that ice is intra- or extracellular. Intracellular ice has to been shown to propagate from one cell to another via intercellular channels.

During thawing the "behavior" of the ice crystals is dependent on the rate of thawing. In contrast to rapid thawing, slow thawing is accompanied by recrystallization and the crystals can grow to damaging sizes. The damaging effect of these intracellular ice crystals, only formed during rapid freezing can therefore be exploited a second time, if slow thawing is allowed, thereby enhancing recrystallization. On the other hand, if tissues have been cooled slowly, causing shrinkage and intracellular dehydration, rapid thawing may be damaging because the cells are exposed to high electrolyte concentrations.

After thawing there is typically a brief period of vasodilation. Additionally the endothelium of blood vessels is particularly sensitive to freeze-thawing, leading to increased permeability of vascular walls, interstitial oedema, slowing of circulation and platelet aggregation. Capillary obstruction and vascular stasis ensues resulting in tissue ischemia and cell death.

Tumors, Suitable for Cryosurgical Treatment

A number of benign and malignant ►bone tumors can be treated by cryosurgery. These include aneurysmal bone cyst, symptomatic enchondroma, borderline ►chondrosarcoma, low-grade chondrosarcoma, chondroblastoma, chordoma and giant cell tumor of bone. In addition radio- and chemotherapy resistant bone metastases may also be effectively treated. The same goes for benign aggressive soft tissue tumors.

Indications for Cryosurgery

Active, or aggressive benign and low-grade malignant bone tumors are ideally treated by ►extralesional excision (►Marginal excision or ►wide excision). For tumors located in expendable bones, like ribs this is the treatment of choice. However, since most benign and low-grade malignant bone tumors tend to occur in the ►metaphysis and/or ►epiphysis of long bones marginal or wide excision would imply segmental loss of bone, compromising normal growth in children and loss of articular surface. Therefore ►intralesional excision (curettage), combined with a powerful local adjuvant is advocated in tumors in which this combination is equivalent to at least marginal a excision.

Cryosurgery is a powerful adjuvant therapy and the main advantage is that the surgeon is in charge of the local extent beyond the surgical margin (7–12 mm) and is able to customize the treatment for a specific benign or low-grade malignant bone tumor.

Cryosurgical Technique

After sufficient exposure of the tumor, thorough curettage of the tumor is performed. To monitor the intralesional temperature and the local extent of the freeze thermocouples are positioned in and around the lesion. Liquid nitrogen is sprayed in the cavity in every direction, until the whole cavity is wetted and becomes frosted. The duration of the freeze is based on the temperature readings and visual observation. Intralesional temperatures of at least minus 50°C are pursued. After spontaneous thawing, two more cycles of freezing and thawing is done, to destroy tumor cells, which may have survived the previous cycle. Finally the cavity is filled with allograft bone chips and when feasible the defect is reinforced with ►osteosynthesis to prevent pathological fracture of the bone.

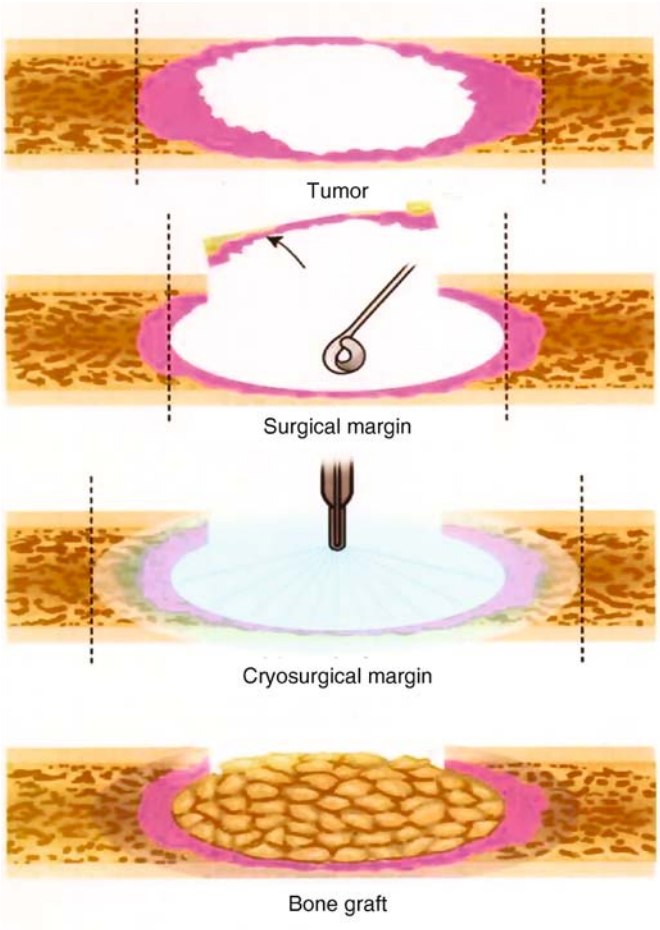
Figure 1 shows this type of cryosurgical therapy for bone tumors.

Results of Treatment

All results will be presented according to the functional evaluation system of the Musculo-Skeletal Tumor Society. Veth et al. reported on 302 patients who had been treated by cryosurgery for a variety of bone and soft tissue tumors. At follow-up 298 of these patients showed NED (no evidence of disease) or CDF (continuously free of disease), whereas 5 were AWD (alive with disease) and 2 DOD (dead of disease). The minimal follow-up period for this review was 2 years.

Of these cryosurgically treated patients 43 had been diagnosed with giant cell tumor of bone, 15 with chondroblastoma, 73 with borderline chondrosarcoma and 44 with chondrosarcoma grade1. Chordoma was diagnosed in seven cases.

Most studies on giant cell tumor report on a rate of local recurrences varying from 0 to 47%. The risk for local recurrence for this tumor is greatly influenced by the method of first surgery. Primary surgery of a giant cell tumor in a non-bone tumor hospital is most likely to induce several local recurrences. The local recurrence rates in chondroblastoma and low-grade chondrosarcoma are respectively 7 and 3%. Figures for chordoma are small and rates of local recurrence vary to a great deal with the extent of the tumor. The functional results according to the MSTS system



Cryosurgery in Bone Tumors. Figure 1 Drawing of cryosurgical technique for bone tumors.

(►MSTS functional evaluation system) for the first 3 tumors are good to excellent in 80% of cases.

Comparing the results it appears, that the risk for local recurrence is small after cryosurgery, compared to different types of treatment and the functional results are at least similar. However an import feature of cryosurgery is that tumor excision is never followed by prosthetic implants, thus the patient keeps a biological reconstruction.

Complications

Possible complications of cryosurgery are:

Wound Infection

Cryosurgery appears to be accompanied by a deep infection rate of about 4%, but this differs between institutions. Sacral lesions are prone for developing an infection.

The following items are of importance in order to avoid infection:

intraoperative broad spectrum antibiotics, adequate drainage of wound fluids, avoidance of accidental freezing of the skin and wound closure with sufficient soft tissue coverage.

Venous Gas Embolism

During cryosurgery liquid nitrogen is either sprayed or poured into the bony cavity and since its boiling point is −195°C nitrogen gasbubbles are rapidly produced at room temperature. In general, whenever a gas is introduced into a body cavity there is the hazard of intravascular introduction of gas bubbles especially when pressure is allowed to develop. Gas emboli in the vascular circulation can cause serious hemodynamic complications.

The risk is increased when the site of the tumor is located in a richly vascularized area such as the metaphysis of the long bones. Unfortunately, this is the location of preference for many bony tumors suitable for cryosurgical treatment.

Fracture

The tumor itself as well as the surgical exposure and resection jeopardize the structural integrity of the bone. Cryosurgery is said to further diminish bone strength

by inducing necrosis of the local bone stock often leading to postoperative fractures.

In the late sixties the pioneers, who used cryosurgery for bone tumors reported rather high fracture rates (up to 10%).

Fractures are most likely to occur 4-8 weeks after the cryosurgical treatment, but they can occur even after 8 months. Diaphyseal lesions are most prone for fracture. Therefore prophylactic internal fixation is advised. Plate and screws are often used, which protects the bone especially from rotating forces. Intramedullary instrumentation is ill advised, because it has the risk of contaminating the entire intramedullary compartment with tumor cells. Titanium alloys are preferred because these implants induce little interference on MRI making tumor follow-up less difficult. Partial weight bearing is usually necessary until three months after the operation.

Experience and improvements in technique have reduced the fracture rate to an acceptable level of 1–2%.

Epiphyseal Damage

Benign bone tumors, especially simple- and aneurysmal bone cysts tend to occur in patients of immature skeletal age. Furthermore these tumors are commonly observed in the metaphysis, often adjacent or very close to the epiphysis. Damage of the epiphysis either by the tumor itself or the use of cryosurgery occurs and may result in arrest or disturbance of normal growth.

Whether an epiphysis is damaged by the bone tumor or by the treatment will not always become clear and in many cases may be the result of both.

Degenerative Osteoarthritis

Some bone tumors like giant cell tumor and chondroblastoma occur almost always extremely close to major joints. Damage of the articular surface either by the tumor itself (intra-articular fracture) or treatment (cryosurgery) may be the result, thus resulting in osteoarthritis.

Damage to Nerves

Nerve palsy is a complication of cryosurgery, which was recognized at the very early beginning of the introduction of cryosurgery for bone tumors.

If nerves are frozen their function is only temporary impaired. Most neuropraxias resulting from freezing will resolve in 6 weeks to 6 months. Very likely regenerating nerve fibers can grow down the nerve sheaths since they are left intact. Furthermore the vital nerve cell nucleus is located away in the dorsal root ganglion. Tourniquets should not be used, in order to keep nerves and skin vascularized and thereby protect them from a freeze injury. Veth et al saw in 302 cryosurgical procedures 10 nerve palsies; only one peroneal nerve failed to regain its function, however not the cryosurgery but surgical traction was very likely the cause of this persistent palsy.

Prospects to the Future

Starting in the mid 1960's, cryosurgery has evolved from a medical tool with limited usefulness for treatment of all kind of tumors into a reliable technique, even for bone tumor patients. A rather recent study showed that 2 instead of 3 freeze-thaw cycles would be sufficient for tumor control. A study by Baust identified apoptosis as a cryosurgery related mechanism of cell death, additive with ice-related cell damage and post-treatment coagulative necrosis. This may provide a possible route to molecular-based optimization of cryosurgical procedures and better results.

The use of cryosurgery in multi recurrent schwannoma of peripheral nerves, chordoma or other sacral tumors as well as its use in bone tumor areas where a peripheral nerve is often involved (proximal fibula) has shown that these nerves may dysfunction after cryosurgery for a period up to 6 months, but in the end mostly recover completely. Additional study on the behavior of nerve tissue during cryosurgery is warranted in order to optimize the temperature for tumor cell kill and reduce the period of nerve dysfunction.

Curcumin

Marc Diederich
Laboratoire de Biologie Moléculaire et Cellulaire du Cancer (LBMCC), Hôpital Kirchberg, Luxembourg

Synonyms

1,7-bis [4-hydroxy-3-methoxyphenyl]-1,6-heptadiene-3,5-dione; Diferuloylmethane; $C_{21}H_{20}0_6$; $[HOC_6H_3(OCH_3)CH{:}CHCO]_2CH_2$; E100; C.I. 75300; Turmeric yellow; Brilliant Yellow S; Natural Yellow 3

Definition

Curcumin (MW 368,3862) (Fig. 1a) is the active ingredient of the natural Indian spice curcuma obtained from the root of the plant *Curcuma Longa L* also called Turmeric, which is a member of the ginger family, *Zingiberaceae* (Fig. 1b). In Ayurvedic medicine, turmeric is thought to have many healthful properties.

Curcumin is known to exhibit anti-oxidant, anti-inflammatory, anti-sceptic, anti-cancer and wound healing properties with low cytotoxicity [1]. Furthermore, it modulates molecular targets including cytokines and growth factors such as tumor necrosis factor (TNF) or interleukins, transcription factors including ►nuclear factor kappa B (NF-κB), ►signal transducer and ►activator of transcription (STAT) 3 or ►AP-1 (activating protein-1) [2]. Pro-inflammatory enzymes like COX-2 (cyclooxygenase 2), LOX (lipoxygenase) and iNOS (inducible nitric oxide synthase), as well as the ►protein kinases c-Jun N-terminal kinase (JNK), protein kinase A (PKA), Janus kinase (Jak) and inhibitor of κB (IκB) alpha were also shown to be inhibited by curcumin [3].

Characteristics

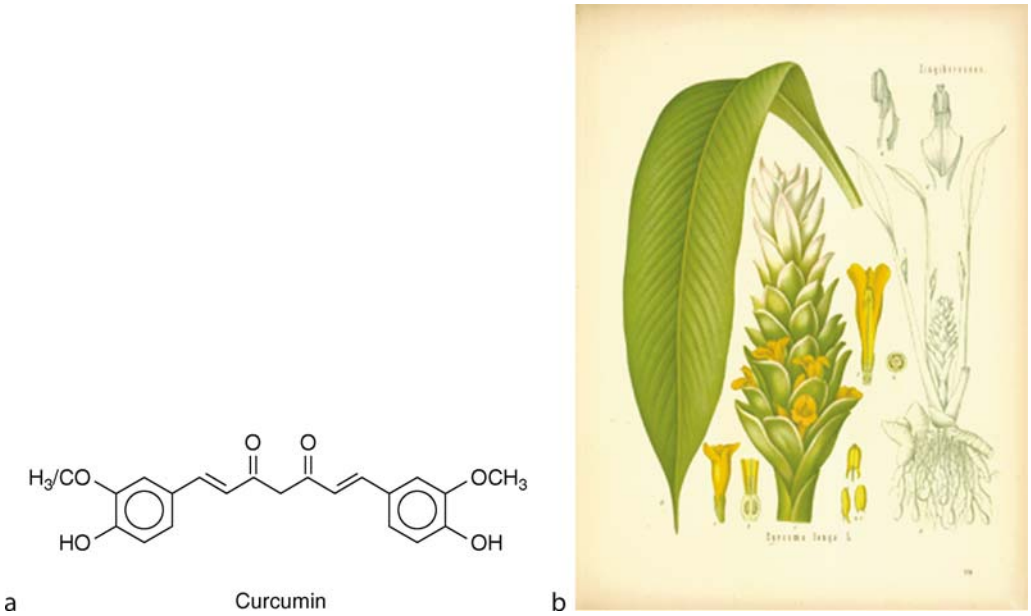
Anti-Carcinogenic Activities

Curcumin inhibits tumor initiation, promotion and progression. It has anti-angiogenesis activities by inhibiting vascular endothelial growth factor (VEGF), angiopoietin 1 and 2 as well as tyrosine kinase Flk-1/KDR (VEGF receptor-2) in various cellular models.

Curcumin leads to reduced expression levels of oncogenes including c-jun, c-fos, c-myc, NF-κB inducing kinase (NIK), mitogen activated protein kinases (MAPK; ►MAP kinase)s, extracellular regulated kinase (ERK), ELK-1, phosphoinosititde-3 kinase (PI3K), protein kinase B (PKB/►Akt) and cyclin dependent kinases (CDK)s. Curcumin can inactivate 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA)-induced activation of protein kinase C (PKC). β-catenin-mediated transactivation is also inhibited and leads to growth inhibition of colon ►cancer cells.

Effect on Cell Signaling Pathways

Curcumin induces ►apoptosis signaling in cancer cells including HL-60, K562, MCF-7 and HeLa.without cytotoxic effects on normal cells. In human kidney carcinoma cells, apoptosis is initiated by Akt dephosphorylation, B-cell leukemia/lymphoma (Bcl) -2, Bcl-XL and inhibitor of apoptosis (IAP) protein inhibition, as well as cytochrome c release and ►caspase 3 activation. Curcumin induces caspase 8 and 9 whereas p53 levels remain unchanged. Curcumin is also able to inhibit chemotherapeutic effects by reducing camptothecin-, mechlorethamine- or doxorubicin-induced apoptosis in breast cancer cells. Curcumin inhibits the activation of NF-κB and AP-1. IκB kinase (IKK) inhibition by curcumin blocks both IκBα phosphorylation and NF-κB p65 translocation and leads to NF-κB inhibition. Curcumin inhibits interleukin (IL) 1α-, TNFα-, TPA-, lipopolysaccharide (LPS)- and thrombin-induced NF-κB activation. Curcumin was described to impair the proteasome-ubiquitin degradation pathways and thus leads to apoptosis.



Curcumin. Figure 1 (a) Molecular structure of curcumin (diferuloylmethane). (Figure modified from ScienceSlides, VisiScience Corp.). (b) *Curcuma longa L.* (© 1995–2004 Missouri Botanical Garden, http://ridgwaydb.mobot.org/mobot/rarebooks).

Curcumin inhibits the signal transduction pathway leading to ►JNK activation at mitogen-activated protein kinase (►MAPKKK). Furthermore, the signaling pathway leading to MAPK p38 activation is attenuated by curcumin in inflammatory bowel disease cells, whereas Akt kinase is completely inhibited in prostate cancer cells. Curcumin was described to act on the Janus Kinase (Jak)-STAT pathway blocking JAK 2 mRNA expression in Bcr-Abl+ human K562 leukemia cells.

Clinical Trials

Clinical trials are aiming to evaluate if curcumin improves the efficacy of gemcitabine in patients with advanced pancreatic cancer. They also evaluate the combination of curcumine with gemcitabine and celecoxib for patients with colon cancer, to assess whether curcumin can regress colorectal adenomatous polyps in patients with familial adenomatous polyposis and to determine the effectiveness of curcumin in reducing the number of aberrant crypt foci in the colon. Curcumin is also under trial to determine the clinical effects in improving the cytopenias of patients with myelodysplastic syndromes.

Cushing Syndrome

Constantine A. Stratakis
Program on Developmental Endocrinology of Genetics, NICHD, NIH, Bethesda, MD, USA

Definition

Cushing syndrome is a rare disease entity. The overall incidence of Cushing syndrome is ~2–5 new cases per million people per year. Approximately 10% of the new

cases each year occur in children. As in adult patients, in children with Cushing syndrome, too, there is a female to male predominance, which decreases with younger age; there might even be a male to female predominance in infants and young toddlers with Cushing syndrome. The most common cause of endogenous Cushing syndrome is overproduction of adrenocorticotropin (ACTH) from the pituitary; this is called Cushing disease. It is usually caused by an ACTH-secreting pituitary microadenoma and, rarely, a macroadenoma. ACTH secretion occurs in a semiautonomous manner, maintaining some of the feedback of the HPA axis. Cushing's disease accounts for ~75% of all cases of Cushing syndrome in children over 7 years. In children under 7 years, Cushing disease is less frequent; adrenal causes of Cushing syndrome (adenoma, carcinoma or bilateral hyperplasia) are the most common causes of the condition in infants and young toddlers. Ectopic ACTH production is almost unheard of in young children; it also accounts for less than 1% of the cases of Cushing syndrome in adolescents. Sources of ectopic ACTH include small cell carcinoma of the lungs, carcinoid tumors in the bronchus, pancreas or thymus, medullary carcinomas of the thyroid, pheochromocytomas and other neuroendocrine tumors.

Rarely, ACTH overproduction by the pituitary may be the result of oversecretion of corticotropin-releasing-hormone (CRH) by the hypothalamus or by an ectopic CRH source. However, this cause of Cushing syndrome has only been described in a small number of cases, and never in young children. Its significance lies in the fact that diagnostic tests that are usually used for the exclusion of ectopic sources of Cushing syndrome have frequently misleading results in the case of CRH-induced ACTH oversecretion.

Autonomous secretion of cortisol from the adrenal glands, or ACTH-independent Cushing syndrome, accounts for ~10–15% of all the cases of Cushing syndrome. However, although adrenocortical tumors are rare in older children, in younger children they are more frequent. Adrenocortical neoplasms account for 0.6% of all childhood tumors.

Cushing syndrome is a manifestation of approximately one third of all adrenal tumors. A number of adrenal tumors presenting with Cushing syndrome can be malignant: the majority of patients present under age 5, contributing thus to the first peak of the known bimodal distribution of adrenal cancer across the life span. As in adults, there is a female to male predominance. The tumors usually occur unilaterally; however, in 2–10% of patients they occur bilaterally.

Bilateral nodular adrenal disease has been appreciated more recently as a rare cause of Cushing syndrome. Primary pigmented nodular adrenocortical disease (PPNAD) is a genetic disorder with the majority of cases associated with Carney complex, a syndrome of multiple endocrine gland abnormalities in addition to lentigines and myxomas. The adrenal glands in PPNAD are most commonly normal or even small in size with multiple pigmented nodules surrounded by an atrophic cortex. The nodules are autonomously functioning resulting in the surrounding atrophy of the cortex. Patients with PPNAD frequently have periodic Cushing syndrome.

Massive macronodular adrenal hyperplasia (MMAD) is another rare disease, which leads to Cushing syndrome. The adrenal glands are massively enlarged with multiple, huge nodules that are typical, yellow-to-brown cortisol-producing adenomas. Most cases of MMAD are sporadic, although few familial cases have been described; in those, the disease appears in children. In some patients with MMAD, cortisol levels appear to increase with food ingestion (food-dependent Cushing syndrome). These patients have an aberrant expression of the GIP receptor (GIPR) in the adrenal glands. In the majority of patients with MMAD, however, the disease does not appear to be GIPR-dependent; aberrant expression of other receptors might be responsible.

Bilateral macronodular adrenal hyperplasia can also be seen in McCune Albright syndrome (MAS). In this syndrome there is a somatic mutation of the *GNAS* gene leading to constitutive activation of the Gsα protein and continuous, non-ACTH-dependent stimulation of the adrenal cortex. Cushing syndrome in MAS is rare and usually presents in the infantile period (before 6 months of age); interestingly, a few children have had spontaneous resolution of their Cushing syndrome.

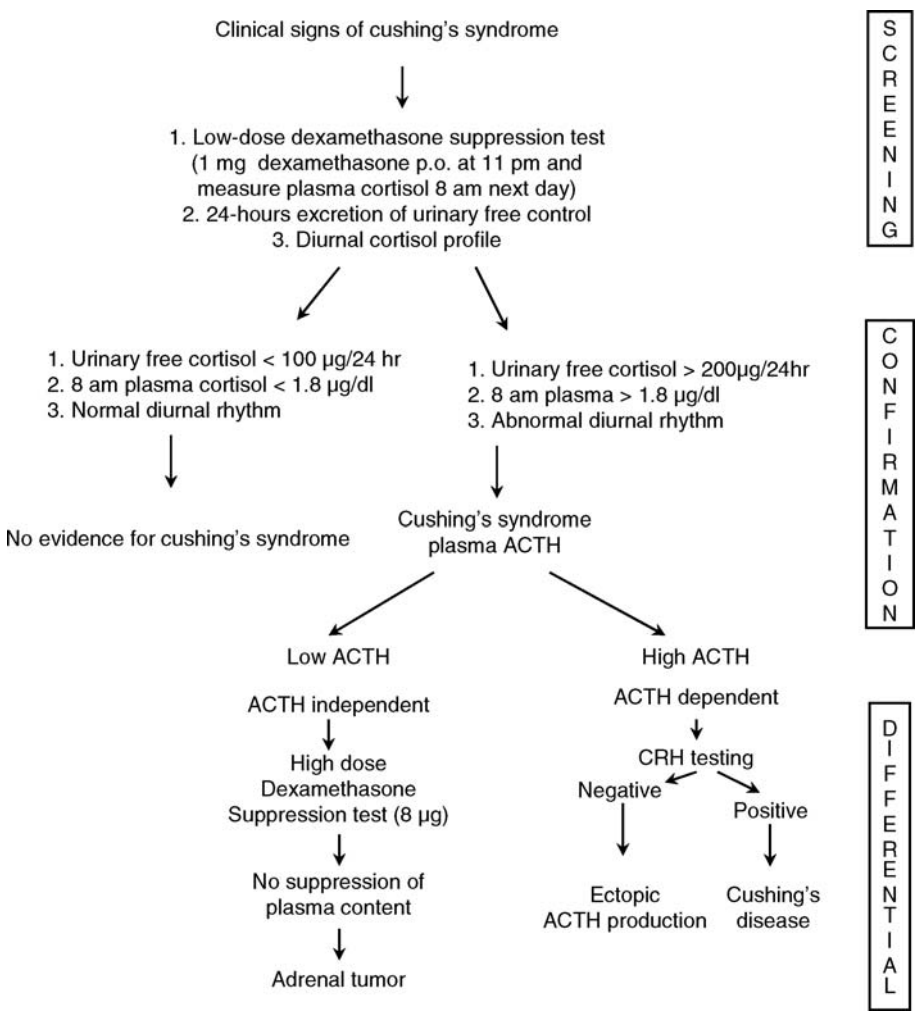
Characteristics

In most patients the onset of Cushing syndrome is rather insidious. The most common presenting symptom of the syndrome is weight gain, although it is not universally present. Almost pathognomonic for Cushing syndrome in childhood is weight gain associated with growth retardation; the combination of the two is among the most consistent and frequently encountered signs. Other common problems reported in patients include facial plethora, headaches, hypertension, hirsutism, amenorrhea, and delayed sexual development. Other patients may present with virilization. Skin manifestations, including acne, violaceous striae and bruising and acanthosis nigricans are also common. In comparison to adult patients with Cushing syndrome, symptoms that are less commonly seen include sleep disruption, weakness and mental changes.

Diagnostic Guidelines

The appropriate therapeutic interventions in Cushing syndrome depend on accurate diagnosis and classification of the disease. The history and clinical evaluation, including growth charts in children, are important to make the initial diagnosis of Cushing syndrome. Upon suspicion of the syndrome, laboratory and imaging

confirmations are necessary. An algorithm of the diagnostic process is presented in the attached diagram (Fig. 1). The first step in the diagnosis of Cushing syndrome is to document hypercortisolism. This step is usually done in the outpatient setting. Because of the circadian nature of cortisol and ACTH, isolated cortisol and ACTH measurements are not of great value in diagnosis. One excellent screening test for hypercortisolism is a 24-h urinary free cortisol (UFC) excretion corrected for body surface area. A normal 24-h UFC value is <70 μg/m^2/day. A 24-h urine collection is often difficult for parents to do in children and may be done incorrectly, especially in the outpatient setting. Falsely high UFC may be obtained because of physical and emotional stress, chronic and severe obesity, pregnancy, chronic exercise, depression, alcoholism, anorexia, narcotic withdrawal, anxiety, malnutrition and excessive water intake (more than 5 l/day). These conditions may lead to sufficiently high UFCs to cause what is known as pseudo-Cushing syndrome. On the other hand, falsely low UFC may be obtained mostly with inadequate collection. Another baseline test for the establishment of the diagnosis of Cushing syndrome is a low dose dexamethasone suppression test. This test involves giving a 1 mg of dexamethasone at 11 P.M. (adjusted for weight for children <70 kg by dividing the dose by 70 and multiplying by the weight of the child) and measuring a serum cortisol level the following morning at 8 A.M. The problem with this test is that it has not been evaluated extensively in children; for adult patients, the cortisol cut-off level should be <1.8 μg/dl (50 nmol/l). If it is greater than 1.8 μg/dl, further evaluation is necessary. This test has a low percentage of false normal suppression; however, at our institution, very rarely we obtain the 1-mg test for screening for Cushing syndrome in children. It should also be noted



Cushing Syndrome. Figure 1 Algorithm of the diagnostic process.

that the 1-mg overnight test (like the 24-h UFCs), does not distinguish between hypercortisolism from Cushing syndrome and other hypercortisolemic states.

If the response to both the 1-mg dexamethasone overnight suppression test and the 24-h urinary free cortisol are both normal, a diagnosis of Cushing syndrome may be excluded with the following caveat: 5–10% of patients may have intermittent or periodic cortisol hypersecretion and may not manifest abnormal results to either test. If periodic or intermittent Cushing syndrome is suspected, continuous follow up of the patients is recommended. Diurnal plasma cortisol variation, including midnight cortisol values, is a fairly good test for the establishment of the diagnosis of Cushing syndrome. In our institution, it has become the test of choice for the confirmation of endogenous hypercortisolemia and is routinely done in patients with confirmed elevated urinary cortisol levels on the outside. There are several caveats for the interpretation of the test of which the most important ones are: (i) The venous catheter has to be placed at least two hours before the test; and (ii) if the patient comes from another time zone, a 1 h per day adjustment should be taken into account prior to obtaining the test. In general, serum cortisol levels are drawn at 11:30 P.M. and 12:00 MN and at 7:30 A.M. and 8:00 A.M., while the patient is lying in bed and asleep; mid-night cortisol levels above 5 μg/dl are abnormal and confirm the diagnosis of Cushing syndrome, whereas an inverted diurnal rhythm is seen in PPNAD and some other adrenal tumors.

If one of the tests is suggesting Cushing syndrome or, if there is any question about the diagnosis, tests that distinguish between pseudo-Cushing states and Cushing syndrome may be obtained. One such test is the combined dexamethasone-CRH test. In this test the patient is treated with low dose dexamethasone (0.5 mg adjusted for weight for children <70 kg by dividing the dose by 70 and multiplying by the weight of the child) every 6 h for eight doses prior to the administration of CRH (ovine CRH – oCRH) the following morning. ACTH and cortisol levels are measured at baseline and every 15 min for one hour after the administration of oCRH. The patient with a pseudo-Cushing state will exhibit low or undetectable basal plasma cortisol and ACTH, and have a diminished or no response to oCRH stimulation. Patients with Cushing syndrome will have higher basal cortisol and ACTH levels and will also have a greater peak value with oCRH stimulation. The criterion used for the diagnosis of Cushing syndrome is a cortisol level of greater than 38 nmol/l (~1.4 μg/dl) 15 min after oCRH administration; all other patients (<1.4 μg/dl) may suffer from a pseudo-Cushing state.

Once the diagnosis of Cushing syndrome is confirmed there are several tests to distinguish ACTH-dependent disease from the ACTH-independent syndrome. A spot plasma ACTH may be measured; if this measurement is <5 pmol/l it is indicative of ACTH-independent Cushing syndrome, although the sensitivity and specificity of a single ACTH measurement are not high because of the great variability in plasma ACTH levels and the instability of the molecule after the sample's collection. Even if one assumes that the sample was collected and processed properly (collected on ice and spun down immediately in a refrigerated centrifuge for plasma separation; the sample should then be immediately processed or frozen at −20°C), ACTH levels that are between 5 and 20 pmol/l are not informative in this era of high sensitivity assays; levels above 20 pmol/l are more suggestive of an ACTH-dependent condition, but again that is not a certainty until single ACTH levels are repeatedly over 70 pmol/l.

The standard six-day low- and high dose dexamethasone suppression test (Liddle's test) is used to differentiate Cushing disease from ectopic ACTH secretion and adrenal causes of Cushing syndrome. In the classic form of this test, after 2 days of baseline urine collection, 0.5 mg of dexamethasone (adjusted per weight for children <70 kg by dividing the dose by 70 and multiplying by the weight of the child) every 6 h are given *per os* starting at 6.00 A.M. on day 3 ("low dose" phase of the test) for a total of eight doses (2 days); this is continued with a 2-mg dose of dexamethasone *per os* (adjusted per weight for children <70 kg by dividing the dose by 70 and multiplying by the weight of the child) on day 5 ("high dose" phase of the test) given every 6 h for another 8 doses (final 2 days) (13–15). Urinary free cortisol and 17-hydroxysteroid excretion are measured at baseline, during, and 1 day after the end of the dexamethasone administration. Approximately 90% of patients with Cushing disease will have suppression of cortisol and 17-hydroxysteroid values, whereas less than 10% of patients with ectopic ACTH secretion will have suppression. Urinary free cortisol values should suppress to 90% of baseline value and 17-hydroxysteroid excretion should suppress to less than 50% of baseline value. The criteria are similar if one uses serum cortisol values obtained at 8 A.M. of the morning after the last dose of dexamethasone, e.g. serum cortisol on day 7 should be 90% of baseline serum cortisol values (obtained at 8 A.M. the day before dexamethasone administration). An increase of urinary free cortisol values of 50% or more over baseline during Liddle test has been used in the differential diagnosis of PPNAD and other micro-nodular adrenocortical disease versus other causes of adrenal causes of Cushing syndrome.

The Liddle test has been modified to (i) giving 2 mg every 6 h (without the preceding low-dose phase);

(ii) administering dexamethasone intravenously over 5 h at a rate of 1 mg/h; or (iii) giving a single high dose of dexamethasone (8 mg, in children adjusted for weight <70 kg) at 11 P.M. and measuring the plasma cortisol level the following morning. This overnight, high dose dexamethasone test has sensitivity and specificity values similar to those of the classic Liddle test. A 50% suppression of serum cortisol levels from baseline is what differentiates Cushing disease (more than 50% suppression) from other causes of Cushing syndrome (adrenal or ectopic ACTH production) (less than 50% suppression).

An oCRH stimulation test may also be obtained for the differentiation of Cushing disease from ectopic ACTH secretion. In this test, 85% of patients with Cushing disease respond to oCRH with increased plasma ACTH and cortisol production. 95% of patients with ectopic ACTH production do not respond to administration of oCRH. The criterion for diagnosis of Cushing disease is a mean increase of 20% above baseline for cortisol values at 30 and 45 min and an increase in the mean corticotropin concentrations of at least 35% over basal value at 15 and 30 min after oCRH administration. When the oCRH and high dose dexamethasone (Liddle or overnight) tests are used together, diagnostic accuracy improves to 98%.

Another important tool in the localization and characterization of Cushing syndrome is diagnostic imaging. The most important initial imaging when Cushing disease is suspected is pituitary magnetic resonance imaging (MRI). The MRI should be done in thin sections with high resolution and always with contrast (gadolinium). The latter is important since only macroadenomas will be detectable without contrast; after contrast, an otherwise normal-looking pituitary MRI might show a hypoenhancing lesion, usually a microadenoma. More than 90% of ACTH-producing tumors are hypoenhancing, whereas only about 5% are hyperenhancing after contrast infusion. However, even with the use of contrast material, pituitary MRI may detect only up to ~30% of ACTH-producing pituitary tumors, although with the use of new modalities (e.g. SPGR-MRI) this percentage may be as high as 60%. Computed tomography (CT) (more preferable than MRI) of the adrenal glands is useful in the distinction between Cushing disease and adrenal causes of Cushing syndrome, mainly unilateral adrenal tumors. The distinction is harder in the presence of bilateral hyperplasia (MMAD or PPNAD) or bilateral adrenal carcinoma (conditions, however, that are rare). Most patients with Cushing disease have ACTH-driven bilateral hyperplasia, and both adrenal glands will appear enlarged and nodular on CT or MRI. Most adrenocortical carcinomas are unilateral and quite large by the time they are detected. Adrenocortical adenomas are usually small, less than 5 cm in diameter and, like most carcinomas, they involve one adrenal gland. MMAD presents with massive enlargement of both adrenal glands, whereas PPNAD is more difficult to diagnose radiologically because it is usually associated with normal or small-sized adrenal glands, despite the histologic presence of hyperplasia.

Ultrasound may not be used to image the adrenal glands for the diagnostic work up of Cushing syndrome, because its sensitivity and accuracy is much less than CT or MRI. A CT or MRI scan of the neck, chest, abdomen and pelvis may be used for the detection of an ectopic source of ACTH production. Labeled octreotide scanning and venous sampling may also help in the localization of an ectopic ACTH source. Since up to 50% of pituitary ACTH-secreting tumors and many of ectopic ACTH tumors can not be detected on routine imaging, and often laboratory diagnosis is not completely clear, catheterization studies must be used to confirm the source of ACTH secretion in ACTH-dependent Cushing syndrome (1–3). Bilateral inferior petrosal sinus sampling (IPSS) may also be used for the localization of a pituitary microadenoma (although not with great accuracy or sensitivity). IPSS is an excellent test for the differential diagnosis between ACTH-dependent forms of Cushing syndrome with a diagnostic accuracy that approximates 100%, as long as it is performed in an experienced clinical center. IPSS, however, may not lead to the correct diagnosis, if it is obtained when the patient is not sufficiently hypercortisolemic or, if venous drainage of the pituitary gland does not follow the expected, normal anatomy. In brief, sampling from each inferior petrosal sinuses is taken for measurement of ACTH concentration simultaneously with peripheral venous sampling. ACTH is measured at baseline and at 3, 5, and 10 min after oCRH administration. Patients with ectopic ACTH secretion have no gradient between either one of the two sinuses and the peripheral sample. On the other hand, patients with an ACTH-secreting pituitary adenoma have at least a 2-to-1 at baseline, and 3-to-1 central-to-peripheral gradient after stimulation with oCRH.

Synonyms

Desmoplastic melanoma

Definition

Desmoplastic (Desmoplasia) ►melanoma (DM) is a rare variant of invasive melanoma of the skin composed of spindle cells surrounded by various degrees of sclerotic stroma. DM has a variable clinical appearance and may mimic several lesions.

Characteristics

Epidemiology

Desmoplastic melanoma (DM) is an uncommon variant of melanoma representing 2–4% of all melanoma cases. Like many melanomas, DM tends to occur in sun-exposed regions of the skin with highest incidence in the head and neck region (>40%), thus suggesting a predilection for chronically sun-damaged skin. Nevertheless, DM may occur anywhere, including acral and mucosal sites. DM predominantly affects elderly individuals; the mean age of onset is consistently 10 years later (~60 years) than it is for patients with conventional (i.e. non-DM) melanoma. DM has a male predominance ratio of ~2:1.

Microscopic Features

Microscopically, DM presents as a poorly circumscribed neoplasm of variable size with dermal and frequently subcutaneous infiltration. There is often an accompanying atypical or frankly malignant melanocytic proliferation in the epidermis. The tumor is present in a sarcoma-like pattern with elongated and usually amelanotic, hyperchromatic fibroblast-like spindle cells arranged singly or in thin fascicles separated from each other by fibrotic stroma. Epitheloid cells may be recognized in the superficial areas of the lesion while in deeper areas the cells are predominantly spindle cell with fibroblast-like features. The spindle cell population varies greatly in appearance: it may be hypocellular and bland with minimal mitotic figures (differential diagnosis: scar, fibromatosis, dermatofibroma) or associated with nuclear atypia and high mitotic activity (differential diagnosis: high-grade sarcoma or sarcomatoid carcinoma). If these latter areas are more than focal, such lesions are not classified as DM but rather as spindle cell melanoma (see below). Focal lymphocytic aggregates are very frequently observed and may aid in diagnosis. By differentiating along Schwannian lines, DM may also mimic neurofibroma, neurotized melanocytic nevus or nerve sheath myxoma. Variants of DM include the "neurotropic" melanoma showing a "neuroma-like" growth pattern with invasion of cutaneous nerves, usually in a spindle cell vertical component with fibrosis. The myxoid (or myxofibrous) variant displays abundant mucinous stroma. DM has been defined as either "pure" if the overwhelming majority of the invasive tumor is desmoplastic or as "combined" or "mixed" DM if the desmoplastic areas constitute less than 90% of the tumor.

The immunohistological profile of DM is different from that of epitheloid melanoma. While S100 is typically positive in 80–94% of cases, other markers often helpful in diagnosing melanoma (►Melanoma antigens) such as HMB45 antigen, tyrosinase, and Melan-A/MART-1, are typically only focally positive or completely negative in DM. Nevertheless, absence of such immunoreactivity does not exclude the diagnosis when the clinical picture and/or histology are characteristic. Inconsistent results regarding the labeling pattern as well as the staining intensity have been noted for antigens such as CD68, NSE (neuron-specific enolase), CD34, and smooth muscle alpha-actin (SMA); as such these markers are usually not helpful in the diagnosis of DM.

Clinical Features

In most cases, DM presents as a slow-growing, painless, and usually amelanotic palpable plaque or nodule that may be associated with a lentigo maligna lesion. The clinical appearance, however, can be variable. Due to its sometimes innocuous appearance and the common lack of pigmentation, it is uncommonly diagnosed at an early stage and thus may be confused with a variety of benign (scars, dermatofibroma, melanocytic nevus) and malignant (carcinoma, sarcoma) lesions. DM commonly presents as a deeply invasive tumor at the time of diagnosis.

Recent studies reported a median tumor thickness between 2.5 and 6.5 mm, and the majority of lesions showed invasion of the reticular dermis or subcutis (►Clark level IV/V). This observation, in conjunction with a commonly described invasion along neural structures (neurotropism) were considered the main reasons for the seemingly locally aggressive biologic behavior and high incidence of local recurrence of 11–55% reported in the literature. Nevertheless, data involving large patient datasets suggest that this may be due to frequent positive, unknown, or relatively narrow

resection margins, particularly in the head and neck region. Excision of DM with a 2 cm margin (e.g. for melanomas over 1 mm in depth) appears to be associated with a reduced rate of local recurrence. This concept has been further substantiated by a recent study involving 65 patients with DM demonstrating no local recurrences after wide local excisions with 2 cm margins.

There is solid evidence to indicate that the incidence of lymph node metastasis in patients with DM is lower than in patients with conventional melanoma of similar thickness, ranging from 0 to 18.8%. With the widespread use of sentinel node biopsy for melanoma, regional lymph node status in patients with DM has often been assessed at the time of diagnosis. So far, all studies assessing SLN status in patients with pure DM showed a lower rate of lymph node involvement as compared to conventional melanoma. Specifically, synchronous microscopic stage III disease among patients with DM of the "pure" histologic subtype is extremely uncommon – i.e. below 3% – and suggests that the behavior of "pure" DM may be more like soft tissue sarcoma, which in general is also associated with a low rate of regional lymph node metastasis. In contrast, DM of the "mixed" phenotype showed a similar rate (~15%) of positive SLN nodes as is generally observed for conventional (i.e. non-DM) melanoma.

Although patients with DM usually present with thicker tumors, survival of patients with DM has repeatedly reported to be equal or better than for other forms of melanoma. The largest study at present reported similar survival rates among patients with desmoplastic and conventional melanoma, with a 5-year survival rate of 75%.

Management

Like any invasive melanoma, wide local excision – with margins appropriate for tumor thickness – represents the mainstay of treatment of the primary DM tumor location. As nerve involvement may be observed, adequate wide excision is in particular advisable in patients with DM whenever possible; such an approach likely enhances local control. The low incidence of regional lymph node metastases in patients with DM suggests that elective (prophylactic) lymph node dissection is not indicated in these patients. While sentinel node biopsy is regarded as the standard of care for patients with intermediate- and high-risk melanoma, only a subset of patients with pure DM may benefit from this procedure due to the expected low yield of positive regional lymph nodes.

In view of studies demonstrating significant local disease control by performing wide local excision with adequate margins, adjuvant postoperative radiation with the aim to reduce the rate of local recurrence may be dispensable in many patients with DM who have had an appropriate wide local excision.

Angiogenic/angiostatic chemokines; ELR+ /ELR- chemokines

Definition

►Chemokines are a large family of small proteins that have been classified into four distinct groups based on the specific pattern of two conserved cysteine residues found within the ►amino terminus. If these two conserved cysteine residues are separated by one aliphatic amino acid, these proteins are classified into the "CXC chemokine" group. CXC chemokines are well known for their role in the immune system. These chemokines mediate ►leukocyte homing to sites of wounding or ►inflammation, thus instigating the immune response. With respect to cancer progression, CXC chemokines have been found to play critical roles in tumor ►angiogenesis, tumor growth, tumor cell invasion, and metastasis.

Characteristics

CXC chemokines are small, soluble proteins that specifically bind and activate their cognate ►cell-surface receptors. CXC chemokine receptors are present on the surface of many different cell types, including endothelial cells, ►epithelial cells, tumor cells, and specific subsets of immune cells. These receptors pass seven times through the plasma membrane and are coupled to heterotrimeric ►G-proteins, through which they mediate ►cell signaling and functional response. Once activated by chemokine ligand, they mediate cellular processes associated with cell motility, cell proliferation, and cell survival.

Chemokines derive their name from the phrase "chemotactic ►cytokines", and function primarily to mediate the process of cellular ►chemotaxis. Chemotaxis refers to the migration of a cell toward an increasing concentration (gradient) of a particular substance (chemoattractant). Therefore, cells expressing CXC chemokine receptors respond to chemokine ligand gradients by migrating in the direction of the increasing concentration of CXC chemokine. Physiological sources of CXC chemokine gradients can include sites of inflammation or sites of active ►wound healing. Interestingly, engagement of CXC chemokine with its cognate receptor not only results in cell movement, but also results in cell proliferation and protection from apoptosis. Therefore, CXC chemokine gradients can act physiologically to recruit immune cells and endothelial cells to stimulate immune response and tissue regeneration. However, dysregulated chemokine expression can either lead to neoplasia and cancer progression, or can result from it. Because of the essential roles that CXC chemokines play in cell survival, proliferation, and chemotaxis, dysregulated chemokine expression has been linked to tumor angiogenesis, tumor growth, tumor cell invasion, and metastatic spread.

Angiogenesis and Tumor Growth

CXC chemokines are intricately involved in the regulation of both physiological and pathological

angiogenesis. Angiogenesis is defined as the growth of new blood vessels from pre-existing vasculature, and is necessary for certain physiological processes such as wound healing, development, or ischemic repair. However, aberrant angiogenesis is not only present within the tumor microenvironment, but is also a requirement of tumor progression and metastatic spread. The more blood vessels that are found within a tumor, the bigger and more invasive that tumor can become. CXC chemokines play a critical role in the regulation of angiogenesis, but can cause dysregulated blood vessel proliferation under tumorigenic conditions.

On a cellular level, angiogenesis involves the migration of endothelial cells away from pre-existing blood vessels, toward an angiogenic stimulus. Once these migrating cells reach the stimulus, they proliferate to form new vessel lumen. Because endothelial cells express CXC chemokine receptors, they will migrate toward CXC chemokine gradients produced by various physiological environments, such as areas of active wound repair. Once CXC-receptor expressing endothelial cells have reached the CXC chemokine source, they will begin to proliferate and result in new vascular networks throughout the environment. However, physiological angiogenesis requires that endothelial cell proliferation and migration signals be shut off in a timely manner, to avoid pathological consequences. Interestingly, the stimulus responsible for this inhibition, or ►angiostasis, is actually a subgroup of CXC chemokines, whose expression is tightly regulated. Therefore, CXC chemokines are broken up into two subgroups: the angiogenic CXC chemokines and the angiostatic CXC chemokines (Table 1). Regulated angiogenesis therefore becomes a delicate balance of timing the activation of the angiogenic CXC chemokines with timing the activation of the angiostatic CXC chemokines. Unfortunately, disruption of this balance leads to pathological consequences. For example, many tumor types express elevated levels of the angiogenic CXC chemokines and their cognate receptors. The secretion of these chemokines activates surrounding endothelial cells to migrate into the tumor, proliferate, and form new vasculature within their new environment (Fig. 1). This activation overcomes angiostatic chemokine activity, and leads to increased vessel growth and increased tumor vasculature. Early evidence showed that those CXC chemokines regulating pro-angiogenic activity contained a motif in the amino terminus of the protein consisting of the amino acids glutamic acid, leucine, arginine (ELR). Furthermore, it was noted that those chemokines regulating anti-angiogenic activity did not contain this motif. Therefore, the angiogenic CXC chemokines became known as ELR+, while the angiostatic chemokines were designated as non-ELR+ chemokines (Table 1). However, the one exception to this rule is CXC chemokine CXCL12. CXCL12 is a non-ELR+ chemokine, but it appears to exhibit angiogenic effects via its cognate receptor CXCR4. CXCR4 is found endogenously on the surface of endothelial cells, and its activation by CXCL12 results in cell migration, proliferation, and cell survival. Interestingly, though, the mechanism by which CXCL12/CXCR4 stimulates angiogenesis may be different than the mechanism by which the ELR+ chemokines stimulate a similar process. Instead of the tumor cells themselves secreting the angiogenic chemokine stimulus, it appears that stromal cells within the tumor microenvironment secrete significant amounts of CXCL12. However, the result is the same. Endothelial cells are activated and recruited by CXCL12 chemokine gradient secreted by the tumor, resulting in an increase of vasculature.

CXC Chemokines. Table 1 ELR+/angiogenic chemokines, non-ELR+/angiostatic chemokines, and non-ELR+/angiogenic chemokine CXCL12

Chemokine	Putative chemokine receptor
ELR+/angiogenic chemokines	
CXCL1 (GRO-α)	CXCR2
CXCL2 (GRO-β)	CXCR2

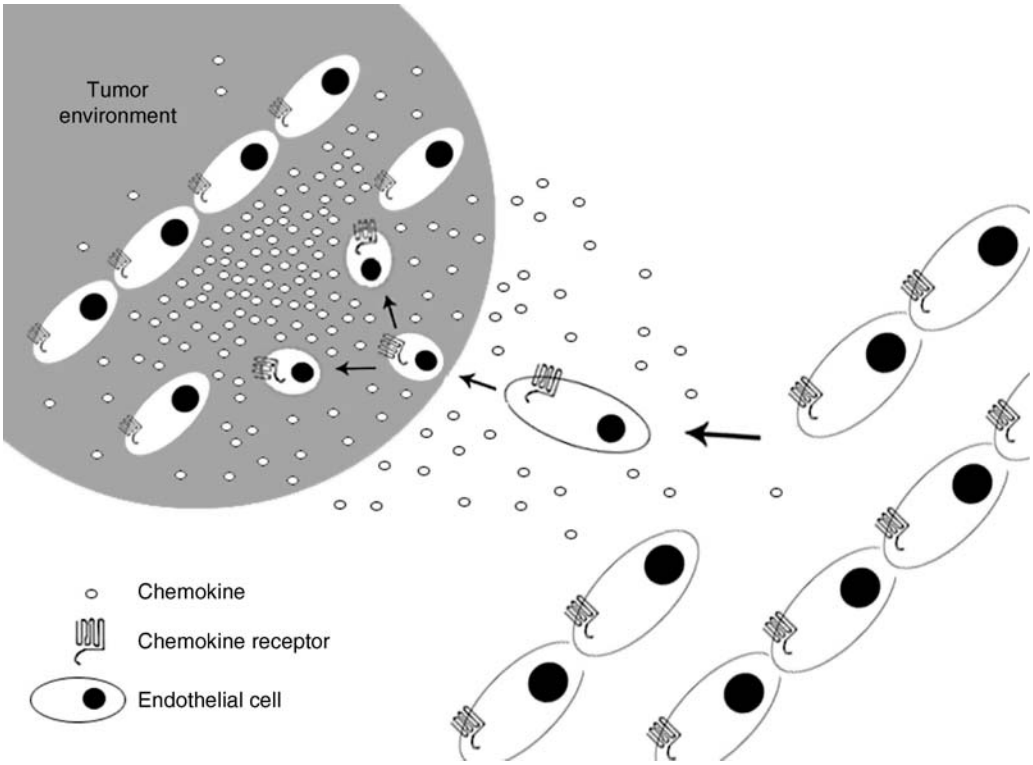
Non-ELR+/angiogenic chemokine	
CXCL12 (SDF-1)	CXCR4

Adapted from Strieter et al. (2006).

CXC chemokines can not only promote tumor growth through their contribution to angiogenesis, but they can also directly stimulate survival and growth of neoplastic cells in a ►paracrine/autocrine fashion. For example, certain tumor cells can gain expression or overexpression of specific CXC chemokine receptors, and so enhance their response to chemokine stimulation. This stimulation can result in cell proliferation and survival, increasing the size and magnitude of the tumor. In some instances, the tumor cells themselves produce the chemokine stimulus. This production of chemokine and subsequent release into the extracellular space binds and activates chemokine receptor on the tumor cell surface. Activation of chemokine receptor can then signal not only for proliferation and tumor



CXC Chemokines. Figure 1 Endothelial cells are recruited by chemokine gradients produced by tumor cells to induce angiogenesis in the tumor environment.

growth, but also for the production of more chemokine, resulting in an autocrine signaling loop. In other cases, chemokine can be produced by other cells within the tumor microenvironment, such as ►fibroblasts or endothelial cells. This chemokine can then bind to and activate receptor on the surface of the tumor cell, resulting in a paracrine loop that signals for tumor cell proliferation and subsequent tumor growth.

Tumor Cell Invasion and Metastasis

Angiogenesis is not only essential for tumor growth, but is also necessary for the metastatic spread of tumor cells. In order to metastasize, tumor cells must enter the blood stream and travel to distant sites within the body. The more vasculature present within a tumor, the more chance there is for invasive cells to escape the primary mass and enter the blood stream. Furthermore, tumor cell motility is a requirement of metastasis. Tumor cells must actively migrate away from the primary tumor to enter the blood stream and establish distant metastatic sites. Because CXC chemokines are important mediators of cell motility, they have been implicated in tumor cell migration during metastatic progression. Therefore, the angiogenic CXC chemokines contribute to the regulation of metastasis as well as angiogenesis.

Importantly, it has long been unclear why particular cancers preferentially metastasize to certain sites in predictable patterns. For example, breast cancer generally metastasizes to lymph node, bone marrow, liver, or brain. It was hypothesized that tumor cells actually migrate away from their primary tumor toward a chemotractant produced at distant sites within the body. Many types of tumor cells have been found to overexpress CXC chemokine receptor CXCR4, and therefore CXC chemokines were implicated in metastatic spread. Interestingly, high levels of CXCR4 ligand are found in organs such as the liver, bone marrow, brain, and lymph nodes, where cancers typically metastasize. Therefore, it is thought that cancer cells "home" to specific metastatic sites by migrating up the CXCL12 gradient produced by specific organs. Once these tumor cells have reached the point in the gradient that saturates all receptors, they stop migrating and proliferate, resulting in a metastatic tumor.

Cyclin D

Rene Bernards
The Netherlands Cancer Institute, Amsterdam, The Netherlands

Definition

D type cyclins belong to a family of related proteins that bind to and activate several protein kinases named ►cyclin-dependent kinases (CDKs), which are involved in regulation of the cell division cycle.

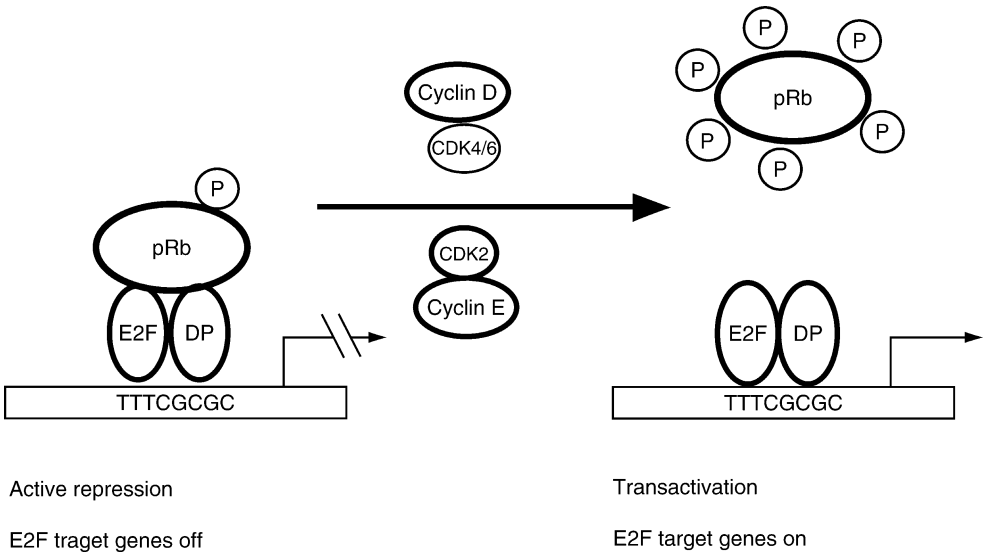
Characteristics

D-type cyclins are encoded by three closely related genes (cyclins D1, D2 and D3) that are expressed in a tissue-specific fashion. Biochemically, D type cyclins act as regulatory subunits of a group of related protein kinases (CDKs), primarily the CDKs 4 and 6. Cyclin D/CDK4/6 complexes, together with cyclin E/CDK2, cause phosphorylation of the family of retinoblastoma proteins (►pRb, p107 and p130) in the G1 phase of the cell cycle, resulting in abrogation of their growth inhibitory activity. Phosphorylation of the retinoblastoma proteins leads to release of ►E2F transcription factors from the retinoblastoma proteins and to progression to the S phase of the cell cycle (Fig. 1).

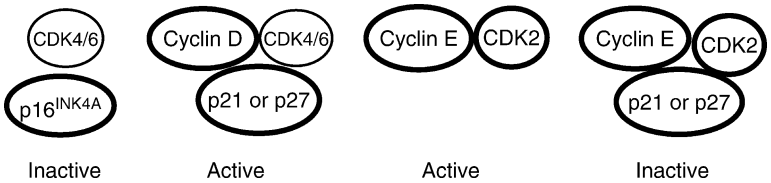
Regulation of D Cyclins

D type cyclins are major downstream targets of extracellular signaling pathways, which act to transduce mitogenic signals to the cell cycle machinery. Transcriptional induction of D type cyclins occurs in response to a wide variety of mitogenic stimuli, including the ►Ras signaling cascade and the ►APC-β-catenin-Tcf/Lef pathway. In addition, cyclin D1 protein turnover and subcellular localization is highly regulated during the cell cycle. Phosphorylation of cyclin D1 by GSK-3β in resting cells renders the protein a target for rapid destruction by the ►proteasome. In contrast, mitogenic stimulation of cells leads to inhibition of GSK-3β and stabilization of cyclin D1 protein. In response to DNA damage, cells initiate an immediate G1 arrest, which is caused by rapid proteolysis of cyclin D1. Together with activation of the p53 tumor suppressor protein, cyclin D1 destruction causes a fast withdrawal from the cell cycle to allow repair of the damaged DNA before DNA synthesis resumes.

Binding of D type cyclins to their CDK partner is antagonized by the ►INK4 family of CDK inhibitors (►CKI). ►INK4 proteins bind to CDK4 and 6 and thereby prevent association of D type cyclins to these CDKs (Fig. 2). The most prominent member of this family is p16INK4A. Mutations in p16INK4A (also



Cyclin D. Figure 1 Regulation of E2F activity through pRb phosphorylation. In the G1 phase of the cell cycle the retinoblastoma protein pRb is hypophosphorylated, allowing it to bind E2F transcription factors. E2F/pRb complexes are able to bind DNA but are inactive in transcription activation. Phosphorylation of pRb by cyclin D/CDK4 and cyclin E/CDK2 complexes causes the release of E2F from pRb. Free E2F is then able to activate transcription of E2F target genes (genes with TTTCGCGC-like E2F sites in their promoters), allowing cells to enter the DNA synthesis phase (S phase) of the cell cycle.

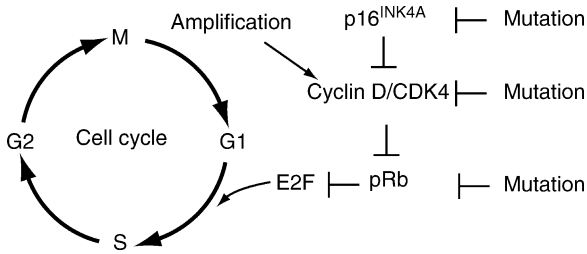


Cyclin D. Figure 2 Effect of CDK inhibitors on cyclin/CDK complexes. CDKs 4 and 6 are activated by binding of D type cyclins. Association of cyclin D to CDKs 4 and 6 is prevented by p16INK4A that binds with high affinity to these CDKs. Thereby, binding of cyclin D to these CDKs is prevented. The CDK inhibitors p21cip1 and p27kip1 bind both to cyclin E/CDK2 and to cyclin D/CDK4 complexes, although with different consequences. Even though these inhibitors antagonize cyclin E/CDK2 activity, they are required for proper assemblage and activity of cyclin D/CDK4/6 complexes.

known as ►CDKN2A) are found in a variety of spontaneous tumors, and heterozygosity for p16INK4A in the germ line predisposes to melanoma. A second family of CKIs consists of three related proteins that bind to cyclin/CDK complexes. Members of this family include p21cip1 and p27kip1. This class of CKIs has quite divergent effects on the different cyclin/CDK complexes. Whereas cyclin E/CDK2 is inhibited by both p21cip1 and p27kip1, cyclin D/CDK4/6 complexes are active when complexed with this class of inhibitors (Fig. 2). In fact, formation of active cyclin D/CDK4/6 complexes requires the presence of p21cip1 or p27kip1 to act as 'assembly factors' of cyclin D/CDK complexes. These opposing effects of p21cip1 and p27kip1 on cyclin E/CDK2 and cyclin D/CDK4 complexes endows cyclin D/CDK4 complexes with an important second, non-catalytic function during the G1 phase of the cell cycle. Synthesis of cyclin D1 by mitogenic stimulation leads to absorption of p21cip1 or p27kip1 into active ternary complexes, thereby facilitating activation of cyclin E/CDK2 by removal of inhibitors.

CDK-Independent Activities of D Type Cyclins

Apart from their role in activation of CDKs, D type cyclins can have several profound effects on cellular physiology independent of their CDK partners. In ►breast cancer, cyclin D1 can bind directly to the estrogen receptor, thereby causing hormone-independent activation of the estrogen receptor. This activity of cyclin D1 may contribute to resistance to anti-hormonal therapy that is often seen in the clinic. In addition, D type cyclins can modulate the activity of Myb transcription factors.



Cyclin D. Figure 3 The p16-cyclin D-pRb pathway: a frequent target in human cancer. E2F transcription factors contribute to G1-S phase progression through the activation of specific target genes. E2F activity is negatively regulated by its binding to the retinoblastoma tumor suppressor gene product, pRb. The ability of pRb to bind E2F is regulated by cyclin D/CDK complexes. The activity of cyclin D/CDK complexes in turn is negatively regulated by p16INK4A that is encoded by the CDKN2A tumor suppressor gene.

In this respect is the ►Myb-like transcription factor DMP1, which has anti-proliferative activity. Expression of cyclin D inhibits this effect on cell proliferation of DMP1 through direct binding to DMP1, which prevents DNA binding by DMP1.

Clinical Relevance

Because of their critical role in linking cytoplasmic signals to nuclear responses it is perhaps not surprising that D type cyclins are frequently deregulated in several types of cancer. Cyclin D1 ►amplification or overexpression is found in a number of human malignancies, the most prominent being breast cancer, in which up to 50% of all cases have elevated levels of cyclin D1 protein. Chromosomal translocations involving cyclin D1 are found in parathyroid adenoma and in mantle cell lymphoma.

Not only is cyclin D1 itself often directly mutated in human cancer, its upstream regulators such as p16►INK4A and its downstream target pRb are frequent targets in human carcinogenesis as well. It is generally believed that this p16INK4A-cyclin D1-pRb pathway is deregulated in virtually all human cancers (Fig. 3).

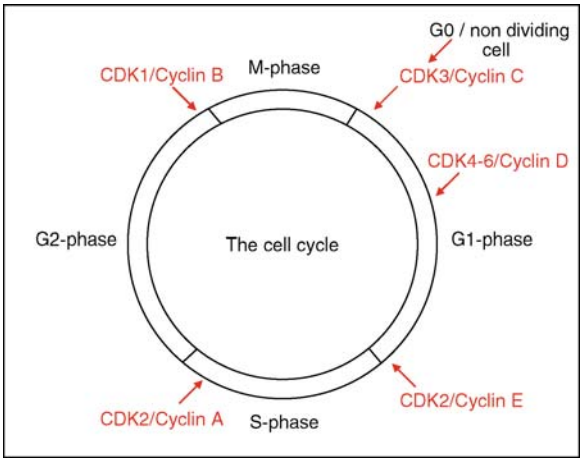
Definition

A class of enzymes that add phosphates to other proteins.

Characteristics

Cyclin-dependent kinases (CDKs) catalyze one of the most important biological events in eukaryotic cells–cell proliferation. When cells proliferate, they follow the four phases of the ►cell cycle that enables them to duplicate their DNA and deliver exact copies into two daughter cells. Many enzymes orchestrate these steps, but the key enzymes that control the phases of the cell cycle are CDKs. (Fig. 1)

CDKs are enzymes in the serine/threonine protein kinase family. They phosphorylate (add phosphate) to substrate proteins on hydroxy amino acids, serine and threonine, but not on tyrosine, which distinguishes CDKs from the tyrosine protein kinase family. Once a substrate is phosphorylated by a protein kinase, the substrate often has different biological properties relative to its nonphosphorylated counterpart. For example, a phosphorylated protein may increase or reduce its catalytic activity, change its cellular localization, bind to or dissociate from other proteins, and increase or decrease its biochemical half-life. The



Cyclin Dependent Kinases. Figure 1 CDKs and the cell cycle. The role of the major CDKs (cyclin-dependent kinases) is shown relative to the four phases of the cell cycle. Each transition from one phase to another during the cell cycle, including entry into the cell cycle from G0 or nondividing cells, requires the formation and activation of a CDK.

prototype CDK, Cdk1, phosphorylates many proteins during the G2/M-phase transition of the cell cycle. The change in phosphorylation state of these proteins causes cells to organize their DNA into chromosomes and begin the process of mitosis and cytokinesis.

CDKs are composed of two protein subunits: a protein kinase catalytic domain and a regulatory cyclin subunit. The catalytic domains of protein kinases can be divided into 11 subdomains, each with a specific sequence that permits the classification of protein kinases into families. Among the 518 protein kinases encoded in the human genome, 13 are members of the CDK family. The signature sequences for cyclin subunits are not as well defined as those of the catalytic subunit, however, it is estimated that there are at least 25 different human cyclin subunits. The one-to-one pairing of a catalytic domain to a cyclin posits that one catalytic subunit can bind to more than one cyclin subunit, although not at the same time. The exact composition of all possible CDKs is currently not known, but it is an important parameter because the pairing combination defines its substrates, its cellular location, and the timing of activation.

Cdk1 is the best-known member of the CDK family. It is composed of the 34 kD Cdk1 catalytic domain that binds to A- or B-type cyclin subunits of 50–55 kD. The Cdk1 catalytic domain is inactive as a monomer and its protein levels do not change during the cell cycle. As cells progress towards mitosis, the cyclin B protein levels increase and bind to the catalytic subunit to form the CDK complex. This complex is now competent to become active, but its activity is constrained by a coordinated network of three other enzymes: Wee1, Cdc25C, and CAK. Wee1 phosphorylates the Cdk1 catalytic subunit on threonine 14 and tyrosine 15, two amino acids that are within the ATP binding site and therefore directly block the interaction between the catalytic subunit and its ATP substrate. Cdc25C, a member of a protein ▶phosphatase family, can dephosphorylate, or remove the phosphates from the ATP binding site. In addition, access to the ATP binding and protein substrate binding sites are hindered by a peptide within the catalytic domain known as the T-loop. Upon phosphorylation of this peptide on threonine by CAK (another member of the CDK family), the domain is displaced thus permitting access of ATP and protein substrates to the catalytic center of Cdk1. The sequential formation of Cdk1 from its subunits followed by phosphorylation by Wee1 enables cells to accumulate a form of Cdk1 that can be rapidly activated. If a number of other cellular events are completed, such as DNA synthesis, then Cdc25C dephosphorylates Cdk1 and the T-loop is phosphorylated by CAK. This system of regulation enables a cell to achieve maximum Cdk1 catalytic activity in a very short time and engages a cell to enter mitosis.

The catalytic activity of Cdk1 is maintained until the cyclin subunit is selectively degraded by a protease. Once cyclin B1 is degraded, the Cdk1 catalytic subunit returns to its inactive state, the cell exits from mitosis and forms two daughter cells. Cdk1 participates in its activation and inactivation by phosphorylating the enzymes that regulate it. This creates an autoactivation loop that results in an all-or-none activity of Cdk1, which is coherent with the all-or-not entry into mitosis during the cell cycle.

The Discovery of CDKs

Cell-division-cycle 2 (Cdc2) kinase was the original name of the prototype Cdk1, based upon the discovery of the role of Cdc2 in mitosis. A convention for naming this family of protein kinases was established by consensus at the Cold Spring Harbor Symposium on the Cell Cycle at Cold Spring Harbor, NY, USA in 1991. The role of Cdk1 in the cell cycle was originally identified by experiments with cells of lower eukaryotic species. The catalytic subunit was first identified by genetic studies in the fission yeast, *Schizosaccharomyces pombe*, as the Cdc2 gene product. Cyclin proteins were first identified in sea urchin eggs. After fertilization, sea urchin eggs enter mitosis in a synchronous manner. This natural synchrony and the experimental methods used to detect new protein synthesis permitted the discovery of B-cyclins, whose levels cycle relative to mitosis. Evidence that cyclins and Cdc2 family members form a complex came from biochemical studies of Xenopus (toad) oocytes and starfish oocytes. Copurification of MPF with the Cdc2 subunit and cyclin B

demonstrated that Cdc2/Cyclin B were the major components of an essential complex for mitosis. The confirmation that Cdc2 was part of a pathway conserved in all eukaryotic cells was made by genetic complementation studies in which yeast cells could proliferate after replacement of the yeast Cdc2 gene with the human CDC2 gene. Human and yeast genomes are separated by 1 billion years of genetic isolation, yet their functional activity has been conserved. Leland Hartwell, Tim Hunt, and Paul Nurse were awarded the Nobel Prize in physiology or medicine in 2001 for their role in the discovery and the characterization of Cdc2 and cyclins in the cell cycle.

Members of the CDK Family

Other CDKs, besides Cdk1, have important roles in progression through the cell cycle. CDK3 with its putative partner cyclin C is activated as cells start the cell cycle from a resting state (G_0). CDK4 and CDK6, which are associated with ►D-type cyclins, respond to extracellular growth signals and permit cells to continue the G1-phase of the cell cycle. CDK4 and CDK6 complexes phosphorylate the ►retinoblastoma protein, which controls the expression of genes required for the G1/S-phase transition and S-phase progression. The CDK2/cyclin E complex also participates in the G1/S-phase transition by phosphorylating replication factors. During S-phase, CDK2/cyclin A phosphorylates different substrates allowing DNA replication and participates in the inactivation of G1 transcription factors. In mouse models, using gene knock-out technology, it has been shown that CDK2 is not essential. By contrast CDK1 and CDK5 are essential genes. In the early phases of the cell cycle, the activity of CDKs is regulated by members of a small protein family, such as ►p21/WAF1 and ►p16/INK4. These proteins bind to the CDK complex and inhibit it. In the final phases of the cell cycle, after DNA synthesis is completed, the Cdk1 complex is activated and triggers the G2/M-phase transition. The cell ends M-phase and enters G1 by phosphorylation of the anaphase promoting complex (APC) by Cdk1. These successive waves of CDK/cyclin activation and inactivation drive the major phases of the cell cycle.

The role of CDK enzymes is not limited to the cell cycle. Some CDKs regulate DNA transcription, including the transcription of genes that are essential for cell cycle progression, therefore, these CDKs have a role that lies at the interface of cell cycle control and basal cell activity. CDK7, which binds to cyclin H, is a component of the transcription factor TFIIH. CDK7 has a dual role because it can phosphorylate RNA polymerase II, which is required for RNA elongation, and it can phosphorylate the Cdk1 and Cdk2 T-loop, which is required for CDK1 and CDK2 activation. The role of CDK8 overlaps with that of CDK7 in transcriptional regulation. CDK9/cyclin T is a component of a transcription elongation factor.

CDK activity can be detected in cells that undergo ►apoptosis (programmed cell death). In some cases, this activity is related to DNA damage, resulting in a type of mitosis that is known as ►mitotic catastrophe, which eventually leads to cell death. Activation of CDKs can occur in nondividing neuronal tissue after chemical shock and may be required for apoptosis. The role of CDKs in apoptosis has implications in chronic inflammation. Neutrophils, a specialized cell that participates in inflammatory response, may be made dependent upon CDKs to engage apoptosis under experimental conditions.

Relative to other CDKs, CDK5 has a specialized role in nondividing neural tissue. Its activity is important for neurite outgrowth and neuronal development, myogenesis and somite organization in embryos. The cyclin subunit, p35, is one of the smallest members of the cyclin family (35 kD) and it can be processed to exist in a smaller form of 25 kD. The three dimensional structure of p35 reveals that it has similar protein folds to other cyclins, which provides a rationale for its capacity to activate CDK5.

The crystal structure of several CDKs has been resolved, which gives insight to the organization of the substrate binding site and the role of the regulatory cyclin subunit. In the case of CDK2, which is composed of Cdk2 catalytic subunit and a cyclin A subunit, it was revealed the kinase complex consists of an amino-terminal lobe rich in β-sheets and a carboxyl-terminal lobe that is larger and mostly α-helical. Between these two lobes is a deep pocket that harbors the ATP binding site, which contains the conserved amino acids that participate in catalysis. The T-loop, which blocks substrate access, moves away from the catalytic cleft after cyclin binding and is then accessible for phosphorylation by CAK. This highlights the role of cyclin and CAK in CDK activation. Cyclin binding also reorientates amino acids within the ATP pocket to permit phosphate transfer from ATP to the protein substrate. The resolution of CDK5 and CDK6 revealed structures that are similar to that of CDK2, suggesting that CDK structures of the entire family are similar.

CDKs in Cancer and Other Human Diseases

CDKs are implicated in a broad range of human disease. Their essential role in cell proliferation, especially in the case of Cdk1, has led to the proposal that these proteins play an important role in human cancers. Although it is known that cancer cells require Cdk1 to proliferate, it remains to be demonstrated that the function of Cdk1 in cancer cells is different from its role in normal, proliferating cells. The overexpression of cyclin E is frequently found in both precancerous and cancerous lesions in human tissue. It is believed that

CDK activation by cyclin E may cause genomic instability. There is much evidence to link CDK5 activity to cytoskeletal abnormalities that can lead to neuronal cell death. This may be, in part, caused by the conversion of its cyclin partner p35 to p25, which leads to activation of CDK5 and alteration of its cellular localization. Uncontrolled activation of CDK5 causes the phosphorylation of neuronal proteins, such as tau, and may be linked to Alzheimer's disease. Chronic inflammatory diseases such as gout, arthritis, Crohn's disease may be partly due to misregulation of CDKs. CDKs also participate in virus replication in infected cells. In the example of HIV, which is linked to the cause of AIDS, CDK9 is recruited by the ►HIV tat protein which enhances transcription of viral genes.

The involvement of CDKs in disease and the detailed knowledge of CDK atomic structure have led to the identification of potent chemical inhibitors that have the potential to become ►small molecule drugs. Many of these have been cocrystallized with CDKs, which gives insight to the molecular docking of inhibitors in the ATP pocket. Pharmacological inhibitors of CDKs are being evaluated for therapeutic use in major human disease such as cancer, neurodegenerative disorders, cardiovascular disorders, viral infections, and parasitic infections.

Synonyms

GAK; Auxilin-2

Definition

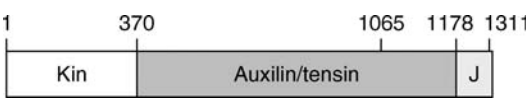
GAK/auxilin-2 is the ubiquitously expressed form of the neuronal-specific protein Auxilin-1. GAK is a member of the Ark/Prk serine/threonine protein kinases family and has an important role in ►endocytosis, uncoating clathrin-coated vesicles (CCVs) in non-neuronal cells, and clathrin-dependent trafficking from the *trans* Golgi network. GAK has been implicated as a transcriptional co-activator of the ►androgen receptor (AR) and may have a role in prostate cancer progression to androgen-independent disease. Expression patterns during androgen-withdrawal therapy suggest a prognostic role for GAK in advanced prostate cancer.

Characteristics

GAK is a large, 140 kDa protein that has three functional domains: (i) an NH_2-terminal Ser/Thr kinase domain, (ii) a central Auxilin/Tensin homology domain, and (iii) a COOH-terminal J-domain (Fig. 1). Although GAK was initially identified by its association with cyclin G, which is a downstream transcriptional target and a negative regulator of the ►p53 tumor suppressor protein, subsequent studies suggest that GAK has an important role in endocytosis and un-coating CCVs in non-neuronal cells.

Kinase assays demonstrated that GAK is one of two kinases present in clathrin-coated vesicles and that the Ser/Thr kinase activity of GAK was directed towards the μ2 component of CCVs. The protein homologue that is responsible for un-coating CCVs in neuronal cells is Auxilin. Consequently, the central Auxilin/Tensin homology domain of GAK is essential for its role in vesicle un-coating and has clathrin-binding motifs that allow for association with CCVs. GAK differs from Auxilin by its kinase domain, and recently GAK was classified as an Ark kinase family member due to its homology with actin regulating kinase (ARK)-1.

The COOH-terminal J-domain of GAK is known to interact with the molecular chaperone Hsc70, which is the constitutively expressed form of Hsp70. Both GAK and Auxilin are DnaJ homologues that possess J-domains. The J-domain recruits ATP-bound Hsc70 to CCVs. The mechanism of clathrin dissociation was first elucidated for Auxilin and then shown to be comparable for GAK. Recruitment of ATP-bound Hsc70 activates dormant ATPase activity of the



Cyclin G-Associated Kinase. Figure 1 Human GAK (hGAK) is a 144 kDa protein that has three functional domains: an NH_2-terminal Ser/Thr kinase domain, a central Auxilin/Tensin homology domain, and a COOH-terminal J domain.

chaperone and destabilizes clathrin-clathrin interactions in CCVs. Hsc70, now in its ADT state, remains tightly bound to clathrin while Auxilin is recycled for another round of un-coating. GAK activity in non-neuronal cells also involves Hsc-70 recruitment and ATPase-dependent destabilization of clathrin interactions. The kinase domain of GAK is indeed functional and, as described above, phosphorylates components of CCVs.

GAK and the Androgen Receptor

The impact of androgens, which are male steroid hormones, on prostate growth is a major consideration when treating advanced prostate cancer. Androgens carry out their function through the androgen receptor (AR), which is a ligand-dependent transcription factor. Activated AR regulates genes that are involved with growth and differentiation of the prostate gland. Dihydrotestosterone (DHT) has up to fivefold greater affinity for AR than testosterone (T) and, consequently, is up to 2.5-times more active as a hormone. For this reason, 5α-reductase inhibitors that prevent conversion of T to DHT were developed for use in prevention and treatment of prostate diseases. Another commonly used therapeutic strategy is removal of androgens by surgical and/or chemical methods to prevent activation of AR. Hormone therapy reduces testosterone levels significantly, down to ~10% of the normal level; low-levels of circulating androgens resulting from adrenal secretions are still present. Removal of hormone by androgen ablation therapy prevents the growth promoting effects of androgens, leads to ►apoptosis of cancer cells, and ultimately results in tumor regression.

The decrease in tumor burden following androgen ablation occurs during the androgen-dependent (AD) stage of prostate cancer when the tumor still requires androgens for survival and growth. Unfortunately, this form of therapy offers limited aid, and the average range of overall survival is only 23–37 months. For reasons that are not fully understood, prostate cancer cells switch from an AD state to one that is androgen-independent (AI), in which cells are able to bypass requirement for the androgenic growth signal, and grow in an uncontrolled fashion. As a result, tumor burden and prognostic disease markers such as ►prostate specific antigen (PSA) increase dramatically.

Transcriptional co-activators of AR interact directly with the receptor to modify AR-mediated transactivation and gene expression. Originally, this class of proteins carried out their role at the level of the promoter, either by altering DNA accessibility to transcription machinery or by bridging AR to the basal transcription machinery. Several of these *classical*, or *Type I*, co-activators have indeed been associated with AR. However, a class of *non-classical*, or *Type II,* co-activators was formed to differentiate their mechanism of action. Non-classical co-activators enhance AR activity by altering other facets of the AR transactivation process. These include: (i) stability of inactive and active AR, (ii) nuclear translocation, and (iii) DNA binding. In addition, non-classical co-activator activity may involve post-translation modification of AR by phosphorylation, acetylation or sumoylation. Unfortunately, the role of co-activators in directing AR-activity is far from clear.

One possible mechanism for AI activation of AR in advanced prostate cancer is related to aberrant activity or expression of transcriptional co-activators. The majority of studies on AR co-activators have been carried out *in vitro* and the relevance of these accessory proteins has yet to be determined *in vivo*. However, transactivation assays with many co-activators have demonstrated that ectopic over-expression of these proteins results in enhanced AR transactivation and increased expression of AR-regulated genes.

GAK was identified as a putative AR interacting protein by using the AR's NH_2-terminal transactivation domain as molecular bait in a modified yeast two-hybrid system. Subsequent studies, including immunoprecipitation and GST-pull down assays, not only confirmed the interaction between AR and GAK in prostate carcinoma cell lines, but also detailed the regions of interaction between the two protein molecules. GAK interacted with all three AR domains (NH_2-terminal transactivation, central DNA-binding, and COOH-terminal ligand-binding domains), whereas only the auxilin/tensin homology domain of GAK is crucial for its interaction with AR.

Transactivation assays, which assess the impact of GAK on AR-mediated transcription, demonstrated that GAK could enhance AR activity from three- to fivefold in the presence of androgens. Importantly, however, over-expression of GAK increased AR activity by up to eightfold in low-androgen conditions, suggesting that increased GAK expression can result in increased AR sensitivity to low concentrations of androgens and may serve as a mechanism for prostate cancer progression to androgen independence.

The exact mechanism by which GAK serves as a transcriptional co-activator of AR is unknown. Also, its role as a Ser/Thr kinase is still being investigated. Upon activation by its ligand, AR is phosphorylated. Additionally, activated AR is sensitive to phosphorylation by signal transduction pathways. Whether these phosphorylation events are integral to the transcriptional activity of AR and whether phosphorylation of AR by GAK or any other kinase has a role in androgen-independent activation of AR remains to be determined.

GAK and Prostate Cancer Progression

The growing incidence of prostate cancer over the past two decades is due, in part, to increased detection through the introduction of PSA screening. PSA is a

useful molecular marker for assessment of disease progression, particularly for emergence of AI disease in patients undergoing androgen ablation therapy, and is used in conjunction with digital rectal exam (DRE) and transrectal ultrasound for diagnosis. In addition, histological grading of prostate biopsies by Gleason score and ►TMN staging are important prognostic tools. Early detection is the most powerful weapon against prostate cancer since the disease is often curable in its early stages. However, patients with advanced disease have poor prognosis and an average life expectancy of 30 months with androgen ablation therapy.

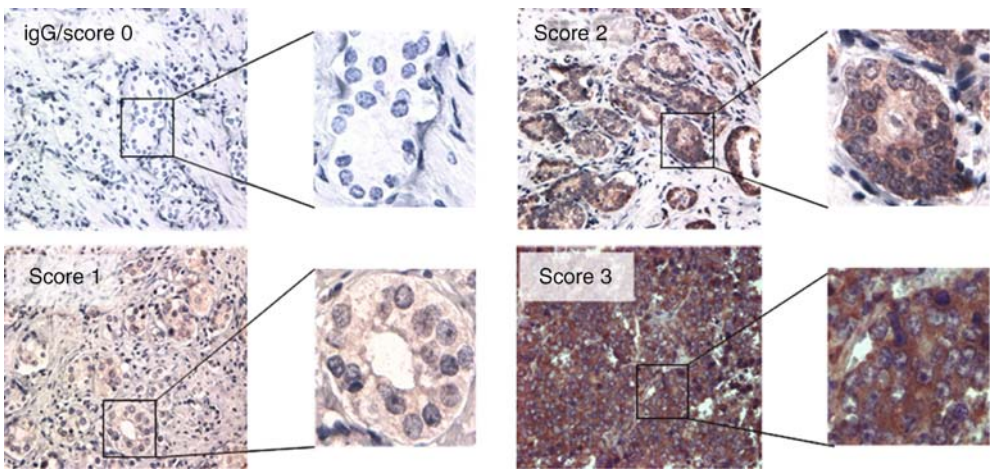
Significant research has been carried out to identify diagnostic and prognostic molecular markers for disease progression as well as molecular targets for therapeutic strategies. Since GAK was identified as an AR-interacting protein with co-activator properties, it may have a role in inappropriate activation of AR in advanced disease. High through-put immunohistochemical analysis of Neo-adjuvant Hormone Therapy (NHT) Tissue Microarray was used to assess GAK's potential as a prognostic molecular marker of prostate cancer.

For the NHT arrays, a total of 112 samples were obtained and sampled in triplicate. Most tissues were radical prostatectomy specimens, while AI tissues were obtained either from transurethral resections from patients with hormone refractory disease or from warm autopsy samples of metastatic tissues. Specimens were chosen so as to represent various treatment durations of androgen withdrawal therapy prior to radical prostatectomy ranging from no treatment (n = 21), ≤6 months (n = 49), and more than 6 months (n = 28). AI tumors were also identified (n = 14).

GAK expression was assessed by immunohistochemistry and staining intensity was scored visually by a pathologist on a scale from 0 to 3, ranging from no staining (score 0) to very intense staining (score 3) (Fig. 2). While GAK expression decreases slightly in response to androgen withdrawal, suggesting that GAK itself may be an AR-regulated gene, the proportion of samples with elevated GAK expression (score 2–3) increases during continued NHT treatment. In AI disease samples, elevated levels of GAK expression are considerably higher than during the AD phase. Since over 95% of AI tumor biopsies exhibit very high levels of GAK (visual score ≥2) the use of GAK as a prognostic marker for disease progression merits further investigation.

The mechanism by which GAK may encourage AI growth of prostate cancer is still unknown. GAK acts as a co-activator of AR and renders AR more responsive to lower androgen levels. Androgen ablation therapy, including NHT, reduces the level of circulating androgens. However, low levels of circulating androgens from adrenal secretions are still present. In prostate cancer cells, it is possible that increased levels of GAK are able to sensitize AR so that the receptor is responsive to these circulating low-level adrenal androgens, as observed *in vitro*. This would allow for AR activation and expression of AR-regulated growth and survival genes.

In summary, recent findings have identified GAK as a putative co-activator of AR and a possible molecular marker for prostate cancer progression. GAK expression may be a useful prognostic tool for assessing prostate cancer progression in patients undergoing androgen ablation therapy. An increase in GAK expression during the therapeutic course would suggest that the cancer has adapted to androgen-withdrawn conditions and are



Cyclin G-Associated Kinase. Figure 2 A NHT tissue microarray was stained with an antibody that recognizes GAK (Santa Cruz Biotechnologies, Inc.). Staining intensity was scored from 0–3 by a pathologist. Examples of IgG control and GAK staining with score = 1, score = 2 and score = 3 are shown. Slides were visualized under × 40 magnification and further magnification of delineated areas is shown.

progressing to an AI stage. These early warnings of disease progression are crucial in allowing physicians the opportunity to re-assess appropriate strategies for disease treatment.

Cyclooxygenases (COX)

Definition

Cyclooxygenase (COX) is an enzyme that is responsible for formation of important biological mediators called prostanoids (including prostaglandins, prostacyclin, and thromboxane). There are three COX isoenzymes: COX-1, COX-2, and COX-3. COX-3 is a splice variant of COX-1, while COX-1 is considered a constitutive enzyme expressed in most mammalian cells and upregulated in various carcinomas involving in tumorigenesis. Whereas, *COX-2* is undetectable in most normal tissues, but is inducible with abundant in cells at sites of inflammation and cancers.

►Anti-Inflammatory Drugs
►Inflammation
►Celecoxib

Cyclooxygenase-2 (COX-2)

Definition

Is an enzyme that is responsible for the formation of a number of important biological mediators. To date, three different COX-enzymes are known (COX-1, COX-2, COX-3) that have different biological functions. Pharmacological inhibition of COX-2 can provide relief from the symptoms of ►inflammation. The main COX-2 inhibitors are the ►non-steroidal anti-inflammatory drugs (NSAIDs), such as ►Celecoxib. However, to date none of the different COX-inhibitors is specific against COX-2, they also inhibit the other COX-enzymes, causing serious side-effects. For instance, inhibition of COX-1 results in inhibition of prostaglandin synthesis, with the result of serious health consequences such as gastrointestinal (stomach) bleeding, acute renal failure, or worse. This is due to the acidity of the stomach, where the cells of the stomach are replaced very quickly, within a few days. One of the major roles of PG's is to keep the lining of the stomach intact, and when the prostaglandin system is disrupted (say by taking COX-1 drugs like many NSAIDS) stomach irritation, digestive tract problems and even intestinal or stomach bleeding and death can occur. Such problems can also arise with alleged COX-2 inhibitors, when they are not specific for COX-2 but inhibit also the other COX-enzymes. Even modern drugs, like ►Celecoxib, are simply not selective

enough, not to mention some of the potentially horrible side effects of COX-inhibitors and the associated lawsuits that have been filed due to side effects such as cardiovascular problems, even heart attacks, stroke and blood clots. Major research efforts are directed towards developing specific inhibitors against COX-2, which is more involved in inflammation.

►Cyclooxygenase-2 in Colorectal Cancer

Cyclooxygenase-2 in Colorectal Cancer

Raymond N. DuBois
Provost and Executive Vice President M.D. Anderson Cancer Center, Houstoun, TX 77030

Synonyms

COX-2; Cyclooxygenase (prostaglandin endoperoxide synthase)

Characteristics

Colorectal cancer (►colon cancer) remains a significant health concern for much of the industrialized world, even though mortality rates are beginning to decline in the USA. Diagnosis often occurs at a late stage in the progression of this disease, which reduces the likelihood of treatment being effective. Current treatment strategies often include a combination of surgical resection and adjuvant chemotherapy (►adjuvant therapy). Because of the unsatisfactory outcome of existing treatment methods, much emphasis has been placed on developing new treatment, prevention and screening strategies. Numerous population based studies indicate that use of nonsteroidal anti-inflammatory drugs (NSAIDs) reduce the risk for colorectal cancer and decrease the incidence of adenomatous polyps. NSAIDs have been shown to induce polyp regression in familial adenomatous polyposis [FAP (►APC gene in Familial Adenomatous Polyposis)] patients and reduce tumor burden in animal models of colorectal cancer.

Cyclooxygenase-2 and Colorectal Cancer Prevention

COX-2 mRNA and protein levels are increased in intestinal tumors that develop in rodents following carcinogen treatment and in adenomas taken from multiple intestinal neoplasia (►Min) mice. When intestinal epithelial cells are forced to express COX-2 constitutively, they develop phenotypic changes that include increased adhesion to ►extracellular matrix (ECM) and resistance to butyrate-induced ►apoptosis. Both of these phenotypic changes are consistent with an increased tumorigenic potential. COX-2 expression has been detected in 80–90% of colorectal adenocarcinomas but in only 40–50% of premalignant adenomas. These data suggest that elevation of COX-2 expression is secondary to other initiating events such as dysregulation of the APC signaling pathway and/or dysfunction of other genes affected during the adenoma to carcinoma sequence (►multistep development).

The observation of elevated COX-2 expression in three different models of colorectal carcinogenesis has led to consideration of the possibility that COX-2 expression may be related to colorectal tumorigenesis in a causal way. Recent studies have demonstrated a significant reduction in premalignant and malignant lesions in carcinogen-treated rats that were given a selective COX-2 inhibitor.

Tumor growth requires the maintenance and expansion of a vascular network. It has been demonstrated using in vitro assays that COX-2 can influence ►angiogenesis, and treatment with selective COX-2 inhibitors blocks angiogenesis. COX-2 appears to contribute to tumor vascularization and there seems to be a link between COX-2 and regulation of ►VEGF expression.

Summary

Both preclinical and clinical data indicate that selective COX-2 inhibitors have anti-neoplastic activity. The precise role of COX-2 and the ►prostaglandins produced by this enzymatic pathway in carcinogenesis remains to be clearly delineated. Overexpression of COX-2 in epithelial cells leads to inhibition of apoptosis and increased adhesiveness to extracellular matrix. Inhibition of COX-2 activity leads to a marked reduction of tumor growth in a number of experimental models. Treatment with selective COX-2 inhibitors have been clearly shown to inhibit tumor-induced angiogenesis. The most effective role for selective COX-2 inhibitors for prevention and treatment of human cancers is currently under investigation.

Cystatins

Lauren M. Nunez, Daniel Keppler
Department of Biological Science,
College of Pharmacy, Touro University-CA,
1310 Johnson hane, Mare Island,
Vallyo, CA 94592

Synonyms

Thiol-protease inhibitors (cytoplasmic α- and β-TPIs; plasma α_1- and α_2-TPIs); Acid, neutral and basic cysteine-protease inhibitors (ACPI, NCPI and BCPI); Thiostatins

Definition

Cystatins were originally defined as endogenous ►inhibitors of thiol- or cysteine-►proteases. Later, the discoveries of several proteins whose primary sequence revealed substantial homology to the typical cystatin domain led to the definition of a cystatin super-family. With the identification of other types of intracellular cysteine-proteases, however, it became clear that cystatins inhibit mainly cysteine-proteases present in ►endosomes and ►lysosomes. Additionally, many of the newer members of the cystatin super-family have less than 30% homology to classical cystatins and do not inhibit lysosomal cysteine-proteases. Moreover, several proteins with little apparent amino acid sequence homology fold into typical three-dimensional structures attributed to cystatins. Thus, the term "cystatins" now refers to a heterogeneous group of proteins still lacking both a uniform identity and a cohesive definition.

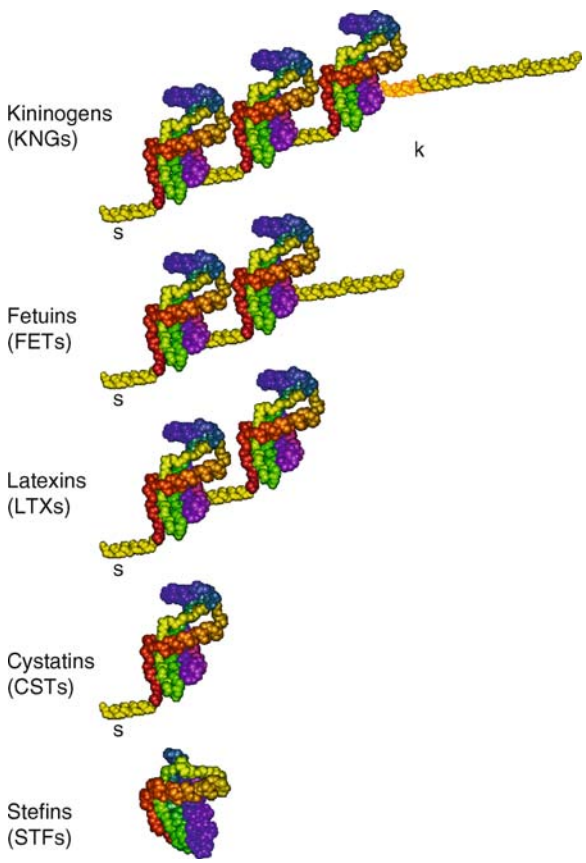
Characteristics

Domain Structure

The primary structure of the archetypal cystatin domain consists of a polypeptide 100–120 amino acids in length. This polypeptide folds into a five-stranded β-sheet, which partly wraps around an inner α-helix, resulting in a three-dimensional structure commonly referred to as the "hot-dog fold." Members of the cystatin super-family have been categorized into several distinct families according to the following criteria: (i) amino acid sequence homology; (ii) location of disulfide bonds; (iii) presence of a ►signal peptide in

the primary translation product; and (iv) number of cystatin-like domains. Based on these criteria, roughly five different families can be distinguished in humans today: stefins, cystatins, latexins, fetuins, and kininogens (Fig. 1). Whether or not these diverse families and all of their respective members are phylogenetically linked remains to be clearly determined. Some members (*i.e.*, fetuins and latexins) may indeed have acquired "cystatin"-like properties through other mechanisms such as convergent evolution.

The stefins (STFs) are 11-kDa cytoplasmic cystatins each containing a single cystatin-like domain and lacking typical features of secreted proteins such as a signal peptide, disulfide bonds and glycosylation. The cystatins (CSTs) are secreted proteins 14- to 24-kDa in mass, which are distinguishable by a single cystatin domain, a typical signal peptide, and disulfide bonds. Some CSTs are ►*N*- or *O*-glycosylated, or exhibit ►Ser/Thr-phosphorylation. The secreted latexins (LTXs) contain two typical cystatin domains, but share little sequence homology to other cystatins, and seem to lack cysteine protease inhibitory activity. Plasma fetuins (FETs) also contain two cystatin-like domains, but share <30% sequence homology to other cystatins, and also lack cysteine protease inhibitory activity. Finally, the kininogens (KNGs) are plasma proteins with three cystatin-like domains, domain 1 being inactive and domains 2 and 3 being active as cysteine protease inhibitors.



Cystatins. Figure 1 Composition of the cystatin super-family. Schematic ball and stick representation of members of the cystatin super-family with one, two or three cystatin-like domains. k, kinin moiety; s, signal peptide.

Gene Structure & Evolution

At the gene level, a typical cystatin domain is generally the product of three coding exons. Consequently, the genes of most members of the cystatin super-family are composed of 3+ (STFs and CSTs), 6+ (LTXs and FETs), and 9+ (KNGs) coding exons. Although the existence of a common evolutionary origin of the individual cystatin genes is still uncertain, a hypothetical model for the evolution of the super-family has been proposed. According to this model, the various members arose from an ancestral STF-like cytoplasmic inhibitor. Upon evolution, the archetype gene acquired additional DNA elements such as, for example, the coding sequence for a signal peptide. This may have resulted in an archetypal gene for a secreted cystatin, which produced members with two and three cystatin domains upon successive gene duplication events. It is also possible that alternative evolutionary mechanisms have contributed to the level of diversity amongst the present members of the cystatin super-family.

Prokaryotes do not seem to harbor any genes even remotely similar to cystatins. Cystatins, instead, seem to have emerged with the development of more complex forms of life in eukaryotes. Typical cystatin-like genes have indeed been identified in various plants, some yeast strains, various unicellular parasites, as well as in worms, insects, fishes, frogs, birds, snakes and mammals.

Function

The primary function of cytoplasmic cystatins, such as STFA (stefin A/CSTA/ACPI/α-TPI) and STFB (stefin B/CSTB/NCPI/β-TPI), is generally assumed to be part of a safeguard mechanism protecting against the transient disruption of the integrity of lysosomes. Lysosomes are intracellular digestive factories filled with hazardous hydrolytic enzymes, including proteases generally referred to as ►cathepsins. Complexes between stefins and lysosomal cysteine-proteases form instantly, and can be readily detected when the integrity of cells and lysosomes is compromised. Shear stress, fever, stress-induced oxidation or glycation of proteins, infection by pathogens, and other stress conditions all contribute to repeated episodes of lysosomal leakage, which must be concealed in space and time for cell survival. In proliferating tissues, these events bear less consequence than in post-mitotic tissues such as cardiac and nervous

tissue. Unsurprisingly, STFB deficiencies have been linked to hereditary forms of monoclonus epilepsies, in which cerebellar granule cells undergo cell death mediated by leakage of lysosomal cysteine-proteases.

Secreted cystatins such as CST3 (cystatin C/BCPI/γ-trace/post-γ-globulin) were long believed to function exclusively as inhibitors of lysosomal cysteine proteases, despite early studies proposing additional or alternate functions. Before CST3 was coined a cystatin, it was believed to be a neuroendocrine peptide hormone. Over the years, five observations have greatly contributed to the need to reconsider the accepted model of CST function: (i) The number of CSTs, which seem to lack cysteine protease inhibitory activity, represents more than 50% of all members of the CST family in mammals. (ii) Several CST functions, such as the modulation of DNA synthesis, cell proliferation, and immune function, do not require cysteine protease inhibitory activity. (iii) Despite the fact that some CSTs form extremely tight molecular complexes with purified proteases *in vitro*, there still is little evidence for the occurrence of such complexes *in vivo*. (iv) Finally, under physiological and healthy conditions, most CSTs would be useless under the current model, as they are secreted proteins and their target enzymes are confined intracellularly.

Based on recent analyses of gene structures, a new model was proposed in which CSTs and ►chemokines evolved from a common ancestral gene and may have conserved similar integrated functions. Comparison of the crystal structures of CSTs and chemokines further underscores this relationship. Besides their similar gene structure (both are generally composed of three exons and two introns), CSTs share similarities in their basic three-dimensional fold: disordered *N*- and/or *C*-terminus, β-pleated sheet comprised of three to five anti-parallel β-strands, one β-strand with a bulge, a central α-helix, and two or three disulfide bonds to stabilize the core domain. CSTs and chemokines also share other intriguing features: Both types of proteins are secreted proteins, of low molecular mass (<24 kDa), which undergo ►*N*- or *C*-terminal processing by serine-proteases, have a tendency to dimerize, and exhibit multiple biological activities. To act like chemokines, however, CSTs would have to bind to specific ►G-protein coupled receptors (GPCRs). Such an interaction was proposed for the cystatin-like protein monellin from African berries, which, upon binding to a GPCR involved in taste perception, elicits an extremely sweet sensation in humans. Further direct evidence is required to establish an unambiguous relationship between CSTs and chemokines.

CSTs may play important roles in the modulation of the humoral and cellular immune responses. As inhibitors of lysosomal cysteine proteases, CSTs can block degradation of ►perforins and ►complement component C3, thus, preventing cytotoxic T cell- and complement-mediated cell lysis, respectively. In antigen presenting cells, lysosomal cysteine proteases play critical roles in major histocompatibility complex class II-mediated antigen processing and presentation. It has, however, not been conclusively determined whether CSTs are able to penetrate inside endosomes and/or lysosomes of antigen presenting cells to modify either process. As potential chemokines, CSTs have been shown to modulate the production of cytokines by various cell types such as macrophages and lymphocytes, as well as the release of nitric oxide, oxidative burst, and ►phagocytosis in neutrophils.

One of the functions of LTXs, as well as of other related members of the cystatin super-family with two tandem cystatin domains, seems to be the inhibition of some serine- and/or metallo- but not cysteine-proteases. LTX is the only known mammalian protein inhibitor of zinc-dependent carboxypeptidases and, thus, could potentially perform an important role in the regulation of peptide hormone activity during tissue growth and differentiation. The FETs regroups major plasma glycoproteins such as FETA (fetuin A/AHSG), FETB (fetuin B), and HRG (histidine- or histidine-and proline-rich glycoprotein). FETA is synthesized in the liver and constitutes a major plasma protein that accumulates in the matrix of bone and teeth. The protein also blocks calcium phosphate precipitation in the blood, thus preventing the spontaneous generation of systemic apatite crystals. This property is shared by HRG but not by FETB. A role for FETA in physiological and pathological mineralization is also evident from FETA knockout mice.

KNGs represent major plasma glycoproteins with three cystatin-like domains, and, like FETs, are also produced in the liver. One important function of KNGs is to serve as precursors of vasoactive kinins, such as bradykinin. Because bradykinin is extremely short-lived, this small peptide needs to be proteolytically released from the precursor molecule in the immediate vicinity of the GPCRs for bradykinin (BKRs). The third cystatin domain in KNGs is assumed to tether KNGs to the cell surface and thus bring the prokinin moiety close to the BKRs. With analogy to the interaction of chemokines with their respective receptors, one could postulate that KNGs perhaps also bind to BKRs in a two-step mode: an initial step in which there is a loose binding of the prokinin moiety, followed by proteolytic excision of the kinin moiety, tight binding, and activation of the receptor. Another important function of KNGs is to scavenge excess lysosomal cysteine-proteases that are locally released from damaged tissue during various injuries, infections, and inflammatory reactions. This buffering capacity of KNGs may limit further tissue damage and, hence, favor tissue remodeling and repair.

Role in Cancer

Lysosomal cysteine proteases have been implicated in multiple steps of tumor progression and recurrence, including early steps of ►immortalization and ►transformation, intermediate steps of tumor invasion and ►angiogenesis, and late steps of ►metastasis and drug resistance. During all these steps, tumor cells must actively ►escape immune surveillance. This may be accomplished, in part, through complete antigen degradation, which would leave no identifiable immunogenic peptides. Alternatively, exocytosis and cell surface binding of lysosomal cysteine proteases could lead to the degradation of the third component of complement C3 or the pore-forming protein perforin and, thus, interfere with immune cell-mediated lysis and the killing of target tumor cells. The importance of lysosomal cysteine proteases in the development of tumors from benign growths to aggressive lesions suggests that cystatins, *i.e.*, STFs and CSTs, may in many ways safeguard against tumor progression. In spite of this, the scenario is not always so simplistic as some CSTs appear to have both tumor promoting and tumor suppressing activities, while others promote metastasis. Thus, STFs and CSTs play important but distinct roles in our current understanding of tumor formation and progression. There is little or no information on LTXs and, the putative roles of FETs and KNGs in tumor ►neovascularization have been recently reviewed elsewhere.

In prostate and breast tissue, STFA is produced in basal and myoepithelial cells, respectively. STFA expression is thus lost with the loss of these cells during progression of most prostate and breast cancers. STFA expression is also lost during skin tumorigenesis, metastasis of oral/pharyngeal squamous cell carcinoma, and lung cancer progression. There is increasing evidence suggesting that STFs regulate initiation or propagation of the lysosomal cell death pathway. This cell death pathway is triggered by many different stimuli, including ►cytokines, ►p53 activation, and ►retinoids. In many tumor cells, the lysosomal cell death pathway involves cathepsin B as a major downstream executioner. Overexpression of STFA in various cancer cell lines indeed reduces their susceptibility to cell death-inducing agents. In addition, administration of STFA to mice bearing myeloid leukemias prolongs their mean survival. Exogenous treatments with STFA also reduce tumor cell ►motility. STFB is a far more ubiquitous and abundant protein than STFA, but like STFA, it also inhibits motility of tumor cells when exogenously administered.

CST3, unlike most other secreted cystatins, is considered a housekeeping-type gene. The mean concentration of this 15-kDa protein in normal human serum is about 77 nM (or 1.16 μg/ml). However, there are considerable differences in the levels of CST3 in other body fluids, suggesting that different tissues exhibit different accumulation rates of the protein or renewal rates of the extracellular fluid. The picture is further complicated by the fact that glomerular filtration is often impaired in patients with advanced cancer. CST3 has been extensively studied as a potential tumor marker, yet clinical studies tend to dismiss this cystatin as a useful diagnostic/prognostic marker. In spite of these clinical data, CST3 displays several noteworthy effects on tumor cells. As a potent inhibitor of lysosomal cysteine proteases, CST3 very efficiently inhibits *in vitro* tumor cell-mediated degradation and invasion of an ►extracellular matrix. In addition, overexpression of CST3 in human glioblastoma cells resulted in little apparent intracerebral tumor take compared to parental and mock controls. CST3, however, can also promote *in vitro* DNA synthesis and long-term proliferation of various cell types including ►stem cells. This may explain the fact that most established cell lines express and secrete this protein. ►Lung colony formation assays, in agreement with a mitogenic function of CST3, reveal that tail vein injection of highly metastatic melanoma cells results in a seven-fold reduction of lung colonies in CST3-null mice, compared to wild-type littermates.

CST6 (cystatin E/M) is expressed in a variety of normal human tissues, but its expression is lost in most established cancer cell lines and tumor tissues. In cancers of the breast, cervix, lung and brain, the CST6 gene is ►epigenetically silenced by promoter hypermethylation rather than deleted or mutated. Overexpression of CST6 in breast and lung cancer cells results in a reduction of colony formation and cell proliferation, suggesting that this cystatin may hold some tumor-suppressing capabilities. This has been confirmed *in vivo*, after inoculation of tumor cell clones into mammary fat pads of ►severe combined immunodeficient mice. CST6 expression in breast cancer cells strongly reduces tumor growth during the first six to seven weeks after inoculation, but has only a minor effect on incidence of metastasis and number of lesions in the lungs. The overall metastatic burden in the lungs and the liver, however, is significantly smaller in the CST6 when compared to the control group. Further studies using the experimental lung colonization assay demonstrated that CST6 expression has no effect on the initial seeding and survival of tumor cells in the lungs, but does reduce the expansion of established lung colonies. Thus, CST6 is a *bona fide* ►tumor suppressor gene for breast cancer.

CST7 (cystatin F/leukocystatin/CMAP) is a highly tissue-specific cystatin, which explains its initial cloning and annotation as leukocystatin. The gene is expressed predominantly in cells of the hematopoietic lineage and not in fetal tissues. CST7 is highly expressed in peripheral blood cells, such as T-cells and monocytes, as well as in stem cell-derived dendritic cells. Most T- and B-cell-derived cell lines, and the promyelo-monocytic

cell line U-937, secrete fair amounts of CST3, but little to no CST7. A significant amount of the CST7 produced by U-937 cells is in fact either retained intracellularly, or is reabsorbed by the cells immediately following secretion. CST7 has also been cloned by RNA differential display as CMAP, a cystatin-like metastasis-associated protein. This gene is preferentially expressed in murine tumor cell lines that metastasize to the liver. ►Transfection of highly metastatic cells with CST7 antisense cDNA led to a reduction of experimental colonization of the liver and spleen by several transfection clones, and improved survival of such tumor-bearing mice more than two-fold. Additionally, CST7 expression was detected in several human tumor cell lines, particularly in those with high propensity to metastasize to the liver (*i.e.* colon, pancreas, and lung cancer cell lines). Other tumor cell lines, which demonstrated high levels of CST7 expression, included cells from melanomas, glioblastomas, and osteosarcomas. Based upon a multivariate analysis of 79 patients with colorectal cancer (including 17 cases with liver metastases), high expression levels of CST7 were identified as the strongest independent factor for liver metastasis. In addition, the 5-year survival rate was significantly lower in patients with high CST7 expression than it was for those who displayed low expression levels.

Conclusion

From the above considerations and hypotheses it is clear that a much better understanding of the dual nature of cystatins could lead to the advancement of novel anti-cancer strategies. Further research could reveal that their roles as protease inhibitors and potential chemokines could be combined to signal anti-cancer immune responses, while also inhibiting tumor growth, invasion, and neovascularization. The literature on CST3 and CST7 suggests that chemokine-like function may need to be disrupted for efficient protease inhibitor-mediated tumor and metastasis suppression. In contrast, the example of CST6 shows that the two functions greatly contribute to tumor suppression.

Cystatins A, B

►Stefins

Cystectomy

Definition

Surgical removal of the urinary bladder.

►Urothelial Carcinoma

Cysteine Proteases

Definition

A group of proteolytic enzymes that use the sulphydryl group of a cysteine residue for the nucleophylic attack of the scissile peptide bond. 148 human genes code for cysteine proteases.

►Stefins

Cystic Fibrosis

Definition

A hereditary disease caused by mutations within the ABC-transporter encoding gene ABCC7 (CFTR).

►ABC-Transporters

Cystic Nephroma

Definition

Benign multicystic renal tumor. Contrary to the cystic partially differentiated ►nephroblastoma it posses no

blastemal component in histology and can be found in adults too.

►Mesoblastic Nephroma

Cytarabine (1-arabinofuranosylcytosine)

Definition

Nucleoside analog used for lymphoma and acute myeloid leukemia chemotherapy, blocks DNA polymerization.

►Chromosomal Translocation t(8;21)

Cytochalasin B

Definition

The alkaloid cytochalasin B is a cell-permeable mycotoxin which inhibits cytoplasmic division by blocking the formation of contractile actin filaments. Cytochalasin B shortens actin filaments by blocking monomer addition at the fast-growing end of actin polymers. It blocks ►cytokinesis thus preventing the separation of daughter cells after mitosis that leads to the formation of binucleated cells.

►Micronucleus Assay
►Microcell-Mediated Chromosome Transfer

Cytochrome c

Definition

Is a protein of the mitochondrial electron transport chain with heme as a prosthetic group. Furthermore, it is involved in the apoptotic process; that is, following initiation of the mitochondrial pathway of ►apoptosis, it is translocated from the intermembrane space of the mitochondria to the cytosol, where it contributes to the activation of the procaspase 9 in the apoptosome.

►Photodynamic Therapy

Cytochrome c Oxidase

Definition

Is a large transformation protein complex (complex IV) found in mitochondria. It is the last protein in the electron transport chain and is the terminal enzyme responsible for 90% of cellular oxygen consumption in mammals

►Nitric Oxide

Cytochrome P450

Ron H. N. van Schaik
Department of Clinical Chemistry, Erasmus University Medical Center, Rotterdam, The Netherlands

Synonyms

CYP450

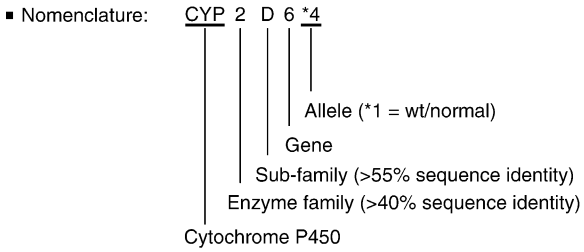
Definition

Cytochrome P450 stands for a superfamily of closely related proteins that protect the individual against potentially harmful substances by modifying these substances by oxidation, hydroxylation, dealkylation or dehalogenation, thereby increasing polarity and solubility and thus facilitating excretion from the body.

Characteristics

The body of an organism has a powerful system to facilitate the excretion of potentially harmful substances: the cytochrome P450 system. Cytochrome P450 stands for a superfamily of more than 50 closely related heme-containing enzymes, which can be divided into families (with at least 40% sequence homology on the amino acid level) and subfamilies (with at least 55% sequence homology), each with their own substrate specificity. The designation P450 is derived from the specific spectral absorbance at 450 nm of these proteins. The nomenclature is "CYP," followed by a Arabic number to indicate the family, then a capital letter indicating the subfamily if more members exist, and finally an Arabic number to indicate the specific enzyme (i.e., CYP2C9 is a member of the CYP2 family, belongs to the CYP2C subfamily) (Fig. 1). Family members include CYP1, CYP2, CYP3, CYP4, CYP11, CYP17, CYP19, CYP21, CYP26, and CYP51. These phase I monooxidases may carry out hydroxylation,

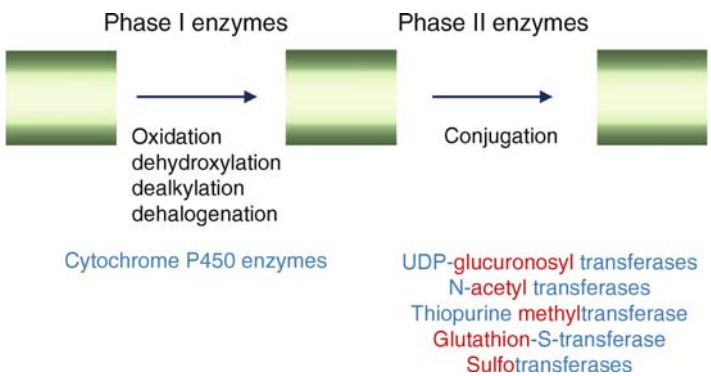
dealkylation, oxidation, or dehalogenation reactions on a variety of lipophilic compounds of exogenous or endogenous origin, which are often followed by conjugation reactions (Fig. 2). Purpose is to increase aqueous solubility by increasing polarity of these molecules, and thus facilitating their elimination from the body. Most of these enzymes are expressed in the liver, but also extrahepatic expression occurs (i.e., intestine, kidney). Within the cell, the enzymes are located in the endoplasmatic reticulum. Besides the systemic action of the CYP450 system, also tumor cells may express CYP450 enzymes, especially those of the CYP1 family, thereby potentially affecting effective treatment with anticancer drugs. Antibodies against the highly expressed CYP1B1 in many tumor types have been developed, which potentially can be used as specific cancer detection. The high CYP1B1 expression in many tumors metabolically inactivates drugs like ►paclitaxel, ►docetaxel, doxorubicin, mitoxantrone, and ►tamoxifen, and as a consequence, mediates anticancer drug resistance. Besides detoxification reactions, part of the CYP450 family is involved in synthesis of endogenous compounds like steroids. The CYP11A1 enzyme catalyzes the conversion of cholesterol to pregnenolone, while CYP21A2 (21-decarboxylase) is involved in the formation of 11-deoxycortisol from 15α-hydroxyprgesterone. If this latter enzyme is deficient, it causes congenital adrenal hyperplasia. The enzyme CYP19 is involved in estradiol formation from androstenedione, making local inhibition of this enzyme in tumors an interesting target in breast cancer therapy.



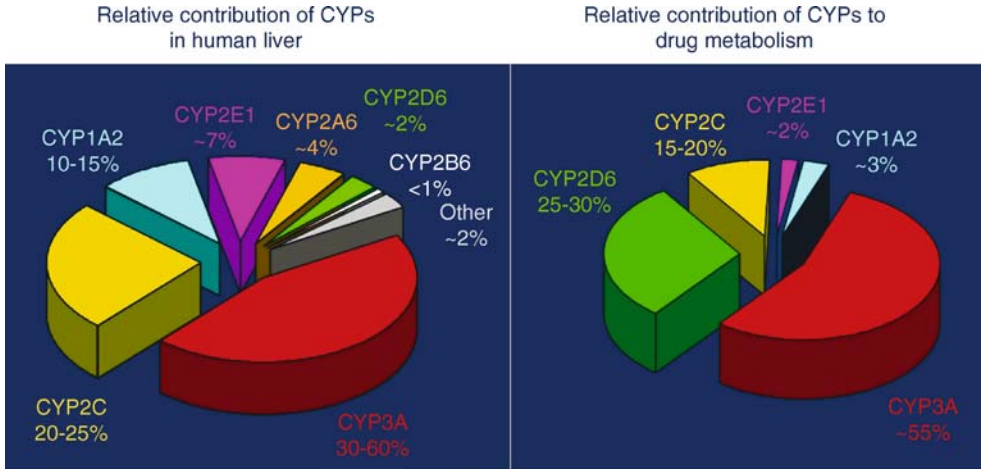
Cytochrome P450. Figure 1 Nomenclature for cytochrome P450 enzymes.

Detoxification

Other important exogenous substrates of the CYP450 enzymes are environmental chemicals, plant toxins, and medical drugs. Metabolism by CYP450 enzymes mostly deactivates these compounds and facilitates urinary or faecal excretion. The best studied members of these detoxifying enzymes are the CYP2D6 enzyme, the CYP3A subfamily, and the CYP2C subfamily. The CYP3A subfamily (CYP3A4, CYP3A5, CYP3A7, CYP3A43), with CYP3A4 being the most important member, accounts for 50% of the total CYP450 protein in the liver in adults. Expression increases during the first year of life, replacing the foetal CYP3A7 expression. CYP3A5 expression is only found in 20% of Caucasians, and the enzyme has considerable substrate overlap with the CYP3A4 enzyme. The role of CYP3A43 is thought to be minimal. The enzyme CYP3A4 is involved in the metabolism of >50% of prescribed drugs, while CYP2D6, accounting only for 2% of total protein, is involved in the metabolism of 25% of these compounds (Fig. 3). Together with the CYP2C family (CYP2C8, CYP2C9, CYP2C19), which metabolizes 5–10% of drugs, these three subfamilies take credit for the majority of phase I reactions of prescribed drugs. Most anticancer agents are substrates for CYP3A4, like docetaxel, vinca alkaloids, paclitaxel, cyclophosphamide, ifosfamide, irinotecan, imatinib, gefitinib, etoposide, teniposide. Important contributions of other CYP450 enzymes are, for instance, CYP2D6, which activates tamoxifen, CYP2B6 for activation of cyclophosphamide, and the prominent role of CYP2C8 in the metabolism of paclitaxel. Furthermore, thalidomide (used in the treatment of chronic myeloid leukemia and prostate cancer) is metabolized by CYP2C19, while the prodrug of 5-fluorouracil, tegafur, needs activation by CYP2A6. All cytochrome P450 enzymes, with the exception of



Cytochrome P450. Figure 2 Reactions catalyzed by cytochrome P450 enzymes.



Cytochrome P450. Figure 3 Percentage contribution of cytochrome P450 subfamilies to total protein in human liver (left panel) or to drug metabolism (right panel).

CYP2D6, are highly susceptible to induction or inhibition by numerous compounds, including drugs and environmental factors. Grapefruit juice, for instance, decreases CYP3A4 activity dramatically, the herb St. John's Wort increases CYP3A4 activity, and smoking increases the transcription and activity of CYP1A2. These inducing and inhibiting events may affect the ability to metabolize drugs, and thus interfere with the expected relationship between dose, blood concentration and effect.

Using CYPs to Improve Therapy

The enzyme CYP1B1 was identified as the main CYP450 present in a wide range of human cancers of different histological types, among which are prostate, lung, and renal cell tumors. It is expressed in primary tumors as well as in metastases and is regarded as a biomarker of the neoplastic phenotype. It thus is an interesting target in the development of novel anticancer prodrugs that need specific activation by CYP1B1. In this way, locally high concentrations of anticancer agents are generated without the high exposure of the total individual, although special precautions are necessary to prevent the premature elimination of those tumor cells expressing the CYP1B1 enzyme. Several patents on this approach have been filed in the last 5 years. Another, novel CYP450 enzyme was recently discovered: CYP2W1, which is expressed during fetal life but can also be found in transformed tissues. This high expression in tumors and the low expression found in normal cells also make CYP2W1 an interesting target for developing new anticancer therapies.

Genetic Polymorphisms

The enzymes of the CYP450 superfamily involved in detoxification reactions are highly polymorphic: genetic variants, usually present as ►single nucleotide polymorphisms (►SNPs), may encode enzymes with reduced activity. Because these ►variant alleles can be determined prior to starting therapy, they can be used to predicting aberrant pharmacokinetics. This discipline of analyzing DNA to predict or explain drug metabolism is called ►pharmacogenetics. These variant alleles are depicted using an asterisk, in which *1 stands for the most common (►Wild-type) active allele, and subsequent variant receive an increasing number (e.g. *CYP2C9*2*, *CYP2C9*3*) (Fig. 1). The power of these predictions depends on the pharmacokinetics of the drug (how much is it dependent on just one CYP450, or is there redundancy?), comedication, kidney and liver function, and environmental factors. For clinical use, these predictions are most valuable for drugs having a narrow therapeutic window, in which the consequences of subtherapeutic treatment on one hand, and toxic side effects on the other hand, are high. Cancer therapy is therefore an important field to explore the potential contribution of pharmacogenetics, in which prediction of metabolism in increasing effectivity and avoiding extreme toxicity are of vital importance.

CYP2B6

Enzymatic activity of CYP2B6 shows a considerable interindividual variation, but in addition, also a difference between males and females exists, the latter having a 1.7-fold higher activity. The *CYP2B6* gene has recently shown to be quite polymorphic, with various variant alleles in the population, encoding CYP2B6 with altered activities. The correlation between specific variations in the DNA and assignment to specific variant alleles has been quite confusing because increasing knowledge showed that certain SNPs proved not as unique as anticipated for a specific variant allele.

The most investigated SNPs at this moment are the 415A > G (Lys139Gln), 516G > T (Gln172His), 785A > G (Lys262Arg), and 1459C > T (Arg487Cys), which can be present in several allelic variants. The prominent role of CYP2B6 in the activation of cyclophosphamide was confirmed in some studies in which the 516G > T polymorphism correlated with a 1.5–2.0-fold increased clearance. Remarkably, this same SNP causes a reduced rather than increased enzymatic activity with respect to another CYP2B6 substrate, efavirenz, stressing the caution for extrapolating conclusions from one substrate to another. The frequency of the variant alleles containing this SNP is 23% for Caucasians and 16% for Japanese individuals, demonstrating that this may affect a substantial part of the patients treated with cyclophosphamide.

CYP2C8

The *CYP2C8*2* (805A > T, Ile269Phe) and *CYP2C8*3* (416G > A, Arg139Lys; 1196A > G, Lys399Arg) genetic variants, occurring with frequencies of 0% (*2) and 13% (*3) in Caucasians, and 18% (*2) and 2% (*3) in African Americans, were tested for their enzymatic activity on paclitaxel. This anticancer drug depends for 85% of its metabolism on CYP2C8 and for 15% on CYP3A4. Both CYP2C8 variant proteins showed a decreased activity on paclitaxel, implying a possible use in paclitaxel metabolism. However, further studies are needed to demonstrate the clinical use of genotyping for paclitaxel therapy.

CYP2C9

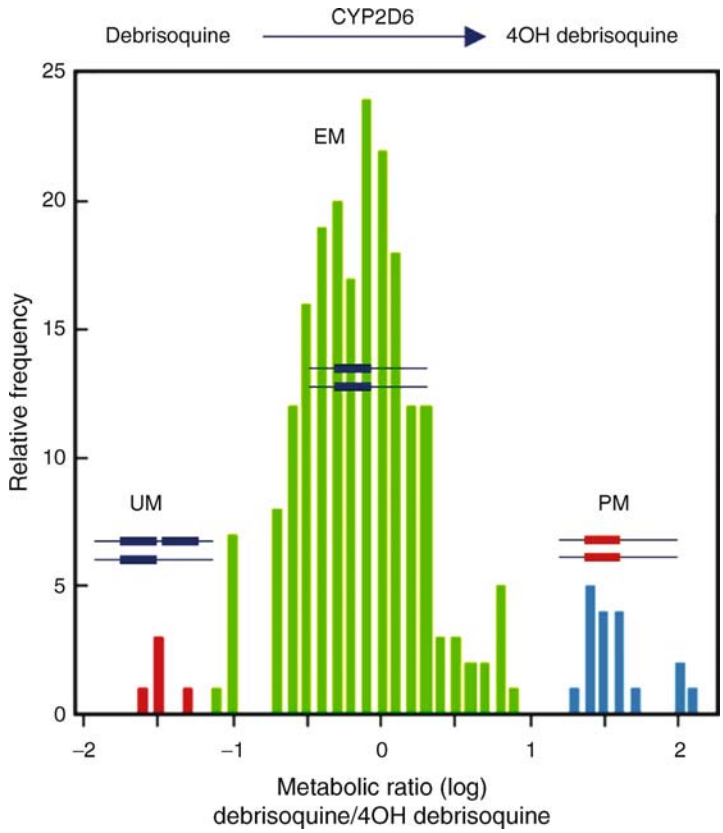
CYP2C9 is the major enzyme of the CYP2C family. The *CYP2C9* gene has numerous variant alleles, yet the *CYP2C9*2* (430C > T, R144C) and *CYP2C9*3* (1075A > C, I359L) are regarded as the most important variant alleles encoding decreased activity. The involvement of CYP2C9 in the metabolism of the anticoagulation drugs warfarin and acenocoumarol, affecting anticoagulation therapy, has resulted in major attention for this enzyme. Allele frequencies are quite high, with 11% (*2) and 7% (*3) in Caucasians while the frequencies of these alleles in Asians (0% for *2 and 3% for *3) and Africans (4% for *2, 2% for *3) are much lower. Although implicated in the metabolism of cyclophosphamide, no correlations between CYP2C9 variant alleles and cyclophosphamide pharmacokinetics are apparent, suggesting a very modest role for this enzyme.

CYP2C19

Population differences in CYP2C19 activity were first described around 1980 in an experiment using mephenytoin. One subject experienced such extreme sedation after taking mephenytoin for several days that he terminated his participation to the study. Based on the amounts of R- and S-mephenytoin in his urine, this individual was shown to be defective in S-mephenytoin 4-hydroxylation. Hereditary defective S-mephenytoin 4-hydroxylation is caused by the inheritance of two defective *CYP2C19* alleles. Approximately 2–3% of Caucasians is a CYP2C19 poor metabolizer, 3–5% of blacks and 10–24% of Asians. The most common defective alleles are CYP2C19*2 (681G > A; splicing defect) and CYP2C19*3 (636G > A; W212X, incomplete protein). Known substrates for CYP2C19 are the proton pump inhibitors (omeprazole, pantoprazole), in which the treatment of individuals for Helicobacter Pylori was found to be less effective in patients with two active alleles compared to patients having one or two deficient alleles. In cancer treatment, a correlation between CYP2C19 genotype and the activation of cyclophosphamide was demonstrated, thereby affecting survival, implicating potential use in cyclophosphamide therapy. Because of the involvement of CYP2C19 in the metabolism of thalidomide, pharmacogenetic analyses for this enzyme in the treatment of chronic myeloid leukemia or prostate cancer might be an interesting option.

CYP2D6

CYP2D6 activity displays a trimodal distribution in Caucasians, differentiating between poor metabolizers (PMs), extensive (normal) metabolizers (EM) and ultrarapid metabolizers (UMs) (Fig. 4). Also an intermediate metabolizer group can be distinguished, although phenotypically this group displays substantial overlap with the extensive metabolizers, and is usually characterized on the genetic level. For CYP2D6, 5–10% of the Caucasian population is practically deficient, which was discovered using the probe drugs sparteine and debrisoquine. This deficiency is due to inheritance of two defective *CYP2D6* alleles, the most common polymorphism being a G to A conversion on position 1846 of the *CYP2D6* gene, leading to a RNA splicing defect, characteristic for the *CYP2D6*4* variant allele. The second most prominent CYP2D6 allele is the *5 allele, in which the whole *CYP2D6* gene is deleted. Over 50 variant alleles have been described until now for CYP2D6, which can be divided in those encoding no activity (null alleles), decreased activity (decreased function alleles), or normal activity (functional alleles). The frequency of variants in the population depends very much on ethnicity. The *CYP2D6*17*, for instance, is mainly found in Africans, while in Asians the decreased activity allele *CYP2D6*10* is found much more frequent than in Caucasians. Patients with a CYP2D6 deficiency who are treated with tamoxifen for breast cancer showed decreased effectiveness of therapy, due to decreased activation. In addition to genetic deficient alleles, *CYP2D6* can also be present as gene duplications in certain individuals, bringing the

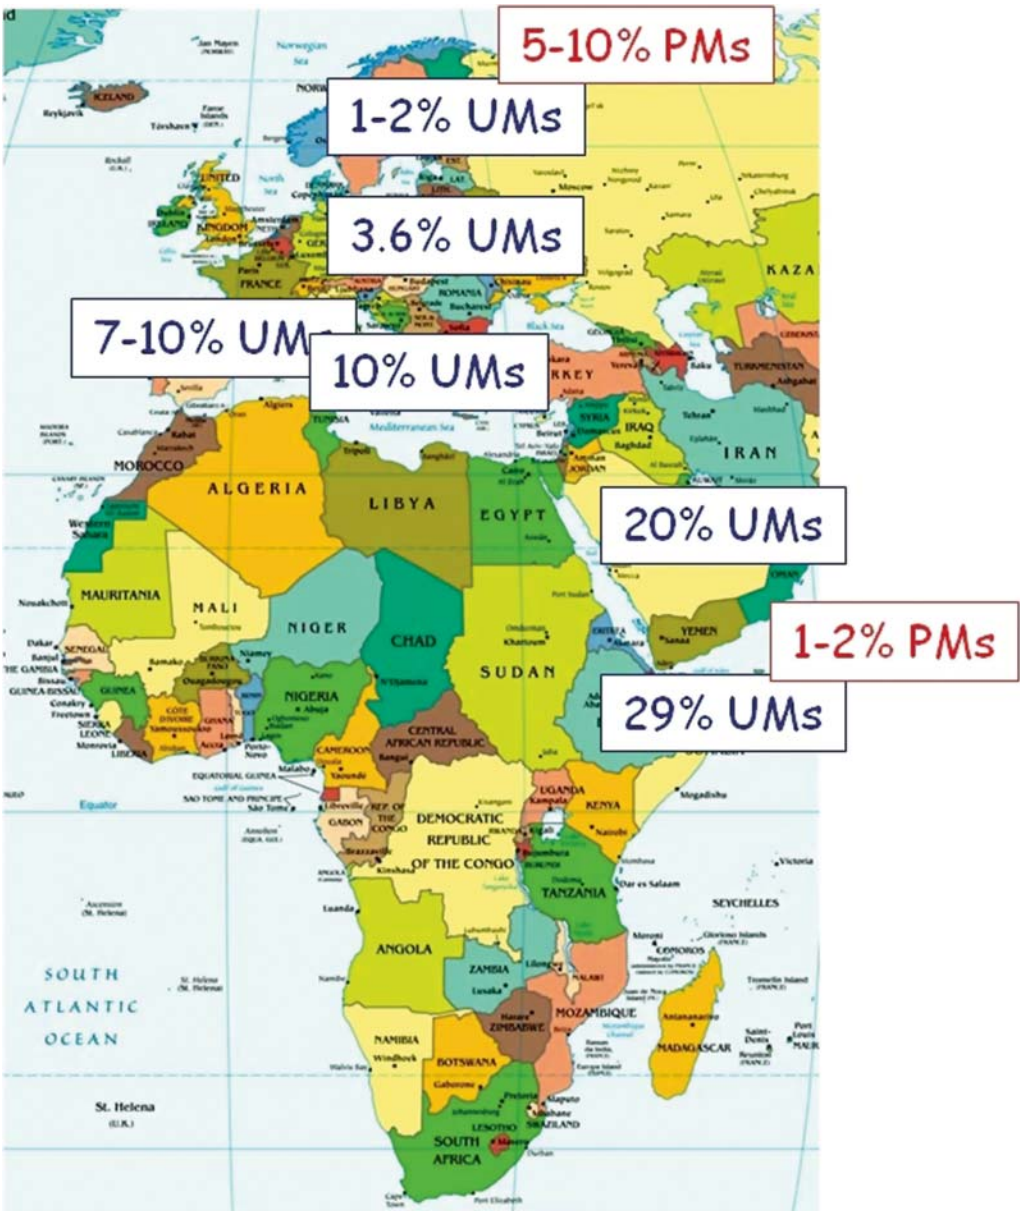


Cytochrome P450. Figure 4 Distribution of CYP2D6 activity in the Caucasian population, showing ultrarapid (UM), extensive (normal) (EM) and poor metabolizers (PM). (Adapted from Guen Guerich 2003, Mol. Intern. 3,194–204).

total number of CYP2D6 alleles to 3, or even higher. In Sweden, a family was identified that had 13 copies of the *CYP2D6* gene. This gene duplication is thought to be a compensating mechanism invented by evolution to circumvent the poor inducibility of CYP2D6. The frequency of this gene duplication displays an interesting north–south gradient, with duplications being present in 1–2% of individuals in Sweden, 3.6% in Germany, 7–10% in Spain, 10% in Italy, 20% in Saudi Arabia, and 29% in Ethiopia. The frequency of poor metabolizers shows the reverse, with 1–2% of poor metabolizers in Ethiopia to 5–10% in Northern Europe (Fig. 5). This gene duplication is accompanied by an increased activity, and leads an ultrarapid metabolizer phenotype. Individuals having these gene duplications may experience severe toxic effects with codeine, which is converted in the liver to morphine by CYP2D6; fatalities have been documented where the breast milk of a mother having codeine contained extreme high levels of morphine, leading to fatal morphine exposure in the child. This high morphine concentration in the milk was a result of the mother being a CYP2D6 ultrarapid metabolizer. In the treatment of cancer, CYP2D6 also plays a minor role in the metabolism of the new anticancer agent imatinib, but thus far the clinical implications of being a poor metabolizer for this kind of therapy are not known.

CYP3A4

This cytochrome is regarded as the most important enzyme, and is involved in the metabolism of over 50% of commonly described drugs. It is highly susceptible to induction and inhibition, with a resulting large interindividual variability in activity. Although extensive research has been done identifying genetic polymorphisms in this enzyme, most SNPs and the 20 variant alleles described until now proved to have low frequencies (<1%) in the different populations. An exception is the promoter variant *CYP3A4*1B* (−392A > G), which has an allele frequency of 2–9% in Caucasians, 35–67% in blacks, but was rarely found in Asians. In vitro experiments demonstrated a slightly higher transcription, and thus CYP3A4 activity, but the clinical consequences of this are not clear yet. Interestingly, this *CYP3A4* polymorphism was shown to be linked genetically to a polymorphism in the *CYP3A5* gene. It was suggested that effects, attributes to the *CYP3A4* polymorhism, were, in fact, due to the



Cytochrome P450. Figure 5 Geographical variation in frequency of CYP2D6 ultrarapid metabolizers (UMs) and poor metabolizers (PMs).

►*CYP3A5* polymorphism. However, several studies have shown correlations with the *CYP3A4*1B* allele without any correlation with CYP3A5 variant alleles. In recent study on cyclophosphamide, a decreased metabolism and a decreased median survival in breast cancer patients were demonstrated having the *CYP3A4*1B* allele. Recently, another variant, the *CYP3A4*16B* (554C > G; Thr185Ser) allele, was indirectly shown by the use of tagging SNPs to be correlated with a 20% decrease in paclitaxel metabolism in Japanese patients, a population in which the allele frequency of this variant was found to be 1.7%.

CYP3A5

For a long time, the interindividual expression of CYP3A5 was poorly understood. However, its expression in only 20% of Caucasians appeared to be caused by a highly frequent genetic polymorphism, 6986A > G, which is characteristic of the *CYP3A5*3* allele, and causes aberrant splicing. About 80% of Caucasians, but only 30% of the African American population, are deficient for this enzyme, most of them having the *CYP3A5*3/*3* genotype. Because of the substantial substrate overlap with CYP3A4, it is not always clear to what extent CYP3A5 contributes to the metabolism of certain drugs.

Cytochrome P450. Table 1 Correlations described for cytochrome P450 enzymes and the incidence of various cancers, either directly or in combination with environmental exposure

	1A1	1A2	2A6	1B1	2C9	2C19	2D6	2E1	3A4	3A5	17	19
Bladder						•						
Breast	•										•	•

This polymorphism does have an impact in the metabolism of the immunosuppressive drug tacrolimus, which was slower in *CYP3A5*3/*3* individuals.

Cancer Incidence

A number of the detoxifying CYP450 enzymes have been associated with cancer incidence, mostly because their involvement in the conversion of procarcinogens to carcinogenic metabolites (Table 1). The xenobiotic benzo(a)pyrene, for instance, is a common environmental pollutant produced from the burning of coal, from the combustion of tobacco products, from food barbeque on charcoal briquettes, and from industrial processing. It is a weak carcinogen, but is converted to a potent carcinogen by CYP1A1, CYP1A2, and CYP1B1, making that variable activities in these enzymes correlate with cancer incidence. CYP1A1 alleles have been implicated in lung, gastric, colorectal, hepatocellular, breast, prostate, and dermatologic cancer, while CYP1B1 variant alleles correlated with colorectal, hepatocellular, prostate, head and neck, renal, and gynecological cancers. For CYP3A4, the *CYP3A4*1B* allele was discovered because it correlated with a more aggressive form of prostate cancer. In nonaggressive bladder cancer, a lower frequency of CYP2C19 poor metabolizers is found while, in contrast, for squamous cell carcinoma a higher frequency of CYP2C19 poor metabolizers was apparent. Also correlations with lung cancer and colorectal cancer have been reported, while CYP2C9 variant alleles showed correlation with colorectal cancer. *CYP2E1* polymorphisms were associated with an increased risk of lung, esophageal, head and neck, gastric, colorectal, and hepatocellular cancer, while CYP2D6 poor metabolizers appeared to be relatively protected for hepatocellular carcinoma but were at some increased risk for prostate cancer in patients who were using tobacco. Although not all mechanisms behind the correlation between variant CYP alleles and cancer incidence are known, it is obvious from the described observations that CYP450 enzymes not only play a role in the treatment of cancer, but may also be involved in the development of cancer.

Cytochrome P450 (CYP)

Definition

Member of a superfamily of heme-containing monooxygenases involved in xenobiotic metabolism, cholesterol biosynthesis, and steroidogenesis, in eukaryotic

organisms found mainly in the endoplasmic reticulum and inner mitochondrial membrane of cells.

►Toxicological Carcinogenesis

Cytochrome p450 2 E1 (CYP2E1)

Definition

Inducible enzyme forming part of the cytochrome p450 family of enzymes capable of metabolizing ethanol to acetaldehyde

►Hepatic Ethanol Metabolism

Cytochrome P-4502E1

Definition

A specific cytochrome from the huge cytochrome family which is involved in the oxidation of ethanol but also of other ►xenobiotics (procarcinogens and drugs) and which is induced by chronic alcohol consumption.

►Alcohol Consumption

Cytochrome P450 CYP-P450 3A4

Definition

Cytochrome P450 CYP-P450 3A4 is an iron containing enzyme responsible for chemical oxidation (metabolism) of 60% of all drugs.

►ADMET Screen

Cytochrome P_{450} Enzymes

Definition

(CYP) enzymes are a large group of monooxygenase enzymes responsible for the metabolism (both synthesis/bioactivation and breakdown) of thousands of endogenous and exogenous compounds including drugs (Phase I metabolism), toxins, hormones, cholesterol, and vitamins.

►Carotenoids

C

Cytogenetic

Definition

Is the modifier of ►cytogenetics, the study of heredity by examining chromosome structure, learning and describing the relationships between chromosome structure and phenotype, and seeking out the causes of chromosomal abnormalities.

Cytogenetic Alteration

Definition

Chromosomes changes such as deletions, duplications, translocations, and amplifications that are associated with disease states.

►Gastrointestinal Stromal Tumor

Cytogenetic Analysis

Definition

Provides a technique for the evaluation of damage to chromosomes on the basis of direct observation and classification of chromosomal aberrations. Cells arrested in metaphase are examined microscopically for both numerical and structural chromosome aberrations.

Cytogenetic Karyotype

Is the characterization of the chromosomal complement of an individual or a species, including number, form and size of the chromosomes, by conventional banding techniques.

Cytogenetics

Definition

Laboratory analysis of chromosome structure. This analysis requires first growing cells, then "freezing" them in metaphase just prior to the completion of cell division in order to get a good viewing of condensed, paired chromosomes.

►Minimal Residual Disease
►Biomonitoring
►Leukemia Diagnostics

Cytokeratin 19 Fragments (CYFRA 21-1)

Definition

Is a soluble fragment of cytokeratin 19 expressed in normal squamous cells. Elevated serum concentrations are found in tumors of squamous origin, including lung and nasopharyngeal cancer.

►Serum Biomarkers

Cytokeratins

Definition

A large group of proteins expressed in a cell type-specific manner constituting intermediate filaments. They can be used for determining the histological subtype of cancers. A family of intermediate filament proteins that provides structural support to epithelial cells.

►Urothelial Carcinoma

Cytokine

Definition

Any of a variety of secreted polypeptides that control the development, differentiation, and proliferation of hematopoietic cells. The effects of cytokines on lymphocytes are usually mediated through membranebound cytokine receptors and are especially critical during immune responses. A group of proteins mainly functioning as soluble signal transmitters in the immune system. Are primarily released by immune cells but many other cell types can also release cytokines. Direct and mediate various functions of the adaptive and innate immunity and modulate functions of immune cells and other responsive cell types. Their local of systemic effects, elicited by binding to specific cell surface receptors, contribute mainly to innate and adaptive immune responses, so that their production is involved in a range of infectious, immunological, and inflammatory diseases. To this class belong interleukins, interferons, TNF-like molecules, etc. These molecular signals are similar to hormones and neurotransmitters and are used to allow one cell to communicate with another.

►Signal Transducers and Activators of Transcription in Oncogenesis
►Cytokine Receptor as the Target for Immunotherapy and Immunotoxin Therapy

Cytokine Gene Transfer

Definition

Tumor cells can be genetically modified using various gene transfer strategies to transiently or stably express immunostimulatory cytokines in order to enhance their immunogenicity, i.e. their ability to stimulate an anti-tumor immune response. Granulocyte-macrophage colony stimulating factor (GM-CSF) turned out to be one of the most potent cytokines in this regard because it supports growth and differentiation of dendritic antigen-presenting cells which are of key importance for the induction of cellular immunity.

►Melanoma Vaccines
►Granulocyte-Macrophage colony stimulating factor (GM-CSF)

Cytokine Receptor

Definition

Cell surface protein that binds to specific cytokines and transduces intracellular signaling.

►Cytokine Receptor as the Target for Immunotherapy and Immunotoxin Therapy

Cytokine Receptor as the Target for Immunotherapy and Immunotoxin Therapy

Koji Kawakami
Graduate School of Medicine and Public Health, Kyoto University, Kyoto, Japan

Synonyms

Cytokine receptor; Immunotherapy; Cancer vaccines; Immunotoxins

Definition

Cancer ►immunotherapy is the treatment of cancer by improving the ability of a tumor-bearing individual to reject the tumor immunologically. In the case of immunotherapy targeting ►cytokine receptors, delivery of tumor antigen proteins induces immune response against cancer cells bearing such tumor antigen to eliminate them. Cytokine receptor-targeting immunotoxins are proteins containing a bacterial toxin or chemical compound along with an antibody or a ligand that binds specifically to its target receptor. Immunotoxins then internalize through the receptors and achieve cytotoxic effect derived from the toxin moiety.

Characteristics

When cancer cells are generated in a body, a variety of mechanisms cooperate in order to kill the cancer cells. Among these mechanisms, the immune system has an important role to eliminate tumor tissues. First, immunocytes like ►macrophages and ►natural killer (NK) cells are activated to attack the newly formed foreign body. If they were unable to completely remove the cancer cells, T-cells and B-cells are the next players to fight against cancer. Many scientists have tried to find how the natural immune system works in order to control and to beat cancer. As cancer cells are known to express specific antigens or cytokine receptors on their cell surface, these molecules may be utilized as a target for tumor immunotherapy and immunotoxin therapy.

Cytokine Receptor as the Target for Immunotherapy

Cancer immunotherapy attempts to stimulate the immune system to reject and destroy tumors. For example, administration of interferon can activate the systemic immunity. Therapeutic cancer vaccine is also included in this category, which is designed to activate the host immune system against tumor cells. Cancer vaccines take advantage of the fact that certain molecules on the surface of cancer cells are either unique or more abundant than those found on normal or noncancerous cells. These molecules act as antigens, stimulating the immune system to evoke a specific immune response. There are few licensed therapeutic vaccines to date. However, several cancer vaccines are in large-scale ►clinical trials.

The Her2/neu (c-erbB2), the target protein of ►Herceptin®, which is the world's first therapeutic antibody to treat ►breast cancer, has long been studied as a target of cancer immunotherapy. The immunization methodology is variable, including administration of plasmid DNA, recombinant protein, or intracellular domain (ICD) peptide; virus vector delivery; dendritic cell pulse therapy; and combination therapy with adjuvant like granulocyte-macrophage colony stimulating factor (GM-CSF) or with anticancer reagents. Her2/neu immunotherapy has been tested in Phase II clinical trials to treat breast cancer, and in Phase I for various cancer types including ►ovarian cancer, prostate cancer, and ►non-small-cell lung carcinoma. In the Phase II trial contributed by Washington University, the ICD of HER-2 vaccine immunizes breast cancer patients with CD4 + helper T epitopes derived from the HER-2 protein. During ►preclinical testing, the rat neu peptide vaccine is effective because it circumvents tolerance to rat neu protein and generates rat neu-specific immunity. In Phase I study, patients underwent intradermal immunization once a month for a total of six immunizations with GM-CSF as an adjuvant. The endpoint of the study was to evaluate the toxicity and the both cellular and humoral HER-2/neu-specific immunity when the vaccinations were completed. The majority of patients (24 of 27 patients, 89%) developed HER-2/neu ICD-specific T-cell immunity. Out of 27 patients 22 patients (82%) also developed HER-2/neu-specific IgG antibody immunity, and over half of the assessable patients retained HER-2/neu-specific T-cell immunity 9–12 months after the completion of immunizations.

►Vascular endothelial growth factor Receptor-2 (VEGFR2) is highly expressed in neovascular endothelial cells in a tumor tissue. The epitope peptides of VEGFR2 were identified, and stimulation using these peptides induces ►CTLs with potent cytotoxicity in the ►HLA class I-restricted fashion against not only peptide-pulsed target cells but also endothelial cells endogenously expressing VEGFR2. In A2/Kb transgenic mice expressing α1 and α2 domains of human HLA-A*0201, vaccination using these epitope peptides in vivo was associated with significant suppression of the tumor growth and prolongation of the animal survival. A clinical trial has initiated to verify its effectiveness on breast and ►gastric cancer at University of Tokyo, Japan.

Another approach attempts to avoid ►immunologic tolerance to cancer vaccines. Cancer immunotherapy utilizes the host immune system, and tolerance is one of the major causes weakening vaccine efficiency.

If immunologic tolerance could be controlled, it is expected to enhance the effect of a cancer vaccine. There are a variety of other strategies which have shown antitumor activity in mouse model of cancer, e.g., dendritic cells pulsed with EphA2 (►ephrin-A2, an angiogenic factor) epitope peptide, KLH-bound EGF receptor variant III peptide, VEGFR1 epitope peptide, and plasmid DNA of IL-13 receptor α2.

Cytokine Receptor as the Target for Immunotoxin Therapy

Immunotoxins are protein toxins connected to a cell binding ligand or antibody. Classically, immunotoxins were created by chemically conjugating an antibody to a whole protein toxin, or, for more selective activity, by using a protein toxin devoid of its natural binding domain. Immunologic proteins that are smaller than monoclonal antibodies (MAbs), like growth factors and ►cytokines, have also been chemically conjugated and genetically fused to protein toxins. Targeted cancer therapy such as immunotoxin therapy which targets tumor-specific cell surface receptors is one of the most effective strategies against cancer. The targeted agents require a threshold level of receptor expression on the cancer cells to achieve their antitumor activity.

At present, only one agent targeting cytokine receptor, which contains human interleukin (IL)-2 and truncated ►diphtheria toxin (ONTAK), is approved for use in cutaneous T-cell lymphoma (CTCL). ONTAK, or Denileukin diftitox, is a fusion protein designed to direct the cytocidal action of diphtheria toxin to cells which express the IL-2 receptor (IL-2R). Among three forms of IL-2R, the high affinity form consisting of CD25/CD122/CD132 subunits is usually found only on activated hemocytes as T lymphocytes, B lymphocytes, and macrophages. A Phase III randomized, double-blind clinical trial was conducted in 71 patients with recurrent or persistent, Stage Ib to IVa CTCL whose malignant cells express the CD25 component of the IL-2R. Administered with 9 or 18 μg/kg/day of ONTAK as an intravenous infusion daily for 5 days every 3 weeks (median: 6 courses), seven patients (10%) achieved a complete response and 14 patients (20%) achieved a partial response. In 1999, the US FDA approved ONTAK indicated for the treatment of patients with persistent or recurrent CTCL whose malignant cells express CD25 component of the IL-2R.

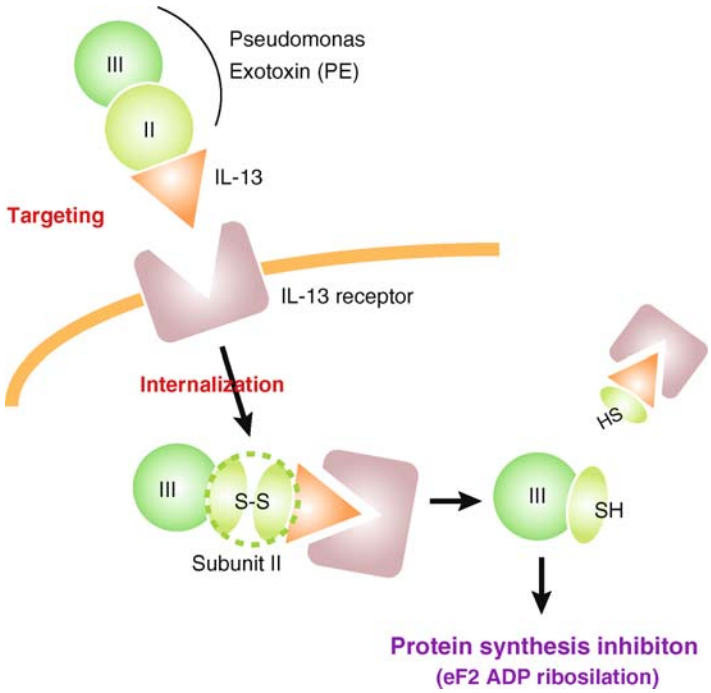
In the case of the IL-13 receptor (IL-13R) system, these receptors are constitutively overexpressed on a variety of human solid cancer cells including ►renal cell carcinoma, glioma, AIDS-associated ►Kaposi sarcoma, head and neck cancer, ovarian cancer, and prostate cancer. To target IL-13R, a recombinant fusion IL-13 cytotoxin termed IL13-PE38QQR, or Cintredekin besudotox, has been developed that is composed of IL-13 and a mutated form of ►*Pseudomonas* exotoxin. In early-phase studies, Cintredekin besudotox was administered via intraparenchymal convection-enhanced delivery (►CED) after resection of supratentorial recurrent malignant glioma. CED is a novel approach for the delivery of small and large molecules in solid tissues, utilizing a pressure gradient to distribute macromolecules to clinically significant volumes of tissue by bulk flow. The CED of Cintredekin besudotox was fairly well tolerated, with a reasonable benefit/risk profile for treatment of patients with glioma. It has received orphan drug designation in Europe and the US as well as fast-track drug development program status from the FDA (Fig. 1).

The ►interleukin-4 receptor (IL-4R), which is related to the IL-13R, is also expressed by a variety of solid tumors and ►hematologic malignancies. The IL-4 cytotoxin, IL4(38–37)-PE38KDEL, which is composed of circular permuted IL-4 and a mutated form of *Pseudomonas* exotoxin, is highly active in killing IL-4R-expressing tumor cells in vitro and in vivo. In a Phase I/II trial of 31 glioma patients, tumor necrosis was observed in 71% of patients, and one patient experienced long-term survival. The Phase II intratumoral study had been completed, but further development has stalled because of severe adverse events as infusion concentration of drug was possibly too high.

TransMID™, a modified diphtheria toxin conjugated to transferrin, is currently in Phase III clinical trials indicated for the treatment of ►Glioblastoma multiforme. Transferrin receptors are particularly prevalent on rapidly dividing cells, and the high level of transferrin receptor expression on glioma cells makes it an ideal target for brain cancer. Phase I and Phase II clinical trials for TransMID™ have been successfully completed in patients suffering from inoperable, recurrent high grade gliomas who have failed to all other forms of treatment. In Phase II study, a reduction in tumor size of 50% or more was noted in 35% of evaluable patients, with a corresponding increase in life expectancy in those patients that did respond. In this study, median survival for patients receiving TransMID™ was ~37 weeks. TransMID™ received fast-track status from the FDA, and orphan drug designation in the US, Europe, and Japan.

TP-38 is a recombinant chimeric targeted toxin composed of the EGFR binding ligand TGF-α and a genetically engineered form of the *Pseudomonas* exotoxin, PE38. A Phase I trial was conducted to define the maximum tolerated dose (MTD) and dose limiting toxicity of TP-38 delivered by CED in patients with recurrent malignant brain tumors. The Phase II studies, in which TP-38 was administered to patients with recurrent glioblastoma using CED, have shown initial encouraging results.

DT388GMCSF has been developed for the treatment of ►acute myeloid leukemia (AML). This molecule



Cytokine Receptor as the Target for Immunotherapy and Immunotoxin Therapy. Figure 1 Model for cytokine receptor-targeted cancer therapy. In this model, IL-13R expressing cancer cells are treated with IL-13 immunotoxin. When IL-13 moiety of this immunotoxin binds to IL-13 receptor, the receptor–immunotoxin complex immediately internalizes into cytosol. Then domain II of *Pseudomonas* exotoxin (PE) is degraded in endosome and domain III of PE shows cytotoxic effect through its irreversible inhibition of eF2.

is composed of amino acids 1–388 of diphtheria toxin (DT), a histidine–methionine linker, and amino acids 1–124 of human GM-CSF. Phase I clinical trial has been completed in patients with AML, and 4 of 37 patients showed clinical remission of disease.

Another unique DT-based approach is VEGF121-DT385 and VEGF165-DT385 immunotoxins, which is a chemical conjugate containing VEGF165, VEGF121, and truncated DT. ►Vascular endothelial growth factor (VEGF) is the most critical inducer of blood vessel formation. In vivo animal studies have shown that these molecules are able to inhibit angiogenesis and tumor growth.

Cytokinesis

Definition

The last stage of cell division whereby the cytoplasm shared between the mother and daughter cells are split, and cellular content and organelles are redistributed. It usually starts during the late stages of mitosis, splitting a binucleate cell into two cells.

►Micronucleus Assay
►Mitosis

Cytologist

Definition

A professional who works in ►cytology. This can be either a cytopathologist or a cytotechnologist.

►Aspiration Cytology
►Fine Needle Aspiration

Cytology

Definition

Synonym cytopathology; The study of the origin, form, and function and pathology of cells. The medical specialty dealing with the microscopic examination of individual cells and small clusters of cells for the diagnosis of diseases, including cancers.

►Fine Needle Aspiration
►Molecular Pathology

Cytolytic Synapse

Definition

Forms as a cell-cell junction at the contact site between a cytolytic effector (cytotoxic T cell or natural killer cells (NK) cell) and a target cell and serves as a signaling platform; for example cytotoxic granule contents are released into the synapse before entering the target cell; it is also referred to as immunological synapse (IS).

►Natural Killer Cell Activation

Cytometry

Definition

Fluorescence antibodies oustains are applied to cells, and the cell expression of proteins nucleic acids are analyzed to determine the cell type. Cancer cells often show a different pattern of cell surface proteins or DNA content than their normal counterparts.

►Minimal Residual Disease

Cytomorphology

Definition

Microscopic examination of peripheral blood and bone marrow smears using panoptic stains.

►Leukemia Diagnostics

Cytopathologist

Definition

A board certified pathologist who sub-specializes in ►cytopathology. In many countries, an additional year of graduate training in an accredited cytopathology program, followed by successful completion of subspecialty board exams is required.

►Fine Needle Aspiration
►Cytology

Cytopenia

Definition

Refers to a deficiency of cellular element of the blood pancytopenia – an abnormal deficiency in all blood cells (red blood cells and white blood cells and platelets); usually associated with bone marrow tumor or with aplastic anemia haematocytopenia, hematocytopenia – an abnormally low number of red blood cells ►thrombocytopenia – A decrease in the number of platelets.

Cytoplasmic Scaffolding Apoptotic Protease Activating Factor

►APAF-1 Signaling

Cytoplasmic 7SL RNA

Definition

One of the components of the signal recognition particle (SRP) that functions in protein translocation across the endoplasmic reticulum.

►ALU Elements

Cytoprotective Adjuvant

Definition

A drug, chemical or therapy used in conjunction with chemotherapy to reduce or eliminate the adverse effects of chemotherapeutic drugs or radiation.

►Chemoprotectants
►Chemothrapy of Cancer

Cytoreduction

Definition

A surgical procedure that involves visceral resections and peritonectomy procedures so that the peritoneal dissemination is resected to the extent that only cells remain behind as residual disease.

►Appendiceal Epithelial Neoplasms

Cytoreductive Surgery

Definition

Refers to cytoreduction; removal of the major portion of the material composing a lesion. Removal of excess bulk of tissue from a lesion either to assist in healing or as an adjunct to chemotherapy. For instance, cancers of the ovary and fallopian tube tend to spread to the abdominal and pelvic areas. There may be cells found under the diaphragm, on the outsides of digestive organs, or in the omentum, an apron of fatty tissue roughly in front of the small intestine. During cytoreductive surgery, the surgeon carefully looks for all signs of cancer in the abdomen, and removes as much of the tumor as possible. Usually the omentum is removed as well. This makes it more likely that chemotherapy and/or radiation can kill the remaining cancer cells.

►Debulking Surgery
►Surgical Debulking

Cytoreductive Surgery

Definition

►Peritoneal Debulking Surgery

Cytoskeleton

Definition

Is a network of polymeric proteins organized in filaments (microtubules, microfilaments and intermediate filaments) that gives shape to the cell and contributes to transport of molecules inside the cell. It is an intracellular network of structural protein filaments (including actin filaments, microtubules and intermediate filaments like keratins, vimentin, desmin and neurofilaments). The cytoskeleton directs cell shape, mediates the anchoring and movement of cell organelles and is necessary for cell division. It is linked to cell-cell and cell-substrate cell adhesion molecules and increases the structural integrity of tissues and organs.

►Adhesion
►Cell Adhesion Molecules

Cytosol

Definition

The fluid portion of the cytoplasm, outside the organelles.

Cytosolic Transglutaminase

►Transglutaminase-2

Cytostasis

Definition

Arrest of cell growth and proliferation.

Cytostatic

Definition

Resulting in stopping cell division, but not necessarily cell death.

Cytotactin

►Tenascin-C and Cancer

Cytotechnologist

Definition

A medical laboratory specialist who works in the field of ►cytopathology. In many countries, a cytotechnologist must be a graduate of an accredited school of cytotechnology and must have successfully completed board certifying exams. Most cytotechnologists also hold a bachelor's degree.

►Fine Needle Aspiration

Cytotoxic Carcinogen

Definition

A carcinogen causing damage to cell structure or function.

►Toxicological Carcinogenesis

Cytotoxic Chemotherapy

Definition

Involves treatment with chemicals having selective toxicity for cancer cells.

►Chemotherapy
►Estrogenic Hormones

Cytotoxic T Cells (CTLs)

Definition

Synonym Cytotoxic T Lmphocytes; CTLs bear a heterodimeric T cell receptor (TCR) composed of alpha (α) and beta (β) chains that recognize fragments of antigenic proteins, which are associated with Major Histocompatibility Complex (MHC) class I molecules, on the surface of a cell. CTLs bear the CD8 receptor that also associates with MHC class I. This interaction can result in CTL activation and expansion. Activated CTLs secrete cytokines and can kill target cells expressing the same MHC/antigen complex. Since, with a few exceptions, all nucleated cells express ►MHC class I, the role of CTL is to monitor all the cells of the body, ready to destroy any that express foreign antigen fragments in their class I molecules. Thus, they are very important in killing infected cells and clearing viral and intracellular pathogen infections. They are also competent to kill tumor cells that express tumor-associated antigens.

►Immunoediting
►Peptide Vaccines for Cancer
►GAGE Proteins
►Interferon-α

Cytotoxic T Lymphocytes

Definition

Cytotoxic T lymphocytes, or killer T cells, are cells of the immune system that are responsible for the destruction of tumors, elimination of cells infected by virus, organ transplant rejection and autoimmunity.

►BORIS

Cytotoxins

Definition

Cytotoxins are proteins made by cytotoxic T cells that participated in the destruction of target cells. Perforins, granzymes, and granulysins are the major defined cytotoxins.

►Sjögren Syndrome

Cytovilin

►ERM Proteins

DAC

►A5-aza-2′ Deoxycytidine

Dacogen

►A5-aza-2′ Deoxycytidine

DAF

►Decay-Accelerating Factor

DAG

Definition
Diacylglycerol.

Diadzein

Definition
One of several known ►isoflavones, diazein is found in a number of plants, with soybeans and soy products like tofu and textured vegetable protein being the primary food source.

►Chemoprotectants
►Genistein

Daltons

Definition
Are atomic mass units. The simplest atom, hydrogen exists as hydrogen gas (H2) and has an atomic mass of two (2 atoms of mass 1). A single atom of oxygen has 16 mass units (16 Da).

►ADMET Screen

Damage Response

►Stress Response

DAMP

Definition
Acronym for Damage-associated molecular pattern molecules; ►Activated Natural Killer Cells.

Danazol

Definition
A drug used for the treatment of ►endometriosis and other diseases. It combines androgenic activity with anti-estrogenic and anti-progestogenic activity.

DAP6

►Daxx

DAP-10

Definition
DNAX Activation Protein of 10kDa, a signaling adaptor associated with NKG2D. Synonyms are Hcst: Hematopoietic cell signal transducer; KAP10: Killer activating protein 10.

►NKG2D Receptor

DAP-12

Definition
DNAX activation protein 12. A signaling adaptor associated with NKG2D in the mouse. Synonyms are KARAP: Killer-activating receptor-associated protein; TYROBP: TYRO protein tyrosine kinase-binding protein

►NKG2D Receptor

DARC

►Duffy Antigen Receptor for Chemokines

Darier Sign

Definition
Skin lesions that urticate when rubbed or irritated.

►Mastocytosis

Dasatinib

Definition
An oral medication approved as therapy for patients with ►chronic myeloid leukemia and ►Philadelphia chromosome-positive ►acute lymphoblastic leukemia. It is a tyrosine kinase inhibitor, effective against several tyrosine kinases. Is capable of inhibiting ►BCR-ABL, c-KIT, EPHA2, PDGFRβ and ►SRC family kinases (►SRC, LCK, YES, FYN). Dasatinib was originally developed to treat patients with chronic myelogenous leukemia who failed to respond to ►imatinib due to imatinib-resistant mutations in the ►BCR-ABL1 drug target.

►Mastocytosis
►Tyrosine Kinase Inhibitors

Data Over-Fitting

Definition
As in all research with high dimensional data, two practical realities constrain the analysis of mass spectra in ►proteomics. The first is that the data are typically characterized by thousands of features. The second is that the number of samples is limited. Relations that appear statistically significant are just noise. It occurs when the complexity of the statistical model is too great for the present amount of data.

►Oncopeptidomics

Daughter Cells

Definition
Cells that arise from the division of another cell (the parent cell).

►Mitosis

Daunorubicin

Definition
Is an ►anthracycline antineoplastic antibiotic isolated from cultures of *Streptococcus peucetius* var. *caesius*.

►Adriamycin

Daxx

Sheng-Cai Lin
Department of Biomedical Sciences, School of Life Sciences, Xiamen University, Xiamen, Fujian, China

Synonyms

Death-associated protein 6; DAP6; BING2; MGC126245; MGC126246

Definition

Daxx was originally identified as a protein factor that binds to a transmembrane receptor called Fas (►Fas/Apo-1/CD95), one member of the ►tumor necrosis factor receptor superfamily. The extracellular region of Fas is where its ligand, FasL, binds. The intracellular tail shares sequence similarity with another member of the TNF receptor family, TNF receptor I (TNFRI). The shared sequence is termed death domain for its critical role in signaling cell death upon ligand binding.

Characteristics

Since its identification in 1997, Daxx has been intensively investigated for its biological functions. However, up to date the three-dimensional crystal structure of Daxx has not been resolved. Human Daxx protein is a polypeptide of 740 amino acid residues in length. As depicted in the schematic diagram (Fig. 1), Daxx contains several putative domains and many binding sites for interacting with a wide spectrum of proteins including transcription factors, kinases, tumor suppressors, and chromatin remodeling factors. It is worth to note that for the influence from its acidic region, Daxx displays an aberrant molecular weight during electrophoretic migration on gels, being 120 kDa instead of the calculated 81.3 kDa.

Basic Information

Human *Daxx* gene is mapped to 6p21.3 in the major histocompatibility complex (MHC) region, and transcribes a single 2.4 Kb RNA. It is ubiquitously expressed in human tissues, and is highly conserved in mammals with 69% identity between the human and mouse proteins. Currently at least 35 molecules have been known to interact with Daxx, which were identified by various methods including yeast two-hybrid screening, coimmunoprecipitation, and immunofluorescent costaining in the cell. Most notably, Daxx interacts with the ►tumor suppressor ►p53, ►Axin (Axis inhibitor), ►ubiquitin ligase ►Mdm2 (mouse double minute 2), the Ser/Thr kinase ►HIPK2 (homeodomain-interacting protein kinase 2), and the product of the promyelocytic leukemia (►*PML*) gene.

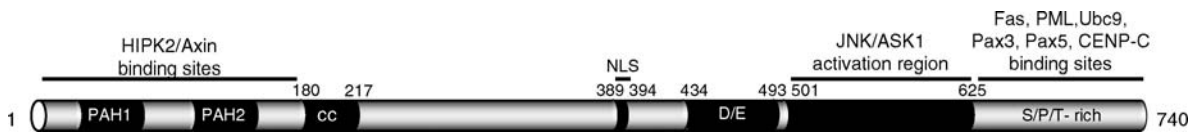
Subcellular Distribution of Daxx Protein

Daxx is predominantly localized in the nucleus. Daxx and PML interact with each other and are colocalized in nuclear punctuate structures known as nuclear bodies (NBs) that have been involved in various processes such as transcriptional regulation, apoptosis, genome stability, and tumor suppression. PML protein is an important tumor suppressor that is essential for the formation of the nuclear bodies, as deletion of the *PML* gene by genetic knockout can fully abrogate the formation of these structures. In $pml^{-/-}$ cells that lack PML-NBs structures, the ability of Daxx to induce cell death is abolished, underscoring the importance of PML for cell death induction by Daxx-mediated signaling.

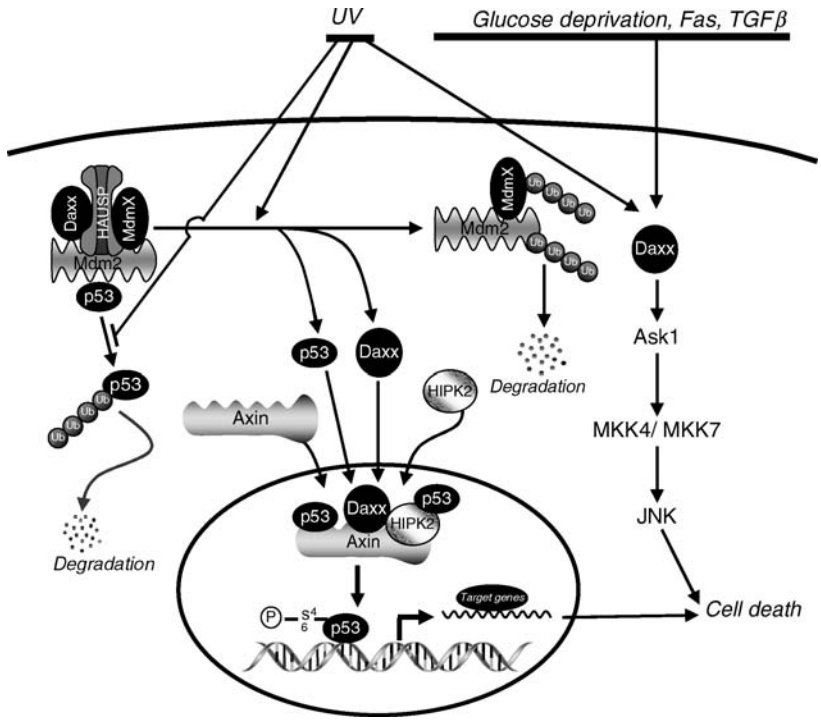
Daxx Mediates Stress-Induced Cell Death

Daxx has been implicated in the modulation of apoptosis induced by a wide range of stimuli, including ►ultraviolet radiation, hydrogen peroxide, ►arsenic trioxide, Fas ligand, transforming growth factor beta (►TGF-β), and interferon-γ. As summarized in Fig. 2, two main apoptotic pathways are thought to be mediated by Daxx.

- The first reported mechanism for Daxx to induce apoptosis is through association and subsequent activation of apoptotic signal-regulating kinase 1 (►ASK1), an upstream kinase of JNK MAP kinase that leads to activation of c-jun N-terminal kinase (►JNK). Recently, glucose deprivation as a stress



Daxx. Figure 1 Schematic diagram showing various domains of Daxx. Human Daxx is a protein with 740 amino acid residues in length that contains several putative domains: two N-terminal paired amphipathic helices (PAH1 and PAH2), a coiled-coil region, an acidic domain (D/E), and a Ser/Pro/Thr-rich domain (S/P/T). Axin and HIPK2 associate with Daxx through binding sites on the N-terminal portion. A region between amino acid 501 and 625 is required for ASK1 binding and the subsequent activation of JNK. The Ser/Pro/Thr-rich domain contains sites for interaction with a series of protein, such as Fas, PML, Ubc9, and CENP-C.



Daxx. Figure 2 Schematic representation of two possible pathways through which Daxx mediates cell death. Upon stimulation by stress signals such as UV and nutrition deprivation, Daxx becomes associated with ASK1, leading to activation of JNK MAP kinase that is required for cell death induction. In parallel, UV irradiation causes dissociation of p53-destabilizing complex to release p53 and Daxx which then assemble into a p53-activating complex consisting of p53, Axin, Daxx, and HIPK2. Upon complex formation, HIPK2 is activated and activates p53 by phosphorylating it at Ser46. As a result, p53 target genes related to apoptosis are activated.

can also stimulate the association of Daxx to ASK1 and activate Daxx-dependent ASK1 activation. TGF-β is a multifunctional growth factor that has principal roles in growth control. In a yeast two-hybrid screening using the cytoplasmic domain of the type II TGF-β receptor as bait, Daxx was found to interact with this receptor and mediate TGF-β-induced apoptosis via facilitating JNK activation. Interference of Daxx function by truncated Daxx mutants or by knockdown of Daxx expression can inhibit TGF-β-, UV-, or oxidative stress-induced apoptosis.

- Another means adopted by Daxx to induce cell death is through Axin/HIPK2/p53 complex. Currently, the best characterized role of Daxx is its ability to modulate the function of the tumor suppressor ►p53, which is mutated in over 50% of all tumor tissues. p53 exerts its tumor suppressional roles by acting as a transcription factor. Upon DNA damage, p53 is activated, which results in cell cycle arrest or apoptosis by inducing expression of a series of proteins such as p21, ►GADD45 (growth arrest and DNA damage), and ►PUMA (p53 upregulated modulator of apoptosis). HIPK2, an upstream Serine/Threonine kinase of p53, can specifically phosphorylate p53 at serine 46 upon UV irradiation and plays an important role in UV-induced p53-mediated apoptosis. ►Axin is a negative regulator of Axis formation in the development of mouse embryos, its deficiency can lead to axis duplication. In recent years, accumulating evidence demonstrates that this protein functions as a tumor suppressor. It has been shown that UV irradiation can enhance the association of Daxx and Axin. Further investigation demonstrates that Axin tethers Daxx to p53, and cooperates with Daxx to stimulate HIPK2-mediated Ser46 phosphorylation and transcriptional activity of p53. Axin is required for Daxx-induced p53 activation and apoptosis, as in $Axin^{-/-}$ cells the ability of Daxx to induce cell death is dramatically attenuated. Downregulation of HIPK2 by specific siRNA remarkably suppresses Daxx-induced apoptosis, suggesting that HIPK2 plays crucial role in Daxx-induced cell death. All above evidence indicates that formation of a new complex containing Daxx/Axin/p53/HIPK2 is important for Daxx-induced cell death. Knock-down of Axin and Daxx by ►siRNA can strongly attenuate UV-induced cell

death, demonstrating that Daxx and Axin complex plays a critical role in UV-triggered cell death.

In Unstressed Cells, Daxx Seems to Play an Antiapoptotic Role

Daxx may also destabilize p53 by promoting the function of Mdm2, a ►ubiquitin ligase E3 that facilitates p53 ►ubiquitination and degradation. In unstressed cells, Daxx simultaneously interacts with Mdm2 (heterodimerized with ►MdmX) and the deubiquitinase ►HAUSP (herpes-associated ubiquitin-specific protease). In this complex, Daxx can stimulate the stabilizing effect of Hausp on Mdm2, which results in accumulation of Mdm2 in the cell. Moreover, Daxx enhances the intrinsic E3 activity of Mdm2 toward p53 leading to the inhibition of the antiproliferative effects of p53. Upon DNA damage, Daxx, HAUSP, and p53 dissociate from Mdm2, which allows Mdm2–MdmX complex to undergo autoubiquitination and subsequent degradation. The dissociated Daxx and p53 may then form an apoptotic complex with HIPK2 and Axin in the nucleus, in which Daxx and Axin cooperatively promote the HIPK2 kinase activity toward p53 at Serine 46. Therefore, in response to stress signals, Daxx enhances the death-inducing function of p53, suggesting that Daxx in fact may exert opposing roles in controlling p53 activity depending on cellular states. However, the detailed molecular mechanisms as to how Daxx dissociates from the Daxx/Mdm2/HAUSP/Mdmx complex and recycles to form an apoptotic complex upon DNA damage remain to be clarified in the future.

Death-associated protein 6

►Daxx

Death Domain

Definition

DD; A conserved cytoplasmic domain of death receptors (►TRAIL-R2 and ►TNF-R1). Via this domain, death receptors can bind other death domain-containing proteins that act as adaptor proteins for binding ►caspase-8 and/or caspase-10. The death domain is a characteristic region of 80 amino acids in the cytoplasmic tail of death receptors of the TNF receptor superfamily that mediates protein–protein interaction with DD-containing adaptor molecules such as FADD or TRADD.

►Caspase-8
►TNF-Related Apoptosis Inducing Ligand (TRAIL)

Death-Effector-Domain

Definition

DED; Is a protein interaction domain comprised of six α-helical structure. DEDs are found in seven pro- or antiapoptotic proteins involved in the regulation of ►apoptosis and proliferation, i.e. ►caspase-8, caspase-10, ►FADD, c-FLIP, PEA-15/PED, DEDD, and DEDD2.

►TNF-Related Apoptosis Inducing Ligand

Death-Inducing Signaling Complex

Definition

DISC; Is a multiprotein complex that is formed upon crosslinking of death receptors such as ►CD95, ►TRAIL-R1, and TRAIL-R2 by their respective ligands, i.e., CD95 ligand or TRAIL, or agonistic antibodies. It consists of oligomerized death receptors, ►FADD, ►caspase-8 and -10 and is essential for transmitting the apoptotic signal from ►death receptors at the cell surface to the cytoplasmic caspase cascade.

►Apoptosis

Death Receptor-3

Definition

DR3; Is a member of the ►tumor necrosis factor receptor superfamily. These receptors are characterized by the presence of a 70–80 amino-acid homologous

region in the cytoplasmic tail called the death domain. The signaling pathways induced by these receptors rely on oligomerization by ligand binding, recruitment of death domain proteins like TRADD, FAD or RIP1 and subsequent activation of the caspases apoptotic cascade or the transcription factor NF-kappa-B. DR3 is preferentially expressed in peripheral blood leukocytes, and lymphocytes-rich tissues and to a lesser extent in small intestine and colon. The precise role of DR3 is unclear. However, its ectopic expression in mammalian cells induces ►apoptosis and activates the transcription factor NF-kappa-B, depending on the cytoplasmic effectors engaged in the signaling complexes downstream of the death domain. DR3 is also expressed in colon carcinoma cells and is involved in binding to E-selectin and in providing a metastatic advantage to the cancer cells.

►E-selectin-Mediated Adhesion
►Nuclear Factor Kappa B

Death Receptor Apoptosis Pathway

Definition

Also known as the extrinsic death pathway, this pathway is initiated by the death receptor at the cell surface. The receptors include Fas (►CD95), TNF-R1 (CD120a), ►TRAIL-receptor I (DR4) and TRAIL-receptor II (DR5). Upon engagement by their ligands, FasL, TNFα or TRAIL, respectively, the receptors oligomerize and internalize, which subsequently recruit adaptor molecules, such as ►FADD and TRADD. The initiator caspases, ►caspase-8 or caspase-10 are recruited to this ►death inducing signaling complex (DISC) and activated. Subsequently, the effector caspases are activated and ►apoptosis occurs. The initiate caspases could also activate Bid, which then activates the ►mitochondria apoptosis pathway. The latter is particularly important for caspase activation in the so-called Type II cells, which include hepatocytes and certainly lymphoid cell lines.

►Bid

Death Receptors

Definition

Belong to the ►tumor necrosis factor (TNF) receptor gene superfamily, which is defined by similar, cysteine-rich extracellular domains. The death receptors also contain a homologous cytoplasmic sequence termed the "►death domain". Death domains typically enable death receptors to engage the cell's apoptotic machinery, but in some instances they mediate functions that are distinct from or even counteract apoptosis. Some molecules that transmit signals from death receptors contain death domains themselves.

Decatenation G2 Checkpoint

William K. Kaufmann
Department of Pathology and Laboratory Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Definition

A surveillance system that ensures that ►mitosis does not begin before ►sister chromatids have been sufficiently decatenated.

Characteristics

During DNA replication, daughter DNA duplexes become catenated or entangled through knots and links. These knots and links must be removed before sister chromatids can be properly segregated during mitosis. Type II DNA ►topoisomerases are enzymes that remove knots and links through a concerted set of reactions in which a protein-associated DNA double-strand break is generated, another segment of DNA is passed through the break, and the protein-associated double-strand break is reversed. The decatenation G2 ►checkpoint is an active signal transduction pathway that monitors topoisomerase II-dependent DNA decatenation and controls the location and/or

activity of ►mitosis-promoting factor to delay the onset of mitosis.

Molecular Biology

Drugs that inhibit topoisomerase II fall into two groups known as poisons and catalytic inhibitors. Topoisomerase II poisons stabilize the enzyme when in a covalent complex with cleaved DNA strands. Proteolysis of the protein produces frank DNA double-strand breaks which are potentially lethal lesions. Topoisomerase poisons such as doxorubicin and etoposide are among the most widely used and successful of cancer chemotherapeutic drugs. The catalytic inhibitors of topoisomerase II prevent the enzyme from forming protein-associated DNA double-strand breaks; by preventing formation of protein-associated DNA double-strand breaks, catalytic inhibitors are able to block the toxicity of the poisons.

There are two type II topoisomerases in mammalian cells. Topoisomerase IIβ is a non-essential enzyme that is constitutively expressed in quiescent and proliferating cells. Topoisomerase IIα is an essential enzyme whose level of expression is tightly regulated in the cell division cycle. Maximal expression occurs in G2 and M when ►topoisomerase II is required to separate linked sister chromatids and condense mitotic chromosomes. Catalytic inhibitors of topoisomerase II include ICRF-193 and ICRF-187. ICRF-193 causes mammalian cells to delay progression from G2 to mitosis, and impedes separation of sister chromatids at anaphase in mitosis. This behavior suggests that cells monitor the state of chromatid catenation in G2 and delay entry to mitosis until ►sister chromatids are sufficiently decatenated. Because chromatids retain some catenations into metaphase of mitosis, the decatenation G2 checkpoint monitors the sufficiency of decatenation, not its completion.

Both ICRF drugs cause cells to delay progression from G2 to mitosis. The G2 delay was established as an active checkpoint when various loss-of-function mutations or genetic alterations were shown to reverse the delay. The decatenation G2 checkpoint requires signaling by ►ATR, ►CHK1, ►BRCA1 and WRN to block cellular entry to ►mitosis. Override of decatenation G2 checkpoint function using caffeine induces chromosome aberrations (breaks and exchanges) as mitotic cells attempt to condense and segregate knotted and linked chromatids.

The transition from G2 to mitosis (►G2/M transition) is controlled by mitosis-promoting factor, a ►cyclin-dependent kinase made up of a catalytic subunit, CDK1, and a regulatory subunit, cyclin B1. Cyclin B1/CDK1 complexes can initiate all steps of mitosis including nuclear envelop breakdown, chromosome condensation and formation of the mitotic spindle apparatus. Cyclin B1 is co-regulated with topoisomerase IIα, with peak levels of expression in G2 and mitosis. The activity of mitosis-promoting factor is regulated by phosphorylation/dephosphorylation. Inhibitory phosphates in the enzyme catalytic site are removed at the onset of mitosis by CDC25B/C. Cyclin B1/CDK1 complexes also are actively exported from the nucleus during G2 but at the ►G2/M transition this exportation is inhibited, intra-nuclear transport is enhanced and mitosis-promoting factor accumulates in the nucleus. The decatenation G2 checkpoint blocks cellular progression from G2 to mitosis by preventing the accumulation of mitosis-promoting factor in the nucleus. The decatenation G2 checkpoint appears to function by inhibiting the activity of the Polo-like kinase PLK1 that stimulates nuclear accumulation of mitosis-promoting factor.

Clinical Implications

The decatenation G2 checkpoint is a dependency checkpoint that ensures that an essential event in the ►cell cycle (chromatid decatenation) is achieved before a dependent downstream event (chromatid condensation and separation in mitosis) is initiated. Failure of decatenation G2 checkpoint function is expected to cause instability of chromosome numbers and structure (►Chromosomal instability). Insufficient decatenation can cause non-dysjunction errors when the mitotic spindle breaks, producing ►aneuploidy; alternatively, linked chromatids may break under the force of chromatid condensation or segregation producing deletions, amplifications and rearrangements. Cells with defective decatenation G2 checkpoint function due to defects in ATR, CHK1, BRCA1 and WRN display severe chromosomal instability.

Some bladder, breast and lung cancer lines display defects in decatenation G2 checkpoint function. The breast cancer susceptibility gene BRCA1 is not only required for decatenation checkpoint function, it also regulates the decatenatory activity of DNA topoisomerase IIα (►Breast cancer genes BRCA1 and BRCA2). BRCA1 contains an ubiquitin-ligase activity that is expressed in the presence of the cofactor BARD1. BRCA1 regulates ►ubiquitination of topoisomerase IIα and ubiquitination stimulates decatenatory activity of topoisomerase IIα. Thus, breast cancers with inactivation of ►BRCA1 may display less chromatid decatenation by topoisomerase IIα. BRCA1 also serves as a mediator in DNA damage and decatenation G2 checkpoints, enhancing phosphorylation by checkpoint kinases of their downstream targets. Breast cancers with defects in BRCA1 are less able to decatenate daughter chromatids and less able to delay mitosis when chromatids are catenated.

►Lung cancer lines with defects in decatenation G2 checkpoint function display hypersensitivity to

killing by ICRF-187. This suggests that topoisomerase IIα catalytic inhibitors may be clinically useful for selected cancers.

►Cancer stem cells represent immortal clones that drive malignant progression (►Stem cells and cancer). Mouse embryonic stem cells and human hematopoietic stem cells when grown in cell culture display a defect in the decatenation G2 checkpoint. Because decatenation G2 checkpoint function preserves chromosomal stability during cell division, a checkpoint defect may promote ►chromosomal instability in cancer stem cells.

Decay-Accelerating Factor

Burkhard H. Brandt
Institute for Tumour Biology, University Medical Centre, Hamburg, Germany

Synonyms

CD55; Decay-accelerating factor for complement; Antigen of the Cromer blood group; DAF

Definition

Decay-accelerating factor (DAF) participates in the regulation of complement system activity by accelerating the decay of the C3/C5-convertase of the classic as well as of the alternative pathway. The highly polymorphic 50–100 kDa protein facilitates complement regulation by cystein-rich complement control protein repeats (CCP). Most of the DAF isoforms are linked to the cell membrane by a glycosyl phosphatidylinositol (GPI) anchor following the CCPs.

Characteristics

DAF has been detected in all mammalians. Physiologically it is expressed in all cells contacting the complement system enclosing cells within the peripheral blood and epithelial as well as endothelial cells. Soluble DAF is detectable in plasma, tears, saliva, and urine, as well as in synovial and cerebrospinal fluids. Besides its function as a regulator of the complement system DAF inhibits ►natural killer cells, is a ligand of the CD97 receptor, and a receptor for viruses and microorganisms. DAF is also involved in the development of spermatozoa and their survival within the female genital tract.

DAF is a glycoprotein appearing as different isoforms depending partially on different posttranslational glycosylation patterns and on alternative splicing. The DAF protein possesses four units for the control of complement activation following each other and that are designated as CCP 1–4. Therefore, the molecular weight of the mature protein varies between 50 and 100 kDa in different cell types.

DAF has been detected in different malignancies, e.g., ►CLL, ►CML, ►ALL, ►AML, ►colorectal cancer, ►gastric cancer, ►thyroid cancer, ►medullary thyroid carcinoma, malignant ►glioma, ►breast cancer, ►renal cancer, ►non-small cell lung cancer, ►ovarian cancer, ►cervical cancer, and also partially in metastases of colorectal carcinomas. Furthermore, DAF is frequently overexpressed within the stroma of colorectal tumors suggesting that DAF comes from the tumor cells and is either cleaved from the cell membrane into the environment or is secreted by the tumor cells as a soluble form. Expression of more than one DAF isoform originated from different glycosylation patterns (colon cancer) or alternative splicing (breast cancer) has been detected.

Actions of DAF in Cancer (Tab.1)

DAF expression in cancer cells is upregulated by ►interleukins (►IL-4, IL-1α, IL-1β), cytokines (►TNF-α, ►IFN-γ), growth factors (►EGF, ►bFGF), ►prostaglandins (E2), and complement regulatory protein protectin (CD59).

DAF decreases complement deposition on tumor cell membranes as well as complement-mediated lysis in melanomas, renal tumors, thyroid, lung, squamous cell, and cervical carcinoma as well as in some hematological malignancies. DAF decreases cell adhesion of T-lymphocytes to leukemic cells as well as inhibiting effect on ►NK cells which could impair immune surveillance of cancer cells.

The GPI-anchored and membrane linked form of DAF is part of a signal transduction cascade. In consequence, tyrosine phosphorylation in malignant tumors functioning within signal transduction goes far beyond immune modulating effects. For example, the tyrosine

kinase p56lck participates in a signal cascade conveying active motility of breast cancer cells.

DAF has been identified as ligand of the surface receptor CD97 (EGF-TM7), which belongs to the family of class B seven-span transmembrane (TM7) receptors. Predominantly expressed in hematopoietic cells, CD 97 is ectopic expressed in human thyroid, colorectal, gastric, pancreatic, esophageal, and oral squamous cell carcinomas. CD97 promotes invasive growth, ►migration, and ►angiogenesis. DAF, being the ligand of CD97, is synthesized and secreted by colorectal carcinoma cells leading to an autocrine stimulation of invasive growth, migration, and ►metastasis of these cells. A similar mechanism takes place in breast cancer cells as ►HER2-positive mammary carcinoma cells showing increased transendothelial invasiveness selectively overexpress and secrete a 45 kDa splice variant of DAF (Table 1).

Perspectives in Cancer Therapy (Table 2)

Removal of DAF from the cell membrane or neutralization of the protein increases the intensity of a potential

Decay-Accelerating Factor. Table 1 Versatile actions of Decay-accelerating factor in cancer

Action	Mechanisms
►Carcinogenesis	Upregulation of DAF in cancer and precancerous lesions (factors regulating DAF expression: IL-4, IL-1α, EGF, PGE2, TNFα, IFNγ, thrombin, βFGF, VEGF, CD59)
Complement inhibition	Decay-acceleration of the C3/C5-convertase leading to decrease in complement deposition and in complement-mediated lysis of cancer cells
Inhibition of natural killer (NK) cells	Downregulation of NK cell-mediated cell lysis
Oncogenic tyrosine kinase pathway activation	Signal transduction through GPI-anchored (tyrosine phosphorylation of src-kinases, TCR-zeta chain and ZAP-70)
Angiogenesis	Increase of DAF synthesis by VEGF
Invasive growth	Increase in DAF expression, ligand binding of DAF to CD97 (autocrine stimulation by tumor-specific DAF isoforms?)
Cell migration	Ligand binding of DAF to CD97, tyrosine phosphorylation of p56lck
Metastasis	Increase in DAF expression, ligand binding of DAF to CD97 (autocrine stimulation by tumor-specific DAF isoforms?)
Survival and apoptosis	Induction of apoptosis through monoclonal SC-1-antibody against tumor-specific DAF isoform (upregulation of c-myc, activation of caspase-6 and -8, cleavage of cytokeratin 18)

Decay-Accelerating Factor. Table 2 DAF targeted therapies

Targeted Cancer	Therapeutic investigational design and benefit
Stomach adenocarcinoma of diffuse-type	Monoclonal antibody SC-1 against a gastric cancer-specific 82 kD isoform of DAF; induced apoptosis in primary tumors as compared to pretreatment biopsy material in up to 90% of the cases, regression of tumor mass up to 50%
Metastasizing gastric cancer in nude mice	Monoclonal antibody SC-1 against a gastric cancer-specific 82 kD isoform of DAF; reduce the number of disseminated tumor cells in the bone marrow
Non-Hodgkin's lymphoma	Rituximab (chimeric anti-CD20 monoclonal antibody); enhancement of complement-dependent killing activity of Rituximab, by additional application of monoclonal anti-DAF-antibody
Cervical cancer	Monoclonal antibody against DAF showed the widest range of specific reactivity
Renal cancer	Bispecific antibodies binding DAF as well as renal tumor-associated antigen G250; decrease of unwanted side effects
Osteosarcoma of children	DAF as a cancer vaccine additionally applied to myelosuppressive chemotherapy; induction of T-cell proliferation 71% and antigen-specific gammaIFN secretion in 59% of the cases; vaccination was well tolerated
Melanoma xenografts in immunodeficient mice	Coxsackievirus A21 infection; rapid viral oncolysis

local inflammatory reaction as well as complement-mediated cell lysis and could also possibly improve response to special therapeutic strategies. In consequence, DAF was used as a target for molecular cancer therapy. Monoclonal antibody SC-1 binding an isoform of DAF expressed in gastric carcinoma induced ►apoptosis of these cells. In first clinical trials, patients with poorly differentiated stomach adenocarcinoma of diffuse-type have been treated primarily with the SC-1 antibody followed by gastrectomy and lymphadenectomy. A significant induction of apoptotic activity in primary tumors as compared to pretreatment biopsy material in up to 90% of the cases and a significant regression of tumor mass in up to 50% was observed. Application of SC-1 antibody therapy in nude mice with metastasizing gastric cancer reduced the number of disseminated tumor cells in bone marrow. Other studies could show that the complement-dependent killing activity of ►Rituximab, a chimeric anti-CD20 monoclonal antibody, in the treatment of ►non-Hodgkin lymphoma cells is enhanced by additional application of monoclonal anti-DAF antibody. The DAF is also expressed in many physiological human cells. Therefore, use of bispecific antibodies binding DAF as well as another tumor-specific antigen like the renal tumor-associated antigen G250 might be a solution to decrease unbeneficial side effects. Additional application of DAF as a cancer vaccine for ►osteosarcoma under myelosuppressive chemotherapy induced T-cell proliferation gammaIFN secretion. DAF as a receptor for viruses enhanced the systemic effect on metastatic melanoma cells by an infection with coxsackie-A21-viruses (Table 2).

Synonyms

DcR3

Definition

DcR3 is a member of the ►TNF receptor superfamily (TNFRSF6B), and the DcR3 gene is mapped to chromosome 20q13.3. DcR3 is a glycosylated protein of 300 amino acids and 33 kD. The receptor lacks a transmembrane domain and exists as soluble protein.

Characteristics

Tissue Expression and Decoy Function of DcR3

DcR3 is generally undetectable in normal tissues, but is highly expressed in several human malignant tissues, such as adenocarcinomas of the esophagus, stomach, colon, rectum, pancreas and lung, glioblastomas and lymphomas. In addition, high serum levels of DcR3 have been detected in many cancer patients. Clinical data indicate the significance of detecting serum DcR3 as a novel parameter for the diagnosis, treatment, and prognosis of malignancies. Several lines of evidence suggest a significant role for DcR3 in immune suppression and tumor progression. DcR3 has been regarded

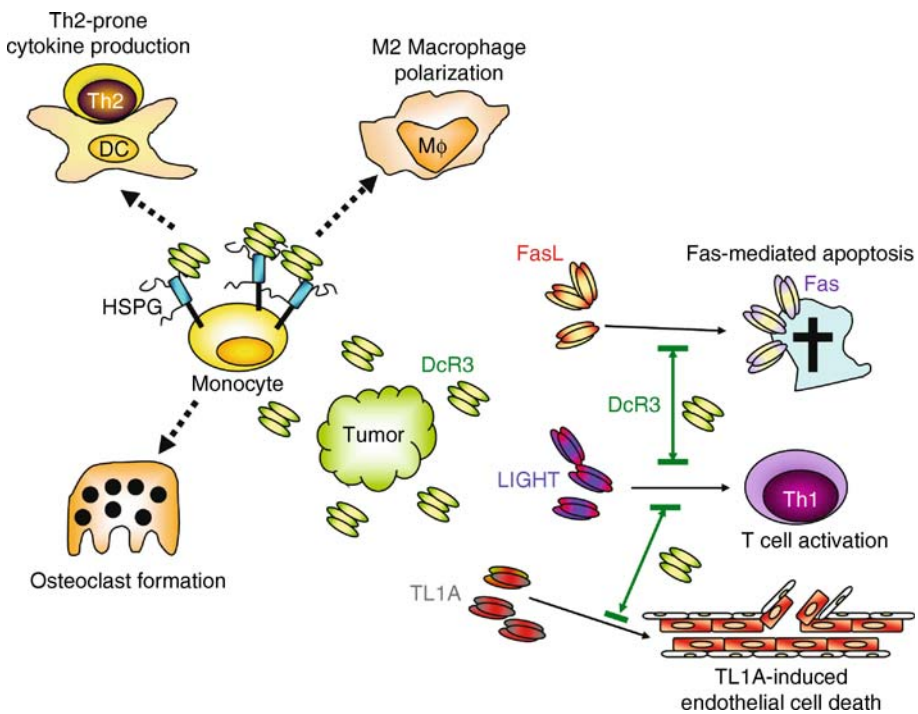
to function as decoy receptor for FasL, LIGHT (homologous to lymphotoxins, shows inducible expression and competes with herpes simplex virus glycoprotein D for herpesvirus entry mediator, a receptor expressed by T lymphocytes) and TL1A, which are three cytokine members of the TNF family. FasL and LIGHT are expressed by activated T cells, and can induce tumor cell death through signaling pathways mediated by Fas and lymphotoxin β receptor (LTβR), respectively. LIGHT is also a T cell co-stimulator, and this action is mediated by receptor herpesvirus entry mediator (►HVEM). Therefore, Fas and LIGHT are two cytokines contributing to the host immune surveillance. TL1A is an angiostatic cytokine releasing from endothelial cells. The cytokine neutralizing actions confer DcR3 function as a tumor molecule to decrease T-cell-mediated immunity and stimulate ►angiogenesis. Tumor cells engineered to release a higher amount of DcR3 may escape from FasL-induced apoptotic cell death.

Decoy Unrelated Novel Actions of DcR3 (Figure 1)

In addition to neutralizing bioactive cytokines, DcR3, which is also an effector molecule, directly modulates the activities of many cell types. DcR3 can regulate ►dendritic cells (DCs) differentiation and down-regulate several co-stimulatory molecules, leading to Th2 polarization. Moreover, DcR3 induces actin reorganization and adhesion of monocytes as well as reducing phagocytic activity and proinflammatory cytokine production in ►macrophages. Osteoclast formation is promoted by the addition of DcR3 to monocyte/macrophage lineage precursor cells. Finally, DcR3 increases monocyte adhesion to endothelial cells via ►NF-κB activation, leading to the transcriptional up-regulation of adhesion molecules and IL-8 in endothelial cells. Thus DcR3 has pleiotropic effects to modulate inflammation and ►osteoporosis. As chronic ►inflammation has long been associated with tumorigenesis, DcR3-induced inflammation might provide a beneficial microenvironment for tumor growth. Increased ►osteoclast activity and decreased bone density are observed in DcR3 transgenic mice; therefore DcR3 might also play an important role in bone erosion and destruction in cancer patients.

New Action Mechanisms of DcR3 (Figure 1)

It is a mystery why DcR3 has such diverse immunomodulatory functions independent of the neutralizing FasL, LIGHT and TL1A. A glycosaminoglycan-binding domain of DcR3 has been identified as binding and cross-linking heparan sulfate proteoglycans (HSPG), such as syndecan 2 and CD44v3, to induce monocyte adhesion via activating ►PKC. Recombinant protein, comprising the HSPG-binding domain (HBD) of DcR3 and Fc portion of human IgG1 (HBD.Fc) has a



Decoy Receptor 3. Figure 1 This figure shows the biological activities of DcR3. Tumor-secreted DcR3 can neutralize FasL, LIGHT and TL1A, and also bind to HSPG of monocytes to trigger signal cascades, resulting in differentiation of M2 macrophages, osteoclasts and Th2- dominant immune response.

similar effect as DcR3.Fc to modulate the activation and differentiation of DCs, macrophages, and induce osteoclast differentiation. Even though Fc stabilizes dimeric DcR3 and enhances cross-linking activity, transgenic mice overexpressing DcR3 also attenuates Th1 differentiation and enhances osteoclast formation. This indicates that the Fc portion is dispensable, and the biological effects of DcR3 in vivo are not restricted to its neutralizing effects on FasL, LIGHT, and TL1A.

Delayed Type Hypersensitivity Reaction

Definition

DTH; reaction is a type of cellular-mediated immune response mainly mediated by T cells for a given antigen. The DTH test is used to detect prior exposure to the antigen. Typically, when small amounts of antigen are injected intradermally, a discrete reaction is elicited which includes redness, swelling, induration and infiltration of immune cells into the site of the lesion within 24–72 h.

DMBT1; Glycoprotein-340 (gp-340; human); Salivary agglutinin (SAG, human); H3 (rhesus monkey); CRP-ductin (mouse); Muclin (mouse); Apactin (mouse); Vomeroglandin (mouse); Ebnerin (rat); Hensin (rabbit)

Definition

DMBT1 located at chromosome 10q26.13 2 was initially identified as a gene that shows frequent homozygous deletions in malignant ►brain tumours. It codes for an extracellular glycoprotein of the evolutionary highly conserved group of scavenger receptor cysteine-rich (SRCR) proteins and it is widely expressed in human tissues with strongest expression in epithelia and associated glands. Based on genomic alterations and loss of expression in several cancer types *DMBT1* has been proposed to play a role in tumorigenesis. The currently available data suggests two physiological functions for DMBT1: a function in innate immunity/mucosal protection and a function in epithelial/stem cell differentiation and regenerative processes.

Characteristics

The human DMBT1-locus is built up by tandem-arrayed repeats with extensive homologies in the coding and non-coding region. The locus spans a region of about 103 kb with 55 exons with the last exon coding for a putative transmembrane domain (TMD). In contrast to the DMBT1 homologues in mouse and rat, the TMD exon has not yet been found to be contained in human transcripts. DMBT1 contains a signal peptide at the N-terminus and ►immunohistochemistry demonstrated that it is expressed and secreted mainly by epithelial cells and glands. The mode of secretion is thought to determine its functions: lumenally secreted ►DMBT1 is part of the mucus (the protective layer of epithelial surfaces) and is assumed to play a role in pathogen defence, while DMBT1 secreted to the extracellular matrix (ECM) may trigger epithelial and stem cell differentiation.

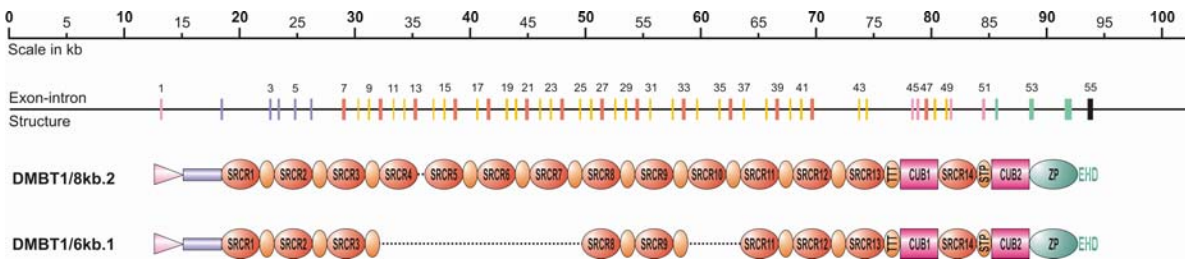
The largest (wildtype) variant of DMBT1 contains 13 highly homologous (87–100% identical) SRCR domains. The SRCR-domains are separated by so called SRCR-interspersed domains (SIDs) harbouring potential sites for *O*-►glycosylation (Fig. 1). The SRCR domains have been shown to function in pathogen binding and in mediating interactions with endogenous proteins involved in pathogen defence.

Functions or ligands for the two C1r/C1s Uegf Bmp1 (CUB) domains and the 14th SRCR domain, which shares less homology to the 13 C-terminal ones, have not been identified so far. The second CUB domain is followed by a so called zona pellucida (ZP) domain (Fig. 1). This type of domain mediates the formation of protein-oligomers in other molecules, which is likely the case for DMBT1 as well. Genetic polymorphisms give rise to DMBT1 alleles with copy number variations resulting in a reduced number of SRCR domains and SIDs. Several DMBT1-alleles were identified coding for transcripts with sizes ranging from 6 to 8 kb (Fig. 1). A hemizygous deletion of SRCR4-SRCR7 was found in approximately 25% of the normal population.

Functional Characteristics

►*DMBT1* and Innate Immunity/Mucosal Protection

There is increasing evidence that DMBT1 is part of the innate immune system against bacteria and viruses. The protein is present at most mucosal surfaces and binds to a broad range of bacteria including ►*Helicobacter pylori*, a human pathogen, which is linked to the development of peptic ulcer and ►gastric cancer. Evidence that the SRCR-domains could mediate the binding to bacteria has been provided by the identification of a small peptide sequence present in these domains, which exerts a broad bacteria-binding and -agglutinating activity. However, several hints have also suggested an involvement of DMBT1-attached



Deleted in Malignant Brain Tumours 1. Figure 1 Genomic organization and domain structure of DMBT1. Topline represents scale in kilobases followed by the exon–intron structure of the DMBT1 gene consisting of 55 exons. The exons are coloured according to the domain that they code for (see below). The presence of a further exon (black box) with coding potential for a transmembrane domain and a short cytoplasmic tail is predicted by homology searches with the cDNA sequences of the rodent homologues. The bottom two lines depict the domain organisation of the wildtype protein (DMBT1/8 kb.2) isolated from human adult trachea and one of the 6 kb transcripts isolated from human fetal lung (DMBT1/6 kb.1). The two variants could represent alternative splice products, but simultaneously also correspond to the largest and the smallest allelic variants identified so far. Pink triangle, signal peptide; blue box, unknown motif; red circles, SRCR domains; orange circles, SIDs, threonine- and threonine-serine-proline-rich domain, respectively; purple boxes, CUB domains; green circle, ZP domain; green letters, Ebnerin homologous domain.

glycosyl-residues in pathogen interactions. Furthermore, DMBT1 binds to viruses like HIV-1 and influenza A and is able to inhibit viral infection *in vitro*. Beside its interactions with microorganisms, DMBT1 is known to interact with mucosal and circulating defence factors among these the surfactant proteins A and D, (s)IgA, ►trefoil factor 2, lactoferrin and complement component C1q. This suggests a potential cooperative action of ►DMBT1 and its endogenous ligands in host defence. Further ►DMBT1 may activate the complement cascade and ►macrophage chemokinesis and regulate neutrophil respiratory burst response *in vitro*. Upregulation of ►DMBT1 has been reported in inflammatory processes for example following tissue injury or infection. Except for a role in innate mucosal protection, ►DMBT1 expression in lymphoid organs may point to a participation in the regulation of the acquired immune system, as has been reported for other proteins of the ►SRCR superfamily.

DMBT1 and Epithelial/Stem Cell Differentiation and Regenerative Processes

Functional studies *in vitro* and *in vivo* suggest a role for ►DMBT1 and its rodent homologues in epithelial/stem cell differentiation. The rabbit homologue of DMBT1 (hensin) was found to be responsible for the switch of cell polarity and the induction of terminal differentiation of intercalated epithelial cells in the kidney. These processes are triggered by the deposition and polymerization of hensin in the extracellular matrix. Localization to the ECM of in human adult multilayered and fetal developing epithelia, and expression along the proliferation-differentiation axis in the intestine may support such function. Rabbit DMBT1 has further been reported to trigger *in vitro* the differentiation of mouse embryonic stem cells towards columnar epithelial cells. DMBT1-deficient mice (termed hensin−/− mice) have been reported to display early embryonic lethality. Based on upregulation of rat DMBT1 in liver stem cells during liver regeneration, a participation in stem cell-mediated regenerative processes has been proposed.

DMBT1 and Tumorigenesis

Genomic alterations in *DMBT1* and a loss or a reduction of its expression in several cancer types have led to the proposal that *DMBT1* might represent a ►tumor suppressor gene. Inactivating point mutations have not been found within *DMBT1*. Homozygous deletions (deletions concerning both copies of the gene) of/or within *DMBT1* initially have been observed in a substantial number of malignant ►brain tumours, ►lung cancer and ►esophageal cancer. Due to the finding that *DMBT1* is a highly polymorphic gene with frequent intragenic deletions within the repetitive SRCR/SID exon containing region, however, it has been proposed that the majority of the previously identified deletions may represent preexisting polymorphisms unmasked by a loss of heterozygosity of the wildtype allele. Hence, inactivation of *DMBT1* at the transcriptional/post-transcriptional level rather than genomic alterations may represent the predominant mechanism. Evidence has been gained that ►epigenetic silencing by DNA ►methylation may account for DMBT1 silencing in a smaller subset of tumours.

Contrary to other cancer types, ►prostate cancer and ►pancreas cancer display highly elevated DMBT1 expression levels, so that ►DMBT1 has been discussed as potential biomarker for these cancer types. A 29 amino acid C-terminal peptide of ►DMBT1 has further been found at high levels in pancreatic cancer and has been suggested as tumor ►biomarker.

These data have led to the suggestion of a complex involvement of DMBT1 in tumorigenesis. Through protection from carcinogenic agents and/or pathogens and/or via regulation of the inflammatory response, DMBT1 may counteract tumour initiation and/or progression. Alternatively or additionally, loss of ►DMBT1 function may interfere with processes of differentiation and promote tumorigenesis.

Deleted in Pancreatic Carcinoma Locus 4

Stephan A. Hahn
University of Bochum, Bochum, Germany

Synonyms

SMA- and MAD-related protein 4; SMAD4; DPC4; Mother against decapentaplegic, drosophila, homolog of 4; MADH4

Definition

Deleted in Pancreatic Carcinoma Locus 4 (DPC4), belongs to the class of tumor suppressor genes (►tumor suppressor genes). It was identified within chromosomal band 18q21.1 which is frequently deleted in pancreatic carcinoma. DPC4 is a component of the transcription complex (►transcriptional complex) that mediates cell surface signals to the nucleus which are initiated by transforming growth factor β [►TGF-β]-related growth and differentiation factors.

Characteristics

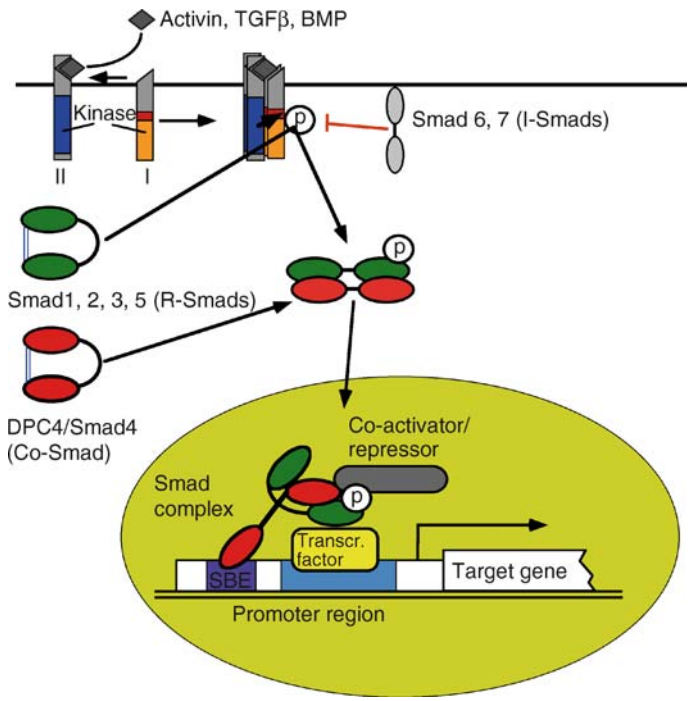
The open reading frame of DPC4 spans 1656 nucleotides and comprises 11 exons that code for a 60 kD protein (552 amino acids). DPC4 belongs to the highly conserved family of Smad genes that has been identified by protein sequence homology studies. The founding member Mad (Mother against decapentaplegic), was identified in ►*Drosophila melanogaster*.

Mad and its homologs mediate signals from cell surface receptors to the cell nucleus (►Smad proteins in TGFβ signaling). Involved in this signaling cascade are serine/threonine kinase receptors of the TGFβ family that become activated upon binding of polypeptides of the TGFβ cytokine family (Fig. 1). At least 25 different cytokines from various species are currently known. They include TGF-β, activin, ►inhibin, ►bone morphogenic protein (BMP) and Müllerian-inhibiting substance and control, among others, important biological functions such as embryonic development, cell growth and cell differentiation, modulation of immune responses and bone formation.

The number of Smad genes identified in humans has grown to a total number of eight (Table 1).

Common to all of them is a characteristic three-domain structure (Fig. 2): a highly conserved region, the Mad homology domain 1 (MH1), is located at the amino (N) -terminal end. Next to it is a poorly conserved, proline-rich linker region which is followed by a second highly conserved domain (MH2) located at the carboxy (C) -terminal end of the protein.

A link between the DPC4 protein and TGFβ signaling cascade was initially established by sequence homology studies of the proteins DPC4 and Mad. At the time of DPC4 discovery its potential tumor suppressor function was hypothesized; it was believed that the loss of DPC4 function in tumors is the reason for the



Deleted in Pancreatic Carcinoma Locus 4. Figure 1 A model for DPC4 signaling. In response to ligand binding to the TGFβ receptor complex, receptor regulated Smads (also called R-Smads) become C-terminally phosphorylated through the receptor kinase. The phosphorylated Smads change their folding pattern and form a heterodimeric or trimeric complex with DPC4. The newly formed ►Smad complex is then translocated into the nucleus. In the nucleus the Smad complex will make contact to transcription factors as well as bind directly to DNA through the ►Smad binding element (SBE), thus stabilizing the higher order DNA binding complex. In addition, transcriptional ►co-activators or ►co-repressors may be recruited into the complex ultimately leading to either activation or repression of target gene expression.

observed resistance towards TGFβ mediated growth inhibition of many tumor types. Although this hypothesis has only been partly proved, a wealth of information regarding the signaling pathway has been collected in recent years. This gave rise to a model of DPC4 protein function within the TGFβ signaling pathway.

TGF-Smad Signaling Cascade

The Smad signaling cascade involves three different classes of Smad proteins: the receptor regulated Smads (R-Smads), the common mediator Smad (Co-Smad) and the inhibitory Smads (I-Smads).

Upon ligand induced TGFβ receptor stimulation, R-Smads can transiently interact with the type I receptor. They become C-terminally phosphorylated by the receptor kinase and, once phosphorylated, are able to form a heterodimeric or trimeric complex with the "common-mediator" DPC4/Smad4 which then translocates into the nucleus. Here it can either up- or down-regulate the transcription levels of target genes by interacting with other nuclear factors and by recruiting transcriptional co-activators or co-repressors.

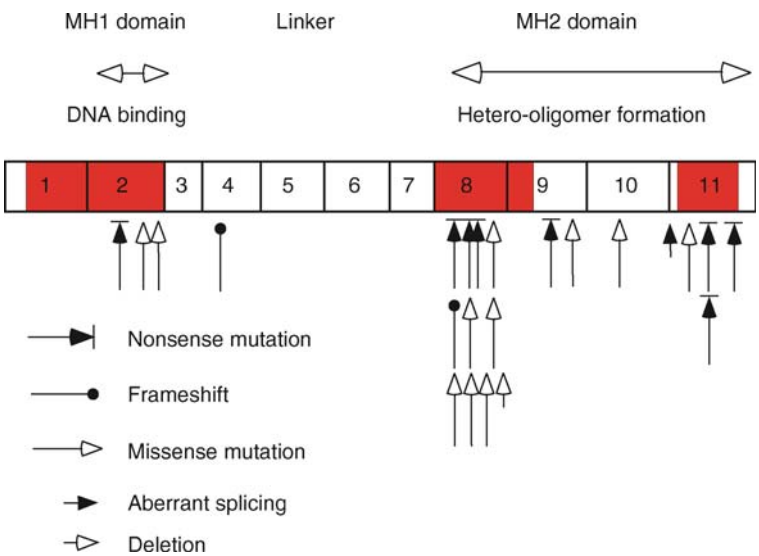
This signaling cascade can be negatively regulated by the I-Smads (Smad6 and Smad7). Whereas Smad7 acts as a more general inhibitor of TGFβ family signaling Smad6 seems to preferentially block BMP signaling. I-Smads can compete with R-Smads for type I receptor binding and can therefore prevent the phosphorylation-dependent activation of R-Smads. Furthermore, Smad7 can interact with the E3 ubiquitin ligases Smurf 1 and 2. Once the Smad7/Smurf complex is bound to the TGFβ receptor it induces TGFβ receptor degradation. Direct binding of I-Smads to R-Smads has also been shown, yielding R-Smads inactive. The expression of I-Smads appears to be regulated by TGFβ and BMP via an autoregulatory feed back loop. Furthermore, it has been shown that ►interferon-γ (interferon-γ) (IFN-γ) via the Jak1/STAT1 pathway, and tumor necrosis factor alpha (TNFα) and interleukin 1 through NFκB (►nuclear factor κB) /RelA can induce the expression of I-Smads to antagonize TGFβ signaling.

Deleted in Pancreatic Carcinoma Locus 4. Table 1
Summary of functional classes of human Smads

Classes of Smad Proteins		
Receptor-regulated	**Common**	**Inhibitory**
Smad 1, Smad 5, Smad 8 } BMP	DPC 4/Smad 4	Smad 6, Smad 7
Smad 2, Smad 3 } TGFβ, Activin		

Transcriptional Regulation through Smads

Since Smad proteins have no intrinsic enzymatic activity, they exert their effector function as transcriptional



Deleted in Pancreatic Carcinoma Locus 4. Figure 2 Functional domains and sites of identified DPC4 mutations. In addition to the mad homology domains MH1 and MH2, DPC4 carries a ►nuclear localization signal (NLS) domain and a ►nuclear export signal (NES) domain responsible for constant shuttling of DPC4 between nucleus and cytoplasm, thus helping the cell to constantly sense the TGFβ receptor activation state. A number of candidate phosphorylation target sites (P) for kinase pathways such as the MAPK (►MAP-Kinase) pathway have been described within the linker region which for example may modify nuclear accumulation rates of DPC4. The numbered squares forming the schematic DPC4 molecule also depict the 11 known exons within the DPC4 transcript.

regulators either directly by binding to specific promoter consensus sequences termed ►Smad-binding elements (SBE) and/or indirectly by associating with transcription factors already bound to the promoter. Therefore, many but not all Smad responsive promoters have two adjacent DNA sequences. One provides the binding site for transcription factors that are cooperating with the ►Smad complex, the other allows direct binding of the Smad complex to the DNA. While R-Smads provide the interface for the binding to ►transcription factors, DPC4 makes the contact to SBE elements. DPC4 thereby stabilizes the formation of a higher order DNA binding complex which is able to recruit transcriptional co-activators or co-repressors.

Many of the factors that cooperate with the Smad complex are regulated independently by other signaling cascades. The function of an active Smad complex can therefore be described as a co-modulator of transcription. It can modulate gene expression positively as well as negatively by integrating various incoming signals -including those mediated by the TGFβ ligand family. Therefore, it is not surprising that currently more than 1,000 genes are described to be either directly or indirectly regulated by DPC4. In addition, many of these DPC4 target genes can only be found in a certain cell type and growth state, again illustrating how much the cellular differentiation and signaling state determines the net gene expression regulation pattern of a DPC4 containing transcription complex.

What makes DPC4/Smad4 Unique among the Other Smad Family Members?

- DPC4 is the only human Co-Smad that is currently known.
- It seems particular to DPC4 that it is, almost without exception, essential for the establishment of a functional active Smad complex, a fact that emphasizes its role as a "master switch" in the regulation of TGF-β-like signals.
- Most somatic and all germ line mutations in human Smad genes identified to date target DPC4. Only very few somatic mutations were found in the human Smad2 gene, none were found in the other members of the human Smad gene family.

Which Human Tumors Show Alterations of the DPC4 Gene?

Changes, resulting in the inactivation of the DPC4 gene were found in approximately 50% of pancreatic carcinomas (►pancreas cancer). Research carried out in a variety of other cancer types suggested that DPC4 may contribute primarily to the formation of pancreatic neoplasia, and to a lesser extend to ►colon cancer ►cervical cancer and biliary cancer (►bile duct neoplasia) as well as the induction of non-producing ►neuroendocrine tumors. However, such changes appear to play only a minor role in the development of other tumor types such as head and neck, ►lung cancer ►ovarian cancer ►breast cancer and ►bladder cancer. The frequency of DPC4 mutations is markedly increased in metastatic colorectal carcinoma (35%) compared to non-metastatic colorectal carcinomas (7%). Furthermore, during pancreatic carcinoma development, a high incidence of biallelic DPC4-inactivation is generally not present before the carcinoma-in-situ stage, suggesting the loss of DPC4 function is critical for the tumor cell to develop characteristics such as the ability to invade into the surrounding tissue and to form metastasis.

In addition, germline mutations of the DPC4 gene have been identified in patients with familial juvenile polyposis, an autosomal dominant disorder that is characterized by a predisposition to hamartomatous polyps as well as an increased risk for gastrointestinal carcinomas.

How are Naturally Occurring DPC4 Mutations Interfering with the Smad Signaling Cascade

Most DPC4 mutations identified to date are located within the C-terminal MH2 domain. Functional studies identified the MH2 domain as providing the binding properties to R-Smads, the latter being important for a functionally active Smad complex. It is therefore likely that compromising mutations of the MH2 domain structure restrict the formation of a functional Smad complex, thus preventing signal transduction to downstream components. In addition, a few mutations have been identified within the N-terminal MH1 domain which was shown to mediate the direct binding of DPC4 to DNA promoter sequences. Such mutations might interfere with Smad signaling by rendering the formation of the higher order Smad-DNA complex unstable. Furthermore, some DPC4 ►missense mutations targeting the MH1 domain result in an instable protein due to a mutation-induced poly-ubiquitination of DPC4 and its subsequent proteasomal degradation.

Does DPC4 Contribute to the Familial Risk for Pancreatic Cancer?

Although the DPC4 gene is most frequently altered in ►sporadic pancreatic carcinoma, to date no germline mutations were found in families with an increased risk of this type of carcinoma. DPC4 is therefore unlikely to play an important role as a heritable genetic risk factor in pancreatic carcinoma.

How does DPC4 Contribute to Tumor Formation?

Although Smad signaling (including DPC4/Smad4) is regarded as central to the TGFβ pathway, there are now numerous examples illustrating that DPC4 inactivation is not simply abolishing TGFβ responsiveness and thus providing the cell a growth advantage. This

can partly be explained by the ability of TGFβ to modulate also Smad-independent pathways such as the Ras (►RAS) -ERK, PI3K (►PI3KSignaling) –AKT (►AKTSignal Transduction Pathway in Oncogenesis) and Rac/Rho pathways. Thus, loss of DPC4 function is not able to completely abrogate TGFβ signaling rather than shifting the balance between DPC4/Smad-dependent and DPC4/Smad-independent TGFβ signaling pathways towards the DPC4/Smad-independent pathways. The output of the latter is dependent on the successful activation of the latent form of TGFβ ligands and intactness of the TGFβ receptors. The cellular context will further modulate the signaling state of the DPC4/Smad-independent pathways through regulating the activity status of their pathway target genes by integrating signals from other signaling pathways. Thus, loss of DPC4 function has been shown cell type dependent to be involved in altering a number of different cell behaviors relevant to tumor formation such as, cell growth rate by modulating the cell cycle and/or the rate of ►apoptosis, altering the extracellular matrix components (►extracellular matrix remodeling), the cell adhesion (►adhesion) properties, and supporting ►epithelial to mesenchymal transition, thereby facilitating tumor ►invasion and ►metastasis, Furthermore, other experiments provided evidence that loss of DPC4 function might promote tumor ►angiogenesis by causing an increase in the concentration of angiogenic factors and/or a decrease its corresponding inhibitors.

Additional insight of DPC4 function was provided by targeted mutagenesis in mice. Mice with two mutated alleles for DPC4 die at embryonic day 7.5, a result that underlines the importance of DPC4 in early embryonic development. DPC4 heterozygous mice develop gastric and duodenal polyps which resemble human juvenile polyps. Furthermore, knockout mice experiments have demonstrated a functional cooperation between the DPC4 and the APC (APC) (adenomatous polyposis coli) gene. In mice that were carrying defect copies of both genes, compared to mice carrying only the mutated APC gene, the induced colonic tumors displayed a much more aggressive phenotype. Lastly, data from primary human tumors and from mice experiments provided evidence that haploinsufficiency of the DPC4 locus may also contribute to progression of cancer. These data clearly support the importance of DPC4 in the suppression of tumorigenesis.

Dendritic Cell-Based Tumor Vaccines

Definition

The system of dendritic antigen-presenting cells derive from hematopoetic precursors and reside as sentinels of the immune system in all tissues, particularly in skin and mucous membranes. They are able specifically equipped with pathogen recognition receptors which enable them to recognize harmful microbial infections and take up foreign antigens. Activation of ►dendritic cells triggers (i) their ►migration to the regional lymph

nodes, (ii) antigen processing and (iii) functional maturation for optimal antigen presentation and stimulation of T cell proliferation. ►Dendritic cells are the key regulators of cellular immunity against both infected as well as malignant cells. They are therefore targets of many ►cancer vaccine strategies both ex vivo (using cultured dendritic cells) as well as in vivo.

►Melanoma Vaccines

Dendritic cells

Nathalie Cools, Viggo Van Tendeloo, Zwi Berneman
Vaccine and Infections Disease Institute (VIDI) Laboratory of Experimental Hematology, University of Antwerp, Belgium

Definition

Dendritic cells are a special subset of ►leukocytes that form a complex network of ►antigen-presenting cells (APC) throughout the body. They play a principal role in the initiation of immune responses to invading micro-organisms (bacteria, fungi and viruses), malignant cells and allografts, by activating naïve lymphocytes, by interaction with innate cells and by the secretion of cytokines. At certain developmental stages they grow branched projections, the dendrites, hence the cell's name.

Characteristics

Origin and Function

Dendritic cells (DC) were characterised for the first time by Steinman in 1973 based on their distinct morphology with different cytoplasmic extensions, such as dendrites, pseudopodia and ►lamellipodia, which give the cell its star-shaped feature. Due to their pronounced morphology, DC have a large surface, ensuring close contact with neighbouring cells.

Variations among the tissue distribution of DC and differences in their phenotype and function, indicate the existence of heterogenous populations of DC. DC originate from different hematopoietic lineages in the bone marrow (Table 1). A myeloid progenitor cell can differentiate *in vivo* to different DC populations: ►Langerhans cells that migrate to the skin epidermis and interstitial DC that migrate to the skin dermis and various other tissues (airways, liver and intestine). Circulating or migrating DC are found in the blood and in the afferent lymphatics, respectively (the latter called veiled cells). Interdigitating DC are found in the paracortex of lymph nodes in close proximity with T cells. In addition, monocytes represent an abundant source of DC precursors during physiological stress. Another subset of DC, plasmacytoid DC (pDC) originate from a lymphoid progenitor cell in lymphoid organs. By contrast, follicular DC (FDC) are probably not of hematopoietic origin, despite similar morphology and function to the above mentioned subsets of DC. FDC are APC of the B cell follicles in lymph nodes and central players in humoral immunity.

DC express several different types of membrane molecules that determine their phenotypic and functional characteristics:

1. DC display a high surface density of antigen-presenting molecules, such as CD1a, ►major histocompatibility complex (MHC) class I and class II molecules. The level of expression of these molecules is 10- to 100-fold higher compared to other APC (e.g. B cells).
2. In addition, mature DC have high expression levels of costimulatory and ►adhesion molecules: CD40, ICAM-1/CD54, ICAM-3/CD50, LFA-3/CD58, B7-1/CD80 and B7-2/CD86. Binding of these molecules with their respective receptors on T cells results in T cell activation and subsequently stimulates the expression of cytokines, cytokine-receptors and genes for cell survival.
3. Several members of the integrin family are expressed by DC. ►Cadherins contribute to the generation of cell contacts and selectins are important for the motility of DC.
4. DC also express pathogen-recognition receptors, e.g. DEC-205, a macrophage-mannose receptor capable of binding bacterial carbohydrates and ►toll-like receptors (TLR), recognising a variety of pathogen-associated molecular patterns (PAMP), such as carbohydrates, nucleic acids, peptidoglycans and lipoteichoic acids.
5. Cytokine and chemokine receptors are also important for DC function, since growth, differentiation and migration of DC as well as antigen processing and presentation is tightly regulated by cytokines and/or chemokines.

The widespread distribution of DC and their expression of a variety of membrane molecules underline their sentinel function: they patrol the body to capture invading pathogens and certain malignant cells in order to induce efficient anti-microbial or anti-tumour ►T-cell responses. In their *in vivo* steady state condition, immature DC are specialised in capturing antigens, i.e. they efficiently take up pathogens, apoptotic cells and antigens from the environment by phagocytosis, macropinocytosis or ►endocytosis. However, immature DC remain tissue-resident, expressing only small amounts of (MHC) class II and of

costimulatory molecules, which leads to T cell unresponsiveness. After encounter of a "danger" signal (e.g. TLR ligand) immature DC mature and migrate to the secondary lymphoid organs. Mature DC are considered to be immunogenic, mainly due to the marked upregulation of MHC class II and costimulatory molecules. This maturation step is believed to be a crucial event to regulate DC function and makes DC potent inducers of T cell immunity.

Dendritic Cell-Based Immunotherapy

Despite our immune system's function to protect us from malignant cells, tumour cells grow undisturbed and, unless treated, are fatal to the host. The reasons for the failure to eliminate tumour burden in a majority of patients can be the consequence of different tumour escape mechanisms. For example, tumour-derived inhibitory factors (e.g. IL-10 and/or TGF-β) or tumour cell-induced T regulatory cells (►Treg) might be involved in downregulating or altering immune function. The goal of cancer ►immunotherapy is to resolve or circumvent these problems and generate tumour-specific immune responses. It is important to realise that immunotherapies will likely only be successful after reducing tumour mass via primary therapies: surgery, radio- and/or chemotherapy i.e. in a ►minimal residual disease (MRD) setting.

Because of their pivotal immune-stimulating capacity and their ability to activate naïve tumour-specific T cells, DC-based ►cancer vaccines could have important applications in the future treatment of cancer. For this, it was necessary to cultivate DC with high yields. Several cultivation protocols were developed for *in vitro* generation of DC. First, DC can be differentiated from CD34+ hematopoietic progenitor cells using granulocyte-monocyte colony stimulating factor (GM-CSF), tumour necrosis factor (TNF-α), stem cell factor (SCF), interleukin (IL)-3 and ►Interleukin-6. Second, DC can be generated starting from monocytes using GM-CSF and ►Interleukin-4. Finally, DC can be directly harvested from the peripheral blood of a patient, where they reside at low percentages (0,1%).

Next, cultivated DC can be loaded with the tumour antigen of importance in different ways:

1. DC can be grown *in vitro* in the presence of ►tumor-associated antigens (TAA). This technique is called peptide pulsing and results in direct binding of the immunodominant epitope on an empty MHC class I molecule on the DC membrane. This circumvents the need for antigen uptake and processing and ensures the stimulation of tumour specific cell-mediated cytotoxicity. However, the number of known TAA is still restricted and highly dependent on the human leukocyte antigen (HLA) haplotype of the patient.
2. DC can also be fused with the patient's tumour cells *in vitro* or pulsed with tumour cell lysates. The former method combines sustained tumour antigen expression with the antigen-presenting and immunostimulatory capacities of DC. DC-tumour cell hybrids will also stimulate an active anti-tumoural immune response.
3. Tumour antigen can also be loaded on DC using plasmid DNA transfection or ►viral vector mediated gene transfer. The former method results in only low transfection efficiencies. On the other hand, viral transduction, for example by using adenoviral or lentiviral, vectors is very effective with regard to transfection efficiency. However, the immunogenic character of the viral vector itself is a serious

disadvantage. In both cases, DC will transcribe and process the tumour antigen. This will result in a cytotoxic immune response, necessary for immunological defence against cancer cells.

4. It is also possible to transfect DC using *in vitro* transcribed mRNA coding for tumour antigens or total tumour RNA. It has been shown that electroporation of RNA is the most effective non-viral transfection method for DC (►non-viral vectors for cancer therapy). mRNA is brought directly into the cytoplasm and the cell's metabolism will translate mRNA into proteins, which can be presented onto MHC class I molecules after processing. This will guarantee a specific cell-mediated anti-tumoural immune response.

In a clinical context, *in vitro* cultured and activated DC loaded with appropriate tumour antigens could be administered to cancer patients in a therapeutic setting (active specific immunotherapy). The aimed generation of anti-tumour immunity, mediated by DC, could be of importance for both treatment (as adjuvant to conventional therapies) as well as to prevent relapse in a MRD setting. On the other hand, tumour antigen-loaded DC can also be used for the *ex vivo* generation of tumour-specific cytotoxic T lymphocytes (CTL) in an autologous system. These tumour-specific CTL can, in their turn, be administered, to the patient to exert a direct cytotoxic effect on the patient's cancer cells (passive or adoptive immunotherapy).

The impact of a DC-based cancer vaccine is clear: an antigen-specific anti-tumour vaccine would influence both morbidity and mortality of various cancers. Currently, several phase I-II or III ►clinical trials using TAA-loaded DC are ongoing worldwide in order to stimulate the patient's immune system against tumour antigens. A number of these trials demonstrated some clinical and immunological responses (as evidenced by T cell proliferation, IFN-γ ►ELISPOT and ►delayed type hypersensitivity [DTH reaction] reaction) without any significant toxicity. However, despite the presence of expanded antigen-specific T cells in patients after vaccination, only a minor population of these patients showed a beneficial biologically relevant clinical response, i.e. tumour regression and increased disease-free survival. Until now, clinical trials using DC have only shown moderate, if any, success. Since DC possess the exceptional capacity to stimulate the patient's own immune system against cancer, the reasons for the failure to eliminate tumour burden in a majority of patients needs to be carefully examined in ongoing and future trials.

Dendritic Cells in Cancers

DC can also infiltrate human tumours where they are involved in the induction of anti-tumour immune responses. It is likely that the establishment of tumour-specific immune responses depends on the migratory capacity of DC from the tumour microenvironment to the draining lymph nodes, where tumour antigen presentation to T cells takes place. Moreover, by their expression of costimulatory molecules and several cytokines, such as IFN-α and IL-12, DC also mediate T cell survival by preventing T cell ►apoptosis. In addition, mature DC have been reported to cause direct lysis, apoptosis as well as cell cycle arrest of cancer cells through the secretion of soluble factors. As a consequence, the presence of a high number of DC in the tumoural or peritumoural area, as well as in the draining lymph nodes of various human tumours has been shown to correlate with patients' survival and a better prognosis. Decreased numbers or dysfunction (e.g. decreased expression of costimulatory molecules) of DC are reported in poor-prognosis tumours. Furthermore, tumour cells can secrete certain factors (e.g. IL-10 and TGF-β) that counteract DC maturation and migration and thus actively contribute to DC dysfunction.

Occasionally, neoplasms of accessory immune cells (antigen-presenting cells, dendritic cells) can occur. These are primarily found in lymph nodes and extranodal lymphoid tissues (lymph node interdigitating cell sarcoma), but are also reported from other sites such as the skin (►Langerhans cell histiocytosis). The incidence of dendritic cell tumours is very rare: until now, only a few dozens of cases have been reported in literature.

Dental Pulp

Definition

Forms a functional and interdependent unit together with ist adjacent tissue, the dentin. Physiologic or pathologic reactions in one compartment will affect the other compartment as well. Dentin and the dental pulp are of mesectodermal origin. They are also called "pulp-dentin complex"or "pulp-dentin organ".

►Dental Pulp Neoplasms

Dental Pulp Neoplasms

Klaus Neuhaus MMA
Department of Operative, Preventive and Paediatric Dentistry, School of Dental Medicine, University of Bern, Bern, Switzerland

Definition

Are tumors that are located in the dental pulp.

Characteristics

Dental pulp neoplasms (DPNs) are rare tumors of the dental pulp tissue which is not exposed to the oral cavity. Two types of DPNs can be distinguished: Type 1 originates from the dental pulp itself (primary DPN) and type 2 originates from tissue outside of the tooth (secondary DPN). Most DPNs are somewhat incidental findings in patients with a known tumor anamnesis. Therefore the number of histologic examples of DPNs is rather limited, and one also has to take into account articles from old literature in order to draw a complete clinical picture.

History

In the late nineteenth century, when systematic dental care and oral hygiene in general were considerably more deficient than today, dentists encountered numerous teeth with deep ►caries and sometimes massive exposed pulp tissue. This phenomenon was called "pulpitis chronica sarcomatosa", a chronically inflamed dental pulp supposedly caused by a sarcoma. Later it was found out that this pulpal alteration was in fact nothing to do with a sarcoma but rather was the result of colonization of the exposed dental pulp by free epithelium cells of the gums. This entity is a so-called "dental pulp polyp". However, the first true description of a type 1 DPN was made in 1904 by V. A. Latham from Rogers Park, Illinois. He presented the case of a 56-year-old woman presenting with an upper right canine with a greenish-white tinge. The tooth was vital, symptomless and caries-free, i.e. the dental pulp was not exposed to the oral environment. After tooth extraction (for prosthodontic reasons) and histological processing, this canine proved to have an epithelioma of the pulp. The extraction socket was curetted and subsequently cleaned with iodine and carbolic acid. According to his report, Latham thus seems to have cured the patient from a tumor by simply extracting the tooth. Until today, descriptions of type 1 DPNs are very rare.

First descriptions of type 2 DPNs also date back to the early 20th century where reports of involvement of dental pulps in patients with ►breast cancer, ►lymphoma or neuroma have been given. Three to thirty percent of tumors of the head and neck region (HNR) are associated with involvement of the dental pulp. Carcinomas are more likely to be associated with DPNs than sarcomas or any other type of tumors of the HNR. The maximum incidence of DPNs lies between the fifth and sixth decade of life.

Inflammatory Pulp Reactions

A DPN causes inflammatory reactions (►inflammation) in the dental pulp. Chronic inflammation of the pulp may either lead to calcification of parts of the dental pulp tissue or to resorption of the surrounding hard tissue, i.e. ►dentin. Calcifications – as regularly observed histological findings in dental pulps with a neoplasm – can be explained by the behavior of primary and secondary ►odontoblasts. These cells are determined to secrete dental hard substance. If a bacterial impact is directed towards the pulp (as is the case with dental caries), the primary odontoblasts immediately start to produce tertiary dentin in the targeted area. Thus increasing the distance between the bacteria and the pulp, an early opening of the pulp chamber in the course of the carious process is evaded. Meanwhile, the chronic inflammation of the dental pulp in slowly progressing caries may lead to the calcification of parts of the pulpal tissue via secondary odontoblasts. These particular cells are differentiations of former pulpoblasts. Pulpoblast differentiation can be modified by ►bone morphogenetic protein (BMP) 2, 4, and 11, ►GDF, ►TGF-β, or high calcium concentrations, all of which are present in dentin. It can also be modified by certain medicaments, which originally were only used in periodontal regenerative therapy but have now also been introduced in endodontic therapy as well as dental traumatology as a means of direct pulp capping.

Radiotherapy

As an additional point of discussion the possibility of therapeutically induced DPNs by radiotherapy has to

be mentioned. It is a given fact that one of the risks of radiotherapy of the HNR consists in radiation-induced tumors (►radiation-induced sarcomas after radiotherapy). Establishing a causal connection is often difficult due to a latency period of several years. However, teeth after radiotherapy sometimes show calcifications of the dental pulps, which can be detected in postirradiation radiographs. Since there has not been a study distinguishing between bacterial and abacterial calcifications as signs of chronic inflammations of the dental pulp in postirradiated cases, no predication can be given about a higher risk of DPN after radiotherapy.

Animal Investigations

As to DPN-cases, the pulp tissue reaction with respect to calcifications seems to be the same as in cases of dentin caries. At this point, observations made in experimental animal models become of interest: After several days calcification of the dental pulp tissue (with a simultaneous breakdown of the odontoblast layer) can be detected when inoculating the dental pulps of rodents with virulent sarcoma cells. Regular findings in these studies consist in massive development of intrapulpal dental hard substance like denticles, osteoids, or pulp stones. Also destruction of pulpal cells, particularly of the odontoblasts, by tumor tissue has been described in an animal study. In none of these investigations do the dental pulps survive longer than three weeks. Nevertheless, it is a matter of speculation whether this effect is really due to the sarcoma cells or rather to the increased extravasal pressure of the inflamed pulpal tissue. In these animal models, the sarcomata are able to infiltrate the dental pulps and to proliferate to adjacent tissue like ►periodontium, mandibular bone and masseteric muscle. In later stages, ►metastasis in the regional lymph nodes as well as in the sublingual, submandibulary and parotid glands can be found.

The fact that rodent teeth are substantially different from human teeth must not be neglected. While rodent teeth are growing lifelong and have a largely open apex, human tooth formation literally comes to an endpoint in a constriction at the tip of the root(s).

Clinical Relevance

Since systematic autopsies of the jaws are no longer common, the entity of DPNs have somewhat moved out of the focus of scientific attention.

Type 1 DPNs are certainly of small clinical relevance. In the dental pulp, fibroblasts, subodontoblastic progenitor cells, pericytes, stem cells, and, occasionally, Malassez epithelium remainders of the Hertwig root sheath are cells with mitotic competence and thus are able to undergo neoplastic alteration. A relatively high grade of differentiation of the pulpal tissue limits further differentiation of purported neoplasms.

Due to the restricted anatomical macroenvironment of a tooth and possibly further due to ►microenvironmental interactions a type 1 DPN is more or less self-limited. Concerning the formation of a DPN, the capability of the dental pulp to regularly form calcifications under certain circumstances as well as the fact that one encounters a terminal blood supply in the pulp play a crucial role. Growth of a neoplasm will increase extravasal pressure within the dental pulp and thus stimulate secondary odontoblasts to secrete irritation dentin. A large amount of irritation dentin might influence the blood supply of the dental pulp and thus will probably lead to a hemorrhagic infarct. A growing tumor in the root canal system will contribute to this effect. While becoming necrotic in such a way, the dental pulp does not necessarily have to show clinical symptoms (such as tooth ache). Teeth with necrotic pulps will normally receive endodontic treatment (i.e. root canal therapy) or they will be "cured" by tooth extraction. It can be acclaimed that the specialty about a type 1 DPN lies in its possibility to be removed successfully and in a relatively easy way. The anatomic prerequisite of the root canal system presents the unique fact that while growing atumor is already limiting its further existence.

The risk of metastasis of a DPN is not given in normal-sized teeth. The volume of the dental pulp chamber and the root canal system do not provide sufficient space for a tumor to gain a critical cell mass in order to disseminate clonal cells. Only teeth with incomplete root formation (as in children or adolescents) or ►taurodonts, i.e. teeth with an abnormally large crown and roots, might provide enough space allowing a tumor to gain a critical cell mass. Large animal teeth, whose pulp chambers can surely provide enough space for a tumor (for instance in large mammalians), are not systematically screened for dental pulp diseases.

Type 2 DPNs seem to be mere incidental findings in patients with tumors mainly of the HNR. This leads to the assumption that DPNs are normally symptomless and of relatively small clinical relevance. Nevertheless, type 2 DPNs may also lead to tooth-related symptoms (pain) as has been described in single case reports.

Far more often (and clinically more important) is the opposite case when seemingly healthy teeth with no sign of caries, filling or a positive trauma history mimic toothache. The projected toothache is thus drawing off the attention of a true HNR tumor, which often leads to unnecessary root canal treatment or tooth extraction. Therefore, apart from regular or ofacial neuropathic or nociceptive pain conditions, differential diagnosis therefore should always consider a neoplasm in the HNR.

In common classifications of dental pulp diseases, inflammation of the dental pulp due to neoplasms are neglected. However, animal tumor models (►mouse models) should be reinvestigated for changes within the dental pulp.

D

Characteristics

Cell Junctions

Epithelial cell-cell junctions consists of four junctions, ►tight junctions, ►adherens junctions, ►desmosomes, and ►gap junctions (Fig. 1). Two adhering-type junctions, the adherens junctions and the desmosomes, are responsible for strong cell-cell adhesion. Each of these junctions consists of a transmembrane cadherin and a complex cytoplasmic plaque that serve to link cadherin to actin microfilaments or the intermediate filament cytoskeleton.

Desmosome

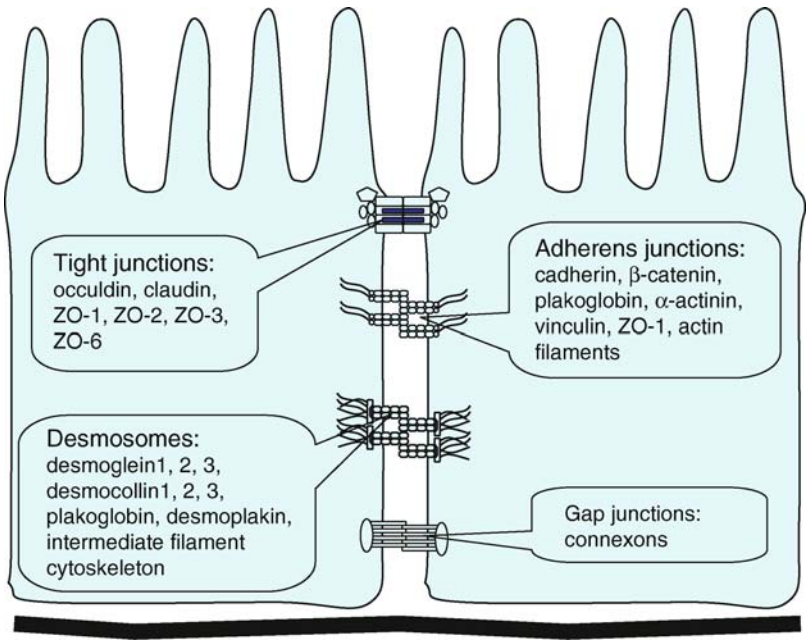
Intercellular junctions known as desmosomes are multimolecular membrane domains that provide intercellular adhesion and membrane anchors for the intermediate filament cytoskeleton. Desmosomes are essential adhesion structures in most epithelia that link the intermediate filament network of one cell to its neighbor, thereby forming a strong bond. Desmosomes contain the desmosomal cadherins, desmoglein (Dsg) and ►desmocollin (Dsc) that are linked to the intermediate filament cytoskeleton through interactions with ►plakoglobin and ►desmoplakin (Fig. 2).

Desmoglein and Cancer

Epithelial cell-cell adhesion is important in tumor development. Dsgs are transmembrane glycoproteins of the desmosome, a cell-cell adhesive structure prominent in epithelial tissues, which have been reported to be associated with tumor development. cDNA and protein studies have revealed that there are subfamilies of Dsg (types 1, 2 and 3) and Dsc (types 1, 2 and 3) [3]. Dsg2 and Dsc2 are widely expressed and are found together in desmosomes of the basal layer of stratified epithelia, simple epithelia, and nonepithelial cells such as in the myocardium of the heart and lymph node follicles, whereas Dsg3/Dsc3 and Dsg1/Dsc1 are more restricted to complex epithelial tissues. Although considerable overlap is exhibited in the distribution of these isoforms in stratified tissues, their expression is clearly differentiation-dependent. Dsg2, but not Dsg1 or Dsg3, is expressed in stomach epithelia. ►Gastric cancers have been classified into two histological types: intestinal-type and diffuse-type. Diffuse-type gastric cancers show decreased cell-cell adhesion, which is associated with metastatic potential. These histological features indicate that a decrease in adhesive junctions may be involved in the emergence of diffuse-type gastric cancers. A decrease in E-cadherin has been reported to be one cause of the decrease in adhesive junctions, but not all diffuse-type gastric cancers show such a decrease. Decreased expression of Dsg2 is associated with diffuse-type gastric cancers and poor ►prognosis in gastric carcinoma.

Adherens Junctions

The adherens junction is composed of a classic cadherin (e.g. E-, P- or N-cadherin) linked to ►β-catenin or plakoglobin [5]. Thus, plakoglobin is found in both adherens junctions and desmosomes, while β-catenin is restricted to the adherens junction. Alpha-catenin links the cadherin/catenin complex to the actin cytoskeleton



Desmoglein-2. Figure 1 Cell junctions. Epithelial cell-cell junctions consist of four junctions, tight junctions, adherens junctions, desmosomes, and gap junctions.

Desmoid Tumor

Sue Clark
The Polyposis Registry, St Mark's Hospital
Harrow, UK

Synonyms

Aggressive fibromatosis; Mesenteric fibromatosis; Gardner syndrome

Definition

Desmoid (meaning tendon-like) tumors are a heterogeneous group of rare connective tissue neoplasms, which can occur at almost any anatomical location.

Desmoids have been classified as fibromatoses, along with pathologies such as palmar fasciitis, which are due to proliferation of well differentiated fibroblasts and are locally infiltrative and tend to recur after excision, but do not metastasize.

Characteristics

Desmoids are rare, accounting for less than 0.1% of all tumors, and have an annual incidence of 2–4 per million. While most occur sporadically, 2% are associated with ►familial adenomatous polyposis (FAP), an autosomal dominantly inherited cancer predisposition syndrome due to mutation of the tumor suppressor gene *APC* (►APC gene in familial adenomatous polyposis). Desmoids are over 1,000 times more common individuals with FAP than in the population in general, occurring in about 10–20% of them, and are an important cause of death in this group.

It is useful to classify desmoid tumors as being either sporadic or FAP-associated, and by their location into intra-abdominal, abdominal wall or extra-abdominal.

Pathology

Both sporadic and FAP-associated desmoids have been shown to be clonal proliferations of myofibroblasts. Those associated with FAP result from acquired mutations in the ►wild-type copy of *APC*. Somatic loss of the *β-catenin* gene has been described in sporadic desmoids, and *APC* mutation has also been identified in some cases ►APC/β-catenin pathway. Thus abnormal activation of the Wnt pathway seems to have an important role in desmoid tumorigenesis ►Wnt Signaling. A variety of complex chromosomal abnormalities, including trisomy 8 and gain of 1q21, has also been found in some tumors.

There is no true capsule, and the desmoid compresses and infiltrates surrounding tissues as it grows. Desmoids range in size from a few centimetres to large masses weighing several kilograms. A photograph of a mesenteric desmoid tumor taken at surgery can be found in ►APC gene in familial adenomatous polyposis. Growth rates are very variable. There have been reports of spontaneous resolution, and some desmoids grow relentlessly. The majority, however, either display cycles of growth and resolution or stabilize.

The cut surface is usually pale and whorled. There may be central hemorrhage, necrosis or cystic degeneration. Histologically desmoids consist of mature, highly differentiated spindle shaped fibroblasts in an abundant collagen matrix. The histological appearances are not

necessarily diagnostic, and need to be interpreted in the light of the macroscopic findings.

Aetiology

Trauma, sex hormones and genetics have all been implicated in their aetiology. Many sporadic abdominal wall desmoids seem to arise in women in pregnancy, perhaps as a result of low-grade trauma of stretching, coupled with high levels of ►female sex hormones. There have been numerous reports of desmoids arising at sites of surgical wounds, although many, particularly at extra-abdominal sites, seem to occur in the absence of any previous trauma.

The higher incidence of desmoids in females, association with pregnancy, presence of estrogen receptors, and results of some experimental studies on desmoid cell lines all suggest that estrogens may have a role in stimulating desmoid development.

Desmoids are very much more common in individuals with FAP. Within this group some familial clustering has been observed, in part explained by a ►genotype-phenotype correlation in which families with an *APC* mutation 3′ of codon 1444 have an attenuated colorectal phenotype but a high risk of desmoid development. There is also evidence of the influence of as yet unidentified modifier genes.

Clinical Features

Desmoids most commonly occur in young adults (mean age of onset around 30 years), but have been described in children and even babies. Sporadic desmoids are more frequent in women than men (reported gender ratio 2–5:1), but in FAP there is a less marked gender difference.

Sporadic desmoids are found predominantly in the abdominal wall (50%) and at extra-abdominal sites (40%), whereas about 80% of desmoids associated with FAP are within the abdomen, most in the ►small bowel mesentery. It is not uncommon for an individual to develop desmoids at multiple sites.

Intra-abdominal desmoids characteristically arise in the small bowel mesentery. Potential "desmoid precursor lesions," consisting of small plaques of peritoneal thickening, have been observed in patients with FAP. It is thought that these enlarge, causing a diffuse thickening and puckering of the mesentery which can be seen on ►CT scans. In some cases a frank desmoid mass develops.

Most extra-abdominal desmoids cause symptoms because of their bulk and resulting mechanical effects. At some sites, for example in the neck, they can compress nerves and blood vessels. The overlying skin may ulcerate and abdominal wall desmoids occasionally adhere to and erode abdominal organs. Intra-abdominal desmoids can cause major morbidity and even death, usually due to ureteric obstruction, bowel obstruction or perforation, either due to direct erosion or to compromise of the vascular supply.

►CT and ►MRI are the most useful imaging modalities, showing both tumor size and relationship to neighboring structures. Signal intensity on T2 weighted MRI may reflect cellularity and is correlated with tumor growth.

Treatment

The treatment of desmoids is difficult and controversial. There are numerous case reports and small uncontrolled series in the literature, but these are difficult to interpret, particularly as the natural history of these tumors is so variable.

The drugs most widely used are ►non-steroidal anti-inflammatory drugs (NSAIDs) (particularly sulindac), and anti-estrogens (►tamoxifen or toremifene). Overall the response rates to a variety of drugs in these classes is claimed to be in the region of 50%, but in reality is likely to be considerably less than this. There have been a handful of reports of acute desmoid necrosis, with abscess formation or bowel perforation in some, occurring in the weeks after initiation of drug treatment.

As NSAIDs have little in the way of adverse effects they are often used as first-line treatment. The mechanism of action in this setting is not clear, but there is some evidence that Cox-2 inhibition my inhibit desmoid growth ►celecoxib, ►cyclooxygenase-2 in colorectal cancer. There have been no trials of Cox-2 inhibitors used therapeutically. Anti-estrogens can be used alone or in combination with NSAIDs.

Surgery is widely accepted as the first line treatment for extra-abdominal and abdominal wall tumors. Recurrence rates are high (20–80%), but unaffected by use of prosthetic mesh in reconstruction. Serious morbidity and mortality rates are generally very low, although some sites, such as the neck, pose particular challenges. There are some reports suggesting that radiotherapy given postoperatively might reduce recurrence rates.

Excision of intra-abdominal desmoids is also associated with frequent recurrence, but carries a substantial risk of perioperative mortality or major morbidity. The commonest reason for this is that the tumors lie close to or encase the superior mesenteric blood vessels, so that the blood supply of a large part of the intestine may be damaged or deliberately sacrificed during surgery. This may result in the need for lifelong parenteral nutrition, and in a handful of cases small bowel transplantation has been performed in these circumstances. Careful case selection, using CT angiography and multiplanar reconstruction, together with accumulation of expertise in a specialized institution has been shown to produce better surgical results in the last 10 years. Generally, however, major resection of intra-abdominal desmoids should be avoided. Ureteric obstruction can be successfully overcome by ►stenting, and intestinal obstruction

or fistulation may be managed in many cases, at least acutely, by defunctioning.

Cytotoxic chemotherapy has been used to treat life-threatening desmoids. Response rates of 50% have been obtained using doxorubicin and dacarbazine in combination, and also with a less toxic regimen of methotrexate and vinblastine. In view of the potential toxicity of this type of treatment, it should probably be reserved for progressive, inoperable desmoid tumors in which other treatments have failed.

Synonyms

Stroma; Stromal cell response; Schirrous (*archaic*)

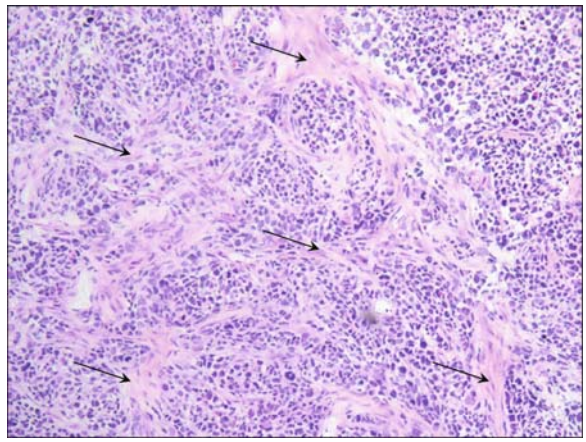
Definition

Desmoplasia is the formation of fibrous connective tissue by proliferation of ►fibroblasts. Desmoplasia is a key component of solid tumor stroma (Fig. 1).

Characteristics

Tumors have many parallels to wounds, including similar inflammatory and desmoplastic responses, and fibroblasts are the key cellular component in development of desmoplasia. Fibroblasts are recruited into the wound or tumor, secrete and remodel ►extracellular matrix (ECM) (►Extracellular Matrix Remodeling), and serve as scaffolding for other cell types in connective tissue. As fibroblasts incorporate into a tumor environment, they undergo a phenotypic change and acquire an "activated fibroblast" appearance, which are also known as a ►myofibroblasts or tumor-associated fibroblasts. Myofibroblasts have similar markers to fibroblasts, but myofibroblasts upregulate proteins such as α-smooth muscle actin (α-SMA), fibroblast activation protein (FAP-1), and ►fibronectin fibrils. During wound repair, the number of myofibroblasts return to a normal level upon wound resolution. In contrast to wound repair, ►tumor microenvironments simulate a chronic wound in many ways. Thus, local fibroblasts and those that were recruited into the expanding stroma are continuously exposed to activation signals. Activated fibroblasts expand and contribute to an increased stromal response known as desmoplasia. Desmoplasia can be associated with increased tumor stage and poor prognosis in ►breast cancer patients, but it is unclear whether fibroblasts are *active* inducers or *passive* participants in cancer progression. It is clear, however, that activated fibroblasts play a large role in the expanding tumor stroma (►Stromagenesis).

Fibroblastic stromal cells and desmoplasia have been linked to several activities that promote cancer growth



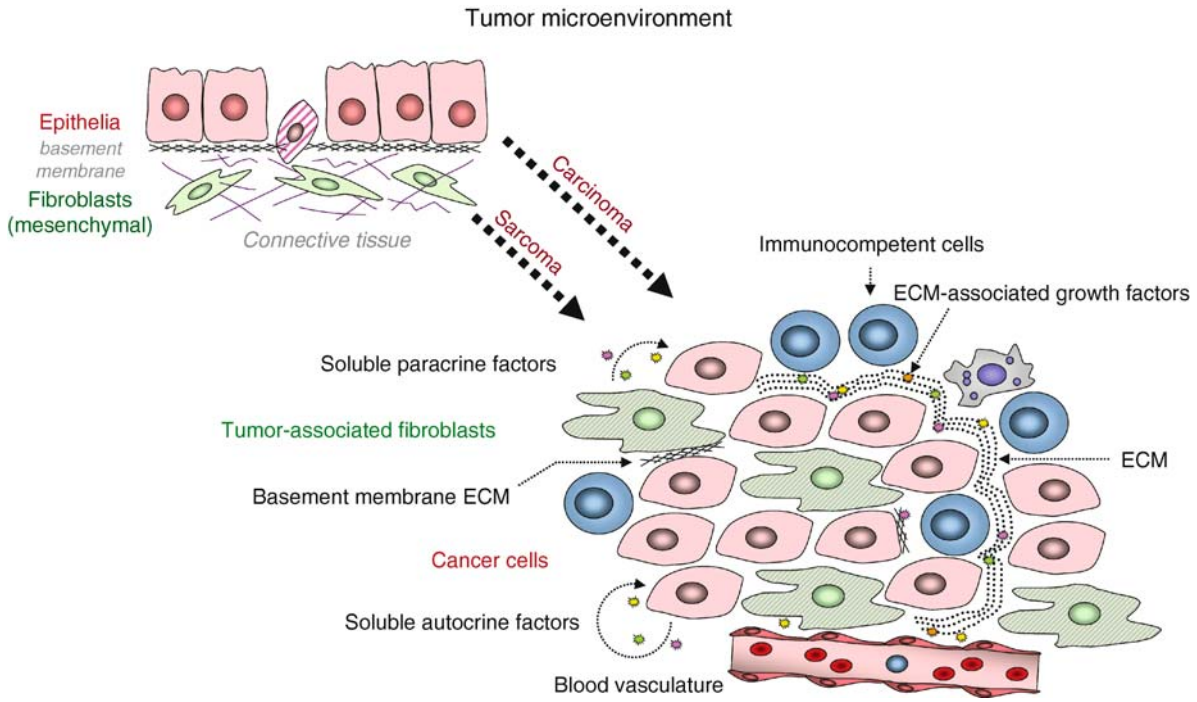
Desmoplasia. Figure 1 Hematoxolin and Eosin (H&E) stain. Tumor fibroblasts (i.e., desmoplasia) appear pink.

and ►metastasis (►Seed and Soil) including ►angiogenesis, ►epithelial to mesenchymal transition (EMT), and progressive ►genetic instability. Additionally, fibroblastic stromal cells can dysregulate anti-tumor immune responses, as exemplified by experiments demonstrating that ►allogeneic murine tumor cells, when co-injected with fibroblastic stromal cells, can engraft across immunologic barriers. Together, these studies suggest that tissue-specific fibroblasts are influential players in progression of metastatic cancer. However, with the exception of promoting epithelial to mesenchymal transition, the direct biological impact on cancer cells themselves has been difficult to distinguish from indirect mechanisms such as enhanced support for angiogenesis or recruitment of inflammatory cells.

The origins of desmoplastic fibroblasts are not fully understood. Some studies have suggested that stromal cell fibroblasts are recruited to the expanding tumor mass from local tissue fibroblasts. However, other experimental evidence supports that additional tumor-associated fibroblasts can be recruited from peripheral fibroblast pools, such as ►bone marrow-derived mesenchymal stem cells (MSC) or fibrocytes. It has been shown that once fibroblasts are recruited into the expanding stroma they change their phenotype and may also undergo selective genetic alterations, which may drive additional tumor growth. Desmoplastic tumor fibroblasts have also been shown to carry unique genetic lesions when compared to those found in expanding tumor cells. These observations offer an additional insight into potential mechanisms for how genetic lesions can induce tumor cell expansion.

The mechanism for recruitment of desmoplastic fibroblasts into a developing tumor remains poorly defined. Yet, several groups have shown that ►platelet-derived growth factor (PDGF) can contribute to the formation of desmoplasia. In a ►xenograft model using the human breast carcinoma cell line MCF-7 expressing the cellular oncogene, c-ras, investigators demonstrated that blocking tumor PDGF inhibited the formation of desmoplasia. Others have shown that blocking TGF-α, TGF-β, IGF-I, and IGF-II had no effect on the desmoplastic response. Since these models used murine xenografts it remains unclear whether PDGF is as critical for development of desmoplasia in human carcinomas (►Epithelial Tumorigenesis).

One important way that desmoplastic fibroblasts can contribute to tumor growth and metastasis is through the production of multiple growth factors (►Fibroblast Growth Factors). ►Paracrine growth factors such as the stroma derived factor 1 (SDF-1/CXCL12) (►angiogenesis), vascular endothelial growth factor (►VEGF) (angiogenesis), ►fibroblast growth factor (FGF) family, ►hepatocyte growth factor (HGF), ►transforming growth factor beta (TGF-β) family, ►interleukin-6 (IL-6), and epidermal growth factor (EGF) have all been linked to increased tumor growth. Desmoplastic fibroblasts also contribute to tumor stroma through the



Desmoplasia. Figure 2 The tumor microenvironment is composed of many cell types that support tumor cell growth and survival.

production of fibrous connective tissues and extracellular matrix proteins (►Fibronectin) (►Focal Adhesion Kinase (FAK)). ►Collagen production is a hallmark feature of desmoplasia. As fibroblasts convert to myofibroblasts or tumor-associated fibroblasts, parallel increases in production of collagen are observed. A pathologist can readily visualize increased levels of tumor collagen using standard histology procedures (►Pathology), and collagen types I and IV are the most prevalent forms of collagen found within most desmoplastic reactions. Collagen bundles interact with extracellular matrix and cell surface proteins such as ►integrins (►Cell Adhesion Molecules) (Focal Adhesion Kinase (FAK)) to influence the stiffness of a given tumor ►microenvironment.

Desmoplasia varies extensively between tumors and even within the same tumor. Some studies have suggested that desmoplasia is a defensive mechanism used to wall off the expanding tumor, but other data demonstrate that desmoplasia is associated with increased tumor growth, invasion, and metastasis. It is unclear, however, which underlying mechanisms determine the extent to which desmoplasia may promote tumor progression. As investigators continue to recognize the importance of the tumor microenvironment (Fig. 2), more detailed studies will allow clarification of the biological impact of desmoplasia in tumor development, survival and metastasis.

Definition

DSRCT; Is a rare and highly aggressive tumor occurring mostly in the abdominal peritoneal cavity of adolescents and young adults. In rare cases, the tumors can also be found in other sites such as pleural cavity, pelvis, bone, and head and neck region. DSRCT belongs to a group of undifferentiated small round cell tumors, which include ►Ewing sarcoma/primitive peripheral neuroectodermal tumor (PNET)/Askin's tumor and ►rhabdomyosarcoma. DSRCT is invariably defined by a ►chromosomal translocation involving chromosomes 11 and 22, t(11;22)(p13;q12), leading to a fusion of two unrelated genes, ►*EWS* and ►*WT1*, into a single ►chimeric gene.

Characteristics

Clinical and Pathological Features

DSRCT was first described in 1989 and is a poorly understood cancer that primarily affects young adults in their second and third decades of life. DSRCT occurs

predominantly in males than females but the reason for this is unknown. Symptoms of DSRCT are usually associated with abdominal pain or pain in the primary site of tumor involvement, distention, and palpable mass. Local invasion or metastasis to liver, lungs, and bone is commonly found at diagnosis. DSRCT displays distinct histological and immunological features. Most of DSRCT cases are presented as tumors in the serosal surface of abdominal cavity, displaying nests of tumor cells surrounded by dense stromal components (hence the term ►desmoplastic) containing spindle-shaped fibroblasts and hyperplastic blood vessels. Though rare, the primary tumors in sites other than abdominal region have been documented. The tumors are positive for various cell lineage markers, such as epithelial membrane antigen, keratin (epithelial), desmin (muscle), and neuron-specific enolase (neural). Thus, the tumor cell origin of DSRCT is not known.

DSRCT is a clinically aggressive tumor with a high risk of recurrence and an overall poor prognosis. The most recent report on the comparison of different treatments of DSRCT patients suggests that compared to patients who received conventional treatments, a multimodal therapy, which include high-dose multiagent chemotherapy, aggressive debulking surgery, and radiotherapy, can prolong overall survival at 3 years (55%) and may provide a possibility of achieving a long-term survival, albeit at a low rate. The two key elements of the multimodal approach are the use of high-dose polychemotherapy, so-called ►P6 protocol, and greater than 90% removal of tumor by surgery. P6 protocol consists of seven courses of high-dose alkylating agents ►cyclophosphamide, ►doxorubicin, ►vincristine, ifosfamide, and ►etoposide. This is followed by aggressive ►debulking surgery, which was shown to be the major determinant in patient survival. Postoperative radiotherapy also contributed to improved survival. Although the multimodal therapy can improve survival at 3 and 5 years, the prognosis of DSRCT still remains extremely low (median survival of 2.5 years).

Molecular Diagnosis

Although clinical, histologic, and immunologic features of DSRCT are distinct, a definitive diagnosis of DSRCT can be provided by genetic techniques. FISH technique, using fluorescently labeled genomic DNA probes derived from *EWS* and *WT1*, can be used to identify the specific t(11;22)(p13;q12) translocation of DSRCT. Alternatively, a definitive DSRCT diagnosis can be made with the use of reverse transcriptase-polymerase chain reaction (►RT-PCR) technique to amplify and detect the DSRCT-specific EWS/WT1 hybrid mRNA transcripts using DNA primers specific for *EWS* and *WT1* genes. This is an extremely sensitive detection method that can provide accurate diagnosis with limiting tumor materials.

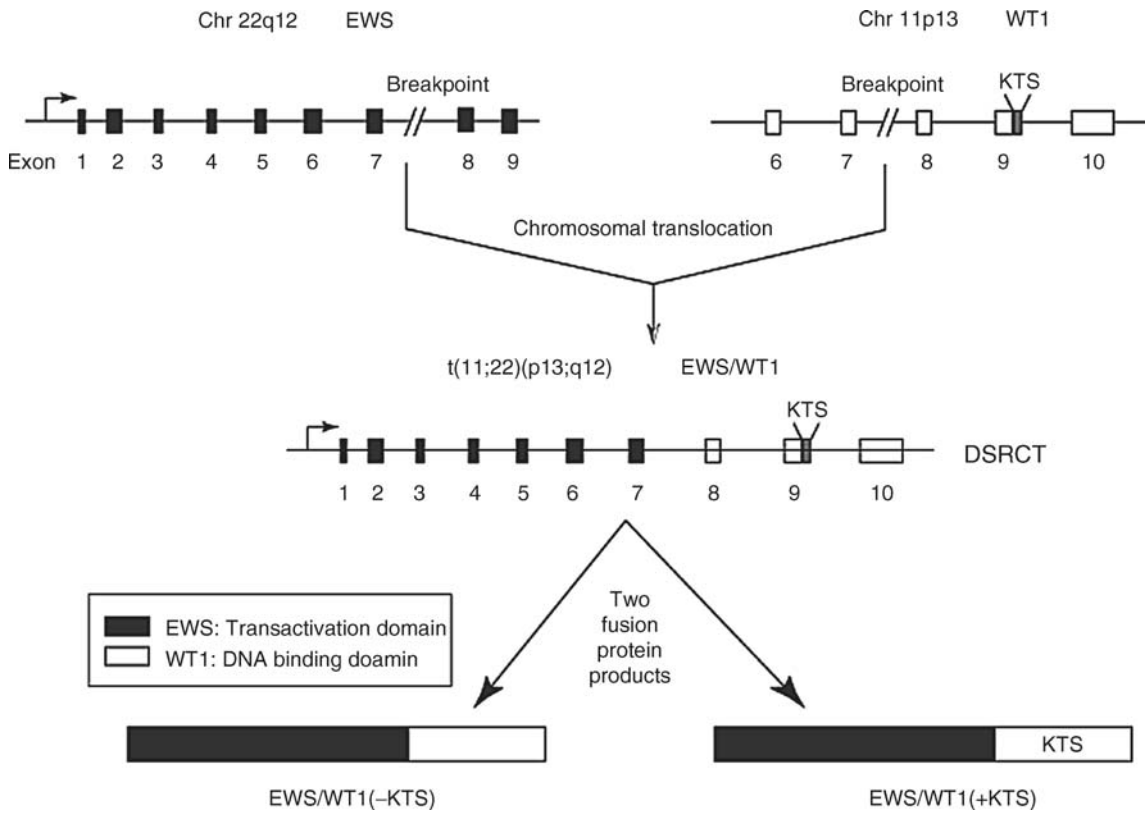
Molecular Genetics

Molecular genetic studies revealed that all cases of DSRCT harbor a balanced reciprocal chromosomal translocation, t(11;22)(p13;q12) (►reciprocal translocation) (Fig.1). The breakpoint in chromosome 22 has been mapped to the intron 7 of Ewing sarcoma gene, *EWS*, (breakpoints in other sites of *EWS*, such as in introns 8 and 10, have also been observed in rare cases), while the other breakpoint in chromosome 11 has been invariably mapped to the intron 7 of ►Wilms tumor gene, *WT1*. This DSRCT-specific chromosomal translocation between *EWS* and *WT1* results in a fusion of the N-terminal domain (NTD) of *EWS* to the C-terminal DNA-binding domain of *WT1*.

EWS gene was first isolated from the Ewing sarcoma chromosomal breakpoint, where the translocation generates a fusion between *EWS* and an ETS-family transcription factor gene, *FLI-1*. *EWS* encodes a putative RNA-binding protein with presumptive roles in transcription and splicing. The NTD of EWS mediates potent transcriptional activation when fused to a heterologous DNA-binding domain, while its C-terminal domain, which is lost in the translocation gene product, is involved in RNA recognition. *WT1* encodes a transcription factor which is mutated in a subset of Wilms' tumor, a childhood kidney cancer. *WT1* encodes four Cys_2-His_2 zinc-fingers in the C terminus that mediate sequence-specific DNA binding and the NTD containing both transcriptional activation and repression domains. *WT1* is subjected to two ►alternative RNA splicing events, one of which involves the usage of two alternative splice donor sites at the end of exon 9, leading to inclusion or exclusion of three amino acids, lysine, threonine, and serine (termed KTS), between the zinc-fingers 3 and 4 (Fig.1). The KTS insertion leads to a markedly decreased DNA-binding affinity of WT1. In all *EWS/WT1* translocations examined, only the last 3 exons of *WT1* (exons 8–10) encoding the last three zinc-fingers are fused to the NTD of EWS (Fig. 1), while the first zinc-finger of WT1 is invariably lost. The alternative KTS splicing of *WT1*, however, is preserved. As a result, *EWS/WT1* produces two isoforms: EWS/WT1(−KTS) and (+KTS) that differs in the DNA binding affinity and specificity (Fig. 1). In vitro study has shown that only the EWS/WT1(−KTS) isoform, but not the EWS/WT1(+KTS), possesses the oncogenic activity in ►NIH3T3 ►transformation assay.

DSRCT is a rare disease and has been recognized only recently as a distinct cancer type. Therefore, not much is known about the mechanisms of DSRCT but molecular details are starting to emerge. The novel fusion protein EWS/WT1(±KTS) acts as an aberrant transcription factor to presumably initiate the oncogenic

D



Desmoplastic Small Round Cell Tumor. Figure 1 Schematic representation of DSRCT-specific chromosomal translocation. A reciprocal balanced chromosomal translocation that results in the fusion of *EWS* gene to *WT1* gene is shown. The arrow indicates the promoter of *EWS* which drives the transcription of the fusion gene and the boxes mark the exons. Alternative KTS splicing (grey box, KTS) within the exon 9 of *WT1* is shown. Two isoforms of the fusion product are shown separately. See text for details.

process. To date, a number of direct transcriptional targets of EWS/WT1(−KTS) have been identified, which include *PDGF-A* (platelet-derived growth factor A), *IGFR1* (insulin-like growth-factor receptor 1), *IL2RB* (interleukin 2 receptor beta), *BAIAP3* (BAI1-associated protein 3), a potential regulator of growth-factor release, and *TALLA*-1 (T-cell acute lymphoblastic leukemia-associated antigen 1), a gene encoding a tetraspanin-family protein. There is only one target gene identified for EWS/WT1(+KTS), which is *LRRC15* (leucine-rich repeat containing 15), a gene implicated in cell invasion. All of these target genes are not transcribed by the native WT1 and thus represent EWS/WT1-specific transcripts. Identification of the EWS/WT1 target genes may provide clues to the molecular and cellular pathways that are central to DSRCT. For example, expression of IGFR1 and IL2RB can promote proliferation and survival of the tumor cells, while expression of PDGF-A and BAIAP3 by the tumor cells can enhance recruitment and proliferation of surrounding fibroblasts and stromal tissues, which may further enhance the growth of the tumor cells and may explain the dense stroma (desmoplastic feature) associated with DSRCT. Some of these target genes may also have diagnostic and therapeutic values, but it will require further evaluation.

Definition

Desmosomes are intercellular junctions that mediate cellular ►adhesion and maintain tissue integrity. They are found in ►epithelial cells, myocardial and Purkinje fiber cells of the heart, arachnoid cells of brain meninges and follicular dendritic cells of lymph nodes.

Characteristics

Desmosomes are localized at sites of close cell-cell contact (Fig. 1a). They are less than 1 μm in diameter, have a highly organized structure at the ultrastructural level and act as anchoring points for intermediate filaments of the cell cytoskeleton (Fig. 1b). By linking intermediate filaments of adjacent cells desmosomes confer structural continuity and mechanical strength on tissues. Desmosomes are particularly prevalent in tissues, such as the epidermis and heart, that experience mechanical stress. The proteins that form desmosomes belong to three genes families, the ►desmosomal cadherins, the ►armadillo family and the ►plakin family of cytolinkers.

Desmosomal Cadherins

The desmosomal cadherins are the membrane spanning ►cell adhesion molecules of desmosomes. In humans there are seven, four ►desmogleins (Dsg1–4) and three ►desmocollins (Dsc1–3). Each desmoglein and desmocollin is encoded by a distinct gene that is located in the desmosomal cadherin gene cluster on chromosome 18q21. All three desmocollin genes encode a pair of proteins, a larger "a" protein and a smaller "b" protein, that are generated by alternative splicing; the role of the smaller protein in desmosomal adhesion is not yet clear. All desmosomes contain at least one desmoglein and one desmocollin and both are required for adhesion. The desmosomal cadherins show tissue-specific patterns of expression with Dsg2 (►desmoglein-2 adhesion molecule) and Dsc2 ubiquitously expressed in tissues that produce desmosomes and the others largely restricted to stratified epithelial tissues. The extracellular domains of desmosomal cadherins produced by adjacent cells interact in the intercellular space. Within the cell desmosomal cadherin cytoplasmic domains associate with armadillo proteins (Fig. 1c).

Armadillo Family

Armadillo proteins that are found in desmosomes include ►plakoglobin (γ-Catenin) and ►plakophilins. Plakoglobin is indispensable for desmosome function and interacts with desmosomal cadherins, plakophilins and ►desmoplakin. Plakoglobin is also found in ►adherens junctions where it is interchangeable with a closely related armadillo protein, β-catenin. In addition to its structural role in adherens junctions, β-catenin acts as a signaling molecule in the ►APC/β-catenin pathway. There is a strong possibility that plakoglobin also has a signaling function in this pathway although its role has yet to be fully defined. There are three plakophilins (PKP1–3) that exhibit complex tissue-specific patterns of expression. All three plakophilins show dual localization in desmosomes and in the nucleus. The plakophilins have an important structural role in desmosomes and, because of their nuclear localization and similarity to other armadillo proteins, it is possible that they act as signaling molecules.

Plakin Family

►Plakin family proteins bind intermediate filaments and several, including desmoplakin, plectin, envoplakin and periplakin, localize to desmosomes. Of these only the presence of desmoplakin is obligatory for normal desmosomal adhesion. It is a dumbbell shaped molecule with two globular domains separated by a coiled-coil rod domain and is thought to exist as a homodimer. The desmoplakin gene encodes two proteins (DPI and DPII) that are generated by alternative splicing and differ only in the length of their central rod domain; the role of DPII, the smaller of these proteins, is unclear. The N-terminal end of desmoplakin binds to plakoglobin and plakophilins whereas its C-terminal end binds to intermediate filaments. In epithelial tissues desmoplakin anchors keratin intermediate filaments to the membrane, but in myocardial and

Purkinje fiber cells it interacts with desmin intermediate filaments and in arachnoid and follicular dendritic cells it associates with vimentin intermediate filaments.

Null Mutations in Mice

►Genetic ablation studies in mice have shown the importance of desmosomes for embryonic development and normal tissue biology. ►Knock-out mice of either Dsg2, Dsc3 or desmoplakin display early embryonic lethality at around implantation or before. Mice without either PKP2 or plakoglobin survive longer but die during mid-gestation as a result of heart defects. Embryonic survival is not affected by absence of either Dsg3, Dsg4 or Dsc1 but loss of these molecules does result in defects in keratinocyte adhesion and skin and hair abnormalities.

Clinical Relevance

Loss of desmosomal adhesion can result in skin blistering diseases. Pemphigus is an autoimmune blistering disease that is caused by pathogenic ►autoantibodies against desmogleins. Staphylococcal scalded-skin syndrome is caused by toxins with serine protease activity that are released by the bacterium *Staphylococcus aureus* and specifically cleave Dsg1. Mutations in DNA encoding desmosomal constituents result in a variety of diseases that can affect the skin, hair and heart, and sometimes all three.

No mutations in desmosomal cadherins, plakophilins or desmoplakin have been found so far in cancer. However, many reports have documented altered expression of desmosomal constituents in tumorigenesis. For example, loss of Dsg2, Dsc2 and Dsc3 occurs in ►gastric ►colorectal and ►breast cancer respectively. By contrast Dsg2 is overexpressed in ►skin cancer and Dsg3 is overexpressed in head and neck cancer. PKP3 levels are elevated in ►lung cancer and loss of desmoplakin has been correlated with progression in a variety of epithelial tumors. A causal relationship between these changes and cancer has yet to be established.

Mutations in plakoglobin, concomitant with strong nuclear accumulation, have been linked to the pathogenesis of prostate cancer. Nuclear accumulation and improper activation of transcriptional targets as a result of a failure to degrade cytoplasmic β-catenin has been implicated in FAP (►APC gene in Familial Adenomatous Polyposis), a familial syndrome that predisposes to ►colon cancer, and sporadic colon cancer. It remains to be seen whether plakoglobin has, in common with β-catenin, pro-proliferative effects in cancer. In many cancers loss of expression of plakoglobin has been observed and it may be that plakoglobin is anti-proliferative in some cell types. There is little doubt that plakoglobin plays a role in cancer but whether this is related to its participation in desmosomes remains unclear.

Overall it appears that the importance of desmosomes in cancer is twofold. Firstly, as mediators of cell-cell adhesion reduced expression of desmosomal constituents could lead to loss of cell-cell adhesion, ►epithelial-mesenchymal transition, increased invasiveness and metastasis. Secondly, desmosomes may act as signaling centers and variations in expression levels of desmosomal proteins could trigger intracellular signaling cascades that contribute to cancer pathogenesis.

Detoxication; Drug metabolism; Xenobiotic metabolism; Carcinogen metabolism; Xenobiotic biotransformation

Definition

Metabolic and transport processes used to chemically inactivate noxious compounds and eliminate them from cells for subsequent excretion from the body.

Characteristics

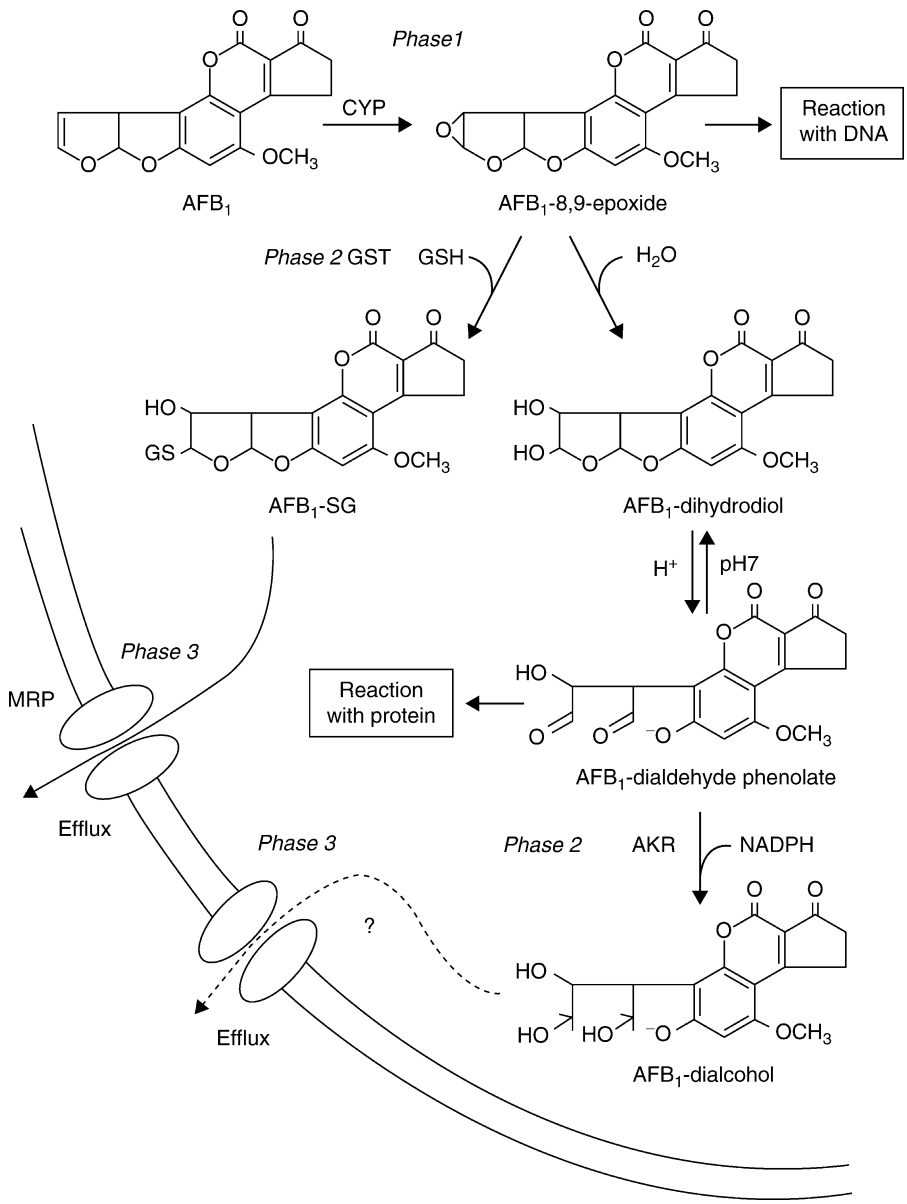
Humans are continuously exposed to foreign chemicals (xenobiotics (►Xenobiotic)) through administration of medicines, the consumption of food and drink, and air breathed. Protection against the detrimental effects of xenobiotics is achieved by the concerted actions of a battery of proteins that metabolize, transport and ultimately pump out of cells modified forms of the compounds originally encountered. This process is called detoxification, or detoxication (in instances where no toxicity occurs). Although detoxication occurs primarily in the liver, all cells possess some capacity to metabolize and eliminate unwanted chemicals. The xenobiotics subject to this process are numerous and include mycotoxins, phytoallexins, pesticides, herbicides, environmental pollutants, cytotoxic anti-cancer agents and many pharmacologically-active drugs. Detoxication processes also confer protection against harmful compounds of endogenous origin, many of which arise as a consequence of interaction with reactive oxygen species, such as the superoxide anion, produced normally in the body.

Detoxication is achieved in two distinct stages, the first involving metabolism of the xenobiotic, and the second involving energy-dependent efflux of the xenobiotic from the cell. Historically, description of xenobiotic biotransformation has been divided into phase 1 and phase 2 metabolism, and consequently efflux of xenobiotics is referred to as phase 3 of detoxication.

- Phase 1 drug metabolism involves an initial chemical modification of the xenobiotic that results in the introduction, or exposure, of a functional chemical group (e.g. –OH, –NH_2, –SH, –COOH) into the compound. This usually entails enzyme-catalyzed oxidation reactions by ►cytochrome P450 (CYP) or flavin monooxygenase.
- Phase 2 drug metabolism often involves a second chemical alteration of the xenobiotic, usually at the same region of the molecule where the functional group was introduced. This is performed by enzymes catalyzing conjugation reactions (such as ►glutathione S-transferase (GST), ►N-acetyltransferase (NAT), ►sulfotransferase (SULT) and ►UDP-glucuronosyl transferase (UGT). It should be noted that use of the terms phase 1 and phase 2 to define the detoxication enzymes is somewhat arbitrary and does not necessarily reflect the pathway of biotransformation of all chemicals. Thus, a number of xenobiotics are subject to several modifications by the phase 1 CYP isoenzymes before serving as substrates for the phase 2 enzymes. Alternatively, some xenobiotics do not require modification by phase 1 enzymes before metabolism by phase 2 enzymes, and others are subject to modification by more than one phase 2 drug-metabolizing enzyme. As a result of differences in drug metabolism, the group of enzymes catalyzing reduction of hydrolysis reactions (e.g. ►aldehyde dehydrogenase (ADH), ►aldo-keto reductase (AKR), ►epoxide hydrolase (EPHX) and ►NAD(P)H-quinone oxidoreductase (NQO)) are variously referred to as phase 1 or phase 2 detoxication, depending on the individual xenobiotic being considered and the preferences of research workers. Clearly, these enzymes provide a highly flexible metabolic defense that has evolved to protect against a diverse spectrum of chemicals.
- Finally, phase 3 of detoxication involves ATP-dependent elimination of the parent compound or modified xenobiotic by proteins that are drug efflux pumps (e.g. ►multidrug resistance protein (MDR) and ►multidrug resistance-associated protein (►Multidrug resistance protein) (►MRP)). As a consequence of the combined actions of phase 1 and phase 2 enzymes, a diverse spectrum of xenobiotics acquires a limited number of molecular "tags" (i.e. acetate, glutathione, glucuronide or sulfate moieties) that are recognized by the MRP trans-membrane pumps. Furthermore, the xenobiotic metabolites produced by phase 1 and phase 2 are usually more soluble, and easily excreted, than the parent compound.

Whilst the ability of CYP to oxidize xenobiotics is generally desirable, as it facilitates further metabolism and elimination of harmful chemicals, it can sometimes result in the generation of highly reactive products that may not be readily detoxified. In such instances, modification of intracellular macromolecules will occur resulting in necrosis, ►apoptosis or malignant ►transformation. As an example of the interplay between toxification and detoxification reactions, a scheme depicting metabolism of ►aflatoxin B1 (AFB1), modification of macromolecules by AFB1 metabolites, and efflux of the AFB1-glutathione conjugate from a cell is shown in the illustration (Fig. 1).

D



Detoxification. Figure 1 Detoxification pathways for aflatoxin B1. The mycotoxin is converted to the ultimate carcinogen AFB1-8,9-epoxide, by the actions of the hepatic phase 1 CYP enzyme system. The epoxidated AFB1 is highly reactive, and if it is not detoxified it will form DNA adducts that may cause hepatocarcinogenesis. The phase 2 GST enzymes can achieve detoxification of this unstable intermediate, and the resulting AFB1-glutathione conjugate is eliminated from the liver cell by MRP. In addition, AFB1-8,9-epoxide can rearrange to form a dialdehyde-containing metabolite which will covalently modify proteins by forming Schiff's bases. The dialdehyde can be reduced by phase 2 AKR to yield a dialcohol that may be a substrate for SULT or UGT before being transported out of the cell, presumably by MRP.

Genetic Variation

Numerous proteins have evolved that detoxify drugs, and certain of the families listed above comprise over twenty genes. In total, the human probably possesses between 100 and 150 genes encoding detoxication proteins. Substantial variation can occur in the levels of these proteins in tissues from different individuals, and this can result in increased sensitivity of cells to chemical insult. In part, this inter-individual variation is due to ►genetic polymorphisms. By definition, such differences must be present in at least 1% of the population in order to be considered a ►genetic polymorphism. In some instances the variation involves deletion of detoxication genes with complete loss of

specific functions, whereas in other instances point mutations result in alteration of protein structure causing only a modest attenuation of activity. In other cases mutations alter the regulatory regions of genes causing altered expression of normal protein. Detoxication genes that are polymorphic in the human include those for the enzymes CYP3A4, CYP2C9, CYP2C19, CYP2D6, CYP2E1, AKR1C4, GSTM1, GSTP1, GSTT1, NAT2, SULT1A1, SULT1E1, SULT2A1, UGT1A1, UGT1A4, UGT1A6 and UGT2B7, EPHX and NQO1, as well as the MRP2 efflux pump. It is clear additional polymorphisms remain to be identified.

Cellular Regulation

In addition to genetic polymorphisms, induction of detoxication proteins by xenobiotics and environmental agents is a further mechanism that can cause inter-individual differences in detoxification capacity. Induction of detoxication proteins represents an ►adaptive response to chemical and ►oxidative stress, which can be brought about by synthetic drugs or by naturally occurring compounds such as coumarins, indoles and isothiocyanates that are found in edible plants. Increased expression provides short-term resistance to toxic xenobiotics. Enzyme induction also results in increased metabolism of therapeutic drugs. Many of the enzymes and pumps such as CYP, GST, ADH, AKR, NQO and MRP are inducible, often by transcriptional activation of genes encoding the proteins. The promoters of these genes contain enhancers that enable a transcriptional response to a diverse spectrum of chemical agents. The enhancers that are involved in induction of detoxication proteins include ►AP-1 binding sites, the antioxidant responsive element, the xenobiotic responsive element, the phenobarbital responsive enhancer module, progesterone X receptor and peroxisome proliferator-activated receptor enhancer.

Clinical Relevance

It is apparent from studies into the mechanisms of selective toxicity between species that variation in the activity of detoxication proteins influences sensitivity to chemical insult. Increasing evidence suggests that genetic polymorphisms in detoxication enzymes can confer an inherited predisposition to a number of malignant diseases that are influenced by environmental factors (e.g. lung and colorectal cancer). They may also confer a predisposition to adverse drug reactions.

Induction of some phase 2 detoxication systems is believed to represent a major mechanism of cancer ►chemoprevention, and is thought to explain in part the epidemiological data suggesting that consumption of diets rich in fruit and vegetables protect against certain malignant diseases.

Acquired ►drug resistance to chemotherapy is a major problem in the treatment of many cancers. There is overwhelming evidence that the overexpression of several detoxication proteins, particularly GST, MDR and MRP, contributes to the drug-resistant phenotype.

Detoxication

Definition

Synonym Detoxification; Process, or processes, of chemical modification which make a toxic molecule less toxic.

►Toxicological Carcinogenesis

De-ubiquitinase

Definition

DUB; An enzyme that can specifically remove ►ubiquitin proteins from substrates through an enzymatic cascade that cleaves an isopeptide bond.

►Herpesvirus-Associated Ubiquitin-Specific Protease (HAUSP) De-Ubiquitinase
►Ubiquitination

De-ubiquitinating Enzymes

Definition

Are a large family of enzymes that cleave chemical bonds formed at the C-terminus of ►ubiquitin. By virtue of their action, the ►ubiquitination of a given protein is reversible. Ubiquitin-protein conjugates are not always degraded by the proteasome, an alternative fate is the protein is spared from degradation through the activity of any of a large family of de-ubiquitinating enzymes. De-ubiquitinating enzymes can remove ubiquitin from ubiquitin-protein conjugates. These enzymes break down abundant multiubiquitin chains that are nor attached to any substrate and produce mature ubiquitin from the precursor forms in which it is synthesized. A second alternative fate for ubiquitin-protein conjugates is that ubiquitinated cell surface proteins may be targeted for endocytosis and eventual degradation via the lysosome rather than the proteasome.

Diabetes

Definition

Diabetes mellitus; People who are Type 1 Diabetes mellitus must use manufactured ►insulin, usually in an injectable form, to replace the natural insulin that is no longer produced by their body (for instance as the result of beta-cell degeneration). People with Type 2 Diabetes sometimes need to use insulin when their cells become too resistant to the insulin that they produce naturally and when oral medications are no longer working.

Diabetes Type 2

Definition

Type 2 Diabetes, is a metabolic disorder characterized by insulin resistance, relative insulin deficiency, and hyperglycemia. A disorder of glucose and insulin metabolism that is characterized by inappropriately increased blood glucose levels and resistance of tissues to the action of insulin. Insulin levels are elevated during early stages of the disease. Previously referred to as adult-onset diabetes or non-insulin-dependent diabetes.

►Adiponectin

Diabody

Shuji Ozaki
Department of Medicine and Bioregulatory Sciences, The University of Tokushima Graduate School of Health Biosciences, Tokushima, Japan

Synonyms

Engineered antibody; Single-chain Fv dimer; Multimeric antibody fragments

Definition

Diabody is a noncovalent dimer of single-chain Fv (scFv) fragment that consists of the heavy chain variable (V_H) and light chain variable (V_L) regions connected by a small peptide linker. Another form of diabody is single-chain $(Fv)_2$ in which two scFv fragments are covalently linked to each other.

Characteristics

Advances in antibody technology are enabling the design of antibody-based reagents for specific purposes in cancer diagnosis and ►monoclonal antibody therapy. First, to minimize the immunogenicity and enhance the efficacy in human use, mouse monoclonal antibodies are engineered to ►chimeric antibodies or ►humanized antibodies by grafting to the human constant region or framework. Moreover, fully human antibodies are developed by the use of ►transgenic mice or phage display technology. Second, monoclonal antibodies are designed as immunoconjugates to deliver the cytotoxic agents such as chemotherapeutic drugs, toxins, enzymes, and radioisotopes. These therapeutic antibodies have emerged as potent agents and are used worldwide for cancer therapy. More recently, engineered antibody fragments have been investigated as alternative reagents because of their unique properties resulting from the structure.

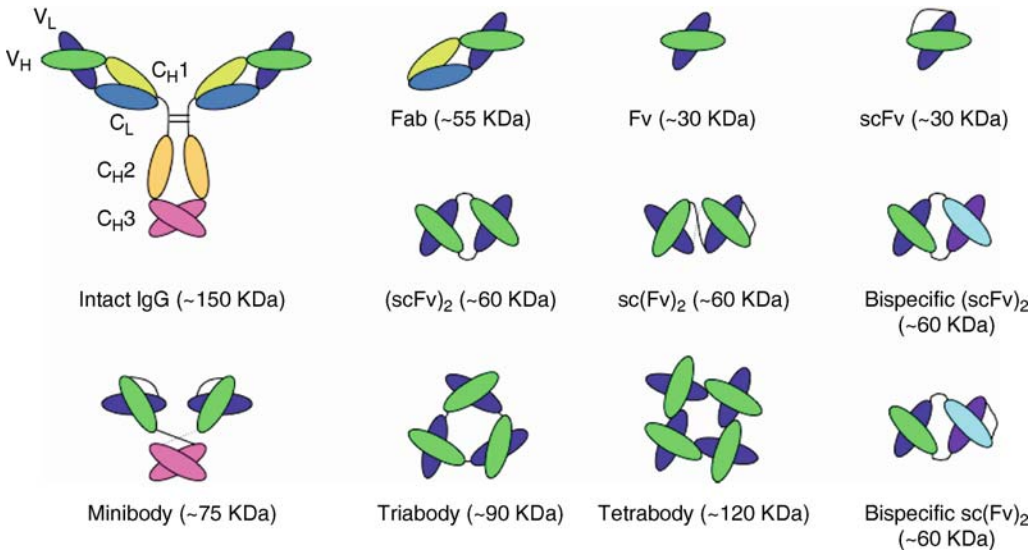
Structure

A variety of antibody fragments are developed including single V_H domain, Fab, scFv, and multimeric formats such as multivalent scFvs (diabody, triabody, and tetrabody), bispecific scFv, and minibody (scFv–CH3 dimer) (Fig. 1). In scFv fragments, the V_H domain binds to its attached V_L domain when the linker is flexible and long enough (a length of at least 12 amino acids). For example, the linker sequence of $(Gly_4Ser)_3$ provides sufficient flexibility for the V_H and V_L domain to form Fv comparable to the parent antibody. In contrast, when the linker is shortened to less than 12 residues (e.g., five amino acids of (Gly_4Ser)), the V_H and V_L domains are unable to bind each other and instead the scFv fragment form a noncovalent dimer by another scFv molecule [$(scFv)_2$ diabody]. Shortening of the linker length between the V_H and V_L domains (less than three residues) promotes the assembly of trimeric or tetrameric structures (triabody or tetrabody). However, this multimer formation also depends on the V-domain orientation either V_H–V_L or reverse V_L–V_H orientation in the scFv constructs. The bivalent Fv fragment can also be designed by linking two scFv domains covalently as a single chain version [$sc(Fv)_2$ diabody]. The $sc(Fv)_2$ version is more stable than $(scFv)_2$, and this structure may form a noncovalent dimer $[sc(Fv)_2]_2$.

The capacity of multivalent binding of these fragments offers a significant opportunity to design multifunctional antibody reagents. The diabody structure is used to form ►bispecific antibodies by linking different V_H and V_L domains of two antibodies (e.g., V_HA–V_LB and V_HB–V_LA). However, when two different polypeptides are produced within a single cell, purification steps are necessary to obtain the active heterodimeric antibody among the inactive homodimers. Therefore, bispecific $sc(Fv)_2$ version is developed by connecting two different scFv domains with the middle-length linker (e.g., V_HA–V_LB–V_HB–V_LA or V_HA–V_LA–V_HB–V_LB).

Pharmacokinetics and Distribution

The ►pharmacokinetics of these antibody fragments is markedly different from intact IgG antibodies that exhibit prolonged circulation ($t_{1/2}$ of up to 3 weeks). The lower molecular weight constructs (below than 60 kDa) are subject to be excreted by renal clearance, resulting in a shorter serum half-life than intact IgG. In most cases, the $t_{1/2}$ values of scFv and diabody are extremely short such as 2 and 6 h, respectively.



Diabody. Figure 1 Schematic structure of intact IgG antibody and engineered antibody fragments. The variable regions of heavy (V_H) and light chains (V_L) contribute to the antigen binding. The V_H and V_L domains can be connected by a peptide linker to form single-chain Fv (scFv). The scFv fragments can form multimers such as $(scFv)_2$ diabody, triabody, and tetrabody depending on the linker length and the V-domain orientation. The bivalent $sc(Fv)_2$ can be generated by connecting two scFvs covalently. Bispecific diabodies can also be engineered by using two different Fv domains.

This rapid pharmacokinetics is the most favorable for imaging applications and ►radioimmunotherapy because of the lower background levels in normal tissues. ►Drug biodistribution studies of radiolabeled scFv and $sc(Fv)_2$ have shown high tumor-to-blood ratios in xenograft models compared with intact IgG antibodies. The fast blood clearance of antibody fragments contributes to avoid undesired toxicity, and these fragments have the remarkable advantage for ►targeted drug delivery of toxins or radioisotopes.

In addition, antibody fragments show better penetration into the tumor mass, but these smaller constructs have shorter retention to tumor cells at the same time. Thus, the valance of penetration and retention of antibodies is an important factor for therapeutic use, especially in solid tumors. The Fab and scFv fragments are monovalent and exhibit poor retention on target cells, but multivalent forms of these fragments such as diabody, triabody, and tetrabody exhibit dramatically increased affinity and high tumor retention compared with the parent scFv. The ideal tumor-targeting reagents are intermediate-sized multivalent antibodies such as bivalent diabodies that show a longer half-life as well. In another approach, the Fc portion is fused to antibody fragments to control the serum levels of the antibody. The scFv–Fc or scFv–CH3 fusion antibodies (minibodies) are expected to have a more prolonged half-life and increased tumor accumulation in vivo. The serum half-life of antibody fragments can also be extended by modification such as linkage to polyethylene glycol (►PEG).

Agonistic Activity

In terms of mechanism of action, intact IgG antibodies kill tumor cells mainly by Fc-mediated effector functions such as ►antibody-dependent cell-mediated cytotoxicity (ADCC) and ►complement-dependent cytotoxicity. In contrast, antibody fragments have the compact structures without the Fc portion, and have unique characteristics for using cancer treatment. The two binding sites of diabodies are located at a distance of about 70Å less than half for those of intact IgG antibodies. Therefore, diabodies can place the antigens more closely to each other than by the parent IgG antibodies, which efficiently induces the ligation of target molecules on the cell surface. When the targets are functional receptors, the diabody can mediate a direct effect or signal transduction in tumor cells, including the stimulation of ►apoptosis or cell death. For example, we and our collaborators have generated $(scFv)_2$ and $sc(Fv)_2$ diabodies that recognize CD47 or ►HLA class I molecules. These diabodies can cross-link the target antigens and show the enhanced cytotoxic activities against hematological malignancies such as leukemia, lymphoma, and myeloma cells when compared with the original IgG antibodies. Thus, enhancement of the cross-linking potential is one of the important bioactivity of antibody fragments.

Application of Diabodies

A variety of target antigens have been evaluated for therapeutic purposes including CD19, CD20, CD22,

epithelial cell adhesion molecule (Ep-CAM), epidermal growth factor receptor (EGFR), HER2, MUC1, and carcinoembryonic antigen (►CEA). Several types of diabodies and minibodies are engineered for targeting these candidate antigens on tumor cells. Immunotoxins are also constructed to deliver the cytotoxic agents, radioisotopes, enzymes, cytokines, and liposomes by using antibody fragments. Previous studies have shown the effectiveness of these reagents in preclinical and clinical trials.

►Bispecific antibodies that comprise two different binding specificities have been studied extensively in cancer diagnosis and therapy. Most of the bispecific reagents are designed for the retargeting of effector cells such as cytotoxic T lymphocytes and NK cells. Recombinant bispecific diabodies such as anti-CD19 x anti-CD3, anti-Ep-CAM x anti-CD3, and anti-HER2 x anti-CD3 have been used in the immunotherapy of ►B-cell lymphoma ►breast ►ovarian and ►colorectal cancer. Another strategy of bispecific antibodies is the recruitment of effector molecules including toxins, drugs, ►prodrugs, ►cytokines, and radionuclides in vivo. First, the tumor cells are targeted by the tumor-specific binding site of the diabody. After the unbound diabody is cleared from the serum, cytotoxic drugs or radiolabeled hapten are administered to be captured by another binding site of the bound diabody.

Future Directions

In principle, selection of target molecules and modification of antibody constructs are key issues of antibody-based strategies in clinical utility. Based on the properties of pharmacokinetics, biodistribution, and manufacturing production, engineered antibody fragments have been investigated as alternative reagents to target cancer cells. Although the efficacy of these antibody fragments needs to be evaluated in clinical settings, the drastic potential of agonistic activity or multivalent activity of these reagents will provide new promises for development of the next generation of antibody drugs in cancer diagnosis and treatment.

Diet

Definition

Dietary factors may contribute to enhancing risks for the various cancers. These factors are heterogeneous. In many cases individual compounds have been suggested to be involved but little definitive evidence is available. The individual risk factors are specific for different tissues, and the state of current knowledge has recently been published. In general diets high in total fat or animal fat are considered causative for several common tumors including those arising from tissues of the gastrointestinal tract. In contrast, vegetables and fruits are considered to be protective for many tissues and for all cancers discussed in the review listed below. Phytoprotectants are implicated as contributing to risk reduction by different mechanisms, but it has not been possible to pinpoint individual compounds as the responsible factors. Tissues that seem to be most protected are esophagus, stomach, colon, lung, pancreas and bladder. The least clear cut protection is achievable in the hormone dependent tissues, prostate and breast, although a dietary component can not be excluded for these tumors. Altogether the estimates indicate that at least 35% of all human tumors are dietary related, which means a large proportion of tumors could be prevented by adequate dietary regimens; biomarkers

Diethylstilbestrol

Rosemarie A. Ungarelli, Carol L. Rosenberg
Boston Medical Center and Boston University School of Medicine, Boston, MA, USA

Synonyms

DES

Definition

Diethylstilbestrol is a synthetic non-steroidal estrogen with biological properties similar to endogenous estrogens such as estradiol-17-beta and estrone (►Estradiol).

Characteristics

Pharmacology

Diethylstilbestrol is administered orally, is lipid-soluble, and readily absorbed from the proximal gastrointestinal tract. It is metabolized via the hepatic microsomal system to dienestrol, and quinone and epoxide intermediates. It crosses the placenta and is thought to be metabolized by the fetus.

Initial Use and Early Epidemiologic Studies

Diethylstilbestrol (DES), first manufactured by Dodds and associates in London in 1938, was used to treat several gynecologic conditions. In particular, it was

prescribed for the treatment of frequent or threatened miscarriages. As early as 1953, Dieckmann and colleagues demonstrated that DES did not improve pregnancy outcomes. (In fact, in a later re-analysis of these data in 1978, Brackbill and Berendes showed that women exposed to DES had higher risks of premature births, perinatal death, and miscarriages than women who were given placebo.) Other studies also found DES to be ineffective in preventing adverse pregnancy outcomes, but physicians continued to prescribe the drug to try to maintain high-risk pregnancies because its use seemed logical and it was well-established. It was administered to approximately 5–10 million pregnant women in the United States between 1940 and 1971. It remained in use in Europe until the early 1980s.

In 1971, Herbst and colleagues established a strong connection between DES exposure *in utero* and subsequent development of clear-cell adenocarcinoma of the vagina and cervix in young women, aged 14–21 years. The incidence of this cancer in women whose mothers had been administered DES during pregnancy (►DES daughters) is estimated to range from 1.4 cases per 1,000 exposed to one case per 10,000 exposed persons (►Cervical cancer). Previously, clear-cell adenocarcinoma of the vagina and cervix had been observed only rarely, primarily in post-menopausal women (over age 50) not exposed to DES. Consequently, the U.S. Food and Drug Administration issued a drug bulletin recognizing DES as a ►transplacental carcinogen, and banned its use during pregnancy (►Carcinogen). Since then, DES exposure has been observed to cause a range of teratogenic and neoplastic changes in humans and animals. It is used now mainly for treatment of a small subset of hormonally responsive refractory cancers. However, DES exposure can serve as a model for evaluating the potential effects of xenoestrogens (►Hormonal carcinogenesis; ►estrogenic hormones). Therefore, its investigation remains important and should not be limited to the study of the consequences of a specific, unintentionally deleterious administration.

Animal Studies

DES has been studied extensively in animal models. In the Syrian hamster model, exposure to DES induces neoplasms of the liver and kidney, as well as aneuploidy (particularly chromosome gains) in the renal neoplasms (►Aneuploidy, ►chromosome instability). DES exposure in rats elicits tumors of the reproductive tract, pituitary and mammary glands. In addition, Green and colleagues have observed that DES metabolites produce DNA adducts (►Adducts to DNA) and, ultimately, cancer in the breast of female ACI rats. Tumors of the reproductive tract and mammary glands are seen in the murine model as well, along with alterations in the genetic pathways governing uterine differentiation. Data from Newbold and colleagues suggest that an increased susceptibility to tumor formation is transmitted along the maternal lineage to subsequent generations, both male and female. Thus, not only is the developing organism sensitive to the endocrine-disrupting chemical, but transgenerational effects are plausible as well.

Neoplastic Effects in Humans

The only increased risk of hormone-dependent cancers observed in women who took DES during pregnancy (►DES mothers) is ►breast cancer (Table 1). Hatch and colleagues found that DES mothers had a 30% increased rate of breast cancer compared to the general population. In contrast, DES daughters have an increased risk of two types of hormone-dependent cancers, clear cell adenocarcinoma of the vagina and cervix (mentioned above) and breast cancer (►Breast cancer). Clear cell adenocarcinoma of the vagina and cervix generally presents in these women when they are in their teens and twenties; however, because some women have been diagnosed in their thirties and forties, concerns have arisen about whether

Diethylstilbestrol. Table 1 Effects of diethylstilbestrol exposure

	Non-neoplastic effects	Neoplastic effects
DES Mothers	Increased risk of • Adverse pregnancy outcomes	Increased risk of • Breast cancer
DES Daughters	Increased risk of • Adverse pregnancy outcomes • Infertility • Reproductive tract structural abnormalities • Vaginal adenosis	Increased risk of • Clear-cell adenocarcinoma of vagina and cervix • Breast cancer over age 40
DES Sons	Increased risk of • Epididymal cysts • Cryptorchidism • Testicular hypoplasia • Semen and sperm abnormalities	No increased risk of hormone-related cancers

another increase in risk will occur as DES daughters approach the age at which this type of cancer is seen in the general population (the postmenopausal period).

Until recently, there was a paucity of information on breast effects in DES daughters. However, the National Cancer Institute's Continuation of Follow-Up of DES-Exposed Cohorts has proven a rich source of information to study the long-term effects of *in utero* estrogen exposure in humans. These cohorts include over 4,000 women who had documented *in utero* exposure to DES and more than 2,000 unexposed women from the same record sources; all have been followed from 1994 or earlier. As women exposed *in utero* to DES have begun to reach the ages at which breast cancer is more common, it appears that these women have an increased risk. In the most recent data from the National Cancer Institute collaborative follow-up study of DES health effects (Continuation of Follow-Up of DES-Exposed Cohorts), Palmer and colleagues found that at ages 40 and older, DES daughters had double the risk of breast cancer of unexposed women; no association was seen prior to age 40.

To date, males exposed *in utero* to DES (►DES sons) do not exhibit an increase risk of developing hormone-related cancers. However, DES sons do display non-neoplastic abnormalities (see below) that place then at increased risk of developing testicular cancer regardless of DES exposure (►Testicular cancer).

Non-Neoplastic Effects in Humans

In utero exposure to DES has been shown to elicit a variety of non-neoplastic reproductive tract abnormalities, including structural cervical, vaginal, or uterine abnormalities, in addition to changes in the vaginal epithelium such as adenosis (see Table 1). DES dosage and the stage of pregnancy during which the drug was administered appears to be directly linked to the severity of the adenosis, with the most severe manifestations seen in DES daughters whose mothers took the drug during their first trimesters. It is unclear whether these areas of adenosis progress to vaginal clear cell adenocarcinoma. DES daughters have an increased risk of poor pregnancy outcomes, such as ectopic pregnancy or miscarriage, and also have a higher incidence of infertility than the general population.

DES sons are more likely than unexposed men to exhibit genital abnormalities such as epididymal cysts, cryptorchidism, and testicular hypoplasia. Although DES sons show an increased incidence of semen and sperm abnormalities, they have not demonstrated an increased risk of infertility, but this is still under investigation.

Mechanism of Toxicity

The mechanism by which estrogens in general, and DES in particular, exert their toxic and carcinogenic effects is not fully understood. Both proliferative and genotoxic mechanisms have been postulated. Classically, estrogen exerts its effects through interaction with the estrogen receptor α (ERα), which stimulates cell proliferation and inhibits apoptosis (►Estrogen receptor). ERα may also interact with other receptors (such as ERβ, insulin-like growth factor 1 receptor and epidermal growth factor receptor) to influence proliferation, or may act through non-genomic pathways, since it is found in non-nuclear subcellular fractions such as the plasma membrane and the mitochondria. An alternative or additional mechanism that may mediate estrogen's and perhaps DES' toxic effects is through the metabolites' genotoxic capacity. ►Estrogens, and specifically DES, can be oxidatively metabolized into potentially genotoxic intermediates. Estrogen and its metabolites have been reported to induce DNA damage (►DNA damage), manifesting as ►allele imbalance and ►DNA amplification in human breast epithelial cells *in vitro* (►Amplification). DES metabolites have been reported to produce DNA adducts and cancer in mammary glands of female rats. DES is a strong mitotic inhibitor in cell lines, blocking equatorial plate formation, tubulin polymerization, and spindle assembly. This may, in turn, induce ►aneuploidy. Tumors associated with DES exposure exhibit ►genetic instability, such as whole and partial chromosome gains *in vitro* and *in vivo*, in the Syrian hamster model. ►Microsatellite instability has been reported in human vaginal clear cell adenocarcinomas associated with *in utero* DES exposure, as well as in murine endometrial carcinomas after DES treatment.

In contrast to the substantial microsatellite instability seen in human vaginal clear cell adenocarcinomas associated with *in utero* DES exposure, breast neoplasms in DES daughters do not exhibit an increased amount of microsatellite instability. Breast tumors of DES mothers have not been investigated. In fact, little microsatellite instability was observed in breast tumors in both exposed and unexposed women, which is consistent with previous results from unselected human breast cancers, confirming that microsatellite instability is unusual in human breast cancers and suggesting that prenatal DES exposure does not affect ►DNA mismatch repair mechanisms in the breast. Similarly, equivalent amounts of allele imbalance have been observed in breast tissue regardless of exposure, which differs from findings in animal models and *in vitro* systems. Therefore, the effect of *in utero* DES exposure may be tissue, timing and/or species specific, as is the case with other hormonal agents such as ►tamoxifen, which has variable effects on human endometrium and mammary tissue. It remains under investigation as to whether the potential effects of *in utero* DES exposure on human breast carcinogenesis

are mediated by enhanced proliferation, by alternative genotoxic effects, or by other pathways entirely.

Summary

The unfortunate consequences of DES administration to pregnant women have yielded clinical and scientific insights into estrogen's effects on developing and mature tissues. Its continued investigation should provide additional clinical and mechanistic information about these effects, and have relevance to understanding the effects of exposure to xenoestrogens.

Differentiation

Definition

A process whereby a cell undergoes morphological transition from a cell which is capable of undergoing cellular division to a state where the cell becomes post-replicative. Often accompanied by changes in cellular function. The process during which young, immature (unspecialized) cells take on individual characteristics and reach their mature (specialized) form and function. Describes the process by which cells acquire a "type or assignment." The morphology of a cell may change dramatically during differentiation, but the genetic material remains the same, with few exceptions.

Diffuse, Small Cleaved Cell Lymphoma

►Mantle Cell Lymphoma

Diffuse Large B-Cell Lymphoma

Michael B. Møller
Department of Pathology, Division of Hematopathology, Odense University Hospital, Odense, Denmark

Synonyms

KIEL classification: Centroblastic, B-immunoblastic, B-large cell anaplastic; Working Formulation: Diffuse large cell, Large cell immunoblastic, Diffuse mixed small and large

Definition

Diffuse large B-cell lymphoma is a ►non-Hodgkin lymphoma entity composed of malignant large lymphoid cells with blastic morphologic features, expression of B-cell markers, and with a diffuse growth pattern. The postulated cells of origin are germinal or post germinal centre B-cells. This lymphoma entity is morphologically, clinically and genetically heterogeneous.

Characteristics

Diffuse large B-cell lymphoma is the most common type of lymphoma comprising 30–40% of adult non-Hodgkin lymphomas and approximately 20% of non-Hodgkin lymphomas in childhood and adolescence. Diffuse large B-cell lymphoma can be seen in all age groups, but the incidence increases with age. The median age at diagnosis is approximately 65 years. There is a slight male preponderance. In most patients the tumor resides in lymph nodes, but 40% of patients have predominant extranodal disease. Virtually any extranodal site may be involved, but the most frequently involved organs include the gastrointestinal tract, soft tissue, thyroid, skin, central nervous system, liver, bone, gonads, breast, kidney, lung and salivary glands. So-called transformed diffuse large B-cell

lymphomas arise from indolent lymphomas such as small lymphocytic lymphoma/►chronic lymphocytic leukaemia, ►marginal zone B-cell lymphoma and ►follicular lymphoma. The aetiology of most diffuse large B-cell lymphoma cases is unclear. However, patients with immunodeficiency such as human immunodeficiency virus-infected patients or patients receiving immunosuppressive therapy are at increased risk of developing lymphoma. Diffuse large B-cell lymphoma is the most frequent lymphoma arising in this setting, and these lymphomas are often ►EBV associated.

Diagnosis

The typical clinical presentation of diffuse large B-cell lymphoma patients with nodal disease is rapidly enlarging ►lymphadenopathy. Patients with extranodal presentation of the disease often have symptoms related to dysfunction of the involved organ(s). One third of the patients have ►B symptoms. Approximately half of the patients have localized lymphoma, i.e. Ann Arbor stage I or II, and the remainder have disseminated disease.

The morphological diagnosis is based on the World Health Organization Classification. Diffuse large B-cell lymphoma typically consists of a diffuse proliferation of medium-sized to large transformed B-lymphoid cells with a nucleus at least twice the size a normal lymphocyte. These large cells are a mixture of cells that resemble either the centroblasts or the immunoblasts that normally reside in reactive germinal centres. The diffuse large B-cell lymphoma entity is morphologically quite heterogeneous with several morphologic variants. The two most common variants are the centroblastic variant which is dominated by centroblasts and the immunoblastic variant with >90% immunoblasts. In the T-cell/histiocyte rich variant the majority of cells are small T-cells and histiocytes and less than 10% of the cells are neoplastic B-cells. An anaplastic variant of diffuse large B-cell lymphoma is recognized which has a similar morphology and ►CD30 expression as the T-cell lymphoma anaplastic large cell lymphoma. However, anaplastic diffuse large B-cell lymphoma is clinically and genetically unrelated to anaplastic large cell lymphoma. Other rare variants include plasmablastic diffuse large B-cell lymphoma and diffuse large B-cell lymphoma with expression of full-length *ALK*.

Diffuse large B-cell lymphoma cells usually express CD45 and B-lymphoid markers such as CD19, CD20, CD22, CD79a and PAX5. The proliferation rate is high with most cases expressing the proliferation associated marker ►Ki-67 in >40% of the tumor cells. In some tumors >95% of the malignant cells express Ki-67.

The prognosis is variable with a 5-year overall survival rate for all patients of 45–50%. The International Prognostic Index is widely used for prognostication of diffuse large B-cell lymphoma. It consists of five clinical factors (age, stage, performance score, serum lactate dehydrogenase, number of extranodal sites involved) each with independent prognostic value regarding overall survival. The index allocates 35–40% of the patients to the low risk group with a 5-year overall survival rate of >70%, while 15–20% of the patients have high risk lymphoma and a 5-year overall survival rate of <30%. By adding the anti-►CD20 antibody ►rituximab to the treatment regimens the survival rates cited above may increase with up to 10% or more.

Therapy

Multidrug chemotherapy and radiotherapy represent the mainstay of diffuse large B-cell lymphoma treatment. For several decades CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) or CHOP-like regimens have been the gold standard chemotherapy regimens with the achievement of complete remission rates of 70–80% and cure rates of 40–50%. Recent trials have documented that the addition of rituximab to CHOP or CHOP-like regimens significantly increases event-free and overall survival for most diffuse large B-cell lymphoma patients. The treatment strategy is influenced by the age and the International Prognostic Index risk group of the patient, as well as the location and stage of the disease. Patients with non-►bulky stage I lymphoma may be treated with 3 series of CHOP (-like) chemotherapy and radiotherapy of the involved field and possibly with the addition of rituximab. Patients with higher stage disease are typically treated with 6–8 series of CHOP(-like) chemotherapy with the addition of rituximab. The role of autologous stem cell transplantation is not well defined, but may be beneficial to younger patients with high risk disease who are unlikely to do well with standard therapy.

Approximately half of the diffuse large B-cell lymphoma patients either do not attain complete remission or develop a relapse after remission and most of these patients require second-line therapy. A variety of second-line chemotherapy regimens are used, and these regimens typically have a response rate of 50–70%. For patients with chemotherapy-sensitive relapse autologous stem cell transplantation is considered the treatment of choice.

Genetics

The cellular origin of diffuse large B-cell lymphoma is germinal or post germinal centre B-cells. Two major pathogenic mechanisms related to normal germinal centre function contribute to the lymphomagenesis of diffuse large B-cell lymphoma: aberrant ►somatic hypermutation and ►chromosomal translocation often involving the ►immunoglobulin genes. Virtually all diffuse large B-cell lymphoma cases have rearranged

immunoglobulin genes, and most cases are somatically hypermutated in the immunoglobulin variable region genes.

Somatic hypermutation is a physiologic process in the ►germinal center that target immunoglobulin genes and thereby creates antibody diversity. However, aberrant somatic hypermutation is considered an important transformation mechanism in diffuse large B-cell lymphoma. In most diffuse large B-cell lymphoma cases aberrant somatic hypermutation targeting non-immunoglobulin genes results in hypermutation of multiple proto-oncogenes such as ►*MYC*. This process is thought to contribute to the clinical and biological heterogeneity of diffuse large B-cell lymphoma.

Another important mechanism involved in the pathogenesis of diffuse large B-cell lymphoma is chromosomal translocations bringing a proto-oncogene under the influence of an active locus such as the immunoglobulin gene, and thereby causing deregulated overexpression of the oncogene. These translocations may occur as (accidental) by-products of the immunoglobulin remodeling processes, i.e. ►V(D)J recombination, somatic hypermutation and ►class switching, which take place in the germinal centres and require DNA strand breaks. The t(14;18) brings the anti-apoptotic ►*BCL2* gene in juxtaposition with the joining segment of the immunoglobulin heavy chain gene and is a hallmark of follicular lymphoma. Twenty to thirty percent of diffuse large B-cell lymphomas also carry this translocation, and these cases probably evolved from clinical or subclinical follicular lymphoma. The presence of the *BCL2* rearrangement is associated with disseminated and nodal disease but not with prognosis or expression of the bcl-2 protein. In 10% of the cases bcl-2 overexpression is achieved by way of gene ►amplification. Approximately one third of diffuse large B-cell lymphoma cases have a rearrangement of the proto-oncogene ►*BCL6*. Deregulation of bcl-6 expression in germinal centre cells may contribute to lymphomagenesis by functional inactivation of p53 and thereby suppressing p53-mediated ►apoptosis. *MYC* is rearranged, often as a translocation to an immunoglobulin gene, in 10–15% of diffuse large B-cell lymphoma. Cases with rearrangement of both *MYC* and *BCL2* appear to have a very poor prognosis.

Other frequent genetic lesions include ►*TP53* mutations in 20–25% and ►*CD95* mutations in 20% of the tumors. ►*TP53* mutations are associated with poor response to treatment and poor prognosis, whereas ►*CD95* mutations correlate with extranodal disease and autoimmune phenomena.

Gene expression profiling studies with ►microarray technology have identified two major subgroups of diffuse large B-cell lymphoma. One type has an expression profile that resembles normal germinal centre B-cells (GCB-like), and the profile of the other group is similar to activated B-cells (ABC-like). In addition to having expression profiles with hallmarks related to B-cells of different stages of differentiation, these two subgroups of diffuse large B-cell lymphoma also utilize distinct oncogenic mechanisms. For example, *BCL2* is dysregulated by way of the t(14;18) in up to half of the GCB-like cases, but this translocation is not found ABC-like cases. In stead, as an alternative mechanism of *BCL2* activation, amplification of the *BCL2*-containing chromosome region 18q21 is present in 20% of ABC-like tumors, but it is rare in GCB-like cases. Furthermore, 20–25% of ABC-like cases have gain on chromosome 3q and/or trisomy 3, whereas these lesions are not identified in GCB-like lymphomas. Moreover, a major difference is that ABC-like diffuse large B-cell lymphoma has a constitutively active ►NF-κB pathway which is a potentially important therapeutic target. Finally, these molecular differences translate into clinical differences, as GCB-like diffuse large B-cell lymphoma has a better prognosis than ABC-like.

Subtypes of Diffuse large B-cell Lymphoma

From the heterogeneous group of diffuse large B-cell lymphoma several subtypes have sufficiently distinct clinical, morphological and/or genetic features to be recognized as entities.

Mediastinal (thymic) Large B-Cell Lymphoma

Mediastinal large B-cell lymphoma presumably arises from thymic B-cells. These cases comprise up to 10% of all diffuse large B-cell lymphomas. It is a disease with a female predominance. The patients are younger, in general in the third to fifth decade. Typically the lymphoma presents at diagnosis as a bulky and locally invasive anterior mediastinal mass which often causes airway compression and vena cava superior syndrome. In contrast to other diffuse large B-cell lymphoma types, mediastinal large B-cell lymphomas seldom harbor rearrangements of *BCL2*, *BCL6* or *MYC*. Mediastinal large B-cell lymphoma has a gene expression profile distinct from ABC-like and GCB-like diffuse large B-cell lymphoma. However, in common with ABC-like diffuse large B-cell lymphomas mediastinal large B-cell lymphomas have a constitutively active ►NF-κB pathway.

Intravascular Large B-Cell Lymphoma

Intravascular large B-cell lymphoma is a rare neoplasia characterized by proliferation of large CD20-positive lymphoid cells primarily in the lumina of small vessels. The disease is often widespread at diagnosis causing a highly variable clinical picture. The symptoms are mainly caused by occlusion of capillaries in the involved organs. The prognosis is very poor.

Primary Effusion Lymphoma

►Primary effusion lymphomas occur most often in immunocompromised patients and the outcome is extremely poor. Patients usually present with serous effusions without overt tumor masses. Characteristically the lymphomas cells are pleomorphic and lack B-cell-associated antigens such as CD19 and CD20. Instead they often express CD30 and the plasma cell-associated marker CD138. Reflecting the aetiology the lymphoma cells contain ►Kaposi sarcoma herpes virus/human herpes virus 8.

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis is a rare ►Epstein-Barr virus-associated angiocentric lymphoproliferative disease involving extranodal tissues, most commonly the lung. The lesions are composed of large EBV-positive B-cells in a background dominated by small reactive T-cells. Based on the proportion of EBV-positive B-cells lymphomatoid granulomatosis is graded from grade I (few cells) to grade III (numerous cells). Grade III lymphomatoid granulomatosis fulfil the morphological criteria of a diffuse large B-cell lymphoma subtype and should be treated as such.

Diffuse Neuroendocrine System

Definition

Consists of a network of specialized cells (neuroendocrine cells), distributed in a variety of organs that release hormones in response to stimulus from the nervous system to control different body functions.

►Neuroendocrine Carcinoma
►Neuroendocrine Tumors

Diffusion

Definition

Is a passive transport mechanism that results in the dispersion of an agent, relying largely on a concentration gradient.

►Convection Enhanced Delivery (CED)

Diffusional Flux

Definition

Is the amount of a substance or gas diffusing from one location to another.

►Oxygenation of Tumors

2′,2′-Difluoro-2′-deoxycytidine

►Gemcitabine

Difluoromethylornithine

Definition

DFMO; An oral agent that irreversibly binds to ►ornithine decarboxylase and inhibits its function, resulting in polyamine inhibition and decreased tumorigenesis in model systems. As such, DFMO has been widely used in ►chemoprevention research as an active cancer preventive agent, with tolerable safety profile.

►Arginine

Dihydrogen Dioxide

►Hydrogen Peroxide

Dihydrotestosterone Receptor

►Androgen Receptor

1,25-Dihydroxyvitamin D_3

►Calcitriol

2-Dimensional Gel Replicon Mapping

Definition

A physical method in which two different concentrations of agarose are used to separate origins of replication from replication forks. ►Origins of replication have a lower mass than replication forks and therefore migrate faster in low concentrations of agarose. However, in higher concentrations of agarose replication origins migrate at a slower rate than replication forks because of their complex structure. Thus, the 2-dimensional gel mapping technique is capable of distinguishing replication origins from ►replication forks.

►S-Phase Damage-Sensing Checkpoints

Dimer Formation

Definition

In biochemistry and molecular biology, dimers of macromolecules like proteins are frequently observed. The dimerization of identical protein subunits is called homodimerization, the dimerization of different subunits or unrelated monomers is called heterodimerization. Most dimers in biochemistry are not connected by covalent bonds with the exception of disulfide bridges. An example of this would be the enzyme ►reverse transcriptase, which is made of two different amino acid chains.

Dimesna

Definition

►Mesna is rapidly oxidized to its biologically inert disulfide metabolite, mesna disulfide or dimesna.

►Chemoprotectants

Dimethyl Benz(a)anthracene

Definition

DMBA; Is a strong ►carcinogen used only in laboratory settings that has not been found in the environment. It induces primarily mammary gland tumors in animal models.

►Sulforaphane

7, 12 Dimethylbenz[a]anthracene

Definition

DMBA; A polycyclic aromatic hydrocarbon chemical that acts to initiate mutations in codons 12, 13, 59, and 61 of the v-Ha-*ras* oncogene in skin.

►Skin Carcinogenesis

Dimethylfumarate

Peter Petzelbauer, Robert Loewe
Department of Dermatology, Division of General Dermatology, Medical University of Vienna, Vienna, Austria

Definition

Fumaric acid is one of two isomeric unsaturated dicarboxylic acids with the formula $HO_2CCH{=}CHCO_2H$

(the other being maleic acid with carboxylic acid groups in cis). Reactions with alcohol create fumaric acid esters (FAE) and water.

Chemistry and Pharmacodynamics

Dimethylfumarate (DMF) is a lipophilic ester of fumaric acid (Fumaric acid is a dicarbonic acid and a component of the intracellular citric acid cycle). DMF is rapidly hydrolyzed to methylhydrogenfumarate (►MHF) in aqueous solutions at physiological pH.

In both, DMF and MHF, nucleophiles can be added to the double bonds in the center of the molecule by a so called ►Michaelis-type addition. Thus, they interact with ►thiols, as given in the tripeptide ►glutathione (►GSH) or with cystein residues in larger proteins. This reactivity of DMF is higher than that of MHF (Fig. 1).

Characteristics

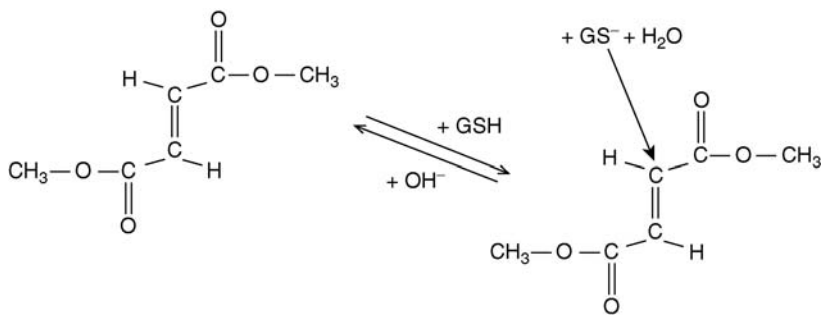
Biological Effects of FAEs In vitro

Due to the chemical structure of ►FAEs as low-molecular weight electrophiles, much work has focused on their antioxidant effects. FAEs directly react with GSH. They initially deplete intracellular GSH levels, which return to normal or even supra-normal levels 6–18 h thereafter. Possibly as a consequence of this GSH-FAE interaction, FAEs induce transcription and activity of so-called phase 2 enzymes, which are important in the intermediate cellular metabolism for ►detoxification. Induction of Phase 2 enzymes, as e.g., DT-diaphorase (NQO1 = NAD(P)H:quinone oxidoreductase I) and cytochrome b5 reductase, enhance cellular metabolism and decrease sensitivity towards environmental toxins. Phase 2 enzymes generally share similar antioxidant or electrophilic response elements (ARE/EpREs) within their promotor sequences. Interestingly, the induction of phase 2 enzymes by DMF is unevenly distributed within different tissues. In astrocytes, DMF leads to the induction of genes containing ARE/EpREs within their promotor sequences. Also in the gut and to a lesser degree in the liver, DMF increases activity of phase 2 enzymes, whereas in prostate tissue, no phase 2 enzymes are induced by DMF. Recently it has been shown that DMF induces heme oxygenase 1 (HO-1) in human peripheral blood mononuclear cells. The induction of HO-1 expression by DMF was paralleled by the DMF-induced depletion of intracellular GSH, but a direct proof for a causal connection is pending.

A second approach towards identification of FAE effects was based on the clinical observation that FAEs reduce tumor necrosis factor (TNF)-induced cell activation. This effect of FAEs was identified in various different cells such as endothelial cells, fibroblasts or ►melanoma cells. FAEs exert these effects by interacting with the ►nuclear factor-κB (NF-κB) pathway downstream the Iκ-kinases (IKK), they retain activated ►NF-κB proteins in the cytosol and prevent their ►nuclear translocation. As a result, NF-κB cannot bind to DNA thereby preventing NF-κB-mediated gene transcription. In these experiments, DMF proved superior to MHF. Although the mode of this inhibition is not yet completely elucidated, it has been speculated that this is also mediated through interaction of FAEs with the redox status of the cell.

Drug Formulations of Currently Used Fumaric Acid Esters (FAEs)

1. Fumaderm®, a mixture of FAEs (120 mg DMF, 87 mg Ca^{2+} Ethylhydrogenfumarate, 5 mg Mg^{2+} Ethylhydrogenfumarate, 3 mg Zn^{2+} Etyhlhydrogenfumarate) was registered in Germany in 1994. It is used for oral treatment of psoriasis, a chronic inflammatory skin condition. Off-label use revealed anecdotic efficacy in other inflammatory skin conditions such as granuloma anulare, cutaneous sarcoidosis or necrobiosis lipoidica. Moreover, Fumapharm has initiated a phase IIa clinical trial



Dimethylfumarate. Figure 1 Reaction between DMF and thiols (modified from Schmidt et al. [5]).

with Fumaderm® for the treatment of multiple sclerosis. This study showed a significant reduction of gadolinium-enhancing lesions on T1-weighted magnetic resonance imaging (MRI) brain scans. This study could also show that exacerbations of the disease could be reduced by low-dose FAE therapy.
2. DMF as a monosubstance, named BG12®, was used for a European placebo-controlled multicenter phase III trial in psoriasis patients. In this study, treatment with BG12 for 16 weeks led to clinical response and improvement in 68% of the BG12 treated patients, whereas placebo treated patients improved only for 10%. Biogen has now initiated a phase III study in patients with multiple sclerosis using BG12.

In dendritic cells and keratinocytes, FAEs possess anti-proliferative and pro-apoptotic properties. It is yet not clear whether this is based on the ability of FAEs to alter the redox status of the cell and/or by a direct interaction with the NF-kB pathway.

In malignancies *in vitro*, effects of DMF have been evaluated in ►lung cancer, ►breast cancer, ►neuroblastoma and ►glioblastoma. DMF has been shown to increase cytotoxicity of chemotherapeutics when given in combination with for example ►mitomycin C or streptonigrin. This was shown for glioblastoma, lung cancer and mammary cancer cell lines. DMF also sensitizes fibroblasts, neuroblastoma cells as well as human ►bladder cancer cell lines to irradiation (and therefore increases their ►radiation sensitivity.

Biological Effects of FAEs In vivo

Anti-inflammatory effects of oral treatment with Fumaderm® and BG12 in psoriasis are well documented in human patients. Although DMF is more active than MHF *in vitro*, it is still unclear, whether DMF or ►MHF mediate biological effects *in vivo*. This is because (i) DMF hydrolyses into MHF and (ii) pharmacokinetic studies failed to detect DMF in human plasma, whereas MHF was measurable. However, these studies did not rule out that DMF was bound to cystein-containing plasma proteins or – due to its lipophilia – has rapidly entered cells and thus escaped detection by HPLC techniques.

For malignant disease, only preclinical data in animal models exist. DMF has been tested in a model of chemically induced ►colon cancer, where DMF reduced cancer ►progression and ►invasion. In humanized ►SCID mouse models for ►melanoma, oral treatment with DMF has reduced tumor growth and ►lymphogenic metastatic spread. In this model, beneficial effects of DMF were based on its anti-proliferative and pro-apoptotic properties on melanoma cells.

Clinical Aspects and Future Perspectives

In many human malignancies the NF-κB pathway is constitutive active. This causes increased expression of many ►tumor progression genes (regulating cell cycle and apoptosis of tumor cells and the composition of the ►tumor matrix). Indeed, animal models have provided a direct link between activation of NF-κB and tumor progression. Moreover, NF-κB-dependent genes are clearly involved in the development of ►chemo-resistance; inhibition of NF-κB has been shown to reduce chemoresistance.

DMF fulfills several criteria to justify clinical trials in human malignancies; first, it has been shown to be beneficial in animal models for malignant diseases; second, it inhibits NF-κB-dependent gene expression, which would reduce tumor growth and ►metastasis and also may reduce the development of chemo-resistance; third DMF has been clearly shown to be safe even in long term treatment in human psoriasis patients.

Dioxin

Thomas A. Gasiewicz
University of Rochester Medical Center, Rocheser, NY, USA

Synonyms

TCDD; 2,3,7,8-TCDD; 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin

Definition

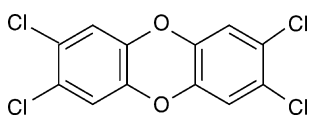
Dioxin is an unwanted by-product of a number of chemical and industrial processes. It was first observed as a contaminant formed in the synthesis of trichlorophenols used for the production of certain herbicides. Later it was recognized that small amounts of dioxin (as well as other dioxins) can be produced during different types of combustion processes including the burning of chlorine-containing materials such as chemical and hospital wastes, and sewage sludge. Dioxin may also be formed during manufacturing processes utilizing chlorine. These include the bleaching of pulp and paper, and chlorine-dependent regeneration of metal catalysts. Dioxin and numerous dioxin-like chemicals are ubiquitously present in trace amounts in the environment (Fig. 1).

Characteristics

Based on studies in experimental animals, dioxin is considered to be one of the most potent tumorigenic agents known. The results of epidemiologic studies are more equivocal in terms of carcinogenic potency in humans. These and other responses elicited by dioxin occur through a unique mechanism involving binding to a transcription factor of otherwise unknown function, and subsequent modulation of gene expression. The exact relationships between particular gene alterations and ultimate carcinogenic responses to dioxin remain obscure. However, several putative functions of the transcription factor and endogenous ►ligands, whose action dioxin likely impedes, offer novel targets for future drug discovery and therapeutic intervention.

Carcinogenic Activity

Dioxin is considered to be one of the most toxic synthetic compounds known with acute lethal doses in several animal species being in the range of μg/kg body weight. In addition, numerous experimental studies have consistently shown dioxin to be a potent carcinogen. Although there are differences in sensitivity among species, some rodents exhibit significantly increased and dose-dependent tumor incidence with average daily exposures of 100 ng/kg body weight and higher. A variety of tumor types in several tissues including liver, lung, and thyroid have been reported. The findings that in most experimental systems dioxin fails to induce mutations, dioxin-derived ►adducts to DNA have not been detected, and dioxin enhances the incidence of various tumor types following initiation with known ►carcinogens, are consistent with dioxin acting primarily, if not exclusively, as a tumor promoter. However, although there is little or no evidence for dioxin to be directly genotoxic, it may appear to be a complete carcinogen due to its exceptionally high potency as a tumor promoter.

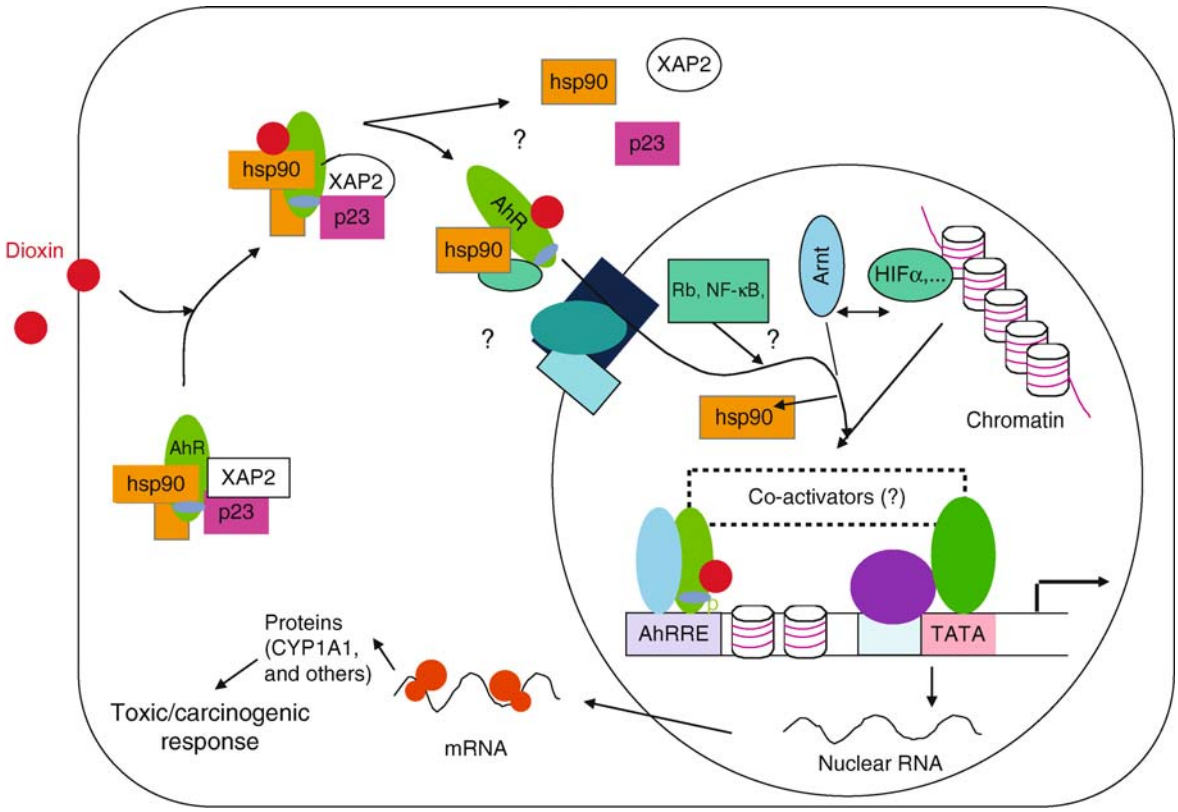


Dioxin. Figure 1 Chemical structure of dioxin.

Mechanisms

The toxic and carcinogenic effects of dioxin are mediated by its binding to and activation of a transcription factor termed the ►aryl hydrocarbon receptor (AhR). This belongs to a family of proteins containing a basic-helix-loop-helix (bHLH) – PAS (Per-Arnt-Sim) ►domain structure. The known ►bHLH-PAS proteins are involved in regulating responses to signals in the tissue environment such as oxygen tension and circadian rhythms, and serve regulatory roles in development and cellular differentiation. Like many of these proteins, the AhR has been conserved through evolution. However, unlike most other proteins in this family, the AhR is ligand-activated and its exact normal function in tissue processes is not clearly resolved. Evidence that the AhR mediates most, if not all, biological responses to dioxin is based in part on studies examining structure-activity relationships of other dioxin-like chemicals, and genetic studies in mice that have a mutant AhR protein. In particular, mice in which expression of a functional AhR has been "knocked out" (►knock-out mice) are insensitive to the toxic effects of dioxin. In the absence of ligand, the AhR appears to be localized primarily in the cellular cytosol complexed with several proteins including the ►chaperone protein ►hsp90, co-chaperone ►p23 protein, and an ►immunophilin-like protein XAP2 (Fig. 2). Upon ligand binding, the AhR is translocated to the cell nucleus, dimerizes with another bHLH-PAS protein, Arnt (also known as ►hypoxia inducible factor (HIF) β) and binds to specific ►response elements (AhR response elements; AhREs) (also called xenobiotic response elements (XREs) or dioxin response elements (DREs)) within regulatory domains of responsive genes to modulate the expression of these genes. The AhR has been shown to interact with several proteins involved in other signaling pathways. These include the ►estrogen receptor and ►NF-κB. As such, some responses elicited by dioxin may not be dependent on the ability of the AhR-Arnt complex to bind AhREs. Nevertheless, the toxic and carcinogenic actions of dioxin are believed to result from its interference with unknown endogenous AhR ligands and/or the inappropriate and prolonged alteration of AhR-responsive genes and signaling pathways.

There are several postulated mechanisms whereby dioxin may act at stages involved in cancer initiation and progression to facilitate the development of malignancies. Of the identified AhR-responsive genes,



Dioxin. Figure 2 AhR signaling pathway. Dioxin binds to the AhR to initiate a series of events leading to modulation of gene expression.

many of these encode enzymes (e.g. ►cytochrome P450 (CYP) 1A1 and 1B1) are known to metabolize and activate carcinogens to intermediates that cause DNA mutations. Although dioxin is resistant to metabolism, the induction of these pathways enhances the likelihood of bioactivation of other potential carcinogens that are in the environment. It has also been proposed that induction of the CYPs may generate ►reactive oxygen species that can directly damage DNA. Several studies have observed dioxin exposure to result in the expression of genes such as ►*p53* and ►*p21Waf1* indicative of DNA damage or cellular stress. Other studies have linked high CYP1A1 enzyme activity with increased cancer risk, and several carcinogens, including benzo[a]pyrene, induce tumors in normal mice but not AhR knock out mice. Increased expression of these genes by dioxin is also known to affect tissue levels of several hormones and growth factors, including estrogen and thyroxine, as well as their receptors. The progression of several tumors is known to be hormone dependent. Dioxin has been shown to alter several signaling pathways regulating cellular differentiation, proliferation and cell death (►apoptosis). Furthermore the modulation of these cellular processes, intrinsic to metastatic progression, are affected in a variety of cell types by dioxin. In particular, many studies demonstrate a role, although as yet not clearly defined, of the AhR in regulating the cell cycle. This may occur through several complex pathways involving AhR-dependent activation of cellular kinases, e.g. ERK, or direct AhR interaction with cell cycle regulatory proteins including the tumor suppressor ►retinoblastoma protein (Rb). The latter interaction has been suggested to regulate key cell cycle components mediated by an alteration of ►E2F transcription factors.

Immune surveillance mechanisms are important in the control of malignant cell growth. In experimental animals, dioxin has consistently been shown to be a potent immunosuppressive agent affecting both humoral and cell-mediated immune pathways. Furthermore, dioxin exposure has been shown to increase tumor cell survival following engraftment. Prolonged inflammation is also associated with increased cancer development, and the AhR is known to interact with NF-kB proteins that are involved in regulating ►inflammatory responses. In addition, several pro-inflammatory genes (e.g. ►cyclooxygenase-2) are AhR-responsive. There is also recent evidence that the AhR may be involved in the regulation of ►angiogenesis important for tumor growth; AhR

knockout animals exhibit defects in tissue vascularization. This has been postulated to be related to cross-talk between the AhR and HIF signaling pathways, since Arnt is also a dimeric partner for HIFα. Ultimately, the exact mechanisms underlying the carcinogenic activity of dioxin are poorly understood. As indicated above, there are likely many complex, and possibly tissue-specific, mechanisms whereby dioxin exhibits potent tumor promoter activity. Clearly, however, the multi-faceted nature of the responses to dioxin reflect an importance of the AhR signaling pathway in fundamental processes, deregulation of which may contribute to altered cellular phenotype and uncontrolled growth.

Clinical Relevance

Several epidemiologic studies link dioxin exposure with cancer in human populations. Among the increased cancers reported were lung cancer, ►lymphomas, and ►leukemias. However, in all of these studies the body burden exposure levels were very high, being often greater than several hundred μg/kg body weight. In many studies the increased cancer incidence was relatively small and the association, although significant, was weak. Based on limited human evidence and sufficient evidence in animals, the International Agency for Research on Cancer (IARC) and the National Toxicology Program classified dioxin as a human carcinogen. Human exposures to dioxin and dioxin-like chemicals occur mainly through food consumption. Average current background body burden levels for most human populations are approximately 10 ng dioxin-eqivalents/kg body weight, and many fold lower than that observed in animal investigations or human epidemiologic studies in which a positive association with increased cancer incidence was observed. As such, the actual risk for cancer development at a low level exposure remains uncertain. Several studies indicate that the human AhR has lower affinity for dioxin than the AhR in most animal species. Identified human AhR ►genetic polymorphisms have not yet been clearly associated with increased or decreased cancer risk. Nevertheless, the ►half-life of dioxin, a molecule resistant to metabolism, appears to be considerably longer in humans, ranging from 7 to 10 years. Furthermore, a variety of human cells and tissues respond to dioxin exposure in a manner similar to those of animals, at least in terms of some acute biochemical and cellular responses (e.g. *CYP1A1* induction and altered cellular differentiation). The full clinical significance of dioxin exposure may not be realized until we have a greater understanding of the physiological role of the AhR. This role and any putative endogenous ligands regulating AhR activity have yet to be clearly defined. The findings that dioxin exposure and/or altered activity of the AhR are associated with direct modulation of particular ►gene batteries resulting in altered immune responses, modulated angiogenesis, as well as deregulated cell cycle and altered cellular proliferation and differentiation, may offer new and unique targets for drug discovery and therapeutic intervention for the treatment of various cancers.

Definition
DLC1 is a ►tumor suppressor gene frequently underexpressed in various types of cancers. Genomic deletion and ►promoter hypermethylation may account for the inactivation of *DLC1* in human cancers. Functionally, overexpression of *DLC1* can result in the ►tumor suppression in cancer cells and regulation of cytoskeleton organization.

Characteristics

Deleted in liver cancer 1 (*DLC1*), also known as *Rho-*►*GTPase activating protein 7* (*ARHGAP7*) and *START domain-containing protein* (*STARD12*), is a putative tumor suppressor gene identified from primary ►hepatocellular carcinoma (HCC) in 1998. Human *DLC1* gene was mapped to chromosome region 8p21.3–22. The full-length *DLC1* mRNA is 6 kb long and consists of 14 exons which encode a protein of 1,091 amino acids. In-silico analysis indicated that *DLC1* shares 86% sequence homology with rat *p122 RhoGAP* and is likely to be its human homolog. DLC1 protein contains three major functional domains, namely, SAM (sterile alpha motif), RhoGAP (GTPase-activating protein for Rho-like GTPases), and START (steroidogenic acute regulatory (STAR)-related lipid transfer) (Fig. 1). The RhoGAP domain is a characteristic of RhoGAP family proteins, functions to catalyze the intrinsic GTPase activity of Rho proteins.

Functions of DLC1

RhoGAP protein converts the active GTP-bound Rho to the inactive GDP-bound form. On the other hand, guanine nucleotide exchange factor (GEF) acts to activate Rho proteins. Rho proteins are important regulators in the remodeling of ►actin cytoskeleton, regulation of transcription, cell proliferation, metastasis, and tumorigenesis (Fig. 2). The best characterized members of Rho proteins are RhoA, Rac1, and Cdc42. RhoGAP serves tumor suppressor function by downregulating Rho GTPase activity. Therefore, negative regulation of Rho proteins by RhoGAP activity contributes to the functional role of DLC1.

Negative Regulation of Cytoskeleton

The in vitro GAP activities of DLC1 specific for RhoA and Cdc42 have previously been demonstrated. In cell model, expression of DLC1 resulted in inhibition of stress fiber formation and extensive cell rounding. These morphological changes were similar to the effects of Rho inhibitor, C3 exoenzyme, implicating that DLC1 negatively regulates cytoskeletal organization via inhibition of Rho proteins. The importance of RhoGAP of DLC1 was further supported by failure of DLC1 RhoGAP mutant to induce morphological changes. ►Tensin2, a focal adhesion protein has been identified as the first and novel binding partner of DLC1. DLC1–tensin2 protein complex localizes in ►caveolae where Rho GTPases are concentrated. It is postulated that DLC1–tensin2 complex brings DLC1 in close proximity to Rho GTPases which are enriched in caveolae and facilitates the inactivation of Rho proteins by DLC1.

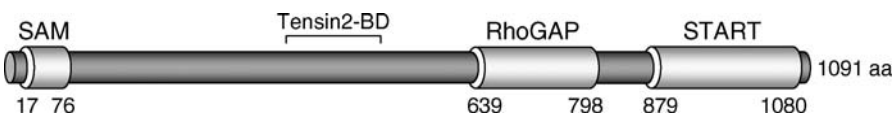
Mouse model of DLC1 revealed that $DLC1^{+/-}$ heterozygous deletion mutant did not display any phenotypic abnormalities, while $DLC1^{-/-}$ homozygous deletion mutant (►knock-out mice) was embryonic lethal. $DLC1^{-/-}$ embryos showed defects in several organs, including neural tube, brain, heart and placenta. Fibroblasts isolated from $DLC1^{-/-}$ ►homozygous deletion embryos displayed aberrant cytoskeletal organization with diminished actin stress fiber formation and focal adhesions.

Tumor Suppressive Effect

Besides the role in the regulation of cytoskeletal reorganization, DLC1 also possesses growth inhibitory activity in cancer cell lines. The growth inhibitory effect of DLC1 was first demonstrated in HCC cell lines. Loss of growth suppressive effect with the DLC1 RhoGAP mutant demonstrated that the RhoGAP activity of DLC1 was associated with its growth suppressive effect in tumor cell lines. Expression of *DLC1* in HCC cells resulted in significant inhibition in cell proliferation, anchorage independent growth, and in vivo tumorigenicity in ►nude mice. Apart from HCC cells, the tumor suppressive effect of DLC1 has also been demonstrated in breast cancer and non-small cell lung carcinoma cells. Moreover, stable expression of *DLC1* resulted in inhibition of migratory and invasive abilities of HCC and breast cancer cells. Furthermore, expression of *DLC1* in HCC cells induced caspase 3-mediated apoptosis. The tumor suppressive role of *DLC1* has also been implicated in genome-wide expression profiling approach. Transcriptional profiling analysis of breast cancer cells that exhibit different metastatic efficiencies using microarrays identified *DLC1* as one of the differentially expressed genes. Functional analysis has further demonstrated that *DLC1* acts as a metastasis suppressor in breast cancer cells.

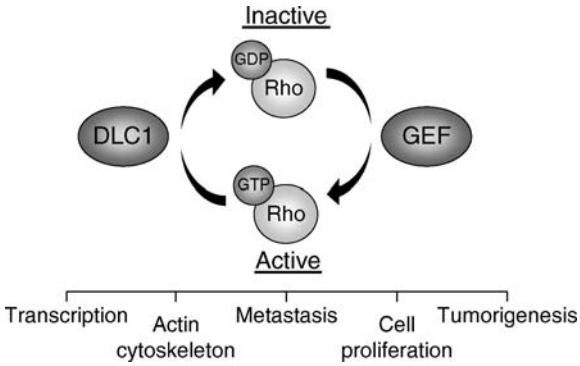
Clinical Relevance

DLC1 was first discovered from a subtractive hybridization screening study in primary HCC. Recent studies have indicated that *DLC1* possesses tumor suppressing



DLC1. Figure 1 Schematic representation of DLC1 protein. Structural domains of DLC1, namely, sterile alpha motif (SAM), Rho GTPase activating protein (RhoGAP), steroidogenic acute regulatory (StAR)-related lipid transfer (START) and the tensin2 binding domain (*Tensin2-BD*) are shown.

D



DLC1. Figure 2 Functional role of DLC1 protein. Rho proteins exist as active GTP-bound form and inactive GDP-bound form. RhoGAP functions to convert the active Rho to the inactive state. On the other hand, guanine nucleotide exchange factor (GEF) acts to activate Rho proteins. Rho proteins are important regulators in the remodeling of actin cytoskeleton, regulation of transcription, cell proliferation, metastasis, and tumorigenesis. Negative regulation of Rho proteins by RhoGAP activity may contribute to the functional role of DLC1.

function and is implicated in human ►carcinogenesis. *DLC1* mRNA is frequently underexpressed in various human cancers, particularly in non-small cell lung carcinoma and nasopharyngeal carcinoma, and down-regulation of *DLC1* mRNA expression has been observed in more than 90% of primary tumor samples. The inactivation of *DLC1* in human cancers could be due to both genetic and epigenetic alterations.

Genetic Alteration

DLC1 is mapped at chromosome 8p21.3–22, which is one of the most commonly deleted regions in human cancers. As indicated by its name, *DLC1* gene is frequently deleted in human HCC. ►Loss of heterozygosity and ►single nucleotide polymorphism (SNP) analyses have revealed that hemizygous deletion of *DLC1* gene is present in approximately half of primary HCC and almost 90% of head and neck squamous cell carcinomas. Although not at a high frequency, homozygous deletion has also been reported in human HCC and ►medulloblastoma. Somatic mutation is rarely found in *DLC1* gene and SNP on *DLC1* also shows no association with human cancers.

Epigenetic Silencing

In established cancer cell lines, frequent loss of *DLC1* gene expression, even in the absence of gene deletion, has been observed. In these cancer cell lines, *DLC1* expression can be significantly restored by administrating demethylating drugs or ►histone deacetylase inhibitors to the cells. This indicates that in addition to gene deletion, epigenetic alterations including ►DNA methylation and ►histone deacetylation also play important roles in *DLC1* inactivation. In all human cancer types tested, recurrent DNA ►methylation on the promoter region of *DLC1* gene has been detected in the primary cancer samples, and *DLC1* ►promoter methylation is closely associated with loss of gene expression. In ►cervical cancer, ►nasopharyngeal carcinoma and ►multiple myeloma, DNA methylation accounts for more than 80% of *DLC1* gene inactivation in these diseases. Interestingly, *DLC1* promoter methylation has also been found in 71% of benign prostatic hyperplasia and was closely associated with the serum prostate-specific antigen level. These findings suggest that *DLC1* promoter methylation may occur in early stage of carcinogenesis and has a potential value for early diagnosis of ►prostate cancer.

Definition

DNA damage refers to the myriad of chemical or structural perturbations that can affect the function of genes encoded along the DNA macromolecule of the cell. The continuous exposure of all cells to many types of DNA damaging agents can alter the backbone of the DNA double helix or the ►nucleotide base components that connect the two strands together and make up the four-lettered genetic code – guanine (G), cytosine (C), thymine (T) and adenine (A). Un-repaired or inappropriately repaired DNA damage can therefore alter genetic information controlling cell function, resulting in mutation, ►chromosomal instability or ►aneuploidy – the hallmarks of all cancers.

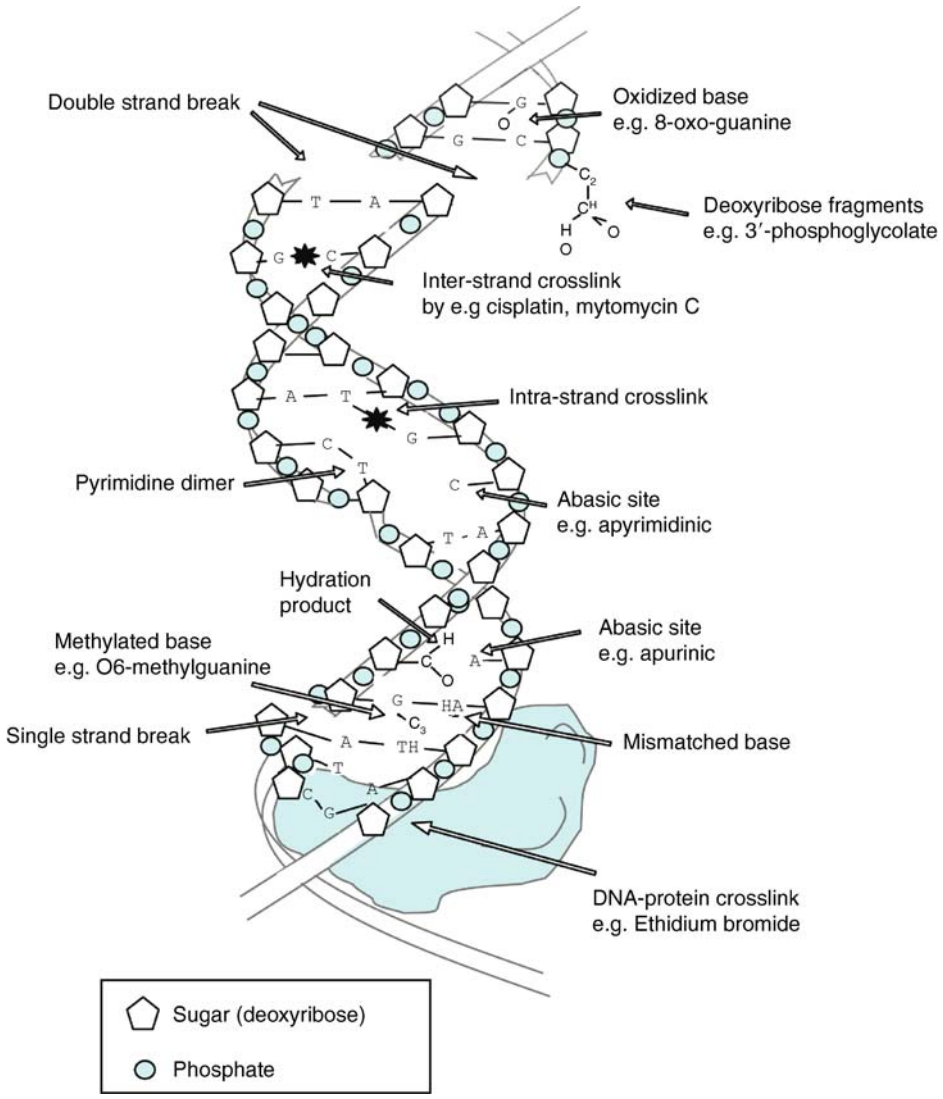
Characteristics

DNA resides in both the nucleus and mitochondria of human cells and both cellular regions contain significant levels of potentially damaging agents, derived either from the environment (exogenous) or from metabolic processes continually occurring inside the cell (endogenous). Although DNA is heavily protected by a complex packaging arrangement of supercoiled strands, wrapped around ►histone proteins within protective chromosomal structures, it is estimated that anything from 1,000 to 1,000,000 DNA lesions occur in any given cell per day. Because genomic DNA inside the nucleus contains the genetic code for expressing most of the proteins required for normal cell function, un-repaired or incorrectly repaired damage to nuclear DNA threatens the integrity of the genome and can result in disruption of cellular processes that control cellular growth and differentiation and therefore the development of cancer. DNA damage and subsequent mutagenesis in somatic cells also drives the processes of ageing, degenerative diseases and evolution.

Constant exposures to a barrage of environmental and cellular metabolic DNA damaging agents creates enormous selective pressures on all prokaryotic and eukaryotic cells on Earth, from bacteria to human, to evolve a complex protective array of DNA damage sensing, signaling and repair proteins. Subsequently, most of these proteins are conserved from single cell organisms to humans. These enzymes and molecular scaffolds constantly interact to scan, recognize, alert and repair many forms of DNA damage. They represent crucial cellular defense pathways that not only protect the integrity of the genome of a single cell but coupled to abortive programmed cell death (or ►apoptosis) pathways, allow whole organisms to clear themselves of problematic and potentially malignant tissue. This is triggered when levels of DNA damage pass a certain threshold and this defines the repair capacity of a cell. This can vary from cell to cell and tissue to tissue and some DNA repair pathways are more error-prone and less efficient than others. Some repair pathways may become dysfunctional or deregulated and indirectly promote ►carcinogenesis, due largely to the activities of inappropriate cellular responses rather than the damage itself. Not surprisingly, individuals who inherit defects or mutations in specific DNA damage sensing and/or repair proteins are predisposed to and significantly more likely to develop early onset cancers, premature ageing and degenerative disorders. There are many types of DNA damage and these are dealt with by several pathways of DNA repair that specialize in recognizing and repairing particular types of lesion.

Agents Causing Bulky, Structurally Distorting DNA Adducts

1. ►UV radiation – predominantly UV-B and UV-C, with UV-B representing the wavelength from ►solar ultraviolet light that can penetrate the Earth's ozone layer. This form of radiation reacts with DNA to form 6,4-photoproducts and cyclobutane pyrimidine dimers (CPDs) (Fig. 1). Chronic exposure of skin cells to solar radiation dramatically increases the cellular load of these adducts and increase the risk of ►skin cancers such as ►malignant melanoma.



DNA Damage. Figure 1 Examples of DNA damage.

An illustration showing examples of structural and chemical alterations to the deoxyribose backbone and the nucleotide bases in between the two strands of DNA. Chemical cross-links are indicated by bold asterisk and a large protein-DNA interaction is shown as a blue globular protein distorting the nucleotide structure.

2. ►Polycyclic aromatic hydrocarbons (PAHs) – atmospheric pollutants found in smoke, soot and tar. The adducts formed by PAH predominantly result in the conversion of G to T (called transversions) (Fig. 1). This results in the mutagenic transformation of affected genes and is responsible for the majority of smoke-related ►lung cancer. ►Tobacco cigarette smoke contains significant amounts of PAHs but also contain extremely high concentrations of acrolein that is one of many ►carcinogens also stimulating G to T transversions. Cigarette smoke is also known to oxidize bases (see Base Damage in next section).
3. Antibiotics such as ►Mytomycin C and ►Adriamycin – These can induce DNA-protein and DNA–DNA inter/intrastrand cross-links (Fig. 1) that covalently join together the nucleotide bases on one/both strands of DNA, respectively.
4. Genotoxic chemotherapeutic drugs such as ►Cisplatin and ►Camptothecin. These are also classed as DNA crosslinking agents and their cytotoxic properties are exploited by oncologists to kill tumor cells such as testicular carcinomas. ►Cisplatin can also induce intrastrand crosslinks (Fig. 1).

Bulky adducts are typically removed by the ►nucleotide excision repair (NER) system. This removes a stretch of DNA harboring the lesion (typically about 30 bases long) and replaces it with the correct sequence of nucleotide bases. Examples of NER enzymes are XPA, XPG and TFIIH. Individuals with genetic defects that affect the function of these components are at a higher risk of developing cancers associated with ►xeroderma pigmentosum.

Nucleotide Base Damage

Many environmental as well as endogenous factors can induce smaller chemical alterations to the DNA sequence-encoding bases – G, C, T and A. Although they are small alterations in comparison, they can have dramatic effects upon the integrity of the genetic sequence encoded along the particular stretch of DNA that harbors such damage. Examples include:

1. ►*Oxidative DNA damage*. The most common form of base damage that can stimulate the conversion of e.g. guanine to ►8-oxoguanine (Fig. 1). Oxidizing agents such as ►reactive oxygen species (ROS) are frequently produced during normal cellular metabolic processes and these are responsible for a significant proportion of base oxidation. ROS are present in the nucleus and cytoplasm and especially inside the mitochondria where energy production from ATP hydrolysis produces high levels. Subsequently, mitochondrial DNA is particularly vulnerable to such damage. Chemicals such as ►hydrogen peroxide (H_2O_2) can also oxidize nucleotide bases and represent powerful DNA damaging agents. Vinyl chloride and chromium (►chromium carcinogenesis) represent industrial chemicals that damage DNA by inducing, among others, etheno-►DNA adducts and base oxidization, respectively. Occupational health hazards such as these are well documented to cause mutations and cancer among exposed workers. Anti-oxidants such as circulating uric acid, the enzyme superoxide dismutase, and those provided in many types of food e.g. ►vitamin C (ascorbic acid) and ►curcumin, work to absorb the free radicals that can oxidize DNA and are generally considered to be important agents that protect cells from cancer-causing oxidants.
2. ►*DNA alkylating agents and* ►*DNA methylation agents*. These can stimulate the conversion of e.g. cytosine to O_6-methylcytosine by adding a methyl group ($–CH_3$) (Fig. 1). DNA alkylating agents like MNNG and 6-TG have been developed as chemotherapeutic agents to kill proliferating tumor cells by damaging their DNA. Unrepaired methylated bases are therefore very toxic to cells.
3. *Mismatched bases*. Unrepaired methylated lesions are also subject to secondary repair by the ►mismatch repair system that normally functions to replace the occasional mismatched base (Fig. 1) with its correct partner (A with T and C with G) (defects associated with ►microsatellite instability, ►colorectal cancer and ►Lynch Syndrome). In doing so, the repair system can become "fooled" by the structural change exerted by ►methylation and, if not sent round a futile cycle of toxic repair, can promote the fixation of potentially carcinogenic mutations.

The ►base excision repair (BER) system is responsible for recognizing and replacing many types of altered bases and there are several components involved. Examples include the APE-1 endonuclease and Nth1 glycosylase enzymes that excise apurinic and apyrimidinic bases and Ogg1, MUTHY and MTH1 that recognize and replace oxidized bases such as 8-oxoguanine.

Single and Double Strand Breaks

DNA damaging agents such as ionizing radiation (X-rays, α and β particles) and free radicals can physically break the covalent bonds between the phosphates, ribose and bases and result in single and double strand DNA breaks (SSB and DSB) (Fig. 1). SSBs are recognized and processed efficiently by dedicated SSB repair proteins such as PARP-1 (►poly (ADP-ribose) polymerase-1), and XRCC1 (which also functions in BER). DSBs are by far the most toxic form of DNA damage and one unrepaired DSB inside a cell is capable of killing that cell. Almost immediately after a DSB forms i.e. after exposure to ionizing radiation, a particular variant of the histones, ►H2AX, which coats the DNA along the entire genome becomes phosphorylated up- (5′-) and down-stream (3′-) of a DSB, some million base pair distances away, thus amplifying the signal and initiating a global cellular response. Other histone modifications are now being linked to DNA damage responses in what seems to be a histone code of responses.

DSBs represent highly reactive substrates for DNA end repair proteins. These are components of the non-homologous end-joining and (NHEJ) and ►homologous recombination ►repair systems. Defects in the protein components of these DSB repair pathways predispose individuals to a range of neurodegenerative disorders and many forms of cancer, e.g. ►ATM (ataxia telangiectasia), ►BLM (►Bloom Syndrome) Ligase IV, MRE11, NBS (lymphoma, ►Nijmegen Breakage Syndrome, ►multiple myeloma), ►BRCA1, ►BRCA2, Fanc D (►Fanconi anemia, ►breast cancer). DSBs are therefore potentially extremely mutagenic lesions, capable of translocating and rearranging gene sequences that can give rise to cancer. A classic

example of malignancy resulting from ►chromosomal translocation and rearrangement is ►Burkitt lymphoma.

The deoxyribose sugars at the ends of SSB and DSBs (3′ or 5′, depending on the direction of the gene transcript) often exist in fragmented forms, particularly if the breaks result from free-radical attack. Examples of these are phosphoglycans. These have to be removed by specific repair enzymes before SSB and DSB repair can proceed. This extensive end-processing can result in loss of base sequence information, loss of heterozygocity (LOH) and cancer-causing mutations if not tightly regulated.

SSBs and DSBs are also actively induced during normal cellular processes such as ►V(D)J recombination and cell division but the way in which these DSBs are discriminated from *bona fide* DNA damage is not fully understood. DSBs can also result from the collapse of regions undergoing DNA ►replication called replication forks Collapse can result from pre-existing DNA lesions that interrupt the DNA replication process.

Furthermore, existing DSBs in the genome represent easy target sites where foreign DNA, such as invading viral DNA, can insert, integrate and rearrange genetic sequences. These random, sequence-independent events are called insertional mutagenic events and can be extremely carcinogenic. Indeed, this process was responsible for the unfortunate development of leukemia in a significant proportion of X-SCID patients who underwent ►gene therapy clinical trials to correct their immunodeficiency. The corrective gene was incorrectly inserted into a region close to the ►oncogene LMO-2 and resulted in uncontrolled proliferation. Metnase is a protein recently identified which promotes NHEJ and the random integration of foreign DNA into human cells.

Cancers Associated with Failure to Signal DNA Damage

A cell requires intricate signaling proteins that alert the presence of DNA damage and activate the appropriate responses. For example, if a cell does not repair DNA damage before it is replicated during cell division, daughter cells will inherit DNA with mutations around that region and the next generation or progeny of cells will be defective. Therefore, appropriate responses such as DNA replication ►checkpoints, or ►cell cycle arrest pathways must be activated to prevent permanent alterations from being passed on. If this is not activated then damaged cells can lose control of proliferation and lead to cancer. Key regulators of this response are the ►p53, ►STRAP, ►MDM2 and Rb (►retinoblastoma protein) that lie at the interface between cell cycle arrest and cell death responses.

Mutations or expression defects in ►p53 are associated with most human cancers, demonstrating the importance of this key responsive network in suppressing cancer development. Prolonged suppression of this response has long been known to contribute to ►tumor progression. It has also been confirmed that, in mice engineered to have p53 expression under inducible control, restoring its function dramatically reduces the size of sarcomas and lymphomas. Furthermore, a whole range of p53 post-translational modifications and down-stream cofactors now seem to govern cell fate after exposure to various DNA damaging agents.

Therapeutic Approaches

The DNA of cancer cells remains one of the most effective targets to damage and destroy cancerous tissue in patients. Traditional DNA damaging ►chemotherapy and ►radiotherapy approaches have served cancer patients very well over the past four to five decades. However, long-term survival rates under such management across the cancer spectrum have not improved that much over the same period of time, clearly defining the need for more advanced techniques.

As we learn more about how cells respond to such damage, it is not surprising that genes such as p53 have been singled out as potentially powerful targets to treat human cancers. Restoring the functions of tumor suppressors such as p53 and suppressing oncogenes and DNA repair proteins that can promote carcinogenesis and cancer cell survival, respectively, are all validated approaches to kill tumor cells and are under current investigation.

►Gene therapy holds great promise for treating all genetically tractable diseases including many cancers. Identifying individuals with DNA repair polymorphisms or mutations and replacing or enhancing the expression of wild-type protein may help restore appropriate responses to DNA damage and protect against cancer development. Furthermore, randomly positioned DNA DSB sites in the genome represent preferential regions where viruses insert their genomes and integrate. Inhibiting DNA repair pathways that promote this random integration may suppress viral infection and reduce the chances of insertional mutagenesis that has so far plagued the promising use of ►viral vector-mediated gene transfer for gene therapy in clinical trials.

DNA Damage Responses

Mau-Sun Chang
Institute of Biochemical Sciences, National Taiwan University, Taipei 106, Taiwan

Definition

Damage to DNA invokes several cellular responses that enable cells either to eliminate the damage or activate programmed cell death. These responses include activation of ►checkpoints to arrest progression through the ►cell cycle; removal or repair of damaged DNA to prevent the transmission of damaged chromosomes to daughter cells; induction of genes required for DNA repair, cell cycle arrest, and ►apoptosis; and apoptosis to eliminate cells too seriously damaged or deregulated to repair.

Characteristics

Sources of Damage

Endogenous attack by ►reactive oxygen species can induce several types of damage to DNA bases, including oxidation and the generation of DNA strand interruptions; alkylation, depurination, and depyrimidination; and wrongly mismatched bases coupled to a new DNA strand. Exogenous damage is caused by a variety of external agents. ►Ultraviolet light from the sun causes crosslinking between adjacent thymine bases, creating pyrimidine dimers. Ionizing radiation from X-rays and gamma rays results in breaks in the DNA double strands. DNA intercalating compounds create a huge variety of DNA adducts.

Checkpoint Pathway

►Checkpoint responses trigger cell cycle arrest, providing time to repair damaged chromosomes before they enter ►mitosis, thus maintaining genomic integrity. There are five major components of this system. First are checkpoint sensors which include the Rad9–Hus1–Rad1 (9-1-1) complex, the Rad17–RFC clamp loading complex, and the ►Mre11–►Rad50–►Nbs1 (MRN) complex. Second, checkpoint mediators include ►BRCA1, MDC1, 53BP1 and Claspin. Third are the apical signal transducing kinases including ►ATM and ►ATR kinases. Fourth, distal signal transducing kinases are represented by ►Chk1 and ►Chk2. Finally, there are checkpoint effectors encompassing cell cycle regulators such as the ►cdc25 phosphatases, various DNA repair proteins, transcription factors ►p53 or ►E2F1, and chromatin components such as histone ►H2AX (Fig. 1).

G1 Checkpoint

To prevent a cell with damaged DNA from entering the S phase, cells activate checkpoint transducing kinases ATM/ATR and Chk1/Chk2, which target Cdc25A and p53 at the G1 checkpoint. When DNA is damaged, p53 is phosphorylated at Ser15 and Ser20 in its transactivation domain. This stabilizes p53 by inhibiting its interaction with ►Mdm2, thus stabilizing p53. The key transcriptional target of p53 is p21 which inhibits cyclin E-cdk2 activity and prevents the phosphorylation of Rb by cyclin D-cdk4. This sequence of events results in suppression of the Rb/E2F pathway, prolonging transition from G1 to S. The phosphorylation of cdc25A by Chk kinases creates binding sites on cdc25A with ►14-3-3 proteins and excludes them from the nucleus. Lack of active cdc25A in the nucleus results in the accumulation of inactive ►cdk4. The inactive molecule is incapable of loading cdc45 onto chromatin, a step required for initiation of replication origin firing.

Intra-S-phase Checkpoint

When a double-strand break or DNA nick occurs during the S phase, the intra-S checkpoint, involving ATM, the ►MRN complex, and BRCA1, is activated. The ATM-Chk2-Cdc25A-Cdk2 pathway is responsible for the checkpoint response. In contrast, when DNA is damaged by ►uv radiation or chemicals that create bulky base lesions, the main damage sensor is the ATR-ATRIP complex. Activated ATR phosphorylates Chk1, which in turn phosphorylates and down-regulates cdc25A, and thus inhibiting replication origin firing.

G2/M Checkpoint

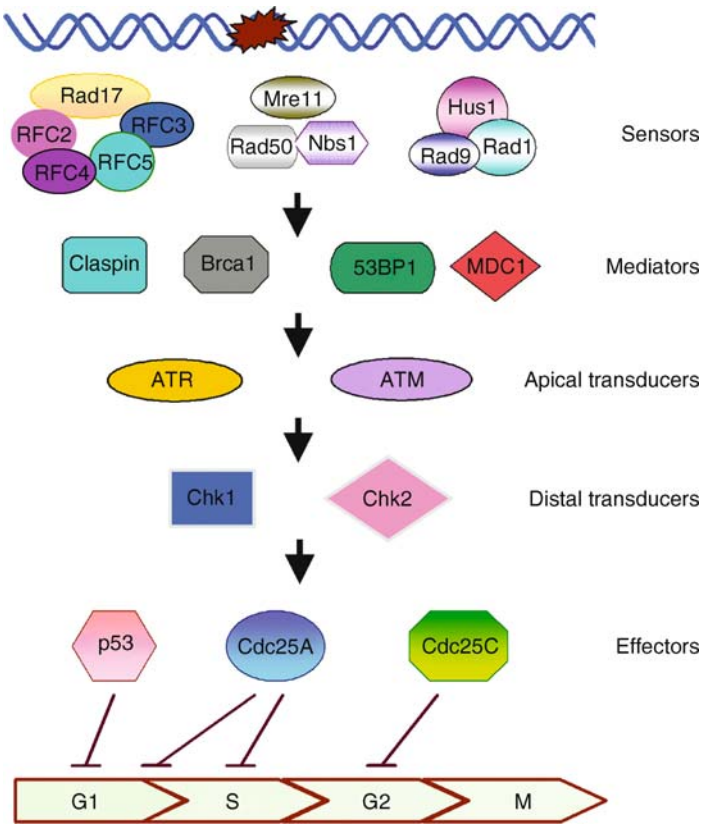
The key downstream target of the ►G2/M checkpoint is the mitosis-promoting activity of the cyclin B/Cdk1 kinase. After DNA damage, ATM/ATR and Chk1/Chk2 kinases downregulate cdc25A and cdc25C. Upregulated Wee1 and downregulated cdc25 collaboratively inhibit the activity of cyclin B/Cdk1 kinase at the G2/M boundary. Again, the phosphorylated cdc25A binds 14-3-3 proteins and is sequestered in the cytoplasm, promoting degradation by the ►ubiquitin-proteasome pathway. Y15-phosphorylated cdk1 accumulates, and ►mitosis is arrested.

DNA Repair Responses

DNA damage alters the spatial structure of the helix, and such alterations can be detected by the cell. Once damage is located, specific ►DNA repair molecules are recruited to the site, inducing other molecules to bind and form a complex that enables actual repair to take place.

Excision Repair

►Base excision repair corrects damage to a single nucleotide. In this process, DNA N-glycosylases



DNA Damage Responses. Figure 1 Signal transduction of the DNA checkpoint responses in human cells. The DNA damage is detected by sensors that, with the aid of mediators, transmit the signal to transducers. The transducers activate or inactivate effectors that directly participate in inhibiting the G1/S, S, or the G2/M transition.

recognize oxidized, alkylated, or deaminated bases and catalyze the hydrolytic removal of the mutated bases. Lesions are then repaired by DNA Pol β/δ/ε, DNA ligase III, ►PCNA, and FEN1. Nucleotide excision repair amends longer strands of 2–30 damaged bases. This process, involving RPA, XPA, and XPC, recognizes bulky, helix-distorting changes such as thymidine dimers as well as single-strand breaks. TFIIH, XPG, and XPF-ERCC1 are recruited to the site to form an incision complex. The gap is filled by DNA Pol δ/ε with the aid of replication accessory proteins PCNA and RFC. ►Mismatch repair fixes errors of DNA replication and recombination that result in mispaired nucleotides.

Double Strand Break Repair

Double strand breaks are produced by ►reactive oxygen species, ►ionizing radiation, and certain antineoplastic chemicals. Two mechanisms exist to repair this damage. The nonhomologous end-joining pathway directly joins the two ends of the broken DNA strands without a template. The Ku heterodimer binds to the two ends of a double-strand break and recruits DNA-PKcs and the ligaseIV-XRCC4 heterodimer to ligate the two duplex termini. The second mechanism, ►homologous recombination repair, requires an identical or a nearly identical sequence as a template. This pathway allows a damaged chromosome to be repaired using the newly created ►sister chromatid as a template. A key intermediate in this pathway is the Holliday junction in which the two recombining duplexes are joined covalently by single-strand crossovers.

Translesion Synthesis Repair

►Translesion synthesis is an error-prone method of DNA repair. This pathway is mediated by DNA polymerases that insert extra bases at the site of damage and thus allow replication to bypass the damaged base.

Interstrand DNA Crosslink Repair

Patients with ►Fanconi anemia have a predisposition to cancer. Their cells are hypersensitive to agents that cause interstrand cross-links. Repair of this type of damage is poorly understood but may involve excision repair and recombination.

Arrest, Repair, or Die?

p53-Dependent Mechanisms

A key determinant as to whether cells with DNA damage live or die is ►p53. ATM phosphorylates p53 at Ser15 and ►MDM2 at Ser395, while ►Chk1 and ►Chk2 phosphorylate p53 at Ser20. These modifications prevent the p53-MDM2 association that targets p53 for proteolysis, thereby allowing increments in cellular levels of p53. The consequences of p53 activation include transcriptional activation of DNA repair activities, cell cycle inhibitors (p21 and 14-3-3σ), and pro-apoptotic factors (►PUMA, ►FAS/APO-1/CD95, and ►Apaf-1).

p53-Independent Mechanisms

One possible mechanism for p53-independent apoptosis involves E2F1, under the control of Chk1- and Chk2-mediated activation. The transcriptional targets of E2F1 include proteins associated with DNA repair (BRCA1, Msh2, Msh6, RFC, and PCNA), cell cycle checkpoints (ARF and Chk1), and apoptosis (Caspase 7, Apaf1). Thus, like p53, E2F1 may determine whether cells live or die.

Cancer Susceptibility

Loss of ►ATM strongly predisposes humans to ►lymphoma and, to a lesser degree, to other malignancies. Patients with mutations in ►NBS1 or ►MRE11, for example, are predisposed to develop cancer. ►Seckel syndrome, in which there is a low level of ATR expression, involves ►chromosome instability after ►mitomycin C exposure. Inherited mutations in one allele of p53 and Chk2 are found in families with the extremely cancer-prone ►Li-Fraumeni syndrome. The inheritance of a single mutated allele of either ►BRCA1 or ►BRCA2 markedly increases the incidence of breast and ovarian cancers in women.

Nucleotide excision repair, homologous recombination, and translesion synthesis are all thought to be defective in ►Fanconi anemia cells. Nucleotide excision repair is defective in ►xeroderma pigmentosum and ►Cockayne syndrome, while ►mismatch repair malfunctions in children with ►Turcot syndrome and in tumor cells derived from ►hereditary nonpolyposis colorectal cancers (HNPCC). Tranlesion synthesis repair is defective in patients with a variant of xeroderma pigmentosum.

DNA-Damage Tolerance

Xianghong Wang
Department of Anatomy, The University of Hong Kong, Hong Kong, China

Synonyms

DNA lesion bypass; Replicative DNA lesion bypass; Postreplication repair

Definition

DNA-damage tolerance is a biological mechanism in response to DNA damage which overcomes arrested DNA replication, as a result of unrepaired DNA damage, leading to elimination of its potential lethal effects.

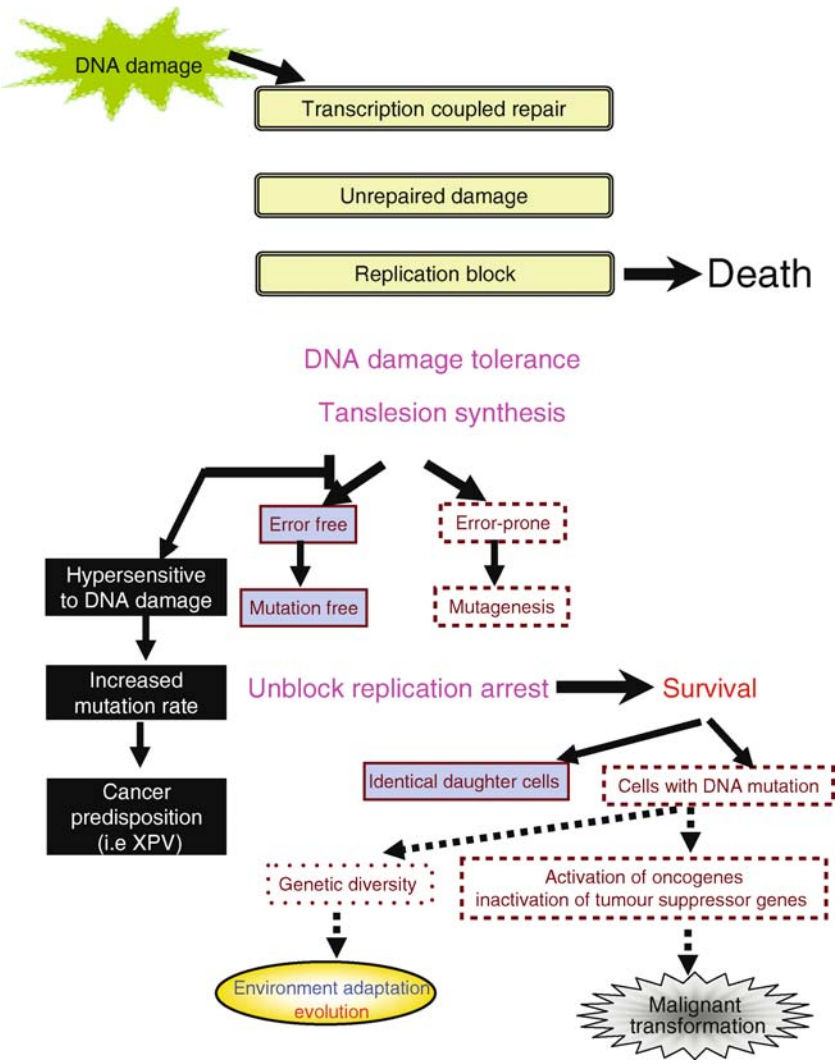
Characteristics

DNA is frequently damaged by endogenous and environmental factors. Base damage in DNA template strands blocks transcription to allow time to activate ►transcription-coupled repairpathways and eliminate DNA base damage. However, some lesions are persistent during replication therefore causing replication blockage and cell death. In order to overcome this problem, cells have evolved a damage tolerance system to allow complete replication in the presence of DNA damage. This process bypasses, rather removes, DNA damage, therefore, it is also named replicative bypass. It enables the cell to tolerate DNA damage and promote cell survival at the expense of high mutation rate. In fact, this process is responsible for most of the damage-induced point mutations and particularly important for oncogenesis. On the other hand, mutations are essential for evolution and adaptation which help a species to survive in a changing environment. The schematic summary of consequences of DNA damage is shown in Fig. 1.

Mechanism

Nonreplicative DNA Polymerases

A number of DNA polymerases have been identified specifically responsible for overcoming damage-induced replication arrest in human cells, which are also called specialized DNA polymerase (or bypass



DNA-Damage Tolerance. Figure 1 Schematic summary of consequences of DNA damage in mammalian cells. Note that DNA-damage tolerance mechanism promotes cell survival, and defects in error-free translesion DNA synthesis result in predisposition to cancer.

polymerase). So far ten of those polymerases have been identified in human including Rev1, Polyη, κ, ι, λ, μ, β, θ, υ, and ζ. Unlike ►replicative DNA polymerases, which can only use the opposite strand as template to initiate DNA synthesis, the specialized polymerases are able to promote stable incorporation of nucleotides opposite the lesion when replication is blocked by a damage. In addition to the conventional domains commonly found in all DNA polymerases such as "fingers," "thumbs," "palm" domains, many of the specialized DNA polymerases have a "little finger" domain and catalytic sites which provide flexible active site and allow the replicative bypass of various types of template structure. During an arrested replication, these polymerases take over temporarily from the replicative DNA polymerases and use either the damage DNA strand or the newly synthesized DNA strand as a template to proceed replication. This event is referred as "polymerase switching." This step is essential for the specialized polymerases to transiently occupy the primer template for initiating synthesis to bypass the damaged site. Unlike the high fidelity replicative DNA polymerases, these specialized polymerases have low fidelity of DNA synthesis and are responsible for mutagenesis in the genome. It is speculated that the reason that these polymerases are excluded from normal DNA replication is to maintain genomic stability in normal cells.

Translesion DNA Synthesis

The predominant and most well-studied DNA tolerance mechanism is known as ►translesion ►synthesis

(TLS). This process allows tolerance of DNA damage by employing specialized DNA polymerases to synthesize DNA directly in order to bypass template DNA damage. The outcome of this process can be both error-free and error-prone. When normal DNA synthesis is blocked by a lesion on one of the template strands, the specialized DNA polymerase(s) use the newly synthesized daughter strand as template to proceed DNA synthesis. Therefore, copying of the damaged site of DNA template is avoided and the DNA replication continues. Because the newly synthesized daughter strand, instead of the damaged strand, is used as template, this process is also named "template switching." In this process, the correct nucleotide is incorporated opposite the damage site; therefore, it is error-free. In contrast, when specialized polymerase(s) use the damaged template to proceed with DNA synthesis, errors may occur. This process is called lesion bypass and usually error-prone because of lack of correct template. However, if the correct nucleotide is incorporated opposite to the damage site, it can be error-free. When an incorrect nucleotide is incorporated opposite the damage site and subsequently extended, a base mutation occurs. Therefore, the error-free lesion bypass is mutation-avoiding mechanism, and error-prone lesion bypass is a mutation-generating mechanism. In human, the poly η is demonstrated to be one of the error-free specialized polymerases while Pol ι, κ, ζ, and Rev1 are found to be mutagenic specialized polymerases. The error-prone translesion synthesis contributes a major mechanism of DNA damage-induced mutagenesis in human.

Association with Cancer

Although the majority of polymerase errors are corrected by ►mismatch repair mechanism, the repair system may not function with 100% efficiency; therefore, errors are likely to escape correction and extended during subsequent replication. In addition, some unrepaired DNA damage, spontaneously formed or induced by environmental agents, will be processed by error-prone lesion bypass mechanism leading to mutagenesis. Therefore, mutations are generated every time the cell replicates itself. Accumulation of mutations in DNA results in activation of ►proto-oncogenes and inactivation of ►tumor suppressor genes resulting in malignant transformation. The significance of translesion synthesis in the development of human cancer comes from the identification of germ line mutations of the *Poly η* gene in a form of hereditary disease named ►xeroderma pigmentosum variant (XPV). Poly η is a highly specific bypass polymerase in repairing UV-induced thymidine dimers in an error-free manner. Loss of its function leads to increased UV-induced mutagenesis and hypersensitivity to sunlight. These XPV patients are hypermutable by ►UV radiation and develop cancer on sun-exposed skin at very young age. Skin abnormalities are caused by defects in bypassing UV-induced DNA damage leading to cell death or malignancy.

DNA Damage Triggered Death Signaling Pathways

►DNA Damage-Induced Apoptosis

DNA Damage-Induced Apoptosis

Bernd Kaina
Department of Toxicology, University of Mainz, Mainz, Germany

Synonyms

DNA damage triggered death signaling pathways; DNA repair and damage processing

Definition

►DNA damage-induced cell death is executed by apoptosis, necrosis, mitotic catastrophe and autophagy. From these different forms of cell inactivation ►apoptosis is the main route of death following DNA damage. Cells undergo apoptosis upon genotoxic stress via the death receptor and/or the intrinsic mitochondrial pathway. DNA damage-induced apoptosis is thought to be a mechanism protecting against cancer because it eliminates genetically damaged cells. This is most obvious in sun burned skin in which ►p53 upregulation initiates

the apoptotic process in response to light-induced DNA damage.

Characteristics

Summary

Not every type of DNA damage induces apoptosis. Many DNA lesions are tolerated by the cell, some are mutagenic without being toxic and some are more toxic than mutagenic. Apoptosis-inducing lesions are O^6-methylguanine, O^6-chloroethylguanine, base N-alkylations, cyclobutane pyrimidine dimers (CPDs) and (6–4) photoproducts, benzo[a]pyrene guanine adducts, cisplatin and mustard-induced crosslinks and ►DNA double-strand breaks (DSBs). It is reasonable to suppose that any ►transcription and DNA ►replication blocking lesion bears apoptotic potential, and that transcription blockade and DNA replication fork stalling are apoptosis initiating events. ►Apoptosis signaling competes with DNA repair processes that either remove apoptosis-inducing lesions from DNA or tolerate them by replication bypass. Extended replication inhibition may lead to collapse of replication forks and the generation of DSBs, which are supposed to be the ultimate critical downstream apoptotic lesions for many, if not all, genotoxins. Primary DSBs induced by ionizing radiation and radiomimetic drugs and secondary DSBs derived from chemical DNA adducts during DNA replication are sensed by ►ATM (ataxia telangiectasia mutated) or ►ATR (ataxia telangiectasia related) protein. These ►PI3 kinases phosphorylate a large number of proteins including p53 that regulates apoptosis by upregulating the death receptor ►FAS/Apo-1/CD95, ►PUMA, Bak or translocating Bax to the mitochondrial membrane. Another mechanism implicated in apoptosis signaling rests on sustained upregulation of the transcription factor ►AP-1 by c-Fos and c-Jun activation, thus triggering the Fas ligand expression. The apoptotic pathway that finally becomes activated is cell type- and genotoxin-specific, depending on the p53 status, ►FAS/Apo-1/CD95 responsiveness and DNA repair capacity. DNA damage-induced apoptosis is executed by caspases, with caspase-8 activated by death receptors and caspase-9 by mitochondrial damage. The main executing ►caspases are caspase-3 and -7. These caspases cleave the inhibitor of caspase-activated DNAse (CAD) that in turn cleaves DNA in the typical 180–200 bp nucleosomal fragments.

Physiological Role of Apoptosis Induced by DNA Damage

DNA is subject to spontaneous and induced damage by environmental genotoxins. These include ►alkylating agents, ►polycyclic aromatic hydrocarbons, biphenyls, ►heterocyclic amines, ►ultraviolet light and ►ionizing radiation. DNA is also the main target for most anticancer drugs that react directly with DNA or interfere with DNA metabolism. Two cellular strategies have evolved for coping with DNA damage: (i) the damage is repaired or tolerated and (ii) cells harboring DNA damage are removed from the population by death. DNA damage has harmful consequences, which manifests as chromosomal changes, mutations, gene ►amplification and misregulation, cell death and malignant transformation. Cells respond to genotoxins in a complex way by evoking numerous cellular responses that may ultimately lead to damage repair, damage fixation as mutations, or damage elimination by various routs of cell death (►necrosis, apoptosis, reproductive cell death, interphase death, ►autophagy, ►mitotic catastrophe). Programmed cell death (apoptosis) following DNA damage is based on a complex enzymatic machinery. Apoptosis occurs continuously in the body, notably in changing tissues, and it appears that DNA damage-triggered cell death utilizes the normal cellular suicide program as a strategy to eliminate genetically damaged cells.

DNA damaging agents. There are three lines of evidence that apoptosis induced by genotoxic agents is related to DNA damage: (i) Inability of cells to repair DNA lesions results in hypersensitivity to the killing effect (an exception to the rule is DNA mismatch repair, see below). This has been shown for mutants defective in O^6-methylguanine-DNA methyltransferase (MGMT), base excision repair (BER), nucleotide excision repair (NER), DSB repair and DNA crosslinks repair. (ii) Modified nucleotides such as 6-thioguanine or gancyclovir incorporated in DNA induce apoptosis. (iii) DSBs induced by restriction enzymes in the cellular genome induce a strong apoptotic response. They hardly induce necrosis. The apoptotic pathways activated by a single DNA lesion, O^6methylguanine, as well as its interplay with DNA repair pathways has been studied in great detail. O^6MeG does not block DNA replication. It mispairs with thymine, giving rise to GC to AT point mutations. In the presence of ►mismatch repair (MMR) the O^6MeG/thymine mismatch is recognized by MutSα (consisting of MSH2 and MSH6) and MutLα (heterodimer of MLH1 and PMS2) that provoke a futile mismatch repair cycle leading to the formation of DSBs and apoptosis signaling. MMR deficient cells are highly resistant to simple alkylating agents because they do not undergo apoptosis. They tolerate O^6MeG adducts at the expense of mutations. Therefore, MMR driven apoptosis eliminates pre-mutated cells from the population, reducing mutation load (►Mismatch repair in genome stability).

Apoptotic pathways. The apoptotic pathways employed by cells following the exposure to O^6-methylating agents and other genotoxins differ depending on their p53 status. In p53 mutated cells the mitochondrial apoptotic pathway becomes activated, characterized by a decline in Bcl-2 that increases the Bax/Bcl-2 ratio and allows for the

release of ►cytochrome c from the mitochondria. This release of cytochrome c leads to the activation of the apoptosome consisting of Apaf-1, ATP, cytochrome c and procaspase-9. In turn, ►caspase-3 becomes activated that cleaves the inhibitor of caspase-activated DNAse (ICAD) that degrades DNA, resulting in the characteristic apoptotic DNA fragmentation. In p53 wild-type cells, e.g. human lymphocytes, DNA damage activates the death receptor pathway (Fas/CD95/Apo-1). There are cell types, such as glioma cells, wild-type for p53 in which both the Fas receptor and the mitochondrial damage pathway becomes activated in response to DNA damage. However, a higher level of DNA damage is required in order to induce apoptosis by activating the mitochondrial compared to the death receptor pathway.

Another role for p53 has been ascribed to the regulation of PUMA. DNA damage localizes p53 to the nucleus and transcribes PUMA. PUMA in the cytoplasm liberates cytoplasmic p53 from Bcl-xL, thereby freeing p53 to activate BAX and facilitate mitochondrial apoptosis. Another player in DNA damage-induced apoptosis is caspase-2, the only nuclear localized caspase that seems to act upstream of the mitochondria (►Apoptosis signaling).

DNA damage-triggered signaling: sustained JNK/p38 kinase activation. Some DNA damaging agents provoke the activation of stress-activated protein kinase/c-Jun N-terminal kinase (SAPK/JNK) and p38 kinase, which results in an increase in c-►Jun level and ►AP-1 activity. This sustained activation of AP-1 is accompanied by transcriptional activation the Fas-L gene. NER repair defective mutants display a higher level of sustained JNK/p38 kinase activation, indicating DNA damage is responsible for the response. Together with DNA damage-induced p53 upregulation that triggers transcription of the Fas receptor, the upregulation of the Fas ligand via AP-1 is effective in driving apoptosis upon DNA damage.

The ATM/ATR/p53 connection. ►DSBs are the most lethal DNA lesions and, therefore, cells have to be equipped with sensors that recognize DSBs immediately upon formation. These sensors signal repair or, if this fails, cell death. DSBs are recognized by proteins containing both signaling (kinase) and repair activity. The most important players are ►ataxia telangiectasia mutated (ATM) protein and A-T and Rad3-related (►ATR) protein. Both are activated by DSBs. Once activated, ATM phosphorylates various downstream substrates such as ►Nbs1. Phosphorylated Nbs1 acts as an adapter molecule for ATM dependent phosphorylation of Chk2 which activates Cdc25 responsible for S phase checkpoint control. Other substrates of ATM are p53, MDM2, ►CHK1 and ►CHK2, ►H2AX and ►BRCA1. While ATM is activated by ionizing radiation-induced DSBs, ATR is activated in response to UV light and presumably all chemical agents that give rise to stalled DNA replication forks. ATM/ATR is implicated in three crucial functions: regulation and stimulation of DSB repair (homologous recombination), signaling cell cycle checkpoints, and signaling apoptosis via p53. The phosphorylation of p53 by ATM leads to its stabilization, nuclear translocation and upregulation of p21 that triggers G1/S arrest. Low levels of DSBs activate only a minor fraction of p53 that is sufficient to drive the p21 gene, causing cell cycle arrest. With a higher level of DSBs, p53 becomes activated strongly and thus drives pro-apoptotic genes such as *bax* and the *fas receptor*. Therefore, the ATM/p53 activation level is very important in DNA damage-triggered apoptosis. Although AT cells (cells in which the ATM gene is mutated) are more sensitive to ionizing radiation, they exhibit less apoptosis after ionizing radiation than normal cells. ATM ►knockout mice also showed a lower apoptotic response after ionizing radiation than the corresponding wild-type mice, indicating the importance of the ATM/p53 pathway in triggering DNA damage-induced apoptosis. However, in a p53 mutated background, ATM knockout fibroblasts are more sensitive to apoptosis induced by alkylating agents than corresponding lines expressing ATM. This suggests that ATM is not indispensable for triggering apoptosis in response of DNA damage. It thus appears that DSBs, notably those induced by chemical genotoxins, are able to trigger apoptosis very efficiently also by another mechanism not involving ATM/p53 signaling. The high level of resistance of ATM wild-type cells to ►MNNG is explained by the role of ATM in DSB repair.

p53 is considered a major player in the apoptotic response, which is in line with the finding that p53 knockout mouse are resistant to the toxic effect of ionizing radiation, which is largely due to impaired death of thymocytes. While p53 deficient thymocytes are more resistant to ►ionizing radiation, p53 deficient mouse fibroblasts are more sensitive. This indicates that in fibroblasts, p53 is not required for inducing apoptosis in response to DSBs. It rather exerts a protective effect, which is most likely due to its involvement in DNA repair and inhibition of DNA synthesis by blocking cells in ►G1/S, transition. The decision of whether p53 exerts a pro- or anti-apoptotic effect appears to be cell type-specific, and the conditions determining whether p53 stimulates or protects against apoptosis have yet to be explored.

DNA Vaccination

Holger N. Lode
Charité University Medicine Berlin, Pediatrics, Berlin, Germany

D

Synonyms

Genetic immunization

Definition

Vaccination with deoxyribonucleic acid (DNA) against cancer is the most basic type of vaccination that, rather than consisting of the tumor-associated antigen itself, provides genes encoding for the antigen. Once produced in vivo following DNA delivery, the antigen is presented to the immune system inducing an antigen specific immune response. This response is augmented by the immunological properties of the DNA itself, mediated by unmethylated ►CpG sequences. This essay reviews accomplishments and challenges in this area.

Characteristics

DNA vaccination represents a young field in cancer immunotherapy. It started with the observation that injection of plasmid DNA into a mammal resulted in the synthesis of the encoded protein. The unformulated or "naked" plasmid DNA containing a simple expression cassette, consisting of a promoter functioning in mammalian cells and of a gene encoding for a protein antigen, was injected into the muscle of mice. The subsequent induction of antigen specific ►CD8+ cytotoxic T-cells and antibodies was effective in protecting mice from challenges with the pathogenic agent expressing the antigen. This observation was surprising, given the low amount of antigen produced, the apparent lack of transfection of professional antigen presenting cells (APC) and the absence of any replicative step. The robustness of the technology was demonstrated for a variety of disease models.

Mechanisms of Action

The method of DNA delivery critically affects the mechanisms involved in the induction of an immune response. Intramuscular injection of plasmid DNA leads to in vivo transfection of myocytes. Mechanistic studies revealed that antigen specific immune responses following intramuscular injection of DNA is a result from ►cross priming. This mechanism describes production of the antigen by the myocyte and subsequent uptake and presentation by professional APCs. This was clearly demonstrated in bone marrow chimeric mice and in experiments with transfected myoblasts. In both systems,

the induction of an antigen specific immune response depended on the antigen presentation by APCs, and not by the myocyte. The transfer of the antigen from myocyte to APC follows different routes, ranging from uptake of secreted protein, processed peptide alone or with heat-shock proteins or apoptotic bodies by APCs. The transfer of DNA into the myocyte and subsequent induction of an antigen specific immune response can be largely improved by in vivo ►electroporation. The technique involves the application of an electric field around the DNA injection site. There are also needle free systems available, injecting DNA in solution using high pressure liquid jets. Clinical devices were developed by the pharmaceutical industry for application in humans, which are well tolerated.

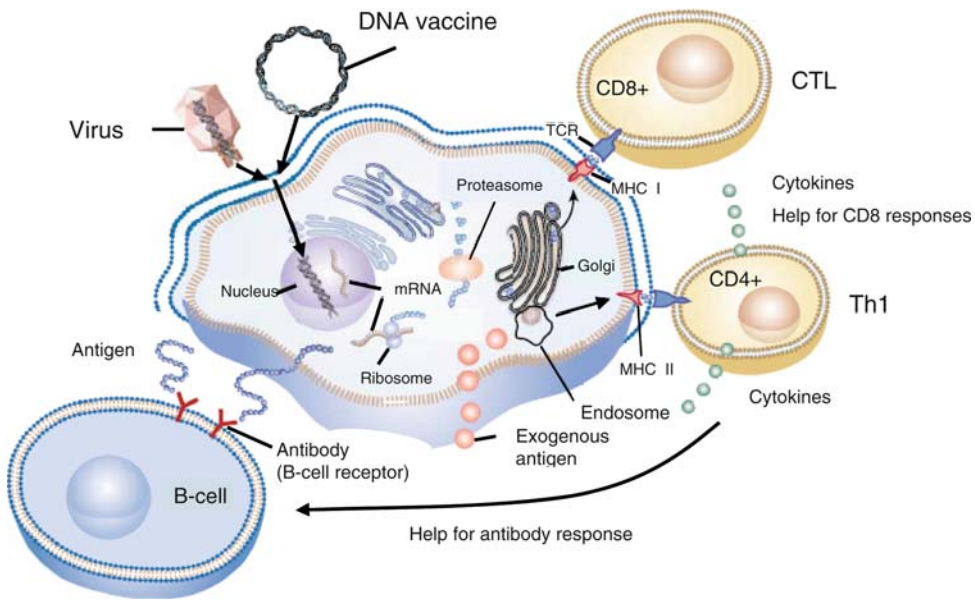
Bombardment of the epidermis with plasmid loaded onto gold particles using the ►gene gun directly transfers DNA into APCs of the skin called ►Langerhans cells. Once the protein antigen is expressed, professional antigen presentation is mediated by this cell type. Efficient induction of an immune response occurs after migration of these APCs from the skin into regional lymph nodes.

Gene transfer of plasmid DNA into APCs is also accomplished by the use of life attenuated bacteria such as salmonella typhimurium or listeria monocytogenes. In both cases, these micro organisms are infectious, but not pathogenic, and therefore serve as in vivo carrier systems for plasmid DNA vaccines. After in vivo application, ►Peyer patches and the spleen become infected. Subsequently, the carrier microbes die due to distinct mutations in their genome and liberate multiple copies of the plasmid DNA vaccines in these ►secondary lymphoid organs. There, the DNA vaccines are expressed by APCs leading to the induction of an antigen specific immune response.

A central role for induction of an immune response by DNA vaccines is antigen expression by APCs and subsequent presentation to $CD8^+$T-cells, ►$CD4^+$ T-cells and B-cells (Fig. 1).

Adjuvant Activity of DNA

Plasmid DNA derived from bacterial expression systems naturally contain unmethylated DNA sequences called CpG motifs. These sequences bind to Toll-like receptor 9 and are strong activators of ►innate immunity. This



DNA Vaccination. Figure 1 Mechanisms involved in the generation of antigen specific humoral and cellular immune responses upon DNA vaccination. Antigen specific activation of cytolytic T lymphocytes ($CD8^+$T-cells) occurs after proteasome dependent antigen processing of intracytoplasmic proteins into peptides associated with newly synthesized MHC class I molecules. MHC class I/peptide complexes are presented on the surface of APCs in conjunction with costimulatory molecules to $CD8^+$T cells. The activation of ►$CD4^+$T-cells is primarily achieved by exogenous protein antigens taken up by the endolysosomal compartment. After degradation, peptides associate with MHC class II molecules which are then translocated to the cell surface. Specific $CD4^+$ helper T cells recognize these MHC class II/peptide complexes and are activated to produce cytokines. These cytokines have multivarious activities helping B-cells to mature into antibody producing plasma cells and $CD8^+$T-cells to transform into cytolytic effector cells. For antibody responses, B-cells recognize and respond to antigens that are either present extracellularly or exposed extracellularly by being transmembrane proteins.

receptor is also expressed on APCs leading to improved antigen processing and presentation as well as the release of pro-inflammatory cytokines and chemokines that help to shift ►adaptive immunity responses from ►Th2 immune response to ►Th1 immune response. Th1 responses are required for most effective anti-tumor immunity. Therefore, CpG motifs in the DNA vaccine backbone can be considered endogenous adjuvants linking innate immunity with ►adaptive immunity, which provides for robust and long lasting antigen specific immune responses.

Tailoring Immune Responses by DNA Vaccine Design

In order to improve antigen specific immune responses, the versatility of DNA vaccine design allows for the simultaneous expression of antigen, co-stimulatory molecules and chemoattractants. These include cytokines, chemokines, molecules of the B7 family and CD40 ligand. The design of the protein antigen itself can be altered to be secreted for induction of B-cell responses or to be targeted into the endopasmatic reticulum or the proteasomal degradation pathway for the generation of T-cell epitopes. Protein antigens can be redesigned as mini genes only encoding for immunodominant peptide antigens. In summary the versatility of DNA vaccines allows for specific tailoring of an optimized immune response following a rational vaccine design.

Formulation

The formulation of DNA vaccines to improve antigen specific immune responses includes transfection-facilitating lipid complexes, nanoparitcles and classical adjuvants. Lipid complexes are varying combinations of DNA with cationic lipids. Microparticles are generated with DNA entrapped in biodegradable poly-lactide-co-glykolactide or complexed with non-ionic block copolymers or polycations. Among the classical adjuvants, aluminium phosphate is noteworthy for its effectiveness and simplicity of preparation. Microparticles appear to improve the trafficking of DNA to APCs by facilitating the transfer of DNA into regional lymphnodes.

Mixed Modality Vaccines

A very promising strategy that is entering clinical trials is to combine DNA vaccines with other gene delivery systems. This is based on observations that if DNA encoding an antigen is given as a prime followed by another gene-based vector system as a boost such as recombinant viruses encoding the same antigen, most optimal immune responses and protection are achieved. The responses are significantly greater than using DNA or the virus for both the prime and the boost or if the order of the administration is reversed.

Results from Clinical Trials

First generation DNA vaccines have been evaluated clinically as a therapeutic vaccine approach for cancer. These vaccines encoded for viral epitopes from transforming viruses, self-antigens expressed on tumors, and tumor specific antigens. In most trials so far, the plasmid DNA was injected intramuscularly, intradermaly or intranodaly. Antigen specific humoral and cellular responses were observed in human cancer trials. However, this did not translate into clinical responses in the trial patient populations characterized by large tumor burden and progressive disease. The clinical trials so far have proved the principle that immune responses can be generated in humans. They also highlight the need to apply strategies to increase the potency of the technology as outlined above and to generate second generation DNA vaccines for future application in cancer patients.

In summary, DNA vaccines hold great potential as immunotherapeutic tools to prevent and treat human cancer. Their advantages include cost effectiveness, versatility, safety, stability, ease of construction and mass production and most importantly ability to induce robust humoral and cellular immune responses. Lack of success in early clinical trials so far is similar to early clinical results with treatments based on monoclonal antibodies which are now established cancer therapeutics. To push for success, the next generation of DNA vaccines will have to incorporate multiple strategies to enhance plasmid DNA immunogenicity. Additional avenues may involve exploring the possibilities of combining adoptive cell therapies with DNA vaccines such as ex vivo gene transfer into autologous dendritic cells.

Docetaxel

Ricardo Hitt[1], Cristina Rodríguez[2]
[1]Medical Oncology Service, University Hospital 12 de Octubre, Madrid, Spain
[2]Human Cancer Genetics Programme, Spanish National Cancer Center (CNTO), Madrid, Spain

Synonyms

►Taxotere

Definition

Docetaxel is a new class of anticancer agent that exerts the cytotoxic effects on microtubules. It is a semisynthetic drug with significant activity in a broad range of tumor types that are generally refractory to conventional therapies, including chemotherapy-resistant epithelial ►ovarian cancer, ►breast cancer, ►non-small cell lung cancer, head and neck cancer, ►bladder cancer, and ►gastric cancer.

Characteristics

Docetaxel is derived semisynthetically from 10-deacetyl-baccatin III, is more water soluble than ►paclitaxel and is more potent antimicrotubule agent in vitro.

Mechanism of Action: Docetaxel induces polymerization of ►tubulin, ►microtubule bundling in cells, formation of numerous abnormal mitotic asters. The cytotoxic effects of docetaxel are also severalfold greater than paclitaxel in vitro and in tumor xenografts. Docetaxel inhibit proliferation of cells by inducing a sustained mitotis block at the metaphase–anaphase boundary at much lower concentrations than those required to increase microtubule polymer mass and microtubule bundle formation. These inhibitory effects at low drug concentrations are associated with the formation of an incomplete metaphase plate of chromosomes and an arrangement of spindle microtubules resembling the abnormal organization that occurs at low concentrations of the ►vinca alkaloids.

Docetaxel primarily block cell-cycle traverse in the mitotic phases and prevents the transition from Go to S phase. The inhibitory effects in the nonmitotic cell-cycle phases include the disruption of tubulin in the cell membrane and direct inhibitory effects on the disassembly of the interphase cytoskeleton. These effects may result in the disruption of many vital cell functions such as locomotion, intracellular transport, and transmission of proliferative transmembrane signals.

After disruption of microtubules and other processes by docetaxel, the precise means by which cell death occurs is not clear. Morphologic features and a DNA fragmentation pattern (►nucleosomal DNA fragments) that are characteristic of programmed cell death, or apoptosis, in docetaxel-treated cells indicate that this taxane trigger apoptosis as do many other chemotherapeutic agents. Whether docetaxel-induced ►apoptosis requires a functional ►p53 pathway is unclear and probably depends on the cell line under study. The consensus seems to be that in most cell lines, disruption of p53 has little effect on drug sensitivity.

Mechanism of Resistance: Selection of taxane-resistant cells in vitro is associated with changes in β-tubulin isotype expression. Six different isotypes of β-tubulin are expressed in nonmalignant tissues, with the class I isotype comprising 80–99% of cellular β-tubulin. The β III isotype increase the dynamic instability of microtubules, impairs rates of microtubule assembly, and increases resistance to taxanes.

A second mechanism of acquired taxane resistance fits the general pattern of ►MDR. The particular species of Pgp found in taxane-resistant murine ►macrophages is similar, but not identical, to that found in ►vinblastine- and ►colchicine-resistant cells derived from the same parental line. These cells are cross-resistant with many other natural products, and resistance to docetaxel conferred by ►mdr-1 can be reversed by many classes of drugs, including ►tamoxifen, ►cyclosporine A, antiarrhytmic agent.

Other changes in tumor cells selected for drug resistance have included upregulation of ►caveolin-1, a principal component of membrane-derived vesicles involved in transmembrane transport of small molecules and in intracellular signaling.

Pharmacokinetics

The single 1-hour infusion every 3 weeks is the most common administration of docetaxel. The ►pharmacokinetics behavior on 1 or 2 h schedules is linear at doses of 115 mg/m2 or less and optimally fits a three-compartment model. Docetaxel binds rapidly and avidly to plasma proteins (>90%), especially to albumin, α1-acid glycoprotein, and lipoproteins. In addition, peak plasma concentrations generally exceed levels required to induce relevant biologic effects in vitro. Limited information is available about the distribution of docetaxel in humans. Immediately after treatment, tissue uptake of radioactivity is highest in the liver, bile, and intestines, a finding that is consistent with substantial hepatobiliary extraction and excretion. High levels of radioactivity are also found in the stomach, which indicates the possibility of gastric excretion, as well as in the spleen, bone marrow, myocardium, and pancreas. Docetaxel has hepatic metabolism and biliary excretion and urinary excretion accounts only 2%. Approximately 80% of the administered dose of total radioactivity is excreted in the feces within 7 days after treatment, with the majority of excretion occurring in the first 48 h. In the hepatic ►cytochrome P450-mixed function, oxidases are responsible for the bulk of drug metabolism, and CYP3A, CYP2B, and CYP1A isoforms may play major roles in biotransformation. The main metabolic pathway consists of oxidation of the tertiary butyl group on the side chain at the C-13 position of the taxane ring as well as cyclization of the side chain.

Toxicity

►Neutropenia is the principal toxicity of docetaxel. At dose of 100mg/m2, neutrophil count nadirs are <500/mcl in 50–80% of courses in previously untreated patients. The onset of neutropenia is early, with nadirs usually on day 9 and complete recovery by days 15–21. Neutropenia is not cumulative.

Hypersensitivity reaction (HSR) with premedication with dexamethasone is present in less of 10% of the cycles. Another possible toxicity is fluid retention that is cumulative doses, characterized by edema, weight gain, ►pleural effusion, and ►ascites. Neither hypoalbuminemia nor cardiac, renal, or hepatic dysfunction is found, and capillary filtration studies suggest that docetaxel causes a capillary permeability abnormality. Fluid retention is not usually significant at cumulative doses of <400 mg/m^2.

The incidence of this effect may be reduced by premedication with dexamethasone 8 mg orally twice daily for 5 days, beginning from day 1.

Between 50 and 75% of patients receiving docetaxel develop skin toxicity, typically characterized by an erythematous pruritic maculopapular rash that affects the forearms and hands. Other cutaneous effects include onychodystrophy, onycholysis, soreness and brittleness of the fingernails. Docetaxel also induces palmar-plantar erythrodysthesia and ►alopecia. With respect to neurotoxicity has been reported in 40% of previously untreated patients and may be higher in patients who were previously treated with ►platinum antitumor compounds. The peripheral neuropathy predominately affects large fiber sensory function.

Asthenia has been observed in as many as 60–70% of patients and usually is moderate in severity, and when it is severe, it warrants dosage reduction or discontinuation of treatment. Nausea, vomiting, and severe diarrhea are rare.

Dosage

Docetaxel is indicated at a dose range of 60–100 mg/m^2 over 1 h. Although untreated or minimally pretreated patients generally tolerate docetaxel at a dose of 100 mg/m^2 without severe toxicity, emerging data indicate poorer tolerance in more heavily pretreated patients, in whom 75 mg/m^2 may be a more reasonable dose from a toxicologic perspective. Although weekly drug administration has no clear benefits in terms of antitumor activity, hematologic toxicity is much less than conventional schedules and an unacceptable degree of asthenia and neurotoxicity is evident at doses that exceed 36 mg/m^2 per week.

Indications

Docetaxel has demonstrated antitumor activity in patients with metastatic breast cancer as first line or salvage treatment, recurrent ovarian cancer, non-small cell lung cancer, adjuvant breast cancer, squamous cell head and neck cancer, and gastric cancer. In addition to these indications, docetaxel has demonstrated activity in previously treated patients with carcinomas of ►endometrial cancer, ►esophageal cancer, ►bladder cancer, ►prostate cancer, ►small cell lung cancer, as well as ►lymphomas and other neoplasms.

Domain

Definition

A portion of a polypeptide that folds to form a compact unit that remains distinct within the tertiary structure of the whole protein. Domains are usually compact globular units within proteins that are the basic units of their tertiary structures. Immunoglobulin-like domains appear to resist proteolysis and are therefore a feature of a large family of mostly extracellular proteins.

Domain Structure

Definition

Refers to an element, motif, or particular amino acid sequence, within the overall protein that often folds and functions independently of the rest of the protein.

Dominant

Definition

Describing an ►allele of a gene that determines the phenotype in spite of the presence of the second allele (►recessive) that specifies a different phenotype. Referring to one of several alternative traits (phenotypes) that can be specified by a genetic locus; when the locus is ►heterozygous and carries information specifying two distinct traits, the dominant trait will be the one actually exhibited.

Dominant Negative

A mutation that occurs in only one ►allele but is able to effect the cellular or organismal phenotype by virtue of inactivating the normal allele at the protein level. Implies that an altered gene product acts antagonistically to the wild-type allele; this usually results in an altered molecular function, which is often inactive.

Dopamine

Definition

A neurotransmitter substance produced in the hypothalamus and elsewhere in the nervous system. It negatively regulates prolactin secretion.

►Prolactin

Doppler Ultrasound

Definition

Doppler effect is a shift in the frequency of a wave produced by motion of a source or reflector. The change in pitch of a train whistle or emergency siren as the vehicle passes the listener is a familiar example of the Doppler effect. In vascular ultrasound imaging, red blood cells are the primary moving reflectors. The Doppler frequency shift observed when an ultrasound pulse reflects from moving red blood cells depends on the velocity of blood flow, the original frequency of the transmitted ultrasound pulse, the angle between the ultrasound beam and the direction of flow, and the speed of sound. Measurements of Doppler frequency shift can therefore be used to estimate blood flow velocity.

Dormancy

Judah Folkman
Children's Hospital and Harvard Medical School, Boston, MA, USA

Synonyms

In situ cancer or carcinoma; Occult cancer; Cancer without disease; In situ carcinoma

Definition

Tumor dormancy describes human tumors with three characteristics: (i) Visible only under a microscope, and therefore, cannot be detected by conventional diagnostic imaging methods. May have an average diameter the size of a pinhead, but range from 0.1 mm to ~2 or 3 mm. (ii) Usually do not expand or spread to other organs. (iii) Usually asymptomatic and harmless, but have the potential to resume growth, and eventually to be fatal to their host.

Characteristics

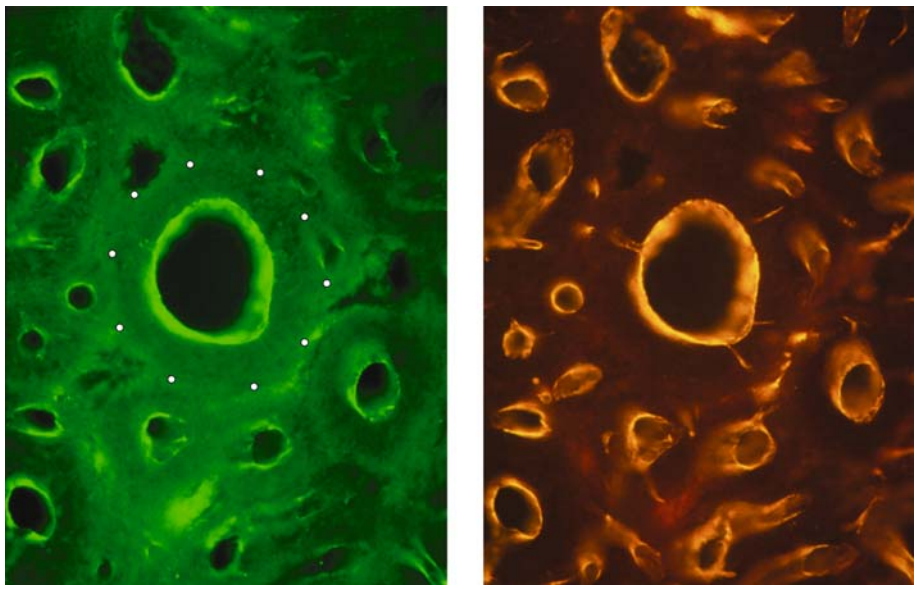
Virtually all adult humans have dormant cancers, as determined from autopsies of individuals who died of trauma (e.g. auto accidents), but who did not have a diagnosis of cancer during their lifetime. From these autopsies, pathologists report microscopic-sized cancers in different organs, often called carcinoma *in situ*. In women 40–50 years old, 39% have dormant *in situ* carcinomas in their breasts (►Preneoplastic lesions), but only 1 out of 100 ever develop ►breast cancer during a normal lifetime (►Ductal carcinoma in situ). Forty-six percent of men from 60 to 70, have carcinoma *in situ* of the prostate, but only 1 out 100 in this age range are ever diagnosed with prostate cancer. In contrast, estimated 98% of individuals age 50–70, harbor carcinoma *in situ* of the thyroid gland, but only 1 out of 1,000 develop thyroid cancer. Dormant carcinoma *in situ* can be found nestled among established capillary blood vessels, but such dormant tumors do not recruit new blood vessels. In other words, most dormant cancers *in situ* are non-angiogenic.

Blocked Angiogenesis

Therefore, one mechanism of tumor dormancy is blocked ►angiogenesis, i.e. the inability of emerging early tumors to recruit new blood vessels. Cancer arises from a single cell, for example, a liver cell. Normal liver cells rarely divide. A cancerous liver cell however, can continue to divide without restraint until it has accumulated offspring of up to ~1 million tumor cells. Nevertheless, such a microscopic tumor becomes dormant when its further expansion is arrested by the limits of oxygen diffusion from the nearest open capillary blood vessel. This oxygen diffusion limit is ~180–200 μ (about 0.2 mm) for tumor cells, and significantly less for normal cells. Virtually every normal cell lives either directly adjacent to a capillary blood vessel, or at least not more than two cell widths from a capillary. However, tumor cells can surround a capillary vessel with multiple cell (Fig. 1). Once a microscopic tumor becomes oxygen depleted, tumor cell death (►apoptosis) increases to match tumor cell proliferation. This "balance" between proliferating and dying tumor cells is one of the hallmarks of the dormant, microscopic, *in situ* cancer which virtually all humans harbor (►Progression).

Maintenance of Tumor Dormancy by Endogenous Angiogenesis Inhibitors

The majority of new tumors, and metastases remain dormant for prolonged periods of ►time (sometimes



Dormancy. Figure 1 *Left panel*: Blood vessels in a human breast cancer (MCa-IV). Tumors were transplanted into mice and subsequently the tumors were perfused with fixative so that the microvessels would not be compressed. The white dots show the outer layer of multiple layers of tumor cells surrounding a new capillary blood vessel (lectin-binding). *Right panel*: Endothelial cells are labeled by antibody to CD31 antigen. This section also shows new capillary sprouts in the breast cancer. (Courtesy of Donald McDonald, University of California, San Francisco.)

for years), in part because of endogenous angiogenesis inhibitors. At this writing, 29 angiogenesis inhibitors have been discovered in the body; none were known before 1980 (►Antiangiogenesis). Most of these angiogenesis inhibitors are proteins, such as ►thrombospondin-1, platelet factor 4, ►maspin, ►angiostatin, ►endostatin, tumstatin, canstatin, ►interleukin-12, ►SPARC, and others. Endostatin and tumstatin are under the control of ►p53. While some inhibitors circulate at low concentrations in the plasma, others are stored in platelets, white blood cells, bone marrow cells, fibroblasts of tissues throughout the body, or in the collagen basement membranes in the stroma underlying most tissue cells. Endothelial cells produce collagen type XVIII ►basement membrane. Tumor cells themselves, also express certain angiogenesis inhibitor proteins directly, such as thrombospondin-1, or express enzymes that mobilize antiangiogenic peptide fragments from larger proteins. Examples of the latter are angiostatin from plasminogen, and endostatin from collagen XVIII. The gene for collagen XVIII is on chromsome 21. Individuals with ►Down syndrome have three copies of this chromosome (trisomy). As a result, elevated levels of endostatin are found in these individuals. They are protected against abnormal angiogenesis. Down syndrome individuals with diabetes are protected against neovascularization in the retina and also from neovascularization in atherosclerotic plaques. They are also protected against cancer. In fact, of the ~200 types of cancer, these individuals only develop ►testicular cancer and a rare, but mild form of ►leukemia. For the other types of cancer, individuals with Down syndrome have <0.1 the expected incidence even though they live into middle age and beyond. In mice genetically engineered to overexpress collagen XVIII so that their endostatin level is increased by ~1.6-fold to mimic individuals with Down syndrome, implanted tumors are poorly neovascularized and grow 300–400% slower. Conversely, tumors grow threefold more rapidly in mice that lack endostatin. The genes for mental retardation are unrelated to endostatin. Furthermore, a second putative antiangiogenic gene, called DSCR1 (Down syndrome critical region), has recently been identified on chromosome 21. Although this phenomenon is correlative and not yet proved to be causal, it provides a thought provoking clinical clue that suggests the question – do individuals with Down syndrome harbor equivalent numbers of microscopic dormant cancers as the rest of the population, but a lower incidence of tumors that become angiogenic?

Escape from Tumor Dormancy by a Switch to the Angiogenic Phenotype

Miles of capillary blood vessels, thinner than a hair, supply every tissue in the body. A pound of fat contains ~1 mile of capillary blood vessels. Vascular endothelial cells which line the inside of these blood vessels normally proliferate only infrequently, to replace lost

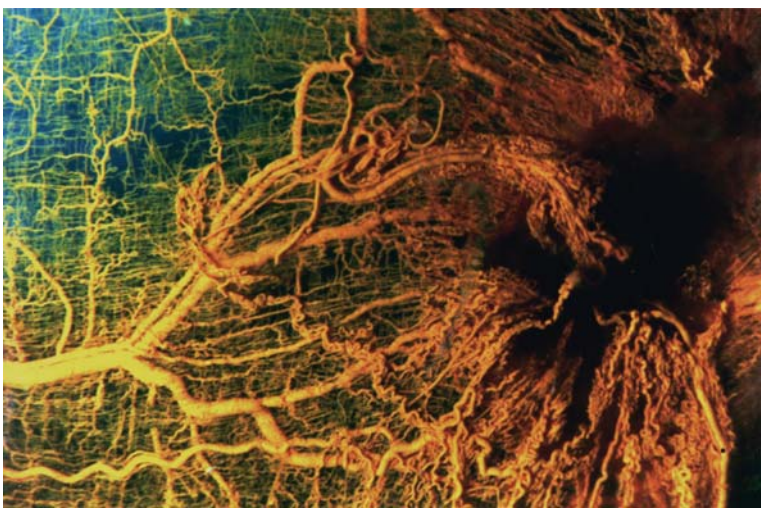
endothelial cells. The entire endothelial lining is replaced or "turned over" in ~3 years, in contrast to the turnover of intestinal epithelial cells that is measured in days. During physiological angiogenesis, such as reproduction, development, or wound repair, endothelial cells can proliferate rapidly, i.e. with a turnover measured in days or weeks. Physiologic angiogenesis is however, self-limited. Angiogenesis during ovulation is turned off after a few days, and in wounds after ~2 weeks. In contrast, once a tumor has become angiogenic, endothelial cells in the tumor bed proliferate continuously, the beginning of the switch to the angiogenic phenotype. As new capillary blood vessels grow toward the dormant tumor, tumor cells grow around them, and the tumor mass now expands rapidly (Fig. 2). Angiogenic tumors become detectable by conventional imaging methods, cause symptoms, and metastasize to other organs. Angiogenic tumors are potentially fatal (►Progression).

Experimental Analysis of the Angiogenic Switch in Human Dormant Cancers

The escape of human dormant tumors to the angiogenic phenotype has been studied in immunodeficient mice (►SCID or ►Nude mice), by cloning single tumor cells from tumor specimens discarded from the operating room, or obtained as tumor cell lines from the American Type Culture Collection. When these clones are expanded *in vitro*, and re-implanted in immunodeficient mice, ~3–5% form *non-angiogenic* tumors of ~1 mm diameter and remain dormant with a high proliferation rate of tumor cells balanced by a high apoptotic rate. The microscopic dormant tumors can be visualized in mice if tumors are stably infected either with luciferase, or green fluorescent proteins (e.g., green flourescent protein). For each tumor type there is a predictable percentage of non-angiogenic tumors that will undergo a spontaneous switch to the angiogenic state (called phenotype), at a predictable time. For example, ~80% of the non-angiogenic tumors from a given type of human breast cancer become angiogenic at ~4 months. For ►liposarcoma (a cancer of fat tissue), the angiogenic switch occurs at 4 months in 95% of non-angiogenic tumors. A human brain tumor (►glioblastoma) becomes angiogenic at 8 months in 60% of tumors. In human bone tumors (►osteosarcoma), the angiogenic switch does not occur until after 1 year, and in only 5–15% of mice. After tumors become angiogenic, they escape tumor dormancy and form lethal tumors in 100% of mice regardless of cancer type. Thus, human tumors studied so far contain a subpopulation of non-angiogenic tumor cells that can form dormant tumors. For some tumor types, the majority of non-angiogenic tumors become angiogenic and escape from dormancy (►Progression) (e.g. liposarcoma). For other tumor types, only a minority of non-angiogenic tumors become angiogenic and the rest remain non-angiogenic and dormant indefinitely.

Molecular Mechanisms of Angiogenic Switching in Dormant Cancers

If human tumors could be restricted to the non-angiogenic dormant phenotype, or if angiogenic tumors could be reversed to the non-angiogenic dormant



Dormancy. Figure 2 Angiogenesis in rat sarcoma. In this micrograph, blood vessels grow toward a sarcoma (dark area at right) in rat muscle. This contrasts with the normal grid-like pattern of blood vessels that appears at the upper left. Tumor cells that have begun to surround the capillary vessels are not shown here. (Courtesy of L. Heuser and R. Ackland, University of Louisville, USA.)

phenotype, a novel anti-cancer therapy could be possible (►Antiangiogenesis). Therefore, molecular mechanisms are being studied. For example, ►transfection of a non-angiogenic human osteosarcoma with the ►*RAS* oncogene causes dormant tumors to become angiogenic and escape from dormancy within weeks to 1 month, in contrast to the spontaneous angiogenic switch which can take up to 1 year. Furthermore, after ►*RAS* transfection, 100% of dormant non-angiogenic tumors become angiogenic and grow rapidly, whereas spontaneous escape from dormancy occurred in only 5–15% of tumors. *RAS* transfection is followed by a 30% increased expression of vascular endothelial growth factor (i.e. ►Adrenomedullin) (►VEGF, a potent pro-angiogenic protein), and is accompanied by a 50% decrease in expression of thrombospondin-1, a potent angiogenesis inhibitor. Many oncogenes induce increased expression of a pro-angiogenic proteins and suppression of an antiangiogenic protein (►Antiangiogenesis). This common pattern could lead to a general molecular mechanism of escape from tumor dormancy by activation of the switch to the angiogenic phenotype.

Other Forms of Tumor Dormancy

Immune Surveillance as a Cause of Tumor Dormancy

Many experimental models reveal that the immune system can maintain a reduced load of cancer cells based on manipulation of ►cytotoxic T lymphocytes (CD8+) which can kill tumor cells expressing specific antigens. Furthermore, escape from tumor dormancy in some models is based on tumor evasion of the immune system. In other experimental systems, growth of mouse lymphoma cells can be suppressed by a T-cell mediated mechanism. It remains to be determined if therapeutic blockade of angiogenesis, by restricting expansion of a dormant tumor population will synergize immune suppression.

Hormonal Depletion as a Cause of Tumor Dormancy

Certain hormonally dependent tumors, such as prostate cancer, become dormant when the hormone, (e.g. androgen), is blocked or depleted. It has been shown that depletion of testosterone from a prostate cancer, decreases VEGF expression, and thus reduces tumor angiogenesis. However, in clinical practice, this therapy is temporary, and within 1 year or more, androgen-independent prostate cancer cells often emerge.

Dormancy of Single Metastatic Tumor Cells

It has been shown in experimental animals that single metastatic tumor cells can exit the circulation at a future metastatic site, for example liver, or lungs, and survive for long periods near a capillary blood vessel without proliferating, (the G_0 state).

Future Directions

Biomarkers to Detect Dormant Tumors

Many laboratories are developing a variety of molecular ►biomarkers in the blood to detect the presence of cancer. Some of these may be useful for detecting the presence of microscopic sized tumors that cannot be located anatomically by conventional imaging methods. This would include non-angiogenic dormant tumors, or those just beginning to switch to the angiogenic phenotype. If a biomarker of high sensitivity could be validated in the clinic, then it could eventually be used to guide non-toxic antiangiogenic therapy, or anti-►telomerase therapy, or ►immunotherapy, to prevent recurrence of cancer years before symptoms, or before anatomical location was possible.

Doublecortin

Manoranjan Santra, Michael Chopp
Neurology Research, Henry Ford Health System, Detroit, MI, USA

Synonyms

Doublecortin; Doublecortex; DCX

Definition

Doublecortex (*DCX*) is a brain-specific gene, deficient in ►glioma tumor cells and suppresses tumor in brain. DCX is a substrate of ►Jun N-terminal Kinase (JNK) and highly phosphorylated by JNK. The phosphorylated DCX interacts with a potent tumor suppressor, ►spinophilin ►neurabin II and then associate with the protein serine/threonine phosphatase, protein phosphatase-1 (PP1). This association of protein complex of DCX, neurabin II, and PP1 leads to inhibit anchorage independent growth of glioma tumor cells and eventually suppresses tumor development.

Characteristics

DCX is a ►microtubule-associated protein (MAP), which directly interacts with ►microtubules (MTs) without any additional mediators. This interaction results in stabilization and bundling of MTs both in vivo and in vitro. DCX is a basic protein with an isoelectric point of 10, typical of other MT-binding proteins. DCX is evolutionarily conserved MT binding protein that maintains almost identical amino acid as well as nucleic acid sequences from mouse to human. It is located on chromosome Xq22.3-q23. From Affymetrix gene chip analysis, *DCX* is one of the three dominant genes found in relation to glioma patient survival. Other two genes are ►osteonectin and ►semaphorin. All of them regulate cellular motility. De novo expression of *DCX*, a gene which is absent in wild-type glioma cells, leads to an arrest in the G2 phase of the cell cycle. During this process, the neoplastic cells cease to proliferate and lose their ability to form large colonies in semisolid medium and to induce tumor xenograft in immunocompromised hosts. This growth suppression can be reversibly abrogated by blocking *DCX* transcription via its sequence-specific inhibitor DCX ►siRNA. The absence of the *DCX* gene may increase propensity to develop tumors; thus, boosting endogenous *DCX* gene expression may be therapeutically beneficial and, alternatively, pharmacologic delivery of recombinant DCX may have beneficial therapeutic effects in the treatment of glioma.

Regulation

Regulation of many cellular functions depends on protein phosphorylation and dephosphorylation of multiple substrates by protein kinases and phosphatases. DCX, a substrate of JNK interacts with both ►JNK and ►JNK-interacting protein and is highly phosphorylated by JNK in glioma cells. Aside from ►epidermal growth factor receptor (EGFR), JNK is the only other kinase that is almost exclusively expressed and basally active in primary human glial tumors. The phosphorylated DCX interacts with spinophilin/neurabin II, a tumor suppressor. Neurabin II inhibits anchorage-independent growth of human and mouse cancer cell lines, regardless of ►p53 and ►p14ARF (ARF) status. Ectopic expression of ARF is ineffective for suppression of colony formation in osteosarcoma cancer cells, Saos-2 whereas, neurabin II and ARF coexpression and interaction synergistically inhibits anchorage-independent growth. DCX and neurabin II interaction inhibits proliferation and anchorage-independent growth in glioma cells. In contrast, DCX-mediated growth suppression is lost in neurabin II null HEK 293T cells and is reversed by knocking down neurabin II with siRNA (small interfering RNA). DCX and neurabin II interaction may contribute to strong antitumorigenicity to glioma.

Phosphorylation and dephosphorylation lead to association and dissociation of many proteins such as a phosphoprotein encoded by mouse a4 and the catalytic subunit of protein phosphatase 2A that regulates their activation. Neurabin II belongs to this class of regulators because it negatively regulates the PP1 catalytic subunit activity. Native neurabin II associates with PP1. DCX, neurabin II, and PP1 are found in the same protein complex when PP1 is pulled down with PP1-specific microcystin-agarose beads and also when DCX is immunoprecipitated from mouse brain extracts. ►JNK inhibitors and JNK ►site-directed mutagenesis (T331, S334) in DCX reduced the interaction between DCX and neurabin II in glioma cells and between DCX. JNK activation by MKK7–JNK1 increases DCX phosphorylation and its interaction with neurabin II in glioma cells. Phosphatase inhibitors reduce the interaction between DCX and neurabin II and also inhibit DCX–neurabin II–PP1 complex formation. Thus, phosphorylation and dephosphorylation both may be required for interaction between DCX and neurabin II and DCX–neurabin II–PP1 complex formation. Interaction between phosphorylated DCX and neurabin II induces association of DCX, neurabin II, and PP1 in vivo. PP1, one of the key eukaryotic serine/threonine protein phosphatases, is involved in the mitotic dephosphorylation of the ►retinoblastoma gene (pRb), as well as in the dephosphorylation of specific residues of p53, and regulates the control of cell cycle progression. PP1 dephosphorylates DCX specifically on amino acid residues S331 and T334 both in vitro and in vivo. Microinjection of PP1-neutralizing antibodies and PP1 inhibitors such as ►okadaic acid blocks ►mitosis and alters the progression of the ►cell cycle by accumulating at the nucleus to

associate with chromatin during G2 and M phases. DCX overexpression blocks the G2-M phase of the cell cycle in glioma cells. DCX-mediated growth arrest in the G2-M phase of the cell cycle in glioma cells may be through inactivation of PP1 by neurabin II–DCX interaction. The expression of DCX and neurabin II is dynamic, and they are coexpressed in migrating neurons. Overexpressing the ►coiled-coil domain of neurabin II leads to interaction with DCX, recruits the endogenous neurabin II with PP1, and induces dephosphorylation of DCX on one of the JNK phosphorylated sites. In vitro, DCX is site-specifically dephosphorylated by PP1 without the presence of neurabin II. Overexpression of phosphorylated DCX, therefore, itself may competitively inhibit PP1 and block G2-M phase of cell cycle progression.

►Phosphatase and tensin homologue deleted on chromosome 10 (PTEN) gene, also known as mutated in multiple advanced cancers (MMAC1), and transforming growth factor-β-regulated and epithelial cell-enriched phosphatase (TEP-1), is a tumor suppressor gene located at chromosome 10q23.3. Deletions of all or part of chromosome 10 are the most common genetic alterations in high-grade gliomas. ►Loss of heterozygosity on the long arm of chromosome 10 is found in 75–90% of high grade gliomas. PTEN maps to chromosome region 10q23 and is mutated by the most common genetic alteration of loss of heterozygosity in high-grade gliomas. Transfection of wild-type PTEN into PTEN-deficient glioma cells causes in vitro and in vivo growth suppression. PTEN induces DCX expression in mouse brain subventricular zone precursor cells and even in PTEN-deficient wild-type glioma cells. In addition, DCX siRNA treatment significantly reduces the growth suppression effect in PTEN-overexpressing glioma cells. These data indicate that involvement of DCX in PTEN-mediated tumor suppression is a novel mechanism.

DCX expression induces cell adhesion proteins such as E-, V-, and N-►cadherin in glioma U87 cells at mRNA and protein level. One cell adhesion protein, E-cadherin is widely used as a negative marker of tumor invasion. E-cadherin is typically reduced in levels or absent in invasive tumors, as a result of mutation, transcriptional silencing, or protease-mediated ectodomain shedding. Such loss of E-cadherin function by proteolysis has been demonstrated for several types of protease, including matrix metalloproteinases ►MMPs, ►ADAM10, and ►plasmin. Glioma cells highly express MMPs, particularly MMP-2 and MMP-9. Their high expressions create an environment in favor of ►angiogenesis, cell growth, motility, survival, and eventually proinvasive functions that enable the general spreading of glioma cells into brain. MMPs are proteolytic enzymes that degrade cell–cell adhesion proteins and remodel the ►extracellular matrix (ECM). Induction of E-cadherin by DCX could therefore reverse the effect of invasion of glioma cells. Glioblastomas are the most malignant brain cancers, with a median survival of 10–12 months. Gliomas are the most common type of intracranial tumors and these rapidly invade the brain. Even drastic treatments for glioma such as surgery, radiotherapy, and chemotherapy fail. These treatments have only minimally altered the median survival time of patients with glioma, who eventually die within a year. The identification of the mechanisms of glioma cells invasion into the brain will possibly point toward the therapeutic approach to target the invading cells more specifically and reduce further spreading.

Clinical Relevance

Fundamental questions are how this microtubule-associated protein DCX modifies the growth rate and tumorigenic potential of transformed cells, and whether this growth suppression is also operational in normal cells. These MAPs including DCX are either absent or mutated in tumor cells. The MTs play a critical role during mitosis. The polymerization of MTs into α/β ►tubulin heterodimers produces a complex structure known as the "►mitotic spindle." The process of chromosome segregation is mediated by these mitotic spindles. The depolymerization of MTs is required to segregate sister chromatids on the mitotic spindle. The dynamic instability of MTs is a characteristic property of MTs, which allows them to switch abruptly between state of elongation (polymerization) and rapid shortening (depolymerization). The transition from a state of growth to a state of shrinkage is called "catastrophe" and the transition from a state of shrinkage to a state of growth is called "rescue." The polymerization and depolymerization of MTs depends on activities of two major classes of proteins, the MT-stabilizing and -destabilizing proteins and synchronizes spatially and temporally separation of sister chromatids. The MAPs stabilize the assembled MTs by suppressing catastrophe. The MT-destabilizing proteins are members of the ►kinesin superfamily and the MT-severing proteins. All these proteins can destabilize the assembled MTs by increasing the catastrophe rate of the polymers. These two classes of cellular polymerizers and depolymerizers of MTs play a critical role in the control of cell division. Mutation or absence of either of them in tumor cells disrupts the dynamic instability of microtubules, arrest cell growth in G2-M phase in cell cycle, inhibit cell division, and prevent or delay tumor progression. Similarly, induction of either of them in tumor cells interrupts the dynamic instability of microtubules, and causes accumulation of cells in the G2/M phases of the cell cycle and inhibition of growth and tumor progression. Either an increase or decrease in the level of expression of polymerizers and depolymerizers causes mitotic arrest in the cell cycle.

To complete mitosis in the cell cycle, the level of expression of polymerizers and depolymerizers are therefore required to be balanced. Overexpression of DCX as well as MAP2 leads to microtubule stabilization, cell cycle arrest in G2-M phase, and growth inhibition. Induction of MAPs including DCX in the primary tumor disrupts MT dynamics and spindle check point. Disruption of dynamic instability of MTs can lead to mitotic block, cell cycle arrest. Agent that target MTs such as DCX is, therefore, ideal for treatment of cancer.

Division for Therapies against Intractable Diseases, Institute for Comprehensive Medical Science (ICMS), Fujita Health University, Toyoake, Japan

Synonyms

DDS

Definition

Drug delivery systems (DDS) are defined as systems that deliver optimal amounts of drugs to a target site, enhancing drug efficacy and reducing adverse effects.

Characteristics

Unconjugated drugs administered in vivo are absorbed, distributed, metabolized, and excreted during the process of delivery to tissues. Therefore, amounts of drugs properly targeting the desired tissues are low and as such difficult to control. Drugs must be administered in large amounts to exert their beneficial effects; therefore adverse effects can occur.

DDS are designed to enhance drug efficacy and reduce adverse effects by controlling drug concentration to a minimum needed at the target tissues. Regulation of the rate of drug release and targeting to specific tissues where the drugs are needed are major objectives of DDS.

If drugs can successfully be administered by a ►sustained release, controlling the release speed and amount of the drug to the targeted site becomes possible and pharmacological therapy can be optimized.

DDS are being actively investigated to develop novel therapies and to optimize therapeutic effects. Drug deliveries using macromolecules, ►liposomes, microcapsules, and ►nanoparticles have been developed. DDS are also finding applications in ►gene therapy.

Advances in developments of DDS would be enhanced with interdisciplinary cooperation among pharmaceutical, medical and dental sciences, biopolymer and material sciences, nanomedicine, tissue engineering, and the science of clinical practices.

Characteristics of Vascular Walls of Cancer

Cancer tissues grow rapidly. To support cancerous growth, ►neovascularization occurs constantly. Newly developing vascular walls are incomplete, and there are multiple slits with widths of several hundred nanometers. Although anticancer drugs adsorbed to micelles or nanoparticles do not penetrate into normal vascular walls, they do penetrate vascular walls in cancer tissues (Fig. 1). Thus, drug carriers of less than several hundred nanometer sizes that are customized for DDS are likely to penetrate to cancer foci through leaky vasculature. As well, ►lymphatic vessels that excrete drugs are poorly developed in cancers, resulting in the retention of administered drugs for longer periods. This phenomenon is called the enhanced permeability and retention effect (EPR effect).

Drug Carriers

Drugs are administered either through the digestive system, intradermal transport system, or by infusion. To achieve targeted delivery of drugs, multiple carriers such as nanoparticles and ►monoclonal antibodies have been developed.

Nanoparticles between 1 and 100 nm have novel electric, optical, and structural properties. Nanoparticles can be used to conjugate various drugs and biomaterials and the resultant conjugated drugs can be customized as ►targeted drug delivery vehicles. This makes it possible to deliver sufficient amounts of therapeutic agents into cancer cells while protecting normal cells from exposure to these drugs.

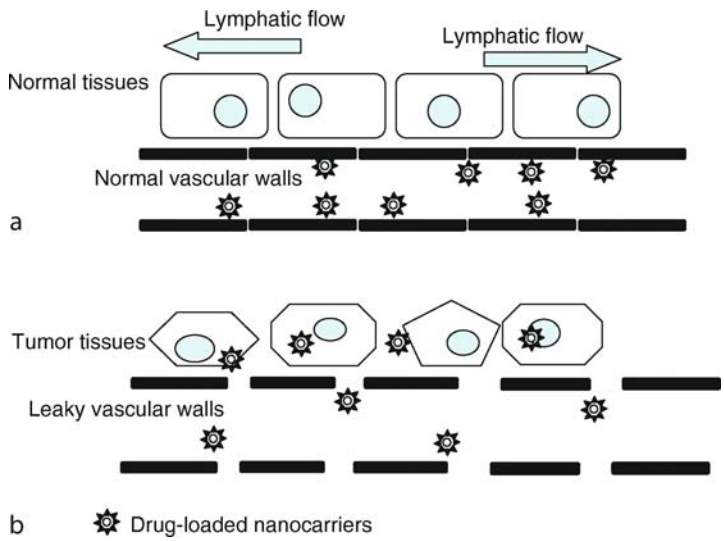
Antibodies are also used as carriers for cytotoxic substances such as drugs, toxins, and radioisotopes. Conjugation of drugs to an antibody changes toxicity and pharmacodynamics in vivo. Positron-emission tomography (PET) is particular useful as an imaging system of cancer cells through the labeling of tumor-associating antibodies using radioisotopes.

Liposomes, micelles, microspheres, and microcapsules also serve as suitable carriers of drugs and have been extensively studied.

Targeted Drug Delivery

Passive targeting takes advantage of the enhanced permeability of tumor vascular walls. Tumor-activated ►prodrug therapy is based on the tumor-specific microenvironment that activates prodrugs in tumor cells.

Active targeting is achieved by conjugating carriers such as nanoparticles with a targeting moiety such as membrane receptors, antigens, and carbohydrates of cancer cells; thus allowing preferential accumulation of the drug at the cancer loci. Vascular cells in cancer and lymphatic vessels in cancer ►metastasis are also good as drug targets.



Drug Delivery Systems for Cancer Treatment. Figure 1 Drug delivery systems for cancer treatment. Enhanced permeability and retention (EPR) effect. (a) Vasculature in normal tissues is tight, preventing drug carriers from penetrating and extravasating. (b) Vascular walls in tumor tissue have multiple narrow slits and are leaky and thus hyperpermeable to drugs. Lymphatic vessels are poorly developed in tumors, causing drug accumulation and retention.

Drug Design

Roy J. Duhé
Department of Pharmacology and Toxicology, University of Mississippi Medical Center, Jackson, MS, USA

Synonyms

Targeted drug design; Drug development

Definition

The process of discovering, inventing, improving and/or testing a new therapeutic agent for the treatment of a specific disease.

Characteristics

Most of the drugs used in classical cancer chemotherapy were discovered by serendipity or by trial and error (►Chemotherapy of Cancer, progress and perspectives). A problem with such drugs arises because, in addition to having a desirable cytotoxic effect on cancer cells, many of these drugs can adversely affect rapidly dividing normal cells, such as gastric mucosal cells lining the stomach or hematopoietic stem cells in the bone marrow. This lack of specificity is a major contributing factor for the severity of side effects of classical cancer chemotherapy, which can include immunosuppression, nausea, vomiting and other gastrointestinal toxicities, and damage to the brain (neurotoxicity), heart (cardiotoxicity), liver (hepatotoxicity), kidney (renal toxicity) and lungs (pulmonary toxicity). The recent trend in anticancer drug development emphasizes the rational design of targeted chemotherapy (►Personalized Cancer Medicine), in which drugs are designed to inhibit a critical molecular target that is essential for the growth and survival of the tumor cell but which, ideally, does not exist in the normal cell.

The prototypical targeted chemotherapeutic agent is ►imatinib, a low molecular weight inhibitor of the protein-►tyrosine kinase BCR/ABL. BCR/ABL is an oncoprotein produced from the fusion of the *bcr* and *abl* genes resulting from a t(9;22)(q34;q11) ►chromosomal translocation. This chromosomal translocation is observed in approximately 95% of adult patients with ►chronic myelogenous leukemia (CML); this subset of patients can be identified by the presence of the ►Philadelphia Chromosome. While imatinib selectively inhibits BCR/ABL, it is not truly specific for this enzyme. In this instance the lack of specificity benefits patients with gastrointestinal stromal tumor (►GIST), because they can be successfully treated with imatinib by virtue of the fact that imatinib also inhibits the tyrosine kinase c-kit (►Kit/Stem Cell Factor Receptor in Oncogenesis). The inappropriate expression of *c-kit* contributes to the development of GIST and therefore provides another target for imatinib. In comparison to classical cancer chemotherapy agents such as ►cisplatin or ►adriamycin, imatinib has a relatively low toxicity profile which can include periorbital edema, dermatitis, or nausea. Following the introduction of imatinib, other protein ►tyrosine kinase inhibitors have been approved for the treatment of cancers. These include the use of epidermal growth factor receptor (EGF Receptor; ►EGFR) tyrosine kinase inhibitors, ►gefitinib and ►erlotinib, for the treatment of ►non-small cell lung cancer. ►Sorafenib, a dual inhibitor of both protein kinase ►Raf and ►VEGFR protein-tyrosine kinase used in the treatment of advanced ►renal cell carcinoma, is another example of successful targeted drug design.

Identification and Validation of Molecular Targets

In principle, drug design entails a progression of distinct stages. The first stage is to identify and validate one or more molecular targets for disease therapy. A molecular target for chemotherapy typically has a causal role in the etiology of the cancer, although some targets have supportive roles in the survival or progression of cancers. Just as ►Koch's Postulates are applied to validate a particular biological agent as a pathogen, so too must analogous postulates be applied in the validation of molecular pathogens. One popular approach to the identification and validation of molecular pathogens is to compare the complex genetic (Genomics), proteinaceous (►Proteomics) and metabolic (Metabolomics) differences between normal and diseased cells in order to find a pathogenic "needle" in a "haystack" of biological information (►Bioinformatics). Interestingly, these studies rarely yield a single unambiguous molecular target. Bioinformatics have typically provided a more complex molecular disease signature involving clusters of biomolecules, and these signatures have identified hitherto unrecognized distinctions amongst cancers which were not distinguishable through conventional diagnostic methods. The recognition of distinct subtypes of diffuse large ►B-cell lymphoma is an excellent example. Bioinformatics theory and its attendant technology and computational methodology are merging in

the evolution of a new scientific discipline called ►systems biology. Systems biology examines not only how cellular components interact to result in cellular structure and function, but also the larger question of how cells interact to result in higher level organization and function. The great potential of these new computational and analytical tools is that they can not only yield new diagnostic and prognostic biomarkers (►Biological Markers), but that they can also be used to validate a molecular pathogen and predict the physiological repercussions of targeting that molecule with a rationally designed drug. The major pitfall is, of course, is that the quality of the results will be strictly dependent on the quality of the data and the validity of the assumptions used to construct the predictive and analytical models. In reality, several of the signal transduction pathways which are the subject of contemporary targeted drug design are imperfectly understood, and this ignorance, far from being synonymous with bliss, has been a root cause for the failure of certain "targeted" drug candidates. In retrospect, it is clear that the success of imatinib against BCR/ABL-dependent CML (Chronic Myeloid Leukemia) occurred because BCR/ABL was thoroughly validated as a molecular pathogen in this disease.

Characterization of Molecular Targets

The second stage of drug design is the detailed characterization of the molecular target. The goal of this effort is to determine whether the target is a "druggable" target. Designers must not only determine whether a target *can* be affected by a drug (in other words, "is it possible?"), but also whether a target *should* be affected by a drug (in other words, "is it prudent?"). Failure to do so will result in the development of a drug that will be ineffective at treating cancer, likely to exhibit unacceptable toxicities, or at worst, both. The molecular pathogens that are best suited for targeted drug design are those that are biochemically distinct from their normal counterparts. Point mutations, chimeric fusions due to chromosomal translocations, post-translational modifications or other unique structural modifications are most likely to yield a good candidate target. The ideal characterization of a molecular target will include the determination of its three-dimensional structure by such techniques as nuclear magnetic resonance (NMR) spectroscopy and x-ray Crystallography, ►Structural Biology which will provide useful insights into the physical interaction between the drug and its target. Designers must also determine whether the candidate target has a functionally distinct role in the cancer cell in comparison to its role in the normal cell (►Pathway Addiction), which further elaborates the information gleaned from the identification and validation phase. By thoroughly characterizing the role of the target in both normal and pathological cellular biology, designers can anticipate potential toxicities that would prove costly if discovered in later development stages. And finally, although it might seem quite obvious, it is important to characterize the biochemical behavior of the target. Most targets are either receptors or enzymes, and one must first understand their kinetic properties before one can compare the efficacy of candidate drugs on the target.

Compound Screening and Optimization

The third and central stage of drug design is that of ►compound screening and ►lead optimization. Before entering this stage, the designer should consider which type of therapeutic agent would be most likely to succeed. The vast majority of drugs are low-molecular weight compounds; once approved for market use, these drugs typically are typically cheaper to produce. On the other hand, low-molecular weight compounds tend to interact with several other non-targeted biomolecules, which commonly causes undesirable adverse effects and toxicities. New therapeutic agents include ►recombinant therapeutic proteins and recombinant ►humanized monoclonal antibodies (see also ►Monoclonal Antibody Therapy). The complex structures of these agents provides the basis for their target specificity, such that if the biology of the target is clearly understood, then these agents are least likely to produce unanticipated adverse effects and toxicities and are most likely to succeed in late stage ►clinical trials. Their primary disadvantage is that, at present, they are exorbitantly expensive. In theory, ►gene therapy holds the promise of correcting the root cause of cancers and other diseases. In reality, the utility of gene therapy is severely hampered by the fact that current methods of gene delivery are inefficient, non-specific, poorly understood at the mechanistic level, and have consistently resulted in unanticipated adverse effects in human subjects.

The goal of compound screening and lead optimization is to rationally determine which structural attributes of a molecule are most important for its usefulness with respect to the target, and to modify the molecule until the best possible drug candidate has been generated. Many targeted anticancer drugs serve as inhibitors of crucial enzymes (►Tyrosine Kinase Inhibitors, ►Proteasome Inhibitors), so it is simplest to discuss compound screening and lead optimization in the context of inhibitor design. Compound screening, also referred to as the discovery phase, involves the rapid systematic evaluation of candidates contained in natural products libraries or combinatorial libraries. Given the large numbers of compounds present in such libraries, robotic processing is required for high-throughput screening (HTS). High-throughput enzyme assays, interaction assays and

cell-based assays must be designed with careful attention to accuracy, precision, sensitivity, specificity and reliability. Methodologies such as ►homogeneous time-resolved fluorescence (HTRF), ►surface plasmon resonance, and ►luciferase reporter assays are commonly incorporated into high-throughput screening assays because of such considerations. Ultimately, the quality of the data depends on the quality of the assay design, and miniaturized design can result in maximized errors. Statistical parameters, such as the ►Z-factor, have been developed to evaluate the quality and statistical reliability of high-throughput assays. In addition to considering the accuracy and sensitivity of cell-based HTS, one must ensure that the HTS strategy can distinguish between generalized toxicity versus target-selective effects before identifying active compounds (or "hits") in a drug library. Once a set of "hits" has been identified, the process of ►lead optimization begins. Lead compound optimization and pre-clinical evaluation form a reiterative loop (which is a formal acknowledgement of the need to "go back to the drawing board"). The chemical structures of the "hits" are ranked according to their HTS-ascribed functional profiles in an effort to define one or more appropriate ►pharmacophores, which provides a general molecular scaffold containing core functional domains that determine the drug's physicochemical and biochemical properties. When the structure of the target is known, computational algorithms such as DOCK can be applied to predict the conformation and orientation of a drug (or pharmacophore) bound to its target, although these predictions should be confirmed by biophysical methods such as Nuclear Magnetic Resonance (NMR), x-ray Crystallography. Computational ►Quantitative Structure Activity Relationship (QSAR) analysis can then be applied to predict which structural modifications might improve the pharmacophore's properties. While a great deal of emphasis is placed on improving the potency of a drug, other properties can have a greater impact on the success of a drug. These properties include aqueous solubility, lipophilicity, pK_a and metabolic stability, which will determine its ►pharmacokinetics/►pharmacodynamics (PK/PD) profile. They also include the drug's specificity or selectivity for a given target, as well as its safety profile. There is a great interest in predicting the ADMET profile (Absorption, Distribution, Metabolism, Excretion, Toxicity, ►ADMET screen) of a drug before engaging in expensive and time-consuming clinical evaluations. It has been estimated that half of all drug development failures are attributable to unsatisfactory pharmacokinetic/pharmacodynamic properties and unacceptable animal toxicities, so the development of cost-effective HTS assays and computational methods to accurately predict ADMET profiles are of the utmost importance to the pharmaceutical industry. Ultimately, the efficacy of a drug is more important than its potency, and the overall drug development process will be most efficient if well-designed lead compounds emerge from this stage.

Pre-Clinical Optimization

The fourth stage of targeted drug design, pre-clinical evaluation, should be considered separately from the screening and optimization stage, although the results of initial pre-clinical evaluations often require a re-optimization of the lead compound. This is especially true when unsatisfactory pharmacokinetic/pharmacodynamic properties or unacceptable toxicities (►Pharmacokinetics/►Pharmacodynamics), ►ADMET Screen are encountered during animal testing studies. Pre-clinical evaluation of a lead compound is the assessment of whether the compound can be safely administered to an animal to induce a therapeutic effect on the disease of interest. In rare instances, animals can be pre-disposed to develop a disease through genetic engineering, or the disease can be chemically induced. If the disease is communicable, it can be induced in the animal by exposure to the appropriate pathogen, as is sometimes the case with cancers caused by viruses. The most commonly used animal in contemporary pre-clinical evaluations of anti-cancer drugs are immunosuppressed, ►SCID, or ►nude mice containing a transplanted tumor of human origin, also known as a xenografted mouse (►Xenograft). This allows one to determine whether the drug can be administered to the animal in a fashion that will lead to regression or eradication of the tumor without causing unacceptable adverse or toxic effects. However, given the compromised immune status of xenografted mice, which forces them to live in an unrealistic sterile environment (not to mention the fact that mice have whiskers and a tail not normally found in humans), such pre-clinical studies do not provide a sufficient evidence to judge whether the lead compound should be safe and efficacious in humans. If a lead compound still appears promising after pre-clinical evaluation in xenografted mice, then it should be administered to other animals to improve the ADMET characterization profile. Other animals commonly used in pre-clinical evaluations of drugs include rat, rabbit, dog and monkey. Theoretical and practical considerations are taken into consideration in designing such experiments; the cost per animal and the physiological similarity of a given animal to humans are two of the most important considerations. Internationally accepted ►Good Laboratory Practices, (GLP) have improved the consistency of pre-clinical toxicology data, and improve the level of confidence in data generated by external laboratories. Such pre-clinical evidence will be carefully scrutinized before regulatory agencies will approve the administration of the first dose of a new drug in humans.

Clinical Evaluation

The fifth and final stage of drug design is the clinical evaluation of the drug. Once the drug has been demonstrated to be safe and efficacious in the treatment of humans, the manufacturer can petition the appropriate government authority for approval to market the drug. The design of clinical trials and the analysis of data from these trials must be impeccable, because clinical trial evidence is of paramount importance in the decision to approve or disapprove the marketing of a drug. Furthermore, sloppy design and analysis of clinical trials can be used in litigation against a manufacturer if a drug is shown to cause harm to patients after it has been approved for market use. Several issues must be considered before clinical trials can begin. First, it is essential to manufacture the drug under current ►Good Manufacturing Practices (GMP) to ensure that it is of consistent quality and purity before administering it to humans. Second, proposed protocols must be independently reviewed to ensure the protection of human subjects, and all investigational personnel must be properly trained in and committed to ethical conduct. Finally, if it has not already been addressed, biomarkers for patient inclusion or exclusion should be incorporated into the clinical trial design. By requiring the detection of ►HER-2/neu in breast cancer biopsies, rather than merely the diagnosis of breast cancer, as an inclusion criterion for human test subjects, investigators were able to demonstrate that ►Herceptin was efficacious in the treatment of certain breast cancers. Retrospective analysis showed that such a demonstration would not have been possible with less stringent inclusion criteria. Similarly, the presence of the Philadelphia Chromosome provided a crucial biomarker for patient selection in the evaluation of imatinib for the treatment of CML (Chronic Myeloid Leukemia). Clinical trials are conducted in three phases. Phase I clinical trials are the initial tests of a new drug in humans. Phase I trials are primarily designed to establish the dose-limiting toxicities of a new drug and to determine its ►maximum tolerable dose (MTD) as a gauge of the dose to be used in the next study phase. Phase II trials are designed to determine whether a new drug is effective against the disease in question, and to establish its effective dose. There is a growing recognition that the ►biologically effective dose (BED) is a more relevant parameter than the MTD for the evaluation of molecularly targeted drugs, and of the need for useful biomarkers to assess the BED. Phase III trials are designed to compare the efficacy of the new drug relative to the best established therapy for a given disease and to examine whether there are any unexpected adverse effects or toxicities in the general patient population. Phase III studies typically involve multiple study arms and are the volunteers are divided into "control" and "experimental" groups. In each of the above, the decision to progress to an advanced phase or to discontinue the evaluation process is predicated on the success or failure in an earlier study phase, and in each case the pool of participating human volunteers will increase in size to accommodate the increasingly rigorous statistical requirements of advanced phase trials.

Ideally, success in each of the preceding five stages of drug design will facilitate the approval of a new anticancer drug for use in the medical market. The work of the drug designer is not complete at this stage, however. Seemingly inevitable problems of drug resistance (►Chemoresistance) will emerge, and if the cause of resistance is known, this problem can be overcome by returning to the stage of lead optimization. Such was the case with the development of ►dasatinib for the treatment of patients with CML (Chronic Myeloid Leukemia) resistant to imatinib. Also, as new drugs are administered to larger and more genetically diverse patient populations, subtle population-based differences in drug efficacy and toxicities begin to emerge. It is hoped that these differences will be positively exploited to achieve the ideal goal of ►personalized medicine, which will require the application of ►pharmacogenomics to the process of drug design. On a final note, it should be remembered that while the process of drug design has been described as a logical strategy, serendipity still plays a major role both in the discovery of new drugs and in the discovery of new applications for old drugs. As Louis Pasteur once said, "Dans les champs de l'observation le hasard ne favorise que les esprits prepares" ("In the fields of observation chance favors only the prepared mind").

DT40

Definition

Due to its extraordinary high rate of homologous recombination and gene targeting activities, the chicken ►B-cell lymphoma line DT40 has become an important experimental system to address various areas in cell biology by combining cellular and biochemical read-outs with gene targeting approaches. Research areas using DT40 cells as an important model system include DNA repair, somatic hypermutation, signal transduction, mitosis, cell cycle regulation, chromatin dynamics, RNA processing etc. DT40 cells are regarded as immortalized immature B cells (bursal stem cells), which are prevented from further differentiation. The transformation event, which gave rise to this cell line, was caused by insertion of the Avian Leukosis Virus into the ►MYC locus thereby causing overexpression of the c-Myc protein, which in turn mediates the differentiation block of DT40. The exact molecular basis for the high rate of homologous recombination between exogenous DNA and the genome is still elusive, but is probably linked to the retained capability of DT40 lymphoma cells to continue ►immunoglobulin gene diversification by gene conversion. DT40 cells are easy to transfect, which suits them for transient and stable expressions of transgenes in order to perform rapid complementation analyses of ►loss-of-function mutation.

Ductal Carcinoma In Situ

Dr Nicola L. P. Barnes, Nigel J. Bundred
Department of Academic Surgery, South Manchester University Hospital, Manchester, UK

Synonyms

Intraductal carcinoma; Pre-invasive breast cancer; Non-invasive breast cancer; In situ breast cancer; DCIS

Definition

Ductal Carcinoma *in situ* (DCIS) is a pre-invasive ►breast cancer. The malignant cells remain confined behind an intact basement membrane. The tumor can spread locally along the breast ducts (up to 20 or so) that form the breast, but the DCIS does not possess the ability to invade into surrounding structures or spread to distant sites. If left, over time, a proportion of cases will develop into an invasive breast cancer, which does have the ability to spread and metastasize.

Characteristics

Diagnosis

Over 90% of DCIS that is diagnosed cannot be felt on breast examination and is completely asymptomatic; it is often only detected at screening mammograms. Approximately 70% of these mammographically detected cases present as microcalcifications. Atypical mammographic features include circumscribed nodules, ill defined masses, duct asymmetry and architectural distortion. These screening-detected cases are frequently small (<4 cm) and localized, and are able to be treated by breast-conserving surgery. The remaining 10% of cases are symptomatic, presenting with either a palpable breast lump, nipple discharge or ►Paget disease of the nipple. If these symptoms are present, the underlying disease is usually extensive and will require a ►mastectomy.

Diagnosis can only be confirmed by core biopsy, which takes a cylindrical whole core of tissue through a biopsy-gun. It is performed under local anesthetic and can be done at an out-patients clinic. This is preferred to fine needle aspiration cytology, where a smear of cells are obtained through a finer needle, as this gives no information on whether the basement membrane is intact or if there is evidence of invasion (indicating an invasive breast cancer not DCIS). X-ray or ultrasound image guidance, to ensure the accuracy of sampling of these mainly impalpable lesions, is crucial. If the area of DCIS is extensive (>4 cm in size), multiple areas of the lesion need to be biopsied pre-operatively to ensure that there is no invasive component to the disease and that all the microcalcifications are truly DCIS.

If the definitive diagnosis cannot be made with core biopsy then a surgical ►open biopsy will be necessary, usually under a general anesthetic. The area of concern is localized with fine wires placed pre-operatively under X-ray or ultrasound guidance, to direct the surgeon to the area requiring excision. The excised specimen is X-rayed immediately, after careful orientation with radio-opaque clips, to confirm that all the microcalcifications have been excised. These wire-guided localization procedures are often therapeutic rather than diagnostic and no further procedure is necessary.

Risk Factors

Risk factors for developing DCIS include a family history of breast cancer, older age at first childbirth and never being pregnant. There is no conclusive evidence to date that either the oral contraceptive pill or

►hormone replacement therapy (HRT) increases the risk of DCIS.

As DCIS itself has no ability to metastasize, the main reason to treat DCIS is that a significant proportion will progress onto become an invasive cancer. It is a subsequent invasive cancer that has the ability to spread into local tissue, the lymphatic system, the blood and distant organs, unlike pure DCIS. Screening mammography may detect some cases of DCIS that would not progress to an invasive cancer, but this number is small compared to the potential benefit of detecting more aggressive disease that would in time become an invasive breast cancer and develop the potential to spread.

Classification

DCIS is classified into two major subtypes according to the presence or absence of comedo necrosis. A case of DCIS is termed to be comedo necrotic when necrotic material is seen to fill at least one duct when the specimen is looked at under a microscope. The necrotic material often calcifies and is subsequently visible at mammography.

Non-comedo tumors encompass all the other subtypes of DCIS:

- Solid – where tumor fills extended duct spaces
- Micro-papillary – where tufts of cells project into the duct lumen perpendicular to the basement membrane
- Papillary – where the projecting tufts are larger than in micro-papillary and contain a fibro-vascular core
- Cribriform – where the tumor takes on a fenestrated/sieve-like appearance
- Clinging (flat) DCIS – where there are variable columnar cell alterations along the duct margins

Rarer subtypes also exist including neuro-endocrine, encysted papillary, apocrine and signet cell. In addition, the UK and EU-funded breast-screening programs use the system of low, intermediate and high nuclear grade to classify DCIS. This definition is based on the characteristics of the lesion as seen with a high power microscope lens (×40) and uses a comparison of tumor nuclear size with normal epithelial and red blood cell size. If a lesion contains areas of varying grade it is awarded the highest grade present.

Poorly differentiated high-grade comedo DCIS has low ►estrogen receptor (ER) expression, high rates of cell proliferation, high rates of ►apoptosis (programmed cell death), and over-expresses c-erbB-2 (►HER-2/neu) and ►EGFR. Low-grade lesions have high ER expression, with lower rates of cell proliferation and apoptosis than high-grade lesions and they rarely express c-cerbB-2. ►Progesterone receptor (PR) expression correlates with ER expression in both low and high-grade tumors. In comparison, normal breast epithelium has a low expression of ER, PR, and a very low rate of apoptosis and c-erbB-2 expression.

Treatment

Breast-conserving surgery is now the treatment of choice for small, localized areas of DCIS, <4 cm in diameter; where only the segment of breast containing the tumor is excised. When the specimen is examined under a microscope if the DCIS extends close (<1 mm) to the edges of the specimen the patient should undergo cavity re-excision, as clear margin status is a key factor in predicting a good prognosis.

The multi-disciplinary consensus conference on the treatment of DCIS (1999) recommends mastectomy for patients with large areas of DCIS (>4 cm), for multicentric disease and for patients where ►radiotherapy is contraindicated. Women should also be offered mastectomy if the excision margins are persistently involved following breast-conserving surgery and cavity re-excision. The recurrence rate following mastectomy for DCIS is <1%.

The incidence of macroscopic lymph node metastasis in DCIS is <1%, and formal axillary staging (removal of lymph nodes from the armpit) in women with DCIS should be avoided.

In the USA all patients who have undergone breast-conserving surgery for DCIS are recommended to receive a course of radiotherapy. In Europe, ►adjuvant radiotherapy is recommended for all high-grade DCIS. Intermediate and low-grade DCIS is selected for adjuvant radiotherapy on an individual patient basis.

The use of drug therapy following treatment for DCIS is not yet standardized. The anti-estrogen ►tamoxifen can be used in ER positive women who have undergone breast-conserving surgery; its use is decided upon on an individual patient basis. There is little point in using tamoxifen in ER negative cases. ►Chemotherapy is not offered to women with pure DCIS regardless of type.

Following primary treatment for DCIS and radiological and pathological confirmation that there has been complete excision of all suspicious microcalcifications with clear margins, patients should be given the opportunity to participate in clinical trials. Follow-up in out patient clinics, after the initial post-operative reviews, should be by annual bilateral mammography to detect recurrence. Although most DCIS recurrence is impalpable, clinical examination is still important to detect invasive recurrences.

DCIS in Men

DCIS accounts for up to 15% of breast cancers in men. It mainly presents clinically with symptoms of a cystic-type mass behind the areola or bloody nipple discharge. The standard treatment for DCIS of the male breast is total mastectomy with excision of the nipple areola

D

complex. The percentage of men with DCIS that go onto develop an invasive cancer is not known.

Recurrence

Patients with a recurrence of DCIS, where the primary was treated with breast-conserving surgery alone, can be offered re-excision (ensuring clear margins) followed by post-operative radiotherapy. Patients who have already received radiotherapy following their primary excision should be advised to have completion mastectomy. A skin-sparing mastectomy with Latissimus Dorsi myocutaneous flap ►breast reconstruction gives excellent results. The management of invasive recurrence is again dependent on the initial therapy for DCIS. If the patient did not receive radiotherapy after initial DCIS excision then wide local excision and radiotherapy may still be an option depending on the size and location of the invasive tumor. If wide local excision is not an option then mastectomy and axillary staging is the treatment of choice, with adjuvant therapy dictated by standard protocol as for primary invasive cancers.

The overall recurrence for breast-conserving surgery alone is ~25% at 8 years follow-up, with up to 50% of recurrences (i.e. 12.5% of all cases) being invasive disease. The women who develop invasive disease are at risk of metastatic spread. The remaining 50% of women develop further *in situ* tumors, which by definition, does not metastasize.

A fundamental risk factor for recurrence is inadequate excision following breast-conserving surgery. This is judged as either close (<1 mm), or involved margins and by failure to remove all suspicious microcalcifications.

High-grade tumors and tumors showing comedo necrosis are independent risk factors for recurrence. The degree of tumor differentiation is also predictive of local recurrence. A further risk factor for recurrence irrespective of tumor grade or type is a young age (<40 years) at diagnosis. None of the major trials have found any statistical significance between recurrence and tumor size.

Duffy Antigen Receptor for Chemokines

Sonia Mohinta, Kounosuke Watabe
Department of Medical Microbiology, Immunology and Cell Biology, Southern Illinois University, School of Medicine, Springfield, IL, USA

Synonyms

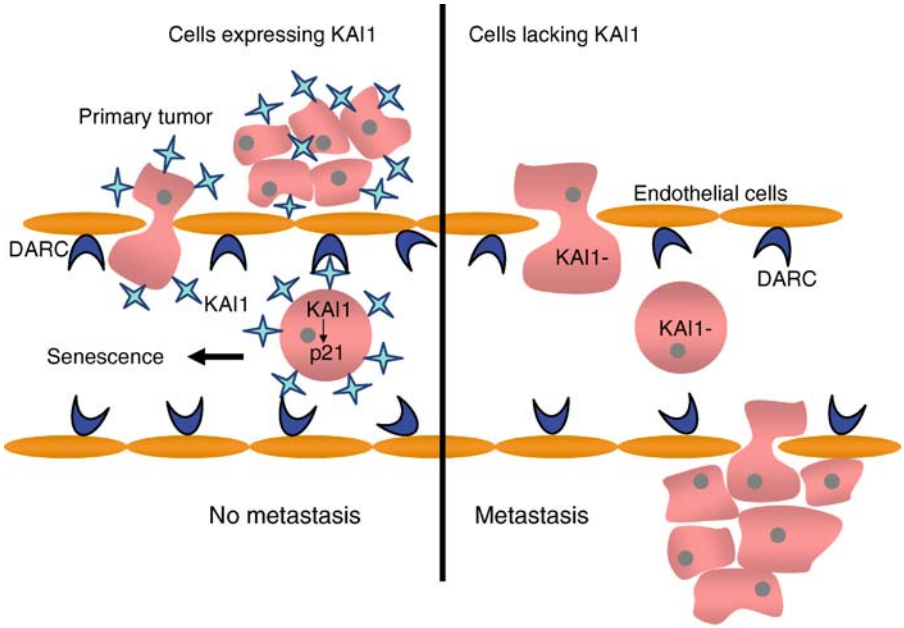
DARC; gp-Fy

Definition

DARC or Duffy antigen receptor for ►chemokines is a seven-transmembrane protein, which has a molecular weight of ~45k Da. DARC is expressed on vascular endothelium (plasma membrane and caveolae) as well as on red blood cells. It binds to chemokines of both C–C and ►C–X–C motif chemokines but signal transduction through the G-protein-coupled receptor or Ca^{2+} flux is not observed. The genomic organization of the *DARC* gene consists of two alleles Fya and Fyb that are associated with a polymorphism at the 44-amino acid residue.

Characteristics

DARC is a receptor for malaria parasite *Plasmodium vivax*, and 70% of the West African population that lack DARC expression on their erythrocytes are resistant to malaria infection. A novel function of DARC has been identified where it has been found to interact with the ►metastasis suppressor *KAI1* CD82. When cancer cells expressing KAI1 intravasate and come in contact with the endothelial lining of small blood vessels during dissemination, KAI1 binds to the DARC expressed on the endothelial cells. The physiologic outcome of this interaction is associated with the inhibition of cell proliferation and induction of cellular ►senescence. DARC constitutes two alleles, Fya and Fyb, and the Fyb allele of DARC is found to be associated with the



Duffy Antigen Receptor for Chemokines. Figure 1 Mechanism of DARC–KAI1 interaction.

KAI1–DARC interaction (Fig. 1). This KAI1–DARC interaction led to the cellular senescence by modulation of the expression of *TBX2* and ►*p21*(WAF1/CIP1/SDI1) genes. Furthermore, the metastasis suppression of KAI1 was significantly compromised in DARC knockout mice, which show that DARC is essential for the function of KAI1 as a metastasis suppressor gene. The majority of West African population, which lacks DARC expression and are resistant to malaria, showed a significantly higher incidence of both ►prostate cancer and ►breast cancer as well as higher rate of metastatic disease than their white counterparts. DARC also serves as a promiscuous receptor for chemokines and is believed to function as "decoy" of excess chemokines. Therefore, DARC is also proposed to have an antitumorigenic role by clearing the angiogenic CXC chemokines. More evidence of DARC's antitumorigenic property has been observed in recent times, where DARC-►knock-out mice were shown to have a significant increase in incidence of prostate tumor in comparison to the wild-type mice. Overexpression of DARC in breast cancer cells significantly suppressed spontaneous lung metastasis. These lines of evidence indicate that DARC functions as an antitumorigenic as well as an antimetastatic protein, and development of drugs that can mimic its function may have a potential utility for the prevention and treatment of cancer.

Dynamic Contrast-Enhanced Magnetic Resonance Imaging

James P. B. O'Connor, Geoff J. M. Parker, Alan Jackson
Imaging Science and Biomedical Engineering, University of Manchester, Manchester, UK

Definition

Dynamic contrast-enhanced ►magnetic resonance imaging (DCE-MRI) is a non-invasive quantitative method of evaluating microvascular structure and function in tumors.

Characteristics

Solid tumors develop a circulatory blood supply of their own by ►angiogenesis to enable growth and survival. Since the vascular networks produce are structurally and functionally abnormal, they offer a potential target for novel anti-cancer therapy. This has led to worldwide interest in identifying and validating ►biomarkers of tumor vascular function that assist diagnosis, inform prognosis or enable the monitoring of treatment effects for both conventional ►chemoradiotherapy and ►anti-angiogenic agents.

T_1 and T_2* DCE-MRI Techniques

Imaging techniques allow repeated measurements of the tumor vasculature to be made in a non-invasive manner. Magnetic resonance imaging, unlike ►positron emission tomography and x-ray computed tomography, does not produce ionizing radiation and is thus considered a safe technique for evaluating functional changes in tumor blood vessels. Two main types of examination can be performed in DCE-MRI. In ►T_1-weighted techniques, repeated images are acquired while an intravenous bolus of ►gadolinium contrast agent traverses the tumor microvasculature. Gadolinium ions are paramagnetic and therefore interact with nearby ►hydrogen nuclei to shorten T_1 ►relaxation times in local tissue water, increasing signal intensity on T_1-weighted images. Signal enhancement within each imaging ►voxel is dependent on tissue perfusion, capillary surface area, capillary permeability and the volume of the extracellular extravascular leakage space (EES), as well as the contrast agent dose, concentration of contrast agent in the artery supplying the tumor vascular bed and native tissue T_1 times. T_1-weighted DCE-MRI is therefore used to estimate the flow, volume and permeability of blood vessels in tumors.

►T_2*-weighted techniques (also known as dynamic susceptibility-contrast MRI) offer an alternative method of investigating the microvasculature. Here, rapid loss of signal intensity observed on T_2*-weighted images is used to calculate the change in concentration of contrast agent for each individual voxel. This method is particularly sensitive to changes in blood flow and volume and assumes that the gadolinium contrast agent remains within the tumor vessels throughout the examination, ignoring the effect of vessel permeability. For this reason, T_2*-weighted methods have generally been limited to studies of the brain where it is assumed that the intact blood-brain barrier limits permeability. While this assumption is untrue in high grade malignancy, numerous DCE-MRI studies of brain tumors employ T_2*-weighted analysis techniques.

Data Acquisition

DCE-MRI protocols are complex. They require considerable technical expertise and interaction between basic

scientists and clinicians. Most examinations are performed on conventional clinical scanners at a magnetic field strength of 1.5 Tesla.

In general, three types of imaging data are acquired in T_1-weighted DCE-MRI. Initial anatomical images are followed by sequences that allow calculation of baseline tissue T_1-values. Finally, dynamic T_1-weighted images are acquired every few seconds over a period of approximately 5–10 min. Most investigators use gradient echo sequences for the dynamic series, as they allow good contrast medium sensitivity, high signal-to-noise ratio, adequate anatomical coverage and rapid data acquisition. Policies for quality control are mandatory to achieve reliable, reproducible data, since DCE-MRI suffers from errors in T_1 calculation, significant motion artefact and difficulties in accurate definition of the tumor region of interest.

Gradient echo pulse sequences are also used in dynamic susceptibility-contrast MRI. Images are ideally acquired every 1–2 s to allow calculation of blood flow and volume. T_2*-weighted techniques are limited by measurement errors and unlike Positron Emission Tomography, usually produce measurements that are relative to large cerebral vessels, rather than absolute values.

Data Analysis

DCE-MRI data analysis may be performed using one or more methods of varying complexity. Most examinations limit the area scanned to around 20 cm or less. Selection criteria for target lesions include size (tumors greater than 2 cm), adequate contrast with background tissue, and organ site free of excessive motion. Initially, a region of interest is defined to cover the entire tumor (for example in three dimensional volume imaging) or part of the tumor (for example one or more two-dimensional slices).

Measures of tumor function are extracted based upon one or more of:

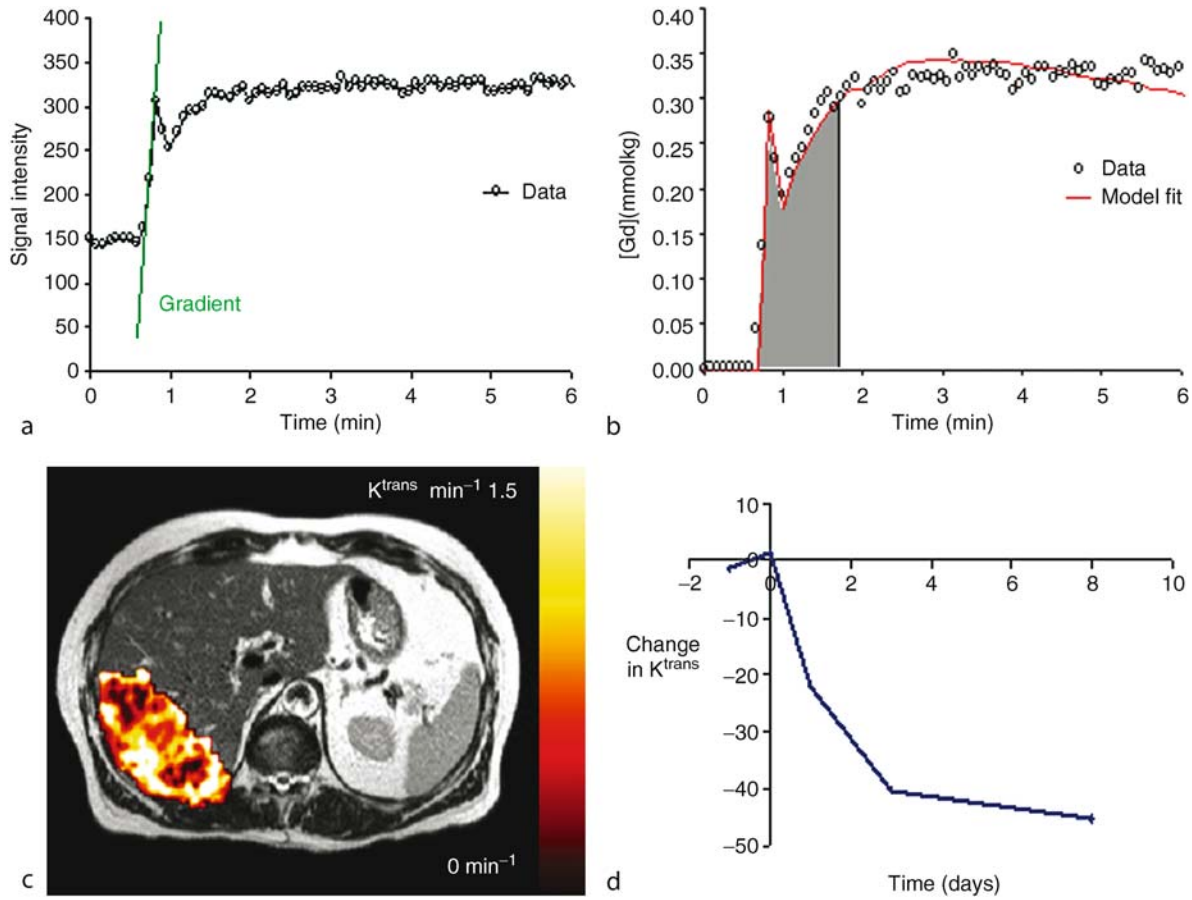
1. Simple features of the signal intensity–time curve (such as fraction of enhancing voxels, gradient or time to 90% peak enhancement).
2. Conversion of signal intensity data into more robust parameters that describe the shape of the contrast agent concentration–time curve. These represent a combination of flow, blood volume, vessel permeability and EES volume (such as ►the initial area under the gadolinium contrast agent concentration–time curve – IAUGC).
3. Fitting data from the contrast agent concentration–time curve to a pharmacokinetic model. This enables parameters that are independent of the data acquisition sequence to be derived.

Modeled parameters enable estimates of physiological characteristics such as flow and capillary endothelial permeability within a tumor; they are more "physiologically meaningful" than either signal intensity or IAUGC measurements. Many related parameters have been described in the literature making comparison between studies difficult. Current expert consensus recommends that the volume transfer coefficient of contrast agent between the blood plasma and the EES (►K^{trans}) and the size of the EES should be preferred in ►clinical trials of Angiogenesis inhibitors using T_1-weighted DCE-MRI, along with IAUGC. ►Cerebral blood volume (CBV) and flow (CBF) are typically derived in brain tumor studies that incorporate T_2*-weighted techniques. Many of the aforementioned quantities have been investigated as potential Biomarkers of tumor biology and drug effect, but are yet to be validated as ►surrogate endpoints.

Finally, a choice of parameter analysis must be made. Median values are most commonly quoted, since both signal intensity and contrast agent concentration within the tumor voxels assume non-normal distributions. Single values may adequately quantify characteristics of tumor tissues, for example median CBV can accurately predict histological ►tumor grading in ►glioblastoma multiforme and discriminate between high grade (higher CBV) and low grade (lower CBV) and identify areas of de-differentiation. However, imaging drug effects in clinical trials of anti-angiogenic agents requires changes in K^{trans} and IAUGC to be calculated from baseline values. Here, percentage change from baseline is frequently quoted. Other forms of data analysis, such as parametric (or calculated) maps demonstrate the spatial heterogeneity of DCE-MRI parameters. Examples of DCE-MRI analyses are illustrated in Fig. 1.

Clinical Findings

DCE-MRI has been used to evaluate tumor microvasculature in numerous clinical studies. Comparison between study methodology and conclusions are difficult since most clinical studies have employed measures of signal intensity, rather than modeled parameters to quantify the microvasculature. Simple signal intensity measures, such as the initial gradient, shape of the enhancement curve and maximum enhancement at 60 s have been shown to reliably distinguish malignant ►breast cancer from benign breast lesions. High and/or increasing relative signal intensity of contrast enhancement in patients with ►cervical cancer before ►radiotherapy has predicted a low incidence of local recurrence. Some centers use DCE-MRI to distinguish between benign bladder wall thickening and ►bladder cancer, to characterize breast cancer and ►hepatocellular carcinoma and to target areas of high grade malignancy in ►glioblastoma multiforme. Despite these encouraging results, DCE-MRI is has few clinical indications at present.



Dynamic Contrast-Enhanced Magnetic Resonance Imaging. Figure 1 Panels a–c illustrate T_1-weighted DCE-MRI data analysis in a patient with a single colorectal liver ►metastasis prior to treatment with an ►anti-angiogenic agent – analysis options include (a) measures from the signal intensity-time curve such as initial gradient, (b) calculated gadolinium contrast agent concentration-time curve with the integrated area under the curve at 60 s after injection (IAUGC), (c) parametric map of median K^{trans} values for each voxel superimposed on an anatomical image. The effect of an anti-angiogenic agent is demonstrated by (d) change in tumor median K^{trans}.

Evaluation of Angiogenesis Inhibitors

One major area of interest in imaging in recent years has been evaluating magnetic resonance based ►biomarkers of changes in tumor microvasculature. An increasing number of clinical trials of ►angiogenesis inhibitors have incorporated DCE-MRI and other forms of imaging in their study design. DCE-MRI is particularly attractive in this setting since anti-angiogenic agents do not typically induce large changes in tumor size, as assessed by traditional imaging endpoints such as ►radiological response criteria.

Significant dose-dependent reductions in K^{trans}, IAUGC and similar parameters have been demonstrated in a number of studies with anti-►vascular endothelial growth factor antibodies and inhibitors of tyrosine kinase ►signal transduction. For example, dose-dependent reduction in a parameter similar to K^{trans} was demonstrated in study of patients with liver metastases from ►colon cancer, following administration of the ►VEGF receptor tyrosine kinase inhibitor vatalanib (PTK787/ZK222584; Novartis, Basel, Switzerland), which correlated with response rate and disease progression. Similar findings have been demonstrated in other studies, where DCE-MRI has been utilized alongside other functional imaging, histology and ►serum biomarkers of tumor pathophysiology.

This study highlights the potential use of DCE-MRI, namely that change in tumor vasculature can be followed at regular intervals in a non-invasive manner. However, it also identifies the shortfalls of the technique – the precise mechanism of action cannot be determined by a technique that measures changes in composite processes at the millimeter scale. Furthermore, while changes in DCE-MRI parameters may be necessary to identify successful therapeutic compounds, they are not sufficient to identify success in a phase III

randomized controlled trial – vatalanib has not produced an improvement in overall survival in patients with metastatic colon cancer when combined with cytotoxic chemotherapy.

Conclusion

The parameters obtained in DCE-MRI analysis undoubtedly provide valuable insight into how the tumor ►microenvironment responds to chemoradiotherapy and novel therapies, but the quantities produced are estimates of composite processes, rather than measurements of physiological mechanisms. Further work is required to validate their role in diagnosis, prognosis and follow-up of solid tumors and as Biomarkers of drug efficacy and mechanism in Clinical Trials.

Dysplasia

Definition
Is an alteration found principally in epithelial tissues, characterized by a number of changes including loss of single cells uniformity and architectural orientation. Dysplastic cells are highly pleomorphic (variation in size and shape) and often exhibit hyperchromatic nuclei and increase in the nucleus/cytoplasm ratio. Mild-to-moderate dysplasia is often reversible following the removal of causative stimuli. However, severe dysplasia becomes irreversible and may be considered a premalignant lesion due to its ability to progress to carcinoma. Dysplastic epithelium may be precursor of carcinoma and may per se be malignant when associated with direct invasion beyond the muscularis mucosae in the submucosa of the bowel wall. Dysplasia is identified on the basis of a series of microscopic features including architectural alteration of the tissue and cytologic abnormalities, mainly nuclear pleomorphism and hyperchromatism, loss of nuclear polarity, and marked stratification of nuclei. On the skin, dysplasia may appear as a red patch on the mucosa that is not attributable to any obvious cause. Generally, these lesions have a well defined border and a soft, velvet-like appearance. Their atrophic nature contributes to the red coloration, as underlying vasculature is more prominent. Around 90% show signs of severe dysplasia or ►carcinoma in-situ and may progress to invasive squamous cell carcinoma.

►Preneoplastic lesions

E2F

Pidder Jansen-Dürr
Institute for Biomedical Ageing Research, Austrian Academy of Sciences, Innsbruck, Austria

Definition

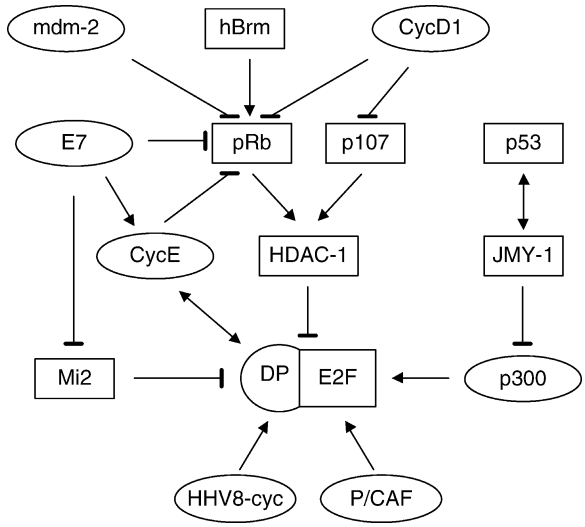
Family of transcription factors involved in cell-cycle regulated transcription; they control the expression of genes coding for growth regulatory proteins.

Characteristics

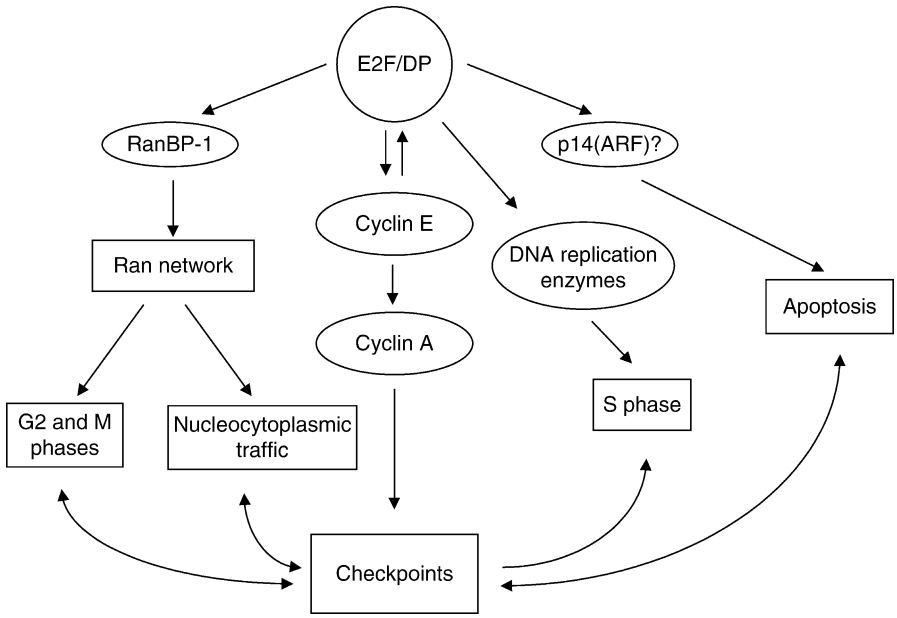
The E2F family of transcription factors has the five members, E2F-1–5, which are capable to either activate or repress transcription, depending on the promoter context and the composition of E2F complexes (see later). A sixth member of the E2F family, referred to as EMA or E2F-6, also binds E2F recognition sites but only acts as a repressor of transcription. Members of the E2F family form heterodimers with members of the DP family. The latter consists of two genes, DP1 and DP2, which encode several isoforms. Heterodimerization is required for DNA binding. E2F/DP heterodimers function as transcriptional regulators of a variety of cellular genes, some of which are involved in cell-cycle checkpoint control.

E2F target genes can be grouped as follows:

- Genes that code for cell-cycle regulators (Fig. 1), such as cyclin E, cyclin A, the ►retinoblastoma protein, p107, and Ran BP1. Expression of these genes is driven by E2F. E2F thereby directly controls the progression from one ►cell cycle phase into the other, particularly at the G1/S and the ►G2/M



E2F. Figure 1 Control of E2F activity in cancer cells. Signals and regulatory pathways that induce or repress the activity of the E2F/DP transcription factors are indicated. The picture contains only proteins with a known function in human cancer; although other proteins that can modulate E2F/DP activity have been identified their role in cancer is not yet clear. The activity of E2F/DP transcription factors is controlled by chromatin-modifying enzymes such as HDAC-1 and Mi2, which block the transcription of E2F-dependent genes by deacetylating histones. In contrast, histone acetyl transferases such as p300 and P/CAF, act as potent coactivators of E2F. These proteins acetylate histones and thereby release E2F-driven genes from chromatin repression. p300 and P/CAF also upregulate the activity of E2F-driven genes by direct acetylation of the E2F partner in the E2F/DP heterodimer. p53 and E2F compete for the adapter protein p300. This interaction is mediated by the currently identified protein JMY1. Finally, human tumor viruses such as HPV-16 or HHV-8, encode genes that directly modulate E2F activity, leading to aberrant activation of E2F target genes.



E2F. Figure 2 E2F regulation of cell-cycle checkpoints. The role of E2F/DP genes in coordination of cell-cycle checkpoint control is schematically depicted. Apart from its role in S-phase entry, E2F acts at the G2/M checkpoint in mammalian cells, which is mediated by Ran-dependent modulation of nucleocytoplasmic traffic. Induction of apoptosis by certain E2F family members is believed to depend on transcriptional activation of the gene encoding p14 (ARF). The major groups of E2F target genes are shown and the interplay of their gene products is indicated by arrows.

transition. E2F also activates expression of the p14 (ARF) gene, an upstream regulator of ►p53.

- Genes that code for enzymes involved in DNA replication, such as thymidilate synthetase, thymidine kinase, dihydrofolate reductase, etc. It is believed that upregulation of these genes prepares cells for DNA synthesis which are in the G1 phase of the cell cycle.

Cellular and Molecular Regulation

- E2F proteins are regulated by cellular tumor suppressor proteins (Fig. 2). Members of the retinoblastoma protein (►Retinoblastoma protein, biological and clinical functions) family (pRB, p107, and p130) associate with the E2F/DP heterodimers, block their transactivation capacity and, in some cases, convert these activators of transcription into transcriptional repressors. The latter conversion appears to involve the tethering of histone deacetylases to E2F/pRB complexes.
- E2F regulates the activation of the tumor suppressor p53 via p14 (►ARF). In turn, E2F function is regulated by p53 via a competition for the p300 coactivator protein (p300/cBP co-activators).
- The function of E2F is positively regulated by cyclin-dependent kinases. This, at least in part, relies on the phosphorylation and the resulting inactivation of members of the retinoblastoma protein family. However, cdk-dependent phosphorylation of the E2F subunit also contributes to E2F activation.
- E2F activity is upregulated by cellular and viral oncogenes, such as ►MDM2, adenovirus E1A, papillomavirus E7, and SV40 T antigen. Activation of E2F by these oncogenes is thought to be mediated by a displacement of the retinoblastoma protein or its relatives from E2F/DP complexes.

Clinical Relevance

E2F-1 acts as a tumor suppressor and at the same time as an oncogene in the mouse, as was exemplified by the complex phenotype of E2F-1 ►knock out mice. It appears that tumor suppression by E2F depends on its interaction with the retinoblastoma protein by enhanced transcriptional silencing. The oncogenic activity of E2F-1 is mediated by free E2F-1/DP complexes which enforce the transcription of E2F-dependent target genes, some of which are required for cell proliferation.

►Amplification of the E2F-1 gene was described in human erythroleukemia cells; the *E2F-5* gene is amplified in some human breast cancers.

Definition

E-cadherin, a 120 kDa molecule, is a prototypical member of the classical cadherin family of single-pass transmembrane proteins that mediate calcium-dependent cell-cell adhesion. Normally, ►epithelial cells are tightly interconnected through several junctional structures, including ►adherens junctions, ►tight junctions, and ►desmosomes. E-cadherin is the main adhesion molecule of the adherens junctions of epithelial cells, and via catenins it is linked to the underlying actin cytoskeleton. Two other members of the cadherin family, desmoglein and desmocollin, mediate adhesion in desmosomes. Via plakoglobin and desmoplakin they are connected to intermediate cytoskeletal filaments. Thus, E-cadherin and other members of the cadherin family play a crucial role in establishing and maintaining the integrity of epithelial tissues.

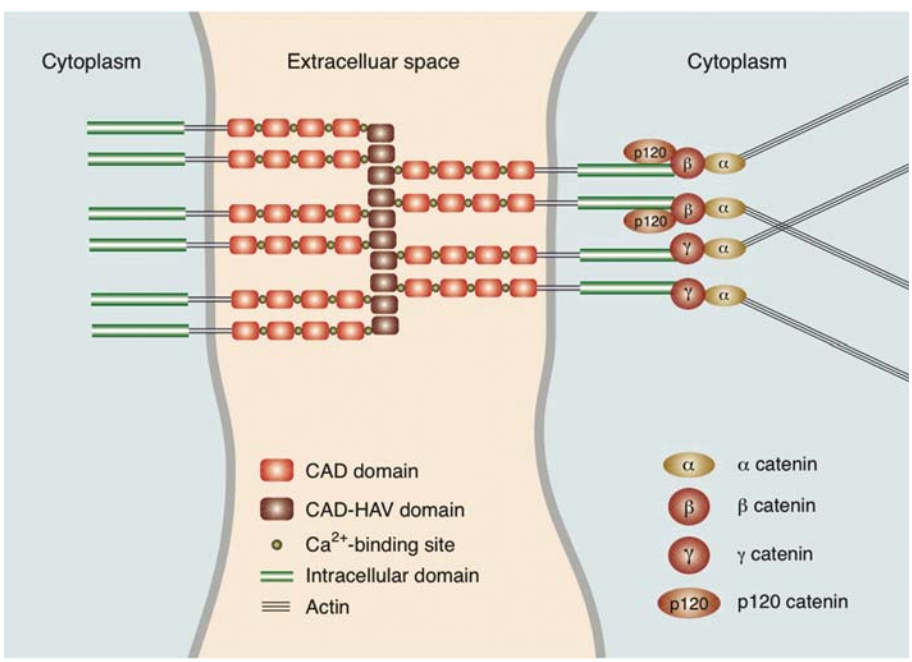
The majority of human cancers (80–90%) are of epithelial origin. Loss of E-cadherin expression correlates with late stage tumorigenesis characterized by tumor cell de-differentiation, invasive tumor growth and metastasis. Moreover, studies in a transgenic mouse model of carcinogenesis have demonstrated that the loss of E-cadherin is a rate-limiting step in the transition from ►benign tumors to ►malignant tumors and the subsequent formation of metastases. In addition, germline mutations of E-cadherin predispose to diffuse gastric cancer.

Characteristics

The extracellular region of E-cadherin consists of five highly conserved cadherin (CAD) domains that combine with calcium ions to form rod-like structures (Fig. 1). The outermost CAD domain contains a conserved His-Ala-Val (HAV) motif, which is thought to mediate homotypic binding *in trans* to an E-cadherin molecule on the surface of an adjacent cell. Dimerization of E-cadherin molecules *in cis* appears to be mediated by their transmembrane domains. Depletion of calcium ions results in the disassembly of E-cadherin mediated adhesive structures and the loss of cell-cell adhesion. Critical for E-cadherin-mediated cell-cell adhesion is the interaction of its cytoplasmic domain with catenins. β-catenin and γ-catenin/plakoglobin associate directly with the cytoplasmic domain of E-cadherin. They bind to α-catenin, which in turn connects the cadherin cytoplasmic complex to the actin cytoskeleton (Fig. 1). An additional catenin, p120 catenin, has been originally identified as a substrate of the non-receptor tyrosine kinase pp60$^{c\text{-}src}$ and binds to the juxtamembrane region in the cytoplasmic tail of classical cadherins. Depending on the cell type, p120 catenin has been found to positively or negatively modulate the strength of cell-cell adhesion.

E-cadherin and the Formation of Adhesion Junctions

Upon contact of the cell membrane with adjacent cells, pre-existing E-cadherin is recruited to the site of the



E-Cadherin. Figure 1 E-cadherin-mediated cell-cell adhesion. E-cadherin homodimers on the plasma membranes of adjacent cells interact in a zipper-like fashion. The most N-terminal CAD domain on each E-cadherin molecule contains a HAV motif thought to interact with an E-cadherin molecule on an adjacent cell. The cytoplasmic cadherin complex, which consists of α-catenin, β-catenin, γ-catenin and p120 catenin, mediates the interaction between E-cadherin and the actin cytoskeleton.

interaction and the junctional complex is formed. Once in place, E-cadherin-mediated cell-cell adhesion can be rapidly dismantled by growth factor-mediated signals. p120 catenin and to a lesser extent β-catenin and γ-catenin are phosphorylated upon treatment of cells with the growth factors hepatocyte growth factor (HGF), epidermal growth factor (EGF) (►Growth factor), or ►platelet-derived growth factor – either directly by the respective receptor tyrosine kinases or indirectly by downstream effector kinases, such as $pp60^{c\text{-}src}$. Phosphorylation of the catenins causes their release from the cell adhesion complex resulting in the disruption of cell adhesion and eventually cell scattering. Similarly, treatment of cells with potent inhibitors of tyrosine phosphatases induces dissociation of the cytoplasmic cell adhesion complex. Deletion of the cytoplasmic catenin-binding domain or any disruption of the intracellular E-cadherin-catenin complex results in loss of cell-cell adhesion. Hence, mutations in genes other than E-cadherin itself might also affect E-cadherin function.

The mechanism through which β-catenin and α-catenin increase the adhesive strength of E-cadherin is not clear. Recent studies indicate that α-catenin may not simultaneously bind E-cadherin/β-catenin and actin, but rather influence the structure of the actin cytoskeleton via ►Arp2/3. The formation of adhesive junctions is also regulated by Rho-GTPases (►GTPase). Forced expression of constitutive-active forms of Rac or Cdc42 inhibits HGF-induced scattering of epithelial cells. Similarly, overexpression of Tiam-1, a guanine nucleotide exchange factor (GEF) for Rac, enhances E-cadherin-mediated adhesion.

Signals Elicited by the Loss of Cell Adhesion

Besides being a major component of the cytoplasmic cadherin complex, β-catenin also takes part in ►Wnt signaling. In the absence of a Wnt-signal, free β-catenin is rapidly phosphorylated by glycogen synthetase kinase 3β (GSK3β) in the adenomatous polyposis coli (APC)-GSK3β complex and subsequently degraded by the ►ubiquitin-proteasome pathway. If the tumor suppressor APC is non-functional, or if GSK3β activity is blocked by the activated Wnt signaling pathway, β-catenin accumulates at high levels in the cytoplasm. Subsequently, it translocates to the nucleus, where it binds to a member of the TCF/LEF-1 family of transcription factors and modulates the expression of TCF/LEF-1 target genes. Loss of function mutations of APC are a hallmark of ►colon cancers and stabilizing mutations of β-catenin are frequently found in a number of cancer types. However, in several human cancer types and experimental tumor models, tumor progression induced by the loss of E-cadherin was shown to be independent of β-catenin. Therefore, β-catenin that is released from the E-cadherin adhesion complex does not necessarily feed directly in the Wnt signaling pathway, unless β-catenin degradation is inhibited.

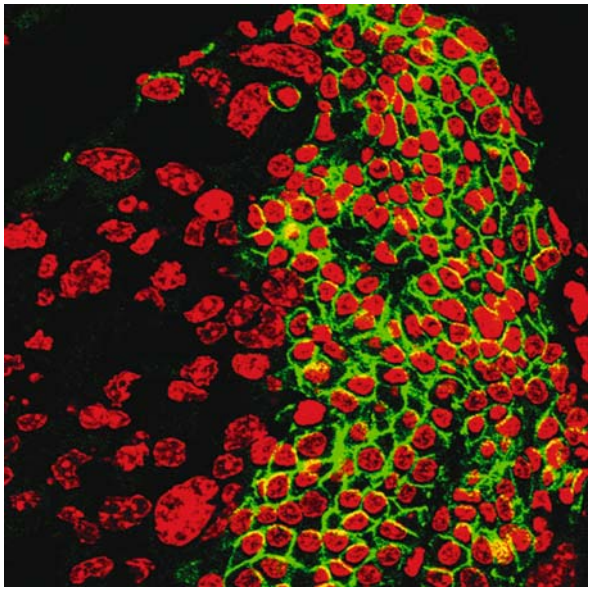
α-Catenin is not only connecting adherens junctions with the actin cytoskeleton but also interacts with several actin binding proteins, including vinculin, ZO-1 (►Zonula occludens (ZO) protein-1) and α-actinin. It is also involved in the communication between cell adhesion and changes in cellular phenotype. As outlined above, E-cadherin and the junctional complex can also interact with Rho-GTPases. Experiments suggest a direct influence of Rac and Cdc42 on the cadherin-catenin complex via the protein IQGAP1 (►IQGAP1 protein). IQGAP1 accumulates at contact sites of cells expressing E-cadherin, where it directly interacts with the N-terminus of β-catenin and the cytoplasmic tail of E-cadherin. Active Rac and Cdc42 prevent the interaction of IQGAP1 with β-catenin by sequestration of IQGAP1. Upon release of IQGAP1 from GDP-bound, inactive Rac and Cdc42, however, IQGAP1 displaces α-catenin from β-catenin, resulting in the dissociation of α-catenin from the cytoplasmic cadherin complex and concomitant loss of E-cadherin-mediated cell adhesion. Thus, Rac and Cdc42 seem to positively regulate cell adhesion by suppression of IQGAP1 activity. Finally, p120 catenin was shown to translocate to the nucleus, interact with Kaiso (a transcriptional repressor), and thereby modulate gene expression. Furthermore, recent evidence suggests that Frodo, a functional regulator of Dishevelled, may link p120 catenin to the Wnt pathway as well.

Apart from signaling through the catenins, the intracytoplasmatic tail of E-cadherin can be cleaved by presenilin1, a γ-secretase, and participate in the regulation of cellular transcription and lysosomal degradation of amyloidogenic proteins.

E-Cadherin in Animal Models of Cancer

The effect of loss of E-cadherin on tumor progression was studied in two animal models of human cancer. In the Rip1Tag2 mouse model of insulinoma, the expression of a dominant-negative E-cadherin (resulting in a complete ablation of E-cadherin-mediated adhesion) promoted the formation of carcinomas and induced lymph node metastasis (Fig. 2). Forced expression of E-cadherin in the same model arrested tumor progression at the stage of an adenoma. Furthermore, the transgenic expression of ►podoplanin, a small mucin-like glycoprotein, led to the formation of carcinomas in the presence of E-cadherin and the other components of the zonula adherens.

In the p53 knock-out ($K14Cre;Trp53^{F/F}$) mouse model of breast cancer, somatic inactivation of E-cadherin shifted the invasion pattern of carcinomas from an expansive (ductal-like) to an infiltrative (lobular-like) invasion pattern and induced the formation of distant metastasis. Interestingly, isolated knock-out of E-cadherin in the mammary epithelium was not sufficient to induce breast cancer formation.



E-Cadherin. Figure 2 Loss of E-cadherin expression during tumor progression. Right hand: E-cadherin (green) is expressed at the plasma membranes of tumor cells with benign, epithelial phenotype and normal nuclei (red). Left hand: In contrast, E-cadherin expression is focally downregulated within the portion of the tumor that exhibits invasive growth and atypic nuclei (red).

Taken together, loss of E-cadherin increases the formation of carcinomas, shifts the invasion pattern from collective to single cell invasion, and thereby promotes metastasis. However, in certain animal models the formation of carcinomas was possible in the presence of E-cadherin, and those carcinomas which expressed E-cadherin tended to invade by adopting an expansive/collective invasion pattern.

E-Cadherin in Human Cancer

E-cadherin's adhesive function can be lost during the development of human epithelial cancers, including carcinomas of the breast, colon, prostate, stomach, liver, esophagus, skin, kidney and lung. In general, decreased E-cadherin function correlates with de-differentiation of tumor cells, infiltrative tumor growth, metastasis and poor prognosis. Several different mechanisms appear to cause the loss of E-cadherin function in human tumors. Hereditary mutations in the E-cadherin gene are evident in cases of familial gastric cancers. Patients with a germline mutation of E-cadherin have a 70–80% lifetime risk to develop diffuse gastric cancer, indicating that the penetrance of the E-cadherin mutation is similar to that of ►BRCA1 carriers in breast cancer.

Considering the penetrance and the aforementioned animal models of cancer, mutation of E-cadherin predisposes to neoplasia, but the mutation alone is not sufficient to induce the disease.

Apart from mutations of E-cadherin, expression of truncated α-catenin or truncated β-catenin abrogate E-cadherin function. Whereas mutations in the α-catenin gene or reduced α-catenin protein levels thus far have only been found in cultured tumor cell lines, mutations in the β-catenin gene are evident in many primary human tumors, including melanoma, colon cancer, gastric cancer and prostate cancer.

Epigenetic mechanisms such as chromatin rearrangement and loss of transcription factor binding also coincide with suppression of E-cadherin promoter activity in invasive carcinoma cells. In many tumor types, ►hypermethylation of the regulatory region of the E-cadherin gene and thus transcriptional silencing of the gene appears to be a major mechanism underlying E-cadherin loss of function. In several cellular systems, the epigenetic silencing of E-cadherin is mediated by the activation of transcriptional repressors. One of these repressors, Snail (►Snail transcriptional factor), has been shown to downregulate E-cadherin expression along with claudin-3, a protein involved in the formation of tight junctions. Finally, proteases that are upregulated during tumor progression are able to degrade the extracellular portion of the E-cadherin molecule resulting in the disruption of cell-cell adhesion and the cytoplasmic cadherin complex.

Other family members of classical cadherins are expressed in epithelia. Recently, it was observed that in several cancer types expression of N-cadherin was upregulated during tumor progression concomitant with the loss of E-cadherin function. This phenomenon was termed "cadherin switch," and is related to ►epithelial to mesenchymal transition (EMT), a process implicated in the transition from benign neoplasia to malignant cancer. In these cases, N-cadherin appeared to induce tumor cell invasion and metastasis.

Clinical Relevance

E-cadherin is used as a diagnostic and prognostic marker for several human cancers. In particular, expression of E-cadherin is lost in most lobular breast cancers, making the lack of E-cadherin a diagnostic criterium for the disease. Moreover, detection of mutations in the E-cadherin gene is diagnostic for hereditary diffuse gastric cancer. Therapeutic approaches that are based on the loss of E-cadherin function will have to await the identification of downstream effector genes that may be more amenable to therapeutic intervention.

Definition

►Adhesion of circulating cancer cells to the ►endothelium is a prerequisite for ►metastasis. The specificity of the cancer cell-endothelial cell interactions constitutes the basis of the organ selectivity or homing of metastatic colonization. Subsequently to adhesion, cancer cells form metastases either by growing locally in the capillaries or by invading the surrounding tissue following ►extravasation. This latter process is associated with the induction of a bidirectional signaling that contributes to increase the motile potential of the cancer cells and the permeability of the endothelium.

Characteristics

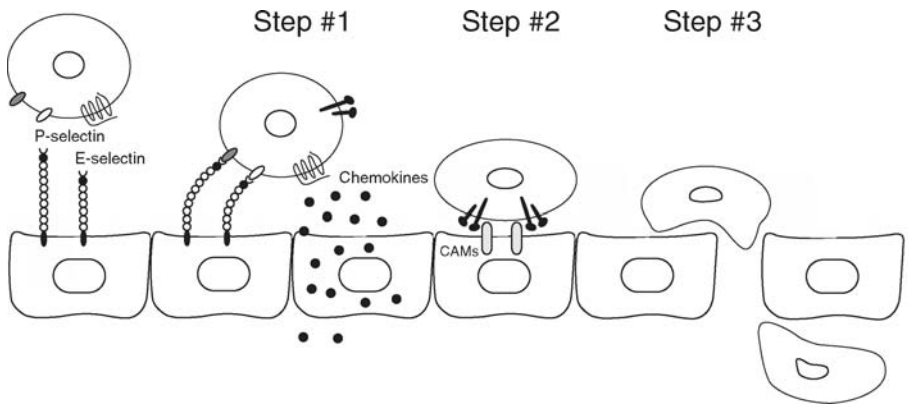
E-selectin is a calcium-dependent transmembrane receptor of the selectin family that also contains L- and P-selectin. L-selectin is expressed constitutively by lymphocytes. P-selectin is found in platelets and endothelial cells where it is stored in α-granules and Weibel-Palade bodies before being translocated at the cell surface by stimulation. E-selectin is expressed exclusively by endothelial cells, following a challenge by pro-inflammatory stimuli such as TNFα and interleukin-1β. The selectins are characterized by an extracellular domain containing a C-type lectin domain of 120 amino acids in the N-terminal followed by an epidermal growth factor (EGF) domain of 30–40 amino acids and 2–9 short repeats of ~60 amino acids found in complement regulatory proteins. The selectins are anchored in the membrane through a single helicoidal transmembrane domain that is completed by a short cytoplasmic tail. The usual role of selectins is to mediate the adhesion and rolling of leukocytes to the endothelium allowing their extravasation into inflamed tissues. Several lines of evidence indicate that cancer cells "parasite" the inflammatory system and interact with selectins to extravasate and form metastases. For example, several studies showed that breast carcinoma, bladder cancer, gastric carcinoma, pancreatic carcinoma, leukaemia and lymphoma form metastases in an

E-selectin-dependent fashion in organs as various as liver, bone marrow, skin and lung. Interestingly, immunohistochemical studies on colon cancer tissues have shown that the small blood vessels surrounding cancer cell nests frequently express E-selectin and that its expression is inversely correlated with the distance of blood vessels from the cancer nests. These results suggest the possibility that E-selectin expression may be involved in ►angiogenesis and that cancer cells have the ability to induce the expression of vascular E-selectin. This hypothesis was confirmed by *in vivo* experiments. For example, Lewis lung carcinoma cells trigger the expression of E-selectin by liver sinusoidal endothelium, increasing their metastatic potential and suggesting that E-selectin contributes to the organ-specificity of metastatic colonization. Along these lines, it is well documented that ►colon carcinoma metastasizes specifically to the liver in an E-selectin-dependent manner. Most interestingly, highly metastatic human colorectal and mouse lung carcinoma cells, on their entry into the hepatic microcirculation, trigger a rapid host pro-inflammatory response by inducing TNF-α production in resident Kupffer cells. In turn, this triggers E-selectin expression by endothelial cells, presumably enhancing the binding and extravasation of the cancer cells. As discussed in the next section, the binding of cancer cells to E-selectin involves a counter-receptor for E-selectin that is composed of ►sialyl Lewis-a/x determinants that are borne by a carrier protein or lipids on cancer cells.

Mechanisms

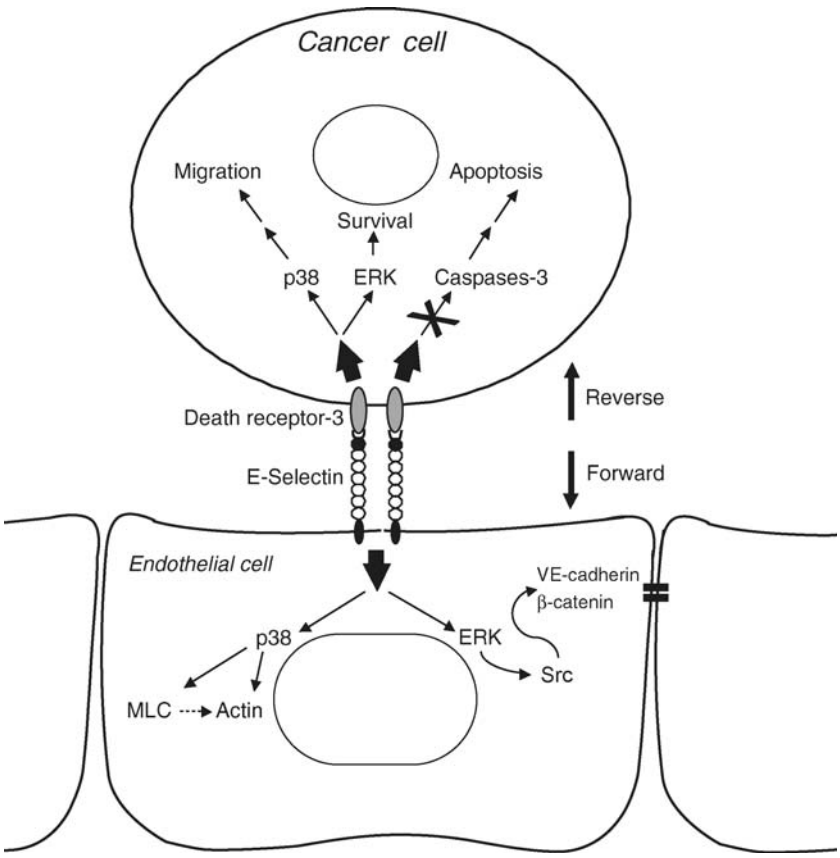
The binding of E-selectin to sialyl Lewis-a/x determinants borne by binding cancer cells is Ca^{2+}-dependent, and it is mediated through the N-terminus lectin domain of E-selectin. This primary adhesion is transient and unstable under shear stress and it allows the rolling of cancer cells on endothelial cells. Moreover, it induces signaling in the cancer cells that may confer them a metastatic advantage, as reported below. The E-selectin-dependent adhering and activated cancer cells are released into the circulation unless secondary adhesion mechanisms are brought into play. In particular, many chemoattractants are produced in response to E-selectin-mediated attachment, and these ►chemokines contribute to activate adhesion receptors in order to mediate firm attachment. Both β_1 and β_2 integrins present on cancer cells are able to modulate the binding to ►cell adhesion molecules like ICAM-1, ICAM-2 and VCAM-1 on endothelial cells. In each step, soluble factors and activated receptors trigger signaling pathways that regulate the endothelial barrier integrity. The destruction of endothelial cell-cell junctions and endothelial ►cell-extracellular matrix junctions combined with retraction of endothelial cells enable extravasation of the cancer cells (Fig. 1). In capillary beds submitted to lower blood pressure, the firmer adhesion that follows the primary adhesion to E-selectin may be associated with the local proliferation of the adhering cancer cells that will form metastatic foci in the blood vessel without extravasating.

Sialyl Lewis-a borne by carrier proteins plays major roles in the binding to E-selectin of cancer cells derived from the lower digestive organs, such as the colon and rectum, as well as from the pancreas and biliary tract. Sialyl Lewis-x is the representative carbohydrate involved in the E-selectin binding of breast, ovarian and pulmonary cancer cells. In contrast, little is known



E-Selectin-Mediated Adhesion in Cancer. Figure 1 Extravasation of cancer cells is a multi-step process. The first step consists in the transient adhesion of cancer cells to the endothelium. It involves endothelial adhesion molecules such as E-selectin and P-selectin and their counter-receptors present on cancer cells. This step is associated with the rolling of the cancer cells on the endothelium. The second step consists in a firmer adhesion of cancer cells to endothelial cells. It is mediated through chemoattractants and adhesion molecules on the endothelium and integrins on the cancer cells. The third step is characterized by the extravasation of cancer cells through endothelial cell-cell junctions.

about the proteins that bear these carbohydrates and that serve as E-selectin counter-receptors on cancer cells. A retrospective study suggests that recombinant P- and E-selectins and sialyl Lewis-x antibodies transmit activation signals through tyrosine phosphorylation of several proteins in Hodgkin's lymphoma-derived cell lines. In turn, this results in changes in cell morphology. On cancer cells from solid tumors, LAMP-1, LAMP-2, ►CD44 and ►death receptor-3 (DR3) were identified as E-selectin ligands. Among them, only DR3 has been described as a functional and signaling sialylated ligand that binds E-selectin on colon cancer cells. The subsequent DR3 activation increases the motile and survival potentials of the cancer cells through activation of the p38 and ERK ►MAP kinase pathways, respectively. On the other hand, the activation of E-selectin induces a forward signaling in endothelial cells that initiates its endocytosis and degradation through lysosomal compartments. In addition, the activation of E-selectin by adhering colon cancer cells or cross-linking antibodies stimulates both ERK and p38 MAP kinase pathways in the endothelial cells. In turn, this contributes to increase endothelial permeability enabling transendothelial ►migration of cancer cells by regulating the opening of the inter-endothelial spaces (ERK) and the contractility of endothelial cells (p38). Overall, these findings suggest that E-selectin-mediated adhesion of cancer cells regulates their metastatic potential by inducing a bidirectional signaling that contributes to increase their intrinsic motile and survival potential as well as the permeability of the endothelium. This mechanism is illustrated in Fig. 2.



E-Selectin-Mediated Adhesion in Cancer. Figure 2 Reverse and forward signaling induced by E-selectin in cancer cells and endothelial cells. Adhesion of colon cancer cells to endothelial cells expressing E-selectin induces a reverse signaling in the cancer cells that increases their motile potential, and a forward signaling in the endothelial cells that increases interendothelial permeability and enables extravasation. For example, we found that adhesion of colon carcinoma cells to endothelial cells involves the binding of E-selectin on endothelial cells to Death Receptor-3 (DR3) on cancer cells. This interaction induces the reverse activation of p38 and ERK MAP kinases in cancer cells, which increases their motile and survival potentials. Reciprocally, the interaction between DR3 and E-selectin triggers the forward activation of the same MAP kinase pathways in endothelial cells. This results in myosin-light chain (MLC)-mediated cell retraction and in dissociation of the VE-cadherin-β-Catenin complex and thereby destruction of *adherens* junctions leading to increased endothelial permeability and extravasation of cancer cells.

Clinical Relevance of E-selectin and its Ligands in Cancer

The finding that cancer cell binding to E-selectin-expressing endothelial cells is associated with metastasis is of great clinical relevance and opens several therapeutic avenues. Since this adhesion process requires expression of endothelial E-selectin as well as sialyl Lewis-a/x determinants on cancer cells, various efficient strategies targeting these molecules are promising to suppress E-selectin-mediated cancer cell adhesion. The approaches include: antibodies directed against E-selectin or sialyl Lewis-a/x antigens, compounds that mimic the sialyl Lewis-a/x determinants, and antisense-cDNA of the genes encoding for the enzymes that synthesize these carbohydrates. Controlled clinical trials are still waiting but their reliability is strongly supported by solid experimental findings. For example, interfering with the binding of colon carcinoma cells to lung endothelium, by using an anti-E-selectin-antibody, impairs lung metastasis. Similarly, antibodies directed against sialyl Lewis-a/x determinants inhibit the formation of metastasis by human pancreatic and gastric cancers in nude mice. Moreover, sialyl-Lewis-a mimetic compounds inhibit the metastatic potential of tumor cells expressing sialyl Lewis-a, whereas antisense-cDNA for fucosyltransferase genes (FUT III/VI) suppresses metastatic colonization by colon cancer cells. Along the same lines, encouraging results are obtained in colon cancer by using cimetidine to inhibit E-selectin expression or celecoxib, an inhibitor of ►cyclooxygenase-2, to impair the expression of sialyl Lewis-a.

The expression of E-selectin as well as sialyl Lewis-a/x determinants may reveal to be efficient markers of metastasis. In cancer patients, an elevated level of serum E-selectin is generally recognized as a marker of endothelial cell activation and is associated with clinical metastasis. For example, in patients with breast cancer, high concentrations of circulating soluble E-selectin are associated with liver metastasis. In contrast, low levels of circulating sE-selectin are associated with a strong prognostic value for an overall and disease-free survival in patients with node-negative breast cancer. In patients with non-small cell lung cancers, a high serum concentration of E-selectin correlates with a worse prognosis when the cancer cells express sialyl Lewis-a/x. Similarly, elevated levels of serum E-selectin is indicative of a poor prognosis in patients with colon cancer, when the cancer cells express sialyl Lewis-a. Hence, the determination of blood sE-selectin coupled to the determination of sialyl Lewis-a/x determinant on tumor biopsies might become a useful and quick assay to evaluate the metastatic potential of a tumor.

Overall, E-selectin-mediated endothelial adhesion seems to have a key role for cancer cells in metastasis, which opens new avenues for therapeutic interventions aim at inhibiting this fatal complication of cancer.

E2A-PBX1

Brandy D. Hyndman, David P. LeBrun
Department of Pathology and Molecular Medicine, Queen's University Cancer Research Institute, Queen's University, Kingston, ON, Canada

Definition

E2A-PBX1 is an oncogenic transcription factor expressed in neoplastic cells consequent to a somatic chromosomal translocation (t(1;19)) in some cases of ►acute lymphoblastic leukemia (ALL).

Characteristics

Leukemia cells commonly contain somatic chromosomal translocations that contribute to the induction and, presumably, perpetuation of the disease. They do this by altering proto-oncogenes that reside close to the involved ►breakpoints on the participating chromosomes. Translocation (1;19)(q23;p13.3) is the second-most frequently observed recurrent translocation in ALL, detectable in approximately 5% of cases using conventional cytogenetics. In the vast majority of instances, t(1;19) fuses coding regions from two genes, *E2A* and *PBX1*, that reside respectively on chromosomes 19 and 1. Subsequent transcription and pre-mRNA splicing lead to expression of E2A-PBX1, an abnormal, ►chimeric transcription factor with potent oncogenic activity. Abundant evidence supports the notion that E2A-PBX1 contributes to the abnormal accumulation of primitive lymphoid progenitors that characterizes ALL by deregulating the transcription of key target genes.

Clinical Aspects

ALL is primarily a pediatric disease, so most patients with t(1;19)-positive, E2A-PBX1-expressing leukemia are children. Although the neoplastic cells in ALL most often have immunophenotypic (►Flow cytometry in cancer diagnosis) and genotypic (►Molecular pathology) features characteristic of the very early stages of B-lymphoid development, prior to the initiation of immunoglobulin gene rearrangement or expression, the vast majority of cells associated with t(1;19) generally manifest characteristics typical of more mature "pre-B cells," including rearrangement of the immunoglobulin heavy chain gene locus and expression of cytoplasmic, but not surface, immunoglubulin heavy chain protein. Other clinical features associated with t(1;19)-positive ALL include: especially high leukocyte counts at presentation, non-caucasian race and central nervous system involvement. Although the translocation was originally associated with unfavorable clinical outcomes, the more intensive treatment regimens used currently have largely or completely abrogated this association.

Wild-type E2A and PBX1 Gene Products

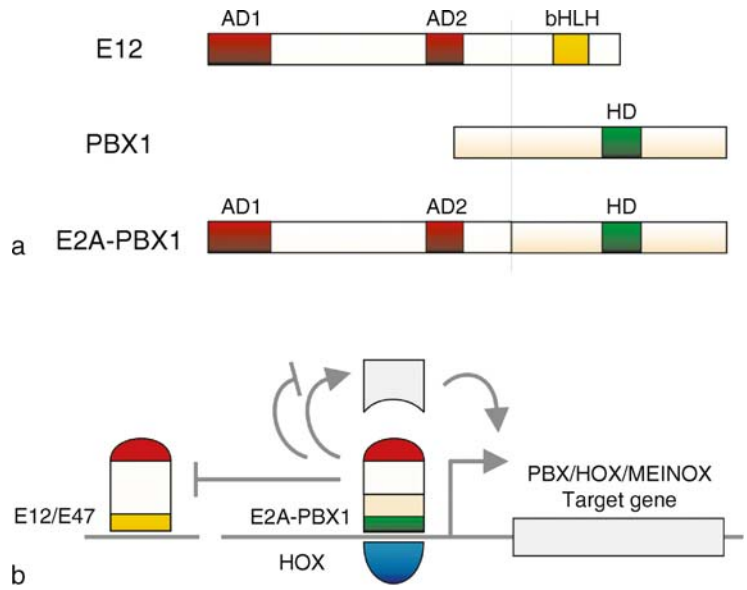
The *E2A* gene resides at chromosome band 19p13.3 and encodes two proteins, called E12 and E47, which are generated by alternative splicing of exons (Fig. 1). E12/E47 (or "E2A proteins") possess a C-terminal ►basic helix-loop-helix (bHLH) domain that mediates homo- or hetero-dimerization as well as binding to DNA at sites that contain the consensus sequence CANNTG (the ►E-box). E12/E47 function as transcriptional activators, inducing the transcription of genes that lie in the general vicinity of the E-boxes to which they bind. The E2A proteins have important roles in regulating lineage-specific cellular differentiation; their contributions to various aspects of lymphocyte development have been especially well delineated.

The *PBX1* gene, at chromosome band 1q23, was identified through its involvement in the 1;19 translocation. Its protein products, PBX1a and PBX1b, contain a homeodomain, an evolutionarily ancient domain involved in DNA binding and protein-protein interactions (►Homeobox genes and cancer). PBX1 binds to DNA and regulates the transcription of target genes in cooperation with other homeodomain-containing proteins of the HOX and MEINOX classes. These physical and functional interactions have important roles in embryonic development and tissue homeostasis. In particular, important roles in hematopoiesis are well documented.

Structure and Function of E2A-PBX1

The recombination of exons brought about by t(1;19) essentially fuses the amino-terminal two thirds of the E2A proteins (a portion that is invariant between E12 and E47) to most of PBX1. The *E2A*-encoded portion includes two transcriptional activation domains capable of inducing target gene transcription by recruiting transcriptional co-activators (►Chromatin remodeling in cancers), whereas the *PBX1*-derived portion includes the DNA-binding homeodomain.

E2A-PBX1 can function as a potently transforming oncoprotein in several cellular lineages. For example, enforced expression induces lethal lymphoproliferative diseases in transgenic mice and aggressive myeloproliferative diseases in a murine bone marrow transplantation model. The impaired cellular differentiation and accelerated proliferation that are associated with E2A-PBX1 expression result from the cumulative or cooperative effects of physical or functional interactions between E2A-PBX1 and other macromolecules. The available experimental evidence supports a general model the basis of which was originally suggested by the nature of the functional domains that are brought together in the oncoprotein (Fig. 1). Largely by means



E2A-PBX1. Figure 1 Structure and function of E2A-PBX1. (a) Translocation 1;19 results effectively in fusion of the amino-terminal two thirds of the E2A proteins (this portion is identical in the E12 and E47 isoforms) with most of PBX1. The vertical line indicates the point of fusion. AD1 and AD2, transcriptional activation domains 1 and 2; bHLH, basic helix-loop-helix domain; HD, homeodomain. (b) A model illustrating hypothetical mechanisms of neoplastic transformation by E2A-PBX1. The oncoprotein may deregulate the expression of critical genes normally controlled by PBX/HOX/MEINOX complexes, alter the function of transcriptional coactivators, or impair the function of wild-type E12/E47.

of its *PBX1*-encoded portion, E2A-PBX1 retains the ability to bind cooperatively with HOX proteins and cognate PBX/HOX binding sites on the DNA. This probably results in the abnormal expression of target genes whose transcription is normally regulated by PBX/HOX/MEINOX complexes. The retention of potent transcription-inducing potential by the E2A portion of the oncoprotein, and the documented involvement of HOX proteins (and, by implication, the target genes that they regulate) in normal and leukemia-associated hematopoiesis, are consistent with this mechanism. In a perhaps complementary mechanism, the interaction with E2A-PBX1 may alter the function of transcriptional co-activator proteins, including the histone acetyltransferases p300 and CREB-Binding Protein (CBP) (Chromatin remodeling in cancers), so as to promote neoplastic transformation in a manner at least superficially analogous to oncoproteins encoded by DNA tumor viruses such as ►Simian virus 40. Finally, E2A-PBX1 may exert dominant-inhibitory effects on the wild-type E2A proteins, as these possess tumor suppressor activities.

The *E2A* locus is involved in another translocation, t(17;19)(q22;p13), seen relatively rarely in cases of ALL. Here, a similar portion of the E2A proteins is fused to a portion of the transcription factor ►hepatic leukemia factor (HLF), including the DNA binding domain. These observations indicate the promiscuity of the *E2A* locus with respect to translocation partners and suggest the involvement of common oncogenic mechanisms in cases of ALL associated with t(1;19) or t(17;19).

Early B-cell Factors

Daiqing Liao
Department of Anatomy and Cell Biology, Shands Cancer Center, University of Florida College of Medicine, Gainesville, FL, USA

Synonyms

Early B-cell factors; EBF; Olfactory neuronal transcription factor; Olf; Olfactory/Early B-cell factors; O/E; Collier-Olf-EBF; COE

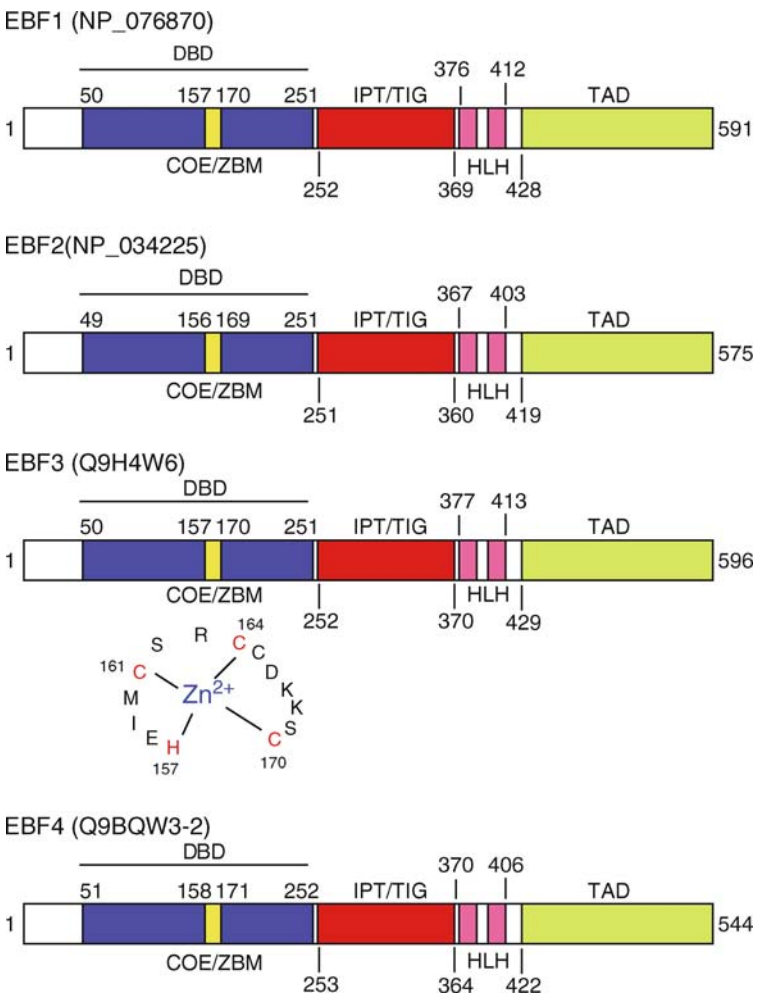
Definition

Early B-cell factors are a group of DNA-binding transcription factors containing the ►helix-loop-helix (HLH) domain. Within their highly conserved DNA-binding domain (DBD), a sequence motif consisting of an atypical zinc finger (H-X_3-C-X_2-C-X_5-C) is unique to this family of proteins.

Characteristics

Early B-cell factor 1 (EBF1) was initially isolated in 1993 from the nuclear extracts of a murine pre-B-cell line through oligonucleotide affinity chromatography. The DNA sequence of the oligonucleotide was derived from the promoter of the *mb-1* gene, encoding an immunoglobulin-associated protein that is only expressed in the early stages of B-lymphocyte differentiation. *EBF1* is essential for B-cell development, as mice lacking *EBF1* gene do not produce functional B cells and immunoglobulins. The cDNA encoding a related factor called Olf-1 was identified in the same year by screening rat cDNA clones that could activate reporter gene in yeast under the control of a synthetic promoter containing DNA elements derived from olfactory specific genes.

The EBF family is found only in the animal kingdom from *Caenorhabditis elegans* to humans. In the mouse and human genomes, there are four ►paralogous genes of the *EBF* family (EBF1–4). In humans, they localize at chromosomes *5q34*, *8p21.2*, *10q26.3*, and *20p13* for EBF1–4, respectively. Like a typical DNA-binding transcription factor, EBF proteins contain well-defined modular structural and functional domains (Fig. 1).



Early B-cell Factors. Figure 1 The structural features of EBF family of transcription factors. Shown are the four paralogs (EBF1–4) and their corresponding accession numbers (GenBank or SwissProt databases). Specific domains are shown in different color. Numbers refer to the position of amino acid residue in each protein. The signature zinc-finger motif of the EBF family of proteins in complex with zinc ion is also depicted. The different domains are DBD, DNA-binding domain; TAD, transactivation domain; COE, the signature sequence of EBF family; ZBM, zinc-binding motif; IPT/TIG, the immunoglobulin-like fold domain; HLH, helix-loop-helix motif.

The DBD near the N terminus consists of approximately 200 residues whose sequence is exceedingly well conserved throughout evolution with >75% sequence identity between distant species. This family of proteins binds directly to DNA sequences with a consensus of 5′-*CCCNNGGG*-3′ as ►homo- or heterodimers. The region following the DBD resembles the conserved domains called ►TIG-IPT (*I*mmunoglobulin-like fold, *P*lexins, *T*ranscription factors, or *T*ranscription factor *I*mmunoglobin). The function of this region in EBF has not been determined, although the TIG-IPT domain may be involved in homo- or heterodimerization in other transcription factors containing this sequence. Located next to TIG-IPT is the HLH domain that includes two helices with similar sequence. This feature distinguishes the EBF family from other HLH-containing transcription factors such as Myc, Max, and MyoD that usually contain two dissimilar amphipathic helices. The EBF HLH domain is probably involved in dimerization, as proteins with the deletion of this domain could not form stable dimer in solution. The C-terminal domain is highly rich in serine, threonine, and proline residues. It is less conserved, but is important for transcriptional activation; nonetheless, mutant without this domain could still activate transcription.

Widespread expression of *EBF* is detected in diverse cell types such as adipocytes and neuronal cells, and during different developmental stages such as limb buds and the developmental forebrain. The EBF ►orthologs in both *Drosophila melanogaster* and *Caenorhabditis elegans* is implicated in neurogenesis. During mouse embryogenesis, *EBF* members are expressed in early postmitotic neurons from midbrain to spinal cord and at specific sites in the embryonic forebrain, indicating that EBF proteins may be involved in regulating neuronal maturation in the central nervous system (CNS). Interestingly, EBF1 is abundantly expressed in the ►striatonigral medium spiny neurons (MSNs). *EBF1* deficiency in mice results in markedly reduced number of striatonigral MSNs at postnatal day 14 (P14), although such neurons are properly specified in $EBF1^{-/-}$ mice by P0. Thus, EBF1 appears to be a lineage-specific transcription factor essential to the differentiation of striatonigral MSNs. Targeted deletion of mouse *EBF2* results in defects in peripheral nerve morphogenesis, migration of hormone-producing neurons, projection of olfactory neurons, and cerebellar development. In addition to B-cell development and neuronal differentiation, EBF transcription factors are involved in other developmental processes. For example, EBF2 is a regulator of osteoblast-dependent differentiation of osteoclasts and *EBF2*-deficient mice have reduced bone mass. Furthermore, EBF1 induces adipogenesis in NIH-3T3 fibroblasts. The expression of EBF proteins in multiple tissues and their involvement in diverse developmental pathways suggest that they have fundamental cellular functions and their roles in lineage determination may be achieved through cooperation with other tissue-restricted factors.

The four paralogs of EBF members are highly similar to each other at the amino acid sequence level. It is therefore surprising that they have quite distinct functions, as *EBF3*-deficient mice exhibit neonatal lethality before postnatal day 2, and *EBF2*-null mice are much smaller than their wild type littermates, with body weight of the former being less than one half of that of the latter 30 days after birth. The N-terminal 50 amino acid residues and the entire C-terminal transactivation domain are the most divergent regions among these paralogs, although these regions are essentially identical among corresponding orthologs in different mammalian species. Therefore, functional specificity of individual EBF member may be determined by these divergent domains or through specific regulation of their expression. Indeed, the promoter sequences of the four paralogs appear quite distinct.

Potential Roles in Cancer

The *EBF3* locus at chromosome *10q26.3* is biallelically altered by genomic deletion and/or ►promoter hypermethylation in most cases of high-grade brain tumors. In a small number of examined clinical samples, the *EBF3* locus is inactivated in 50% of grade II, 83% of grade III, and 90% of grade IV (►glioblastoma multiforme) brain tumors. *EBF3* is expressed in normal brain cells, but is silenced in brain tumor cells. Thus, it is likely that EBF3 may be a tumor suppressor in the brain. EBF3 might also restrict abnormal proliferation in cancer of other tissue origins, as epigenetic silencing of *EBF3* occurs in cancer cell lines derived from breast, colon, bone, and liver. Consistent with epigenetic silencing of the *EBF3* locus, *EBF3* expression can be reactivated by treating cells with 5-aza-2′-deoxycytidine, a demethylating agent, and trichostatin A, an inhibitor of histone deacetylases. Ectopic expression of *EBF3* causes cell cycle arrest and apoptosis in cancer cells through regulating the expression of genes involved in cell cycle control. Specifically, EBF3 directly activates genes encoding the *Cip/Kip* family of ►inhibitors of cyclin-dependent kinases such as $p21^{cip1/kip1}$ and $p27^{kip1}$. Conversely, EBF3 can repress the expression of genes responsible for cell proliferation and survival such as ►*cyclins A* and *B*, *CDK2*, *Daxx*, and *Mcl-1*. Therefore, EBF3 may act as a tumor suppressor by regulating expression of specific set of genes.

In mouse B-cell lymphomas, retroviral insertions occur frequently in two genetic loci encoding Evi3 (ectropic viral integration site 3) and EBFAZ (EBF-associated zinc finger protein, also known as OAZ). Such viral integration results in heightened expression of EBFAZ or Evi3. These two proteins are highly similar to each other, with each containing 30 Krüppel-type

zinc fingers. Via several zinc fingers near its C terminus, EBFAZ or Evi3 binds to EBF and it is suggested that overexpression of EBFAZ or Evi3 in B-cell leukemias and lymphomas causes aberrant expression of EBF1 target genes that might contribute to tumorigenesis in B cells. In support of this notion, *Evi3* is significantly expressed in most human acute myelogenous leukemias. *EVi3* expression is abundant in human hematopoietic progenitors and declines rapidly during cytokine-driven differentiation. Interestingly, Evi3 or EBFAZ could either repress or activate EBF-mediated transcription, depending on cell type and gene promoter. Therefore, the precise implications of the EBFAZ–EBF pathway in cancer development remain to be determined. Finally, focal deletions of the *EBF1* locus have been detected in significant cases of B-progenitor ALL (acute lymphoblastic leukaemia).

Early Detection

Sudhir Srivastava
Division of Cancer Prevention, National Cancer Institute, Rockville, MD, USA

Definition

Refers to testing of a subject or an asymptomatic population (screening) to determine the presence of a particular disease or risk factors associated with the disease. This definition has now been extended to incorporate new thinking on early detection that incorporates (i) determination of the potential of precancerous lesions, i.e. whether or not the lesion is likely to progress and become invasive; and (ii) detection of recurrence.

Characteristics

Sustained research and clinical efforts are needed to further reduce the burden of cancer. For instance, detecting cancer in its earliest stages could provide an opportunity to treat the disease before it spreads while cancer prevention strategies could reduce a person's risk of developing cancer. One of the best ways to decrease the number of cases and deaths from cancer is to prevent the disease before it starts. Cancer prevention, however, means more than avoiding behaviors that may increase a person's risk for the disease: cancer prevention also involves identifying cells that may develop into cancer and individuals who are most likely to have these types of susceptible cells. Early cancer detection and risk assessment allow interventions to be focused on the very early stages of cancer growth, before the disease has spread beyond it site of origin. (►Preneoplastic lesions).

Biomarker Consortium

The work presented in this essay comes from investigators who are part of the National Cancer Institute's Early Detection Research Network (EDRN). The EDRN is structured around four main components: (i) Biomarkers Developmental Laboratories (BDL), which develop and characterize new biomarkers or refine existing biomarkers, (ii) Biomarkers Reference Laboratories (BRL), which serve as a resource for clinical and laboratory validation of biomarkers, including technological development, standardization of assay methods and refinement, (iii) Clinical Epidemiology and Validation Centers (CEVC) which conduct and support the early phases of clinical and epidemiological research on the application of biomarkers, and (iv) Data Management and Coordinating Center (DMCC) which provides statistical, logistical, information support and develops the theoretical statistical approaches to pattern analysis of multiple markers simultaneously. The National Aeronautics and Space Administration's Jet Propulsion Laboratory serves as the Informatics Center.

Approaches

Early Detection Markers

Ovary: Ovarian cancer is highly lethal and, thus far, has no approved or marketed early detection tests. (Transvaginal ultrasound and CA-125 are under study in large screening trials). Recent work within the Early Detection Research Network (EDRN) is leading to a molecular test that is promising and may be widely available soon. Those molecular tests include, proteomic approaches, such as serum protein profiling, testing a panel of serum markers (CA 72-4, CA 15-3, CEA, CA 19-9, SMRP-1, OV-1.10, HE-4, Osteopontin, HK-11, HK-10, Spondin-2, Prolactin and CA-125), and identification and testing of autoantibodies in cancer patients as diagnostic markers. A great focus is on development of noninvasive or minimally invasive test for earlier detection of ovarian cancer. (►Ovarian cancer).

Colon: Colon cancer is the third most frequently diagnosed cancer in the United States and the third most frequent cause of cancer death (►Colon cancer). Successful prevention of deaths from colorectal cancer depends on early detection. The widespread use of current screening technologies (fecal occult blood test, sigmoidoscopy, colonoscopy, and barium enema) could reduce deaths from the disease, but many people avoid these tests due to their discomfort. Alternate strategies to screen for colorectal cancer could identify those at greatest risk or likelihood of disease versus those who need not submit to an invasive test. EDRN investigators have identified genetic, epigenetic and protein biomarkers that correlate with the presence of colorectal cancer using serum, stool, and urine. Investigators at Evanston Northwestern Healthcare Research Institute are using cutting edge optical technologies to create a device that evaluates the anatomical architecture of the cells lining the colon. Using this technology, a doctor would be able to assess whether or not changes in the overall structure of the cells indicate a risk of developing colorectal cancer. In many cancers, small changes occur in all the tissues exposed to potential cancer-causing compounds, a concept known as field carcinogenesis. Their plan to develop a free-standing optical probe will allow a primary care physician to determine the need for colonoscopy during a digital rectal exam. Spectral markers based on two optics technologies are being employed. In a study of more than 254 people, the spectral-assisted approach was able to detect 100% of the people with cancer (sensitivity) and 88% of those without the disease (specificity). The test has ►positive predictive values and ►negative predictive values of 71 and 100%, respectively, highlighting the ability of this technique to accurately detect patients with adenomas or colon cancer.

The Drexel University EDRN BDL is collaborating with the Great Lake New England Consortium to determine whether urine can be used as a source of DNA for early colon cancer detection. Their data indicate that mutant K-ras DNA derived from colorectal cancer cells is present in human urine. While they can reproducibly detect mutant K-ras in urine, this assay does not have sufficient sensitivity and specificity. This issue is being addressed by adding multiple proto-oncogene markers to the assay. Additionally, the use of DNA methylation markers is being explored, based on the observation that the methylation status of several genes in the polyps removed during the first colonoscopy could be used to predict those patients who would have polyps during their follow-up colonoscopies.

Other Gastrointestinal Sites: Despite advances in surgical technique and multimodal therapy, the 5-year survival rate for esophageal cancer remains dismal at 5–15% (►Esophageal cancer). Advanced stage of disease at initial diagnosis and high rates of recurrence contribute to this low survival. Developing and refining methods for early cancer detection is a key to improving survival in this deadly disease. Chronic reflux of acidic gastric contents can cause gastroesophageal reflux disease or GERD. Long-term GERD, in turn, can cause Barrett esophagus, a premalignant condition that increases a patient's risk of developing esophageal adenocarcinoma. Because of this increase in cancer risk, patients with a known diagnosis of Barrett's esophagus undergo endoscopic surveillance at regular intervals, usually every two to three years. Patients may undergo these surveillance endoscopies for the rest of their lives, sometimes submitting to as many as ten in a lifetime. However, most patients with Barrett's esophagus do not progress to cancer, and a biomarker test to predict those likely to progress could reduce the number of endoscopies and improve surveillance.

Methylation of DNA is a common alteration in cancer-related genes and is often associated with complete or partial repression of transcription (►Methylation). This mechanism is an alternative pathway for inactivation of tumor suppressor genes such as *p16* and *APC* in variety of cancers. An EDRN investigator at Johns Hopkins University has developed a three-tiered risk model that incorporates both epigenetic (methylation of tumor suppressor genes) and clinical parameters to improve the efficiency of Barrett esophagus surveillance. As progression-free survival differed significantly among the three risk groups, clinicians may be able to base the frequency of endoscopies on an individual patient's risk calculated using these epigenetic and clinical parameters. A related project also involves analyzing levels of methylated DNA in plasma from patients with Barrett's esophagus or esophageal adenocarcinoma. Among 24 patients with esophageal adenocarcinoma studied to date, 70% had hypermethylated HPP1 in their blood, compared with only 13% of control subjects. Thus, DNA methylation in sera may be useful for early detection of esophageal adenocarcinoma and as prognostic or recurrence biomarkers for this deadly disease.

Markers of Preinvasive Cancer: Prostate cancer is the most frequently diagnosed non-skin cancer in men in the United States (►Prostate cancer clinical oncology). The prevalence of the diagnosis makes the disease a major health burden. While many men will die from prostate cancer, a majority of them will survive the disease as it is not uniformly fatal. Identification of aggressive forms of the disease is needed to spare men who might not need extensive treatments. Promoter methylation of several genes is a common feature of prostate cancer and high-grade prostatic intraepithelial neoplasia (HGPIN), the noncancerous

growth of cells lining the internal and external surfaces of the prostate gland which may increase the risk of developing prostate cancer. The team assembled a panel of methylated genes as a new molecular marker for early cancer detection. The assay is based on the percentage of methylated alleles (PMA). PMA values of *APC* and *RARβ2* are higher than those of *GSTP1* in HGPIN, carcinoma and normal prostate tissue; the median PMA value for all three genes is higher in prostate cancer.

Predictive Markers: Breast cancer is highly prevalent and has well-established early detection strategies available: mammograms and clinical breast exams. Molecular tests exist to help determine treatment options following breast cancer diagnoses, but prospects for blood tests to detect the disease are scant. The Food and Drug Administration has approved a micro-array-based test that looks at the expression of 70 genes linked to breast cancer which can accurately assess a patient's risk of recurrence or death. The correlations of this are vastly superior to those obtained with standard prognostic markers (►Microarray cDNA technology). The usefulness of this test is supported by the fact that the 70 genes in a woman's tumor analyzed by MammaPrint predict the 10-year survival of the patient at a significance level over three times greater than existing methods and with an accuracy level of 96.7%.

Early Genes of Human Papillomaviruses

Massimo Tommasino, Rosita Accardi, Uzma Hasan
Infections and Cancer Biology Group, International Agency for Research on Cancer, Lyon, France

E

Definition

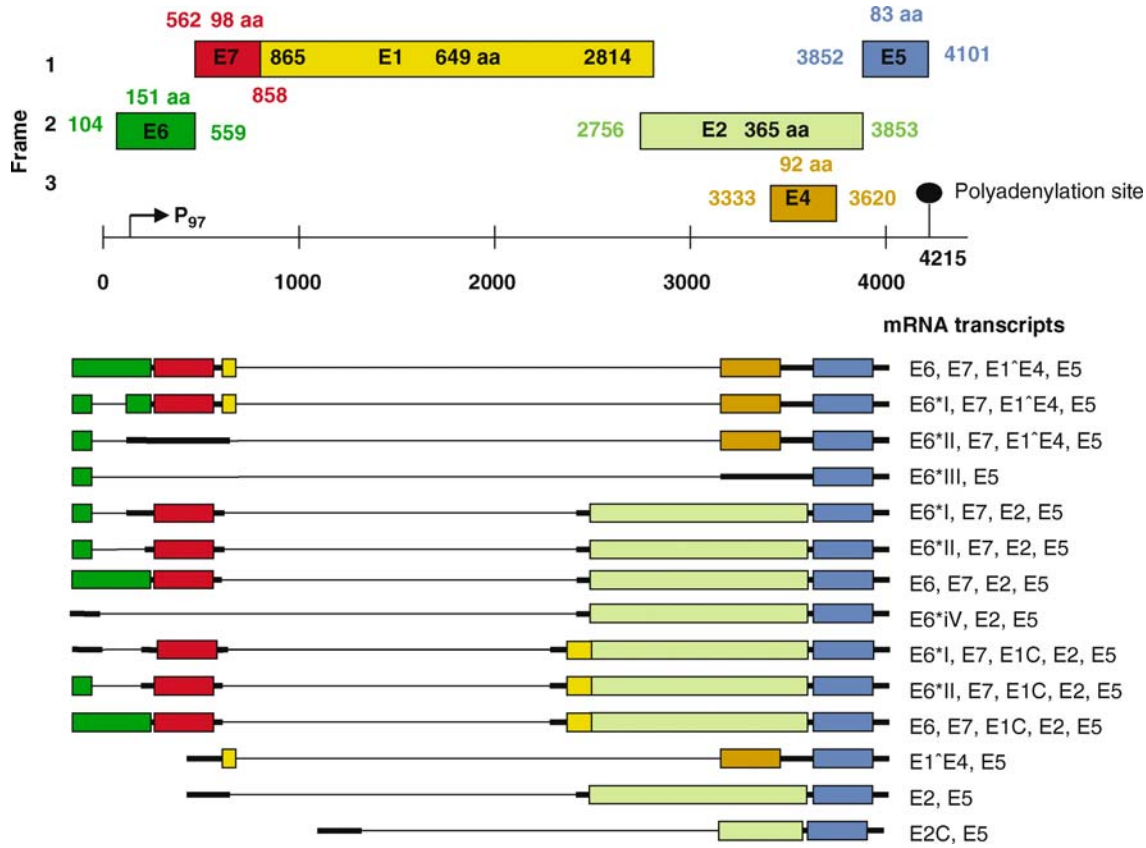
►Human papillomavirus (HPV) 16 has six early genes that are transcribed from the same DNA strand. As in other viruses, the function of the early proteins is to alter several cellular events to guarantee the completion of the virus life cycle. In addition, three early proteins, E5, E6, and E7 are also involved in the induction of malignant transformation of the infected cells. The cutaneous HPV types have a similar organization of the early region, with exception that the majority of these types lack the E5.

Characteristics

HPV constitutes of a heterogeneous group of viruses from the *Papillomaviridae* family. The HPV phylogenetic tree has been designed based on the homologous nucleotide sequence of the L1 capsid protein. So far, 92 HPV types have been fully sequenced, of which 60 belong to the alpha genera and the other 32 belong to the beta and gamma genera. Based on their tissue-tropism, HPVs can be divided in cutaneous and mucosal HPV types. The mucosal HPV types are included in the genus alpha together with certain benign cutaneous HPV types, whereas the beta and the gamma genera exclusively consist of cutaneous HPV types. Biological and epidemiological studies have clearly demonstrated that certain mucosal HPV types are associated with ►cervical cancer. On the contrary, the role of cutaneous types in carcinogenesis is still under debate, although several lines of evidence support their association with nonmelanoma skin cancer (NMSC). The mucosal HPV type 16 (HPV16) is the most frequently found HPV genotype in cervical cancers worldwide, and thus its early gene products are the best studied and characterized. (Fig. 1).

HPV16 E6 and E7 are the major transforming proteins. Three different lines of evidence have demonstrated the involvement of E6 and E7 in cervical carcinogenesis.

1. The first indication came from the analysis of HPV-infected cells, which showed that viral DNA is randomly integrated in the genome of the majority of cervical carcinomas. Integration leads to the



Early Genes of Human Papillomaviruses. Figure 1 Organization of the early region of HPV16. The six early genes are represented by using different colors. The nucleotide positions of each early gene and the predicted size in amino acids are also shown. Several polycistronic transcripts have been identified, which comprise of 2–3 early genes in different combinations and are most likely transcribed from the P_{97} promoter. The function of each transcript is not known, but some of them are only transcribed at different stages of differentiation. Several lines of evidence indicate that the alternative splicing in E6 and E7 transcripts play an important role in the translational regulation of the viral proteins.

disruption of several viral genes with preservation of only the E6 and E7, which are actively transcribed.
