►*Protease Activated Receptors* (PARs) form a family of seven transmembrane ►G- protein coupled receptors consisting of 4 gene members. PAR1, 3 and 4 respond to the serine protease thrombin while PAR2 is activated by trypsin, tryptase and the coagulation factors VIIa and Xa, but not by thrombin. All members are uniquely activated via proteolytic cleavage that exposes an otherwise hindered ligand at their N-terminus extra cellular portion. PARs can be viewed as receptors that carry their own ligands. In addition to thrombin, PARs convey cellular responses to a wide spectrum of serine proteases as also the ►matrix metallo protease 1, MMP1. PARs1-4 are similarly organized, all encoded by two exons and separated by an intron of variable size. Exon 1 encodes a signal peptide, and exon 2 encodes the mature receptor protein. In humans, PARs1-3 are localized on chromosome 5q13.

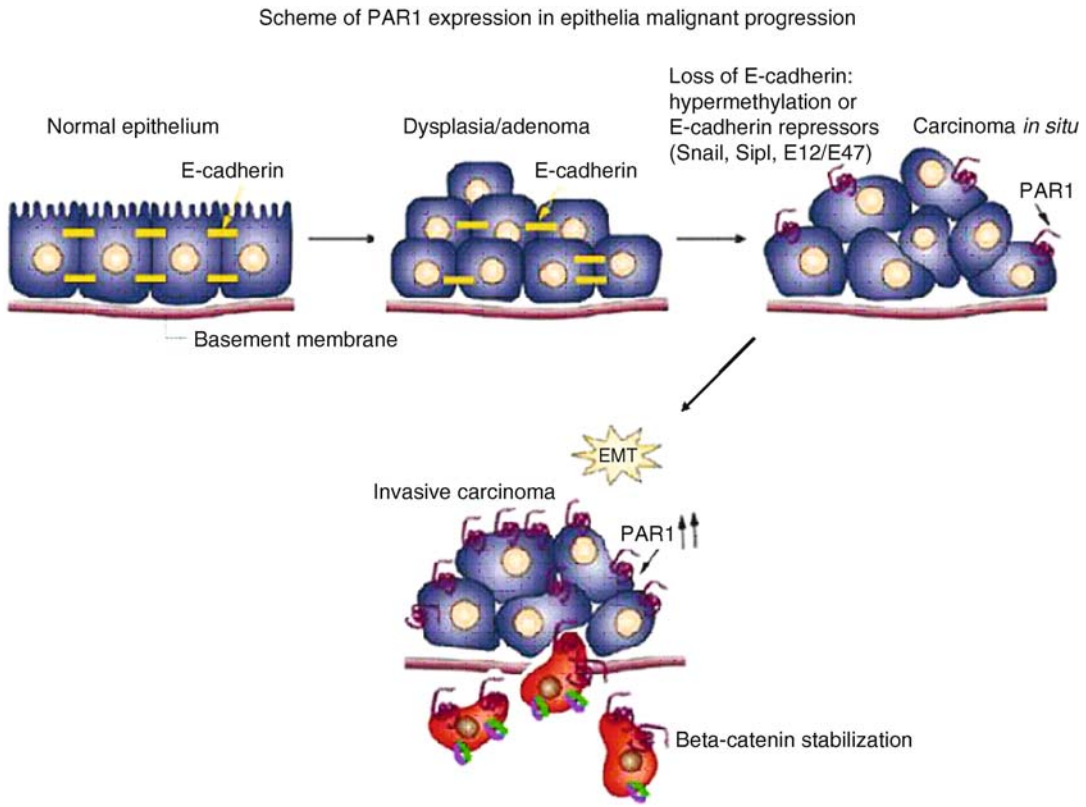
Characteristics

Protease Activated Receptors (PARs) belong to the large group of ►G-protein coupled receptors (GPCRs) of seven transmembrane domain proteins, uniquely activated by proteolytic cleavage. While originally established as thrombin receptors, they serve nonetheless as cell surface sensors that convey signaling to an array of serine-proteases and a matrix metallo protease, MMP-1. In addition to their critical roles in thrombosis, hemostasis, inflammation and vascular biology, PAR1 emerges with considerable assignments in tumor biology (►Epithelial tumors) and ►angiogenesis. PARs possess an unusual mode of activation. These receptors carry their own ligand/s, hindered in the non-activated state and exposed after proteolytic cleavage at their N-terminal, extra cellular portion. Once exposed, the ligand remains tethered and interacting with loop number two and initiates cell signaling. Alternatively, proteolytic cleavage can be bypassed by ectopic application of a synthetic peptide representing the internal ligand sequence that directly associates with loop number two for cellular signaling. The mechanism of PAR1 activation is striking also because of its shut-off mechanism. PARs are irreversibly activated and their desensitization and cell trafficking control, in part, the magnitude and duration of PARs signaling. Human PAR1, PAR3, and PAR4 are all activated by thrombin. In contrast, PAR2 is activated by trypsin and tryptase as well as by coagulation factors VIIa and Xa, but not by thrombin. PAR1 is the first and prototype member of the family, originally discovered in a search for a functional receptor that confers thrombin signaling in human platelets. PAR2 was next identified in a screen of a mouse genomic library using probes homologous to the transmembrane regions of substance K receptor. Studies in PAR1 knock-out mice showed fifty percent lethality with no effect on thrombin signaling in mice platelet, but abrogated thrombin signaling in fibroblasts. These unexpected findings initiated the exploration and identification of PAR3 and PAR4. The latest family members revealed a selective expression pattern in human and mice platelets. While PAR1 and PAR4 are the functional receptors of thrombin in human platelets, PAR3 and PAR4 are responsible for thrombin signaling in the mice platelets.

The notion that *hPar1* is one of a series of genes that are part of an invasive program stems from studies showing that *hPar1* expression correlates directly with the invasion properties of breast carcinoma (Fig. 1) and of trophoblast placenta physiological invasion into the uterine decidua. In fact, *hPar1* plays an active role in breast carcinoma invasion because antisense silencing of the gene abrogates efficiently metastatic breast carcinoma cells (►Breast cancer) from invading Matrigel-coated filters, *in vitro*. PAR1 expression is found high in a wide spectrum of ►epithelia malignancies (e.g., colon, breast, prostate, ovary, esophagus, pancreas, etc) as compared to no expression in normal epithelia shown both in a collection of tissue biopsy specimens and differentially metastatic cell lines. In prostate cancer (►Prostate cancer clinical oncology) PAR1 has been implicated in bone metastasis and the over expression of PAR1 in murine and human melanoma have yielded enhanced experimental lung metastasis in mice. In colon cancer PAR1 has been demonstrated to cross talk with EGFR, thereby promoting cell proliferation. In parallel, a cDNA expression library screen based on the loss of anchorage-dependent growth and focus-forming activity in NIH3T3 cells have identified PAR1 as a novel ►oncogene. With these observations, PAR1 joins other GPCRs, encoded by *mas* and *g2a*, that behave as oncogene. The oncogenic properties of PAR1 accompany a collection of data showing that *hPar1* is over expressed in a wide range of epithelial tumors, pointing altogether to the central role of PAR1 in carcinoma invasion.

PAR1 has been shown to promote tumor progression through several mechanisms on different levels. PAR1 has been shown to promote cell growth, invasion, and metastasis, and also contribute to tumor cell survival by preventing the apoptotic pathway.

In a xenograft nude mice model, it was demonstrated that the expression of PAR1 in non invasive MCF7 breast carcinoma is sufficient to promote growth and invasion. In contrast, when a truncated form of *hPar1*, devoid of the entire cytoplasmic tail, is introduced to MCF7 cells and injected to the mice mammary fat pads, tumor development was markedly attenuated (Cohen I and Bar-Shavit R manuscript in preparation). This outcome underscores the significance of PAR1 signaling in tumor progression and invasion.

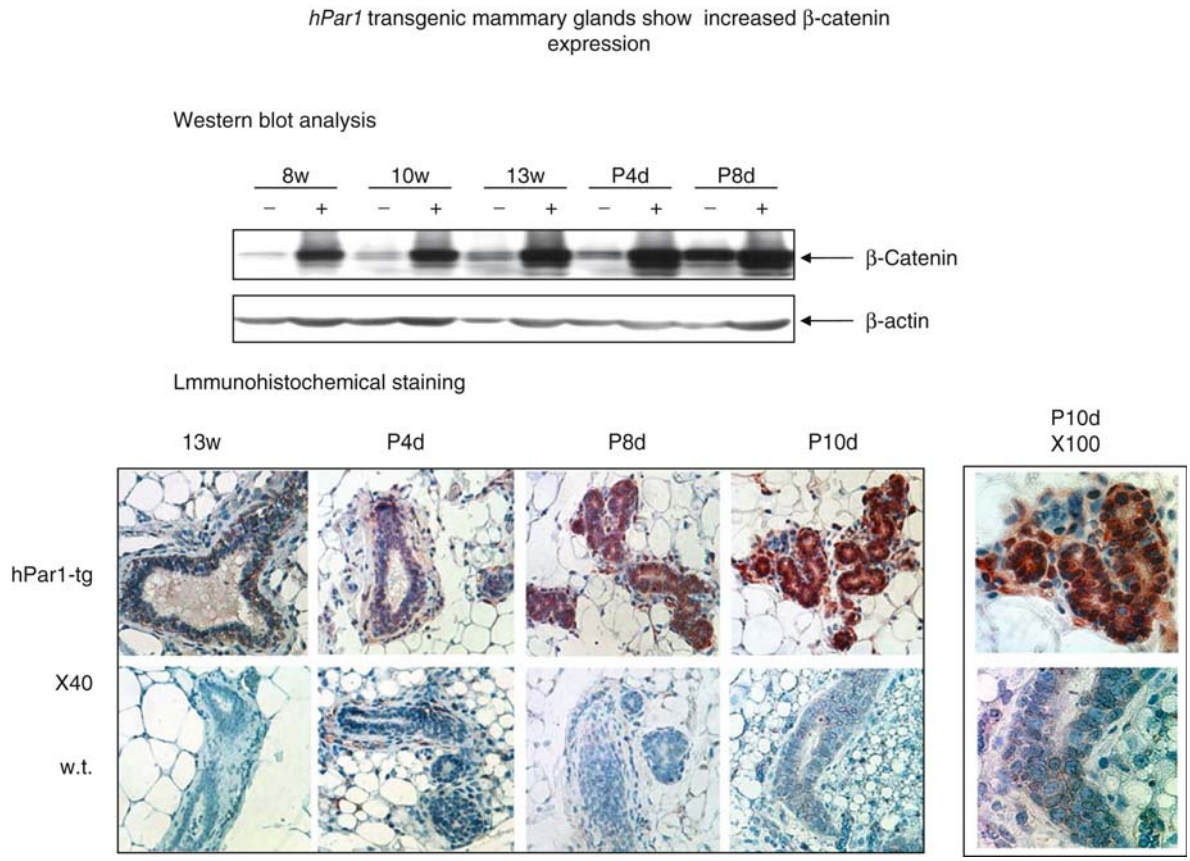


Protease Activated Receptors. Figure 1 Schematic illustration of PAR1 pattern of expression, along the progression of epithelia malignancy. While no PAR1 is seen in either normal or dysplastic tissues, PAR1 expression is high in DCIS (ductal carcinoma in situ) IDC (invasive ductal carcinoma).

Since PARs are irreversibly activated, signaling must be tightly regulated. Part of this regulation is the extent and mode of cell surface receptor internalization targeted to lysosomal degradation. Cellular trafficking of the proteolytically activated PARs leads to its desensitization, thereby controlling the magnitude, duration and spatial aspects of receptor signaling. In breast carcinoma, in addition to PAR1 over expression, these cells display aberrant PAR1 trafficking, which causes persistent signaling and cellular invasion.

Tissue factor is also up regulated in many tumor cells and supports FVIIa and FXa activity. TF bound to FVIIa can activate PAR2, whereas FXa can signal through either PAR1 or PAR2. There is increasing evidence that PAR2 is also an important mediator of tumor progression. Trypsin, a potent and physiological activator of PAR2, is elevated in gastric, colon, ovarian and lung tumors.

To gain further insight into the causal relationship between *hPar1* expression, breast tumor formation and mammary gland development, a line of mice carrying MMTV-driven *hPar1* designated to over express in the mammary glands was established. These mammary glands exhibited hyperplasia characterized by a dense network of ductal side branching and accelerated proliferation. In addition, these glands showed increased levels of *wnt-4* and *wnt-7b* and the striking stabilization of β-catenin. The canonical *wnt/wingless* signaling pathway directs cell fate in many cell types and plays a central role in development and in tumor progression. The core event of the *Wnt* pathway (►Wnt signaling) is the stability of β-catenin. Nuclear localization of β-catenin is observed in *hPar1* transgenic mice tissue sections but not in the wild-type age-matched counterparts (Fig. 2). PAR1 also induces β-catenin nuclear localization in established epithelial tumor cell lines. Once localized in the nuclei, β-catenin forms functional complexes with the lymphoid enhancer factor (Lef)/T-cell factor (Tcf) transcription factors. Introducing *hPar1 Si*RNA constructs depleting efficiently *hPar1* levels efficiently inhibited *wnt-4* expression. Therefore, it is proposed that PAR1 induced ►β-catenin stabilization is mediated in part via the generation of *Wnt/s*. The novel link between PAR1, β-catenin and *Wnt* may impinge significantly on both development and tumor progression processes.



Protease Activated Receptors. Figure 2 *hPar1- tg* mammary glands show hyperplasia and increased β-catenin expression in the nuclei**.** A. Whole mount hematoxylin staining of *wt* and *hPar1*-tg mammary glands at different developmental stages. The epithelial tissue derived from the *hPar1*-tg mammary glands displays increased lateral branching and pervasive intraductal hyperplasia in virgin (V-13w) and pregnant mammary glands (days 8 and 12 of pregnancy, respectively. B. Western blot analysis of β-catenin expression in *hPar1-tg* mammary glands at different developmental stages compared with age matched wt mammary glands. C. Immunohistochemical staining shows β-catenin localization in the mammary glands of *hPar1-tg* and wt mice. At 8 & 10 days of pregnancy, nuclear β-catenin is observed in *hPar1-tg* mice but not in *wt* mice (×40). At 10d of pregnancy a higher magnification is shown (×100).

Protease Signaling

Definition

For example the protease-activated receptors (PARs) convey protease cellular signaling.

Proteases

Definition

Proteins with enzymatic function (or enzymes) capable of catalyzing the hydrolysis of peptide bonds in

proteins. Synonyms: proteolytic enzymes; exopeptidases (amino- or carboxypeptidases); endopeptidases (or proteinases). Depending on the amino acid or chemical group involved in the enzymatic catalysis, proteases are divided into different classes:

- serine-proteases (serine residue)
- cysteine-proteases (cysteine residue)
- aspartyl-proteases (aspartic acid residue)
- metallo-proteases (bivalent cation, e.g. Zn^{2+} or Mg^{2+})
- threonin-proteases (threonin residue)

►Cystatins

Proteasomal Cleavage

Definition

►Proteasomes are large protein complexes that degrade unneeded or damaged proteins by proteolysis. This process is initiated by the addition of an ubiquitine tag to these proteins. The ubiquinated proteins are subsequently cleaved into seven to eight amino acids long peptides, which can be degraded further into single amino acids.

►Proteasome Inhibitors

Proteasome

Definition

Synonym prosome or macropain; Is a large protein complex that functions mainly to degrade unneeded or damaged proteins by proteolysis, a chemical reaction that breaks peptide bonds. Proteasomes are a major mechanism by which cells regulate the concentration of particular proteins and degrade misfolded proteins. Proteasomal degradation yields peptides of about seven to eight amino acids long. Those peptides can be further degraded into amino acids that can subsequently be used for the synthesis of new proteins. Proteins are marked for proteasomal degradation by a small protein called ubiquitin, which is attached to the target protein by enzymes called ubiquitin ligases. Once a protein is tagged with a single ubiquitin molecule, this is a signal to other ligases to attach additional ubiquitin molecules. The result is a polyubiquitin chain that is recognized by the proteasome, whereupon the tagged protein is degraded.

Definition

►Proteasomes are multi-subunit ►protease complexes that selectively degrade ►ubiquitinated intracellular proteins. ►Proteolysis is essential for normal cell cycle progression, inflammation, transcription, DNA replication, and spontaneous ►apoptosis. The ►Ubiquitin-Proteasome System (UPS) mediates normal intracellular protein degradation; conversely, blockade of UPS with proteasome inhibitors trigger apoptosis in tumor cells. Bortezomib (Velcade™), the first in class of proteasome inhibitors, has become a standard therapy for treatment of refractory ►multiple myeloma (MM).

Characteristics

Rationale for Therapeutic Utility of Targeting Proteasome. Many cellular proteins, such as those regulating metabolism, cell cycle, growth, survival, stress and immune responses, are substrates of proteasomes. The UPS pathway is responsible for elimination of most of the misfolded, short or long-lived, proteins in the cell; conversely, blockade of proteasome-mediated protein degradation results in intracellular accumulation of unwanted/toxic proteins, induction of heat-shock response, and apoptosis. Because protein breakdown is a component of normal cellular functioning, the notion of targeting proteasomes as an anti-cancer therapy was initially viewed with cynicism, due to potential apoptotic activity against normal cells. Inhibition of proteasome activity is more cytotoxic to malignant than normal cells, thereby providing an acceptable therapeutic index. Additionally, proteasome inhibition abrogates pro-survival signaling pathways. For example, nuclear factor-kappa B (NF-κB) mediates growth and drug-resistance in cancer cells; conversely, proteasome inhibitors downregulate NF-κB, thereby enhancing

the cytotoxic effects of chemotherapy. Together, these findings support the notion of targeting proteasomes in novel therapeutics.

Proteasome and Its Functional Inhibitors. The 26S proteasome complex consists of 19S units flanking a barrel-shaped 20S proteasome core; the 19S units regulate entry of proteins marked for degradation into the 20S core chamber. Protein breakdown *via* UPS is a multi-step process: protein is first labeled with ubiquitin molecules; E1 ubiquitin enzyme then activates ubiquitin and links it to the ubiquitin-conjugating enzyme E2; E3 ubiquitin ligase then links the ubiquitin molecule to the protein; a long polypeptide chain of ubiquitin moieties is formed; and finally, proteasomes degrade the protein into small fragments and free ubiquitin for recycling.

The three primary proteolytic activities of the proteasome are chymotrypsin-like (CT-L) (beta-5), trypsin-like (beta-1) and caspase-like (beta-2) proteolytic activities; all reside within the 20S proteasome core. Natural and synthetic inhibitors of the UPS pathway include peptide epoxyketones, peptide aldehydes, non-peptide inhibitors, peptide boronates, and peptide vinyl sulfones. Peptide aldehydes (e.g. MG-132, ALLN) potently, but reversibly, block the CT-L activity; they also inhibit lysosomal cysteine and serine proteases as well as calpains, thereby limiting their clinical utility. Lactacystin is a natural, irreversible, nonpeptide inhibitor; the clasto-lactacystin beta-lactone, an analog of its active metabolite, is currently in phase-I clinical trails.

The dipeptidyl boronic acid Bortezomib/PS-341 is a reversible inhibitor of CT-L activity and exhibited remarkable anti-tumor activity against 60 NCI tumor cell lines. Preclinical studies showed that Bortezomib induces MM cell apoptosis, downregulates adhesion molecules, inhibits constitutive and MM cell-adhesion-induced cytokine secretion, and blocks angiogenesis in the BM milieu. These laboratory studies translated into Phase-I trials, which showed safety and acceptable toxicity. Phase II clinical trials showed durable responses, with associated clinical benefits, and these results led to the FDA approval of Bortezomib for the treatment of patients with MM. A randomized Phase-III trial showed higher responses as well as prolonged time to progression and survival in patients treated with Bortezomib versus Dexamethasone, providing the basis for extension of FDA approval to include relapsed MM. While Bortezomib therapy is a major advance in the treatment of MM, it is associated with toxicity and the development of drug-resistance. Ongoing studies are delineating the mechanisms mediating Bortezomib-triggered cytotoxicity and drug resistance in order to design novel therapeutic strategies to both enhance anti-MM activity of Bortezomib and overcome drug resistance.

Mechanisms Mediating Bortezomib-Induced Apoptosis in MM Cells

Blockade of Pro-Survival Signaling. Treatment of MM cells with Bortezomib is associated with inhibition of a major survival signaling pathway mediated *via* NF-κB. Specifically, adhesion of MM cells to bone marrow stromal cells (BMSCs) triggers NF-κB-mediated transcription and secretion of IL-6 and insulin like growth factor-I (IGF-I), both of which promote survival and conventional drug resistance in MM cells in the BM milieu; conversely, treatment of MM cells with Bortezomib inhibits not only NF-κB activation, but also its downstream targets and related cytokine production, thereby overcoming the survival advantage for MM cells conferred by BMSCs. Importantly, NF-κB inhibition alone does not account for the overall anti-MM activity of Bortezomib. Besides NF-κB, Bortezomib downregulates MAPK/JAK-STAT growth/survival signaling pathway, and disables DNA-repair machinery *via* inactivation of DNA-PK. Treatment of MM cells with Bortezomib is not always associated with the inhibition of pro-survival signaling, as in the case of NF-κB, but can also induce pro-survival signaling, such as Akt phosphorylation or heat shock proteins (hsp-27/70/90). These *in vitro* findings have already led to phase-I clinical trials of combined Bortezomib therapy with agents that specifically block Akt or hsp's in an attempt to enhance the anti-MM activity of Bortezomib.

Induction of Pro-Apoptotic Signaling. Gene profiling and proteomic studies show that Bortezomib-induced apoptosis is associated with induction of apoptotic signaling pathways: (i) upregulation of pro-apoptotic c-Jun-NH2-terminal kinase (JNK); (ii) induction of ER-stress response *via* GADD153, CHOP, or PERK; (iii) change of mitochondrial membrane potential and production of reactive oxygen species (ROS); (iv) the release of mitochondrial proteins cytochrome-c/Smac into cytosol, resulting in activation of caspase-9 > caspase-3 cascade; and (v) activation of the extrinsic apoptotic cascade *via* caspase-8 cleavage. Studies using dominant negative strategies and knockout cell line models have established a direct role for JNK and Bax/Bak during Bortezomib-induced apoptosis. Additionally, Bortezomib also affects signaling events upstream of mitochondria; i.e. Ca^{2+} influx into mitochondria triggers cyto-c release and caspase-9-mediated apoptosis, whereas treatment of MM cells with mitochondrial Ca^{2+} uptake inhibitor abrogates Bortezomib-triggered apoptosis. Bortezomib-induced apoptosis involves activation of ER-related stress pathways, including activation of caspase-12.

Clinical Relevance

The multiple signaling pathways associated with Bortezomib-induced cytotoxicity or the development of resistance suggest that combinations of Bortezomib with other conventional and novel agents may both

enhance its anti-tumor activity and overcome drug-resistance. Combined Bortezomib and irinotecan treatment triggers apoptosis in pancreatic tumor xenografts and enhances chemosensitivity in colorectal cancer xenograft models. Studies to date in MM show that combining Bortezomib with Dex, Doxorubicin, or Melphalan, induces additive or synergistic anti-MM activity. Treatment of MM cells with Bortezomib and novel agents Lenalidomide or triterpenoids CDDO-Imidazolide induces synergistic anti-MM activity and overcomes Bortezomib-resistance by activating both intrinsic (*via* caspase-9) and extrinsic (*via* caspase-8) apoptotic signaling, thus providing the rationale for clinical protocols using combination regimens. Microarray analysis of Bortezomib-treated MM cells shows robust induction of hsp-90 in MM cells; conversely, blockade of hsp-90 with 17-AAG enhances sensitivity and even overcomes Bortezomib-resistance. Ongoing phase-1 clinical trials show promise of combined therapy in Bortezomib refractory MM. An alternative aggresome cascade for protein catabolism in MM cells may be significant: histone deacetylase-6 (HDAC-6) is required for the chaperoning of ubiquitinated proteins for aggresomal degradation; and conversely, blockade of HDAC triggers modest anti-MM activity. However, simultaneous blockade of proteasomes and aggresomes with Bortezomib and HDAC inhibitor, respectively, triggers additive/synergistic cytotoxicity, providing the framework for clinical translation of this new class of cancer therapeutics.

New Proteasome Inhibitor NPI-0052

The novel proteasome inhibitor NPI-0052 can overcome Bortezomib-resistance in MM cells. NPI-0052 is a small molecule derived from fermentation of Salinospora, a new marine gram-positive actinomycete. NPI-0052 is a nonpeptide proteasome inhibitor with structural similarity to Omuralide, a beta-lactone derived from naturally occurring lactacystin. NPI-0052, in contrast to Omuralide, possess a uniquely methylated C3 ring juncture, chlorinated alkyl group at C2, and cyclohexene ring at C5, which accounts for its higher anti-tumor activity than omuralide. Initial screening of NPI-0052 against the NCI panel of 60 tumor cell lines showed GI50 of <10 nM in all cases. (i) NPI-0052 triggers apoptosis in MM cells sensitive and resistant not only to conventional, but also to Bortezomib, therapies; (ii) The IC^{50} of NPI-0052 for MM cells is within the low nanomolar concentration; and (iii) NPI-0052 is less toxic to normal PBMNCs than Bortezomib. Importantly, NPI-0052 similarly triggered apoptosis in purified tumor cells from several MM patients relapsing after various prior therapies, including Bortezomib and thalidomide.

The mechanism whereby NPI-0052 overcomes Bortezomib-resistance in MM cells are now been defined. For example, NPI-0052 and Bortezomib differentially affect 20S proteasomal activities. The comparative kinetics of proteasomal activities suggests that NPI-0052, in contrast to Bortezomib, triggers a sustained inhibition of CT-L, T-L and C-L activities (up to 7 days). Simultaneous inhibition of multiple proteasome activities is a prerequisite for significant (i.e. >50%) proteolysis. Therefore NPI-0052 may block more protein breakdown than Bortezomib in MM cells. Moreover, mechanisms conferring Bortezomib-resistance may not be effective against NPI-0052.

NPI-0052 is a potent inducer of apoptosis in tumor cells obtained from Bortezomib-refractory MM patients. Examination of signal transduction pathways further showed that (i) NPI-0052 is a more potent inhibitor of NF-κB and related cytokine transcription and secretion than Bortezomib; (ii) NPI-0052-induced MM cell-death is predominantly mediated by caspase-8; and (iii) Bortezomib-induced apoptosis requires both caspase-8 and caspase-9 activation. These findings confirm differential actions of NPI-0052 *versus* Bortezomib in MM cells. Animal studies using a human plasmacytoma xenograft mouse model showed that NPI-0052 inhibited MM tumor growth and prolonged survival of mice at concentrations which were well tolerated and without either significant weight loss or any neurological behavioral changes. Analysis at day 300 showed no recurrence of tumor in 57% of NPI-0052-treated mice. Together, these data provide the preclinical framework for the ongoing multi-center phase-I clinical trial of NPI-0052 in MM patients.

Proteasome (prosome, macropain) 26S subunit, non-ATPase, 10

►Gankyrin

26S Proteasome

Definition

A multicomponent complex within the cell responsible for processing and degrading ubiquitinated proteins that are target for degradation via the ubiquitin signal. A multicatalytic proteinase complex composed of a 20S core and a 19S regulator. The 19S regulator is composed of a base, which contains six ATPase subunits and two non-ATP subunits, and a lid, which contains up to 10 non-ATPase subunits.

Protein Kinase C

Hans H. Grunicke
Biocenter, Division of Medical Biochemistry, Medical University of Innsbruck, Innsbruck, Austria

Definition

Protein kinase C (PKC) represents a family of serine/threonine protein kinases comprising at least 11 structurally related enzymes. PKC isozymes have been grouped into three subfamilies. The conventional or classical PKCs (cPKCs) can be activated by Ca^{2+}, diacylglycerol (DAG) or phorbol esters and include the isotypes α, β I, β II and γ. Novel PKCs (nPKCs), comprising the isoforms ó, ε, δ, η and θ are also activated by DAG or phorbol esters but are Ca^{2+}-independent. The more recently discovered "atypical" PKCs (aPKCs) ι (the mouse homologue of ι has been termed λ) and ζ are Ca^{2+}- and DAG-independent and do not respond to phorbol esters. Each PKC isozyme is encoded by a separate gene with the exception of PKC β I and β II, which represent alternative spliced variants.

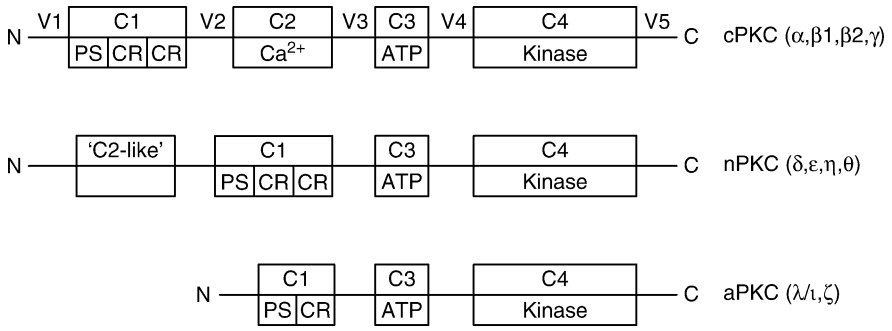
Characteristics

Each PKC isozyme consists of a single polypeptide containing an amino-terminal regulatory domain and a carboxy-terminal catalytic domain connected by a hinge region that is highly sensitive to proteolytic cleavage by cellular proteases (Fig. 1). The enzymes possess regions that are highly conserved between different PKC isoforms (termed C1–C4) and five variable regions (V1–V5).

1. The C1 region, which is present in all PKC isozymes, contains an autoinhibitory pseudosubstrate domain. The amino acid sequence of the pseudosubstrate domain resembles the phosphorylation motifs in PKC substrates but contains an alanine instead of the serine or threonine, which act as phosphate acceptors in PKC substrates. The C1 region of cPKCs and nPKC contains two cysteine-rich domains in tandem orientation, which serve as DAG- or phorbol ester binding sites. Only one copy of this cysteine-rich domain is found in DAG- and phorbol ester- non-responsive aPKCs.
2. The C2 region of the cPKCs has been identified as the Ca^{2+}-binding site. A homologous region is also found in nPKCs but the absence of a critical aspartate residue renders this C2-domain incapable of Ca^{2+}-binding. Atypical PKCs lack a C2 domain. The C3- and C4-domains are parts of the catalytic region. ATP is bound to the C3 region, whereas the C4 domain contains binding sites for substrates.

Mechanism of Activation

Activation of PKC requires an unmasking of the catalytic domain by the removal of the pseudosubstrate. The necessary conformational change is mediated by the binding of DAG or phorbol ester in the presence of a lipid cofactor, especially phosphatidyl-serine. Other lipids, like free fatty acids, phosphatidyl-choline, lysophosphatidic acid and phosphatidyl inositol 3,4,5-trisphosphate, can also act as co-factors for some PKC isotypes. There is evidence that the pseudosubstrate sequence, once removed from its binding site, may contribute to membrane binding through its basic residues; a process that is also controlled by protein-protein interaction. Membrane association or translocation to membrane compartments is often considered as a hallmark of PKC activation. Ca^{2+} has been shown to increase the affinity of cPKCs to acidic phospholipids. In addition to allosteric regulation by Ca^{2+} and lipid co-factor, phosphorylation of PKC is essential for enzyme activation. The enzyme phosphoinositide dependent kinase 1 (PDK1) has been identified as a major upstream kinase catalyzing phosphorylation probably of all PKC isotypes within the activation loop of the C4 domain of the catalytic region. In cPKCs, the PDK1-mediated phosphorylation is followed by phosphorylation on two additional sites within the V5-region of the carboxy-terminal sequence, probably due to autophosphorylation. Autophosphorylation of one site, Thr-641, is essential for the catalytic activity of nPKC δ. Novel PKC δ is the only PKC isoform that is subject to phosphorylation on tyrosine residues. However, the biological significance of the tyrosine phosphorylation of PKC δ remains controversial. Protein-protein interaction appears of particular relevance for the regulation of atypical PKCs. LIP (λ/ι interacting protein) has been identified as a PKC λ/ι



Protein Kinase C. Figure 1 Structure of PKC isozymes: C1–C4, constant regions; V1–V5, variable regions; PS, pseudosubstrate domain; CR, cysteine-rich region; ATP, ATP-binding domain; Ca^{2+}-binding domain (note that the C2 region in nPKCs is uncapable of Ca^{2+}-binding as outlined in the text).

specific activator. Binding of par-4 to aPKC λ/ι or a PKC ζ inactivates the enzyme.

PKC-Binding Proteins

PKC-interacting proteins can be classified into different subgroups according to their function:

1. PKC substrates (also termed STICKS)
2. Regulatory proteins like LIP, par-4, or syndecan-4
3. Docking proteins like RACKS, AKAPS or caveolin that may be involved in regulating the intracellular localization of PKCs
4. Scaffolding signaling proteins that cluster specific PKC isoforms together with other signaling elements in order to regulate a particular signal transduction pathway

Putative PKC scaffolds include ZIP and proteins of the 14-3-3 family. This list of PKC-binding proteins is incomplete and grows continuously. The techniques employed to detect PKC-interacting proteins, e.g. the yeast two-hybrid system or overlay assays, do not always prove that these interactions occur in vivo and do not indicate the biological significance of this interaction. Therefore, these data should be interpreted with caution.

Bioactivity

Enzymes of the PKC family are important elements of intracellular signal transduction. They are differentially involved in the regulation of a broad variety of cellular functions: These include proliferation; differentiation; ►apoptosis; immune response; release of messengers from endocrine, exocrine and neuronal tissues; modulation of ion channels, receptors, transporters; organization of the cytoskeleton; contraction and basal tone of smooth muscles. In many cases, however, the implication of PKC is based on effects obtained with phorbol esters or PKC-inhibitors. Since none of them are PKC-specific, the role of PKC in several systems needs to be re-examined. More specific techniques that are now available include depletion of defined PKC-isozymes by siRNA, antisense techniques, expression of dominant negative or constitutively active mutants of particular isoforms, and generation of "knock-out" mice lacking functional alleles for a defined PKC isoform.

PKC in Cancer

PKC first attracted the attention of oncologists when it was found that PKC acts as a highly specific receptor for the classical tumor promoting phorbol esters like ►TPA. The mechanism by which TPA exerts its tumor promoting activity is still unclear. Elucidation of the mechanism of action of phorbol esters is hampered by the fact that they act in a bimodal fashion; after an initial activation of phorbolester-responsive PKC isozymes, they cause a depletion of these proteins. Thus, it is unclear whether the phorbol ester effect is due to an activation or an inhibition of a PKC-mediated reaction. Furthermore, in addition to PKC, other highly specific non-kinase receptors for phorbol esters have been described, including the chimerins, Munc13/1 and RasGRP. Binding to these receptors is activated by the same co-factors activating c- and nPKCs and inhibited by classical PKC inhibitors. Interestingly, chimerins act as Rac-GAPs, thereby regulating the duration of the active state of the Ras-homology protein Rac. Ras-GRP functions as an guanylate nucleotide exchange factor for Ras and activates Ras by promoting the GTP-charged form of Ras. Thus, the chimerins as well as Ras-GRP should be considered as perhaps equally important as PKC in tumor promotion.

The implication of a role of the enzymes of the PKC family in the regulation of cellular proliferation is documented by a vast number of studies. However, when the effects are analyzed with respect to individual PKC isotypes, the observations are frequently contradictory and generally confusing. For instance, PKC α has been described as activated and overexpressed in several tumors, like hepatomas and breast cancer, and

to transform MCF7 cells following ectopic overexpression. However, in B16 melanoma cells or K562 cells ectopic expression of PKC α was found to inhibit cellular proliferation or to induce differentiation. Similar controversial findings have been reported for PKCs β, γ and ζ. Thus, the function of PKC isozymes is to a great extent cell type dependent. A more general picture has emerged with regard to nPKC ε, which was found to act as a growth-promoting enzyme in most systems, except in neuronal cells. Overexpression of PKC ε leads to transformation in fibroblasts and epithelial cells. Based on these findings, the PKC ε encoding gene is considered to represent an oncogene. Expression of dominant negative aPKC λ/ι reverses transformation by Ras. These and other findings (see below) suggest that PKC λ/ι acts as a positive regulator of cell growth. More uniform effects have also been observed with PKC δ, which appears to act as a general suppressor of tumor growth. A better understanding of the biological role of PKC requires elucidation of their function at the molecular level. Information describing the biochemical function of individual PKC isoforms in mitogenic signal transduction is accumulating.

An implication for the role of PKC isoforms in the regulation of the Ras > Raf > MEK > ERK pathway is well documented. This pathway, also known as the MAP kinase cascade, is a major route for the transmission of mitogenic signals from growth factor receptors or oncogenic Ras. PKCs α and η activate cRaf and PKC ζ stimulates MEK. Evidence for a co-ordinate function of aPKC λ, nPKC ε and aPKC ζ for the Ras-mediated induction of c-Fos by the Ras > Raf > ERK pathway and the transcriptional activation of cyclin D, a critical step for the progression of cells through the G1-phase of the cell cycle, has been published. Other PKC isoforms including α, δ and η have been shown to arrest cells in G1 by enhancing the cell cycle inhibitory proteins p21waf/cip and p27kip. Several PKC isozymes, notably λ/ι and ζ, are implicated in cytoskeletal functions, thereby linking cell shape alterations to the cell cycle.

Activation of survival pathways by an inhibition of apoptosis is of utmost importance for malignant transformation and maintenance of the transformed phenotype. PKC isotypes α, δ and ζ are frequently associated with these mechanisms. The function of PKC α has been reported to act pro- and anti-apoptotic, dependent on cell type. The anti-apoptotic activity of α has been correlated to a PKC α-mediated activation of Akt, an inhibitor of programmed cell death. PKC δ is involved in the execution phase of apoptosis; its function is at least in part explained by a caspase 3-mediated activation of this PKC isoform. A clear picture has emerged with regard to PKC ζ; atypical PKC ζ stimulates cell survival by activating NfκB either by mediating the release from the inhibitor I-κB or by phosphorylating the RelA subunit of NFκB. Similar effects have been reported for the structurally related aPKC λ/ι. Furthermore, par-4, a prominent mediator of apoptosis binds and inactivates PKC ζ.

Resistance to anti-tumor agents has been correlated to overexpression or activation of several PKC isotypes. This also applies to multidrug resistance mediated by an overexpression of the MDR1 gene encoded P-glycoprotein. However, the biochemical basis of this correlation remains obscure. A PKC-mediated phosphorylation of the P-glycoprotein could be excluded, as deletion of all PKC phosphorylation sites did not affect the pumping activity of the P-glycoprotein. The correlation is in part based on observations indicating a reversion of the resistant phenotype by PKC inhibitors. In some cases, however, these PKC inhibitors were found to interact directly with the P-glycoprotein and to inhibit its activity by a PKC-independent mechanism. It is intriguing to speculate that the observed correlation between intracellular PKC activity and drug resistance is due to a PKC-mediated activation of anti-apoptotic survival pathways described above. This may also explain the observed synergistic effects of combinations of PKC inhibitors with established anti-tumor agents.

Clinical Relevance

The implication of PKC isozymes in tumor cell proliferation, invasion and metastasis, apoptosis and drug resistance has led to the development of PKC inhibitors that can be used for the chemotherapy of cancer. Several of these agents have entered clinical trials. Bryostatin-1, a macrocyclic lactone derived from Bugula neritina, occupies the same binding site as phorbol esters but is not a tumor promoter and leads to a depletion of c- and n-type PKCs. Phase II trials with bryostatin including a wide range of tumor types have so far been disappointing. Phase II studies on combinations of bryostatin I with other cytotoxic agents are ongoing. Phase II studies with an antisense construct targeted against PKC α (aprinocarsen, ISIS 3521) are in progress. These studies include patients with brain tumors, breast, colon, ovarian and prostate cancer. Phase II studies in breast cancer patients and patients with high grade astrocytomas did not reveal any activity. A phase III study in NSCLC failed to show any clinical benefit from a combination of aprinocarsen with gemcitabine and cisplatin or paclitaxel and carboplatin. Safingol, a dihydrosphingosine analogue, has been employed in clinical trials as a sensitizing agent in order to potentiate chemotherapy. Many other compounds are now in pre-clinical and early clinical development. The majority of these PKC inhibitors interact with the ATP binding site of the catalytic region. Most of them are bisindolylmaleimides or indolocarbazoles and are structurally related to the

biological compound staurosporine, a product of Streptomyces staurosporeus. Clinical phase I/II trials with the indolocarbazoles midostaurin and enzastaurin (LY317615) revealed some sensitizing effects in combination with doxorubicin or vinblastine (midostaurin) or gemcitabine, 5FU, cisplatin or radiotherapy (enzastaurin). More recently, a series of very potent PKC inhibitors was described that represent derivatives of balanol, an azepine natural product. Balanol analogues also interact with the ATP binding site of c- and nPKCs.

However, PKC inhibitors are not only of interest as potential anti-tumor agents. Other areas in which PKC inhibitors are presently investigated include diabetes, cardiovascular diseases, inflammation and immunological disorders and diseases of the central nervous system.

►Toxicological Carcinogenesis

Protein Kinase C Family

Juha Peltonen, Vesa Aaltonen
Department of Anatomy, Institute of Biomedicine, University of Turku, Turku, Finland

Synonyms

Ca^{2+}-activated phospholipid dependent protein kinase; PKC

Definition

Protein kinase C was found originally in 1977 by Nishizuka and co-workers. The group named this ►serine/threonine kinase as Ca^{2+}-activated, phospholipid dependent protein kinase, or protein kinase C in short, since the kinase activity was found to be increased in the presence of phospholipids and calcium. Today, human protein kinase C (PKC) family is known to consist of at least 11 serine/threonine kinases which are classified into three major groups based on their structure and biochemical properties: classical (α, βI, βII, γ), novel (δ, ε, η, and θ), and atypical (ζ and ι). PKCμ differs structurally from all three major groups. The genes of different PKC isoenzymes are dispersed throughout the genome. Different PKCs play a role in multiple cellular processes, which are important in cancer cell behavior. PKCs exert their functions by phosphorylating their target proteins, which are numerous and largely unknown. Originally, relevance of PKC to cancer development was discovered when PKC was identified as a primary target of tumor-promoting phorbol esters.

Characteristics

Regulation

Activation of classical PKC isoenzymes (cPKC) depends on calcium, ►diacylglycerol, and acidic phospholipids, such as ►phosphatidylserine. Novel isoenzymes (nPKC) are activated by diacylglycerol and acidic phospholipids, and atypical isoenzyme (aPKC) activation takes place independent of calcium and diacylglycerol. Activation of aPKCs takes place by acidic phospholipids, ►ceramides, and protein–protein interactions, such as interaction with other PKCs.

Growth factor-mediated ►phospholipase C activation plays a central role in the activation of cPKC and nPKC. On ligand binding, growth factor receptor activates and induces phospholipase C translocation from cytosol to the plasma membrane. Activated phospholipase C then generates diacylglycerol and ►inositol trisphosphate (IP_3) from plasma membrane phospholipids. Subsequently, diacylglycerol activates both cPKC and nPKC, and IP_3 releases calcium from intracellular stores. Calcium enhances the activation of cPKC. PKC activation also depends on complex series of phosphorylations which make PKC catalytically competent. Following ligand binding on the plasma membrane, PKC acts as a target for different kinases. These kinases phosphorylate PKC at activation loop sites and hydrophobic sites. PKC is stabile and phosphatase-resistant after autophosphorylation. However, PKC activity is not determined by these phosphorylations only. If the ligand dissociates, PKC can diffuse away from plasma membrane but remain phosphorylated. In this case, PKC can be reactivated by diacylglycerol binding alone.

PKC Expression in Cancer

Members of PKC family are normally ubiquitously expressed in a wide range of tissues, isoenzymes α, β,

and δ being the most abundant. However, PKC isoenzymes have been shown to display altered expression in cancer when compared with normal tissues. The most common isoenzymes displaying alterations in expression during cancer progression are α, β, and δ, but change in expression of other isoenzymes may also take place. Immunohistochemical studies on human tumors have shown PKCα overexpression in urinary bladder, prostate, and endometrial cancers, whereas low grade tumors and normal epithelia of the respective organs show significantly lower expression. In contrast, breast, colon, hepatocellular, and basal cell cancers display downregulation of PKCα expression. PKCβ expression has been shown to be high in colon and prostate cancers, and low in high grade urinary bladder cancers. Furthermore, the expression profile of PKCs within a single tumor can be variable, as exemplified by the fact that increased PKCα- and βI expression and activity have been shown to associate with high proliferation areas of urinary bladder tumors. Even single neighboring cells may display manifold difference in the expression of these enzymes. This suggests that PKC expression level is under control even in carcinoma tissue.

Similarly to cPKC expression, PKCδ can be either upregulated or downregulated. For instance, hepatocellular cancer displays increased PKCδ expression, while in urinary bladder cancer the isoenzyme is downregulated. Studies have mainly focused on cPKC and PKCδ, while the expression of other PKC isoenzymes in cancers is less well known. The expression of PKCλ, ι, and ε is decreased in pancreatic cancers, PKCη is increased in renal cancers, and PKCλ is increased in ovarian cancer.

It is unclear, whether PKC isoenzyme expression in cancer can be associated with patient survival. Expression of PKCι has been suggested to be a negative prognostic factor in ovarian carcinoma and PKCγ as positive prognostic factor in B-cell lymphoma. Based on the variability of expression of different PKC isoenzymes in different cancers, it can be stated that no general conclusions can be drawn from the expression patterns with respect to carcinogenesis in general. In addition, the levels of isoenzyme proteins do not directly correlate with the overall enzyme activity, making conclusions difficult.

PKC Activation in Carcinogenesis

Evolution of a malignant tumor is a multistep process, which includes mutations in several genes as well as other molecular changes in cellular proteins. First, initiating agents mutate proto-oncogenes and thus initiate the malignant transformation. Second, a prolonged exposure to ►tumor promoters induces the clonal outgrowth of the mutagen-initiated cell population and increase genetic instability. The primary target of the tumor promoters, such as ►phorbol 12-myristate acetate (PMA, TPA), aplysiatoxin, and teleocidin seems to be PKC. One mechanism of expressional changes seen in human cancers may result from the tumor promoter action. Tumor promoters, such as PMA, bind to the diacylglycerol binding site of PKC and promote chronic activation of PKC. Prolonged activation of PKC leads to degradation of the enzyme by ubiquitin–proteasome pathway. In fact, changes in expression and activity of PKC are apparently not due to genetic chances, since mutations in PKC genes are found very rarely in human cancers. However, evidence has been provided for loss-of-function mutation of PKCα gene in thyroid and pituitary cancers. Furthermore, a deletion has been reported in PKCα gene in melanoma. Significance of this mutation is unknown, but several melanoma cell lines display decreased PKCα expression.

The role of PKCs in cancer seems to result from their action as targets of tumor promoters or from their action as downstream effectors of growth factor receptors. Tobacco smoke contains a number of substances considered as tumor promoters which activate PKCs, such as catechol and hydroquine. Furthermore, high consumption of dietary lipids is carcinogenic. Carcinogenicity of dietary lipids may, at least in part, be exerted through direct or indirect PKC activation, which have also been shown in animal models. PKC expression and activity seems to be modulated by a wide variety of genetic and epigenetic factors. Chemical carcinogens such as nitrosamines which are present in tobacco smoke are known to induce increased expression and activation of PKCα and β, while PKCδ is downregulated. Furthermore, oncogenic ►Ras increases PKCα, ►c-myc oncogene increases PKCβ expression, and wild type ►p53 tumor suppressor decreases PKCα expression.

Targets of PKC and its Cancer-Related Functions

PKCs are involved in multiple physiological processes of cells. Short-term activation of PKC is often associated with short-term events such as secretion and ion influx. In contrast, sustained activation has been shown to induce cellular proliferation, differentiation, ►apoptosis, ►migration, ►adhesion, tumorigenesis, and epithelial barrier function.

The role of PKC in the control, or rather in the loss of control of cancer cell growth is well established. However, different isoenzymes function differently and have variable effects on cell growth which may also vary depending on the cell type. Thus, general conclusions with respect to PKC function in cell growth may be difficult to make. PKCα has been linked to decreased and increased cellular proliferation, and to induction or inhibition of apoptotic cell death of cancer cells. However, most of the studies consider PKCα as an inducer of proliferation and suppressor of apoptosis.

Also PKCβ has been associated with increased proliferation rate of cancer cells. Of novel isoenzymes, PKCδ has been strongly associated with control of apoptosis. PKCδ activity results in many proapoptotic signals, such as increased mitochondrial ►cytochrome *c* release and ►c-Abl activation. In malignancies, downregulation of PKCδ activity has been shown to lead to inhibition of apoptosis and resistance to DNA-damaging agents.

►Telomerase activity is associated with immortalization and malignant phenotype of a cell. PKCα, βI, δ, and ζ isoenzymes phosphorylate and activate telomerase, and PKC inhibitors inhibit its activity. The target of PKC appears to be telomerase reverse transcriptase, hTERT, one of telomerase subunits.

There is strong evidence that PKCα activity is associated with increased motility and invasion of cancer cells. This has been suggested to occur through inhibition of ►adherens junctions and ►desmosomes, inhibition of hemidesmosomes, and changes in focal adhesions. Also, ε, βII, and ζ isoenzymes have been associated with cellular motility.

Other cancer-related associations for PKC include ►multidrug-resistance (mdr), since PKCα activity has been shown to phosphorylate, and PKCα and θ to increase expression of ►P-glycoprotein. Furthermore, simultaneous loss of P-glycoprotein and PKCα expression is associated with reversion of mdr, while inhibition of PKCα attenuates resistance to cytotoxic agent.

PKCs may also regulate tumor vascularization, since PKCβ has been shown to act as a mediator of vascular endothelial growth factor (VEGF) signaling and its inhibition leads to decreased endothelial cell proliferation and reduction of neovascularization of a malignant tumor. Furthermore, PKCα- and ζ isoenzymes regulate VEGF expression through posttranscriptional mechanisms.

A high number of different potentially cancer-related direct or indirect targets have been reported. Some of the most important include, in addition to the targets mentioned above, the following: PKCα, βI, and γ have been shown to phosphorylate and inactivate ►glycogen synthase kinase-3 beta (GSK-3β), leading to increased c-Jun DNA binding activity. C-Jun is an important controller of cell growth and apoptosis. PKC can directly activate ►Raf-1/MEK/MAPK pathway by phosphorylating Raf-1. Raf-1/MEK/MAPK pathway affects several targets related to cell growth. Transcription factor ►nuclear factor kappa beta (Nf-κB), which is a central regulator of several apoptosis-related genes, is also activated by PKC. PKC also regulates intercellular communication through gap junctions and PKC has been shown to be directly phosphorylate ►gap junction protein, connexin 43. Recently, it was shown that PKCα directly phosphorylates ►neurofibromin, a Ras GTPase-activating tumor suppressor, and increases its association to actin cytoskeleton.

PKC as a Target in Cancer Therapy

Since many tumor promoters act as PKC activators and as PKCs play an important role in diverse cellular functions, PKCs are potential therapeutic targets. Multiple PKC modulating approaches have been developed during the last decades. PKC inhibitors may be divided to isoenzyme selective and broad spectrum inhibitors. However, PKC agonists, such as bryostatin-1, may also be used to inactivate PKC, since long-term activation of PKC leads to its downregulation.

Many PKC inhibitors have been tested in vitro and in vivo animal models, with promising results. The most tested PKC inhibitors are bryostatin-1, PKC412 (broad spectrum inhibitor, *N*-benzoyl staurosporine, also named CGP41251 and midostaurin), UCN-01 (cPKC pointed broad spectrum inhibitor, 7-hydroxy-staurosporine), aprinocarsen (PKCα antisense oligodeoxynucleotide, also named ISIS3521, LY900003, CGP 64128A, or affinitak), enzastaurin (PKCβ inhibitor, also named LY317615), safingol (PKCα inhibitor), and Go6976 (PKCα/βI inhibitor, also named Gö6976). PKC412, aprinocarsen, and Go6976 have shown impressive anti-invasive properties. Furthermore, reduced growth of cancer cells has been shown with UCN-01, PKC412, aprinocarsen, Go6976, and enzastaurin. The antiproliferative mechanism of these agents has been suggested to be cell cycle arrest and increased apoptosis. Also bryostatin-1 inhibits proliferation, induces differentiation, and apoptosis. In addition to its direct effects on cancer cell growth, enzastaurin has been shown to reduce plasma ►VEGF levels and inhibit angiogenesis in a tumor model.

Combining different PKC inhibitors with classical ►chemotherapeutic agents or radiotherapy has resulted in additive growth inhibiting effects. It has been speculated that these additive effects result from inhibition of ►mdr or modulation of apoptosis. An interesting mechanism for PKC inhibitors in increasing cancer cell death is ►cell cycle checkpoint abrogation. When a cell faces DNA damage induced by chemotherapy or ionizing radiation, it activates its cell cycle checkpoints, resulting in cell cycle arrest. It has been demonstrated that many PKC inhibitors inhibit, either directly or through PKC, kinases that control especially G2 checkpoint of the cell cycle. Therefore, cancer cells that are arrested to G2 by chemotherapy can be forced from G2 to mitosis by using selected PKC inhibitors. This treatment kills the cancer cells very effectively by ►mitotic catastrophe or apoptosis.

Bryostatin, aprinocarsen, UCN-01, PKC412, enzastaurin, and safingol have been tested in clinical trials as single agents and in combination with various chemotherapeutic drugs. Go6976 has not been studied in

clinical trials. The clinical responses for the substances have varied considerably. For instance, aprinocarsen displayed some promising effects, but phase III studies showed that the substance did not improve response or survival when used in combination with chemotherapy in advanced non-small cell lung cancers. Additionally, major thrombocytopenia was observed. The clinical efficiency of UCN-01 and PKC412 has been poor as well. UCN-01 has shown unusually prolonged half-life and low clearance, which results from high binding to plasma proteins. Several human studies are ongoing with these substances and results are eagerly awaited. www.gancer.gov/clinicaltrials.

Protein Microarray

Definition

Protein microarray is composed of array containing full-length functional proteins or protein domains. It is fabricated by depositing a library of proteins or antibodies immobilized in a 2-D addressable grid on a chip coated with a chemically or physically functional layer for covalent or noncovalent immobilization of proteins or other capture reagents. Quantification of microarray-based assay is achieved by capturing array images with an optical device and using compatible image analysis software to determine fluorescent, chemilluminescent, or colorimetric intensity of each spot on array images. Protein microarray is used to study the biochemical activities of an entire proteome in a single experiment, such as protein–protein, protein–DNA, protein–RNA, protein–phospholipid, and protein–small molecule interactions.

Protein Stabilization

Definition

A generalized term that represents the process of preventing protein degradation, either through de-ubiquitination or some other type of cellular process.

►Herpesvirus-Associated Ubiquitin-Specific Protease (HAUSP) De-Ubiquitinase

Protein-tyrosine Kinase Inhibitors

►Tyrosine Kinase Inhibitors

Proteinase

Definition

Synonym protease; An enzyme which catalyses hydrolysis of peptide bonds. Endopeptidase refers to proteinase activity within an intact protein.

►Proteasome Inhibitors

Proteinase-Activated Receptor-1

Anke Rattenholl, Tobias Görge, Stefan W. Schneider, Martin Steinhoff
Department of Dermatology, University of Münster, Münster, Germany

Synonyms

Thrombin receptor; Coagulation factor II receptor; PAR_1

Definition

►PAR_1 is a ►G protein-coupled receptor which can be activated preferentially by ►thrombin, ►trypsin, ►factor Xa, activated ►protein C, ►plasmin and ►matrix metalloproteinase-1 (MMP-1). It consists of 425 amino acids (47 kDa) including the amino-terminal signal sequence, and is widely expressed in different tissues and overexpressed in numerous cancers. The gene maps to 5q13.3 (gene name: F2R).

Characteristics

PAR_1 is stimulated by specific cleavage at the site LDPR^{41} ↓ S^{42}FLLRN to expose the tethered ligand SFLLRN which binds to the second extracellular loop, thus activating the receptor, resulting in ►signal transduction. A synthetic peptide ("activating peptide") that mimics the tethered ligand domain (TFLLRN-NH_2) directly binds to and activates PAR_1 *in vitro* without proteolytic cleavage. Thrombin can activate PAR_1 by a two-step mechanism. First the proteinase binds to a ►hirudin-like site distal to the cleavage site, subsequently cleaving the receptor. This mechanism allows efficient activation of the receptor. Hence, PAR_1 is a high-affinity receptor for thrombin, mediating rapid and transient cellular responses. Moreover, evidence exists that uncleaved PAR_1 can also be activated intermolecularly by another activated PAR_1 receptor molecule (transactivation).

Overexpression of PAR_1 in breast cancer cells correlates with tumor progression. Activation of PAR_1 in these cells induces reorganization of the cytoskeleton and the formation of focal contact complexes. These complexes are important for cell migration and invasion. Moreover, overexpression in murine mammary glands results in accelerated cell proliferation due to persistent activation of ►β-catenin. In contrast, experimental downregulation of PAR_1 in an aggressively metastatic breast cancer cell line reduces invasion. In prostate cancer, PAR_1 has been implicated in bone metastasis. Metastatic human melanoma cell lines express PAR_1, and overexpression of PAR_1 in melanoma cells leads to enhanced invasion and metastasis. Deregulation of PAR_1 expression was found to be associated with a loss of the transcription factor activator protein-2α. PAR_1 activation also contributes to tumor growth by enhancing tumor cell proliferation, as has been shown for melanoma and colon carcinoma cell lines. Moreover, the ability of tumor cells to activate the coagulation system and to generate thrombin has been shown to enhance metastasis, while anticoagulant therapies can interfere metastasis formation. Thrombin and potentially other coagulation proteinases can modify tumor cell behavior directly through the activation of PAR_1 or other thrombin receptors.

PAR_1 is present on ►platelets, where it mediates platelet aggregation, a central event in ►thrombus formation. Thrombus formation is a crucial step during metastasis: cancer cells circulating in the blood stream produce thrombin which promotes ►fibrin (Factor Ia) and platelet deposition. This enables tumor cells to adhere to the blood clot, facilitating penetration through the vessel wall. Interestingly, factor Xa (FXa), apart from its role in the extrinsic and intrinsic ►coagulation pathways to activate ►zymogens, can directly cleave PAR_1. However, optimum cleavage capacity is only achieved when the factor is immobilized on the cell membrane via ►tissue factor (TF) as a complex together with ►factor VIIa (FVIIa). Both TF and FVIIa can be produced by the cancer cells themselves.

PAR_1 is able to couple to ►epidermal growth factor receptor (EGFR) signaling. This receptor ►transactivation was found to promote migration of renal carcinoma cells.

Metastasis requires adhesion of tumor cells to endothelial cells of the vessel wall. Melanoma cells secrete MMP-1 which is able to activate PAR_1 on endothelial cells. This leads to secretion of ►von Willebrand factor (vWF) and proangiogenic ►interleukin-8. ►Angiogenesis has also shown to be stimulated in the presence of the PAR_1 agonists thrombin and activated protein C. Tumors induce the formation of new blood vessels. These provide nutrition for the tumor cells which have a high metabolical turnover. In addition, MMP-1 that was secreted by stromal cells of the tumor microenvironment was shown to activate PAR_1 on breast cancer cells, increasing tumor cell migration and invasion.

In addition to the hypercoagulable state which is associated with advanced cancer, activation of the fibrinolytic system has also been linked to poor prognosis: plasmin can activate PAR_1 to induce the angiogenic cytokine Cyr61. In turn, Cyr61 expressed by the tumor cells induced MMP-1 secretion by the stromal host cells. Together, the role of PAR_1 in tumor progression involves not only the tumor cells themselves but also a close interaction between the cancer cells and the surrounding tumor microenvironment.

Proteinase-Activated Receptor 2

Anke Rattenholl, Tobias Görge, Stefan W. Schneider, Martin Steinhoff
Department of Dermatology, University of Münster, Münster, Germany

Synonyms

Thrombin receptor-like 1; Coagulation factor II receptor-like 1; G-protein coupled receptor 11; PAR_2

Definition

►PAR_2 is a ►G protein-coupled receptor which can be activated by ►trypsin, ►tryptase, ►factor VIIa, ►factor Xa, ►matriptase (MT-SP1), and ►proteinase 3. It consists of 397 amino acids (44 kDa) including the amino-terminal signal sequence, and is widely expressed in different tissues and upregulated in numerous cancers. The gene maps to 5q13.3 (gene name: F2RL1).

Characteristics

PAR_2 is activated by specific proteolysis at the site $SKGR^{36} \downarrow S^{37}LIGKV$ to expose the tethered ligand SLIGKV which binds to the second extracellular loop, thus activating the receptor, resulting in ►signal transduction. A synthetic peptide ("activating peptide") that mimics the tethered ligand domain (SLIGKV-NH_2) directly binds to and activates PAR_2 *in vitro* without proteolytic cleavage. *In vivo*, PAR_2 can also be stimulated by ►transactivation through PAR_1: the tethered ligand domain of PAR_1 is able to bind to and activate uncleaved PAR_2. Hence, the peptide sequence SFLLRN, derived from the tethered ligand domain of PAR_1, can stimulate both PAR_1 and PAR_2 *in vitro*. In addition, it was observed that thrombin is able to activate PAR_2 on melanoma cells indirectly and independent of receptor cleavage. The underlying mechanism, however, is yet unclear.

PAR_2 activation in cancer cells induces cytoskeletal reorganization. This results in enhanced ►migration, ►invasion and ►metastasis. Moreover, PAR_2 is able to promote proliferation of various tumor cells. This is achieved at least partly by ►transactivation of the epidermal growth factor receptor (EGFR). In ►pancreatic cancer, PAR_2 was reported to induce fibrosis.

As observed with PAR_1, the complex TF-FVIIa-FXa can also activate PAR_2. In breast cancer cells, PAR_2 is able to promote migration and invasion via TF-FVIIa-FXa and TF-FVIIa. Activation of PAR_2 in these cells leads to release of the angiogenic factor ►vascular endothelial growth factor (VEGF). PAR_2 promotes proliferation of most cells. An exception are epidermal keratinocytes of the upper skin layer, where activation of PAR_2 inhibits cell growth. Although PAR_2 is overexpressed in several tumor cell lines, the receptor is downregulated in poorly differentiated ►squamous cell carcinomas of the skin and esophagus, which are derived from keratinocytes, and in certain ►gastric carcinomas. These findings point to a tumor-suppressing role of PAR_2 in certain tissues. However, the underlying mechanisms are not elucidated yet. Another serine proteinase with trypsin-like activity is ►matriptase (MT-SP1), a transmembrane proteinase. PAR_2 can be cleaved by this enzyme, and matriptase is overexpressed in numerous cancers and has been implicated in tumor progression and ►metastasis.

Proteinase-Activated Receptor-3 (PAR_3)

Anke Rattenholl, Tobias Görge, Stefan W. Schneider, Martin Steinhoff
Department of Dermatology, University of Münster, Münster, Germany

Synonyms

Thrombin receptor-like 2; Coagulation factor II receptor-like 2; PAR_3

Definition

►PAR_3 is a G protein-coupled receptor which can be activated by ►thrombin (Factor IIa). It consists of 374 amino acids (42 kDa) including the amino-terminal signal sequence, and is highly expressed in ►megakaryocytes of the bone marrow. A lower expression is found in mature ►megakayrocytes, platelets, heart and gut. The gene maps to 5q13.3 (gene name: F2RL2).

Characteristics

PAR_3 is activated by specific proteolysis at the site $LPIK^{38} \downarrow T^{39}FRGAP$ to expose the tethered ligand LPIK which binds to the second extracellular loop, thus activating the receptor. No synthetic peptides exist which are able to stimulate PAR_3 *in vitro*, as observed with the other members of this receptor family. Distal to the thrombin cleavage site, there is a ►hirudin-like binding site located. This enables binding and concentration of thrombin at the cell surface, rendering PAR_3 a high-affinity receptor for thrombin. However, it seems that PAR_3 needs the interaction with other PARs for ►signal transduction, since it was found that mouse PAR_3 is unable to signal when expressed in the absence of other PAR receptors. PAR_3 is well expressed in mouse platelets, which are deficient in PAR_1. Here, PAR_3 is a cofactor for PAR_4. Thus in mouse platelets, PAR_3 adopts the role played by PAR_1 in the human system. PAR_3 does not seem to play a major role in tumorigenesis. However, it was reported to be expressed in ►renal cell carcinomas together with PAR_1.

Proteinase-Activated Receptor-4

Anke Rattenholl, Tobias Görge,
Stefan W. Schneider, Martin Steinhoff
Department of Dermatology, University of Münster, Münster, Germany

Synonyms

Thrombin receptor-like 3; Coagulation factor II receptor-like 3; PAR_4

Definition

►PAR_4 is a ►G protein-coupled receptor which can be activated by ►thrombin (Factor IIa), ►plasmin, ►trypsin and ►cathepsin G. It consists of 385 amino acids (41 kDa), including the amino-terminal signal sequence, and is widely expressed in various tissues. It is not expressed in brain, kidney, spinal cord and peripheral blood leukocytes. The gene maps to 19p2 (gene name: *F2RL3*).

Characteristics

PAR_4 is activated by specific proteolysis at the site $PAPR^{47} \downarrow G^{48}YPGQV$ to expose the tethered ligand GYPGKV which binds to the second extracellular loop, thus activating the receptor. A synthetic peptide ("activating peptide") that mimics the tethered ligand domain ($GYPGQV\text{-}NH_2$) directly binds to and activates PAR_4 *in vitro* without proteolytic cleavage. PAR_4 does not carry a ►hirudin-like binding site for thrombin as observed in PAR_1 and PAR_3. Thus, PAR_4 is a low-affinity receptor for thrombin. Despite this fact, cellular responses mediated by PAR_4 are sustained, and the receptor desensitizes only slowly in contrast to the high-affinity thrombin receptor PAR_1, leading to a prolonged signal. PAR_4 is involved in ►invasion and ►angiogenesis, and it was reported to be overexpressed in adenocarcinomas and ►squamous cell carcinomas of the lung.

Proteinase-Activated Receptors

Anke Rattenholl, Tobias Görge,
Stefan W. Schneider, Martin Steinhoff
Department of Dermatology, University of Münster, Münster, Germany

Definition

►Proteinase-activated receptors (PARs) belong to the protein family of ►G protein-coupled receptors with seven transmembrane domains. So far, four different PARs are known. They are stimulated by specific proteolytic cleavage of the extracellular N-terminus (see Fig. 1). The newly formed N-terminus, the so-called "tethered ligand," is then able to bind intramolecularly to the receptor to initiate multiple signaling cascades. There is no known function of the removed N-terminal peptide fragment. Despite the irreversible activation mechanism, PAR signaling is efficiently terminated by desensitization (phosphorylation and uncoupling from ►G proteins) and degradation. A wide range of proteinases, most of them serine proteinases, cleave and activate PARs. They include proteinases from the ►coagulation cascade, inflammatory cells, the digestive tract, and the tumor microenvironment as well as the malignant cells themselves. PARs are ubiquitously expressed but are often found to be overexpressed in many different tumor types. In certain tumor types, downregulation of PARs has also been described.

Proteinchip

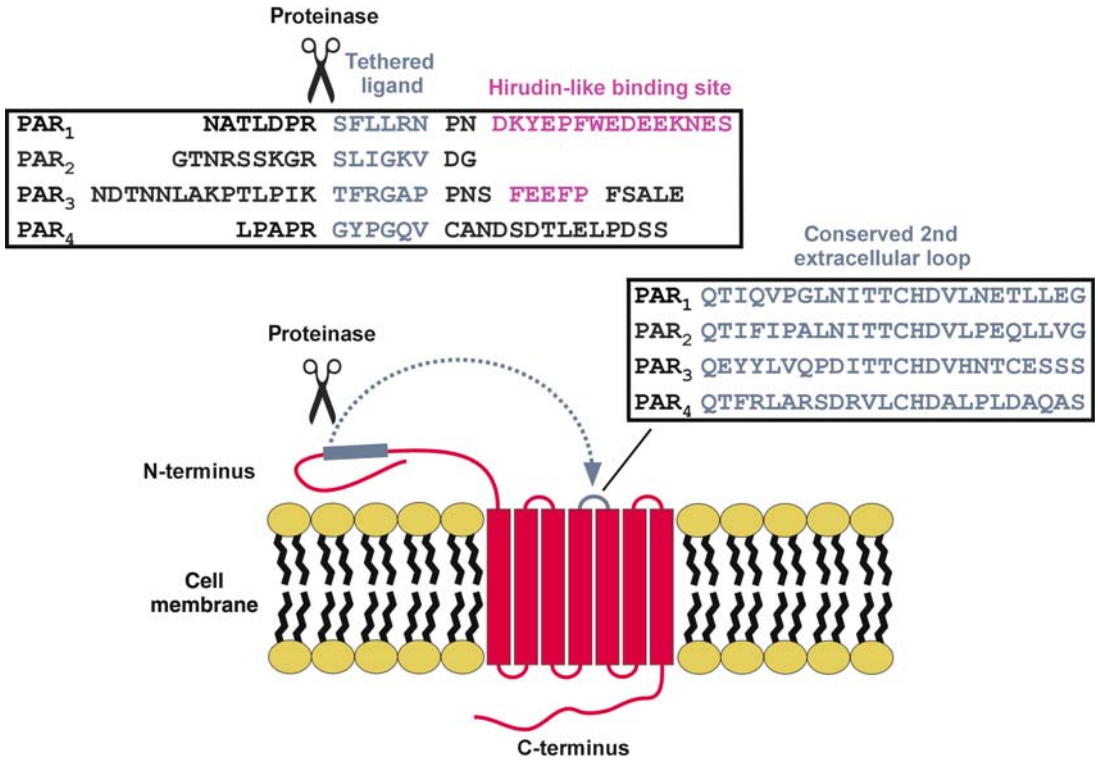
William Chi-Shing Cho
Department of Clinical Oncology, Queen Elizabeth Hospital, Kowloon, Hong Kong

Synonyms

Protein array; Biochip

Definition

The functional proteinchip is a small size planar analytical ►protein microarray with probes arranged in high density on which different molecules of protein are affixed at separate locations in an ordered manner to form a microscopic array. The recent development of protein microarray offers the possibility to simultaneously analyze the expression of several hundred proteins. It is used to identify protein–protein interactions, the substrates of protein kinases, or the targets of biologically active small molecules. The innovative reverse-phase protein microarray has the potential to



Proteinase-Activated Receptors. Figure 1 Schematic presentation depicting the mechanism of PAR activation. The particular proteinase cleaves the PAR receptor at a specific site (scissors), unmasking a previously hidden peptide sequence, termed "tethered ligand" (*blue box*). The newly formed N-terminus then binds to the conserved second extracellular loop (*dotted arrow*). This interaction leads to conformational changes and subsequent receptor activation (a detailed description of PAR_1 and PAR_2 signal transduction pathways is given by Steinhoff et al. [1]). The human sequences of the "tethered ligand" domains and the second extracellular loops (both *printed in blue*) are presented in the boxes. The hirudin-like binding domain sequences of PAR_1 and PAR_3 are depicted in *purple color*.

provide information about the state of cellular circuitry from minute samples. Nevertheless, the most common functional proteinchip is the ►antibody microarray, where antibodies are spotted onto the proteinchip and are used as capture molecules to detect proteins from biological samples.

The analytical proteinchip is used in conjunction with a ►time-of-flight (TOF) ►mass spectrometry (MS) detector to enable protocols of protein capture and detection from complex samples without additional labels. Based on chromatographic interactions, protein–protein interactions, DNA–protein interactions, or receptor–ligand interactions, the analytical proteinchip is designed with a wide variety of capture affinities. The techniques include reverse-phase, cation exchange, and anion exchange. The most common analytical proteinchip is the ►surface-enhanced laser desorption/ionization (SELDI)-TOF MS array, where proteins are captured and enriched on a chemically or bioaffinity active solid phase surface to detect proteins in tissue, blood, urine, or other clinical samples.

Characteristics

Technologies

There are three main types of proteinchip formats. The glass slide chips are relatively inexpensive and they are usually compatible with standard microarray equipment, however, the samples are prone to evaporate and there may be cross-contamination between spots. Using well chips or 3-D matrix gels these problems can be reduced, but they are more expensive and can not be used with DNA microarray spotting equipment.

To prepare the proteinchip, coating with a substance should be bound to the slide without denaturing the proteins. There are several types of binding methods, which include the absorption, cross-linking, and hybridization. With the absorption method, the noise level of

the attachment layer is high due to nonspecific medium, such as sugary gel. In contrast, the cross-linking or hybridization methods allow the binding of specific groups of proteins covalently. However, the conformation or activity of the proteins may be affected.

Many proteinchips are spotted using automated technology, with spot densities greater than 30,000 spots per chip. Besides, synthesis of peptides can be performed on the chip by ►photolithography.

Analytical Approaches

The labeled analytical approaches involve fluorescence or radioisotope labeling techniques. The label is directly attached to the protein or capture agent and detected straight away. It is then attached to a different molecule (such as antibody, antigen, or substrate) with subsequent washing of the proteinchip to avoid altering the conformation of proteins. The most common labeled detection methods include the enzyme-linked immunosorbent assay, sandwich immunoassay, isotopic labeling, planar waveguide, and electrochemical. However, although the approaches try to prevent label from altering protein conformation, interference with protein interactions may still exist. As label influence on binding properties, along with a knack for having a lack of reproducibility, some studies thus shift to use the label-free approaches.

There are three main types of label-free analytical approaches. With the MS, proteinchips are coupled to a ►matrix-assisted laser desorption/ionization-TOF MS detector. Improved resolution can be obtained using SELDI-TOF MS. Following the sample fractionation and subsequent processed with a proteinchip reader, protein profiles are generated and analyzed by specific software. Unlike MS, ►surface plasmon resonance is an optical effect produced when polarized light is shone on a specially designed proteinchip. It can be coupled to MS for protein identification using microrecovery from the chip surface. A third method is the atomic force microscopy, which uses changes in surface topology to detect protein interactions. It is a high resolution technique and the data is collected in the form of topographical maps.

Applications in Cancer Research

The main applications of proteinchip profiling in ►cancer research include identifying cancer ►biomarkers, investigating protein–protein and protein–drug interactions, study of ►posttranslational modifications, cancer profiling, determining the amount of protein in a sample, detection of microorganisms and toxins in cancer fluid, as well as testing for the presence of antibodies in a cancer cell. Proteinchip profiling has been used successfully to discover biomarkers with potential clinical usefulness in some cancer types, several examples are illustrated underneath.

There was a development of integrated antibody microarray for simultaneous detection of multiple antigens and antibodies of five human ►hepatitis viruses (HBV, HCV, HDV, HEV, and HGV). This integrated antibody microarray can be used for clinical diagnosis and epidemiological screening of ►hepatitis virus-associated hepatocellular carcinoma.

Serum samples from the patients with malignant or benign prostatic disease and control subjects were analyzed on antibody microarray targeting multiple candidate prostate cancer biomarkers to distinguish malignant from benign prostatic diseases. With the several detected disease-associated protein alterations, thrombospondin-1 was found to be the most significantly altered protein. It was decreased in the patients with prostate cancer, but increased in the patients with benign prostatic disease.

To explore the use of combined measurements for serum sample classification, antibody microarray was also used to examine the associated proteins of pancreatic cancer. The antibodies that had reproducibly different binding levels between the patients with malignant and benign pancreatic diseases revealed different types of alterations, reflecting ►inflammation (high C-reactive protein, alpha-1-antitrypsin, and serum amyloid A (SAA)), immune response (high IgA), leakage of cell breakdown products (low plasma gelsolin), and possibly altered vitamin K usage or glucose regulation (high protein-induced vitamin K antagonist-II).

Using SELDI-TOF MS, two isoforms of SAA protein that were useful in the diagnosis of relapse in ►nasopharyngeal carcinoma were identified. Monitoring the patients longitudinally for SAA level both by proteinchip and immunoassay showed a dramatic increase in SAA correlated with relapse, and a drastic fall in SAA correlated with response to salvage chemotherapy. Subsequent tandem MS sequencing and immunoaffinity capture assay identified platelet factor-4 as a treatment-associated serum biomarker that might serve for the triage of patients with nasopharyngeal carcinoma to appropriate chemotherapy treatment.

The SELDI-TOF MS was also used to identify differentially cytosolic expressed proteins with a prognostic impact in node-negative ►breast cancer patients with no relapse versus patients with metastatic relapse. The proteinchip laser desorption ionization-tandem quadrupole-TOF MS was used for biomarkers identification. Results showed that a high level of cytosolic ubiquitin and/or a low level of ferritin light chain were associated with a good prognosis in breast cancer.

Challenges and Perspectives

There are many challenges when developing a protein microarray, such as creating an expression clone library, actual protein production that includes isolation and purification, adaptation of microarray technology, stabilizing the proteins on the array, as well as keeping the concentrations of the protein constant between slides and spots on the same slide. The analysis of proteinchips also comes with many challenges. Protein concentration is dynamic within a cell and there is trillion fold of difference between the low abundant proteins and the high abundant proteins. Unfortunately, the proteins that are usually of interest are normally in low concentration. Although purification and enrichment of proteins can address this problem, it is quite laborious and time-consuming. Besides, the application of protein microarray is limited by various fundamental problems, such as its multiplexing ability is limited by the cross-reactivity in parallel sandwich immunoassays. Therefore to determine a specific probe for each protein constitute another challenge. In addition, to integrate the proteomic profiling data with genomics and metabolomics, as well as translated them from bench to bedside applications is also a major challenge.

Nevertheless, protein microarray is among the novel classes of rapidly evolving proteomic technologies that holds great promise in biomedicine. Out of a large background of immunoglobulins including natural antibodies, patients with cancer produce a minute amount of specific ►autoantibodies against protein antigens. The ability to identify the fingerprintings of antibody signatures in malignancies can be useful in cancer diagnosis and prognosis. The great power of multiplex antibody microarray lies in its potential for rapid identification of antibody biomarkers found in blood and other biological fluids, which is sorely needed in the clinic to improve diagnosis, prediction of prognosis, and selection of ►targeted therapy. With the development of advanced technologies, such as improved quantitative ►proteomics methods, MS of ultra resolution, speed, and sensitivity, the development of functional protein assays, as well as sophisticated ►bioinformatics, further advancement of the high-throughput proteinchip technology will be achieved. After confirmation in independent proteinchip profiling studies, promising potential cancer biomarkers should be submitted to higher-throughput methods practical for large-scale multi-institutional validation studies and, ultimately, for clinical and epidemiological applications.

Proteins

Definition

Are relatively large organic compounds made of amino acids arranged in a linear chain and joined together between the carboxyl atom of one amino acid and the amine nitrogen of another. This bond is called a peptide bond. The sequence of amino acids in a protein is defined by a gene and encoded in the genetic code.

14-3-3 Proteins

Definition

Are abundant, highly conserved adaptor proteins of ~30 kDa found in all eukaryotes. Similar to the binding of ►SH2 domains to phosphorylated tyrosine residues, 14-3-3 proteins usually bind to their client protein *via* a phosphorylated Ser- or Thr-residue in a sequence-specific context (mode I: RSXpS/TP; mode II: RXXXpS/TXP with p indicating the phosphorylated residue and X any amino acid). 14-3-3 proteins assist in the stabilization of the client protein in either an active or inactive conformation. 14-3-3 proteins regulate a multitude of biological processes ranging from metabolic control to the regulation of apoptosis, cell cycle progression and mitogenic signaling. One of the seven of human 14-3-3 genes, 14-3-3σ/Stratifin, is frequently epigenetically silenced in breast, lung and prostate cancer and is discussed as a ►tumor suppressor gene.

Proteoglycan

Definition

Glycosaminoglycans that are covalently linked to a core protein. Proteoglycans are complex macromolecules present primarily at the cell surface, in the extracellular matrix that surrounds most mammalian cell types, and also in body fluids. By virtue of the multiplicity of their protein binding partners (e.g., growth factors, chemokines, enzymes, and other extracellular matrix proteins), they have been shown to play major roles in regulating normal cellular processes, such as ►adhesion, proliferation, remodeling, ►migration, or ►angiogenesis, which can become dysregulated in ►inflammation and during cancer progression. Structurally, PGs consist of a core protein, of variable size and structure, and one or more associated glycosaminoglycan (GAG) chains. These GAGs can be of five types: chondroitin sulfate (CS), dermatan sulfate (DS), heparan sulfate (HS), heparin or keratan sulfate (KS). Growing evidence suggests that DS, like the better studied heparin and HS, is an important cofactor in a variety of cell behaviors.

Proteomics

Won-A Joo, David W. Speicher
The Wistar Institute, Philadelphia, PA, USA

Definition

Proteomics is any systematic large scale study of a proteome or sub-proteome. The term proteome was coined in the mid-1990s as a linguistic equivalent to the concept of the genome. It refers to the complete set of proteins present in a biological specimen such as a single cell organism, a cell line, tissue, or biological fluid (serum, urine, saliva etc.). The proteomes of complex organisms are far more complex than the set of expressed genes because genes are usually alternatively spliced and expressed proteins are often extensively and heterogeneously posttranslationally modified. Unlike a genome that is largely static over the lifetime of a cell or organism, proteomes are constantly changing in response to changes in the environment of the cell, tissue or organism. Hence terms such as the "human proteome" or even the proteome of a cell line in tissue culture are meaningless because there are an essentially infinite number of proteomes.

Characteristics

Because many proteomics studies are discovery-based rather than hypothesis driven, they are not constrained by prior knowledge. Proteomics, therefore, provides opportunities for unprecedented progress in biomedical and biological research. These discovery based studies are highly complementary to hypothesis driven research, and they are quite often appropriately referred to as "hypothesis generating."

Three major types of proteome analyses are: (i) protein profile comparisons, where quantitative changes in proteins between two or more experimental conditions are compared; (ii) compositional analyses, where the goal is to identify all proteins present in a single biological sample; and (iii) analysis of protein–protein interactions. Another way of phrasing proteome studies is as an attempt to define: who, when, where and with whom. Protein profiling and compositional analyses often utilize similar separation and analysis tools, with the latter type of study simply lacking a requirement for quantitation.

The successive steps and associated critical issues for most types of proteome studies are: (i) experimental design – this includes selection of the organism and biological sample, conditions to be studied, goals of the study, and methods that will be utilized; (ii) sample preparation – method should be reproducible and care must be taken to avoid introducing artifacts that may be difficult to segregate from biologically important features; (iii) analytical separations – how will the proteins in the targeted proteome or sub-proteome be separated and how many tandem separation methods will be used; (iv) protein identification – while tandem mass spectrometry (MS/MS) is used to identify proteins in most proteomics studies, important considerations include the type of mass spectrometer to be utilized and whether intact proteins or proteolytic fragments will be analyzed in the mass spectrometer; and (v) proteome informatics – issues include the sequence database that will be searched, the computer program(s) used to compare the MS/MS data to the database, and the software tools used to manage, view and data mine search results.

Subproteomes and their Advantages

The complexity of most proteomes from multi-cellular organisms is usually much greater than the capacity of most current analytical methods both in terms of the number of unique protein forms present and the wide range of protein abundance. As a result, when one attempts to analyze entire complex proteomes, only a small portion of the total proteins present in the biological specimen are analyzed. Hence, where feasible, it is advantageous to focus on a sub-proteome that can address the biological question of interest. Key factors are to select the appropriate sub-proteome and to ensure that isolation of this sub-proteome is highly reproducible as variations in sample preparation could be misinterpreted as experimentally important changes. Sub-proteomic approaches rely on enrichment techniques for isolation of proteins with similar biochemical characteristics, with similar function or within a specific cellular compartment. In many cases, widely used methods are used for sample isolation, such as sucrose gradient centrifugation for isolating organelles or cellular machines. Affinity purification using antibodies, the tandem affinity tag system or similar methods are typically used to isolate large multi-protein complexes.

Common Protein Profiling Methods

The most common type of proteomics analysis involves the quantitative comparison of protein changes under two or more experimental conditions. Two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) is the oldest and most commonly used method for comparative proteomics, despite several well known limitations. A newer version of 2D gels is 2D differential in gel electrophoresis (DIGE) where two to three different samples can be compared in a single gel after fluorescently tagging each sample with a different cyanine dye (Cy2, Cy3 or Cy5). Even though 2D-PAGE and 2D-DIGE can provide high resolution separation of proteins with detection of many single charge changes,

some groups of proteins are poorly recovered and detected, including very basic or acidic proteins, large proteins and membrane proteins. Quantitative changes are detected on 2D gels using either the cyanine dyes or conventional protein stains. Protein spots that are observed to change in intensity in the biological samples being compared are identified by excising the spot, digesting it with trypsin and analyzing it by LC–MS/MS

An alternative strategy for quantifying protein changes in complex biological samples is to digest the entire sample with a protease, usually trypsin, and then separate the extremely complex mixture by ion exchange chromatography prior to capillary scale reverse phase chromatography interfaced directly with a mass spectrometer. This LC/LC–MS/MS approach is often referred to as "bottom up" or shotgun proteomics. It is better than 2D gels at detecting low abundance, acidic, basic, and membrane proteins but it provides very little information about changes in protein splicoforms, closely homologous proteins or posttranslational modifications because most protein identifications are inferred from identification of a few tryptic peptides. Quantitative comparisons are usually achieved in shotgun proteomics analyses by tagging two samples to be compared with a reagent that is chemically identical where one form is heavier than normal because it contains heavy stable isotopes of one or more atoms. Where feasible, the best method of introducing a heavy label is achieved by growing cells or simple organisms in media enriched in stable isotope-containing metabolites such as ^{13}C labeled essential amino acids. This stable isotope labeling in culture (SILAC) approach has the advantage that labeling occurs before any sample processing occurs, thereby avoiding the potential to interpret variable recovery of specific proteins during sample processing as biologically important changes. The alternative methods for introducing mass tags including modifying reactive groups on the proteins or chemical end labeling of peptides after proteolysis by a variety of different chemistries. An alternative method of quantitating proteins that is gaining in popularity is "label-free" quantitation, which compares the intensity of the ion current for a given peptide in a tandem MS experiment on an instrument with an electrospray interface (ESI). Label-free methods have somewhat larger errors and lower reproducibility than stable isotope tagging methods, but they may prove adequate for detecting most biologically meaningful changes. Ion currents from ESI MS analysis are substantially more reproducible than signals from matrix assisted laser desorption/ionization (MALDI) MS measurements and the related surface enhanced laser desorption/ionization (SELDI) method.

Other methods of comparing protein changes include using antibody arrays, reverse arrays where biological lysates are immobilized and probed with specific antibodies or other ligands of interest, and "top down" proteomics. Top down proteomics uses one or more modes of protein separation prior to introducing the intact protein into a mass spectrometer where the intact mass is measured prior to fragmenting the protein in the mass spectrometer in an attempt to identify the protein from the fragment information. Each method has its strengths and weaknesses and most of these methods are likely to continue to be useful for the foreseeable future.

Proteome Informatics

Computational analysis of the complex data resulting from most proteomics studies is often quite challenging. The importance of having good informatics tools for data interpretation and management has continued to increase as sequence databases become more complex, proteomes are divided into more fractions in attempts to dig more deeply into biological samples, and mass spectrometer become faster and more sensitive, thereby producing far larger datasets than older models. There is a need for standard methods to: describe proteomics experiments; store, manage and analyze MS data; and exchange data within the scientific community. The Proteome Standards Initiative of the Human Proteome Organization (HUPO), leading proteomics journals, and others are developing standards for data management, interpretation and dissemination in proteomic research across instrumentation and software platforms.

Clinical Aspects

Most diseases are expected to substantially alter the composition of the proteomes of affected cells and tissues. Such changes can include differences in protein levels, post-translational modifications, proteolytic processing, and sub-cellular location. Invariably when diseased and normal cells or tissues are compared, many protein changes are seen. The major challenge is to discern those changes that are most critical from incidental or nonspecific changes. Direct analysis of proteome changes in disease studies has great potential to identify novel diagnostic and therapeutic targets because protein activities are directly responsible for observed phenotype and most known drug targets are proteins. Logically, one focus of disease related proteomics studies is to compare diseased tissue with normal tissue, ►Biomarkers. An alternative promising approach is to analyze changes in the blood or other biological fluids that are proximal to the affected tissue, ►Serum Biomarkers. In general, potential disease biomarkers should be easiest to detect in the most proximal biological fluid but ultimately a blood test would be preferred since collection of blood is routine and minimally invasive. While proteomics has great potential for discovery of new disease diagnostic

and therapeutic targets, progress has been slowed by: the high complexity of human proteomes, especially blood; the substantial biological variability among the human population, the polygenetic and often heterogeneous nature of many diseases, and the limited detection and throughput capacity of current proteomics technologies. The discovery of cancer serum biomarkers is particularly challenging because the most specific markers are likely to be shed by only the tumor and not by other tissues. Hence, these proteins will be very low abundance in blood and very hard to detect, especially for early stage, small tumors, ►Early Detection. However, proteomics technologies continue to evolve steadily and promising advances are being made in investigation of cancer and other diseases using proteomics approaches.

Proton Beam Therapy

Masaharu Hata
Department of Radiology, Yokohama City University, Graduate School of Medicine, Yokohama, Kanagawa, Japan

Synonyms

Proton therapy; Proton radiation therapy; Charged particle therapy

Definition

Proton beam therapy is a form of advanced radiation therapy that uses charged particles; it is used principally for the treatment of malignant tumors and occasionally for benign diseases.

Characteristics

Advanced radiation techniques that use photons (X-rays), such as ►three-dimensional conformal radiation therapy (3D CRT) and ►intensity-modulated radiation therapy (IMRT), have seen rapid recent development. The common goal of these treatments is to deliver a high dose to the target while minimizing the dose given to normal tissues. This is essential to achieve better local control and lower toxicity in the treatment of malignant tumors. Although advanced radiation therapies such as these enable higher-dose irradiation to a target, they produce a larger low-dose irradiated volume of normal tissues around the target due to the dispersion of radiation; this will increase the risk of radiation-induced secondary malignancies, especially for children, or unexpected late adverse events.

In contrast, proton beams can theoretically produce excellent dose localization to a target compared with photons because of the sharp distal fall-off of the Bragg peak, which gives no dose to normal tissues beyond the target. This physical characteristic is extremely useful for dose escalation to malignant tumors and is expected to yield enhanced treatment efficacy and reduced toxicity, especially in the treatment of tumors adjacent to critical organs.

Physical Properties

A proton is a positively charged elementary particle and is the nucleus of the hydrogen atom. It is 1,836 times more massive than an electron, which is the other constituent particle of a hydrogen atom. When a proton obtained by stripping a hydrogen atom of an electron is accelerated to high energy in electric fields using a particle accelerator such as a cyclotron or synchrotron, it becomes a type of ionizing radiation and can penetrate a deep area of the tissue. The charged proton decelerates

as its energy is lost due to interactions with electrons in atoms of the tissue; eventually it stops. Just before the proton stops, the interaction rapidly augments and abruptly increases ►excitation and ►ionization of the atoms. This sharp increase in dose absorption is called the "Bragg peak." Once the proton stops, the interactions no longer arise, and no dose is given beyond the Bragg peak. The penetration depth of the Bragg peak depends on the initial energy of the charged proton. Accordingly, the Bragg peak can be precisely placed according to the depth of the target; however, pristine and unmodulated monoenergetic protons are unsuitable for clinical use because the dimensions of most targets are far greater than that of the narrow Bragg peak. To overcome this problem, the Bragg peak is modulated in practical treatment, the so-called "spread-out Bragg peak (SOBP)," to cover the targets effectively (Fig. 1).

Biological Properties

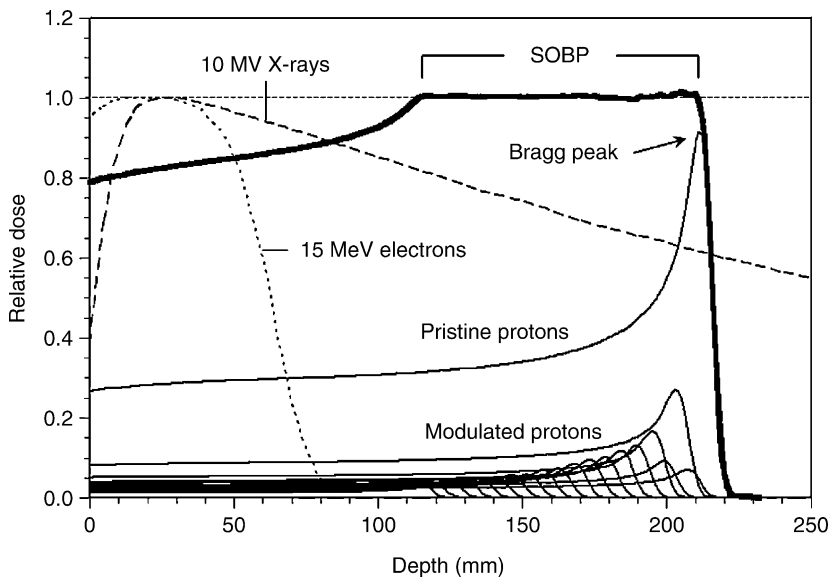
Excitation and ionization occur in tissues along a proton path, producing chemically active ►radicals that impair DNA in the chromosome of a cell. Although cells usually have the ability to self-recover from such impairment, they cannot divide normally or proliferate when the impairment exceeds a certain level. Proton beams are used for cancer treatment utilizing these actions in the same way as photons. Relative biological effectiveness (RBE) is defined as the ratio of the physical dose required to produce a specified effect using reference photons (usually ^{60}Co) relative to that of a specific radiation required to produce the same effect. RBE values in the mid-SOBP of proton beams obtained from outcomes of various experiments in vitro and in vivo range from 0.7 to 2.1. It is known that different accelerators of protons or instruments for beam delivery used at each institution have different RBE values. Furthermore, different RBE values occur even in different measured points of the SOBP, e.g., in the proximal, middle, or distal SOBP. An RBE value of 1.0 or 1.1 is usually adopted for clinical use, and a physical dose of protons multiplied by the RBE value is indicated using the unit of Gray Equivalent (GyE). An RBE value of 1.0 or 1.1 signifies that there is no great difference between protons and photons in terms of the physical doses required to produce a certain specified effect. Thus, the abundant medical data available concerning treatment efficacies for tumors and toxicities of normal tissues using photon irradiation are directly applicable to proton beam therapy.

Clinical Aspects

Compared with conventional photon irradiation, proton beam irradiation is expected to yield enhanced treatment efficacy and reduced toxicity in radiation therapy for a wide range of malignancies. Representative diseases that are widely treated with proton beam therapy are described in the following section.

Uveal (choroidal) Melanoma

►Uveal melanoma is one of the most common primary ocular tumors; it was formerly treated with enucleation of the eye. ►Brachytherapy with radioactive plaques



Proton Beam Therapy. Figure 1 Depth-dose curves for 10 MV X-rays, 15 MeV electrons, pristine protons, and the spread-out Bragg peak (SOBP) produced by a composition of variously modulated protons. For pristine protons, the dose suddenly increases and the Bragg peak is formed before the dose abruptly decreases to zero due to sharp distal fall-off; X-rays penetrate a deeper area, while electrons do not penetrate deeply.

has been used as an eye-preserving therapy in place of enucleation over the past few decades. This approach provides local control of more than 80% at 5 years. Proton beam therapy has recently been applied as a less invasive treatment, and total doses of 50–70 GyE in 4–5 fractions achieves an excellent 5-year local control rate of approximately 95%.

Sarcomas of the Skull Base and Spine

►Chondrosarcoma and chordoma are common tumors of the skull base and spine. Surgical resection is performed for these tumors with curative intent, but they are frequently resected incompletely because of their proximity to critical organs such as the brain and spinal cord. Although conventional photon irradiation is used for unresectable tumors, it is very difficult to give a sufficient tumoricidal dose due to the limited tolerable doses of the adjacent critical organs. Proton beam irradiation allows the delivery of higher doses over 70 GyE and provides 5-year local control of almost 100% for chondrosarcoma and 50–60% for chordoma.

Head and Neck Cancers

Radiation therapy alone or in combination with chemotherapy is widely used for head and neck cancers for the purpose of preserving the function and configuration of organs. Proton beams facilitate the prevention of brain and bone necrosis and the conservation of salivary function while delivering high doses to tumors. The advantages of proton beams are of particular benefit in irradiation of paranasal sinus and ►nasopharyngeal carcinomas located adjacent to the central nervous system. Although few reports describe the use of proton beams for head and neck cancers, this group is among the most suitable subjects for proton beam therapy.

Lung Cancer

Surgical resection remains the most standard and curative treatment for early stage ►non-small cell lung cancer (NSCLC); however, radiation therapy is a feasible treatment option for patients who are inoperable because of comorbidities or who refuse surgical procedures. The irradiated volume and dose given to a pulmonary tumor are frequently restricted due to the low tolerable dose of the lung, and irradiation with large radiation fields and high doses causes severe and occasionally mortal ►radiation pneumonitis. The use of proton beams for lung cancer may reduce the incidence of radiation pneumonitis and enable the safe delivery of high doses to tumors adjacent to the heart, esophagus, and spinal cord. Hypofractionated high-dose proton beam therapy, e.g., with a total dose of 60 GyE in ten fractions, provides local control of approximately 95% for Stage I NSCLC.

Hepatocellular Carcinoma

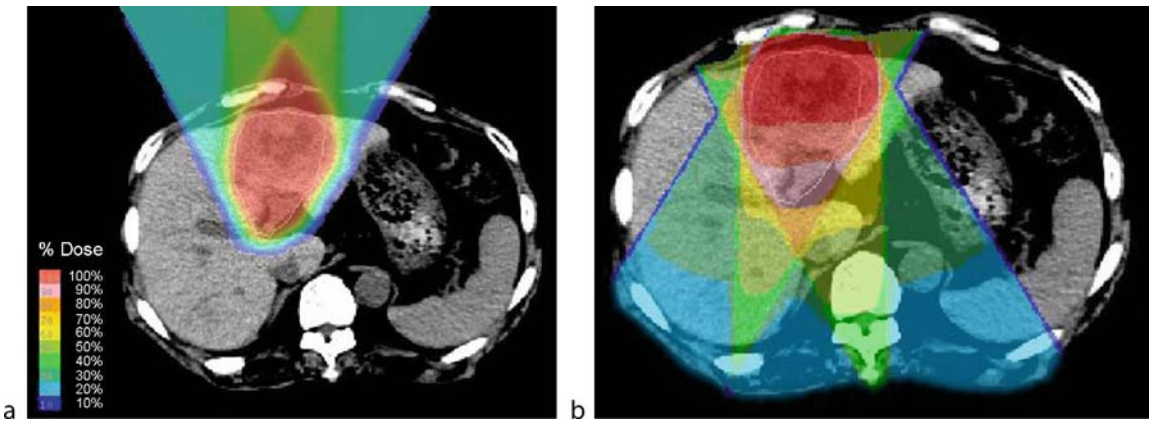
The most reliable curative treatment for ►hepatocellular carcinoma (HCC) remains surgical resection; however, approximately 80% of HCCs are unresectable due to advanced tumors and coexisting cirrhosis at diagnosis. Although nonsurgical treatments such as transcatheter arterial chemoembolization (TACE), percutaneous ethanol injection (PEI), and radiofrequency ablation (RFA) are usually applied to inoperable HCC patients, local failures are common following TACE, and PEI and RFA are unsuitable for patients with bleeding tendency due to cirrhosis, large-sized tumors, or unfavorable tumor location. Therefore, there are numerous patients who have limited treatment options and are unable to undergo effective treatments. Proton beam therapy is widely available for such patients, and provides local control of approximately 90% at 5 years. Furthermore, almost all unresectable HCCs with portal vein tumor thrombus are locally controlled with proton beam therapy. HCC patients commonly develop new intrahepatic lesions remote from the initial tumor after irradiation. In these cases, proton beams enable reirradiation of the new lesions because the irradiated volume and dose given to the normal liver was minimized at the time of previous irradiation. The difference in isodose distributions between protons and photons is shown in Fig. 2.

Prostate Cancer

►Prostate cancer is one of the diseases that are most commonly treated with proton beam therapy worldwide. Radiation therapy can almost match the treatment results of surgery in patients with localized prostate cancer. Prostate cancer is more likely to arise in the elderly; the number of prostate cancer patients is expected to increase because the average life span has been prolonged in many countries. As a less invasive treatment is generally more favorable for aged patients, the proportion of prostate cancer patients receiving radiation therapy will probably increase in the future. Because the prostate is located adjacent to the urinary bladder and rectum, high-dose irradiation to the prostate causes an increase in the incidence of radiation-induced urinary and rectal complications. Proton beam irradiation is used with the aim of decreasing these toxicities. Proton beam therapy alone or in combination with photon irradiation with total doses of 74 GyE or more in conventional fractions provides a biochemical disease-free (►prostate-specific antigen failure-free) rate of approximately 80% at 5 years for patients with early-stage prostate cancer.

Childhood Cancers

Proton beams are used for the treatment of ►childhood cancers, e.g., brain tumors such as ►medulloblastoma and optic pathway glioma, ►retinoblastoma, ►malignant



Proton Beam Therapy. Figure 2 Treatment planning with CT for a hepatocellular carcinoma patient with tumor thrombus in the left main portal vein. (a) Isodose distribution of proton beams delivered through three ports (one anterior and two oblique) to a tumor, including portal vein tumor thrombus. The entire target (contoured by the white line) is homogeneously encompassed by the 100% dose level (red color). Critical organs such as the spinal cord and digestive tract are located entirely outside the irradiated volume, due to the sharp distal fall-off of the Bragg peak of proton beams. (b) Isodose distribution shaped by 10 MV X-rays delivered through the same ports. The irradiated volume increases considerably, meaning that normal structures, including the above-mentioned critical organs and normal liver, are exposed to radiation.

lymphoma, and soft-tissue sarcomas including ►rhabdomyosarcoma. As proton beam therapy is useful in reducing the risk of radiation-induced secondary malignancies, growth failure, and neurological deficits, it is a treatment of great significance for this group.

Miscellaneous

Proton beam therapy is also attempted for other various malignant tumors such as ►glioblastoma multiforme, ►breast cancer, ►esophageal cancer, ►bladder cancer, and ►cervical cancer, as well as benign diseases such as pituitary adenoma and arteriovenous malformation.

Facilities and Costs for Proton Beam Therapy

There are more than 20 facilities for proton beam therapy in operation worldwide; more than 48,000 patients have received proton beam therapy as of January 2007. Although several new facilities are being built internationally, the number remains insufficient to meet the needs of cancer patients. The large area and great expense involved in building a new facility hamper the spread of proton beam therapy; however, construction of a new facility is becoming easier because miniaturization of the particle accelerator has reduced the size requirement of the site, and construction costs have fallen with the rationalization of production procedures. This reduction in cost will reduce the cost disparity per treatment between radiation therapies using protons and photons. Furthermore, the greater the number of patients that receive proton beam therapy, the lower the cost per treatment. The relative cost of proton beam therapy compared to IMRT with photons is currently estimated at approximately 2.4, but is predicted to decrease to 1.7–2.1 over the next few years. There is a need for a future environment in which more patients can undergo proton beam therapy at lower cost.

Proto-oncogene

Definition

A proto-oncogene is a normal cellular gene that, when activated by mutations, acquires oncogenic function. The activating mutations can include intragenic point mutation, translocation (creating a fusion transcript or resulting in transcriptional up-regulation) or amplification with the consequence of enhanced expression; oncogene. Also referred to as cellulor Oncogene (c-onc).

►Transduction of Oncogenes

Protoporphyrin IX

Definition

PpIX; Is the precursor of heme, which is the prosthetic group of hemoglobin, myoglobin, cytochromes, and metalloproteins. PpIX is a potent fluorescent dye and photosensitizer. Its induced accumulation in malignant cells is used for fluorescence-guided resection or fluorescence diagnosis and photodynamic therapy of malignant and nonmalignant diseases.

►Photodynamic Therapy

Provirus

Definition

The double-stranded DNA form of a retroviral genome.

►Transduction of Oncogenes

Prox-1

Definition

A transcription factor expressed in lymphatic endothelial cells but not vascular endothelial cells that is required for development of the lymphatic system. This factor regulates expression of a number of lymphatic endothelial cell genes and suppresses vascular endothelial cell specific gene expression.

►Lymphangiogenesis

Proximal-type Epithelioid Sarcomas

Definition

Highly aggressive soft-tissue tumors of young adults, characterized by both epithelial and mesenchymal phenotype; they harbor a variable amount of rhabdoid cells and occasional *hSNF5/INI1* inactivation.

►Tumor Suppressor hSNF5/INI1

Proximate Carcinogen

Definition

A metabolite of a carcinogen intermediate in the conversion to an ultimate carcinogen.

Prozac

►Fluoxetine

Prune

Massimo Zollo
Department of Genetics, Faculty of Biotechnological Sciences Federico II, Naples, CEINGE, Biotecnologie Avanzate, Naples, Italy

Definition

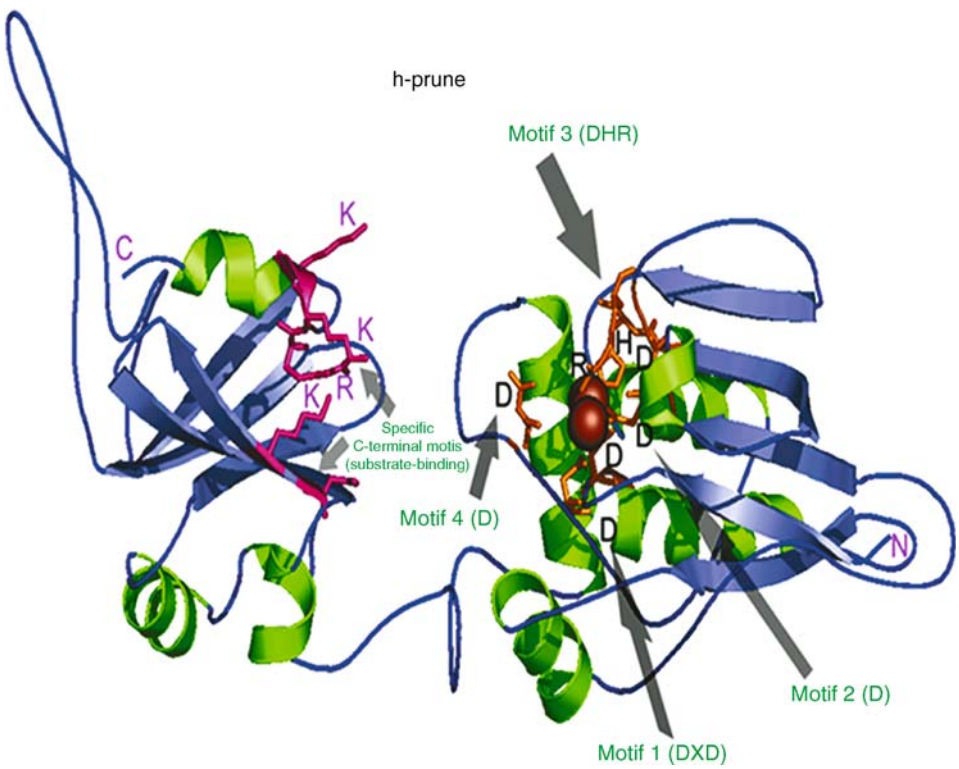
Prune stands for the human homologue of the Drosophila prune gene. Prune protein was initially identified in *Drosophila*, in which its mutation caused a brownish-purple "prune" eye color due to significant loss of drosopterins "red pigments," compared to the bright red eye of the wild-type fly, thus explaining its mutant name.

Characteristics

Prune is appertaining to the DHH family phosphoesterase proteins including RecJ DNA repair Exonucleases, Pyrophosphatases (PPASEs) and Exopolyphospatases (PPX). The DHH super-family can be divided into two main groups on the basis of a C-terminal motif that is very well conserved within each group, but not across the groups. All the members of this super-family possess four other motifs that contain highly conserved charged residues predicted to be responsible for binding ions and catalyzing the phosphoesterase reaction. The most characteristic of these is the third motif, with the signature DHH (Asp-His-His), after which this super-family was named. Prune is a cyclic nucleotides phosphodiesterase. Due to its protein similarities, Prune might possess other biochemical functionalities within the DHH family of proteins.

Human prune, a 62 kDa protein, acting as a cytoplasmic cyclic nucleotides phosphodiesterases (cNMP-PDE) is involved in both promoting cellular mobility and stimulating expression of genes involved in metastatic pathways.

In breast cancer, metastatic spread is responsible for virtually all cancer deaths. ▶Metastasis is a highly complex molecular and cellular process. To become invasive, tumor cells need to change their adhesive properties, to lose contact with other cells in the primary tumor, and make new contacts with the extracellular matrix of host cells they encounter as they invade. They also need to be able to penetrate into the surrounding host tissue, and here the modulation of protease activity in the vicinity of the tumor cells plays a critical role.



Prune. Figure 1 Ribbon structure of the h-prune protein based on the crystal structure of PPASE and the RecJ protein. Red balls indicate potential cofactor ions (Mg2+ and/or Mn2+) and the region of binding to motif III. Arrows indicate the aspartic acids (D). Aspartic acids of the four DHH motifs are represented, indicating the potential catalytic site of DHH protein family [1].

To migrate away from the primary tumor, tumor cells also need to gain motility functions. These same properties are also thought to be important when circulating tumor cells exit the circulatory system and start metastatic colonization in secondary organs.

Prune possesses a cAMP phosphodiesterase activity, which is responsible for increasing cell motility in breast carcinoma cell lines. Within the breast cancer cellular model, using gene expression analyses, several key players were identified acting as signals of cytoskeleton remodeling and cell motility, thus influencing the malignancy of Prune overexpressing breast cancer cells.

The physical interaction between Prune and nm23-H1, a suppressor of metastasis protein, enhances Prune cAMP-PDE activity, thus the interaction causes the subtraction of unbound nm23-H1 proteins into the cell. The major component of the nm23-H1 anti-metastases function is its capability to induce "low motility cellular processes" if overexpressed in aggressive breast cancer cells, although this activity was found in other solid tumors such as prostate, colon, lung, head and neck.

Amplification of Prune copy numbers induces cell proliferation and high levels of Prune expression compared to the moderate or lower nm23-H1 level of expression that is correlated to aggressiveness of sarcoma and breast carcinoma, colon and gastric carcinoma, thus postulating an inhibitory role of Prune versus the anti-metastasis nm23 function "in vivo."

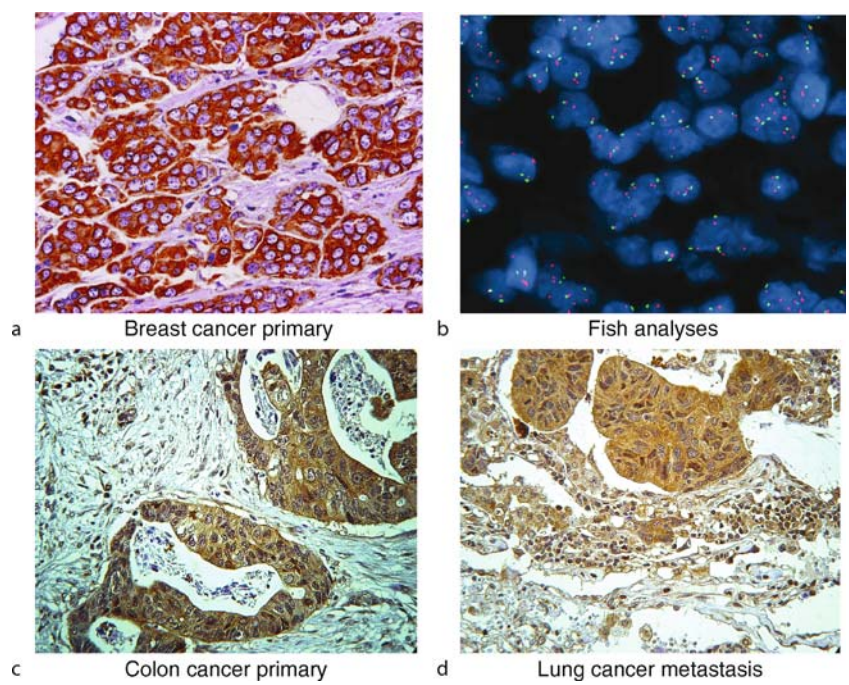
The region of the nm23–h-prune interaction lies between S120 and S125 of nm23, where missense mutants show impaired binding; this region can undergo serine phosphorylation by casein kinase I. Thus, the casein kinase I δ-ε specific inhibitor IC261 impairs the formation of the nm23–h-prune complex, which translates "in vitro" into inhibition of cellular motility in a breast cancer cellular mode.

Regulation

Prune participates in the complex network of interactions with proteins involved in cell cycle and cell motility. It is known that: (i) Prune together with glycogen synthase kinase-3 (GSK3β), a kinase involved in ►WNT signaling pathway, cooperatively regulates the disassembly of focal adhesions to promote cell migration, and (ii) Prune via interaction with Gelsolin, an ATP severing protein acting in focal adhesions, leads to invasion properties of cancer cells. Both of these pathways promote cancer metastasis. Interestingly, Prune has also been shown to be highly expressed in brain development together with nm23-H1, expression was observed in cortex, hippocampus, midbrain and during cerebellum development.

Clinical Relevance

Prune has a role in the metastatic processes through specific inhibition of the anti-metastasis function of



Prune. Figure 2 (a) Expression and cytogenetic analysis of h-prune in breast carcinomas. (b) FISH analyses on the same samples using h-prune/ PAC279-H19 (*red*) and control pUC177 (*green*) as probes [4]. (c) Expression and cytogenetic analysis of h-prune in colon cancer. (d) Expression and cytogenetic analysis of h-prune in a metastasis site in lung from primary colon cancer (see c) (data unpublished).

►nm23-H1 in vivo. Overexpression of Prune is involved in cancer progression and tumor aggressiveness, particularly by defining the lymphnode positive status and correlated to breast cancer advanced disease status. This condition is enhanced in colon carcinoma where Prune positive tumors have a bad sign of malignancy and prognosis. Significant statistical analyses of Prune immunostaining positive colon carcinoma associates the level of expression to tumor grade (T1-T2/T3-T4) (►grading of tumors), lymphnode status (N0/N1-N2) and metastases grade (M0/M1), while only to tumor grade (T1-T2/T3-T4) and lymphnode status (N0/N1), in pancreatic cancer. Two reports described h-prune involvement with tumor progression in gastric cancer and in esophageal squamous cell carcinoma as an independent prognostic marker.

Inhibition

Four ways of inhibition of Prune pro-motility activity in cancer cells (in breast, colon and pancreas) are postulated at this time. Firstly the use of Dipyridamole, which alters its cAMP-PDE function in breast cancer cells, and thus negatively influencing its pro-motility effect. Secondly, the strategy of using the inhibition of Prune-GSK3β functional interaction in focal adhesion using SB216763 (a specific GSK3β inhibitor) or a combination of dipyridamole and SB216763. Thirdly, by using a peptide mimicking the region of interaction between Prune and GSK3β including the amino-acid region position 333–443 of Prune protein. Fourthly, by using IC261, a drug that impairs the CKI function thus inhibiting nm23-H1 S125 phosphorylation and consequently impairing the binding with Prune.

PSA

Carsten Stephan
Department of Urology, Charité Universitätsmedizin, Campus Charité Mitte, Berlin, Germany

Synonyms

Human kallikrein 3; KLK3

Definition

Prostate-specific antigen (PSA) is a serine protease (33 kD) secreted mainly by prostatic epithelium. It is important for its role in the liquefaction of seminal coagulum.

Characteristics

After a tissue specific antigen was identified in the human prostate in 1970 and the discovery of prostatic antigens in seminal plasma, PSA was subsequently isolated and characterized in 1979. PSA was cloned in 1987. PSA mRNA encodes for (261) 244 amino acid (pre)proforms of the protein, although the mature, catalytically active, single-chain form of the protein contains 237 amino acid residues. As member of the human ►kallikrein family, PSA shares considerable structural and functional homology with all other 14 human kallikreins, together with a gene location on the long arm of chromosome 19 (19q13.2-q13.4). Kallikreins are proteases that cleave vasoactive kinin peptides from kininogen. PSA, however, functions as a chymotrypsin-like serine protease cleaving substrates such as seminogelin I, seminogelin II, fibronectin, and insulin-like growth factor/binding protein in the seminal plasma which helps maintain sperm motility. PSA is made primarily by prostatic epithelium and periurethral glands in males, but it has also been detected in endometrium, breast tissue, breast cancer, breast milk, and female serum. In normal prostate, the epithelium secretes PSA into the seminal fluid, where it reaches concentrations of 0.4–5 g/L. In the normal male, PSA is detected in the circulation at low concentrations of 0–1 (2) μg/L.

Approximately 75% of PSA found in serum is irreversibly bound to the protease inhibitor alpha-1-antichymotrypsin (ACT). Serum PSA also binds to alpha-2-macroglobulin (A2M). Measured PSA in serum comprises 5–50% unbound or free (fPSA). PSA has five immunoreactive sites. Two of these epitopes are hidden in ACT-PSA, allowing commercial immunoassays to differentiate bound from free PSA. All five epitopes are hidden in A2M-PSA. Therefore, total PSA (tPSA) measured by commercial assays corresponds to fPSA plus PSA bound to proteins other than A2M-PSA.

A small part of tPSA (0.9–1.6%) is also bound to alpha1-protease inhibitor (API-PSA). Complexed PSA (cPSA), defined on the basis of an assay utilizing a blocking antibody to fPSA, detects ACT-PSA and API-PSA, but not the A2M-PSA complex. Several uses of the cPSA test have been proposed.

Free PSA has recently been shown to exist in at least three molecular forms; "benign" PSA (bPSA), inactive "intact" PSA (iPSA), and proPSA. An overview of all PSA forms is given in the figure. The bPSA is a specifically clipped subform of fPSA, which is highly associated with the transition zone containing benign prostatic hyperplasia (BPH) nodules in prostate tissue. BPSA represents 0–60% of fPSA but it cannot discriminate between BPH and ▶prostate cancer (PCa). Based on the development of novel anti-PSA antibodies that do not recognize internally cleaved PSA at Lys145-Lys146 and thus are specific for intact, unclipped PSA, an assay has been developed for "intact" PSA (iPSA). The iPSA assay detects both proPSA and other inactive non-clipped fPSA entities and can discriminate between BPH and PCa. Recently, proPSA forms were isolated in serum and tissue from PCa patients. The proPSA in serum and prostate tissue exists as a mixture of differently designated forms including the (–7), (–5), (–4) forms and, partially, the (–2) and (–1) forms. Whereas the (–5, –7) proPSA have limited validity to improve PCa detection, the (–2) proPSA seems to better discriminate BPH and PCa and may further detect more aggressive PCa, as indicated by Gleason score 7 or greater.

The ratio of free to total PSA used in literature as f/tPSA ratio (percent free PSA, %fPSA) tends to be increased in benign disease compared to PCa. The reason for this difference is not completely understood. It is assumed that due to the loss of tissue architecture in PCa the intracellular active PSA gains quicker access to the circulation and protease inhibitors, like ACT and A2M, can bind PSA easily. If PSA reaches the circulation from normal or BPH cells, it first has to leak into the extracellular space, where it is susceptible to proteolytic degradation. After degradation, the inactive PSA can still form complexes with A2M but only to a very small degree with ACT. This may explain the decreased capability of PSA to form complexes with ACT and the higher concentration of PSA-A2M in BPH patients.

Clinical Aspects

PSA is organ-specific, but not cancer-specific, since it can by produced by normal, hyperplastic, and neoplastic prostate epithelial cells. PSA synthesis is influenced by testosterone levels.

It has limited sensitivity and specificity in appropriately detecting the earlier stages of abnormal prostate growth. The elevated circulating PSA levels can be due to PSA leakage into the bloodstream from abnormal prostate growth or inflammation, such as prostatitis.

PSA as Diagnostic Marker

Measurement of serum PSA is commonly used to aid the diagnosis of PCa. The introduction of routine PSA-based screening, together with digital rectal examination (DRE), over the past 20 years has led to a dramatic increase in the rate of disease detection and a subsequent stage shift at the time of diagnosis. For many years, a PSA value of 4 μg/L has been used as the cutoff for prostate biopsy. However, in 2004, an analysis of 2950 men, who never had a PSA level >4.0 μg/L or an abnormal DRE, PSA levels of 0–4 μg/L were associated with a positive predictive value (PPV) for PCa of 6.6% (PSA 0–0.5 μg/L) to 26.9% (PSA 3.1–4 μg/L). Overall, 15% of men with PCa had high-grade disease, with this rate reaching 25% among men with a PSA level of 3.1–4 μg/L. Thus, there is no PSA level, where PCa or even aggressive PCa can be excluded.

A further problem is evidence that PSA screening can reduce PCa mortality in large randomized prospective studies and therefore population screening is debated. In 2008/2009, results of two large randomized studies in Europe and USA will provide sufficient information whether PSA screening can reduce PCa mortality. Despite these controversies, PSA has revolutionized the management of PCa especially for the early disease detection, which has improved curative treatment. To date, the most commonly used and easy available PCa screening tool is the combined use of DRE and PSA as each can identify cancers not detected by the other. It has been shown, that screening intervals can be extended to 5–8 years for men with an initial serum PSA level of <1 μg/L, and to 2 years for men with an initial PSA level of 1–2 μg/L. In men older than 65, with PSA levels of <1 μg/L, it is presumed that follow-up may be omitted.

A principal problem with PCa screening is that only approximately a third of men with elevated serum PSA have cancer in prostate biopsies. Most false-positive PSA results are caused by BPH. False-positive results cause unnecessary prostate biopsies, generating anxiety, discomfort and costs.

To improve this dilemma, several calculated parameters, such as PSA density (PSA divided by the prostate volume), PSA transition zone density, PSA velocity (PSA change over time) or age- and race-specific PSA ranges were introduced but have only been partially successful in enhancing the specificity of PSA. Due to large biological variations in the measured PSA concentrations up to 20–30%, a repeat measurement of PSA can also avoid significant numbers of unnecessary prostate biopsies.

Percent free PSA

The use of %fPSA has been established as a clinically routine test since the mid 1990s, especially for indication of a repeat biopsy. Various studies have demonstrated a significant improvement in specificity for the 4–10 μg/L tPSA range and for lower tPSA values (<4 μg/L). Generally, with %fPSA cutoffs at 90–95% sensitivity, the number of unnecessary biopsies could be reduced by approximately 15–20%. Possible influencing factors such as prostate volume, tPSA, race, sample stability, prostate manipulation or drug treatment should all be considered. It has been proposed to use %fPSA as a priority decision tool for first time biopsy in men with unsuspicious DRE within the tPSA range 4–10 μg/L, as well as for lower PSA values. Expanding the range of additional fPSA measurements from 4–10 μg/L to 2 or 2.5–10 μg/L could be beneficial for detecting significant PCa at low tPSA values. Using %fPSA-based multivariate models like logistic regression or artificial neural networks for prostate biopsy decision can further improve PCa detection rate. These models include tPSA, %fPSA, prostate volume, age, DRE status or other clinical variables and this may decrease the overdiagnosis of PCa when using PSA alone.

PSA, %fPSA for Staging and Grading

It is well established that serum tPSA has both a diagnostic utility for the detection of PCa, and a prognostic impact. Clinical stage, ►Gleason grade and serum tPSA individually and independently correlate with pathological stage and prognosis of PCa. Subsequently, tPSA is always taken into consideration before planning PCa therapy. For example, patients with elevated levels of tPSA (>20 μg/L) are considered to be at high risk of non-localized disease, and are often contraindicated for curative treatment alone (radical prostatectomy, brachytherapy, or radiotherapy). However, the use of tPSA alone is not sufficiently sensitive or specific for staging. Although tPSA directly correlates with clinical and pathological tumor stage, studies have revealed that this marker cannot accurately predict the final pathological stage for individuals.

The ability of %fPSA to improve PCa staging has been controversial. Several centers have reported that %fPSA was useful to predict pathological stage, while others noted no significant improvement in staging, even when %fPSA was combined with Gleason score and clinical stage. The same situation exists when using %fPSA to predict grade. It is assumed that lower %fPSA values correlate with more aggressive disease. However, an individual prognosis is not possible by using tPSA or %fPSA.

PSA for Recurrence of PCa

After initial diagnosis and treatment, PSA plays a vital role in the follow-up of PCa. Serial PSA measurements demonstrate the growth characteristics of each tumor. Thus PCa control, recurrence or hormonal escape can be determined. This allows detection and treatment of skeletal metastases prior to fracturing. Second line treatments can then be introduced before the onset of symptoms.

Monitoring After Radical Surgery

The clinical use of ultrasensitive tPSA assays in recent years has increased the lead time for identifying recurrence of PCa following local therapy. The most effective method to monitor disease recurrence postoperatively is serial tPSA determinations. After radical prostatectomy, the majority of men have a rapid decline in serum tPSA to undetectable levels. As a corollary, the failure of PSA to become undetectable is highly suggestive of persistent disease. PSA elevations following the attainment of undetectable levels postoperatively provide an early warning sign of disease progression. The preoperative tPSA level and the timing of PSA recurrence after surgery can predict disease-free survival and the pattern of recurrence, respectively. Very recently it has been proposed that biochemical recurrence, defined as a tPSA of at least 0.4 μg/L followed by another increase, best identifies metastatic progression after radical prostatectomy.

Use of PSA to Monitor Radiation Therapy

PSA has been used as a surrogate end point to monitor disease activity following prostatic irradiation and this has been a major advance recently. The simplicity of serum PSA measurements, avoidance of routine radiographic imaging and cost savings are apparent. Like radical prostatectomy, PSA elevations provide early biochemical evidence of disease recurrence before clinically significant local disease or metastasis develops. The response of PSA to irradiation is more unpredictable than surgery in which PSA levels often become undetectable. After radiation therapy PSA levels decline more slowly and may not reach undetectable levels. The kinetics of a rising PSA (PSA doubling time) appear to be the best surrogate marker for disease risk, clinical progression, and ultimately cancer-specific death.

PSA monitoring After Androgen Deprivation Therapy

Androgen deprivation therapy is a commonly used treatment modality for men with advanced PCa, and includes bilateral orchiectomy, various antiandrogens, luteinizing hormone-releasing hormone agonists and 5-alpha-reductase inhibitors. Since PSA production and secretion require hormonal influence, androgen deprivation therapy diminishes the ability of benign and malignant prostatic epithelial cells to manufacture PSA. Unless the cancer comprises a critical mass of androgen independent neoplastic cells, serum PSA usually declines significantly and often to undetectable levels.

Further increases in serum PSA values, despite androgen deprivation therapy, indicate progression due to an emerging subpopulation of hormonally resistant clones. PSA levels should decline within the first 6 months after androgen deprivation therapy. However, progression of PCa may occur despite undetectable or low PSA levels. This likelihood increases in patients with high-grade, locally advanced tumors, especially when atypical histological variants are present.

Conclusion and Future

PSA has revolutionized the clinical care of PCa. It is vital to the diagnosis and subsequent follow-up of the disease, despite all the controversies with PSA screening and the urgent need for better tumor markers. One of the most important goals for PCa serum marker development is the search for a marker which can predict the Gleason grade 4/5 which to date is the only independent prognostic factor for a biochemical failure after radical prostatectomy.

Pseudarthrosis

Definition

False joint. Typically located in tibia in patients with neurofibromatosis 1.

►Neurofibromatosis Type 1

Pseudogene

Definition

DNA sequences thought to be non functional that are very similar to sequence encoding a functional gene product.

Pseudokinase

Definition

A protein that presents a conserved kinase-like domain in its structure that lacks at least one of the conserved catalytic residues. Although these proteins are predicted to be catalytically inactive they regulate important cellular processes via protein-protein interactions.

►Cannabinoids

Pseudomonas Aeruginosa

Definition

A gram-negative bacteria that is an opportunistic pathogen.

►Cytokine Receptor as the Target for Immunotherapy and Immunotoxin Therapy

Pseudomonas Exotoxin

Definition

Toxin produced by ►Pseudomonas aeruginosa that inactivates eEF-2 and inhibit translocation during eukaryotic protein synthesis.

►Cytokine Receptor as the Target for Immunotherapy and Immunotoxin Therapy

Pseudomyxoma Peritonei

Definition

A mucinous appendiceal neoplasm rupture causing the release of mucus-producing epithelial cells into the free peritoneal cavity. These tumors accumulate and then grow in large volume beneath the hemidiaphragms, within the greater omentum, and within the pelvis.

►Appendiceal Epithelial Neoplasms

Pseudomyxoma Peritonei

Synonym

Jelly belly

Definition

Pseudomyxoma peritonei (PMP) is a rare epithelial neoplasm, arising in the majority of cases from the ►appendix, characterized by disseminated peritoneal mucinous tumor deposition and progressive accumulation of mucinous ascites. PMP is a registered rare disease (no. 843) by the National Organization of Rare Disorders.

Characteristics

Epidemiology

In Western populations, the estimated incidence is 1–2 per million, accounting for approximately 1,500 new cases per year in the USA; 50–70 new cases per annum in the UK. Most series show a female predominance; typically a 70:30 ratio. The mean age at presentation is in the mid-sixth decade of life, ten years younger than the mean age for colorectal cancer. Although of "colorectal origin," it is not known whether PMP shares PMP aetiological risk factors such as family history, westernized diet, obesity, and physical inactivity, as there is a paucity of large-scale epidemiological studies in this area.

Historical Perspective

PMP was originally described by Rotikansky in 1842, and for many decades, was believed to arise from mucinous tumors of the ovary. It is now widely held that the majority of PMP arise from an ►appendiceal epithelial neoplasm.

Natural History

The process of tumor dissemination may start with an occult perforation of the appendix, and while the appendiceal lesion often maintains indolent histological features, if unabated, the disease disseminates aggressively throughout the abdominal cavity. Large volumes of mucinous deposits may accumulate within the greater and lesser omentum, the spaces between the liver and diaphragm and within the pelvis, but the small bowel is often free of disease (except for the jejunum that is adjacent to the ►ligament of Treitz). It has been suggested that the principles of fluid hydrodynamics and gravity control this "redistribution phenomenon" such that the movements by small bowel peristalsis spares these structures. However, this does not explain dissemination in the absence of appendiceal perforation and the tumor's biology may be an alternative explanation.

The accumulation of extra-cellular mucin is central to the pathogenesis of the disease. Longstanding disease may fistulate into retroperitoneal spaces and beyond, including crossing the diaphragm into the lungs. The disease may also "burrow" into anatomical corners such as the reflection of the diaphragmatic peritoneum onto the liver and the insertion of the Ligamentum teres on to the liver, and may invade organs such as the spleen. However, PMP seldom metastases in a conventional manner via lymphatics to the nodal system or via blood to the liver and lungs. Untreated, progressive mucinous accumulation (over years in most cases) leads to extrinsic compression of bowel, malnutrition, and eventual death.

Appendiceal Origin

The reasons why it is now widely held that the majority of PMPs arise from an appendiceal primary tumor (as opposed to ovarian origin) are as follows:

- Careful histological examination of the appendix reveals an adenoma in most cases.
- Perforated appendix is frequently observed at laparotomy and/or histological examination.
- Immunohistochemistry staining is predominantly cytokeratin (CK) 20 positive (a marker of gastrointestinal epithelium), rather than CK7 positive (a marker of ovarian origin).
- PMP in males accounts for 30–50% of cases (arguing against an ovarian origin).

- K-ras mutational analysis supports the view that PMP is clonally derived from an associated appendiceal mucinous adenoma.

A small proportion of PMP cases arise from organs other than the appendix including stomach, colon, pancreas, gallbladder, urachus, and (confusingly) ovaries. PMP has also been described in the presence of dual pathologies such as ovarian teratoma.

Pathological Classification

Pathological nomenclature and histological classification in relation to PMP is potentially confusing. If the histological description is confined to that of the appendiceal lesion, the terms low-grade appendiceal mucinous neoplasm (LAMN) or appendiceal mucinous tumor of uncertain malignant potential are used.

For disseminated disease, the Ronnett classification of three groups is widely used: disseminated peritoneal adenomucinosis (DPAM), peritoneal mucinous carcinomatosis (PMCA) and PMCA with intermediate or discordant features (PMCA-I/D). In the original description of 109 peritoneal tumors, 95% were considered appendiceal primaries. This classification correlates well with 5-year and 10-year survivals: DPAM (75% and 68%, respectively); PMCA-I/D (50% and 21%); and PMCA (14% and 3%). Recently, Bradley et al reviewed 101 patients with PMP of appendiceal origin and applied a new (simplified) classification using the term mucinous carcinoma peritonei-low grade (MCP-L) to those cases referred to as DPAM and PMCA-I/D by Ronnett, and mucinous carcinoma peritonei-high grade to those referred to as PMCA.

Presentation

The classical presentation is one of advanced disease with a distended abdomen, mucinous ascites and peripheral wasting. In a contemporary practice, it is not uncommon for PMP to present earlier as an incidental finding, for example: a cystadenoma of the appendix on CT scan; mucinous tumor deposit noted at ►herniorrhaphy; on histological examination after appendicectomy; and during gynaecological laparoscopic diagnostic examination.

Staging Systems

There is no universally held pre-operative staging system. The correlation between pre-operative assessment by imaging (usually contrast-enhanced CT scan) and tumor volume found at surgery is modest. The following serum tumor markers has been evaluated in the pre-operative setting – ►CEA, CA19.9, CA125 and CA15.3 – but their accuracy to discriminate histological types and/or the prediction of the completeness of cytoreduction is modest.

A variety of intra-operative staging systems (Gilly Peritoneal Carcinomatosis Staging; Japanese system; Peritoneal Cancer Index; and Dutch Simplified Peritoneal Cancer Index) have been described to quantify tumor volume in other peritoneal tumor diseases, but they do not readily extend to quantifying PMP and its prognosis.

Cytoreductive Surgery

Until a decade ago, the mainstay of treatment for patients with PMP was repeated interval debulking surgery for relief of symptoms but with no expectation of improved survival and/or cure. Since then there has been a major paradigm shift towards management by complete surgical cytoreduction and the application of intra-peritoneal chemotherapy. This operation is often referred to as the ►Sugarbaker procedure after the surgeon who promulgates this approach. It involves up to six different peritonectomy procedures in combination with visceral resections as required, with the aim to remove all visible tumor, or if this is not possible, to leave tumor deposits less than 2.5 mm (2.5 mm being the maximum direct penetration of locally applied chemotherapy). This is a lengthy operation (may take 8–12 h) with a list of recognized complications including haemotological toxicity, substantial blood loss, re-operation, and 30-day mortality in the order of 2–4%.

Rationale for Intra-Peritoneal Chemotherapy

Traditionally, systemic chemotherapy for PMP is ineffective and thus intra-peritoneal chemotherapy as become part of the loco-regional multimodality standard in combination with cytoreductive surgery. There are two approaches: hyperthermic intra-peritoneal chemotherapy (HIPEC) or early post-operative intra-peritoneal chemotherapy (EPIC), and in combination. A randomized trial has shown that HIPEC is associated with lower complication rates. In HIPEC, the chemotherapy agent is typically perfused within the abdominal cavity for ninety minutes at 42°C. Based on historical in vitro experiments using ovarian and colorectal cancer cell lines, mitomycin has been the most widely used chemotherapy agent. Others include: doxorubicin, cisplatin, oxaliplatin, irinotecan and 5-fluorouracil.

Prognosis

Completeness of cytoreduction is the single most important predictor of patient prognosis. The completeness of cytoreduction score (CC score) is used to assess this and complete (CC-0 or CC-1) or incomplete (CC-2 or CC-3) cytoreductions are determined. A CC-0 is apparent when there is no peritoneal seeding visualized within the operative field; CC-1 indicates nodules persisting after cytoreduction less than 2.5 mm; CC-2 indicates nodules between 2.5 mm and 2.5 cm; and CC-3 indicates nodules greater than 5 cm or a

confluence of tumor nodules at any site within the abdomen or pelvis. The 5-year survival for complete cytoreduction is 86% versus 20% for incomplete surgical excision of tumor.

Palliative Treatment Options

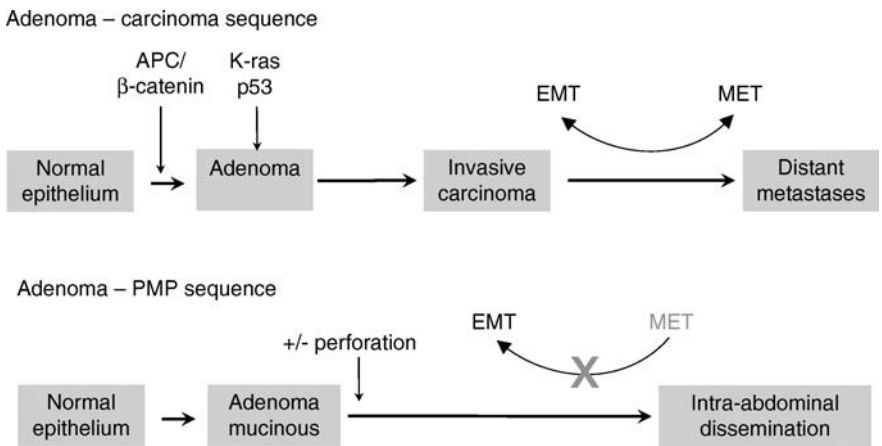
In the absence of effective systematic chemotherapy, in patients deemed unsuitable for cytoreductive surgery, the main option has been debulking surgery for symptom relief. However, oncologists are now beginning to explore the use of combinations of new chemotherapeutic agents, effective in colorectal cancer, and administer systemically. These approaches, however, stabilize disease rather than reduce tumor volume.

There have been a small number of studies on quality of life in patients with PMP, which in general support the role of intensive loco-regional multimodality therapy and debulking, though long-term depressive symptoms are common and information needs are high in these patients.

Basic Science

Given the rarity of this tumor, molecular investigation of PMP has been scarce. However, the following have been elucidated from a number of small studies:

- In common with colorectal neoplasia, ►K-ras mutations seem to be common.
- Unlike most colorectal adenomas, loss of heterozygosity of ►*APC* (adenomatous polyposis coli) is not a prequisite in PMP.
- ►P53 mutation occurs but perhaps not as common as sporadic colorectal cancer.
- Consistent with the more indolent nature of PMP, proliferation indices tend to be lower than counterparts in colorectal carcinomas.
- ►Microsatallite instability, common amongst right-sided colonic tumors, has not yet been studied.
- Given that PMP is characterized by excessive mucinous deposition, not unexpectedly, there is increased expression of MUC-2 (a mucin with gel-forming physicochemical properties similar to those exhibited by PMP), and of interleukin-9 (which induces MUC-2 and MUC-5AC gene expression).
- Recent data demonstrate that PMP has a specific pattern of adhesion-related protein expressions of increased N-cadherin, reduced ►E-cadherin, and increased vimentin; a phenotype suggesting an ►epithelial-mesenchymal transition state. During this transition, cells loose polarity and adherens junctions, and become more "fibroblast-like." These observations suggest that a specific phenotype may characterize the distinct non-metastasing behavior of PMP (Fig. 1), and form the basis for future mechanistic and therapy-targeting research.



Pseudomyxoma Peritonei. Figure 1 The "Vogelstein" adenoma-carcinoma sequence of sporadic colorectal adenocarcinoma (upper panel). The pathological transitions from normal epithelium through adenoma to invasive carcinoma are characterized by a multi-step accumulation of molecular events including APC mutation, accumulation of nuclear β-catenin, and mutations of p53 and K-ras. It is increasingly recognized that during the processes of invasion and metastases, the intestinal epithelial cells under phenotypic changes and take on the features of a mesenchymal cell – the epithelial-mesenchymal transition (EMT). Once a cancerous cell metastasizes, it establishes itself in a new micro-environment and reverts back to an epithelial phenotype – the ►mesenchymal-epithelial transition (MET). PMP arises from an appendiceal adenoma (lower panel), but unlike sporadic colorectal adenocarcinoma, it disseminates throughout the abdominal cavity rather than metastasize. In this disseminated state, PMP seems to have an "exaggerated" EMT phenotype but without an ability to undergo MET and establish metastases. It is unclear whether perforation of the appendix is a prerequisite to dissemination. This is currently a hypothesis.

Definition
PTEN (phosphatase and Tensin homolog deleted on chromosome Ten) is a tumor suppressor gene located in human chromosome band 10q23. The protein product of the PTEN gene (PTEN) is a phosphatase, a protein that removes phosphate groups from other molecules. Specifically, PTEN is a phosphatase for both phosphorylated lipids and phosphorylated proteins. The former activity is linked to the ability of PTEN to block cellular signals that promote growth and survival.

Characteristics
Somatic Mutation of PTEN
All normal cells have two copies of the PTEN gene. However, loss of one or both copies of the PTEN gene in the tumor cells of a number of common cancer types has been increasingly recognized. These tumors types include cancers of the prostate, endometrium, brain (►glioblastoma multiforme), thyroid, ovary, kidney (►renal carcinoma) and skin (►melanoma). In cancers of the prostate and in glioblastoma, PTEN mutation is associated with the more aggressive forms of the disease. For example, astrocytic brain tumors are classified by the histological grade of the tumor. While PTEN mutations are rare in anaplastic astrocytoma (less aggressive), mutations are common in glioblastoma multiforme (the most aggressive). Similarly, loss of the PTEN protein product is associated with higher grade prostate tumors, and PTEN mutations are found more frequently in metastatic prostate tumors when compared to those that remain confined to the prostate organ.

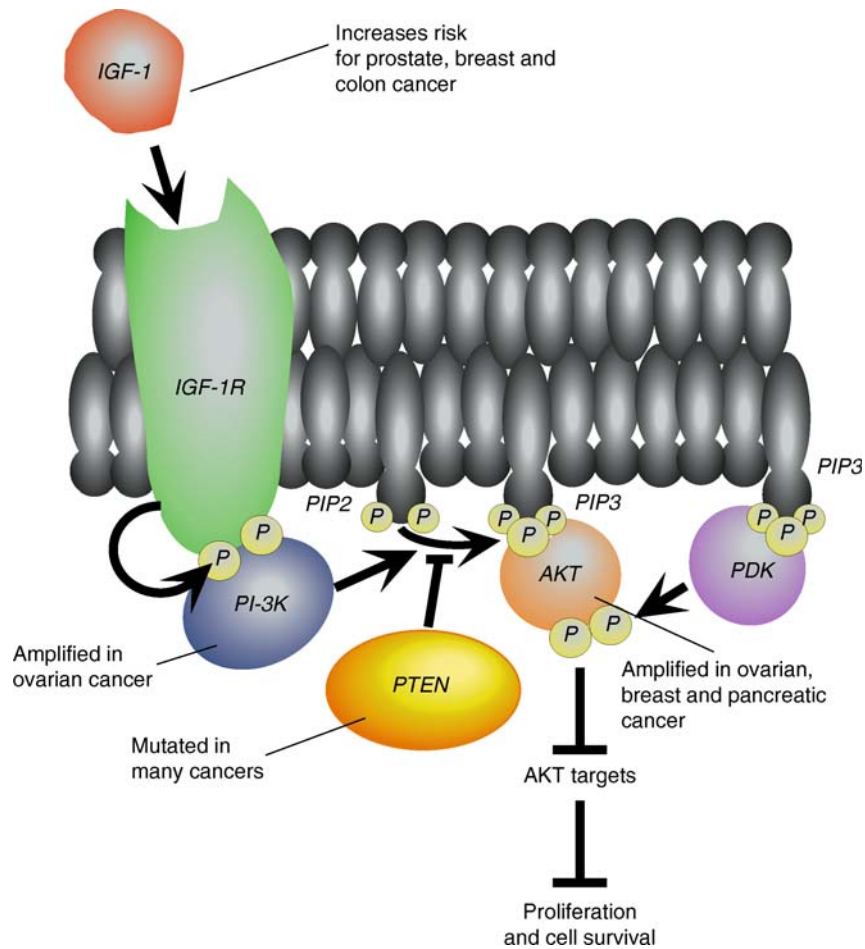
Germline Mutation of PTEN
Mutation of PTEN in the germ line DNA is associated with the development of two inherited syndromes with overlapping clinical features. Patients with these syndromes, Cowden disease and Bannayan-Zonana syndrome, develop abnormal growths (hamartomas) of the skin, hair follicle (trichilemmoma), breast, thyroid and intestinal tract, as well as neurological abnormalities. Such patients also have a higher incidence of cancers of the breast and thyroid. Thus both common cancers and certain rare inherited cancer predisposition syndromes can result from mutation of PTEN and the consequent loss of function of the gene product.

Biochemical Functions
Biochemical and structural studies of the PTEN protein have revealed that it is a member of the phosphatase family of proteins. These proteins typically remove phosphate groups (often the elements transferred during cellular signaling) from other macromolecules including proteins, lipids and nucleic acids. When assayed in vitro, PTEN can dephosphorylate (removes the phosphate from) protein substrates and in particular has a strong preference for acidic protein substrates (such as poly-glutamic acid:tyrosine co-polymers). In addition,

and more importantly with respect to its in vivo function, PTEN dephosphorylates specific membrane associated lipids. Specifically, PTEN can dephosphorylate the phosphate on the third position of phosphoinositide-3,4,5-trisphosphate (PI3,4,5P3) and phosphoinositide-3,4-bisphosphate (PI3,4P2). These lipids are produced in cells by the action of a specific kinase known as phosphoinositide-3 kinase (PI3K) (discussed further below). Of note, the vast majority of mutations in PTEN, which are derived either from tumors or from the germ line of patients with Cowden disease, alter the PTEN protein such that is can not dephosphorylate these lipids, while in some case these mutations do not alter protein phosphatase activity. These data suggest that PTEN lipid phosphatase activity is essential for preventing tumor growth. These considerations suggest that PTEN functions as a tumor suppressor, primarily by acting as a damper on the transmission of signals through the pathway governed by phosphoinositide-3 kinase.

Phosphoinositide-3 Kinase Signaling

The signals carried by this pathway typically begin at the cell surface, where growth or survival factors in the extracellular environment bind to their cognate receptors at the cell surface (Fig. 1). For example, insulin-growth factor I (IGF-I) binds to the IGF-I receptor (IGF-IR). These receptors are typically tyrosine kinases (proteins that phosphorylate other proteins on tyrosine residues), and when triggered by growth factor binding there is an activation of the kinase activity and a resulting auto-phosphorylation on the part of



PTEN. Figure 1 The Phosphoinositide-3 kinase/PTEN signaling pathway. Growth factors such as IGF-I (*red*), bind to their cognate receptors (*green*). Binding triggers receptor autophosphorylation and recruitment of phosphoinositide-3 kinase (PI3K) (*blue*). Activated PI3K phosphorylates phosphoinositide-4,5-bisphosphate (PIP2) and converts it to phosphoinositide-3,4,5-trisphosphate (PIP3). PIP3 recruits AKT (*orange*) to the membrane where it is phosphorylated and activated by PDK1 (purple). Activated AKT can then phosphorylate a number of downstream targets and thereby typically inactivating them. Usually, these proteins exert an inhibitory effect on proliferation or survival. PTEN (*yellow-orange*) inhibits signaling through this pathway by dephosphorylating PIP3 back to PIP2.

the receptor that resides on the inner surface of the plasma membrane. This auto-phosphorylation creates a docking site for PI3K, which is recruited to the receptor and activated. PI3K then phosphorylates the inositol head group of the lipid creating PI3,4,5P3 or PI3,4P2. Once these new phosphoinositides are generated they in turn serve as docking sites for other protein kinases. In particular, a kinase known as AKT is recruited to the membrane where it in turn becomes activated. AKT is then free to phosphorylate a number of other proteins. AKT phosphorylation typically acts to inhibit downstream targets such as BAD, GSK3 and the forkhead transcription factors (AFX, FKHR, and FKHRL1). As a result AKT is a potent survival factor and can induce cellular proliferation.

How is the Pathway PI3K/PTEN Relevant to Cancer?

The association between activation of the PI3K and the development of cancer is well established and can be achieved through multiple mechanisms: In animals, a number of tumor causing viruses produce proteins that activate this pathway. For example, the DNA tumor virus known as Polyoma produces an oncogenic protein known as Middle T antigen. Middle T can activate PI3K by recruiting it to membrane through a growth factor-independent mechanism. In chickens, a form of the avian sarcoma retrovirus (ASV 16) contains a copy of the chicken PI3K gene which has been modified so that it directly targets to membrane where it can activate signaling, again without growth factor induction. Finally, a murine retrovirus known as AKT8 contains a copy of the AKT gene that is activated by fusion to the retroviral gag protein.

In human cancers, activation of this pathway can be achieved through loss of PTEN, which results in constitutive phosphorylation and activation of AKT. In addition, the gene for the catalytic subunit of PI3K (PI3KCA) undergoes amplification in ovarian cancer. Finally, there are three AKT kinases in mammalian cells (AKT-1, -2, -3) and amplification of AKT-2 has been noted in breast, ovarian, and pancreatic cancers.

Conservation of the PI3K/PTEN Pathway in Caenorhabditis Elegans

The PI3K pathway is remarkably conserved through evolution. In C. elegans this pathway regulates life span and also regulates the induction of a so-called dauer state. The pathway includes homologs of the IGF-I receptor (daf-2), PI3K (AGEI), PTEN (daf-18), AKT 1 and AKT 2 (AKT1, AKT2), PDK1 an enzyme that activates AKT (PDK1) and a forkhead transcription factor (daf-16). The connection between AKT and forkhead has proved illuminating with respect to this pathway in mammalian cells, where homologues of daf-16 appear to regulate both proliferative and apoptotic signals downstream of PTEN and AKT. In the future, additional relationships and genes discovered in C. elegans are likely to have relevance to human cancers.

Loss of PTEN Deregulates PI3K Signaling

As predicted from the biochemical considerations, loss of PTEN leads to constitutive deregulation of components of the PI3K pathway. Murine cells genetically engineered to lack PTEN have elevated levels of PI(3,4,5)P3, and AKT is found in a constitutively phosphorylated and hence constitutively activated state. Tumor cells that lack PTEN, likewise, are marked by a dramatic increase in AKT activation and in the phosphorylation state of AKT substrates, including downstream targets such as FKHRL1, GSK3 and 4EBP1. Tumor cell lines that lack PTEN can be used to ask about the cellular consequence of PTEN restoration. As described below PTEN, like p53, can act as a negative regulator of proliferation and as an enhancer of apoptosis. In addition, PTEN can alter cellular motility, invasion and potentially tumor angiogenesis.

PTEN as a Cell Cycle Regulator

Reconstitution of PTEN to certain tumor cell lines (786-O renal carcinoma cells and U87MG glioblastoma cells) that lack PTEN results in the accumulation of these cells in the G1 phase of the cell cycle and a decrease in their proliferative rates in culture. When these cells are suspended in soft agar cultures, growth is arrested. The ability of PTEN to regulate cell-cycle progression requires lipid phosphatase activity and is antagonized by constitutive activation of AKT kinase. In addition, the connection to cell cycle regulation appears to be mediated through the induction of the cyclin dependent kinase inhibitor, p27, by PTEN. This latter step is probably mediated through the forkhead transcription factor family. These transcription factors, in the absence of a functional PTEN protein, are constitutively phosphorylated by AKT, and are consequently held in the cytoplasm through interactions with 14-3-3 proteins. When forkhead proteins are relocalized to the nucleus, they can induce p27 and arrest cells in G1.

The effects of PTEN reconstitution on cell cycle control are in keeping with the resulting proliferative lesions seen in tissues and cells genetically engineered to knock-out the PTEN gene. In cells that are heterozygous or homozygous null for PTEN, AKT is aberrantly phosphorylated, with evidence for a dose dependent effect of PTEN loss. In tissues, PTEN heterozygosity results in excessive proliferation (hyperplasia) in the thyroid and prostate. Labeling studies indicate that this results from an excessive number of cells entering the cell cycle. In addition, murine cells genetically engineered to lack both copies of PTEN have abnormal cell cycle kinetics. Thus, PTEN plays a necessary role in preventing unwanted cellular proliferation.

PTEN as a Regulator of Cell-Death

The PI3K pathway and in particular AKT have been previously linked to the regulation of cell survival. In keeping with this idea, PTEN reconstitution to certain PTEN null cells, results in the induction of cell death. Again, loss of function studies have been revealing. Specifically, PTEN null murine fibroblasts have a defective response to apoptotic stimuli, and PTEN heterozygous mice develop a lymphoid hyperplasia syndrome that results from a failure of these cells to undergo cell death at the appropriate time.

Mechanistically there are a number of ways that PTEN could influence apoptotic signaling. AKT kinase is known to phosphorylate a number of substrates that are particularly relevant to apoptosis, including the pro-apoptotic proteins BAD and Caspase 9. For example, AKT phosphorylation of BAD results in BAD binding to and being sequestered by 14-3-3 proteins. In addition, the Forkhead transcription factors (FKHR, FKHRL1 and AFX) that are AKT substrates can all induce apoptosis in certain cells. Furthermore, FKHRL1 appears to be capable of regulating the transcription of Fas ligand, a potent inducer of apoptosis. This is of particular interest because the lymphoid hyperplasia syndrome that develops in PTEN +/− mice phenocopies (mimics) a similar syndrome seen in mice bearing mutations in elements of the Fas signaling pathway. Thus, one possibility is that loss of PTEN leads to constitutive phosphorylation of forkhead factors, defects in Fas mediated signaling and a subsequent failure to undergo apoptosis in response to pro-apoptotic signals.

PTEN as a Regulator of Cell Motility and Adhesion

Cancer cells, especially those that metastasize, must acquire the ability to escape their local environment, and thus cancer cells are often more motile and invasive then normal cells. PTEN can regulate adhesion and motility in at least two ways: First, the PI3K pathway, in addition to regulating AKT, also regulates a set of small GTPase proteins (Rho/Rac/Cdc42) that regulate motility and invasion. Loss of PTEN can lead to deregulation of this arm of the PI3K pathway. In addition, PTEN protein phosphatase activity has been linked to the regulation of cell spreading through the dephosphorylation of focal adhesion kinase (FAK). With respect to FAK regulation, the protein phosphatase activity was sufficient, as the aforementioned tumor derived mutants lacking lipid phosphatase activity remain active in these assays.

PTEN as a Regulator of Angiogenesis

Lastly, AKT activation has been associated with the regulation of endothelial cell nitric oxide (eNOS), and PTEN loss has been associated with the loss of regulation of the hypoxia-inducible factor 1 (HIF-1) gene product. These connections suggest that PTEN null tumors may have an increased tendency to become vascularized, and in certain PTEN null prostate tumors there is evidence that this may be the case.

Clinical Relevance and Therapeutic Implications

The demonstration that PTEN, a commonly mutated tumor suppressor, functions primarily as an antagonist of signaling through the PI3K pathway has triggered considerable enthusiasm for the development of small molecule inhibitors of the protein kinases activated by PTEN loss. Drugs that inhibit certain kinases have been developed previously and thus strategies and methods are in place for doing so again. In this pathway the therapeutic targets include the IGF-I receptor, PI-3 kinase, AKT kinases and PDK kinases. The hope for the future is that loss of PTEN will serve as a molecular marker or so-called predictive factor. That is, PTEN loss would lead to the development of a tumor that is particularly dependent upon constitutive signaling through the PI3K pathway. If so, then these tumors might be exquisitely sensitive to small molecule inhibitors of the kinases in this pathway.

Departments of Pathology and Pharmacology, University of Pittsburgh Cancer Institute, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

Synonyms

JFY1; bbc3; Bcl-2 binding component 3

Definition

PUMA (p53 upregulated modulator of ►apoptosis) is a p53 target and an initiator of apoptosis. PUMA is a member of the ►Bcl-2 protein family, which are evolutionarily conserved regulators of apoptosis.

Signaling by PUMA is critical for the apoptosis induced by p53 and a wide range of anticancer agents.

Characteristics

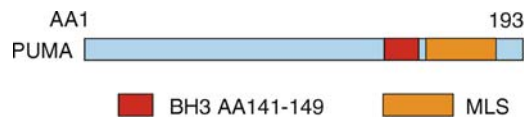
Discovery and Function

PUMA was independently identified by three groups in 2001 based on its transcriptional induction by the tumor suppressor ►p53, and interaction with the antiapoptotic protein Bcl-2. It is highly conserved between mouse and human, with over 90% of sequence identity at both DNA and protein levels. However, no PUMA ►homolog has been identified in lower eukaryotes.

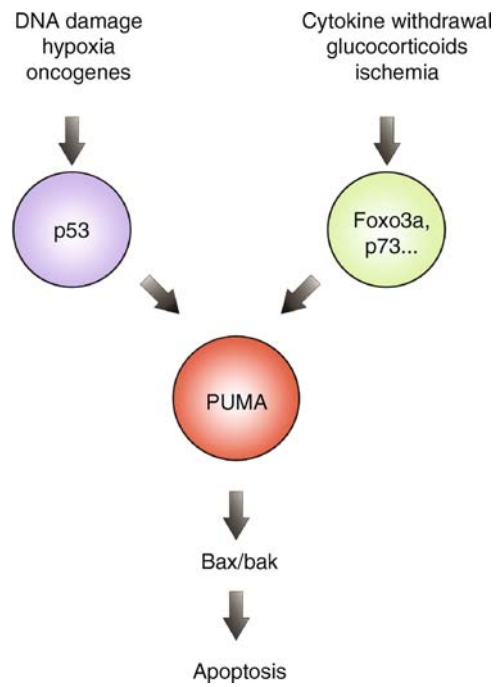
PUMA belongs to the ►BH3-only subgroup of Bcl-2 family proteins, which share sequence similarity only within the BH3 (Bcl-2 homology 3) domain, a short nine amino acid stretch. More than ten BH3-only proteins have been identified in mammalian cells. They function in a tissue- and stimulus-specific manner to initiate apoptosis. In contrast, only a single BH3-only protein EGL-1 has been found in the worm nematode *Caenorhabditis elegans*, which is responsible for all the somatic cell death during development. The BH3 domain of PUMA is required for its interactions with other Bcl-2-like proteins, such as Bcl-2, ►Bcl-xL, and ►Mcl-1 (Fig. 1). The C-terminal portion of PUMA contains a hydrophobic domain that is required for its mitochondrial localization (Fig. 1). Both domains are essential for its ability to induce apoptosis.

BH3-only proteins often display different binding affinity with the antiapoptotic Bcl-2 family members and function as their selective inhibitors. Unlike most other BH3-only proteins, PUMA potently antagonizes the antiapoptotic functions of all Bcl-2-like molecules. ►Bax and ►Bak, two Bcl-2 family members containing multiple BH domains, appear to work downstream of PUMA, and are necessary for PUMA-induced apoptosis (Fig. 2). PUMA does not physically interact with Bax or Bak, but indirectly activates Bax/Bak by dissociating them from the antiapoptotic Bcl-2-like proteins. Activation of Bax/Bak leads to the disruption of mitochondrial integrity and release of the apoptogenic proteins such as ►cytochrome *c* and ►SMAC/Diablo. Subsequently, ►caspases are activated, and irreversible cell death ensues.

Studies using gene targeted human somatic cells and mice have yielded insight into the function of PUMA. Human colorectal cancer cells deficient in PUMA are resistant to apoptosis induced by p53, hypoxia, endoplasmic reticulum stress, and DNA damaging agents. PUMA-deficient mice develop normally, but are protected from tissue damage and apoptosis induced by gamma irradiation in the thymus, hematopoietic system, small intestine, and developing neurons. Other pathological stimuli, including oncogenic stress, hypoxia, growth factor deprivation, glucocorticoids, and ischemia reperfusion, are also dependent on PUMA to induce apoptosis in mice (Fig. 2). Importantly, some of the apoptotic defects seen in *PUMA* knockout mice or cells resemble those seen in p53-deficient mice or cells. The ability of PUMA to antagonize all Bcl-2-like molecules might explain why loss-of-function mutants of PUMA display profound deficiencies in the responses to a wide range of stresses in multiple tissues.



PUMA. Figure 1 Schematic representation of PUMA protein. The major form of PUMA (alpha form) protein contains 193 amino acids and two functional domains. The amino acid residues 141–149 consist of a BH3 domain responsible for its interactions with Bcl-2-like proteins. The C terminus contains a mitochondrial localization signal (MLS) which is not well-defined.



PUMA. Figure 2 PUMA mediates p53-dependent and -independent apoptosis. Upon stress, PUMA transcription is activated to induce apoptosis via the mitochondria through a Bax/Bak-dependent manner. p53 activates PUMA to induce apoptosis following DNA damage, hypoxia, and oncogene activation. Transcription factors, such as p73, FOXO 3A, and those yet to be identified, activate PUMA to induce apoptosis following cytokine withdrawal, glucocorticoids, and ischemia/reperfusion.

Regulation

PUMA is normally expressed at a very low level but rapidly induced when cells are exposed to agents that damage DNA, such as gamma irradiation and commonly used chemotherapeutic agents (Fig. 2). Under these conditions, the tumor suppressor p53 directly binds to the two p53 responsive elements in the *PUMA* promoter to activate its transcription. This p53-dependent induction of PUMA occurs within several hours of exposure, and is required for subsequent apoptosis in many cell types. Most studies have convincingly placed PUMA downstream of p53. However, recent studies suggested that PUMA can also modulate the apoptotic function of cytoplasmic p53 in response to ultra violet irradiation, thus serving as a link between the nuclear and cytoplasmic p53. Such a mechanism still awaits additional supporting evidence.

Some stresses that do not typically damage DNA, such as growth factor deprivation and cytokine withdrawal, can activate *PUMA* transcription independent of p53. The underlying mechanism is not well understood (Fig. 2); the transcriptional factors ►p73 and ►FOXO 3A, which can induce PUMA in p53-deficient cells, might be involved.

PUMA transcripts exhibit extensive ►alternative splicing, which results in mRNA species that may encode proteins without the BH3 domain. The functional role of these spliced variants is currently unknown. The *PUMA* promoter and its first two exons contain a high percentage of guanine and cytosine nucleotides, suggesting a propensity of forming secondary structures capable of inhibiting its basal transcription. The complex regulation of PUMA expression perhaps reflects its critical role in apoptotic responses to multiple stress conditions, which are important in oncogenesis and tissue damage.

Clinical Considerations

It is increasingly apparent that apoptosis acts as a barrier against oncogenesis. Alterations of apoptosis regulators, which are common in human malignancies, contribute to tumor formation, progression, and impaired responsiveness to anticancer therapies. Several lines of evidence suggest that the function of PUMA is defective in cancer cells. First, more than 50% of human tumors contain *p53* mutations, which abrogate the induction of PUMA by radiation and many chemotherapeutic drugs, and render resistance to the killing effects of these agents. Second, PUMA function might be compromised because of altered expression of Bcl-2 family proteins. For example, overexpression of antiapoptotic Bcl-2 family proteins has been commonly observed in tumors. PUMA expression was also found to be reduced in malignant cutaneous melanoma, and reduced PUMA expression was correlated with shorter survival of patients and poorer response to therapies. Third, *PUMA* is located on 19q3.3, a region frequently lost or deleted in several tumor types, including glioma, neuroblastoma, B-cell lymphomas, head and neck squamous cell carcinoma, and lung cancer. Animal studies using a Eμ-Myc-induced mouse lymphoma model also suggested that PUMA functions as a tumor suppressor. However, to date, there is no evidence that *PUMA* is a target of mutation in human cancer.

Manipulation of PUMA expression can be explored as a therapeutic strategy. PUMA has been shown to sensitize lung and esophageal cancer cells to several commonly used anticancer agents. The rationale is that activation of PUMA via p53-independent mechanisms restores the apoptotic response in tumor cells while sparing normal cells. Compared with p53, it might be advantageous to target PUMA because it can induce rapid and extensive apoptosis in a variety of cancer cells regardless of their p53 status, and it is a much more potent killer of cancer cells than p53 itself.

On the other hand, several recent studies suggest that inhibiting PUMA function in normal tissues might be beneficial in cancer treatment. Radiation and chemotherapy often cause severe side effects on the rapidly proliferating normal tissues, such as bone marrow, hair follicles, and gastrointestinal tracts, which limit the dose that can be used to treat patients. Because PUMA is an important mediator of these side effects in these tissues, PUMA inhibitors might be clinically useful in controlling the side effects of chemo and radiation therapies.

In summary, PUMA mediates both p53-dependent and -independent apoptosis. It plays a central role in regulating mitochondria-mediated cell death induced by a wide range of stimuli, including many anticancer agents. Selective activation of PUMA in cancer cells and inhibition of PUMA in normal tissues might be useful for improving the therapeutic responses of cancer patients. These intriguing possibilities certainly need to be carefully examined in the future.

Pyrexia of Unknown Origin

►Fever of Unknown Origin

Pyrimidine

Definition
A heterocyclic organic compound that contributes to the structure of RNA and DNA.

►Fluorouracil

Pyrophosphate

Definition
Is a chemical compound formed by the hydrolysis of ATP into AMP in cells.

►Zoledronic Acid

Qi

Definition

Is a philosophical conception developed in ancient China; it is believed to be the basic element that constitutes the cosmos and produces everything in the world through its movement and changes. In Chinese medicine, qi refers to the basic element comprising the human body and supports its vital activities, such as food essence and fresh air. Since the existence of qi in the body can only be perceived through the resultant activities of organs and tissues, it is more frequently used with the meaning of functional activities.

►Chinese versus Western Medicine

Qigong

Definition

Refers to a method of physical and mental self-exercise created by the Chinese people to strengthen health and cure diseases, mainly by regulating postures, training respiration, concentrating, and conducting mind so as to integrate and coordinate the mind will, vital energy and vitality.

►Chinese versus Western Medicine

QSAR

►Quantitative Structure Activity Relationship

Quadriradial Chromosomes

Definition

Are four-armed, aberrant chromosomes probably formed by unresolved recombination between homologous chromosomes.

Quality Adjusted Life Year

Definition

QALY; Measure of health gain from an intervention used in pharmacoeconomic evaluation. The additional survival gained by the use of an intervention is adjusted to account for the degree of health impairment experienced by the patient. For example one year of additional survival in full health or two years of additional survival with 50% impairment both equate to a gain of one QALY.

Synonyms

QSAR

Definition

The use of chemical descriptors and mathematical models to quantitatively describe the relationship between molecular structure and biological activity and predict structural modifications that increase compound potency.

Characteristics

Quantitative structure activity relationship (QSAR) analysis is based on the observation that the structures of active small molecules and the resulting molecular properties are directly related to biological activity. In other words, structure determines activity, similar molecules should have similar activity, and many (but not all) structural modifications cause changes in activity. This concept is intuitive and provides the basis for QSAR analysis, which is one of the major techniques in small molecule-based drug design (►Drug design). The basic ideas of QSAR analysis are also related to the ►pharmacophore concept. However, pharmacophores are designed to represent parts of a molecule that are responsible for biological activity and are qualitative in nature. By contrast, QSAR analysis attempts to capture the relationship between structure and activity in quantitative terms through the use of mathematical functions. QSAR models are applied to predict small structural modifications of active compounds that significantly increase their potency. As such, QSAR analysis has become the major computational approach to support hit-to-lead transformation and ►lead optimization studies in drug discovery (►Small molecule drugs). The traditional small molecule focus of QSAR explains why this methodology since its formal introduction during the 1960s has become the most widely used computational approach in the field of medicinal chemistry.

An important distinction between QSAR and pharmacophore modeling is that QSAR correlates structure and activity through calculation of molecular property descriptors. Such descriptors are used to represent molecular structure and properties and are an integral part of QSAR analysis. Property descriptors are mathematical models of greatly varying complexity and can be divided into different categories. Some descriptors are designed to calculate physico-chemical properties such as "logP (o/w)," the logarithm of the octanol/water partition coefficient, a measure of the hydrophobic character of a molecule. By contrast, others are purely mathematical in nature, for example, descriptors accounting for "molecular connectivity" or "topology." Another way to distinguish chemical descriptors is to consider the dimensionality of the molecular representation from which they can be calculated. For example, a one-dimensional (1D) descriptor like "molecular weight" is simply calculated from the composition formula, 2D descriptors like "atomic partial charges" or "aromatic character" can be calculated from a 2D graph representation of a molecule, and 3D descriptors such as "molecular volume" or "surface area" are derived from molecular conformations.

The fundamental premise of QSAR analysis is that differences in biological activity can be quantitatively described through mathematical functions that utilize property descriptors as variables. The classical and most widely used assumption is that activity can be expressed as a linear combination of chosen descriptors:

$$A = c_1D_1 + c_2D_2 + c_3D_3 + \ldots + c_nD_n + const$$

In this formulation, A is the predicted biological activity, D_i ($i = 1,\ldots,n$) are molecular descriptors, and c_i ($i = 1,\ldots,n$) coefficients that determine the relative weight and importance of each descriptor. This formalism establishes a linear relationship between molecular structure and activity, which is the basic assumption of traditional two-dimensional (2D-) QSAR ("2D-QSAR" means that molecules are studied using 2D-graph representations). However, generally assuming the presence of a linear relationship is clearly an approximation because many structure-activity relationships are at least in part non-linear in nature. Therefore, some advanced QSAR methods attempt to take non-linearity into account, for example, by deriving QSAR equations using machine learning techniques such as neural network simulations. Nevertheless, modeling linear structure-activity relationships represents the most widely applied form of QSAR analysis.

Building a QSAR model depends on the availability of a training set that consists of molecules having similar activity but different potency levels. QSAR modeling is generally limited to similar compounds sharing the same core structure (often called "congeneric" molecules). Otherwise, it would be very difficult to identify preferred descriptor sets and derive linear models of activity. Consequently, series of closely related structures (often called "analogs") are used for building a QSAR model. The ultimate purpose of the model is the prediction of novel analogs with improved potency, following the paradigm "small chemical changes, large

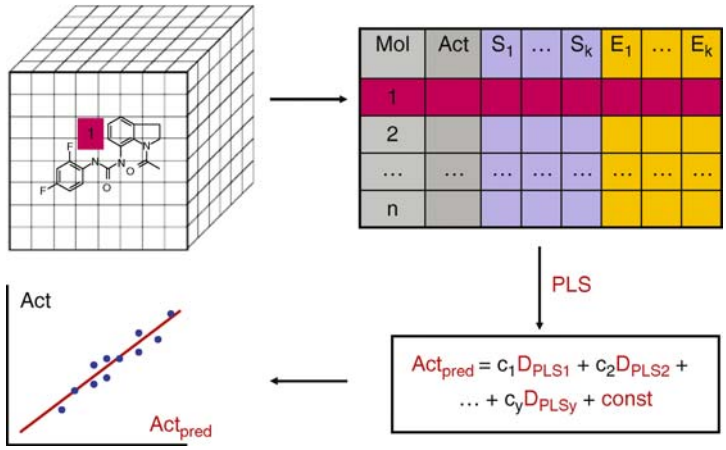
biological effects." This theme perfectly fits the challenges of chemical lead optimization efforts (and rationalizes the popularity of QSAR in medicinal chemistry).

QSAR model building begins with the assembly of the training set and the selection of an initial set of relevant descriptors. Training set compounds should have sound potency values associated with them (if possible, determined in the same assay system) and span a wide potency range so that later predictions are not attempted far outside the training set range, which typically cause inaccuracies. It is also important to avoid the inclusion of statistical outlier values in the training data. Descriptor pre-selection is attempted either on the basis of chemical experience and intuition or computational descriptor selection protocols (e.g. genetic algorithms). An experienced QSAR scientist usually has an empirical set of "successful" descriptors at hand that address effects known to be important for mediating receptor-ligand interactions (e.g., hydrophobicity or hydrogen bonding). The values of initially chosen descriptors are then calculated for the training set compounds. During descriptor selection and model building process, care must be taken to remove redundant or strongly correlated descriptors and reduce the number of descriptor variables to a required minimum. In 2D-QSAR, there should be significantly fewer descriptor variables than observations (i.e. compound potency values). Otherwise, the resulting model will be too specific for the training set compounds and will have low predictive value outside the training set, a process commonly referred to as "over-fitting" of a model. Multiple linear regression calculations are used to derive the values of the coefficients and the constant of the linear equation from predicted activity values. Statistical tests and cross validation studies are carried out in order to determine how well the model reproduces the potency values of training set compounds and, subsequently, of single compounds removed from training. In an iterative manner, descriptors are eliminated or added and coefficients are adjusted to re-build and refine the model until training set data can be reproduced with typically greater than 80% accuracy. Then the model is used to predict the activity of test set compounds. The test set consists of similar compounds with known potency not used for training. On the basis of these calculations, the prospective predictive performance of the QSAR model is statistically assessed and it is subjected to further refinement. Once the accuracy of the model is satisfactory and cannot be further improved through descriptor modification and linear regression, novel predictions can be attempted. This is done by calculating descriptor values for analogs other than training or test set compounds and predicting their potency using the model. New compounds with predicted increases in potency become candidates for synthesis and biological evaluation. These model building and (statistical) validation procedures generally apply to QSAR analysis, irrespective of the descriptors and mathematical methods used.

Classical 2D-QSAR analysis has been extended through the introduction of three-dimensional (3D-) QSAR methods. "3D-QSAR" means that QSAR equations are derived from 3D conformations of active compounds. The basic idea of 3D-QSAR is to quantitatively estimate the interaction between ligands and hypothetical receptor binding sites ("hypothetical" because binding sites are not known or taken from experimental structures, but computationally constructed around active compounds). Pharmacophore models provide popular starting points for 3D-QSAR analysis to model and orient compound conformations, thus providing a link between a qualitative and quantitative evaluation of structure-activity relationships. The prototypic approach that introduced 3D-QSAR is called Comparative Molecular Field Analysis (CoMFA). In CoMFA, superposed active compounds are placed on a computational grid and an artificial probe atom is used to calculate interaction energies with these molecules at each grid point. Different probe atoms produce steric (van der Waals) or electrostatic (Coulombic) interaction energies. These grid point energies represent the descriptors for 3D-QSAR analysis. In contrast to the principles of 2D-QSAR, CoMFA generates many more descriptor variables than the observations that are used (i.e. compound potency values). Therefore, the application of descriptor reduction techniques is required for 3D-QSAR model building. Among others, Partial Least Squares (PLS) regression is a popular statistical technique to select latent descriptor combinations that best account for training set activities. PLS generates multiple new and uncorrelated descriptors that are linear combinations of the original grid point energies. Regression analysis is carried out on these new descriptors to produce the 3D-QSAR model in "PLS space" (Fig. 1).

Since original grid point energies are retained in the PLS equations, the final PLS solution can be projected back into the original grid space and grid points with similar coefficients are displayed as contours that represent molecular interaction fields surrounding active molecules. Graphical analysis of these fields can suggest where compound modifications (e.g. by introducing bulky or charged groups) might produce more favorable interaction energies. For modified analogs, all the descriptors in the QSAR equation are calculated and used to predict compound potencies, and the best candidates are selected for further study. Over the years, many variants of the CoMFA approach have been introduced that mainly differ in the types of energy calculations. For example, to name just one,

Q



Quantitative Structure Activity Relationship. Figure 1 Foundations of 3D-QSAR. Conformations of active molecules are superposed on a three-dimensional grid and a QSAR table is generated. This table records n test molecules, their experimentally determined activity (Act), and interaction energy descriptor values. For each molecule (only compound 1 is shown), each of k grid points is associated with two descriptors, steric (S) and electrostatic (E) interaction energy. The descriptors in the QSAR table are subjected to PLS analysis, which produces a reduced number of novel descriptors (D_{PLS}) that are linear combinations of the original ones. Applying the resulting QSAR equation, compound activities are predicted (Act_{pred}) and the correlation between experimental and predicted training set (and, later on, test set) potency values is analyzed. For evaluating the performance of the QSAR model, statistical measures such as a squared correlation coefficient (R^2) are conventionally used.

Comparative molecular similarity index analysis (CoMSIA) calculates steric, hydrophobic, electrostatic, and hydrogen bonding energy terms.

Similar to pharmacophore modeling, the major principal limitation associated with 3D-QSAR analysis is the correct prediction of bioactive ligand conformations. If the binding conformation of an active molecule is incorrectly predicted, the resulting QSAR model has little, if any value. Since 3D-QSAR models are derived from multiple active compounds, there is an additional requirement: active conformations must not only be correctly predicted, but must also be correctly superposed in three dimensions (which represents the so-called "alignment problem"). In order to address the conformational problem, the 4D-QSAR formalism has been introduced. Here conformational flexibility is added as a fourth dimension to 3D-QSAR and instead of single conformations, conformational ensembles are used for each active molecule. Thus, 4D-QSAR models become largely independent of single compound conformations. However, the alignment problem must still be solved, which becomes more difficult in the presence of an increasing number of diverse compound conformations. Therefore, multiple alignment schemes are evaluated when deriving a 4D-QSAR model to select the one yielding most accurate predictions.

Traditionally, 3D-QSAR methods have not incorporated information from receptor sites. In fact, when 3D-QSAR became popular during the late 1980s, very few 3D structures of popular drug targets were available so that much emphasis had to be put on small molecule-based approaches. In recent years, this situation has changed and the increasing availability of target structures is also beginning to influence the QSAR field, giving rise to the development of "receptor-dependent" QSAR techniques. Basic ideas of receptor-dependent QSAR are that experimental structures of target-ligand complexes greatly simplify the generation of bioactive compound conformations, guide the construction of a pharmacophore model, and enable the calculation of energy descriptors directly from observed target-ligand interactions. Thus, receptor-dependent QSAR alleviates some of the uncertainties associated with conventional 3D-QSAR and is capable of utilizing more realistic (albeit still approximate) interaction energies as descriptors, which makes further development of such techniques an attractive task.

In conclusion, QSAR methods are one of the most widely applied and traditional approaches in computer-aided drug design and the dominant ligand-based approach. This is at least in part due to the high relevance of QSAR analysis for analog design and lead optimization. Future directions for research in the QSAR field include a more systematic exploration of the complementarity of QSAR and structure-based design methods and the development of multi-dimensional QSAR formalisms where additional degrees of freedom are added to 3D-QSAR analysis.

Radiation Carcinogenesis

Colin K. Hill, Parvesh Kumar
Department of Radiation Oncology, USC Keck School of Medicine, Los Angeles, CA, USA

Synonyms

Ionizing radiation induced cancer; Gamma-ray induced cancer; X-ray induced cancer; Radiation induced neoplastic transformation

Definition

Radiation ►carcinogenesis is a biological phenomenon whereby living normal cells are damaged by ionizing radiations which starts a progressive process causing the surviving cells to change their phenotype such that normal controls of cell death and apoptosis are lost and uncontrolled cancerous growth is initiated.

Characteristics

Radiation

Radiation is the deposition of energy into mass. Energy can appear as both corpuscles or electromagnetic quanta, or photons. Some of the elementary forms are protons, neutrons, electrons, x-rays, and gamma rays. X-rays originate outside of the nucleus of an atom while gamma rays originate within the atomic nucleus. Both are identical electromagnetic radiation with varying energies. The equivalence of matter expressed as energy is given by Albert Einstein's relation:

$$E = mc^2$$

Where E is energy, m is mass, and c is the velocity of light (3×10^8 m/s).

People are exposed to radiation naturally from the surrounding environment, from space radiation arriving on earth, and from man made causes such as chest and dental x-rays, and fall-out from nuclear weapons testing. Due to the nature of radiations, that is they cannot be seen, or smelled, governments, and states have taken a conservative regulatory approach to containing and minimizing exposure of both those who may be exposed occupationally and for the general public. There are strict regulations that must be followed to keep exposures very low and thus the risk from exposures is also very low.

Interaction of Radiation with Matter

Matter is composed of atoms, which in turn are composed of protons, neutrons, and electrons. High-energy x-rays, photons, used in diagnostic radiology and radiation therapy and gamma rays from natural sources are electromagnetic radiation that can interact with the orbiting electrons which consequently cause the expulsion of secondary high-energy electrons. The energy of these secondary electrons is in millions of electron volts [MeV]. The binding energy of electrons with molecules is only a few electron volts. Therefore, the energetic secondary electrons can collide with many atoms and molecules knocking out electrons as they give up energy until they no longer have enough energy to break any more chemical bonds. Each time an electron is dislodged from an atom or molecule, an ion is created that can combine with other atoms and molecules which therefore change the chemical composition of the molecules involved. It does not take very much ionizing radiation exposure to "hit" all the cells in the body. The number of times each cell will be hit will depend on the total dose and the time between hits will depend on the total dose and the rate at which dose is delivered. In general, calculations show that at total body dose of 1 cGy, each cell nucleus will be hit about 3.2 times if Cesium 137

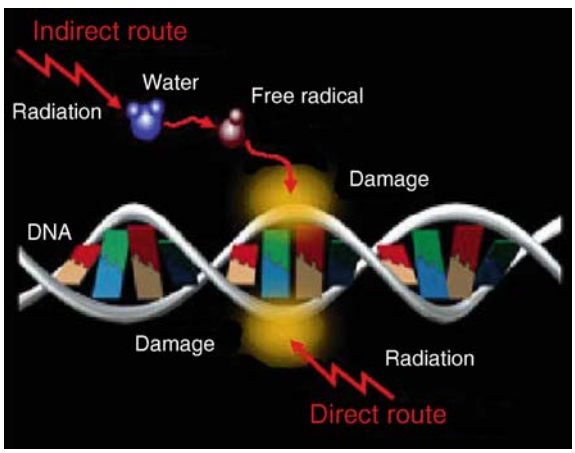
is the source of the gamma rays and these expected hits produce about 18 single strand breaks per nucleus per 1 cGy. The whole cell will record four times as many hits on average (12.5 hits).

Interaction with Living Cells

DNA in the nucleus is the most sensitive region of the cell. Damage to DNA can take place by either direct or indirect action as a result of radiation exposure. Fig. 1 shows this interaction schematically.

In direct action, the secondary electron interacts with the DNA directly. In indirect action, the secondary electron reacts with water to produce hydroxyl radicals which react with DNA. Approximately two thirds of the x-ray damage to DNA in mammalian cells is caused by the indirect action. It should also be noted that all the other types of radiation including alpha particles, neutrons, heavy ions and protons have been shown to interact with DNA and cause damage that could lead to cancerous events. The biological consequences of DNA damage can take from days to many years to become manifest. DNA is a double-stranded molecule held together by hydrogen bonds. Single strand breaks of DNA can be repaired efficiently in mammalian cells under normal physiological conditions. Double strand breaks on the other hand (some of which maybe formed from two fairly closely aligned single strand breaks) are more difficult to repair and are responsible for most of the biological consequences of radiation including cell death and genetic changes that may lead to disease, some of which manifests itself as cancer (►DNA Damage).

In the context of the a human going through life the genetic changes are mutations in the DNA that lead to changes in chromosome shape and function and ultimately changes in the genes that can be expressed as changes in the protein coded for by the gene or if a gene is lost the loss of a protein (►DNA damage responses).



Radiation Carcinogenesis. Figure 1 Schematic depiction of the interaction of radiation with DNA in cells. Reproduced with permission of Engstrom, Lipscomb and Lack LLC.

Clearly the cells that make up human bodies and the bodies of all other living organisms must be endowed with repair systems to counteract damage done both internally by the machinery of the cell and by external forces such as radiations or cells would very quickly die from the accumulating DNA damage produced by radiation exposure (►Repair of DNA). Cells would surely die much sooner than is the case. In fact best estimates suggest that of every 1,000 single strand breaks produced by gamma rays 99% are quickly and correctly repaired, however that does leave ten that are not repaired or not repaired correctly (►DNA damage-induced Apoptosis). Since there are trillions of cells in the body there are also trillions of single strand breaks that do not get repaired or do not get repaired correctly. Gamma rays also produce ►DNA double strand breaks. About 40 for every 1,000 single strand breaks. These double strand breaks are much more difficult to repair and some may also be repaired incorrectly. These incorrect repair events are the basis for mutation events in the DNA that lead to chromosome changes and or permanent genetic change in the cells affected when the cells divide and multiply. It is this damage (refered to as ►initiation) that is the first step in the process known as carcinogenesis if a cell was previously undamaged. If a cell already carried genetic damage, which many do, the radiation damage may supply the next step in the progression to a cancerous event. In both cases the direct effect of radiation exposure is causal in the eventual expression of a cell that can form a diagnosable cancer. As we will see later the consensus of radiobiological opinion at present is that carcinogenic events (or overt cancers) are induced in a linear fashion by radiation as dose is increased. That is as the dose increases so does the number of cancers in a proportional manner. A tenet of this type of response is that any dose can have an effect. There is no threshold. From what has been said above where it is clear that almost all cells in the body are hit multiple times even by a small whole body dose it is not difficult to deduce that the chance (or risk) of one of those many billions of cells eventually forming a cancer is real and thus no dose can be assumed to be free of the potential for causing a cancerous event (►Radiological Response Criteria).

What do we know about carcinogenic events induced by radiations? In brief, the present state of scientific knowledge gained from cell, animal and human studies regarding exposure to radiation at low doses or protracted low doses tells us that carcinogenic events are:

1. Linear with dose, meaning there is a straight-line proportionality between exposure size and the cancer endpoint measured.

2. There is no threshold in radiation dose for carcinogenic events. This means there is no dose below which radiation has been shown to have no effect.
3. There is a latent period between exposure and the appearance of the carcinogenic event. For example, in the human body this means that exposure may be separated by many years from the onset to the diagnosis of cancer.
4. Radiation is capable of causing most types of cancer in most tissues of the body.
5. There is no biological signature or "finger print" to tell us radiation was the cause of a cancer.
6. There is a lifetime risk of developing a cancer associated with any exposure (the size of the risk may change with time however).
7. Effects of repeated (fractionated) or low dose rate continuous exposure are cumulative. However due to the efficient repair systems present in mammalian cells, the effect of each dose when many doses are given and of continuous low dose is reduced compared to the same dose given in one exposure at a high dose rate. In other words, protracted exposures produce fewer cancers.
8. Age at exposure is important. In most cases, if you are young when exposed to radiation, the risk of a cancer occurring is higher than if you are an adult when exposed.
9. Total body risk is not a good measure of overall risk, if exposure is for some reason concentrated in one or more organs but the whole body.

Clinical Issues

Medicine owes a lot to the discovery of x-rays, which can be used to image the body. Since that discovery over 100 years ago, diagnostic radiology has become an integral part of modern medicine. There is a strong belief in the medical community as well as by the public that the small risk associated with medical exposures is far outweighed by the health benefits. Another use for radiations also started nearly 100 years ago. This is the use of much larger doses of directed radiation to treat (kill the cells of) cancers. Today, this use of radiation is called radiation oncology and has become a sophisticated part of the treatment of almost 70–80% of all human cancers (►Radiation Oncology). Patients are given doses of radiation of about 2 Gray each in fractions usually five times per week over several weeks. The radiation field is carefully planned to encompass the tumor but spare the surrounding healthy critical organs. There have been many technological advances in the delivery of radiation in radiation oncology, all of which are aimed at reducing side effects of treatment while enhancing the effect on the tumor. In other words, radiation oncologists and medical physicists have and still are striving to minimize risk to healthy surrounding critical organs in treated patients (►Ionizing Radiation Therapy, ►Radioimmunotherapy, ►Chemoradiotherapy) There is a cancer risk associated with these treatments but this risk is offset by the health benefits to the patients, many of whom might die or die sooner but for the radiotherapy treatments. As treatments for cancer have improved and many cancer patients now live for many years there are now some studies that show increases in secondary cancers due to the exposures the patients were given to treat their tumors.

Radiation Dose

Definition

Is the mean amount of energy imparted to matter of certain mass. The special name for the absorbed dose is the Gray (Gy) after the British radiation physicist Louis Harold Gray. 1 Gy corresponds to energy absorption of 1 Joule/kg. In a routine multiple-slice CT scan dose ranges from 10 to 60 mGy (1 mGy = 10^{-3} Gy). The majority of radiation therapy patients receive 2 Gy once *per* day five days *per* week for 7 weeks for 70 Gy total dose.

Definition

Cahan's criteria for diagnosis of radiation-induced sarcomas (RIS): (i) history of radiation therapy (RT), (ii) asymptomatic latency period of several years, (iii) occurrence of sarcoma within a previously irradiated field, (iv) histological confirmation of sarcomatous nature of the postirradiation lesion.

Characteristics

►RIS are a rare but recognized complication of RT and are associated with poor prognosis. The first case of bone sarcoma, related to external irradiation was described in 1922 by Beck. Soft tissue sarcoma occurring in the treatment volume after breast cancer was described first by Warren and Sommer in 1936. In 1948, Cahan et al. defined the criteria for the diagnosis of RIS. Independent of RT, chronic ►lymphoedema is an important predisposing factor for angiosarcoma. Stewart and Treves in 1948 were the first to describe six cases of ►angiosarcoma occurring in lymphadematous extremities after radical mastectomy. This is a Stewart–Treves sarcoma and can appear in nonirradiated patients (not to confuse with RIS).

Carcinogenesis

Carcinogenesis is multifactorial. Drugs, genetics, chemotherapy agents, irradiation, and others have been shown to be risk factors.

There are still a lot of uncertainties about the biological effects of radiation. The most popular theory for the mechanism of radiation carcinogenesis is that human cancers frequently result from different irreversible DNA lesions, which are induced by the irradiation. Carcinogenesis is a long-term multistage process comprising gene mutations and gene deletions. Human cancers result from activation of dominant acting ►oncogenes or the deletion of a ►suppressor gene. Oncogenes are activated by a ►point mutation, ►chromosomal translocation, or by gene ►amplification.

Dose–Effect Relation

The biological effects that occur provide information about the dose–effect relation at high dose. The somatic effects that have been ascribed to radiation include induction of various types of cancers such as lymphomas, leukemia, solid tumors, and skin cancer. The incidence of the cancer is the function of the dose. The most commonly reported dose for RIS is 60–80 Gy with a minimal dose of 10 Gy in conventional fractionation. In some series there was a tendency that for higher total dose there was a longer latent period. On the other hand, they showed that the rate of tumor induction was induced as the dose increased. Some authors studied the risk of subsequent bone cancer among 9,170 patients, treated for cancer in childhood; have found a sharp dose–response gradient reaching a 40-fold risk after doses of more than 60 Gy to the bone. Other authors have found that the risk increased linearly with the integral dose to 150–200 J and stabilized at higher energies. In their experience the odds ratio (OR) was 2.4 (95%, CI: 1.4–4.2) for an energy of 50 J, approximately corresponding to the radiation of the breast after breast-conserving surgery.

Megavoltage or Orthovoltage Radiotherapy

Several authors have reported different characteristics of RIS according to RT modalities (megavoltage or orthovoltage). Some authors reported that megavoltage RT is associated with shorter latency period. Others indicated that bone tumors were more frequent in the megavoltage group. In the IGR series of 11 patients, 9 developed RIS after megavoltage RT and 2 after total body irradiation delivered using an orthovoltage machine. All the patients received megavoltage RT (^{60}Co or combination of ^{60}Co and electrons).

Latent Period

For RIS there are reports of a latent period from 2 years to 50 years.

Histological Findings

Robinson et al (1988) described in their series more high grade RIS. Some authors described a predominance of ►osteosarcoma and ►fibrosarcoma in RIS of the chest wall. Stout and Lattes described the light microscopic findings of malignant fibrous histiocytoma (MFH) in 1967. In the series of Laskin et al. with 53 RIS, 36 were MFH. Other papers report that postradiation

►angiosarcomas form a significant subgroup of skin and soft tissue sarcoma, especially in the series after conserving breast treatment.

Age and RIS

There is no correlation between age and onset of RIS.

Incidence

The risk to develop RIS is extremely low for the individual patient but increases as the number of long-term survivors' increase. Numerous studies reported cases of RIS after RT for different cancers. The largest series is published after breast cancer treatment (Table 1).

[a]50% in field.

SIR, standardized incidence ratio; AR, absolute risk; RR, relative risk; SML, secondary malignancies; STS, Stewart–Treves Syndrome.

Genetic Findings

Molecular biology analyses of 27 RIS by genomic hybridization suggest that ►chromosomal gains at 7q or 8q are associated with a poor prognosis or large tumors.

Treatment

RIS are associated with poor prognosis because most of them are diagnosed in advanced stage and frequently they are located in areas where radical surgery cannot be performed. The conventional treatment for RIS is surgery, and Robinson et al. postulated: "…The radical surgical approach is the only chance of cure." The results of chemotherapy treatment tend to be poor. The treatment of most cases is late and ineffective.

Conclusion

RT can induce malignancy after a latent period of several years. The risk is not high for the individual patient but becomes higher as the number of long-term survivors increases. RIS are associated with poor overall prognosis. The treatment of most cases is late and ineffective; therefore careful and longer follow-up is needed for early detection. The future development of treatment modalities will be possible with advances of genetic changes.

Radiation therapy; Radiotherapy

Definition

Radiation oncology is the use of ►ionizing radiation to treat cancer and some non-malignant conditions.

Characteristics

The goal of radiation therapy is to eradicate cancer cells without damaging surrounding normal cells. In theory, this can be accomplished by delivering a sufficiently high ►radiation dose to a tumor volume, while simultaneously sparing normal tissue. These two conflicting demands have challenged radiation oncologists, physicists and radiobiologists for more than 100 years.

Ionizing radiation is a potent agent for controlling tumor growth of locally advanced cancer, because ionizing radiation kills cells by releasing of large amounts of energy within the genetic material (DNA) in individual cells. Irradiation induces both single- and double-stranded breaks in the DNA molecule. The induction of ►DNA double strand breaks is generally considered a lethal event. In a mammalian cell 2 *Gy* of X- or γ-rays there are about 1,000 single- and about 40 double strand breaks of DNA molecules immediately following irradiation but only 20 breaks remain a few hours later. This demonstrates the important role of ►DNA repair mechanisms: only a small fraction of the initial ►DNA damage is irreparable or incorrectly repaired. However, un-repaired DNA damage is biologically important because it may result in loss of genetic information after the cell divides and, subsequently, lead to various biological outcomes including cell death.

Cell death following ionizing radiation is defined as the irreversible loss of reproductive capacity. This definition is relevant to radiotherapy because a tumor is locally controlled when all its cells have lost the ability of indefinite proliferation and hence of local invasion and distant ►metastasis. In the same way, the damage to normal tissue is caused by loss of cellular viability. The manifestation of cell death is more evident in tissues with rapidly dividing cells (e.g. tumors, crypt cells in the intestinal jejunum) of than those of slowly dividing cells (e.g. skin stem cells).

The second component of radiation damage relevant to radiation therapy is sublethal damage, a type of damage occurring after an initial dose that is not lethal by itself and can be repaired unless additional sublethal damage is added by a second dose of radiation. Post-radiation repair of sublethal damage results in a decrease of cell killing and is observed if a given radiation dose protracted, that is split into smaller amounts (called fractions) separated by a time interval, or delivered at reduced dose rate. Sublethal damage repair is one of the four known biological responses of cancer cells following irradiation and is often referred to as the first "R" of radiation therapy. The remaining three "Rs" are ►redistribution (throughout the ►cell cycle),

repopulation (or the rate of proliferation after irradiation) and ►reoxygenation (the diffusion of oxygen into a tumor as it shrinks in size). All four of these Rs have different mechanisms and occur in different rates in normal versus cancer cells. Fractionated radiation in modern radiation therapy, that is delivering a limited dose each day over several weeks rather than delivering a large amount of radiation in a single dose in a short time, takes advantage of these four Rs. Until recently, the choice of 70 Gy given in 2 Gy fractions has been considered "the gold standard" for achieving a good tumor control (that is destroying the cancerous tissue) and avoiding short and long-term side effects. Short-term effects occur within a few weeks into a fractionated therapy, whereas long-term effects become evident after the conclusion of therapy. More recently, observed differences in the Rs among tumors as well as early responding and late responding tissues led to more tumor- and tissue-specific fractionation schemes. Listed below are examples of dose fractionation schedules currently used in external beam radiation therapy. Each fractionation schedule is described in terms of the number of fractions, dose per fraction, total dose and the treatment duration (weeks, days).

- The gold standard: 35 fractions × 2 Gy/day = 70 Gy in 7 weeks
- The silver standard: 30 fractions × 2 Gy/day = 60 Gy in 6 weeks
- Hyperfractionation: 70 fractions × 1.15 Gy × 2/day = 80.5 Gy in 7 weeks
- Accelerated treatment: 45 fractions × 1.5 Gy/day = 72 Gy in 5 weeks
- Continuous hyperfractionated accelerated radiation therapy (CHART): 36 fractions × 1.5 Gy × 2/day = 54 Gy in 12 days
- Hypofractionation: 16 fractions × 2.65 Gy/fraction in 22 days

Over the past decade new imaging technologies, notably ►computed tomography (CT) have greatly improved clinicians' ability to identify tumors in three dimensions (3D). Three-dimensional (3D) CT scans replaced flat two-dimensional X-ray films for selecting the treatment targets, and are now considered the standard imagining modality for radiotherapy. This 3D modality approach represents a major advance because it takes into account cross-sectional anatomy and complex tissue contours. However, a number of recent studies demonstrated that there is a considerable inter-observer variation with CT, and that ►magnetic resonance imaging (MRI) is more precise in defining the anatomy of tissues.

CT scans are used for accurate dose calculations for complex and irregular 3D shapes of selected treatment targets. Present technologies allow simulation for radiation therapy by integrating data from the CT scanner with the 3D treatment computer planning systems. The current capability of planning and calculating doses is accurate to within millimeters. Simulation is a critical part of a treatment planning session prior to starting radiation therapy. Other procedures occurring during a planning session are measurements of the area to be treated as well placing markings on the patient's skin to help with positioning during the actual treatments. Usually during a planning session, it is necessary to make appropriate immobilization devices to prevent body movements. Examples of immobilization devices are a porous mesh mask to immobilize the head when treating patients with cancers of the head and neck, and plastic casts to immobilize the patient's pelvic area. Immobilization devices have special brackets riveted to the sides; these brackets lock into the treatment couch, allowing little body movement. Effective strategies that address involuntary target movements such as caused by respiration or digestion remain to be developed.

There are several new techniques for the accurate delivery of radiotherapy based on 3D planning. In conventional two dimensional radiation therapy, treatment planning was based on flat X-ray films and bony anatomy, and the optimization of dose distribution was achieved by manual lead blocking, that is the lead shielding to block out the radiation to certain vital structures within the treatment field. Beam setups were usually quite simple and consisted of a single intensity beam coming in from one to four directions. Treatment plans frequently included opposed lateral fields. The new "standard" in radiation therapy is 3D conformal therapy (3D-CRT) that links treatment planning and software with the actual treatment delivery devices. As a result, multiple radiation beams can be shaped exactly (conform) to the contour of the area. A medical ►linear accelerator (LINAC), the device most often used in radiation oncology to deliver treatment doses, produces high-energy X-rays in a typical clinical setting. Beams can be directed from any number of angles (typically nine). Where the beams intersect is the region of the highest intensity and is centered on the treatment target. To improve dose distributions further, the beam cross-sectional shapes are conformed to the 3D outline of the target area by passing the beam through a multi-leaf collimator (MLC). The MLC is a computer-controlled device inside the linear accelerator head with as many as 120 tungsten leaves that slide in and out of the radiation beam during treatment, thus varying the dose at a given point. This results in radiation dose distribution that can be sculpted to cover the target in three dimensions.

A more advanced form of three-dimensional conformal approach is intensity modulated radiation therapy (IMRT). IMRT uses 3D imaging and radiation delivery as described above for 3D-CRT, but in addition allows for varying intensity within beam cross-sections to produce dose distributions that conform more

accurately than those possible with standard 3D conformal therapy. The cross sectional distribution of intensity is achieved by dividing the beam shaped by MLC into "beamlets" or 1-cm^2 areas of isointensity (also called "pixels" or "blocks"). The cross-sectional intensity distributions are calculated for each direction and then programmed directly into the treatment equipment. IMRT is gaining widespread application as a curative treatment for tumors that might be have been considered untreatable in the past due to close proximity of vital organs and structures. For example, in the case of head and neck tumors, IMRT allows sparing of the spinal cord, optic nerves and salivary glands. In the case of ►prostate cancer exposure to the nearby bladder or rectum is greatly minimized. Other tumor sites suitable for IMRT include the ►brain cancer, ►breast cancer, ►liver cancer, ►pancreas cancer, ►uterus cancer and ►lung cancer.

The present limitations of conformal approaches (3D-CRT and IMRT) to external beam radiation therapy include the logistic difficulties of immobilizing a patient for the duration of an IMRT treatment, lasting 15–40 min per daily session as well as tumor motions caused by respiration or digestion (1 mm in a target movement translates into 10% deviation in dosimetry). Tumors tend to shrink as treatment progresses, but 3D dosimetry planning in real time and based on the actual changing tumor anatomy remains to be developed. In addition, the ►radiation biology of conformal therapies is poorly understood. There are considerable uncertainties concerning the impact of prolonged fraction delivery time in IMRT on cell survival, compared to conventional beam therapy that requires only 2–5 min to deliver the same fractional dose. Second, compared to conventional therapy, 3D-CRT and IMRT involve the use of more fields and thus larger volumes of normal tissue are exposed to low-levels of radiation (up to 20% of treatment fraction dose). Third, multi-leaf collimators allow more ►leakage radiation than conventional collimators. The above considerations add up to a prediction that IMRT may more than double the risk of ►secondary cancers, especially in long-term cancer survivors or young patients. IMRT is currently not recommended for treatment of childhood cancers.

Newer 3D CRT and IMRT approaches are based on charged particle radiation. This type of therapy differs from photon therapy in that it involves the use high-energy protons or accelerated light ions (mainly carbon ions) to treat localized tumors. Although particle radiation therapy was developed in the 1950s, the real advantages of particle therapy could not be realized until imaging systems (CT, MRI) for tumor localization were invented. The intrinsic advantage of proton (and light ion) radiation over photons is the well-defined range. Consequently, the maximum dose is delivered at the target depth (►Bragg (curve) peak), an intermediate dose is delivered at the entrance surface, and a minimum dose is delivered beyond the target. In contrast, photons lose energy along the track and deposit more dose at the surface (skin) than they do at depth. Because of their depth-dose distribution profile, proton (and light ion) therapy is intrinsically conformal. Dose conformity using protons (or light ions) is superior to that presently achievable with 3D planned photons or IMRT and can be realized with a substantially fewer beams. Although protons and light ions have similarly favorable physical dose distribution profiles compared to photons, light ions such as carbon ions kill cells more efficiently than do protons and photons. In addition, the lethal effects of light ions are considerably less influenced by the tumor biology (that is, the four Rs) and its microenvironment (►hypoxia). Radiotherapy with proton and carbon beams is becoming a clinically available modality at several radiation therapy centers around the world, especially in Europe and Japan. There are currently two operating ►proton beam therapy centers and three more are under development in the USA. Carbon ion therapy is now available in Japan and Germany. Clinical indications for proton or ion therapy are similar than those for photon 3D CRT or IMRT. That is, particle therapy is most frequently used to treat tumors that are near critical tissues, such as optic nerve, functional centers of the brain, spinal cord, rectum, intestine, heart, and urinary tract. Proton radiation therapy is especially important for pediatric cases, which require radiation delivery through the growing bones or bony structures. Although childhood cancers such as ►retinoblastoma can be effectively treated with photons, photon therapy may result in permanent malformations of the child's face or body from irradiating through the skull or bones.

Another technique for 3D conformal radiation therapy is internal radiotherapy. ►Brachytherapy (also called interstitial brachytherapy) and intracavitary therapy are types of internal therapy. Internal therapy is a form of radiation therapy where radioactive sources ("seeds") are implanted directly into a specific part of the body. Radiation from an implant is delivered directly to small treatment volumes. Normal tissues are largely spared, because radiation does not pass through the body from the outside before reaching a tumor. Internal therapy can be the only form of treatment or it can be combined with external beam radiation, surgery, ►hyperthermia, or ►chemotherapy. Brachytherapy refers to the technique of implanting radioactive sources into cancer tissue. Intracavitary therapy refers to the placement of implants into a body cavity in close proximity to the tumor. Radiation sources used in internal therapy could be high dose rate (HDR) (12 Gy/h) temporary sources or low dose rate (LDR) (<2 Gy/h; typically 0.4–0.6 Gy/h)

permanent sources. The present ►isotopes of choice for LDR or HDR brachytherapy are iodine-125 (►half-life 60 days) and palladium-103 (half-life 17 days) or iridium-192 (half-life 74 days), respectively. Based on the four Rs of radiation therapy, the radiation delivered at a higher dose rate is expected to produce better clinical outcomes than the radiation delivered at a lower dose rate, especially for fast-growing tumors. Other benefits of HDR versus LDR brachytherapy include a short treatment time (<1 h), greater ease and comfort for the patient, a more precise dose delivery, and less radiation exposure to medical personnel. However, because HDR therapy uses sources of very high ►radioactivity (10 ►Curie), it requires specialized dosimetry and source deployment and retrieval approaches as well as the ability to produce isotopes for HDR brachytherapy applications. The development of technology for the remote and rapid insertion and retrieval of implants, called computer controlled after loading, and industrial production of isotopes such as iridium-192, has led to widespread adoption of HDR techniques. HDR brachytherapy is presently used for cancers of the breast, uterus, cervix and lung. LDR brachytherapy with iodine-125 or palladium-103 is frequently used for prostate cancer, a slowly proliferating tumor. Iodine-125 or palladium-103 produce lower ►energy of photons (20–30 keV) than iridium-192 (380 keV) and so the dose from iodine-125 or palladium-103 falls more rapidly with distance outside the treatment volume than the dose from iridium-192. Consequently, the iodine-125 or palladium-103 seeds efficiently spare the adjacent rectum and bladder and can be left permanently in the prostate. At the same radiation dose, low energy photons kill about 50% more cells than do high-energy photons (6–10 MeV) in used in external beam therapy. These advantages are offset by cell proliferation and sublethal damage repair during LDR brachytherapy in fast growing tumors, but present less of a problem in slowly proliferating tumors, such as carcinoma of the prostate.

Radiation-Resistant DNA Synthesis

Definition

RDS; When mammalian cells are exposed to ►ionizing radiation, DNA synthesis is inhibited. Failure to inhibit DNA synthesis in response to ionizing radiation, which occurs in ►ataxia telangiectasia (AT) cells, is termed radiation-resistant DNA synthesis.

►S-Phase Damage-Sensing Checkpoints

Radiation Sensitivity

Marie Fernet, Janet Hall
INSERM U612, Institut Curie-Recherche, Orsay, 91405, France

Synonyms

Radiosensitivity

Definition

Refers to an increased susceptibility to cellular damage following exposure to radiation.

Characteristics

Radiation sensitivity can be measured by testing cultured cells for various endpoints, including cytoxicity (survival assays), clastogenic responses (chromosome damage),

mutagenicity and DNA repair. Sensitivity to ionizing and ►ultraviolet radiation is associated with rare cancer-prone syndromes. Ionizing radiation sensitivity is a characteristic phenotype of patients with the distinct but closely related rare cancer-prone syndromes ►Ataxia telangiectasia (AT) and ►Nijmegen Breakage syndrome (NBS). Homozygote carriers of mutated *ATM* and *NBN* alleles showing acute radiation reactions when treated with conventional radiotherapeutic doses for cancer and cell cultures extreme sensitivity in *in vitro* assays. The ATM protein kinase is a key component in the cellular response to DNA double-strand breaks. It becomes rapidly activated in response to such damage and initiates signaling cascades in which various substrates, each of which are key factors in damage response pathways and some of which are themselves protein kinases, are phosphorylated, thus ensuring a coordinated and rapid response to this toxic DNA lesion. The NBN protein is a component of the MRE11-NBN-Rad50 complex which acts as a sensor in mammalian cells of DNA double stand breaks in addition to its DNA processing activities. Indeed ATM activation depends on the presence of this complex and the interaction of the damage sensors and activators amplifies the damage response. Ultraviolet radiation sensitivity is the hallmark of patients with ►nucleotide excision repair (NER) diseases, the major pathway for UV-DNA photoproducts, with patients with ►xeroderma pigmentosum (XP) in addition having an increased risk of developing cancer. The total number of genes directly involved in NER is estimated to be around 40 with a dozen found to be deregulated in NER-related human diseases.

Clinical Radiation Sensitivity or "Adverse Radiation Effects"

Clinical radiation sensitivity or "Adverse radiation effects" can generally be defined as undesirable clinical and physiological responses secondary to radiation treatment. Adverse radiation responses can be observed during and within several weeks after radiotherapy – acute side effects, or can develop at later times – late effects. The significant improvements in cancer treatment over the last decades have resulted in longer survival but this also means that a proportion of cancer patients are living with such late, adverse effects and growing numbers of radiation-related second cancers have been observed and in particular following treatment for childhood cancer. A number of radiation toxicity scoring systems have been developed for reporting the adverse reactions as the Radiation Therapy Oncology Group (RTOG) or SOMA-LENT scales which assign quantitative descriptive grades from 0 to 5 for the appearance of specific side effects. Acute skin side effects include erythema, oedema and dry or moist desquamation, whilst the late effects include telangiectasia and fibrosis and develop over time. Pulmonary injury manifested as sub-acute pneumonitis and late fibrosis is also found in some patients following radiotherapy.

It is known that a variety of patient, tumor, cellular and molecular factors contribute to the severity of normal tissue reactions exhibited after radiotherapy. Patient characteristics include age, nutritional status, medications, coexisting morbidities (e.g. diabetes, recent surgery) and tumor-related factors such as size. Variation in treatment-related parameters, including treated volume, field size, total dose, dose fraction and use of concomitant adjuvant chemotherapy may also contribute to response heterogeneity. In addition individual genetic variation may also influence the development of adverse radiation responses. Indeed the known ionizing radiation radiosensitivity syndromes arising from single-gene defects, such as AT and NBS, involve mutations in components of DNA double-strand break signaling and repair pathways and common sequence variants in genes implicated in the cellular responses to radiation, which may alter protein function and thus an individual's capacity to repair damaged DNA modifying the response of the normal tissue, are good candidates to influence the response to therapeutic radiation.

One major focus of research in ►radiobiology is the development of assays designed to predict individual radiosensitivity of normal and tumor tissue prior to radiotherapy. Studies correlating *in vitro* radiosensitivity using a variety of biological endpoints and clinical sensitivity in breast cancer patients have lead to contradictory results or have not been found to predict well the side effects among patients receiving radiotherapy. The *in vitro* assays that have been used to date include testing the ability of a "surrogate target" such as skin fibroblasts or lymphocytes from patients to survive and replicate after exposure to ionizing radiation, cytogenetic test systems counting the frequency of specific ►chromosomal aberrations or micronuclei (►micronucleus allay) in irradiated cells, the ability of the cells to repair radiation-induced damage or other radiation-induced endpoints such as ►apoptosis induction or ►TGF-β plasma levels. However to date no assays have proved to be consistently sensitive and accurate for the prediction of side effects amongst patients receiving radiation, and none have been incorporated into routine clinical practice.

New insights into the underlying molecular mechanisms of therapeutic radiation sensitivity are coming from radiogenomics studies and the characterization of molecular profiles that predict tissue and tumor responses to radiotherapy and chemotherapy. There have been a limited number of studies screening for abnormalities in expression of candidate proteins. For instance the level of expression of proteins involved in DNA double strand break repair in fibroblast cultures or

lymphoblastoid cell lines established from patients who showed different degrees of clinical radiosensitivity has been examined in relation to clinical radiation sensitivity. No association between abnormalities in expression levels and radiosensitivity were reported. However, western blotting was used to assess protein expression levels, and this technique cannot generally accurately detect lower than two-fold differences and may not be a sufficiently sensitive technique to detect subtle differences between the different cell lines that might still be functionally relevant. It is also feasible that certain changes may not alter protein levels but may modify the function of the protein. There are several other possible reasons why no correlation between protein expression or activity and radiation sensitivity have been reported to date. One possibility is that the activity of the proteins *in vitro* may not reproduce their *in vivo* activity. The tissue environment is clearly very different and cannot easily be simulated *in vitro*. This has also been invoked as a possible reason why some of the *in vitro* test systems investigated to date, as potential predictors of radiation sensitivity show no clear correlation between *in vitro* and *in vivo* cellular responses. A second possibility is that correlations may be masked by the simultaneous effects of other variables; that is to say the variations noted are real and relevant but are not the only determinants of the reaction to IR which is controlled by a complicated network of inter-linked pathways. One recent study in this area has shown promising results in which the high constitutive expression of DNA repair-related genes measured in peripheral blood lymphocytes seemed to protect from acute adverse reactions.

A number of large scale studies have been initiated to establish banks of biological samples linked to detailed radiation treatment outcome databases for patients treated with head-and-neck, breast, lung, rectal and prostate cancer suitable for genetic studies. Various approaches have been used to try and identify alterations in single genes that may modulate clinical radiosensitivity. This has involved identifying mutations and ►single nucleotide polymorphisms (SNPs) in candidate radiosensitivity genes. The presence of homozygote mutations in genes associated with altered responses to radiation and extreme radiation sensitivity are relatively rare events – for instance the incidence of AT is estimated to between 1 per 40,000 and 1 per 300,000. However whilst the frequency of *ATM* heterozygotes in the general population is of the order of 0.36–1% there are few studies that have screened the whole *ATM* gene, which covers over 160 kb of genomic DNA and contains 66 exons, and it remains to be established whether carriers of *ATM* mutations are over-represented in cohorts of radiation sensitive patients. Several groups have adopted a different approach and investigated whether specific SNPs or haplotypes in genes implicated in the cellular response to radiation are associated with an increased risk of an adverse response to radiotherapy. SNPs and haplotypes in the *XRCC1*, *ATM*, *hHR21, TGFβ1, XRCC3 and SOD2* genes have been found to be associated with an increased risk of developing an adverse normal tissue reaction to radiotherapy in breast cancer patients, and it is not unreasonable to assume that SNPs or specific haplotypes in other genes involved in DNA damage detection and repair, pro-fibrotic and inflammatory cytokines, endogenous anti-oxidant enzymes and general metabolism and homeostasis will also be identified that are associated with such adverse reactions. To date no genetic factors, that specifically influence the temporal occurrence of the adverse reactions, have been identified but it should be noted that many of the studies are relatively small in size and thus lacking in predictive power.

Radiation Therapy

Definition

Synonym radiotherapy, is a kind of therapy that uses radiation energy that comes from radioactive materials to fight neoplastic disease. It is typically performed with an external beam origin.

►Radiation Oncology
►Radiological Response Criteria
►Ionizing Radiation Therapy

Radical

Definition
Radicals (such as OH) are highly unstable ions that attack and damage biomolecules such as DNA.

►DNA Damage
►Oxidative DNA Damage
►Photodamage

Radical Mastectomy

Definition
Removal of the breast tissue including removal of the underlying muscles.

►Oncoplastic Surgery

Radio-Immunodetection

Definition
Radio immunolocalization allows visualization of tumors following injection of an antibody to a tumor marker that is labeled with a radioisotope.

Radio-Isotope Therapy

►Ionizing Radiation Therapy

Radio-Labeled Tracer

Definition
A substance containing a radioactive isotope (radioisotope) that can be visualized by a gamma camera.

►Sentinel Lymph Nodes

Radioactive Seed Therapy

►Brachytherapy

Radioactivity

Definition
Is the process of releasing nuclear particles from unstable atomic nuclei, also called the radioactive decay or disintegration. All elements with atomic number greater than 82 (lead) are unstable and decay with a characteristic time, called the ►half-life, a time for half the atoms to decay. The number of disintegrations *per* unit time is called the activity. The special name for activity is the Curie (►Ci) after the Polish physicist and chemist Maria Sklodowska-Curie.1 Ci corresponds 3.7×10^{10} decays/s.

Systemic antibody-directed radionuclide therapy

Definition

Radioimmunotherapy (RIT) is the most common form of systemic targeted radionuclide therapy (STaRT): monoclonal antibodies directed against tumor antigens (►monoclonal antibody therapy) deliver therapeutic radioisotopes to sites of (disseminated) disease and induce radiolysis in both the targeted cells and neighboring cells.

Characteristics

Principle of RIT

RIT represents an evolving therapeutic approach that combines the tumor targeting attributes of monoclonal antibodies with therapeutic radioisotopes to be delivered to sites of (disseminated) disease. Radiolysis induces cellular damage in both the targeted cells and neighboring cells (the latter also called "crossfire-" or "►bystander effect"), potentially beneficial for treating bulky, poorly vascularized tumors and those with heterogeneous antigen expression. Efficacy of RIT depends largely on tumor characteristics, monoclonal antibody and tumor antigen, and radionuclide.

Tumor Characteristics

RIT may be applied in ►hematological malignancies as well as in solid tumors. The most promising response rates and response durations have been observed in advanced stage malignant lymphoma (►malignant lymphoma, hallmarks and concepts), while antitumor effects in other malignancies have been less impressive. The difference in efficacy is largely due to differences in radiosensitivity (►radiation sensitivity); however, other factors may contribute, like poor vascularization, increased interstitial pressure, and limited diffusion capacity in solid tumors impeding radiolabeled macromolecule uptake. As all these factors amplify with tumor growth, it may be expected that RIT may have its greatest impact when treating microscopic tumor burdens, i.e., in the adjuvant (►adjuvant therapy) or consolidation setting.

Monoclonal Antibody and Tumor Antigen

The ideal target antigen has not been identified yet. It should be specific for the unique tumor type and be expressed stably in high level on all malignant cells allowing formation of a firm antigen–antibody complex. The most extensively studied and, to date, the only approved radioimmunoconjugates, Yttrium-90 (^{90}Y)-ibritumomab tiuxetan (Zevalin®) and Iodine-131 (^{131}I)-tositumomab (Bexxar®) are both directed against the CD 20 antigen. This B-cell specific epitope (►B cell tumors) represents an excellent example of a target antigen, as it is expressed on virtually all B-cell lymphomas, does not internalize or shed from the surface in response to antibody binding and is absent on hematopoietic stem cells. While it can be assumed that radiolysis exhibits the predominant antitumor effect, antibody binding itself may also contribute to efficacy in terms of antibody dependent cellular cytotoxicity (ADCC), ►complement-dependent cytotoxicity (CDC) as well as antibody induced intracellular signaling, as has been shown for malignant lymphoma.

A variety of growth factors and their receptors (e.g., epidermal growth factor (►EGF) and its receptor (►EGFR)) are upregulated in many solid tumors, providing a rationale for therapeutic use of radiolabeled monoclonal antibodies directed against these molecules. Other examples include anti-►CEA antibodies that have been used for RIT in colorectal cancer (►colon cancer), and a recombinant chimeric tumor necrosis treatment (TNT) antibody that was tested in ►non-small cell lung cancer (NSCLC). ►Tenascin is an ►extracellular matrix glycoprotein that is expressed in high grade gliomas, and intracerebral delivery of radioimmunoconjugates directed against tenascin into a surgical resection cavity has been evaluated.

Radionuclides

Today, the most commonly used radionuclides are iodine-131 (^{131}I) and yttrium-90 (^{90}Y). ^{131}I and ^{90}Y differ markedly in their physical properties including type of energy emissions, half-life, path length, intracellular stability, and the organs targeted by the free radionuclide (Table 1). Potential advantages of ^{131}I for RIT include availability, stable chemistry, longer half-life, and an emission spectrum (beta and gamma radiation) that allows for dosimetric studies and therapy with the same immunoconjugate. By contrast, the pure beta emitter ^{90}Y has a longer path length and superior intracellular stability compared with ^{131}I. As ^{90}Y emits no gamma photon,

Radioimmunotherapy. Table 1 Physical properties of commonly used radionuclides

Radionuclide	Yttrium-90	Iodine-131
Gamma emission	No	Yes
Beta emission energy (mev)	2.3	0.6
Half-life (days)	2.7	8.0
Path length (mm)		
Maximum	11.0	2.9
Mean	2.5	0.4

dosimetry studies can only be performed using a surrogate radionuclide such as indium-111 (^{111}In). Both ^{131}I- and ^{90}Y-labeled anti-CD20 antibodies have demonstrated efficacy in treating relapsed/refractory ►non-Hodgkin lymphoma and published results suggest that the two reagents have somewhat similar response rates and response durations, although no comparative clinical trial has ever been performed.

Preclinical and clinical research evaluates radionuclides decaying by the emission of alpha-particles. They offer the possibility of matching the cell-specific reactivity of monoclonal antibodies with radiation with a range of only a few cell diameters. Furthermore, alpha-particles have important biological advantages including a higher biological effectiveness, which is almost independent of oxygen concentration and cell-cycle phase. The three most promising alpha-particle emitting radionuclides encompass Bismut-213 (^{213}Bi, additional beta emission), Actinium-225 (^{225}Ac), and Astatine-211 (^{211}At, additional beta emission).

RIT in Malignant Lymphoma

Although it has been over 20 years since the original publication of ►radioimmunoconjugates being used in the treatment of malignant lymphoma (►malignant lymphoma, hallmarks and concepts), clinical experience is now growing rapidly with encouraging efficacy and favorable safety profiles, exemplified by the following two landmark trials.

Kaminski et al. reported on the experience with the Bexxar® regimen (^{131}I– labeled IgG_2 κ anti-CD20 antibody tositumomab) in 76 previously untreated follicular lymphoma patients. Despite the favorable prognostic profile of this patient population, the high response rates (overall response rate (ORR) 95%, complete response (CR) rate 75%) and the nature of the durable remissions with 59% of the patients remaining in ongoing complete remission with a minimum follow-up of greater than 4 years from treatment are remarkable.

A randomized phase III trial by Witzig et al. including 143 patients with relapsed or refractory low-grade, follicular or transformed NHL compared efficacy of the Zevalin® regimen (^{90}Y-labeled IgG_1 κ anti-CD20 antibody ibritumomab) with ►rituximab (375 mg/m^2 once weekly for 4 weeks). Response rates were significantly higher in the ^{90}Y-ibritumomab tiuxetan arm with an ORR of 80% versus 56% and a CR rate of 30% versus 16%. However, the overall time to progression (TTP) was not different in both treatment groups, but patients treated with ^{90}Y ibritumomab tiuxetan showed a trend toward longer median duration of response (14.2 vs. 12.1 months) and more often achieved responses lasting longer than 6 months (64% vs. 47%).

Both the ^{90}Y-ibritumomab tiuxetan as well as ^{131}I-tositumomab induces considerable ►myelosuppression with a delayed onset 6–10 weeks posttreatment. In the case of adequate bone marrow reserve and normal platelet counts (>150,000/mm^3) the recommended (^{90}Y-ibritumomab tiuxetan dose is 0.4 mCi/kg or 14.8 MBq/kg (to a maximum of 32 mCi or 1,184 MBq), for ^{131}I-tositumomab the desired total body dose is 75 cGy. Furthermore, bone marrow infiltration by lymphoma cells should not exceed 25% because of the observed pronounced and prolonged myelosuppression in these patients. Principally, if murine antibodies are administered, a human anti-mouse antibody (HAMA) response may be seen, but is diminished in patients with prior chemotherapy. By interfering with biodistribution and targeting presence of high titers of HAMAs seem to influence outcome of radioimmunotherapy and also precludes re-administration of the foreign protein.

There are highly encouraging results from several important clinical trials evaluating RIT in other subtypes of lymphoma, earlier in the treatment algorithm, as consolidation therapy or as part of myeloablative regimens (►myeloablative mega therapy) followed by autologous or allogeneic bone marrow/stem cell support.

Radiological Response Criteria

James P. B. O'Connor[1], Gordon C Jayson[2], Alan Jackson[1]

[1]Imaging Science and Biomedical Engineering, University of Manchester, Manchester, UK

[2]Cancer Research UK Department of Medical Oncology, Christie Hospital, Manchester, UK

Definition

Radiological response criteria attempt to provide objective measures of tumor response to therapy. They are widely used as ►surrogate endpoints in clinical trials of cytotoxic chemotherapy and novel therapeutic agents.

Characteristics

Historical Developments

The need for standardized and objective outcome criteria to measure response to anti-cancer treatment has been recognized for over fifty years. In 1960, the Eastern Co-operative Oncology Group proposed that objective measurement of tumor size should be used as an endpoint in the evaluation of ►cytotoxic chemotherapy, since killing tumor cells had been shown to reduce lesion dimensions.

These principles were first codified in a World Health Organisation (WHO) document, published in 1979. In particular four categories of response to ►chemoradiotherapy were defined – complete response (CR), partial response (PR), stable disease (SD) and progressive disease (PD). While many early assessments of tumor size relied on clinical measurement and chest radiography, 2-dimensional evaluation of tumor size using ►computed tomography (CT) became widely adopted as surrogate endpoints in clinical research. However, calculation methods and reporting of the WHO criteria exhibited considerable variation between centers. This discrepancy eventually precipitated formation of new agreed standard criteria for measuring tumor response, the response evaluation criteria in solid tumors (RECIST), published in 2000. The criteria were proposed to unify existing radiological evaluation of tumor response, while at the same time acknowledging the need for subsequent development.

The RECIST criteria are founded on the same principles as those proposed by WHO. Like its predecessor, RECIST criteria were developed to evaluate response to chemotherapy agents that typically produced substantial changes in tumor size. One key difference between the RECIST and WHO criteria was the precise definition of some of the response categories; most crucially, the definition of what constitutes PD was changed, as well as adopting measurements based on one dimension. Emphasis was placed on cross-sectional imaging with CT and ►magnetic resonance imaging (MRI), although use of chest radiographs was permitted, along with some clinical and ultrasonographic measurements. The magnitude of change required to demonstrate partial response or disease ►progression was largely derived from retrospective statistical evaluation of measurements (not image data) from pharmaceutical trials. The quality control for these measurements was not known. Details of the WHO and RECIST response criteria are presented in Table 1 and are discussed thoroughly in the original report of the RECIST criteria by Therasse and colleagues.

Strengths of Radiological Response Criteria

RECIST and the WHO definitions provide an objective standardized method for reporting response to therapy. No extra equipment or analysis steps are required; hence radiological response criteria have been widely and successfully applied over the last few decades to both the trial setting and to routine clinical practice. Since many traditional chemotherapy agents produce a change in tumor size, the criteria have been adopted as an acceptable surrogate endpoint for many clinical trials.

Limitations of RECIST

Criticisms of current radiological response criteria have been widely cited in recent years. It is worth noting that many current limitations were identified by the authors of the RECIST criteria in their initial publication in 2000.

RECIST was not designed to evaluate small lesions. Any radiological definition of complete response is limited by the spatial resolution of the scanning protocol. For instance, a 1 cm breast tumor can contain

Radiological Response Criteria. Table 1 Details of the WHO and RECIST response criteria

	WHO	RECIST
Method		
Lesions	Two dimensional	One dimensional; target lesions identified
Measurement	Area calculated by product of longest diameter *x* longest perpendicular diameter	Longest diameter recorded
Response criteria		
Complete response (CR)	Disappearance of all known disease. Confirmed ≥4 weeks later	Disappearance of all known disease. Confirmed ≥4 weeks later
Partial response (PR)	≥50% decrease in size	≥30% decrease in the sum of longest diameters from baseline
Stable disease (SD)	Patient does not meet criteria for PR or PD	Patient does not meet criteria for PR or PD
Progressive disease (PD)	≥25% increase in size of at least one measurable lesion; appearance of new lesions	≥20% increase in the sum of longest diameters from baseline; appearance of new lesions

approximately 10^9 cells. Since reliable detection of sub-centimeter tumor deposits is difficult with most imaging modalities, reporting 'complete response' can, in reality, miss one or more lesions containing tens of millions of tumor cells. This is evidenced in high dose therapy for breast cancer, where usually the response rate approaches 100%, but where many patients do not achieve long term cure. While advances in CT and MRI hardware can enable increasing small lesion detection, spatial resolution will always limit the specificity of defining complete response by imaging criteria.

Radiological response criteria are difficult to apply to some tumor types. Poorly delineated lesions such as ►mesothelioma and diffuse peritoneal infiltration, typically seen in ►ovarian cancer, are difficult to accurately define in either one or two dimensions. Furthermore, bone lesions, which constitute a common and sometimes solitary site of ►metastasis, are deemed non-measurable by RECIST, as are meningeal deposits, ►pleural effusions and cystic or necrotic lesions.

Furthermore, achievement of objective response in early phase clinical trials (as assessed by radiological response criteria) does not guarantee success at phase III evaluation. The average response rate, assessed by radiological response, is over 40% in phase II studies but is around one third in phase III clinical trials. In addition, many promising early phase studies failed to have their results replicated at phase III testing – this has, in part, contributed new agent failures. Thus, while the RECIST criteria were explicitly designed as a biomarker of response in early phase trials, the response criteria are not as sensitive or specific as investigators would like.

Finally, one major limitation of current radiological response criteria is their dependency on change in tumor size as an indicator of response. while this is a reasonable basis to measure response to cytotoxic chemotherapy, it is not appropriate for many new anti-cancer agents, many of which work by cytostatic mechanisms that halt tumor growth rather than reduce lesion size. Several studies of ►antiangiogenic agents have demonstrated evidence of disease stabilization without evidence of tumor regression in both pre-clinical and human studies. For example, studies of ►sorafenib, ►bevacizumab and other ►protein-tyrosine kinase inhibitors of ►signal transduction have shown significantly improved median progression free survival and overall survival in phase II and III trials. Indeed, the improvement in clinical outcome was sufficient to lead to approval of sorafenib and bevacizumab by the Food and Drug Administration (FDA), despite modest partial response rates in many of these studies of around 5%. These drugs would have been considered ineffective if assessed by the RECIST criteria alone.

Future Developments and Possible Solutions

There is widespread consensus that while traditional radiological response criteria such as the WHO and RECIST approaches provide a useful objective codification of response to therapy, significant limitations exist. This has prompted discussion of how improvements may be made in lesion evaluation, particularly in the context of clinical trials of novel anti-cancer agents.

1. Are size-dependent radiological response criteria valid – should we use them? This question has been prompted by the issues discussed above concerning the limitations of categorizing tumor response based solely on changes in the size of lesions. Despite these concerns, radiological response evaluation based on measures of tumor size is often an appropriate for agents that act through cytotoxic mechanisms in a dose-dependent fashion. In contrast, trials of novel agents that, at best, halt tumor growth may require assessment by both size change and alternative imaging and non-imaging techniques.
2. If they are invalid, then what measure(s) should we use? Here, there are several options. First, there is an argument for keeping the current approach but applying less stringent criteria for response. For example, a decrease of tumor size of just 10% has been used in conjunction with the RECIST criteria to evaluate response in a group of patients with gastrointestinal stromal tumors (GIST), treated with the tyrosine kinase inhibitor imatinib. Here, no statistical difference was found between those defined by RECIST as responders versus non-responders; however, there was a highly significant ($p = 0.0002$) longer time to progression (TTP) in those who exhibited ≥10% reduction in tumor size. Second, new endpoints may be incorporated, in addition to change in size that predict outcome better than RECIST. Decrease in tumor density (measured by Hounsfield units) and was more sensitive than RECIST at detecting response measured by ^{18}FDG-►positron emission tomography and predicted prognosis in GIST treated with imatinib. Thus, in the context of treating GIST with tyrosine kinase inhibitors, measuring a change in size of 10% or decrease in tumor density of 15% (the proposed Choi criteria) may be more appropriate than RECIST. Similar disease specific approaches, each with differences in image modality, parameter and requisite magnitude of change for significance, may end up being formulated and tested alongside traditional response evaluation. Examples already in use include the Southwest Oncology Group lung cancer response criteria. Finally, as imaging capability develops, the measurement techniques employed to assess changes in size require modification. Three-dimensional image acquisition now enables accurate assessment

of tumor volumes. For example, in a study of patients with recurrent anaplastic astrocytoma or ►glioblastoma multiforme, volumetric measurements were predictive of overall survival. No similar correlation was found with WHO or RECIST measurements. However, three-dimensional analyses are at present not widely performed in routine clinical practice (as noted in the original report of the RECIST criteria).

3. What alternatives could be used instead?

If changes in tumor size, based on radiological response criteria, are considered inadequate measures of response, then are there any alternative viable methods that could be readily implemented? One popular option is to implement TTP or progression free survival (PFS) as surrogate endpoints in clinical trials. TTP can directly demonstrate patient benefit, but is vulnerable to significant error in calculation of the time of progression, often caused by infrequent sampling. Addition of a control group may minimize bias of early re-assessment, but necessitates modification of trial design. Also, at present, radiological evaluation is required to define progression in many cases.

Numerous imaging, histology and bio-fluid measurements are being evaluated as potential ►clinical cancer biomarkers of tumor response. Examples include simple measures of circulating tumor antigens and pro-angiogenic growth factors. In addition, more complex biomarkers – such as those produced in ►dynamic contrast-enhanced magnetic resonance imaging and positron emission tomography – are particularly amenable to non-invasive, serial tumor evaluation. Only a small minority of biomarkers have been reasonably well validated, for example, use of ►prostate-specific antigen (PSA) in phase III trials. While biomarkers of tumor function are of particular interest in assessing novel anti-cancer therapies, most biomarkers are not sufficiently validated for use in large scale phase III trials. Therefore, at present, few biomarkers have been approved as surrogate endpoints to evaluate new agents by the FDA.

Finally, symptom control (quality of life) measures offer an alternative endpoint for evaluating treatment success. However, these are labor intensive and expensive. Also, they rely on application of questionnaire-based assessment, which has been regarded as 'less objective' than radiological and other traditional response criteria.

Radiomimetic

Definition

Imitating biological effects of radiation; A radiomimetic drug is one that imitates the effects of radiation as in the case of chemicals such as ►nitrogen mustards, which are used in cancer ►chemotherapy.

Radionuclide

Definition

A nuclide that has artificial or natural origin and that exhibits ►radioactivity.

►Radioimmunotherapy
►Radioimmunoconjugates
►Radiochemotherapy

Radioresistant DNA Synthesis

Definition

RDS; The inability to down-regulate DNA synthesis following treatment with ►ionizing radiation, result from ►checkpoint defect at the ►GI/S transition, in S and at the ►G2/M transition. This way, damaged DNA may undergo ►replication an be passed on in mutated version to next cell formations.

►BACH1 Helicase
►Radiation Sensitivity

Radiosensitivity

Definition

The relative susceptibility of cells, tissues, organs, organisms, or other substances to the injurious action of ►ionizing radiation. In general, it has been found that cell radiosensitivity is directly proportional to the rate of cell division and inversely proportional to the degree of cell differentiation.

►Radiation Sensitivity
►Radiosensitization
►Vascular Disrupting Agents

Radiosensitization

Bernard Gallez
Biomedical Magnetic Resonance, Université Catholique de Louvain, Brussels, Belgium

Definition

Radiosensitization is a physical, chemical, or pharmacological intervention that increases the lethal effects of radiation when administered in conjunction with it. In experimental studies or in clinical practice, the aim of a radiosensitization approach (or the use of ►radiosensitizers) is to make tumor cells more sensitive to ►radiation therapy. A clinical benefit can be expected only if a differential effect can be demonstrated between tumors and normal tissues.

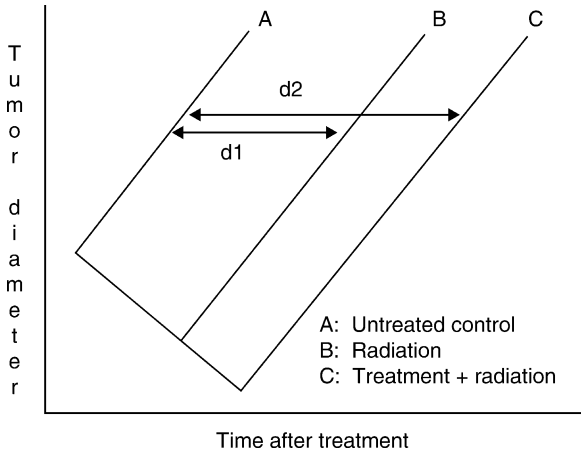
Characteristics

To understand the possible mechanisms to enhance the ►radiation sensitivity, it should first be reminded that irradiation of a biological material initiates a cascade of events that will ultimately lead to cell death, with consequent tumor shrinkage or impairment of tissue functional integrity. The first events between the irradiation beam and the irradiated material consist in transfers of energy through excitations and ionizations. It is accepted that ►DNA damage is the major event leading to clonogenic cell death. Depending on the linear energy transfer (►LET) of the radiation beam, the DNA damage could be the result of direct interaction of radiation with DNA (for high LET), or the result from free radicals created from physical interactions with intracellular water molecules (for low LET). For this latter mechanism, it is well established that the presence of molecular oxygen dramatically increases the extent of DNA damage.

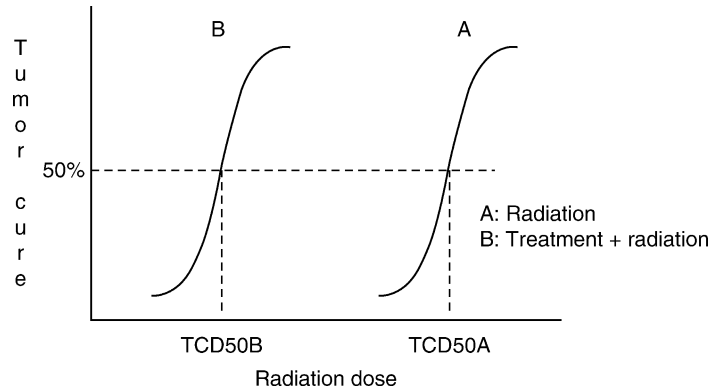
Evaluation of a Radiosensitization Effect

The effects of radiation can be increased or decreased by various interventions or chemical substances called radiosensitizers or radioprotectors. Radiosensitization is the most extensively studied approach because of its possible application in ►ionizing radiation therapy. Radiosensitization should be first considered in terms of efficacy on tumor cells, tumor growth, and effect on other tissues.

The assessment of the radiosensitization of tumor cells includes in vitro and in vivo assays. The most relevant in vitro assay consists in the clonogenic assay by measuring the number of colonies formed after irradiation of tumor cells using several irradiation doses. The efficacy as a ►radiosensitizer is established by comparing cell survival curves after irradiation alone or in the presence of the compound tested. Two tests are classically carried out in vivo to assess the value of a radiosensitizing treatment. The tumor regrowth delay assay (Fig. 1) consists in irradiating population of tumors grown in animals at suboptimal dose. The dose is chosen to avoid tumor cure but to still achieve a measurable regrowth delay. The radiosensitizing property is estimated by comparing the regrowth delay (time in days for tumors to reach a given diameter) with or without agent, compared to the time to reach the same diameter in untreated control animals. The tumor cure assay (Fig. 2) is more clinically relevant, but also is more logistically difficult to carry out. Tumors grown in



Radiosensitization. Figure 1 Tumor regrowth delay assay. The radiosensitizing property is estimated by comparing the regrowth delay (time in days for tumors to reach a given diameter) with or without agent, compared to the time to reach the same diameter in untreated control animals.



Radiosensitization. Figure 2 Tumor cure assay. The number of mice locally cured is calculated for each radiation dose group. Dose–response curves are generated, and the radiation dose yielding local tumor control in 50% of animals (TCD50) are calculated. The radiosensitizing effect is quantitatively expressed by the dose modification factor (DMF), which is calculated by the ratio of the TCD50 for radiation alone (TCD50A) over that for the combined agent and radiation treatment (TCD50B).

animals are randomly assigned to a treatment group, i.e., local irradiation alone or radiosensitizing agent combined with local irradiation. The number of mice locally cured is calculated for each radiation dose group. Dose–response curves are generated, and the radiation dose yielding local tumor control in 50% of animals (TCD50) are calculated. The radiosensitizing effect is quantitatively expressed by the dose modification factor (DMF), which is calculated by the ratio of the TCD50 for radiation alone over that for the combined agent and radiation treatment.

A potential clinical advantage of the combination of a sensitizing agent and radiation can only be foreseen if the potentiation of radiation response is higher in tumors than in normal tissues in the radiation field, indicating that the therapeutic ratio of the combined treatment is above unity. Therefore, the toxicity for normal tissues should be checked. Classically, several normal tissue models are used to determine whether an agent is responsible for toxicity on early responding tissues (e.g., intestinal regenerated crypt assay, acute skin reaction assay) or late responding tissues (e.g., leg contracture assay, rat spinal cord radiation tolerance assay).

Mechanisms of Radiosensitization

There are several ways to enhance the radiation sensitivity. The examples presented below are illustrative rather than exhaustive, and describe some strategies to improve the therapeutic efficiency of radiation therapy. Overall, two types of strategies are described. The first ones include approaches to render DNA as sensitive as possible through direct or indirect interactions. Counteracting tumor ►hypoxia, increasing the initial radiation damages, and redistributing the cell cycles are parts of this first strategy. The second set of approaches tries to modulate the biological response of irradiated cells by inhibiting cellular repair mechanisms, by overcoming the accelerated repopulation, or by targeting some molecular events associated with the radiation response. More precisely, the mechanisms of radiosensitization may include:

1. *Counteracting Tumor Hypoxia*. Many mechanisms are involved in oxygen radiosensitization including the yield and types of free radicals produced after irradiation by low LET radiations as well as by fixation of DNA radical damages. The survival curves for oxygenated and hypoxic cells display an oxygen enhancement ratio for most cells and tissues of 2.5–3. Tumor ►hypoxia is considered as one of the major source of radioresistance. Cells in tumors can become hypoxic as a result of an abnormal tumor blood supply and of an elevated metabolism and rapid tumor cell growth. A first approach to overcome this source of oxygen-dependent radioresistance is the elimination of hypoxic cells. That can be achieved by the use of bioreducible cytotoxins such as mitomycin-C or tirapazamine. These drugs are enzymatically activated in cells to form cytotoxins, which are selectively toxic to hypoxic cells. The second way is to increase the cell death by a transient reoxygenation of the tumor at the time of irradiation. This can be achieved by increasing the oxygen delivery to the tumors, or by decreasing the oxygen consumption by the tumor cells. There are several ways to increase the oxygen delivery: breathing gas enriched in oxygen (hyperbaric oxygen, carbogen), modulating the vascular tone of vessels feeding the tumors and opening the tumor vascular bed, decreasing the tumor interstitial fluid pressure, increasing the oxygen transport of blood by perfluorochemicals, or increasing the oxygen release

by allosteric modifiers of hemoglobin structure. To decrease the oxygen consumption, some drugs have been found to inhibit the mitochondrial respiration of tumor cells: for example, metaiodobenzylguanidine, insulin, antiinflammatory agents. When the therapeutic benefit is mediated by an oxygen effect, a radiosensitizing property on normal tissues is unlikely: the radiosensitizing effect will more than likely be higher for hypoxic tumor regions than for well-oxygenated tissues.

2. *Increase in Initial Radiation Damage*. Some agents, such as halogenated pyrimidines (5-bromodeoxyuridine or 5-iododeoxyuridine) make DNA more susceptible to radiation damage. These compounds are incorporated into DNA in place of the DNA precursor thymidine, and "weaken" DNA molecule, rendering it more sensitive to radiation injury.
3. *Cell Cycle Redistribution*. The cell sensitivity to irradiation depends on the position of cells in the division cycle. Cells in the G_2 and M phases of the cell cycle are more radiosensitive than cells in the S phase. Cell cycles redistribution strategies can be exploited to radiosensitize tumors. As illustrative examples, taxanes (paclitaxel, ►docetaxel) arrest cells in radiosensitive phases of the cell cycle. Nucleoside analogues, such as ►fludarabine or ►gemcitabine, specifically eliminate radioresistant S-phase cells.
4. *Inhibition of Cellular Repair*. Mammalian cells have the capacity to repair sublethal and potentially lethal lesions induced by irradiation. Any drug that interferes with cellular repair mechanisms can enhance cell response to irradiation. Many chemotherapeutic agents such as ►cisplatin, doxorubicin, and nucleoside analogues interact with cellular repair mechanisms.
5. *Overcoming Accelerated Repopulation*. Tissues with rapid cell turnover respond to radiation injury by compensatory proliferation of surviving cells. This accelerated repopulation by tumor cell clonogens can be counteracted by shortening the duration of radiotherapy treatment (i.e., hyperfractionated accelerated radiation therapy). It is also the rationale for the use of chemotherapeutic drugs combined with concurrent radiotherapy.
6. *Modulating Other Biological Determinants of the Radiation Response*. Biologic Response Modifiers (BRMs) represent a diverse group of biologic agents and molecular targets that modulate cellular responses to ionizing radiation in ways that may be exploited to sensitize tumors. BRMs may influence a range of biochemical processes including cytokine networks, DNA repair, cell cycle regulation, stress response, ►apoptosis, and metabolism. As examples, some BRMs targets include cytokines, angiogenic pathways, and cyclooxygenase (►COX) expression.
   a. *Cytokines*. Cytokines are soluble proteins that act as universal modulators of intercellular communication. Several cytokines act on tumor cells with direct cytotoxic or cytostatic effect. Others act on tumor growth by indirect mechanisms such as ►angiogenesis, metastatic potential, or antitumor immune response. One possible target is the ►Epidermal Growth Factor (EGF) and its receptor (►EGFR). In neoplastic cells, EGFR overexpression has been associated with uncontrolled proliferation and increased radioresistance. Increased radiosensitivity has been obtained by blocking the EGFR from binding to its ligands and by inhibiting tyrosine kinase phosphorylation so as to block the signal propagation. Other radiosensitization approaches by manipulation of the cytokines include the targeted delivery of TNF-α, the inhibition of ►RAS with ►farnesyltransferase inhibitors, and the inhibition of ►RAF-1.
   b. *Angiogenic Pathways*. Radiation induces VEGF expression by tumors and stimulates angiogenesis. Inhibition of ►VEGF represents a way to increase the response of tumors to irradiation. Another mechanism by which ►antiangiogenic drugs may sensitize tumors is the transient increase in tumor perfusion at the early phase of antiangiogenic treatments as a consequence of the remodeling of the tumor vascular network (process called "normalization" of the tumor vasculature network).
   c. *COX*. ►COX-2 is an inducible enzyme involved in carcinogenesis, tumor growth, metastatic spread, and resistance to cytotoxic therapy. Several COX-2 inhibitors were identified as radiosensitizers.

Radiosensitization is often obtained by more than one mechanism, a fact that significantly contributes to the increase in the tumor response to radiation therapy. As examples, the C225 anti-EGFR antibody acts by inhibiting the radiation damage repairs, by arresting cells in the radiosensitive G2/M phase of the cell cycle, and by inhibiting the tumor angiogenesis. COX-2 inhibitors radiosensitize tumors by multiple mechanisms involving inhibition of repair of sublethal radiation damage, inhibition of tumor angiogenesis, and ►reoxygenation of the tumors by inhibition of the respiratory chain.

Radon

Dirk Taeger
Berufsgenossenschaftliches Forschungsinstitut für BGFA-Research Institute of Ocuupational Medicine, German Social Accident Insurance, Ruhr-Universität Bochum, Bochum, Germany

Synonyms

Radon daughter products; Radon decay products; Radon progeny

Definition

Radon (Rn) is a chemically inert gas with atomic number 86 in the periodic table. The most stable ►isotope is radon-222 from the decay series of uranium-238. The half-live of radon-222 is 3.8 days. The short-lived daughter products of the noble gas radon are itself radioactive isotopes of the elements polonium, lead, bismuth, and thallium. Rn is an alpha-particle emitter. The decay products generate alpha particles, beta particles, and gamma-rays.

Characteristics

Occurrence

Radon is ubiquitous but of relative low abundance, because of the distribution of its uranium precursor in the earth's crust. The concentration of radon and its decay products depends on the geological situation. In certain areas the radon exposition is naturally high, especially in mountainous regions with some granitic soils or shales. As a decay product of uranium, the gaseous radon then seeps out of the rocks into the environment. The concentration in the ambient air is usually low, due to natural ventilation and dilution with air. Higher concentration can occur after avalanches, because freshly broken rocks emit more radon gas. Radon and radon decay products occur naturally also in ground water and during mining operations. Some hot springs contain high concentrations of radon.

Exposure Situations

If radon and radon progeny cannot disperse they accumulate over the time. The highest concentrations were found in underground ore mines. Radon concentration in homes can be higher than outdoors depending on the underground material, the building material (e.g. clay bricks), and other factors. Radon seeps out of the rocks in the basement of the buildings and can add up to high concentrations. In underground mines the exposure can be reduced by wet drilling, ventilation, and other dust-controlling measures. Ventilation and structural measures of the building decrease exposure indoors.

Population Under Risk

Due to the ubiquitous nature of radon the whole world population is under risk that varies by geological and other conditions and can be a matter of public health in certain regions. For the general population, the radon risk is higher indoors than outdoors depending on the geological situation, state of the building, climate (e.g., wind speed), ventilation habits, and other factors. In regions with low radon concentration but high population density, more persons are under risk than in regions with high radon concentration but low population density. Occupation-related exposure to radon and its decay products is highest in uranium mining and while working with uranium. Exposure can also occur in mining of other ores, spas with hot springs, and in water works.

Health Hazards

Radon is classified as human carcinogen by the International Agency for Research on Cancer (IARC). Radon gas is mostly incorporated due to inhalation. Ingestion by water uptake and incorporation through the skin are minor routes of exposure. Radon, in contrast to its short-lived decay products, is exhaled from the lungs. The radon decay products (as radioactive metal ions) attach to very small (0.1–0.3 μm diameter) particles in the ambient air like quartz dust. The particles can be deposited in the lung, where the cells will be irradiated with alpha particles. Finally, radon decay products can cause ►lung cancer. The strongest evidence came from epidemiologic studies of underground miners. Cohort studies in miners (uranium and other igneous rocks) were conducted in China, Czech Republic, United States of America, Canada, Sweden, Australia, France, and Germany. Lubin et al. analyzed 11 of these cohort studies. The ►excess relative risk (ERR) of radon-induced lung cancer ranges from 0.16 to 5.06 for 100 ►working level months (WLM) in these studies and the overall ERR was 0.005 for 1 WLM with a 95% ►confidence interval (CI) of 0.002–0.010. The risk increased with cumulative exposure and decreased with attained age and time since last exposure. Other known lung carcinogens like crystalline silica, arsenic, diesel exhaust, and tobacco smoke may modify the lung cancer risk and have to be considered as potential confounders or competing risk factors in the analyses. ERR of never-smokers is higher than among smokers although the higher ►relative risk (RR) of lung cancer of smokers compared with nonsmokers remains unchanged by radon exposure. A comprehensive overview on this topic is found in the Committee on Biological Effects of Ionizing Radiation (BEIR) VI report. The BEIR VI committee preferred a submultiplicative (more than additive) relation between radon and tobacco smoke.

Another concern is the lung cancer risk for residential radon exposure. A survey of radon concentrations in U.S. homes revealed a mean of about 50 ►Becquerel (Bq)/m^3. To assess the lung cancer risk of residential (indoor) radon, several case-control studies and ecological studies were conducted. In a pooled analysis of 13 European case-control studies with 7,148 lung cancer cases and 14,208 controls, Darby et al. estimated a smoking-adjusted lung cancer ERR of 0.08 per 100 Bq/m^3 (95% CI 0.03 – 0.16). The *p*-value of 0.0007 for this estimate gave strong evidence for a causal relationship between lung cancer and residential radon. The mean time-weighted average of residential exposure to radon was about 100 Bq/m^3 geographically varying between 50 and 500 Bq/m^3. This analysis of European studies confirmed estimates from well-conducted studies in North America and China and previously published meta-analyses.

Darby et al. as well as the BEIR VI committee concluded that the data from residential and occupational exposure to radon support a linear non-threshold hypothesis, i.e., the dose–response relationship between radon and lung cancer risk is linear with no threshold in dose. Radon levels are usually 10–100 times higher in ore mining than in residential homes. When restricting the analysis of miner studies to workers with radon exposures in the range of residential radon levels, the results are coherent with residential studies.

While there is sufficient evidence for radon-induced lung cancer, the evidence for other malignancies like ►chronic lymphocytic leukemia, myeloid leukemia, and ►Hodgkin lymphoma is limited or even not present. The reported results came mostly from ecological analyses, an epidemiological design that is not able to assess evidence in etiology research. So far, there is insufficient evidence for a carcinogenic effect of radon on other organs than the lung.

Mechanisms

The results from ►epidemiologic studies provided evidence for a causal relationship between radon and lung cancer. A complete biological model that explains the mode of action of radon is yet missing although various mechanisms have been proposed. The BEIR VI report reviewed the present knowledge of radon ►carcinogenesis obtained in experimental and human studies. ►Genomic instability, ►apoptosis as well as radiation-induced perturbation of cellular proliferation may play a major role. ►Stem cells or progenitor cells are possible targets of carcinogens. There are different possibilities for stem cells to protect their DNA from radiation-induced mutations. Cells can have strong ►DNA repair mechanisms, whereas ►apoptosis is inhibited, or stem cells can be protected by apoptotic suicide and subsequent replacement by adjacent stem cells, whereas DNA repair is down-regulated. The latter mechanism is associated with a high sensitivity to ionizing radiation. In case of a compromised apoptosis, a lack of DNA repair would allow an accumulation of carcinogenic mutations. The assumed linear non-threshold model is supported by some experimental findings as well as a bystander mutagenic effect induced by a single alpha particle. In some studies ►small-cell lung cancer was the predominant histological type of lung cancer under radon exposure. In a recent study among 3,414 lung cancer cases in German ►uranium miners, small-cell lung cancer was closer associated with high radon exposure than ►non-small cell carcinoma of the lung. It is known that small-cell lung carcinoma responds better to ►radiotherapy than non small-cell carcinomas of the lung. In cell lines from small-cell carcinoma of the lung, the DNA repair enzyme O^6-methylguanine-DNA methyltransferase was found inactivated by ►methylation. However, the hypothesis

that radon progeny induced small-cell lung carcinoma has to be confirmed yet.

Synonyms

C-Raf; Raf-1; cRaf; EC 2.7.11.1

Definition

Raf-1 (synonym C-Raf; RAF) encodes for a serine/threonine protein kinase that is activated by ►RAS and

in turn phosphorylates and activates ►Map/Erk Kinase (MEK) 1/2 which then phosphorylates ►Extracellular-regulated Kinase (ERK). This signaling pathway is a key mediator of cell proliferation, survival, differentiation and migration.

Characteristics

First discovered as mutant retroviral transforming agent, v-*raf*, Raf is a dual serine/threonine protein kinase. There are three forms of Raf, with Raf-1 being the most studied one. Other forms, A-Raf and ►B-Raf, are not as ubiquitously expressed. A-Raf is primarily in muscles and B-Raf is primarily in neurologic tissue. In contrast, Raf-1 is expressed in multiple tissues.

Raf-1 is 73 kDa and consists of 648 amino acids (aa). Four protein domains have been defined for Raf-1, including an N-terminal RBD (Ras-binding domain) (aa 56–131), a cysteine-finger region (aa 138–184) (CR1), a second cysteine-rich region (CR2) (aa 253–264) and a C-terminal Ser/Thr kinase catalytic domain (aa 354–611). CR2 negatively regulates the C-terminal Ser/Thr kinase domain.

Raf Signaling

Raf is positioned in a signaling cascade to transmit the signal of activated Ras to downstream mediators. Specifically, a number of growth factors such epidermal growth factor and transforming growth factor, activate transmembrane ►receptor tyrosine kinases. These in turn recruit and activate Ras, which then, in turn, binds to Raf and recruits it to the cell membrane. Activation of Raf-1 requires several steps including its phosphorylation by other kinases (e.g. ►Src) in combination with dephosphorylation of inhibitory sites by protein phosphatase 2A. Activated Raf phosphorylates and activates MEK which, in turn, phosphorylates and activates ERK. Once activated, ERK can enter the nucleus and phosphorylates a variety of transcription factors thus completing the signaling path from the extracellular membrane through the nuclear DNA. In addition to transcription factor activation, ERK can regulate cell cycle proteins.

Several endogenous inhibitors of Raf-1 exist. For example, 14-3-3, which binds phosphorylated phosphoserine sites of inactive Raf-1 and maintains Raf-1 in an inactive configuration. Dephosphorylation of these phosphoserine sites release 14-3-3 and its inhibitory effects. Another inhibitor of Raf-1 is Raf kinase inhibitory protein (RKIP). The role of RKIP in cell signaling was identified in a yeast two-hybrid assay for screening clones from a human T-cell library that bound to Raf-1 kinase binding domains. RKIP was shown to bind Raf-1, MEK-1 and weakly bind to ERK-2, interfering with MEK phosphorylation and activation by Raf-1. However, RKIP was not a substrate for Raf-1 or MEK. RKIP did not bind to Ras, nor possess kinase activity. RKIP sets the threshold for Raf-1 activation and subsequent activation of the MEK/ERK pathway. Raf-1 dissociates from its complex with MEK in the presence of RKIP. As a result, downstream ►mitogen-activated protein kinase (MAPK) signaling is interrupted and diminished.

Raf Function

The central position of Raf in the Ras-Raf-MEK-ERK pathway confers on it a multifunctional role. Genetic deletion of various Rafs provides clues to their function. For example, based on these studies it appears that Raf-1 has great importance during development and tissue production. Specifically, Raf-$1^{-/-}$ mice die in utero with many developmental defects. In contrast, other raf mutations have more specific defects. A-raf deficient mice survive birth with intestinal and neurological abnormalities, while mice with a targeted disruption of the B-raf gene die of vascular defects during mid-gestation.

In mature organisms, Raf-1 has been identified to have several specific activities. Raf-1 may promote anti-apoptotic activity. Interactions of Raf-1 and Bcl-2 have been observed that indicate Bcl-2 promotes localization of Raf-1 to mitochondria. Raf may also promotes ►angiogenesis through its ability to diminish endothelial cell ►apoptosis. Specifically, both activation of the ►vascular endothelial growth factor (VEGF) receptor and the basic ►fibroblast growth factor (bFGF) receptor by their respective ligands induces phosphorylation of Raf-1 which diminishes apoptosis. Evidence has also accumulated that Raf-1 alters the cells cytoskeletal architecture. Raf-1 promotes phosphorylation of vimentin, a critical component of the cytoskeleton. This results in altering the polymerization of the vimentin scaffold and thus ties Raf-1 into modulation of the cytoskeleton. This activity appears to occur independent of the MEK-ERK pathway.

Raf in Cancer

The Ras-Raf-Mek-Erk pathway has been identified as being upregulated in at least 30% of cancers. Upregulation of Raf-1 activation may occur due to constitutive activation of upstream factors such as overexpression or activating mutations of growth factor receptors or activating mutations of Ras. For example, the ►epidermal growth factor receptor (EGFR) is overexpressed in a large number of ►non-small lung cell carcinomas. The EGFR overexpression results in stimulation of the Ras-Raf pathway and, thus, is accompanied by Raf-1 overactivation that leads to unregulated cell proliferation and resistance to anti-cancer therapies. In addition to overactivation of Rafs due to upstream factors, Rafs can be mutated themselves, resulting in constitutive activation of Raf. In colon cancer, all Raf family members have been demonstrated to be mutated and associated with increased ►MAP kinase pathway activity. In another example, C-Raf has been shown to

be mutated in ►acute myeloid leukemia. The mutation was able to induce activation of ERK and transformation of cells.

Raf Pathway Inhibitors

The importance of the Raf pathway in the cancer pathophysiology has led to a variety of inhibitors targeted to Raf. Many inhibitors either prevent activation of the kinase domain or compete for co-factor, such as ATP, binding sites resulting in preventing kinase activation. L-779,450 competes with ATP for the Raf catalytic site. It has been demonstrated to prevent DNA synthesis and promote apoptosis in transformed cells. BAY 43-9006 (►Sorafenib) is a urea-based compound that has been shown to inhibit several Raf-family members and tumor growth. Sorafenib is not specific to Raf and in facts targets multiple kinase pathways; however, the inhibitory concentration needed for Raf is much lower than other kinases. A phase III trial was performed on patients with advanced renal cell carcinoma that failed first line therapy. Sorafenib prolonged progression-free survival compared to placebo.

RANK–RANKL Signaling

Andreas Leibbrandt, Josef M. Penninger
Institute of Molecular Biotechnology of the Austrian Academy of Sciences, Vienna, Austria

Synonyms

RANK – Receptor activator of NF-κB, TNFRSF11A, OFE, ODFR, TRANCE-R, ODAR, CD265; RANKL – Receptor activator of NF-κB ligand, TNFSF11, OPGL, ODF, TRANCE, CD254

Definition

RANKL is a member of the ►tumor necrosis factor (TNF) superfamily of cytokines that binds to its cognate receptor RANK. RANKL is a type II transmembrane glycoprotein of 317 amino acids which exists either in a membrane-bound form (40–45 kDa) or a soluble form (31 kDa) and is expressed with highest levels in skeletal and lymphoid tissues, and to lower extent in heart, skeletal muscle, lung, stomach, placenta, and thyroid gland. RANK encodes a type I transmembrane glycoprotein of 616 amino acids (80–96 kDa) and is expressed in skeletal muscle, thymus, liver, colon, small intestine, adrenal gland, osteoclast, mammary gland epithelial cells, prostate, and pancreas. Signaling through RANK provides the essential signal for osteoclast differentiation, activation, and survival. Moreover, genetically RANK(L) signals are also required for lymph node development and the development of a lactating mammary gland during pregnancy.

Characteristics

RANK(L) Function in Bone Remodeling

The most prominent function of RANKL–RANK interactions in vivo lies in the regulation of bone turnover via ►osteoclasts. For all its rigidity, bone is by no means an immutable tissue but is constantly being remodeled. One class of cells, called osteoclasts (OCs, related to macrophages), erode bone matrix, while ►osteoblasts (OBs) deposit new bone matrix, thereby assuring a continuous turnover and replacement of bone matrix.

RANKL was initially cloned as a factor that enhanced differentiation of bone marrow cells into osteoclasts in an in vitro osteoclast coculture system. From these studies, a role of RANKL in regulating osteoclast function and, indirectly, bone mass is inferred. The definite proof of the essential function of RANKL in osteoclastogenesis came by the generation of RANKL-deficient mice. Mice with a targeted deletion of RANKL (►knock-out mice) develop severe ►osteopetrosis and show a defect in tooth eruption due to the complete lack of osteoclasts. Subsequently, these findings were complemented by showing that the receptor for RANKL, RANK, is also essential for osteoclast differentiation and activation. RANK knockout mice are exact phenocopies of RANKL knockout mice, i.e. they are osteopetrotic, have a defect in tooth eruption, and lack osteoclasts.

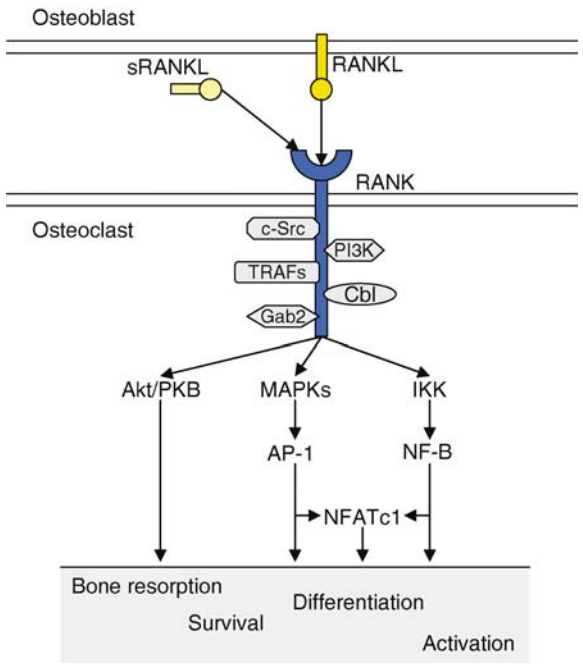
The positive effect of RANKL on osteoclastogenesis is counterbalanced by another member of the TNF superfamily, namely ►osteoprotegerin (OPG). OPG is secreted as a soluble protein and functions as a natural decoy receptor for RANKL by interfering with RANKL binding to RANK to maintain normal skeletal homeostasis. Consequently, the biological effects of OPG on osteoclastogenesis oppose those of RANKL: OPG overexpression in transgenic mice results in increased bone density and osteopetrosis, respectively, while genetic ablation of OPG in mice results in ►osteoporosis. Taken together, these findings unambiguously established the pivotal role of RANKL–RANK interactions in positively regulating osteoclastogenesis, counteracted and balanced by OPG, the natural decoy receptor for RANKL. By elucidating the regulatory interplay of the RANKL–RANK–OPG axis in osteoclastogenesis, a molecular framework emerged which could account for the bone loss observed in various bone diseases, such as osteoporosis, rheumatoid arthritis, or cancer-associated osteolytic lesions.

RANK(L) Signaling

Binding of RANKL to RANK results in the activation of signaling cascades that control lineage commitment

and activation of osteoclasts. In its 383-amino acid cytoplasmic domain, RANK contains binding sites for TNF receptor-associated factors (TRAFs; ►TRAF-1; ►TRAF-2), adaptor proteins that recruit and activate downstream signaling transducers. These TRAF binding domains were shown to be functionally important for ►NF-κB and c-Jun NH2-terminal kinase (JNK) activities in response to RANKL stimulation. RANKL also activates the anti-apoptotic serine/threonine kinase Akt/PKB through a signaling complex involving c-►Src and TRAF6. Moreover, RANK can recruit TRAF6, Cbl family scaffolding proteins, and the phospholipid kinase ►PI3-K in a ligand- and Src-dependent manner. Recently, another molecular adapter was found to be important for RANK signaling. Grb2 associated binder 2 (Gab2) associates with RANK and mediates RANK-induced NF-κB, Akt, and JNK activation. Genetic inactivation of Gab2 in mice results in osteopetrosis and decreased bone resorption due to defective osteoclast differentiation.

Stimulation of RANK eventually induces the expression of a variety of target genes via the transcription factors AP-1 and NF-κB. One important, convergent target of these two pathways is the transcription factor NFATc1, a member of the NFAT (nuclear factor of activated T cells) family of transcription factor genes. NFATc1 has been shown to be essential for RANKL-induced osteoclast differentiation both in vitro and in vivo, switching on and sustaining the transcriptional program for the terminal differentiation of osteoclasts (Fig. 1).



RANK–RANKL Signaling. Figure 1 RANKL–RANK signaling pathways. Membrane-bound RANKL or soluble RANKL (sRANKL) produced by alternative splicing or cleavage by MMPs or ADAMs binds and activates the receptor RANK. RANK activation leads to the cellular context-dependent association of adaptor molecules such as TRAFs and Gab2 or Cbl proteins, and consequently results in the activation and/or modulation of the NF-κB, MAPK, PI3 kinase, and Calcineurin/NFATc1 pathways. In turn, activation of these pathways regulates bone resorption, activation, survival, and differentiation of osteoclasts.

RANK(L) and the Vicious Cycle of Bone Metastases

Many tumors eventually invade bone tissue which causes skeletal complications since the intricate balance between bone resorption and apposition is usually shifted in favor of bone resorption. In patients, tumor-induced osteolysis causes severe bone pain, pathological fractures, nerve compression syndromes (paralysis) and profound hypercalcemia. The strong prevalence of certain tumor types, especially of breast and prostate origin, to metastasize to bone (in ~75% of all breast and prostate cancer cases) is known for a long time but the molecular mechanisms for such osteotropism have begun to unfold only recently. Importantly, the altered regulation in RANKL and OPG expression seems to be of key importance in cancer-induced bone diseases.

The tumor/bone interface is a rich source of factors that are produced either by the tumor cells or by stromal cells upon tumor infiltration and stimulate bone resorption. Amongst these factors are for example ►parathyroid hormone-related protein (PTHrP), ►TGF-β, ►IL-6, ►IL-8, IL-11, or ►prostaglandin E2, which have all been shown to increase RANKL expression in different in vitro or in vivo models. In particular, tumor-produced PTHrP is a well-known bone-resorbing factor and is expressed in ~50–60% of primary human breast tumors. The effects of PTHrP were shown to be mediated by up-regulating RANKL expression in osteoblasts thereby promoting osteoclastogenesis. In addition, several tumors such as prostate cancers seem to express RANKL and could therefore directly contribute to osteolytic lesions themselves by functioning as surrogate osteoblasts to stimulate osteoclast maturation.

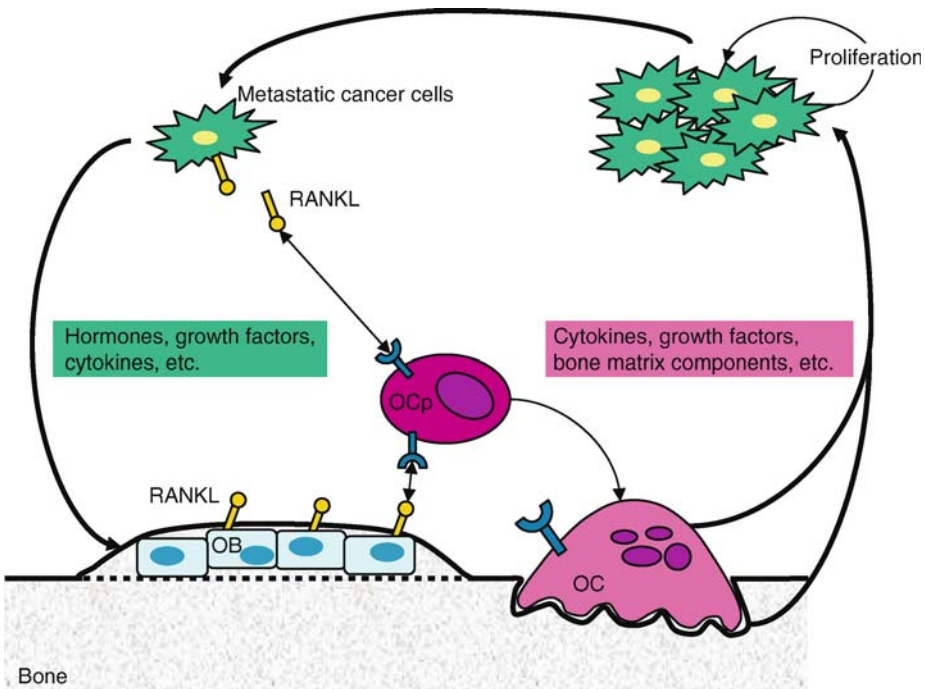
On the other hand, bone resorption by RANKL-activated osteoclasts results in the release of growth factors, such as TGF-β, from the bone matrix which in turn can stimulate the proliferation of tumor cells and thereby increases production of PTHrP in cancer cells. Besides increasing RANKL expression in osteoblastic stromal cells, PTHrP was also shown to decrease OPG levels from osteoblasts, thereby overriding another mechanism to counteract RANKL action and shifting the balance in favor of bone resorption.

Taken together, RANKL – either induced in osteoblastic stromal cells by tumor cells or provided directly by tumor cells – promotes osteoclastogenesis and moreover enhances cancer cell proliferation indirectly through the release of growth factors from the bone matrix during osteoclastic bone resorption. This reciprocal feedback loop between cancer cells and the bone microenvironment fueled by RANKL is referred to as the "vicious cycle" enhancing bone destruction and increasing tumor burden, respectively (Fig. 2).

Given the pivotal role of RANKL in fueling this vicious cycle, the prediction arises that blocking RANKL signals by pharmacological inhibitors, e.g. by OPG-Fc, should be of great benefit to patients suffering from bone metastases. Indeed, in several murine models of tumor-induced osteolytic lesions inhibition of RANKL by OPG-Fc effectively prevented the progression of osteolysis induced by cancer cell lines, such as MDA-MB-231 (breast cancer-derived) or PC3 (prostate cancer-derived). Therefore, clinical trials have been initiated to evaluate the usefulness of RANKL inhibition by a highly-specific monoclonal antibody as a therapeutic approach for treating skeletal complications associated with malignancies of breast and prostate origin, respectively. Moreover, clinical trials are also underway for assessing the clinical benefits of RANKL inhibition prior to the actual formation of bone metastases in prostate cancer patients.

Additional Functions of RANK(L) in Cancer Cells

Several reports have also shown that RANK is expressed in both primary and metastatic tumors of different origin. In particular, RANK (over)expression is frequently found in breast cancer patients and breast cancer-derived cell lines, respectively. Given the observation that both RANK and RANKL female knockout mice fail to produce milk due to impaired proliferation of mammary epithelial cells during pregnancy, it is tempting to speculate that RANK(L) might be directly required for breast cancer cell proliferation and help to explain their strong preference to metastasize to bone. Surprisingly, while RANKL treatment of various RANK-expressing breast and



RANK–RANKL Signaling. Figure 2 The vicious cycle in metastatic bone cancers. Metastatic cancer cells, e.g. of prostate or breast origin, secrete osteolytic factors (PTHrP, IL-11, etc.) that stimulate the production of RANKL in osteoblastic stromal cells (OB). RANKL expressed on osteoblasts binds to and activates RANK expressed on osteoclast precursors (OCp), thereby promoting osteoclast (OC) maturation and increasing bone resorption. Alternatively, some cancer cells express RANKL themselves or secrete soluble RANKL and might thus stimulate osteoclast development directly from osteoclast precursors. Active osteoclasts then release growth factors, cytokines, or bone matrix components that in turn activate tumor cell proliferation. The vicious cycle is closed and results in enhanced tumor burden and bone destruction by shifting the balance between apposition and resorption of bone in favor of the latter.

prostate cancer cell lines did not increase their proliferation, it positively influenced their migration. Exposure of various RANK-expressing cancer cell lines to RANKL triggered cytoskeletal changes and induced cell migration towards the source. Importantly, in vivo inhibition of RANKL with OPG could selectively abrogate metastasis and tumor burden in an in vivo melanoma model of bone metastases. Thus, RANKL may also act as a chemotactic factor for RANK-expressing tumor cells which might help to shed some light as to why certain cancers show a strong prevalence for bone metastases: RANK-expressing cancer cells sense the presence of the chemoattractant RANKL which is provided by osteoblasts and at the same time up-regulated by factors produced by them, such as PTHrP. In such a model, RANKL would serve as one of the long sought-after "soil" factors that facilitates metastasis to bone. In this context, it still needs to be determined if soluble RANKL, which is present in the plasma of humans, could play any role in the development and establishment of a metastatic phenotype, respectively. Whether RANKL inhibition indeed effects the formation of metastases now needs to be tested in human patients.

Rap1

Definition

Ras-proxymity1; Is a small molecular mass G protein (GTPase) of the ►Ras family with the highest homology to classical Ras (K-, H-, and N-Ras) among the family. There are two highly homologous Rap1 proteins, Rap1a and Rap1b, encoded by distinct genes in both human and rodents.

►Rap1/SIPA-1

Rap1 and Sipa-1

Nagahiro Minato
Department of Immunology and Cell Biology, Graduate School of Medicine, Kyoto University, Kyoto, Japan

Definition

Ras-proximity1 is a small molecular mass ►G protein (►GTPase) of the ►Ras family. There are two highly homologous Rap1 proteins, Rap1a and Rap1b, encoded by distinct genes in both human and rodents. Signal-induced proliferation-associated protein 1 is a GTPase-activating protein (GAP) specific for Rap1 and is encoded by the *Sipa-1* gene. There are several proteins with a homologous structure and function, including human ►E6TP1 (human papillomavirus E6-targeted protein 1, also called Spa-L (Spa-1 like) 1 in mouse and SPAR in rat), Spa-L2, and Spa-L3.

Characteristics

Among the Ras family ►G proteins, Rap1 shows the highest overall homology (around 50%) to classical Ras proteins (K-, H-, and N-Ras) with an identical effector region. Rap1GTP is an active form capable of binding a number of specific effector molecules to transduce the signals, while Rap1GDP dissociates from the effectors terminating the signals. Rap1 is activated by a wide variety of external stimuli, and the activation is mediated by specific ►GEFs, which facilitate the dissociation of bound GDP and the reloading of GTP. There are many GEFs that are coupled functionally with various signaling pathways, including C3G recruited by ►receptor protein tyrosine kinases, Epacs activated by binding cyclic AMP, and CalDAG GEFs activated by Ca^{2+} and/or diacylglycerol. Although Rap1 per se has weak GTPase activity, the swift inactivation of Rap1GTP to Rap1GDP can be achieved only by the aid of specific ►GAPs, which enhance the intrinsic GTPase

activity by more than 100 folds. There are two groups of Rap1GAPs, Spa-1 family and RapGA1, sharing a catalytic domain called GAP-related domain (GRD).

Biological Functions of Rap1

Rap1 was discovered by two independent approaches; cloning of the genes with high homology to Ras and search for the genes that could revert the malignant cellular contours of a fibroblastic cell line transformed by oncogenic K-Ras. Although it was thought originally that Rap1 functions as an antagonist of Ras based on the latter effect, subsequent studies have revealed that Rap1 has a number of unique functions on its own.

Interference with Ras-Mediated ERK Activation

Rap1 shares the effector region with Ras, through which it can bind to c-Raf, a MEK1, 2-activating kinase, with even higher affinity than Ras. Unlike Ras, however, Rap1 hardly induces the phosphorylation of c-Raf that is required for the activation of MEK1, 2, and is thus unable to activate MEK1, 2/ERK signal pathway. Rather, when Rap1 is activated strongly concomitantly with or preceding Ras activation, it may competitively interfere with the Ras-induced c-Raf-mediated ERK activation. While such occasions may be rather rare, it is known to occur in certain conditions such as a form of immunological unresponsiveness called anergy in T cells.

Activation of MAP Kinases and Other Signaling Pathways

Rap1 can directly activate ERK independently of Ras in selected cell types that express B-Raf. Unlike c-Raf, ►B-Raf is constitutively phosphorylated at the corresponding sites of c-Raf, and thus Rap1 can bind and recruit B-Raf to the plasma membrane to activate MEK1, 2/ERK pathway in such cell types. While Ras activation by Sos, a RasGEF, is inhibited by the activated ERK forming a tight negative feedback loop for Ras signaling, Rap1 activation is not affected by the activated ERK, and therefore Rap1-induced B-Raf-mediated ERK activation may persist as long as Rap1 activation continues. Thus, Rap1-mediated ERK activation may show distinct kinetics and biological consequences from Ras-mediated ERK activation. For instance, epidermal growth factor (EGF) induces only transient ERK activation via Ras signaling leading to the cell proliferation in PC12 cells, while nerve growth factor (NGF) induces persisted ERK activation via Rap1 causing their neuronal differentiation. Rap1 can also activate other ►MAP Kinases (MAPKs) such as p38MAPK as well as PI3-kinase in certain cell types, leading to the specific gene activation.

Regulation of Cell Adhesion and Migration

The most unique and prominent function of Rap1 is to activate ►integrins. Through the effect, Rap1 activation induces the enhanced cell-matrix ►adhesion and ►intercellular junctions as well as cell migration in many cell types. Rap1 is a major mediator of the "inside–out" activation of integrins in response to various extracellular stimuli including chemokines. Rap1GTP binds to a specific effector called RapL, which associates with the intracellular domain of α-units of integrins and induces the configurational changes to active forms of integrins. Rap1GTP also binds to RIAM (Rap1-interacting adapter molecule) that controls F-actin dynamics via interaction with profillin and Ena/VASP, thereby regulating overall actin-cytoskeletal function as well. Most recent studies further indicate that Rap1 regulates the ►cadherin function in epithelial and endothelial cells. Thus, Rap1 plays a central role in controlling the cell adhesion and migration in many cell types including cancer cells (see below).

Regulation of Rap1 Signal by Spa-1

Sipa-1 was originally isolated in mouse lymphohematopoietic cells as a gene strongly induced in association with the cell proliferation. Purified Spa-1 protein shows a potent and specific GAP activity for Rap1a, Rap1b, and Rap2 without affecting other small G proteins such as Ras, Rac, and Rho. Human and mouse Spa-1 proteins show quite high overall homology (more than 90% amino acids being identical), and are encoded by the genes at the synthetic chromosomal regions, 11q13.3 in human and near the centromere of 19 in mouse, at the close vicinity to *RRAD1* gene encoding cyclin D1. Spa-1 is expressed rather ubiquitously in most tissue cells including cancers (see below), although it is most prominently expressed in the lymphohematopoietic cells. There are several proteins with high homology to Spa-1, including human E6TP1 (called Spa-L1 in mouse and SPAR in rat). E6TP1 was identified as a protein that was specifically bound to ►human papillomavirus (HPV) oncoprotein E6 and targeted to the degradation by E6AP1 via ►ubiquitination in epithelial cells like p53 tumor suppressor protein. E6TP1 has also Rap1GAP activity, and it is reported that the E6 oncoprotein-mediated degradation of endogenous E6TP1 is correlated with the HPV-induced epithelial cell transformation in vitro. Overexpression of Spa-1 abrogates the Rap1 activation via extracellular stimuli, while reduction of the endogenous Spa-1 results in the increased basal Rap1GTP level, and as such Spa-1 functions as one of the major factors controlling Rap1 signal.

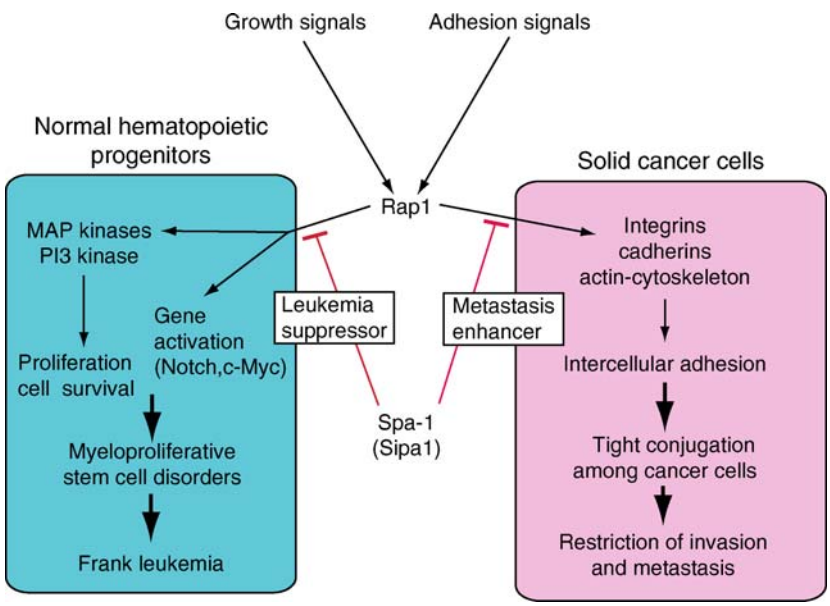
Rap1 and Spa-1 in Leukemia

Overexpression of wild-type Rap1 in Swiss 3T3 fibroblasts, which expressed B-Raf, strongly enhanced the proliferation induced by EGF or cAMP. While such cells remained to be anchorage-dependent in vitro, they formed tumors in nude mice. In contrast to the classical oncogenes such as mutant *Ras* genes that bypass the

normal growth signals, overexpressed wild-type Rap1 may function as a "conditional oncogene" in certain cell types, causing tumors by constitutively activating, rather than bypassing, the growth signals via environments.

The oncogenic effect of Rap1 in vivo was revealed in *Sipa-1* gene-targeted mice. *Sipa-1* gene-deficient (*Sipa-1*$^{-/-}$) mice showed gradual increase in the hematopoietic ►stem cells (HSC) and progenitor cells (HPC) in bone marrow as they aged in association with the constitutive activation of endogenous Rap1. The vast majority of them eventually developed overt myeloproliferative disorders (MPD) after long latency, including ►chronic myeloid leukemia (CML) in chronic phase characterized by the marked increase in granulocytic cells with ►extramedullary hematopoiesis, lethal blast crisis with leukemic invasion to vital organs, and ►myelodysplastic syndrome with severe anemia. Preleukemic *Sipa-1*$^{-/-}$ HPC show enhanced expression of ►MYC-oncogene gene, which promotes the cell cycle progression and controls the interaction of HSC with ►hematopoietic niche stroma cells. Paradoxically, they also revealed enhanced expression of basal ►p53 protein. The simultaneous overexpression of protooncogene c-myc and p53 tumor suppressor protein is reminiscent of so-called oncogene-induced ►senescence and may explain the long latency for leukemia development as well as the infrequent development of severe pancytopenia resembling human MDS in *Sipa-1*$^{-/-}$ mice. The CML and MDS were eventually followed by blast crisis in myeloid or B-lymphoid cells often associated with gross chromosomal abnormalities (Fig. 1).

In human, the majority of CML is caused by ►BCR–ABL1 fusion gene derived from a Philadelphia chromosome with t(9;22)(q34:q11) ►chromosomal translocation. Bcr–Abl oncoprotein can convert HSC, but not committed HPC, to leukemic stem cells, and thus it is suggested that Bcr–Abl oncoprotein transforms HSC by functional collaboration with the intrinsic signals in normal HSC. Rap1 is strongly activated downstream of Bcr–Abl, and Spa-1 overexpression significantly compromises the proliferation and survival of Bcr–Abl^{+} cells in vitro. Conversely in a mouse model, *Sipa-1*$^{-/-}$ HSC transduced with *Bcr–Abl* gene exhibit prolonged survival in vivo followed by the frequent blast crisis as compared with the *Bcr–Abl*-transduced control HSC. This suggests a significant role of Rap1 signal downstream of Bcr–Abl oncoprotein in the human CML genesis. Accumulating evidence reveals that human CML stem cells tend to resist a Bcl–Abl kinase inhibitor, ►imatinib, which is highly effective in reducing the peripheral leukemic cell



Rap1 and Sipa-1. Figure 1 Roles of Rap1 and Spa-1 (*Sipa-1*) in leukemia and cancer metastasis. Rap1 G protein mediates diverse signals depending on the cellular contexts, including proliferation, cell survival, gene activation, and cell adhesion, and the signals are negatively regulated by GTPase-activating protein Spa-1. In hematopoietic progenitors, dysregulated activation of Rap1 in the absence of *Sipa-1* causes myeloproliferative stem cell disorders eventually followed by frank leukemia of various types, and thus Spa-1 functions as a leukemia suppressor. In solid cancer cells such as breast and prostate cancers, the endogenous Rap1 signal contributes to the maintenance of intercellular cancer cell adhesion to restrict their spread, invasion and metastasis. Cancer cells expressing higher levels of Spa-1 show enhanced metastasis, and germline polymorphisms of *Sipa-1* gene in humans significantly affect the metastatic efficiency of cancers such as breast and prostate cancers in the individuals.

burden in the chronic phase, being consistent with the involvement of intrinsic signals in the maintenance of leukemic stem cells. Such leukemic stem cells are bona fide target for the ultimate control of human leukemia, and Rap1 signal may be an important target for controlling CML stem cells in humans.

While *Sipa-1*$^{-/-}$ mice only rarely developed T-cell leukemia probably because of the redundant expression of other Rap1GAPs in the thymic cells, Rap1 signal may be also involved in the development of thymic lymphoma/leukemia. Transduction of C3G-F, a modified C3G to promote the membrane localization, into normal and *Sipa-1*$^{-/-}$ HPC followed by the transplantation into irradiated mice caused thymic lymphoma and thymic acute T-lymphocytic leukemia (T-ALL), respectively, correlating to the extent of endogenous Rap1 activation. The leukemia cells revealed the features of pro/pre-T cells with markedly enhanced expression of ►*Notch*, and *c-Myc* genes, being reminiscent of human T-ALL caused by TAN1 (translocation-associated Notch homolog) derived from t(7;9)(q34; q34.3) chromosomal translocation. Deregulated overexpression of wild-type *Notch* genes has been reported in many types of leukemia and cancers even in the absence of frank chromosomal anomalies, and it may be an intriguing possibility that Rap1 signal plays a part in the constitutive activation of *Notch* genes.

Rap1 and Spa-1 in Cancer Metastasis

Certain human and mouse cancer cells show mutations in *Dock-4* gene. Dock-4 protein is capable of activating Rap1, and the loss-of-function mutations found in such cancer cells result in reduced ►adherence junction among the cancer cells and their enhanced invasiveness. Expression of wild-type *Dock-4* gene in such cancer cells restored the basal Rap1GTP levels as well as the intercellular adhesion and strongly suppressed their invasiveness in vivo.

Experiments using an animal model have provided a genetic evidence that Rap1 signal may control cancer ►metastasis. Transgenic mice of *polyoma middle T* gene under a mouse mammary tumor virus promoter develop mammary tumors irrespective of the genetic backgrounds of mouse strains. Intriguingly, however, such developed mammary tumors show high tendency for lung metastasis in certain strains of mice, while they rarely metastasize in other strains. Genetic analysis revealed that the efficiency of lung metastasis was controlled by a dominant genetic locus termed *Mtes-1*. By using a multiple cross mapping strategy, *Sipa-1* gene has been identified as a candidate gene for *Mtes-1* locus. In mice, there is a nonsynonimous polymorphism in the coding region of *Sipa-1* gene, either alanine (A) or threonine (T) at the amino acid position 741 in the PDZ domain, and all the strains of mice with *Sipa-1/741A* allele showed high metastatic tendency, while those with *Sipa-1/741T* allele revealed significantly less lung metastasis. Spa-1/741A showed stronger Rap1GAP activity than Spa-1/741T in cancer cells probably due to the altered binding affinity of the PDZ domain for yet unidentified proteins. Consistently,\ overexpression of wild-type *Sipa-1* in the mammary tumor cells enhanced the lung metastatic activity, while knockdown of endogenous *Sipa-1* gene significantly reduced it. Interestingly, such procedures barely affected the tumor sizes in the primary sites, indicating that the cancer cell proliferation in the primary sites was not directly correlated to their metastatic potential.

Exact mechanisms for *Sipa-1* gene polymorphisms to affect the efficiency of cancer metastasis remain to be investigated. A probable explanation would be that the basal Rap1GTP level controls the metastatic efficiency of cancer cells by regulating the intercellular adherence junctions among cancer cells in the primary sites via ►cell adhesion molecules such as cadherins and integrins. The phenomenon reinforces a provocative concept for cancer metastasis, that is, the genetic predispositions of the individuals significantly contribute to the metastatic efficiency of cancers in them (Fig. 1).

Clinical Aspects

Human ►prostate cancers with metastasis have been shown to express significantly more *Sipa-1* transcripts than those without metastasis, and it was confirmed that the primary prostate cancer cells with metastasis exhibited significantly more Spa-1 protein by ►immunohistochemistry. Consistently, while human prostate cancer cell lines with little Spa-1 expression hardly metastasized when transplanted into the testes of immunodeficient ►scid mice, those transduced with human *Sipa-1* gene showed efficient metastasis to the abdominal lymph nodes, with the primary tumor sizes being unchanged. Also, Spa-1^{high} prostate cancer cells showed enhanced invasion activity to the matrix in vitro than Spa-1^{low} ones, suggesting that the enhanced metastatic efficiency was a direct reflection of the enhanced tissue invasiveness. Thus, the expression levels of Spa-1 by the immunohistochemistry of biopsy specimens, for instance, may provide a reasonable prognostic estimation for the metastatic potential of primary cancers.

In human *Sipa-1* gene, at least three single nucleotide polymorphisms (SNPs) have been identified, one within the promoter and two exonic, and based on the combinations of *Sipa-1* gene SNPs at least five haplotypes can be discriminated. Analysis in non-Hispanic Caucasian ►breast cancer patients has revealed that a particular *Sipa-1* haplotype shows strong correlation with positive lymph node involvement and another with ►estrogen receptor and ►progesterone receptor-negative tumors. Overall, the *Sipa-1* gene germ line polymorphisms are significantly related to the

aggressiveness in human breast cancer behavior. At present, it remains to be seen whether such germline polymorphisms are indeed reflected to the *Sipa-1* gene expression levels. Nonetheless, this may be one of the first substantial evidence supporting the hypothesis that host genetic predispositions in humans significantly influence the metastatic efficiency of cancers. *Sipa-1* gene may provide not only a useful marker to enhance the staging protocols for prostate, breast, and possibly other cancers but a potential molecular target for the control of cancer metastasis.

Rapamycin

Peter J. Houghton
Department of Molecular Pharmacology, St. Jude Children's Research Hospital, TN, USA

Synonyms

Sirolimus; Rapamune®; CCI779; temsirolimus (Torisel®); RAD001 (everolimus)

Definition

A ►macrolide antibiotic isolated from the soil bacteria *Streptomyces hygroscopicus*.

Characteristics

Discovery of Rapamycin

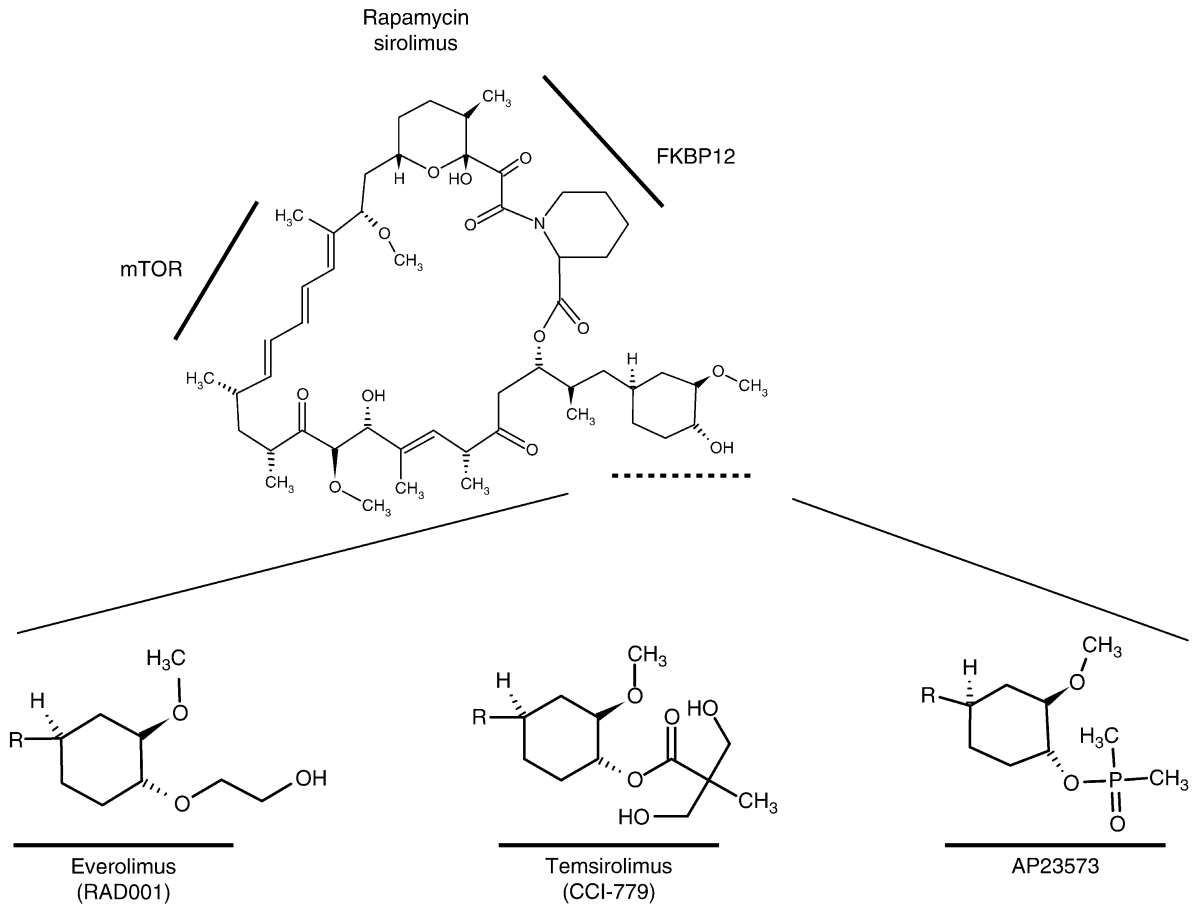
Rapamycin (sirolimus, Wyeth-Ayerst Laboratories; Fig. 1) was originally isolated as a fungicide from the soil bacteria *Streptomyces hygroscopicus*, collected from Easter Island (known as Rapa Nui to the natives) in the South Pacific in 1975. Structurally similar to the immunosuppressive drug ►FK-506 (tacrolimus; Fujisawa Pharmaceutical Co. Ltd.), rapamycin was initially developed to prevent transplant rejection.

While rapamycin was being developed as an immunosuppressant, it was also found to exert potent antitumor activity *in vitro* and *in vivo*. However, perhaps because its mechanism of action was unknown at that time, and a parenteral formulation could not be developed, rapamycin was not further considered as a cancer therapeutic. Rapamycin has emerged as a potent inhibitor of a signaling pathway that may be deregulated in many forms of cancer, leading to both increased growth, survival and malignancy of cells. Rapamycin is a lipophilic macrolide drug, that selectively inhibits ►mTOR (the *m*ammalian *t*arget *o*f *r*apamycin, also known as FRAP1, RAPT1, RAFT1 and SEP) a serine/threonine kinase, that is a member of the ►phosphatidye inositol 3-kinase (PI3K)-like kinases (PIKKs). mTOR lies downstream of PI3K in the signaling pathway. TOR proteins represent a class of evolutionarily conserved kinases in eukaryotes. In the yeasts, *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*, there are two TOR genes, *TOR1* and *TOR2*, both sharing 67% homology and encoding proteins of approximately 280 kDa, whereas in higher eukaryotes a single TOR gene exists. The potential for rapamycin as a cancer therapeutic was refocused, in part, by studies that showed rapamycin potently blocked proliferation stimulated by exogenous insulin-like growth factors (IGF-I/II), and by the development of analogs with minor modifications that were chemically more stable than rapamycin and allowed formulation suitable for parenteral administration (CCI-779, ►temsirolimus, Wyeth Ayerst). Other analogs (RAD001, ►everolimus, Novartis and AP23573, Ariad Pharmaceuticals) are administered orally, Fig. 1.

Mechanism of Action

Rapamycin competes with FK506 for binding to an ►immunophilin (the 12 kD FK506 binding protein; FKBP12) to form an active complex that binds through a hydrophobic face of rapamycin to the FKBP-rapamycin binding domain (FRB) domain of mTOR that is part of the mTORC1 complex with raptor. The FRB domain lies outside the catalytic domain of mTOR, consequently rapamycin is not a direct inhibitor of mTOR kinase activity. Rather, the model suggested is that rapamycin-FKBP12 binds to mTOR and displaces raptor. As raptor binds substrates (4E-BP1 and S6K1) it is postulated that displacement by the rapamycin complex prevents accurate presentation of substrates to the kinase domain of mTOR.

mTOR signaling results in the phosphorylation and inactivation of 4E-BP1, the suppressor of eukaryotic ►initiation factor 4E (eIF4E), a protein that binds the ^{7}mGTPpppN structure (cap) of mRNA. mTOR phosphorylates and activates ribosomal S6K1. By inhibiting mTOR signaling rapamycin treatment results in the inhibition of ►cap-dependent translation that



Rapamycin. Figure 1 The structure of rapamycins under investigation as cancer chemotherapeutic agents. *Bold line*s show the mOR and FKBP12 binding faces of rapamycin. The *broken line* shows the position of structural modifications for the rapamycin analogs RAD001, CCI-779 and AP23573.

is required for translation of mRNA species that have highly structured 5′-untranslated regions. These mRNAs include cell cycle regulators, cyclin D1, and ornithine decarboxylase and the ►transcription factors ►c-MYC and in some cells, hypoxia inducible factor 1α. As a consequence cells accumulate in G1 phase of the cell cycle. Rapamycins have been reported to inhibit cancer stem cell renewal, block cancer cell proliferation, induce apoptosis and prevent cell motility [2]. Rapamycins, through inhibition of mTOR, may have direct actions on cancer cells, preventing secretion of angiogenic factors, or prevent vascular or bone marrow endothelial cells from responding to elicited angiogenic factors, thus inhibiting tumor ►angiogenesis.

Mechanism(s) of Sensitivity and Resistance

Mutations conferring rapamycin resistance were first identified in yeast. Mutants of RBP1, the yeast homolog of FKBP12, that prevent rapamycin binding confer recessive resistance to rapamycins. In contrast, mutations in mTOR that decrease binding of the rapamycin-FKBP12 complex result in dominant resistance. Cellular sensitivity to rapamycin and its analogs has also been related to constitutive activation of Akt (also known as protein kinase B), usually as a consequence of mutation or silencing of the dual specificity phosphatase ►PTEN. Acquired resistance to rapamycin is also associated with decreased levels of ►4E-BP1, thus decreasing the stoichiometry between the suppressor and eIF4E.

Clinical Activity of Rapamycins

Rapamycin was approved by the US Food and Drug Administration in September 1999 and the European Commission in March 2000 for use in kidney transplantation. Rapamycin, and three analogs (CCI-779, RAD001 and AP23573) are currently in various stages of development for treatment of human cancer. Daily intravenous treatment resulted in significant grade 3 toxicities, including hypocalcaemia, vomiting, ►thrombocytopenia, and increase in the level of hepatic transaminases in cancer patients. Objective responses or stable disease were noted (►non-small cell carcinoma, ►cervical carcinoma, uterine carcinoma, ►renal cell carcinoma, and soft tissue sarcoma). On a weekly treatment schedule patients experienced no

grade 3 toxicities regardless of dosage. Partial tumor regressions were noted (renal cell, neuroendocrine, and breast carcinomas). Phase II trials of CCI-779 for renal cell carcinoma yielded an objective response rate of 7%, a minor response rate of 29%, and stable disease in approximately 40% of the patients. Treatment is associated with a increase in survival time of ~4 months. The phase II trial for ►mantle cell lymphoma consisted of weekly treatment with 250 mg (fixed dose) of CCI-779 administered intravenously, resulted in an overall objective response rate of 38%, with a median time to progression of 6.9 months in responders. CCI-779 also appears to have significant activity in ►endometrial cancer, irrespective of ►PTEN status, yielding objective responses in 25% of patients, and causing disease stabilization in over half of the patients on study. For AP23573 there is currently a Phase I trial to determine the maximum tolerated dose (MTD) with oral administration in advanced cancers, and phase II evaluation against ►sarcomas. There are also trials to determine the maximum oral tolerated dose in combination with ►doxorubicin in the treatment of sarcomas, as well as a trial to determine the MTD dose in patients with multiple myelomas, and a Phase II trial of patients with recurrent endometrial cancer. Phase II results suggest significant activity against various subtypes of sarcoma. Phase III trials are in progress to test the efficacy of CCI-779 either alone or in combination with ►interferon-α as a first line treatment of renal cell carcinoma, and the use of the oral form of CCI-779 or RAD001in combination with the ►aromatase inhibitor letrozole for the treatment of locally advanced or metastatic hormone-responsive breast cancer.

RAS

Angel Pellicer
Department of Pathology, New York University School of Medicine, New York, NY, USA

Definition

The word Ras comes from a contraction of Rat sarcoma, the tumor where the first gene of the family was identified, as part of the genome of a ►retrovirus isolated from a carcinogenesis protocol.

Characteristics

Structure

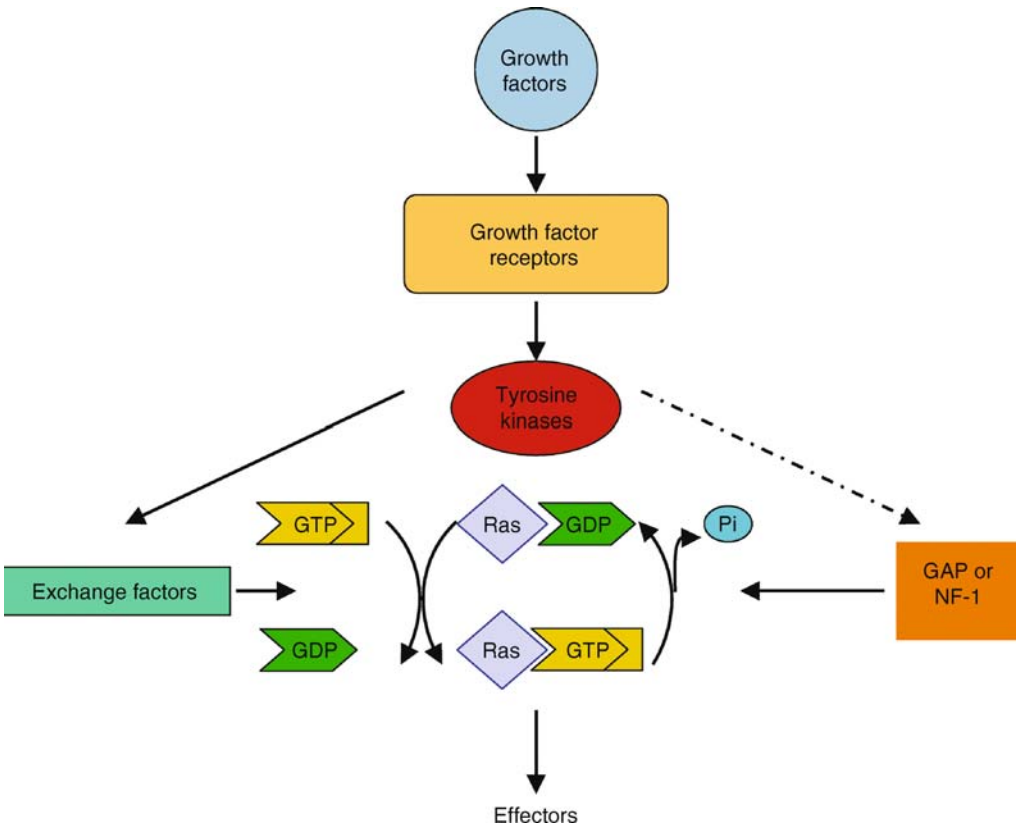
The Ras genes, strictly speaking, are only a small group of a large family of related genes (the Ras superfamily) that perform a host of important cellular functions including ►signal transduction (Ras, ►Ral, ►Rho), cytoskeletal regulation (Rho), vesicle transport (►Rab) and nuclear-cytoplasmic transport (►Ran). The Ras genes more relevant for human cancer are: H-ras, K-ras and N-ras and they will be the subject of this essay. H-ras was initially isolated from the Harvey sarcoma virus. K-ras from the Kirsten sarcoma virus and N-ras was isolated by DNA-mediated gene transfer from a human neuroblastoma cell line. In humans they are located in chromosome 11p15, H-ras; 12p12, K-ras and 1p22, N-ras. These three genes code for very similar proteins of 189 a.a. with four coding exons. Although the proteins are very similar, the genes have very different lengths due to the variable length of their introns. The expression of the three genes is essentially ubiquitous, although different tissues show differences in the levels of expression for the three genes. Analysis of the protein sequence shows that they contain a domain for ►GTP binding, which represents a common characteristic for the whole superfamily.

The H-ras protein has been crystallized with GTP and the main regions that contact the phosphates are G1 (residues 11–17) and G3 (residues 53–62). The regions contacting the guanine ring are G4 (residues 112–119) and G5 (residues 144–146). The biochemical function of ras proteins is to hydrolyze GTP (►GTPase). The

other main structural feature is at the carboxyterminal end where they have the CAAX box motif, where C is a cysteine, A are aliphatic amino acids and X is any amino acid. This box is required for the processing of the protein that is ►farnesylated at the cysteine, cleaved by a protease (eliminating AAX) and carboxymethylated. This processing is essential for the protein to reach the plasma membrane, the main place where it is functionally active. In the last few years evidence has been accumulating that Ras can also localize to the Golgi apparatus and be active there, although the exact functions that specifically elicits from there are still under study. Although the first three exons of the three proteins are quite similar, there is more divergence in the fourth exon and this has resulted in different processing for K-ras versus the other two. H- and N-ras have other cysteine(s) upstream from the one that is farnesylated and they are ►palmitoylated. K-ras lacks these cysteine(s), which are substituted by a run of positively charged amino acids. This feature appears to modify the way by which K-ras is brought to the membrane, and it appears to make it more resistant to inhibition by ►farnesyltransferase inhibitors (FTIs), a potential treatment for tumors. This failure is due to the fact that K-ras can be posttranslationally modified by the geranylgeranyl transferase enzyme in the absence of farnesyltransferase, and this modification allows the protein to localize to the plasma membrane. K-ras also has two alternative exons 4 (4A and 4B). The specificity of the function for each isoform has not been conclusively proven, but it appears to be strongly supported by the gene inactivation studies. Although N- and H-ras knockouts are born normal and only have a few alterations in signal transduction pathways, K-ras is lethal embryonic, but the double knockout between K-ras and N-ras is lethal even earlier than the K-ras knockout, indicating that N-ras is providing a function that cannot be substituted by K-ras.

Cellular and Molecular Regulation

The function of the Ras proteins is to act as signal transducers between the membrane and other cellular



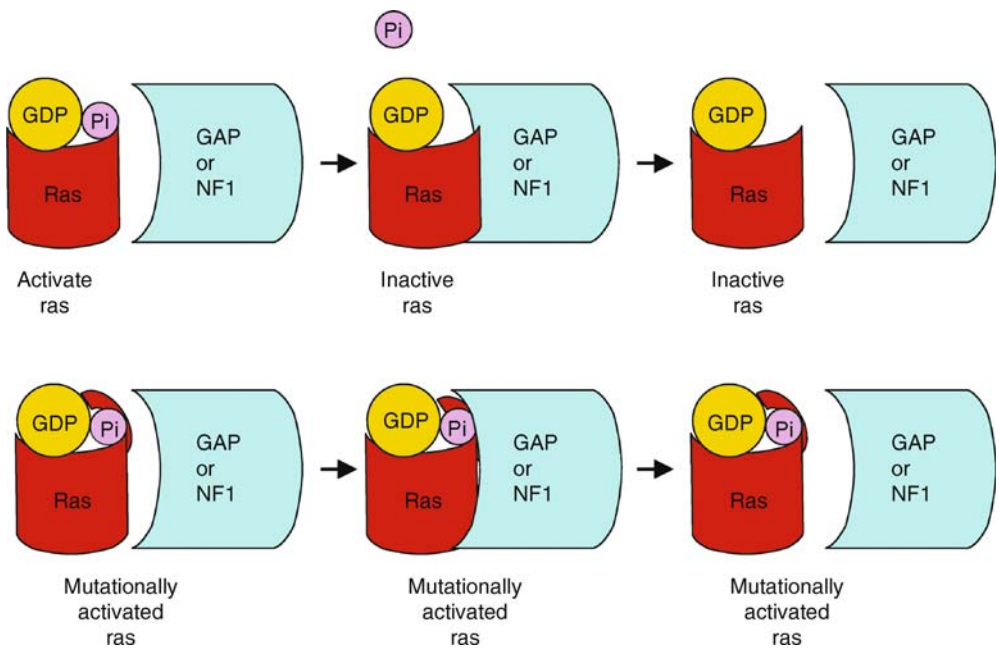
RAS. Figure 1 Biochemical Ras cycle. The Ras protein is a molecular switch that cycles between activated and inactive states. External signals, acting through receptors, elicit the interaction between the exchange factor and Ras-GDP (inactive), which produces the dissociation of GDP from Ras. Given the much higher concentration of GTP in the cytoplasm, Ras binds then to GTP and becomes activated, interacting with its effectors and activating them. To prevent constitutive activation, there are molecules that stimulate the intrinsic GTPase activity of Ras enhancing the hydrolysis and producing Ras bound to GDP, closing the cycle.

structures, most often the nucleus. Ras molecules are in the inner face of the plasma membrane and in the Golgi apparatus in an inactive state, bound to ►GDP. When a stimulus has to be transduced a Ras guanine dissociation stimulator (RasGDS or Ras ►GEF) interacts with Ras resulting in its dissociation from GDP. Given the much higher concentration of GTP in the cellular environment, the next nucleotide to bind to ras is usually GTP. This results in a conformational change that activates Ras, which is now poised to transmit a signal downstream. Ras binds now to its effectors and facilitates their activation. To prevent excessive signaling, Ras has a weak intrinsic GTPase activity. To increase this GTPase activity there are molecules that enhance this GTP hydrolysis and are called GAPs (GTPase Activating Proteins). For Ras, at least two such proteins have been identified GAP and ►NF1 (Fig. 1). Some mutations can abolish the GTPase activity of Ras and block its response to GAPs. This results in a constitutive ►Ras activation with uninterrupted signaling as it has been found in tumors (Fig. 2).

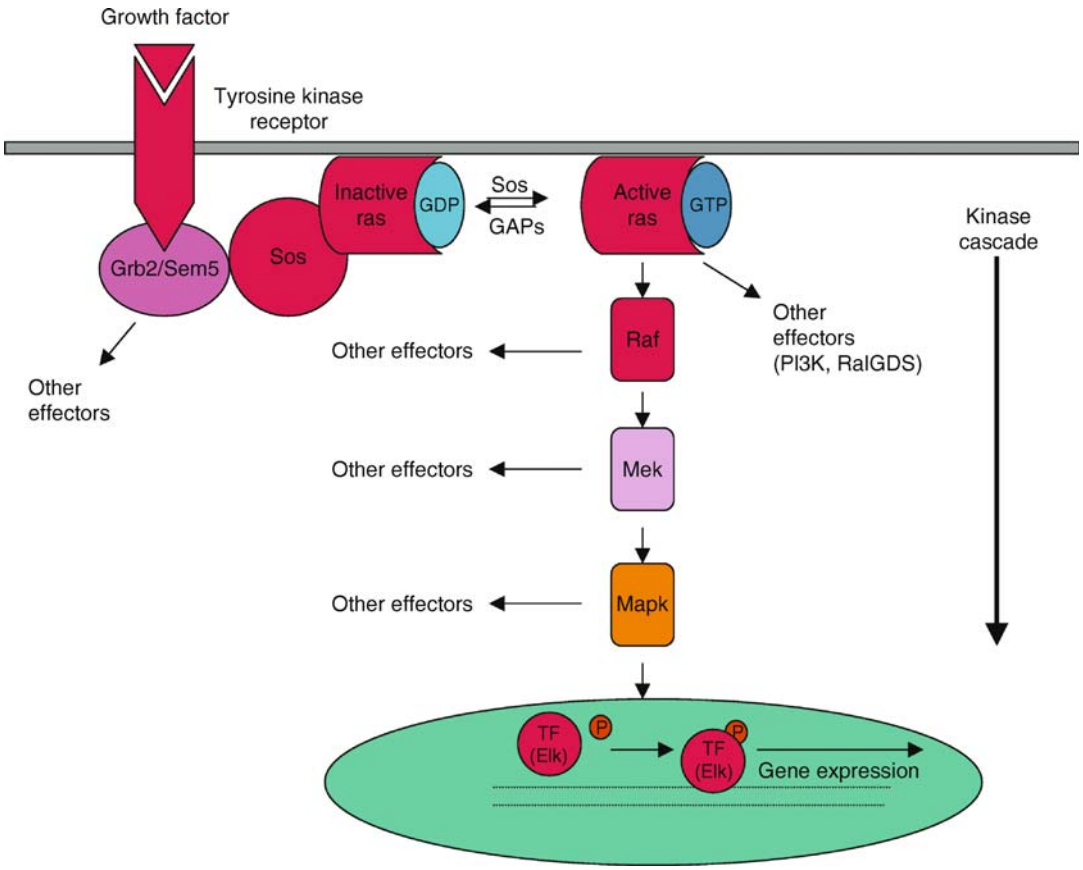
The previous description corresponds to the so-called Ras cycle that involves the steps from a Ras-GDP molecule to Ras-GTP and back to Ras-GDP. The linear ras pathway describes the route followed by an outside signal through Ras and its final destination in the nucleus (Fig. 2). As an example, the signal triggered by EGF is chosen. EGF is a growth factor that interacts with its specific receptor in the cell surface. This interaction triggers a dimerization and autophosphorylation of the cytoplasmic domains. These phosphorylated residues recruit SH2 containing molecules like the adaptor Grb2. This molecule contains also an SH3 domain that recruits to the membrane the Ras ►GEF through its polyproline domain. RasGEF activates Ras, which interacts in its GTP bound conformation with ►Raf (other important effectors are ►PI3 kinase and RalGDS). Raf is a kinase that now activates another downstream kinase called ►MEK, which in turn activates another downstream kinase called ERK. This kinase now translocates to the nucleus and activates a number of transcription factors like Elk, which are responsible for executing the action triggered by the original signal (►EGF) by inducing the appropriate genes (Fig. 3). Although Ras best-known function is to stimulate cell proliferation, signals transduced through Ras can also induce differentiation, growth arrest and ►senescence, depending on the cellular context where its action is studied.

Clinical Relevance

The great effort that has been devoted to study the Ras genes and their regulation stems from its importance in cancer. Nevertheless, recently a number of studies have been reported indicating that some versions of weakly ►activated Ras genes can be found in the germ line of patients with hereditary developmental syndromes like



RAS. Figure 2 Mutational activation of Ras makes it resistant to the inactivating effects of GAP proteins. A crucial biochemical difference between the normal Ras protein and the mutationally activated version found in many tumors is the fact that the abnormal version is unable to respond to the effects of GAP or NF1 by hydrolyzing GTP into GDP.



RAS. Figure 3 A representative signal transduction pathway where Ras is a crucial step. The signal starts from a growth factor and through its receptor activates Ras. Activated Ras activates a kinase cascade which last member translocates into the nucleus activating transcription factors that will be executors of the functions that each particular growth factor induces in a particular cell context. It is relevant to mention that the elements of the pathway in *red* have been shown to be oncogenic in different systems.

Noonan, Costello and cardio-facio-cutaneous syndrome. Only in Costello syndrome the mutations present have been occasionally reported in cancer, for the others the mutations reported in the syndromes are new and in all cases only weakly activating. In Noonan and Costello patients there are tumors associated with the syndrome, but not in the cardio-facio-cutaneous syndrome patients. The relevance of Ras genes in cancer was hypothesized when two of the genes (H- and K-ras) were identified as the ►oncogene in an acute rodent retrovirus and the other (N-ras) as a cellular oncogene in a human neuroblastoma. Using DNA-mediated gene transfer and rodent cells as recipients (usually NIH3T3) a large variety and number of human and animal tumors were tested for the presence of oncogenes in the focus formation assay, and, when positive, most of the time were shown to be one of the Ras isoforms. The ability of ►activated Ras genes to induce ►malignant transformation has its molecular base on mutations acquired in tumor development that render the molecule in a constitutively active conformation. In animal tumors induced by chemical carcinogens it has been shown that the Ras mutations correlate with the chemical reactivity of the carcinogen, suggesting that in some cases Ras mutations could be the initiating alteration in tumor development. The ability of Ras genes to induce tumors has also been approached in transgenic mice where Ras oncogenes under the control of tissue specific promoters have induced tumor development in a number of tissues.

Evidence of the clinical relevance of the Ras genes is its significant frequency of mutation in human tumors. The methods of detecting the mutations started by cloning and sequencing the transforming genes. After the advent of PCR, most of the detection strategies use that technique as part of the protocol. The overall frequency in human cancer is calculated to be between 20 and 30%. There is nevertheless, a large variation in the frequencies depending on the tumors to be considered. The highest frequency is in ►pancreatic cancer (80–90%). In ►colon carcinoma is around 50%, thyroid tumors, 50%, ►non-small cell lung cancer, 30%

and in some acute ►leukemias also around 30%. In ►bladder cancer there has been some controversy about the frequency of ras activation, depending on the techniques utilized for the detection that ranges from 10 to 60%. The frequency of Ras mutations in many other types of human tumors is lower and in particular in ►breast cancer and ►prostate cancer is around 5%. Nevertheless, it appears that in a number of tumors, the presence of a wild type Ras is substituted by activating mutations in ►B-raf, ►PTEN, ►PI3 kinase, ►AKT1 kinase or ►EGFR ►amplification, all of which result in a Ras pathway activation. Therefore, regardless of the fact that Ras genes are mutated or not in the tumors, it appears that the activation of this pathway plays a very important role in many human cancers.

RAS Activation

Laszlo Buday
Department of Medical Chemistry, Semmelweis University Medical School, Budapest, Hungary

Definition

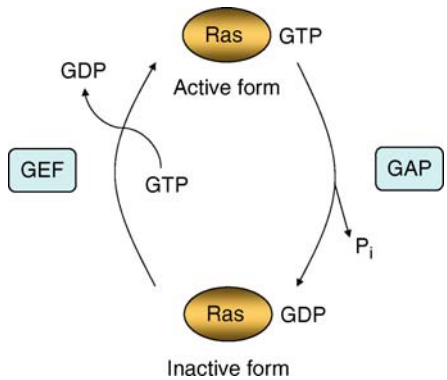
Increase of the active GTP-bound form of Ras proteins promoted by ligand-bound ►receptors or other mechanisms.

Characteristics

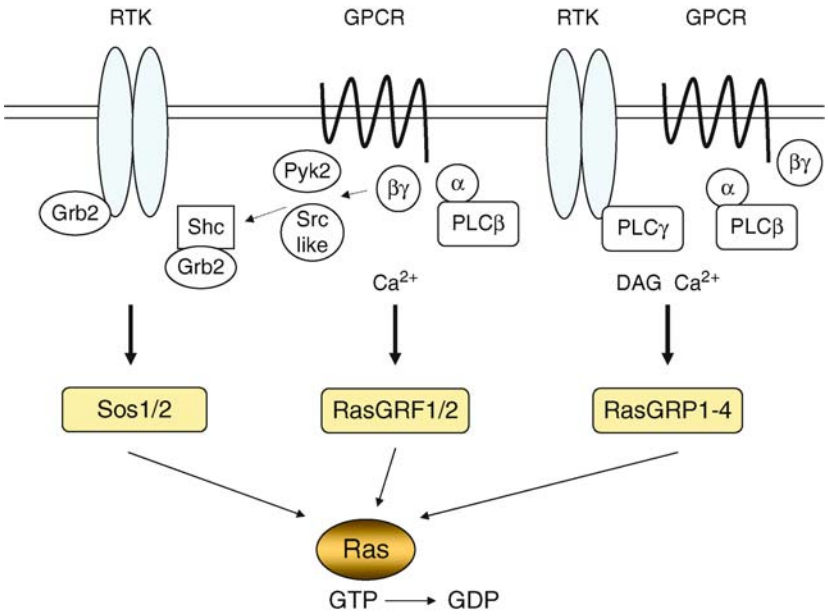
The family of ►Ras proteins (Ha-Ras, N-Ras, Ki-RasA and Ki-RasB) consists of low molecular weight guanine nucleotide-binding proteins that play essential roles in the control of cellular growth and differentiation. Ras alternates between an active GTP-bound state and an inactive GDP-bound state. The slow intrinsic rate of GTP hydrolysis on Ras is stimulated by ►GTPase-activating proteins (►GAPs), such as p120GAP and ►neurofibromin, while Ras activation requires ►guanine nucleotide exchange factors (►GEFs) that stimulate the dissociation and exchange of bound GDP for GTP on Ras in response to upstream signals. (Fig. 1).

Ras proteins are localized mainly at the inner surface of the plasma membrane, where they participate in transmitting signals from ►tyrosine kinase receptors (RTK) and some receptors coupled to ►heterotrimeric G-proteins. It is well established that ligand-bound receptor tyrosine kinases initiate Ras activation through formation of heterotrimeric complexes consisting of autophosphorylated receptors, the SH2/SH3 ►adaptor protein Grb2 and the guanine nucleotide exchange factor Sos. The ►SH3 domains of Grb2 bind to the carboxy-terminal proline-rich domain of Sos, whereas the ►SH2 domain binds to specific tyrosine phosphorylated sequences. Complex formation of Sos with autophosphorylated receptor tyrosine kinases via Grb2 results in the translocation of Sos from the cytosol to the plasma membrane, where its target, Ras, is localized. Interaction of Sos with Ras at the plasma membrane further increases its activity (Fig. 2).

The mechanism(s) whereby G protein-coupled receptors (GPCRs) regulate Ras activation and cell proliferation is not completely understood. It is clear that ligand binding to GPCRs in a variety of cellular systems leads to rapid tyrosine phosphorylation of the Shc adaptor protein, followed by the formation of Shc-Grb2 complexes. The candidate kinases responsible for Shc phosphorylation are Pyk2 and Src-like kinases, which link Gβγ subunits to ►MAP kinase activation through phosphorylation of Shc and subsequent complex formation of Shc with Grb2-Sos. Transactivation of the ►epidermal growth factor (EGF) receptor



RAS Activation. Figure 1 Cycling of the Ras protein between the inactive GDP-bound form and the active GTP-bound form. Binding of growth factors to their receptors promote formation of active, GTP-bound Ras. This is achieved through the action of guanine nucleotide exchange factor (GEF), which stimulates the dissociation of the tightly bound GDP from Ras. Hydrolysis of bound GTP is accelerated by GTPase activating protein (GAP).



RAS Activation. Figure 2 Activation of Ras following ligand-binding to receptor tyrosine kinases (RTKs) or G protein-coupled receptors (GPCRs). Three distinct GEFs specific for Ras have been identified: Sos1/2, RasGRF1/2, and RasGRP1–4. Binding of growth factor (e.g. epidermal growth factor) to its RTK initiates dimerization and autophosphorylation of the receptor and subsequent recruitment of the Grb2/Sos complex to the plasma membrane, where Ras activation occurs. GPCRs that signal through heterotrimeric G proteins can activate all three classes of GEFs. The Gβγ subunit may activate tyrosine kinases that through Shc phosphorylation recruit Grb2/Sos complex to Ras at the plasma membrane. In addition, the Gβγ subunit can also stimulate the activity of RasGRF1. Calcium signals triggered by GPCRs seem to be required for the activation of both Ras GRFs. Finally, RasGRPs, that contains calcium- and diacylglycerol-binding domains, may also contribute to Ras activation downstream of either RTKs or GPCRs.

may also contribute to Ras activation downstream of GPCRs. Two other Ras exchange factors, the brain-specific RasGRF1 and the more ubiquitously expressed RasGRF2, also participate in the signaling events from GPCRs to Ras activation. In addition to their catalytic domain, both RasGRFs contain calcium and calmodulin-binding motifs.

The third class of the Ras exchange factor family is the Ras guanine nucleotide releasing proteins (RasGRP). Although they have different tissue expression profiles, all members contain a C1 domain that binds diacylglycerol (DAG) and DAG analogs such as the tumor promoting phorbol esters. ►Protein kinase C (PKC) family members can phosphorylate RasGRPs resulting in their further activation.

Two distinct GTPase activating proteins (GAP) for Ras have been identified; p120GAP is widely expressed, while neurofibromin is present predominantly in cells of the nervous system. Both GAPs stimulate the weak endogenous rate of Ras GTP hydrolysis, thereby negatively regulating signaling via Ras.

In addition to the plasma membrane, Ras proteins can be activated on intracellular membranes such as the Golgi apparatus, endoplasmatic reticulum, and mitochondrion. Ras is directed to those membrane compartments by posttranslational modifications, including palmitoylation and farnesylation. On the Golgi membranes, Ras activation is mediated by RasGRP1 that is activated in a calcium- and diacylglycerol-dependent manner.

Clinical Aspects

Mammalian Ras proteins have been studied in great detail because mutant Ras proteins are associated with many types of human cancer. These mutant proteins are permanently in the GTP-bound, active state and can cause neoplastic transformation. The point mutations found in Ras genes fall into two functional groups: those affecting codons 12, 13, 59, 61 and 63, reduce the rate of hydrolysis of GTP on Ras protein and critically block its stimulation by GAPs, and those at codons 116, 117, 119 and 146 increase the rate of nucleotide exchange.

One of the Ras GAPs, neurofibromin, is the product of the NF1 gene. Damage to this gene has been implicated in the hereditary disease Von Recklinghausen neurofibromatosis (►neurofibromatosis type 1), which is characterized by a number of developmental defects including benign and malignant tumors of neural crest origin, such as neurofibromas and neurofibrosarcomas.

Germline activating mutation can occur in genes encoding Ras proteins, and other components of the pathway, leading to development defects. ►Costello syndrome, characterized by a complex developmental disorder involving characteristic craniofacial features, failure to thrive, developmental delay, cardiac and skeletal anomalies and a predisposition to develop neoplasia, both benign and malignant, can result from germline mutational activation of H-Ras. ►Noonan syndrome is an autosomal dominant disorder presenting with characteristic facies, short stature, skeletal anomalies, congenital heart defects, and predisposition to tumors. This syndrome is caused by activating germline mutations in K-Ras, Sos1, or a SH2 domain-containing phosphatase (PTPN11).

Synonyms

RASSF1

Definition

The Ras association domain family 1 (*RASSF1*) is a member of a new family of ►RAS or RAS-like small GTPases effectors. There are five other bonafide RASSF members all harboring a C-terminus Ras-Association (RA) and Salvador/RASSF/Hippo (SARAH) domains. Genome databases have classified two proteins as RASSF7 and RASSF8 where the RA domain is located at the N-terminus. *RASSF1* also exists in at least seven isoforms generated by alternative splicing or promoter usage. Only the longest isoform, isoform A, harbors an additional cysteine-rich diacylglycerol (DAG or C1) lipid-binding domain. The RA domain shares a similar structure with the highly characterized Ras-binding protein, Raf. However, unlike Raf, RASSF1 and the other RASSF proteins lack catalytic domains and they are more likely to function as adaptors to recruit additional proteins. The SARAH domain is thought to form a coiled-coil region that mediate homo- and heterotypic interactions with other SARAH domain-containing proteins SAV1 and MST1 and MST2 (Fig. 1).

Characteristics

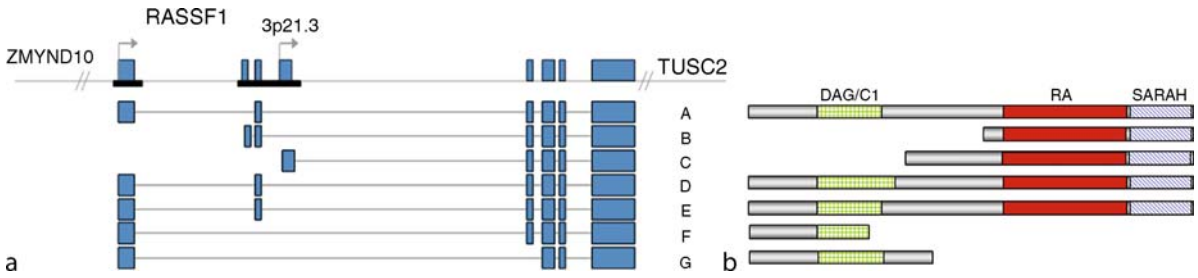
RASSF1A is a novel tumor ►suppressor gene. It is inactivated in a large subset of tumor types by ►hypermethylation of its ►promoter region. The mechanisms of action of this protein are not fully elucidated but it has been implicated in ►cell cycle control, ►apoptosis, cell ►migration, and control of ►mitosis.

RASSF1A as a Tumor Suppressor Gene

Interest in *RASSF1A* started with the consistent observation that alterations of the short arm of chromosome 3 (3p) is one of the most common and earliest events in the pathogenesis of ►lung cancer. Frequent and early loss of heterozygosity and the presence of homozygous deletions, especially at 3p21.3, suggested that at least one tumor suppressor gene may reside in this region. The detection of overlapping homozygous deletions in cancer cell lines narrowed the region of interest to 120 kb. The minimal region contained eight genes; hence mutation and expression analysis was focused on these eight genes. Despite extensive investigation, only rare tumor-associated mutations have been identified in lung, breast, kidney, and nasopharyngeal cancer. Interestingly, however, expression of *RASSF1A*, but not *RASSF1C* is lost or downregulated in a variety of tumors. The main cause for this loss of expression is promoter ►CpG island hypermethylation. *RASSF1A* inactivation by hypermethylation of its promoter region was originally described in lung and breast cancers. Since then it has emerged that *RASSF1A* is one of the most frequently switched-off genes in over 40 cancer types (Table 1).

RASSF1A Methylation as a Cancer Biomarker

Tumor-specific ►methylation of *RASSF1A* in a very broad spectrum of tumor types, in moderate-to-high frequencies makes it an ideal cancer ►biomarker suitable for diagnosis and prognosis. In addition, it is also possible to detect *RASSF1A* methylation in body fluids extracted via noninvasive procedures, such as sputum for lung cancer, nipple aspirate fluids for breast cancer, urine for bladder and kidney cancers, and even DNA collected from tampons for endometrial cancer. An example of a possible clinical application for the



Ras Association Domain Family 1. Figure 1 *RASSF1* is expressed from its locus on chromosome 3p21.3 in multiple isoforms (a) that result in the expression of several proteins (b).

Ras Association Domain Family 1. Table 1 Comparison of *RASSF1* and *TP53* inactivation frequencies in human cancers

Cancer type	*%TP53* mutation[a]	*% RASSF1A* methylation[b]
Lung	45	78 (SCLC)
Breast	48	55
Prostate	40	75
Kidney	29	55
Liver	60	92.5

[a]COSMIC, catalogue of somatic mutation in cancer.
[b]Average of percentages reported in literature.

detection of *RASSF1A* methylation is the screening of populations at risk of lung cancer, such as smokers. The lifetime risk of people who never smoked developing lung cancer is 1 in 10,000 whereas for current and former chronic smokers the yearly risk is 3 in 1,000. About 1 in 5 smokers suffering from lung cancer show *RASSF1A* methylation compared with 1 in 100 nonsmokers with lung cancer. The frequency of *RASSF1A* methylation also increases with heavy smoking. Regular screening for *RASSF1A* methylation in sputum, bronchoalveolar lavages and serum from populations at risk, particularly smokers and lung cancer survivors, may enable earlier detection of lung cancer and the reduction of lung cancer mortality.

RASSF1A methylation in benign growths or hyperplastic lesions can be used as a means of predicting breast cancer risk. *RASSF1A* methylation was found in 70% of samples of benign breast tissues from unaffected women at high-risk for breast cancer, but in only 29% of samples from women at low/intermediate-risk. Demonstrating that in benign breast epithelium, *RASSF1A* promoter methylation is associated with epidemiological markers of increased breast cancer risk. Detection of *RASSF1A* methylation probably means a bad prognosis for a lung cancer patient. Studies have shown that ►NSCLC patients with *RASSF1A* methylation suffer from significantly reduced survival rates compared with patients without *RASSF1A* methylation. This is possibly due to the fact that tumors with *RASSF1A* methylation tend to be more aggressive and metastatic, have increased vascular invasion, pleural involvement, and poor differentiation. *RASSF1A* methylation, therefore, would provide a powerful marker for patient prognosis at an early stage of lung cancer development. Other studies have also suggested that *RASSF1A* methylation may offer a marker for chemotherapeutic drug resistance (cisplatin and tamoxifen) in some tumors and could be monitored throughout the course of treatment to adjust the therapeutic regimen accordingly.

Functional Characterization of RASSF1A

Investigation of RASSF1A has revealed it to be an ►adaptor protein with diverse functions including the regulation of ►apoptosis and ►microtubule dynamics during mitotic progression. The ability of RASSF1A to suppress growth in vitro and in vivo as well as increase susceptibility of Rassf1a-negative mice indicates that it has tumor suppressive functions. Overexpression of RASSF1A results in cell cycle arrest and is accompanied by dramatic changes in gene expression. This includes changes to the expression of important cell cycle regulatory genes such as ►*cyclin D* but also to genes involved in diverse functions including transcription, cytoskeletal organization, ►angiogenesis, signaling, cell ►adhesion, cell ►migration, and apoptosis. RASSF1A regulates apoptosis via at least two pathways. RASSF1A binds the proapoptotic serine/threonine kinases ►MST1 and MST2. The MST1/2 ►ortholog in the fruit fly is called hippo. Hippo functions as a tumor suppressor in fruit fly through its activation of another

kinase, Warts. Warts blocks the cell cycle by preventing the expression of cyclin E and promotes apoptosis by downregulating the antiapoptotic agent, Diap1. The Hippo–Warts pathway is conserved in mammals where Warts have two conserved orthologs, LATS1 and LATS2. Both of these kinases are considered tumor suppressor genes. The fly RASSF ortholog, cg4656, functions in the Hippo pathway, but unlike the mammalian RASSF, it does this through inactivating Hippo. This may suggest that a member of the mammalian RASSFs may have a similar function, but that is yet to be demonstrated since RASSF1A is more likely to be an activator of MST1/2. RASSF1A may also regulate apoptosis in an MST-independent manner through modulator of apoptosis 1 (MOAP-1). MOAP-1 associates with ►Bcl-2 family members Bax and Bcl-2 and initiates caspase-dependent apoptosis when overexpressed. RASSF1A is also involved in the regulation of microtubules dynamics and colocalizes with microtubules, spindles, and centrosomes during metaphase and promotes microtubule stability and polymerization. RASSF1A microtubule association may be mediated by interaction with C19ORF5/MAP1S. MAP1S has been shown recently to function as a spindle-associated microtubule-associated protein with an activity required for correct spindle pole formation and mitosis. RASSF1A has been controversially suggested to control the spindle checkpoint through binding to ►Cdc20, which negatively regulates ►anaphase-promoting complex (APC) and subsequently causes a mitotic block prior to anaphase. Mouse embryonic fibroblasts derived from mice engineered for complete loss of Rassf1a suffer from cytokinesis defects. This aberrant stage of cell division is attributed to inaccurate control of the LATS1/2 kinases due to the loss of Rassf1a. These cells are also more motile and morphologically different than control cells.

Another aspect of RASSF1A function is its relationship with ►oncogenic RAS. Due to the presence of the RA domain in all members of the RASSF family, it has been predicted that they bind and negatively control RAS activation or mediate the proapoptotic functions of oncogenic RAS. However, a conclusive evidence for the association of RASSF1A with RAS remains to be demonstrated. Where one study showed that both proteins interact directly, another showed that this interaction is not direct and it has to be mediated by RASSF5 (NORE1). It is intriguing to postulate that RASSF1A/RAS interaction is cell type and stimulus dependent. An example of the need of stimulation for the involvement of RASSF1 in the RAS pathways comes from the observation that RASSF1C is anchored in the nucleus by binding to DAXX. When cells are exposed to DNA-damaging agents like MMS and UV irradiation, DAXX is degraded allowing RASSF1C to leave the nucleus and attach to the microtubules. RASSF1C can then associate with H-RAS and participate in the activation of the SAPK/JNK pathway.

Conclusion

There is an accumulating body of evidence for the classification of *RASSF1A* as a tumor suppressor gene. However, there is a need to fully understand how it performs its suppressive functions and what cell signaling pathways are involved upstream and downstream of this molecule. *RASSF1A* is epigenetically inactivated by hypermethylation of its promoter in a large majority of cancers of various types, including adult and children's cancers. Hence, it may be a useful methylation marker across multiple malignancies for early detection of cancer and for prognostics and diagnostic purposes. Since hypermethylation is reversible, the search for targeting strategies that can reverse this block on *RASSF1A* expression may yield a very useful therapeutic approach to several types of cancers. Until the function of the RASSF1A protein is well understood, its methylation can serve as a biomarker for diagnosis and prognosis of various cancers using noninvasive methods of screening patient populations.

RAS Transformation Targets

Reinhold Schäfer
Molecular Tumor Pathology, Institute of Pathology, Berlin, Germany

Synonyms

RAS-regulated genes; RAS-responsive genes

Definition

The term "RAS transformation targets" is used for genes whose normal expression is either up-regulated or down-regulated by the permanent activation of ►RAS-mediated ►signal transduction in cancer cells. Critical target genes exert functions essential for the initiation or maintenance of malignancy, while other targets may be deregulated as a consequence of the ►transformation process.

Characteristics

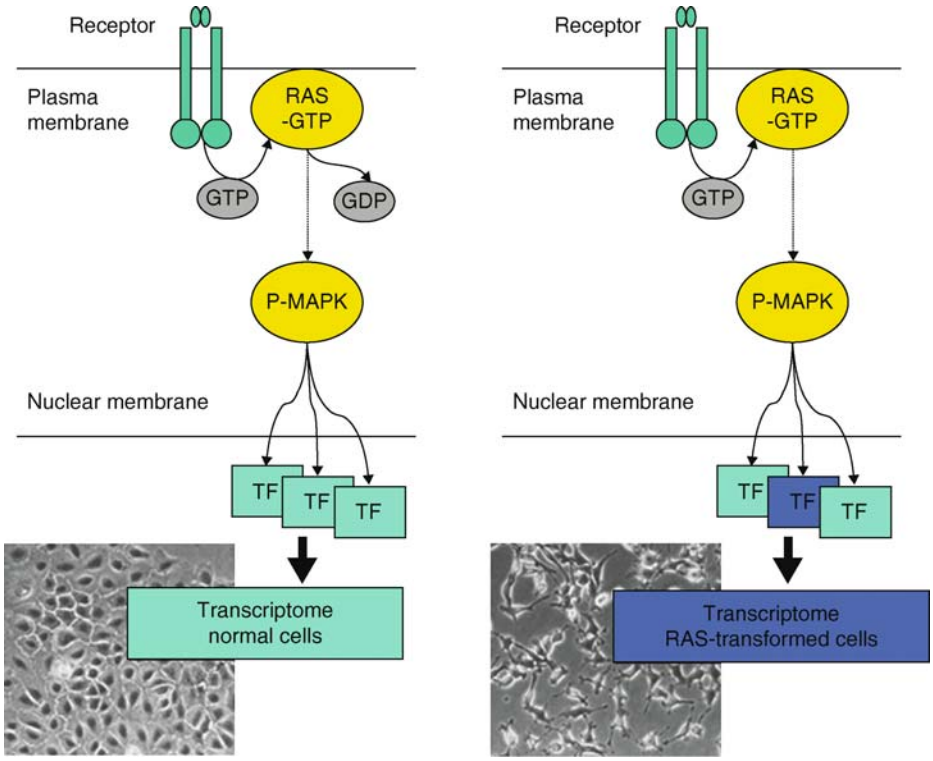
Target gene patterns specific for transformed cells may partially overlap with those obtained in normal cells stimulated with growth factors and in cells in which ►differentiation or ►senescence are induced via the RAS pathway. In a general way, the term "target" defines a gene whose ►transcription is turned on or off by a positive or negative regulator present in the nucleus. In eukaryotic genes, gene regulation is governed by binding of ►transcription factors to defined transcriptional control regions (motifs) on genomic DNA proximal to the coding sequence. RAS proteins are cytoplasmic signaling molecules attached to the inner face of the plasma membrane and thus mediate transcriptional alterations indirectly via a network of cytoplasmic effector molecules. There are short-term and long-term effects on the transcriptional response. Therefore, some authors prefer to designate only those genes as RAS targets that are immediately deregulated when a RAS ►oncogene is expressed (e.g. from a conditional ►promoter). Regardless of the timing of transcriptional alterations, there exist target genes whose transcriptional deregulation is fully or partially reversible, when the ►mitogen-activated kinase (MAPK) pathway, one of the most important RAS effector pathways, is blocked and the phenotypic aspects of cellular transformation are reversed.

Background

RAS pathway activation is a paradigmatic example for a cancer-inducing process at the cellular and molecular level. Cellular oncogenes of the RAS family were discovered in human and experimental tumors. Gene transfer studies (►transfection experiments) showed that mutationally activated RAS proteins induced characteristic morphological alterations in pre-neoplastic, non-tumorigenic cell lines. RAS transfectants showed features of cancer cells including anchorage-independent proliferation and rapid tumor formation following injection into nude mice. After the initial discovery of RAS oncogene function in ►cellular transformation assays, refined experimental approaches showed that cellular transformation requires more than a single genetic alteration. The transformation process requires cooperating oncogenes and the inactivation of ►tumor suppressor genes in normal cells. Genetic analysis of human tumors indicated that RAS activation occurs in conjunction with tumor suppressor gene loss and epigenetic changes. Cellular transformation by RAS is invariably coupled with profound alterations of gene expression (Fig. 1). For this reason, identification of the genes (targets) which respond to the expression of RAS oncogenes is of paramount importance for understanding the biological properties of cancer cells and the transformation process itself.

RAS Proteins Affect Gene Transcription via Cytoplasmic Effectors

►RAS genes encode ►small GTP-binding proteins located at the inner face of the plasma membrane. The RAS proteins affect gene transcription in a global way by acting as major switches in signal transduction processes that couple extra-cellular stimuli, e.g. elicited by growth factors, with the transcriptional machinery (Fig 1). Briefly, the signaling pathway is made of a branched chain (cascade) of interacting proteins located at the cell surface (►receptor tyrosine kinases) and in the cytoplasm (signaling kinases, small GTP-binding proteins). Shuttling of phosphorylated signaling kinases into the nucleus induces transcriptional changes by phosphorylating transcription factors. In normal cells, the RAS signal transduction mediates proliferation, developmental processes and differentiation upon external stimulation. In resting cells, RAS proteins are GDP-bound and inactive. RAS proteins are switched on (activated) by a complex set of subsequent protein interactions initiating with the binding of the ►ligand (e.g. a growth-stimulating polypeptide or hormone outside the cell) to a receptor tyrosine kinase at the cell surface and terminating with the loading of GTP catalyzed by nucleotide exchanger proteins. RAS proteins are switched off (inactivated) by hydrolysis of GTP to GDP. Inactivation is catalyzed by GTPase-activating effector proteins.



RAS Transformation Targets. Figure 1 Differential effects of RAS signaling on the transcriptome. *Left*: In normal cells, the molecular RAS switch is activated via a protein complex of tyrosine kinase receptors, adapter proteins and nucleotide exchangers (ON-state) and then deactivated by GTP hydrolysis (OFF-state). Signaling to downstream cytoplasmic effectors such as the mitogen-activated protein kinase (MAPK) and nuclear targets (multiple transcription factors, TF) is transiently activated and rapidly terminated. The cartoon is highly simplified. Most of the elements of cytoplasmic signaling have been omitted. P-MAPK indicates that the signaling kinases are activated by phosphorylation. *Insert*: rat ovarian surface epithelial cells (phase contrast). *Right*: In transformed cells, the molecular RAS switch is locked in its active, GTP-bound state, generating a permanent stimulus. By transcriptomic profiling, various researchers have discovered profound alterations of gene expression in transformed versus normal cells. Critical RAS pathway targets execute the malignant properties of cells. *Insert*: KRAS-transformed rat ovarian surface epithelial cells.

Oncogenic forms of RAS are locked in their active, GTP-bound state and transduce signals essential for cellular transformation, cell survival, ►angiogenesis, ►invasion and ►metastasis. The transformed cellular features are mediated by several branches of the signaling pathway, each triggered by a different effector protein interacting with GTP-bound RAS. These involve the mitogen-activated protein kinase ►RAF that subsequently activates MEK (MAPKK) and ►ERK (MAPK), the small GTP-binding proteins RAC and ►RHO, phosphatidyl inositol-3-kinase (►PI3K) and others. Transcription factors stimulated in RAS-transformed cells comprise among others the ►ETS-domain transcription factor ►ELK1, serum-responsive factor ►SRF, the leucin zipper protein ►JUN, activation transcription factor 2 (►ATF2), and ►nuclear factor κB (NF-κB). The diversity of factors involved explains the overall complexity of the transcriptional response to oncogenic RAS. Moreover, cell-type specific characteristics, cross-talk of individual pathways downstream of RAS and the duration of signaling stimulation modulate the transcriptional program.

Identification of RAS Transformation Targets

Cellular ►transcriptomes comprise between 5,000 and 15,000 expressed genes at a time, depending on the state of growth, development and differentiation. The common approach for RAS target isolation takes advantage of reproducible mRNA expression differences between normal and RAS-transformed cells. Differentially expressed elements were initially identified on a single gene basis and later recovered by various differential cloning techniques and by interrogating ►microarrays. The experimental strategies for establishing catalogues of RAS-responsive genes vary significantly. Some authors have contrasted expression profiles representative for mRNA steady states related to the normal state and to RAS transformation. Others have used conditional

oncogene expression systems and followed the transcriptional alterations in a time-dependent fashion. RAS pathway targets were also identified in given tumor lines without matching normal precursors by contrasting the expression profile of inhibitor-treated cells and controls. In genome-wide screens for expression differences, a few percent of the total number of expressed transcripts were found to be affected by RAS pathways. Recent progress in ►proteome analysis at high resolution and sensitivity allowed to extend expression studies to the protein level as well.

A Selected List of RAS Transformation Targets

A recent review on the global effects of Ras pathway on transcription summarizes 17 studies based on cDNA subtraction and microarray analysis. For example, a proto-typic genome-wide study lists 393 genes differentially expressed in normal rat fibroblasts versus a RAS-transformed derivative. The targets include 168 up-regulated and 225 down-regulated genes. A meta-analysis comparing all available target gene catalogues is still missing, mainly because data were retrieved on different microarray platforms, under different experimental conditions and with different types of cells. The RAS targets included in Tables 1 and 2 have been chosen for reasons of independent validation and of their specific contribution to the process of tumorigenesis. Thus, the list is highly selective rather than comprehensive. An important cautionary note is that many target genes identified in model systems have not been thoroughly analyzed in human cancers, hence, their general importance is far from being clear. The finding of differential expression in transformed cells as compared to normal cells does not prove a causal role in the transformation process. Verification experiments based on forced expression or gene silencing are required. For example, the functional role of ►matrix metalloproteinase genes was verified by determining their effects on the invasive properties of cancer cells using cell biological assays. Functional studies of differentially expressed genes retrieved in genome-wide expression surveys will be complemented by currently available genetic screens based on ►siRNA libraries.

Clinical Relevance

Permanent activation of the RAS signaling cascade due to mutation in RAS genes or caused by overexpression of cell-surface receptors is a general feature of tumorigenic cells and determines a bad prognosis of many tumors. The malignant properties of cancer cells are executed by an unknown number of RAS pathway-induced genes, some of which are common

RAS Transformation Targets. Table 1 Genes up-regulated by RAS-mediated signaling

Gene product	Gene name	Functional role of gene product
Ornithine decarboxylase	*ODC1*	Polyamine biosynthesis, essential for proliferation
Glucose transporter	*GLUT*	Glucose metabolism, energy supply
v-Jun avian sarcoma virus 17 oncogene homolog	*JUN*	Transcription factor, component of AP-1 transcriptional activator complex, gene regulation
►Cyclin D1	*CCND1*	►Cell cycle stimulation
►Transforming growth factor-β	*TGFB1*	Autocrine growth stimulation
►Matrix metalloprotease 3 (Stromelysin 1)	*MMP3*	Metalloproteases, stimulate invasive properties
Matrix metalloprotease 1 (collagenase)	*MMP1*	
Urokinase-type ►plasminogen activator	*PLAU*	Controls synthesis of the serine protease plasmin, degradation of ►extracellular matrix
►Cyclooxygenase-2	*COX2/ PTGS2*	Prostaglandin synthesis, necessary for cell survival
►Vascular endothelial growth factor	*VEGF*	Stimulates angiogenesis
Integral cell membrane glycoprotein ►CD44	*CD44*	Induces metastasis
Ras homolog gene family member C (►RhoC)	*RHOC*	Small GTPase, induces metastasis
Dual-specificity phosphatases 5 and 6	*DUSP5/ DUSP6*	Dual specificity phosphatases, involved in feedback regulation of MAPK signaling
►Heparin-binding EGF-like growth factor	*HBEGF*	Autocrine growth stimulation

RAS Transformation Targets. Table 2 Genes down-regulated by RAS-mediated signaling

Gene product	Gene name	Properties
Myoblas differentiation factor 1	*MYOD1*	Stimulates myoblast differentiation, commitment to form myotubes
►Fibronectin (large external transformation-sensitive protein)	*FN1*	Structural component of extracellular matrix
Smooth muscle α-actin	*ACTA2*	Structural component of cytoskeleton
Type I collagen α	*COL1A1*	Structural component of cytoskeleton, cytoskeletal tumor suppressor
Lysyl oxidase	*LOX*	Extra-cellular enzyme, stabilizes extra-cellular matrix, regulates NF-κB signaling
►Thrombospondin 1	*THBS1*	Inhibits angiogenesis
Growth-arrest specific protein 1	*GAS1*	Growth inhibitor
►Tissue inhibitor of metalloproteinase 2	*TIMP2*	Inhibits metalloproteases and invasive properties
Fas antigen (CD95)	*APO1/APT1/ TNFRSF6*	Inducer of ►apoptosis
►E-cadherin	*CDH1*	Cell-cell adhesion, suppresses invasion and epithelial to mesenchymal transition
►TGF-β receptor type II	*TGFBR2*	Mediates growth inhibition by TGF-β
►Connexin 43 (►Gap junction protein α-1)	*CX43/GJA1*	Controls gap junctional communication
►Wilms tumor 1	*WT1*	Wilms tumor suppressor, suppresses Ras-induced transformation
Cystein-rich acidic secreted protein 1 (Osteonectin)	*SPARC/ON*	Extracellular protein, tumor suppressor
Suppressor of tumorigenicity 5 (Hela tumor suppression 1)	*ST5/HTS1*	Suppressor of neoplastic transformation, inhibits stimulation of MAPK/ERK2 by EGF
Follistatin-related protein (Follistatin-like 1)	*FSTL1/FRP*	Activin-binding protein regulated by TGF-β, causes growth arrest and inhibits invasion in cancer cell lines
H-Ras revertant protein 107	*HRSL3/H-REV107-1*	Interferon-γ inducible protein, binds to protein phosphatase 2A, induces apoptosis

pathway targets, while others differ among various types of cancers. Thus, genome-wide identification of target genes executing the diverse repertoire of biological activities of RAS-expressing tumor cells will increase our knowledge about the systems biology of cancer cells as well as aid in defining novel tumor markers and therapeutic targets.

Reactive Oxygen Species

Gang Wang
Department of Neurology and Neuroscience, Weill Medical College of Cornell University, New York, NY, USA

Synonyms
Free radicals; *ROS*

Definition
Reactive oxygen species (ROS) are small molecule metabilites of oxygen that tend to participate in redox reactions because of their high reactivity. Redox reactions are divided into two chemical processes: oxidation and reduction. Oxidation is a chemical process to gain oxygen and lose hydrogen or electrons, whereas reduction is a chemical process to lose oxygen and gain hydrogen or electrons.

Characteristics
ROS are composed of free radicals and non-radicals, both inorganic and organic. Free radicals are a cluster of atoms that contain an unpaired electron in the outermost shell of electrons and are an extremely unstable configuration so that free radicals quickly react with other molecules or radicals to achieve the stable configuration of four pairs of electrons in their outermost shell (one pair for hydrogen). Typical free radicals include superoxide anion ($O_2^{\bullet -}$), hydroxyl ($HO^{\bullet}$), nitric oxide radical ($NO^{\bullet}$), alkoxyl ($RO^{\bullet}$) and peroxyl ($RO_2^{\bullet}$). Non-radicals do not contain an unpaired electron but are prone to exchanging electrons with other molecules. Typical non-radicals include hydrogen peroxide (H_2O_2), singlet oxygen ($^1O_2$), ozone (O_3), hypochlorous acid (HOCl), peroxynitrite ($ONOO^-$) and lipid peroxides (LOOH).

Chemistry of Major *ROS*

1. $O_2^{\bullet-}$, a weak oxidant radical, is considered the "primary" *ROS*. $O_2^{\bullet-}$ is produced deleteriously by electron transfers in the mitochondrial electron transfer chain. Other enzymes capable of producing superoxide are the xanthine oxidase, NADPH oxidase and ►cytochrome P450. The life of $O_2^{\bullet-}$ is only milliseconds.
2. H_2O_2 is a more potent without an unpaired electron and has a longer life (minutes) than O_2^-. H_2O_2 is produced from $O_2^{\bullet-}$ by superoxide dismutase (SOD). H_2O_2 is also produced by a wide variety of enzymes including monoxygenases and oxidases. The properties of H_2O_2 include (i) being metabolized by catalase or glutathione peroxidase to H_2O; (ii) being permeable through the plasma membrane to extracellular sides; (iii) reacting with the reduced transition metals (i.e., Fe^{3+}) to become the highly toxic hydroxyl radical (HO^-) or a metal-peroxide complex (Me-OH) (*i.e.,* Fenny reaction).
3. Hypochlorite (HOCl) and hypobromite (HOBr) are produced in lysosome. Through complex redox reactions catalyzed by myeloperoxidase (MPO) in the presence of chloride (Cl^-) or bromide ion, HOCl or HOBr is generated by degrading H_2O_2 to O_2 and H_2O. These ions play an important role in carcinogenesis and allergic reactions.
4. Peroxynitrite anion ($ONOO^-$), a short-lived but highly oxidizing *free radical*, is a product of reaction between $O_2^{\bullet-}$ and nitric oxide (NO) and plays a role in nitrosylation of proteins.

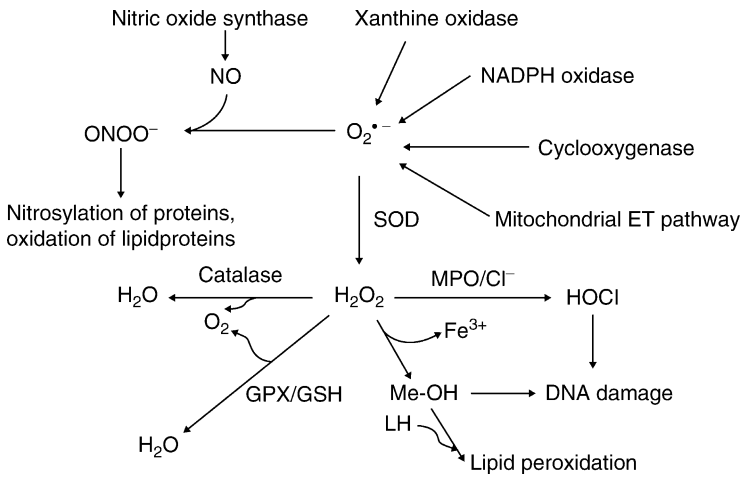
Generation and *Scavenger* of ROS

1. Endogenous generation. Mitochondria produce a large amount of $O_2^{\bullet-}$ and H_2O_2. The source of mitochondrial *ROS* appears to involve a non-heme iron protein that transfers electrons to oxygen. This occurs primarily at complex I and, to a lesser extent, following the auto-oxidation of coenzyme Q, at complex II or III. $O_2^{\bullet-}$ is produced deleteriously by 1-electron transfers in the mitochondrial electron transfer chain. In addition, the NADPH oxidase serves as another major source of ROS and generates superoxide *via* one electron transfer from NADH or NADPH to oxygen. It is comprised of membrane-bound subunits, $gp91^{phox}$ and $p22^{phox}$, and cytoplasmic subunits, $p47^{phox}$, $p40^{phox}$, $p67^{phox}$, and GTPase Rac1 or Rac2. The catalytic subunit $gp91^{phox}$, also termed Nox2, has several homologues, Nox1, Nox3 through 5, the location of which is cell-type specific. The NADPH oxidase generates ROS in a regulated manner, producing $O_2^{\bullet-}$ in response to growth factors, transduction signaling and cytokines. Moreover, the xanthine oxidase is a cytoplasmic oxidase that produces $O_2^{\bullet-}$ and H_2O_2 when converting hypoxanthine and xanthine into uric acid. This reaction may serve as an important source of ROS in a variety of pathophysiological states, including hypoxia, hypertension, atherosclerosis and heart failure. Other sources of *ROS* may include cyclooxygenases and cytochrome P450 metabolism; peroxisomes also contribute to a certain amount of ROS generation.
2. Exogenous insults. Enviromental insults leading to oxidative stress include radiation, ozone, herbicides, ►xenobiotics (i.e., ►polycyclic aromatic hydrocarbons and ►phorbol esters) and ferritin, all of which are capable of inducing steady-state increases in *ROS* production.
3. Anti-oxidant systems. Cells are normally able to defend themselves against *ROS* damage through their scavenger systems: (i) enzymes such as ►superoxide dismutase (SOD), catalases and ►glutathione peroxidase (GPX) with glutathione (GSH); (ii) transition metal chelators; (iii) polyphenol antioxidants such as small molecules tocopherol (►Vitamin E); (iv) ascorbic acid (►vitamin C), uric acid, and glutathione also play significant roles as cellular antioxidants. The most important plasma (extracellular) antioxidant in humans is probably uric acid. Clinically, there is a significant difference between cancer incidence and controls in the GSH-related enzyme function and the ratio of the reduced form of glutathione (GSH) over the oxidized form of glutathione (glutathione disulfide, GSSH).

Oxidative Stress

ROS form as a natural byproduct of the normal metabolism of oxygen and have important roles in the normal cellular signaling, which includes delivery of electrons across membranes, heme oxidation, oxidative modification of proteins and DNA. Another important beneficial effect of ROS is the physiological role in the defense against infectious pathogens. However, under environmental stress or certain pathological conditions such as hypoxia, intracellular ROS levels can increase dramatically, leading to the formation of ►oxidative stress. Oxidative stress exerts significant harmful effects on cell structures by inducing structural changes in lipids, membranes, proteins or nucleic acids. Oxidative stress also induces significant changes in signal transductions (Fig. 1).

1. Oxidative nuclear and mitochondrial ►DNA damage. The hydroxyl radical is known to react with all components of the DNA molecules in nucleus and mitochondria, damaging both the purine and pyrimidine bases. The hydroxyl radical inserts to DNA double bonds of DNA bases as well as the deoxyribose backbone. Permanent modification of genetic material resulting from these "oxidative damage"



Reactive Oxygen Species. Figure 1 Metabolism of reactive oxygen species. $O_2^{\bullet -}$, is considered the "primary" reactive oxygen species and mainly generated by mitochondria, NADPH oxidase, cyclooxygenase and xanthine oxidase. On the one hand, $O_2^{\bullet -}$ can rapidly react with NO to form highly reactive $ONOO^-$ that can modify protein targets. On the other hand, $O_2^{\bullet -}$ is dismutated by SOD to H_2O_2, which has three major fates: (i) H_2O_2 is most efficiently scavenged by catalase, as well as glutathione peroxidase (GPX), into H_2O; (ii) H_2O_2 is broken down by some transition metals to reactive hydroxyl radical (Fenton reaction), which plays an important role in DNA damage or lipid peroxidation; (iii) H_2O_2 is degraded by myeloperoxidase (MPO) to O_2 and H_2O, generating HOCl in the presence of chloride (Cl^-).

incidents represent the first step in mutagenesis, carcinogenesis and ageing. DNA damage may result in the arrest of transcription, replication errors and genomic instability, all of which are linked with carcinogenesis.

2. The hydroxyl radical is able to initiate ►lipid peroxidation. The metal-induced generation of oxygen radicals also results in the attack of the bilayer membrane lipid components, including polyunsaturated fatty acid residues of phospholipids. Hydroxyl radicals are generated *via* Fenton chemistry, to initiate lipid peroxidation. As a consequence, lipid peroxidation leads to structural changes in the membrane, formation of adducts or crosslinks with non-lipids and disruptions of membrane-dependent signaling. This deleterious process of the peroxidation of lipids is apparent in cancer, inflammation and arteriosclerosis.
3. Protein modification. Peroxynitrite anion ($ONOO^-$) is able to nitrosate the cysteine sulphydryl groups of proteins, to nitrate tyrosine and trytophan residues of proteins and to oxidise methionine residues to methionine sulphoxide. As a consequence, these protein thiol oxidations result in the oxidation of the catalytic sites of proteins, formation of sulfide bonds and increased susceptibility to proteolysis.
4. Signal transduction. Oxidative stress plays an important role in the regulation of cell growth because the cell cycle is regulated by intracellular concentrations of GSH. *ROS* can activate the cell growth transcription factors including MAP-kinase/AP-1, NF-κB and p53 pathways that have a direct effect on cell proliferation and apoptosis. *ROS* also regulates protein kinase or tyrosine kinase activities.

Clinical Aspects

1. Oxidative burst is characterised by massive production of ROS during bacterial infections and plays a key role in the defense against invading pathogens. Phagocytosis of micro-organisms is the major impetus for activation of the $gp91^{phox}$-containing NADPH oxidase in neutrophils and macrophages, leading to the production of a large amount of $O_2^{\bullet -}$ and its secondary metabolites. ►Chronic granulomatous disease, a rare genetic disorder, is caused by defects in $gp91^{phox}$, $p22^{phox}$, $p47^{phox}$ and $p67^{phox}$ and results in inactive NADPH oxidase and recurrent infections.
2. Oxidative DNA lesions and cancers. When ROS are overproduced or expression of antioxidants is altered, an imbalance between pro-oxidants and anti-oxidants prevails in cancer cells. As a consequence, *ROS* induce the formation of 8-oxo-7, 8-dihydro-2′-deoxyguanosine (8-oxo-dG), which is the best example of the oxidative stress-induced damage to nucleobases and sugar moieties of DNA and RNA. This damage can cause single- or double-strand breaks, to point and frameshift mutations and to chromosome abnormalities, which may be linked to initiation of cancer. This lesion is clinically important because it is a potential biomarker of carcinogenesis. In addition, the reaction of HOCl with various nucleosides yields chlorinated

nucleosides, including 8-chloro-2′deoxyqunosine, 8-chloro-2′deoxyadenosine and 5-chloro-2′-deoxy-cytidine. DNA oxidation also triggers DNA repair, imbalancing DNA repair enzymes or inducing error prone polymerases.

3. ROS-regulated signal transduction and cancers. Furthermore, oxidative stress can promote cancer cell growth and/or metastasis by activating the growth factor or protein kinase pathway where the transcription factors mitogen-activated protein (MAP)-kinase; activation protein 1 (AP-1), NF-κB and p53 are involved. As a signaling messenger, ROS are able to oxidize the critical target molecules such as protein tyrosine phosphatases (PTPs) and serine/threonine kinases such as protein kinase C (PKC). Inactivation of multiple PTPs by *ROS* may relieve the tyrosine phosphorylation-dependent signaling, triggering directly non-receptor protein kinases and eventually initiating MAP-kinase, NF-κB and p21-activated kinase-1 (PAK) pathways. PAK is an effector of Rac-mediated cytoskeletal remodeling that is responsible for cell migration and angiogenesis. All these ROS-regulated signal transductions are major pathways for driving tumor cell growth and metastasis. In addition, ROS also activate serine/threonine PKC, a member of the tumor growth factor-β (TGF-β) superfamily. MAP-kinase and AP-1 can be activated by PKC and TGF-β1, respectively, in a *ROS* dependent manner, resulting in cancer proliferation and metastasis.
4. ROS and other clinical diseases. Oxidative stress plays a role in pathogenesis of many other human disorders. The ROS-induced oxidative stress plays an important role in various cardiovascular diseases such as atherosclerosis, hypertension, ischemic heart attack, stroke, and congestive heart failure. The major sources of oxidative stress for these diseases include NADPH oxidase, xanthine oxidase and nitric oxide synthase.The ROS-induced oxidative stress in cardiac and vascular cells has been linked with cardiovascular tissue injury. In addition, the pathogenesis of rheumatoid arthritis is associated with the free radical formation at the site of inflammation. Moreover, diabetes is characterized by glucose-induced ROS production. mainly from mitochondria and NADPH oxidase.

The brain is particularly sensitive to *ROS* because of its high oxygen utilization. It has been established that the pathogenesis of several neurodegenerative diseases, such as Alzheimer disease (AD) and Parkinson disease (PD), and ageing, is linked with ROS accumulation. The brain of AD patients is charactrized with a marked accumulation of amyloid-β peptide (Aβ). Aβ and amyloid precursor protein have strong Cu-reductase activity, generating Cu^{+} from Cu^{2+}. This electron transfer process leads to the production of H_2O_2. In the PD brain, one of the earliest detectable changes is a dramatic decrease in GSH in dopaminergic neurons in substantia nigra, resulting in mitochondrial complex I inhibition.

Reactive Species Overload Diseases

Definition

Diseases associated with chronically high levels of reactive oxygen and nitrogen species in specific tissues or the whole body.

►Reactive Oxygen Species

Reactive Stroma

Definition

Describes the altered state of ►stromal cells near tumors.

►Aging

Real-Time PCR

Definition

PCR that follows the general pattern of a polymerase chain reaction, but the DNA is quantified after each round of amplification. It is used to simultaneously

quantify and amplify a specific part of a given DNA/cDNA molecule. It determines whether a specific sequence is present in the sample and the number of copies in the sample.

►Circulating Nucleic Acids
►Leukemia Diagnostics

RecA

Definition

RecA protein is central to homologous recombination in bacteria. It forms a DNA-protein filament utilizing the energy of ATP to catalyze homologous pairing of DNA molecules and strand exchange. It is the product of the recA locus of *E. coli*; a protein with dual activities, activating proteases and also able to exchange single strands of DNA molecules. The protease-activating activity controls the SOS response, and the nucleic acid handling activity is involved in recombination-repair pathways.

►Homologous Recombination Repair

RecA/Rad51-like Proteins

Definition

Share homology to the ►RecA (bacteria) and ►Rad51 (eukaryotes) proteins. They are involved in the repair of DNA damage by homologous recombination. In humans they include the Xrcc2, Xrcc3, Rad51L1, Rad51L2 and Rad51L3 proteins.

►Homologous Recombination Repair

Recall Bias

Definition

Systematic bias in a study, which can occur when participants are asked to report something (e.g. exposure to an agent or behavioral factors) after they already have been diagnosed with the disease under study

►Stress

Receptor

Definition

A protein that binds to a specific molecule (►ligand), such as a neurotransmitter, hormone, or other substance, and initiates the cellular response to the ligand.

►Kit/Stem Cell Factor Receptor in Oncogenesis
►Modular Transporters
►Receptor Cross-Talk
►Receptor Tyrosine kinases
►Nuclear Receptor
►Prostate-Specific Membrane Antigen (PSMA)

Receptor-Associated Coactivator 3

►Amplified in Breast Cancer 1

Receptor Clustering

Definition

Stimulation of many receptors results in a re-organization of activated receptor molecules and the aggregation within a defined area named receptor clustering.

Receptor Cross-Talk

Steven A. Rosenzweig
Department of Cell and Molecular Pharmacology and Experimental Therapeutics, Medical University of South Carolina, Charleston, SC, USA

Synonyms

Receptor interactions

Definition

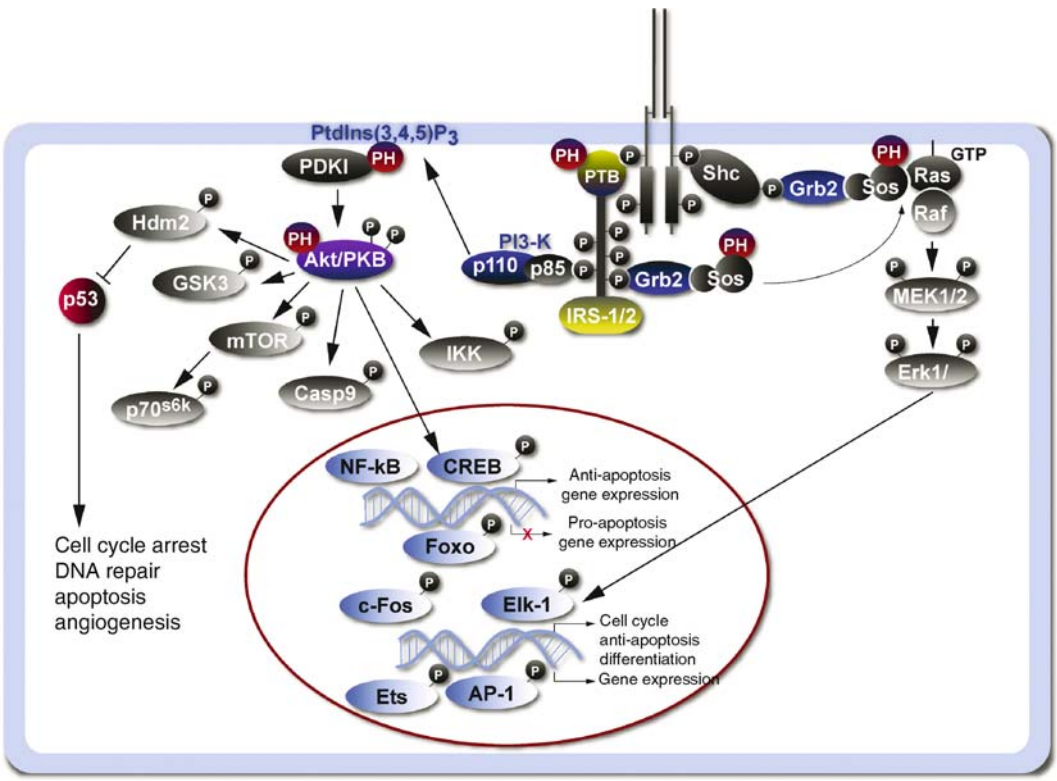
Refers to the ability of a given receptor, whether a cell surface ►receptor tyrosine kinase (►RTK), ►G-protein coupled receptor (GPCR) or ►nuclear receptor, to influence the signaling activity of a second receptor and/or its downstream cascade.

Characteristics

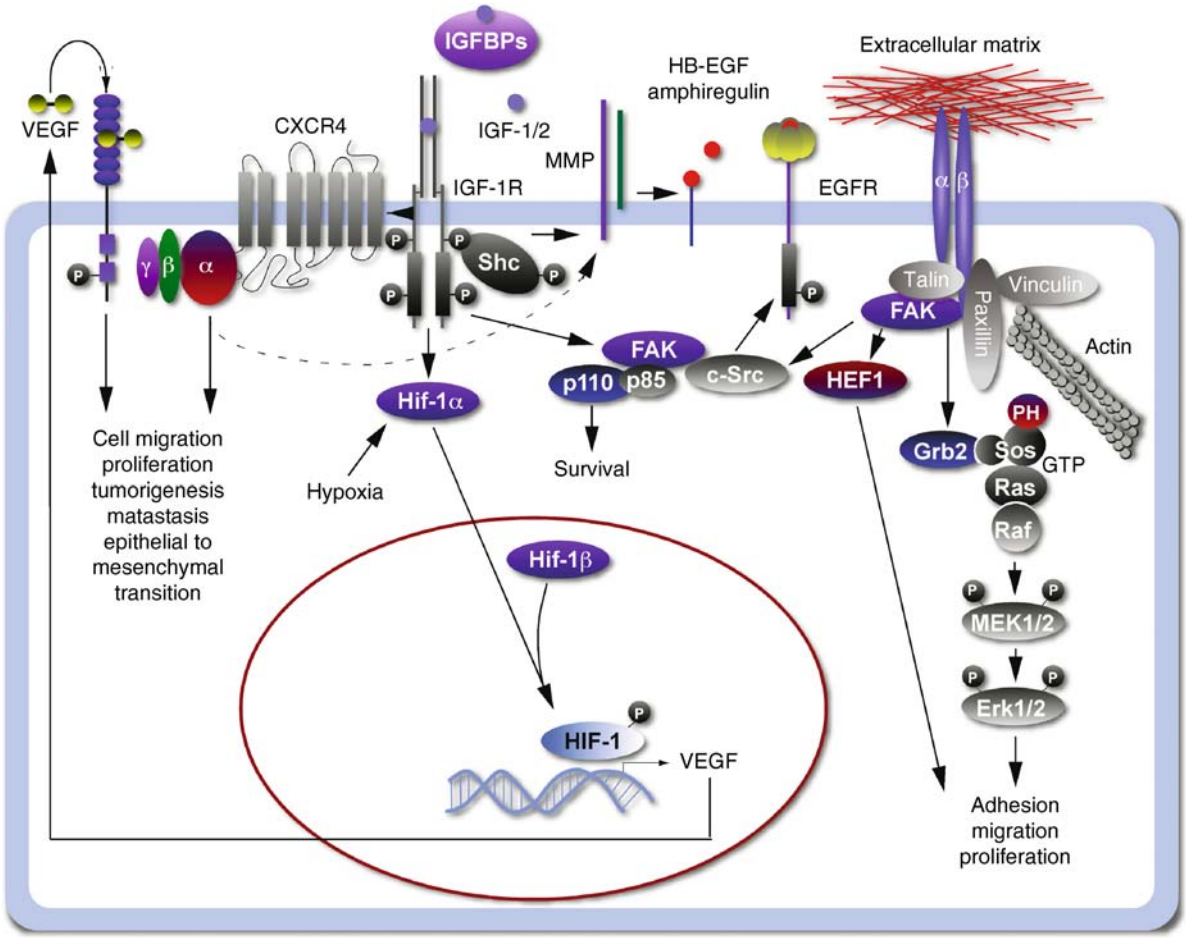
In its simplest terms, receptor cross-talk refers to the up- or down-regulation of receptors or their actions via the actions of heterologous receptors and their signaling intermediates. Over the years this has evolved to include a wide spectrum of receptor interactions both via direct protein:protein interactions and indirectly via interactions mediated by downstream effectors. Receptor cross-talk has been shown to influence cancer cell tumorigenicity, ►proliferation, ►metastasis, death and signaling to ►angiogenesis, particularly via growth factor receptor tyrosine kinases. Cell signaling pathways activated by the insulin-like growth factor 1 receptor (IGF-1R) (►Insulin-like Growth Factors) are shown in Fig. 1. The IGF-1R is an important regulator of cell survival and anti-apoptotic signaling (►Apoptosis; ►Apoptosis Signaling). Work over the last few years suggests that many actions of the IGF-1R are mediated via cross-talk to other RTKs (RTK) and G-protein-coupled receptors (GPCRs – ►G proteins) as illustrated in Fig. 2.

As shown in Fig. 2, IGF-1Rs can activate the epidermal growth factor receptor (EGFR/HER1/ErbB1 – ►HER2) by activating a cell surface proteinase (►ADAM Molecules; ►Matrix Metalloproteinases), that cleaves the membrane tethered ligand, heparin binding EGF (HB-EGF), enabling it to bind to the EGFR. This form of receptor cross-talk is an example of indirect activation, with the action of the first receptor (IGF-1R) stimulating the production of a ligand that acts in an autocrine manner to activate a second receptor (EGFR). A number of GPCRs indirectly activate the EGFR in this manner, either by proteinase release of membrane-bound ligand or by activating a Src family ►non-receptor tyrosine kinase (►SRC), which in turn phosphorylates the EGFR leading to its activation and downstream signaling.

The IGF-1R has been reported to activate the ►chemokine receptor CXCR4 by direct physical association, leading to enhanced migration of breast cancer cells (►Breast Cancer). The IGF-1R may also activate other GPCRs, such as the sphingosine-1-phosphate



Receptor Cross-Talk. Figure 1 Signaling by the IGF-1R. IGF-1 binding to the IGF-1R leads to receptor transphosphorylation and tyrosine phosphorylation of insulin receptor substrate-1 or 2 (IRS-1 or IRS-2) proteins. Phosphorylated IRS proteins serve as docking sites for SH2 domain containing effectors leading to their activation. As shown, following binding to phosphorylated IRS via its regulatory p85 subunit, the catalytic p110 subunit of PI3 kinase dissociates from the p85 subunit – IRS-1 complex. The p110 subunit generates inositol-3,4,5-phosphate at the plasma membrane, which serve as docking sites for pleckstrin homology (PH) domain containing proteins, such as Akt. Akt leaves the plasma membrane and phosphorylates a number of key cytoplasmic and nuclear effectors, leading to cell survival and anti-apoptotic signaling. IGF-1 can also activate the Erk family of mitogen activated protein kinases (MAPKs), to stimulate cell proliferation. IGF action is regulated by a number of transcription factors, some of which are shown.



Receptor Cross-Talk. Figure 2 Signal Cross-talk by the IGF-1R. In addition to directly activating the Erk leg of MAPKs, IGF-1R can also transactivate the EGFR as a result of ADAM proteinase activation. This releases membrane tethered HB-EGF from the cell surface, enabling it to bind EGFRs in an autocrine manner. In addition to indirect cross-talk, there is growing evidence that IGF-1Rs are capable of directly transactivating GPCRs such as CXCR4, to effect a chemokine receptor signaling in response to IGF-1 action. Cross-talk between integrins and growth factor receptor tyrosine kinases mediated by the non-receptor tyrosine kinase, FAK (focal adhesion kinase), that serves as a docking protein for SH2 domain containing effector proteins. In addition to autophosphorylation sites, FAK contains multiple tyrosine residues that are phosphorylated by Src. This underscores the bidirectional signaling paradigm occurring between integrins and RTKs that FAK performs.

receptor (►Lipid Mediators), a ►sphingolipid receptor that impacts cell proliferation and migration. In contrast, IGF-1R activation of the chemokine receptor CCR5, occurs indirectly as a result of IGF-1R induced synthesis and secretion of RANTES, the ligand for CCR5. A similar type of autocrine-based cross-talk occurs for prostaglandin E2 (►Prostaglandins) derived from the activation of COX-2. PGE2 acts at its cognate GPCRs, EP2 and EP4 receptors to increase cAMP levels and stimulate the expression of amphiregulin, an EGFR ligand. These events underscore the concept that IGF-1R signaling can synergize with GPCRs and other RTKs to modulate cell proliferation, tumorigenesis and metastasis.

In addition to IGF-1R cross-talk to the EGFR, EGFR activation can enhance IGF-1R signaling by modulating the expression of downstream mediators of IGF-1R action, including the ►insulin receptor substrate proteins (IRS). Similarly, estrogen and progesterone receptor signaling has also been shown to cross-talk to IGF-1R signaling by modulating IRS levels and MAPK sensitivity. Other nuclear receptors, such as peroxisome proliferator-activated receptors, may influence receptor, ligand or effector expression, resulting in defined receptor cross-talk actions.

Survival Signaling/p53 and Suppressor Cross-Talk

Growth factor RTK signaling leading to the activation of PI3 kinase (►PI3K Signaling) results in the formation of phosphatidyl-inositol-3,4,5 phosphate (►Inositol Lipids), a ►pleckstrin homology domain (PH domain) binding site in the inner leaflet of the plasma membrane.

Consequently, Akt (►Akt Signal Transduction Pathway in Oncogenesis) is recruited to the plasma membrane where its PH domain binds to PI3 enabling its phosphorylation and activation by phosphoinositide-dependent kinase 1 (PDK1). Activated Akt leaves the plasma membrane to effect anti-apoptotic signaling by phosphorylating key downstream effectors such as caspase 9, Bad and Mdm2. ►Mdm2 in turn destabilizes ►p53 by ►ubiquitination targeting it for ►proteasome degradation. In contrast, signaling activity that increases p53 activity results in cell cycle arrest, inhibition of angiogenesis and apoptosis. These actions are effected by a wide spectrum of p53 effectors, including IGFBP-3. Increased IGFBP-3 expression results in the sequestration of IGF-1 and IGF-2 leading to abrogation of IGF-1R action, further contributing to apoptotic signaling.

Signaling to Angiogenesis

A number of receptors have been shown to stimulate ►angiogenesis by regulating the production of ►vascular endothelial growth factor (VEGF), a key mediator of angiogenesis. VEGF mRNA expression and protein synthesis is tightly regulated by the ►hypoxia-inducible factor-1 (HIF-1) transcription factor, which is a heterodimeric complex comprised of Hif-1α and Hif-1β. Hif-1α is regulated by oxygen tension, with normoxia leading to Hif-1α ubiquitination and proteasomal degradation mediated by the von Hippel-Lindau ubiquitin ligase (►von Hippel-Lindau Tumor Suppressor Gene) and hypoxia stabilizing Hif-1α leading to VEGF synthesis and secretion. The IGF-1R, as well as other growth factor receptors can induce the expression of Hif-1α mRNA via Akt activation and elevate Hif-1α protein levels via $p70^{S6K}$/►mTOR activation, increasing VEGF expression. Secreted VEGF acts in an autocrine manner, to activate VEGFRs, leading to enhanced cell proliferation, cell survival or cell motility.

Integrin: Growth Factor Receptor Cross-Talk

Considerable cross-talk occurs between growth factor RTKs and ►integrins (►Cell Adhesion Molecules; ►Adhesion; ►Extracellular Matrix Remodeling). This area of signal cross-talk has significant implications in the context of cancer cell signaling as it relates to cell adhesion, cell migration and epithelial to mesenchymal transition and ►metastasis. Signals from ►extracellular matrix proteins are transduced to the cell interior as a result of integrin engagement, to influence cell adhesion, migration and proliferation. Integration of these signals with those from cell surface RTKs and GPCRs occurs at the level of the cytoplasmic non-receptor tyrosine kinase, ►FAK. FAK is localized to focal adhesions where in addition to signaling activities it fulfills an important role as a scaffolding protein. In addition to influencing cell survival and cell migration, FAK action also protects cells from suspension-induced cell death or ►anoikis. It is notable that elevated FAK activity has been linked to the progression of premalignant cells to malignant carcinoma, which coincides with an integrin switch exhibited by a number of cancer cell types. Taken together, these findings suggest a role for growth factor receptor:integrin cross-talk in this process. Altered integrin expression, particularly of β_1 species, can significantly influence IGF-1R signaling in cancer cells in which an apoptotic response is replaced by a proliferative phenotype.

Receptor Protein Tyrosine Phoshatase Beta/Zeta

Definition

RPTPβ/ζ; Is a member of a family of receptor-type transmembrane protein tyrosine phosphatases, known to exist in three ►splicing variants: a transmembrane

long, a truncated transmembrane short, and a secreted form termed phosphacan. It is predominantly expressed in the central nervous system as a chondroitin sulfate proteoglycan or in a non-proteoglycan form in some tissues, such as the stomach. Several different ligands can bind to the extracellular domain of RPTPβ/ζ, including the growth factors ►pleiotrophin and ►midkine, the ►extracellular matrix molecules ►tenascin-C and -R, the neuronal ►cell adhesion molecules contactin, Nr-CAM, neural cell adhesion molecule, L1/Ng-CAM, and TAG-1/axonin-1, as well as amphoterin and fibroblast growth factor-2.

Receptor for Stromal Cell-Derived Factor-1 alpha

►Chemokine Receptor CXCR4

Receptor for TNF-Related Apoptosis-Inducing Ligand

Definition

►TRAIL, is the ligand for the DR-4 and DR-5 receptor is a member of the tumor necrosis factor (►TNF) family of death signal tranduction proteins with a mechanism of cell death, similar to the Fas (►FAS/APO-1/CD95) and Fas ligand (Fas-L) system.

Growth factor receptors

Definition

RTKs, Are high affinity cell surface receptors for specific polypeptide ligands, which have an intrinsic tyrosine kinase activity: they can transfer a phosphate group from ATP to a tyrosine residue. In the human genome, 58 RTK genes have been identified. RTK are key components of signaling pathways, which control cell proliferation, survival, differentiation, and metabolism. Deregulation of RTKs by different mechanisms may contribute to neoplastic growth or developmental abnormalities.

Characteristics

Receptor tyrosine kinases show a common architecture comprising an extracellular portion that binds polypeptide ligands, a transmembrane helix, and a cytoplasmic portion that displays catalytic activity (Fig. 1). Docking sites for protein-protein interactions with cytoplasmic signaling molecules are also present. The majority of RTKs are formed by a single polypeptide chain in a monomeric conformation in the absence of a ligand. ►MET and its related receptors RON and SEA, after proteolytic processing of a single chain precursor, consist of a short extracellular α-chain that is disulfide-bonded to a membrane-spanning β-chain. Members of the insulin receptor subfamily are disulfide-linked dimers of two polypeptide chains, forming a α2β2 hetero-tetramer.

The extracytoplasmic portion, which binds specific ligands, shows considerable diversity among members of the family, usually containing a linear array of discrete folding modules such as immunoglobuline-like domains, cysteine-rich domains, fibronectin type III-like domains and EGF-like domains. The cytoplasmic portion of RTKs is more conserved. Next to the transmembrane portion is located the so-called juxtamembrane region, followed by the tyrosine kinase (TK) catalytic domain and finally by the C-terminal region.

Physiological RTKs Activation

Ligand-mediated activation of RTKs results in autophosphorylation of both the receptor catalytic TK domain and C-terminal non-catalytic region. The ligand can be provided by a cell different from those expressing the related RTK or by the same cell. The latter is defined as autocrine activation and the former as paracrine activation (Fig. 2). TK domain phosphorylation leads to activation and potentiation of receptor kinase activity. The non-catalytic regions phosphorylation creates docking sites for downstream cytoplasmic targets, which bind to receptor phosphotyrosine residues embedded in specific consensus sequences. Downstream signaling pathways are constructed in a modular fashion. In addition to ►SH2 and ►PTB (phosphotyrosine binding domains), downstream signal proteins also contain catalytic domains and/or domains that recognize other signaling molecules. The arrangement of various combinations of modular domains in

Receptor Tyrosine Kinases. Figure 2 Paracrine (*top*) and autocrine (*bottom*) RTK activation. The latter occurs following an inappropriate expression of a ligand for a constitutively expressed RTK.

different signaling proteins allows for the creation of complex signaling networks and pathways. These proteins, in addition to performing catalytic functions, serve as scaffolds for the assembly of multiprotein signaling complexes as adaptors, transcription factors, and pathway regulators. Understanding the physiological regulation of RTKs may help in identifying the mechanisms causing their oncogenic activation.

Deregulation of RTKs in Malignant Cells

Different mechanisms leading an RTK to a constitutively active form contributing to or driving neoplastic transformation have been identified: (i) over-expression, due to gene amplification or enhanced gene transcription, (ii) ►autocrine or ►paracrine stimulation (Fig 2); (iii) activating mutations including ►point mutation, ►deletion, insertion; (iv) ►chromosomal rearrangements resulting in the expression of ►fusion proteins containing the tyrosine kinase domain of RTK and dimerizing/activating sequences from an unrelated donor gene.

In the last two cases, RTKs undergo germ-line or somatic oncogenic transformation. The common mechanism of activation from the physiological to the neoplastic status implies structural changes that deregulate the receptor kinase activity, with the delivery of a continuous ligand-independent signal.

Gain of function mutations or deletions have been identified in many RTKs. Mutations that promote ligand-independent dimerization are a well-represented activation mechanism. The loss by point mutation of a single cysteine residue in the extracellular domain of Ret in ►MEN2A (multiple endocrine neoplasia type 2) syndrome, which includes medullary thyroid carcinomas and pheochromocytomas, results in receptor constitutive activation. This mutation most likely destroys an intramolecular disulfide bond that frees a cysteine residue that, through the formation of an intermolecular bond, enhances receptor dimerization and results in constitutive activation of the receptor catalytic activity. ►HER2/Neu, belonging to the EGFR family, can be activated by a single point mutation in the transmembrane domain. Different activating mutations of c-KIT are present in ►gastrointestinal stromal tumor (GIST) as well as in ►acute myeloid leukemia (AML), seminoma, germinoma and mast cell leukemia. In AML, seminomas, and germinomas, KIT mutations are mainly clustered in the exon 17 of the TK domain. In GIST, different mutations, occurring in justamembrane, extracellular or TK domains, comprising point mutations as well as short in frame insertions/deletions, are described. All these alterations cause receptor activation. Different RTKs as ►RET, ►TRKA, and PDGFR, are constitutively activated, following chromosomal rearrangements in different tumors. A classical example of RTK activation by chromosomal rearrangement driving neoplastic transformation is represented by RET and TRKA somatic rearrangements, that are alternatively present in about 30 and 5%, respectively, of papillary thyroid carcinoma (PTC) cases. A similar activation mechanism has been described for ►PDGF receptors in chronic myelomonocytic leukemia (CMML) through the production of the fused ►oncogene TEL/PDGFRB. The same receptor/ligand complex has been found constitutively activated in dermatofibrosarcoma protuberans (DFSP) by the activation of an autocrine loop due to the formation of a ►fusion gene COLA1α/PDGFβ that results in the constitutive production of a PDGFβ ligand product.

RTK may also become activated by gene amplification or over-expression. Over-expression leads to constitutive kinase activation by increasing the concentration of dimers. EGF receptor family members, such as EGFR and ERBB2 in breast, colorectal and non-small cell lung (►NSCLC) carcinomas, are frequently activated by these mechanisms.

The same receptor may be activated by different mechanisms in different pathologies. KIT for example is activated by over-expression and paracrine/autocrine mechanisms in SCLC, ►Ewing sarcoma, and ►synovial sarcoma and by mutations in GIST, AML, seminomas, and germinomas, as mentioned above. RET is activated by different germ-line point mutations in MEN2 cancer syndromes, MEN2A, MEN2B, and FMTC (familial medullary thyroid carcinoma), but by somatic rearrangement in PTC. PDGFR is activated by paracrine/autocrine loop, by mutations or by chromosomal rearrangement, in different neoplasias.

In Table 1 the main RTK alterations in malignant cells and the involved neoplasias are listed.

VEGF receptors also act in cancer development, even if not altered in malignant cells, because they are involved in tumor ►angiogenesis. This latter is implicated in the pathogenesis of malignancy and ►metastasis and its inhibition has clinically demonstrated improvements in outcomes in a variety of malignancies.

Clinical Relevance

- HER2/ERBB2 gene ►amplification represents an already validated negative prognostic marker for both mammary and ovary carcinomas. Moreover, a humanized anti p185-ERBB2 monoclonal antibody (►Trastuzumab), which has anti-proliferative effects, enhances the killing of human breast cancer cells, following treatment with different cytotoxic drugs.
- The detection of Ret germ-line mutations offers an invaluable diagnostic tool for the identification of asymptomatic individuals at high risk to develop a MEN2-associated neoplasia.
- Moreover, fusion oncogenic proteins derived from RET and TRKA rearrangements are distinctive diagnostic features of the papillary type of thyroid cancer. In general, this class of oncogenic products (►fusion proteins) are viewed as a potential tumor-specific target for therapeutic interventions.
- A variety of tyrosine kinase inhibitors have now been developed and much progress has been made toward

Recessive

Definition

Referring to an ►allele of a gene that is unable to dictate a phenotype in the presence of a second allele that acts in a ►dominant way. This is particularly true for many mutated alleles.

Referring to one of several alternative traits that can be specified by a genetic locus; when the locus is ►heterozygous and carries information specifying two distinct traits, the dominant trait will be exhibited by the organism and the recessive will not dictate phenotype in the presence of a second allele that acts dominantly. Very often, wildtype alleles are dominant over mutated alleles. In this case, the disease can only become manifest when the second normal allele also suffers inactivating damage.

RECK Glycoprotein

Wen-Chun Hung
Institute of Biomedical Sciences, National Sun Yat-Sen University, Kaohsiung, Taiwan, Republic of China

Synonyms

Matrix metalloproteinase inhibitor; Serine protease inhibitor-like domain; Regulator of extracellular matrix integrity; Suppressor of invasion, metastasis, and angiogenesis

Definition

RECK is named after its isolation, identification, and structural characteristics as a "reversion-inducing, cysteine-rich protein with Kazal motif" protein. RECK negatively regulates matrix ►metalloproteinases (MMPs) and plays an important role in the control of development, extracellular matrix remodeling, angiogenesis and metastasis.

Characteristics

The *RECK* gene was originally isolated from a cDNA clone whose expression induces flat morphology in *v-ki-*►*RAS*-transformed ►NIH/3T3 cells. The gene product is a 110-kDa glycoprotein, which anchors to the plasma membrane via glycosylphosphatidylinositol (GPI) modification. Several specific features are found in RECK protein. First, RECK is rich in cysteine and has a number of typical cysteine knot motifs at its N-terminal region. Second, RECK is glycosylated at asparagine (Asn) 86, 200, 297, and 352 residues. Functional study indicates that the glycosylation of Asn297 residue is involved in the suppression of MMP-9 secretion and Asn352 residue is necessary to inhibit MMP-2 activation. Third, RECK contains three serine protease inhibitor-like domains. The sequence of one of these domains matches well to the consensus sequence of Kazal motif, which is usually found in protease inhibitors.

RECK is a critical regulator for development. ►Knockout mice, show embryonic lethality in due to disruption of mesenchymal tissues and organogenesis. In addition, RECK is involved in the control of myotube formation. The myoblast differentiation factor MRF4 and myoblast determination factor MyoD have been shown to positively or negatively regulate the expression of RECK to modulate myogenesis. Moreover, RECK can regulate the proliferation of endothelial cells and participate in the control of angiogenesis.

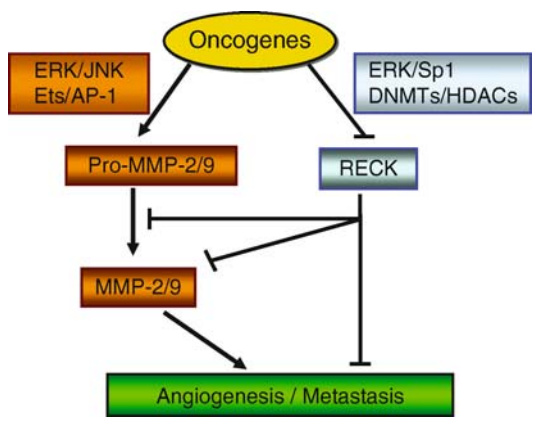
Regulation

RECK is widely expressed in most of human and mouse tissues. On the contrary, expression of RECK is significantly down-regulated or undetectable in many types of human tumor tissues and cancer cell lines. In addition, reduction of RECK is frequently associated with lymph node metastasis and poor prognosis. Cell-based studies indicate that down-regulation of RECK may be caused by oncogene activation. A number of oncogenes including ►Ras, ►Fos, ►Myc, ►HER-2/neu, and ►Src have been shown to repress RECK expression. In addition, viral oncoproteins such as ►Epstein–Barr virus latent membrane proteins may also suppress RECK to promote invasive ability of infected cells. Therefore, RECK is a common and critical target for oncogenic signaling.

The molecular mechanism by which oncogenes repress RECK has been clarified recently. The repression occurs at transcriptional level and is mainly mediated by epigenetic inactivation. For example, RAS oncogene may induce recruitment of histone deacetylases (HDACs) to RECK gene promoter, which causes deacetylation of histones and reduction of promoter activity. In addition, activation of RAS up-regulates the expression of DNA methyltransferase (DNMTs) and increases the binding of DNMTs to RECK gene promoter. This causes ►hypermethylation of ►CpG islands at the RECK promoter and results in silencing of transcription (Fig. 1).

Clinical Relevance

Down-regulation of RECK expression has been reported in lung, breast, glioma, pancreatic, prostate, colorectal, and gastric cancer. In addition, RECK reduction is usually associated with increased lymph node metastasis and poor prognosis. These results suggest that RECK is a typical tumor and metastasis suppressor gene. Indeed, ectoexpression of RECK potently suppresses the invasive ability of cultured cancer cells and inhibits tumor formation in ►nude mice. Reduction of tumor formation is caused by suppression of angiogenic sprouting, which leads to inhibition of tumor growth and invasion.



RECK Glycoprotein. Figure 1 Oncogene-induced gene silencing of RECK and promotion of tumor metastasis.

Because down-regulation of RECK is frequently caused by ►epigenetic inactivation, drugs which can restore RECK expression via reversion of DNA hypermethylation and ►histone deacetylation may effectively suppress cell invasion and tumor metastasis. Indeed, DNMT inhibitor 5-azacytidine and ►HDAC inhibitor ►trichostatin A have been shown to up-regulate RECK expression in cancer cells and effectively suppress tumor formation. Results from in vitro study and clinical investigations suggest that RECK is a rational target for the treatment and/or prevention of tumorigenesis.

Recombinant Therapeutics

Huub Schellekens
Department of Innovation Studies, Department of Pharmaceutical Sciences, Utrecht University, TD Utrecht, The Netherlands

Synonyms

r-DNA derived therapeutic proteins; Biotechnology derived therapeutic proteins

Definition

Recombinant therapeutics are therapeutic proteins produced by recombinant DNA technology

Characteristics

Proteins are used already for more than a century in the treatment of disease. The first generation were proteins derived from animals such as antisera used to treat infectious diseases as diphtheria and tetanus and later bovine and porcine insulin for the treatment of diabetes. The second generation were natural proteins from human source like the plasma derived clotting factors and human growth hormone. The development of the recombinant DNA and cell fusion technology in the seventies of the twentieth century opened up the possibilities to produce human proteins and ►monoclonal antibodies in unlimited amount in microbial and mammalian host cells. In 1982 human insulin was introduced as the first recombinant DNA derived biopharmaceutical and since than more than 160 have gained approval. The pipeline contains many more potential biopharmaceuticals and at present 1 in 4 new drug applications concerns a biotechnology derived product. Many of these products are being used for treatment of cancer either as supportive therapy, like ►epoetins and ►G-CSF, as general immune modulators like interleukine-2 and ►interferon alpha 2 or specific therapy in the form of an increasing number of monoclonal antibodies.

The first generation of biopharmaceuticals were produced by recombinant DNA technology and were intended to be exact copies of naturally occurring regulatory proteins. These supposed physiological proteins showed sometimes severe side effects. ►Tumor necrosis factor (TNF) and some of the interleukins proved very toxic and in some cases even fatal and never reached the market.

Other products like ►interferon were marketed, but for severe conditions with the side effects as dose limiting factors. The most common explanation offered for this type of toxicity is an exaggerated biological activity by non-physiological levels at unnatural sites.

Because many of these proteins act as ►paracrine or ►autocrine factors their ►pharmacokinetic properties are unfavorable for systemic treatment. Protein modification was introduced such as hyperglycosylation (e.g. Darbepoetin alfa, Aranesp®) and ►pegylation (e.g. Peginterferon alpha 2a, Pegasys®) which extend half-life. Also hybrid molecules were developed such as etanercept (Enbrel®), where the soluble receptor of TNF is combined with the Fc-part of IgG to reduce the clearance from the circulation which occurs after injection of the unmodified receptor.

Another major problem of therapeutic proteins appeared to be the induction of antibodies. For foreign proteins such as the murine derived monoclonal antibodies this immunogenicity was to be expected. However the humanization of monoclonal antibodies has reduced but not solved the problem of immunogenicity. And also the proteins which are homologues of endogenous factors such as GM-CSF, interferons etc. induce antibodies, sometimes even in the majority of patients.

By definition we are immune tolerant to products which are copies of endogenous proteins. The products not necessarily need to be exact copies of the natural proteins to share this immune tolerance. When human therapeutic proteins induce antibodies, they are breaking B-cell tolerance, which starts with the activation of autoreactive B-cells. Presenting the self-epitopes in an array form is very potent activator of these B-cells. This explains why aggregates of human proteins are the most important factor in induction of antibodies.

These aggregates may not be immediately present in the product, but may appear during storage making stability and formulation an important issue in predicting the immunogenicity. There are only a few studies in experimental model systems on the properties of the aggregates which break B-cell tolerance, indicating that only multiple order aggregates (>trimers) are involved. The only biological test to study the capacity of a protein product to break B-cell tolerance are mice made transgenic for the specific protein. These mice are immune tolerant and there is a good correlation of an immune response in these mice and in patients. Although these models have helped to identify the factors important for breaking B-cell tolerance and also have been useful in improving the formulation of products, there is not yet enough experience to use them as absolute predictors of immunogenicity of human proteins.

The clinical consequences of immunogenicity may be severe. The most common consequence is loss of efficacy. Sometimes this loss can be overcome by increasing the dose or change the product. However in some cases the antibodies compromise the treatment with a complete class of products. The association between antibodies and inhibition of efficacy has mainly been established at population level. Only with some products can a defined level of antibodies be translated in the treatment strategy of individual patients.

In some cases the unpredictable disease progression, the lack of good efficacy markers and the extended effect after treatment has stopped, also complicate the evaluation of the clinical effects of immunogenicity.

Because of the lack of adequately designed studies and standardized assays for many products the consequences of their immunogenicity is unclear. Some manufacturers and clinicians interpret this lack of reliable data as a lack of consequences. However, it is difficult to explain how high levels of neutralizing antibodies in the circulation could exist without any consequence.

The most dramatic consequence of these antibodies is the neutralization of the native protein with the subsequent loss of its important biological function. This has been observed in patients treated with a specific formulation of epoetin alfa in countries other than the USA. This epoetin induced antibodies in a number of patients which neutralized endogenous erythropoietin leading to the development of pure red cell aplasia (PRCA). In 1998, the formulation of epoetin alfa outside the USA was modified, which most likely led to a decrease in the protein stability, the tendency to form aggregates and thereby to an increased immunogenicity. Additional potential factors have been suggested, such as inappropriate handling of the product, polysorbate 80-epoetin interaction and leachates from uncoated rubber stoppers of the prefilled syringes with an adjuvant effect.

Now the first patents of the first wave of recombinant DNA derived pharmaceuticals have expired or will expire shortly, we are entering the new era of biopharmaceuticals, which includes both improved second generation products as well as the introduction of copy products the so-called biosimilars or follow up biologicals.

In the case of classical drugs, expiration of patents opens the possibility of the introduction of generic products. Limited documentation showing chemical similarity and bioequivalence in a small volunteer study is in general sufficient to obtain marketing authorization. However the concept of generics developed for small therapeutic molecules cannot be extrapolated to the majority of biopharmaceuticals which are large proteins. The technology is lacking to establish whether the structure of two biopharmaceuticals is completely identical. Moreover, the properties of biotechnology products are highly dependent on the production process and their biological behavior remains partly unpredictable. Therefore the European Medicine Evaluation Agency (EMEA) based on EU-legislation expects producers of biosimilars to submit comparative clinical data in addition of full documentation of quality and safety.

The Food and Drug Administration (FDA) which regulates drugs in the USA prefers the term follow up biologicals for these products, but still needs to issue their guidelines.

Recombinase Activating Gene-2

Definition

Rag-1 and *rag-2* encode lymphocyte-specific recombinases that are required to generate B cell (BC) and T cell receptors (TCRs). BCRs and TCRs are constructed from recombined genetic elements V, D and J. These genes are flanked by Recombination Signal Sequences (RSSs) on the 3' side (downstream) of a V region and the 5' side (upstream) of the J region. These are the sides that will be involved in the joining. RAG1 and RAG2 associate with each other to recognize the RSS sequences and induce DNA cleavage at these sites. Following the activity of RAG1 and RAG2, DNA repair enzymes facilitate the joining of the segments. In this way B cells and T cells can use limited numbers of V, D and J genes to generate widely diverse receptor specificities.

Reduced Intensity Conditioning (RIC) Allogeneic Stem-Cell Transplantation

Definition

As compared with standard allogeneic transplantation where tumor cell eradication by high-dose ►radiochemotherapy, RIC-allogeneic transplantation is ►immunotherapy, where the donor stem cell are infused following milder, ►non-myeloablative radiochemotherapy of the recipient with immunosuppressive aim. Subsequently, in weeks-months, the donor-derived stem cells will proliferate and often completely replace (full chimerism) the recipient bone marrow. When full chimerism is achieved, the graft-versus-tumor effect may occur, which eventually may cure (or exert long-term control) the malignancy. RIC-allografting is associated with fewer side-effects and less treatment-related mortality, and allows allogeneic transplantation in patients of somewhat older age than possible with standard myeloablative conditioning.

►Mantle Cell Lymphoma

Reduced Penetrance

Definition

Variable or absent phenotypic effect of a gene known to cause a developmental abnormality or cancer.

►Rhabdoid tumor

Reductases

Edmund Maser
Institute of Toxicology and Pharmacology for Natural Scientists, University Medical School, Kiel, Germany

Synonyms

Carbonyl reductases; Aldo-keto reductases; Hydroxysteroid dehydrogenases

Definition

Carbonyl reduction of aldehydes, ketones and quinones to their corresponding hydroxy derivatives plays an important role in the phase-I metabolism of many

endogenous (biogenic aldehydes, steroids, prostaglandins, reactive lipid peroxidation products) and xenobiotic (pharmacologic drugs, carcinogens, toxicants) compounds (►Xenobiotics).

Characteristics

From the pharmacologist's point of view, carbonyl reduction is of significance in various inactivation processes of drugs bearing a carbonyl group. The carbinols formed may retain therapeutic potency, thus prolonging the pharmacodynamic effect of the parent drug, or, in some instances, a compound gains activity through carbonyl reduction. From the toxicologist's point of view, carbonyl reduction plays an important role in the toxification of drugs such as daunorubicin and doxorubicin (►Adriamycin), whereas numerous reports corroborate the concept of carbonyl-reducing enzymes being involved in ►detoxification processes of endogenous and ►xenobiotic reactive carbonyl compounds.

Carbonyl Reduction by SDRs and AKRs

Carbonyl-reducing enzymes (►carbonyl reductase) are grouped into two large protein superfamilies, the aldo-keto reductases (AKR) and the short-chain dehydrogenases/reductases (SDR).

AKRs are monomeric $(\alpha/\beta)_8$-barrel proteins of about 320 amino acids in length. Their active site consists of a conserved tetrad of the amino acids Y-H-D-K and the hydride transfer from NADPH occurs through an acid/base catalyzed mechanism. A nomenclature system for the AKR superfamily has recently been established and is available on the AKR superfamily homepage (www.med.upenn.edu/akr). At present there are 13 human AKRs, of which, for example, AKR1A1 represents aldehyde reductase and AKR1B1 is aldose reductase. Found in almost every living organism, the AKRs metabolize steroids, sugars, prostaglandins, ►polycyclic aromatic hydrocarbons, and a great variety of endogenous and exogenous aldehydes and ketones.

The SDR superfamily comprises a wide range of NAD(P)(H) dependent oxidoreductases involved in functions as diverse as the metabolism of steroids, sugars, prostaglandins, xenobiotics, drugs and carcinogens, the fixation of nitrogen and the synthesis of antibiotics. The superfamily is made up of enzymes averaging 250–350 amino acids in length. Their three-dimensional structures have a common α/β-folding pattern characterized by a central β-sheet typical of a classical Rossmann-fold with α-helices on either side. The SDRs have a low identity (typically 20–30%), but share common sequence motifs that define the cofactor binding site (TGxxxGxG) and the catalytic tetrad (N-S-Y-K). Their catalytic mechanism resembles the acid/base catalyzed hydride transfer of the AKRs. One of the most prominent SDR enzymes involved in the detoxification of xenobiotics is human carbonyl reductase (CBR1) which has been supposed to have a role in endogenous prostaglandin and steroid metabolism. However, the best substrates for human CBR1 are K region ortho-quinones of polycyclic aromatic hydrocarbons (benzo[a]anthracene and benzo[a]pyrene) and menadione, the latter of which is often used as a model CBR1 substrate.

Among the AKRs and SDRs exists a variety of pluripotent hydroxysteroid dehydrogenases (HSDs) of both superfamilies which specifically catalyze the oxidoreduction at different positions of the steroid nucleus, and which also catalyze rather non-specifically the reductive metabolism of a great number of non-steroidal carbonyl compounds. In target tissues, HSDs convert potent steroid hormones to their cognate inactive metabolites (and *vice versa*) and thus regulate the occupancy of steroid hormone receptors. Therefore, in normal cell physiology, HSDs function as important pre-receptor regulators of signaling pathways by acting as "molecular switches" for receptor-active and receptor-inactive ►hormones. For example, 11β-HSD1 is a microsomal enzyme responsible for the interconversion of cortisone (the glucocorticoid receptor inactive ligand) to the hormonally active 11-hydroxy form ►cortisol. A variety of diseases, including insulin resistance/►diabetes type 2, dyslipidemia, and ►obesity, have been discussed in relation to 11β-HSD1.

Several HSDs exhibit other activities besides steroid oxidoreduction. In addition to being specific for their physiological steroid substrate, they can catalyze the carbonyl reduction of a great variety of non-steroidal aldehydes, ketones and quinones. Accordingly, HSDs participate in drug metabolism and play a significant role in the defense of an organism against the deleterious effects of endogenous and exogenous toxicants and carcinogens. Due to the fact that several enzymes of both superfamilies exhibit pluripotency for steroidal and non-steroidal carbonyl substrates, AKR and SDR seem to be the result of a convergent evolution. Extensively characterized HSDs with carbonyl-reducing activity are four members of the AKR superfamily (AKR1C1–AKR1C4) and 11β-HSD1 from the SDR superfamily.

The "Pro"

Reductases Protect Against Lung Cancer

Among the more than 40 different carcinogens present in tobacco and tobacco smoke (►Tobacco Carcinogenesis), 4-methylnitrosamino-1-(3-pyridyl)-1-butanone (NNK = nicotine-derived nitrosamine ketone) is the most potent and abundant. NNK induces lung tumors in all laboratory animal species tested and is believed to play a role in human ► tobacco-related cancers. NNK requires metabolic activation (►Carcinogen Metabolism) in order to exert its carcinogenic effect and there are competing pathways for NNK activation and

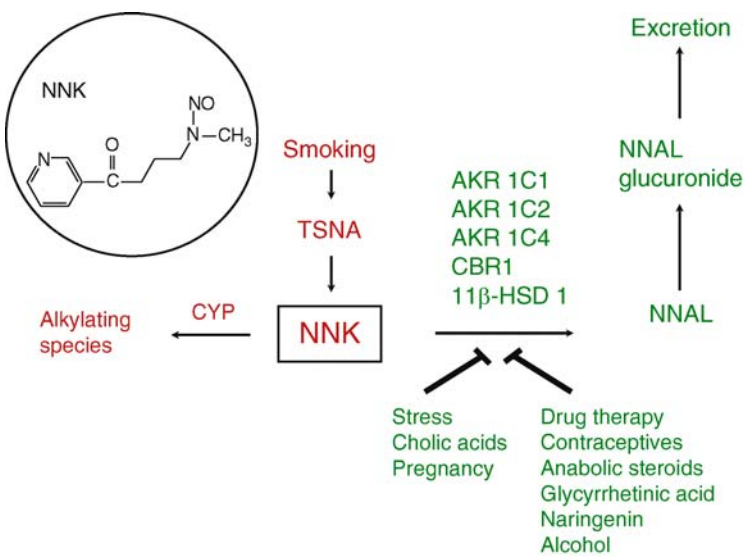
detoxification (Fig. 1). NNK activation proceeds by ►cytochrome P450 mediated α-hydroxylation of the carbon adjacent to the *N*-nitroso group which leads to a series of unstable intermediates that alkylate DNA (►Adducts to DNA) and hemoglobin.

The competing pathway for NNK activation is NNK detoxification, which proceeds via carbonyl reduction of NNK to NNAL, followed by glucuronidation of NNAL. Consequently, the susceptibility of a tissue to tumor formation may vary depending on the extent of the competing pathways α-hydroxylation versus carbonyl reduction. Carbonyl reduction to NNAL is a very efficient pathway of NNK in animal and human tissues and greatly exceeds metabolism by NNK α-hydroxylation. The predominance of carbonyl reduction has been confirmed *in vivo* by a characterization and quantification of NNK metabolites in the urine of smokers and smokeless tobacco users. Five different enzymes catalyzing NNK carbonyl reduction in man have been identified (Fig. 1). These are 11β-HSD1 and CBR1 from the SDRs, and AKR1C1, AKR1C2 and AKR1C4 from the AKRs.

Clinical Aspects

Any impact on NNK carbonyl reduction could have consequences with regard to NNK-induced cancerogenesis (►Chemical Carcinogenesis). For example, differences in tissue expression of NNK reductases may be causally related to the organospecificity of NNK-induced cancerogenesis. Moreover, genetic polymorphisms, age-dependent differential expression and/or modulation by several xenobiotics of NNK reductase activity may impair the activation-detoxification balance in favor of activation, rendering the lung vulnerable to the carcinogenic effect.

The profile of NNK metabolites in smokers' urine reveals high interindividual variations with respect to NNAL, NNAL-glucuronide and NNAL-N-oxide quantities. It is these variations that are of greatest interest, since they may not only be linked to ►lung cancer susceptibility but also to a genetic polymorphism in terms of NNK reductase expression. Only 16% of habitual smokers (►Nicotine Addiction) develop lung cancer, suggesting that individual susceptibility and environmental factors (e.g. air pollution) contribute to the risk of developing this disease. A number of studies have demonstrated a familial component to lung cancer risk. Evidence supporting familiarity suggests that the etiology of lung cancer includes shared genes, shared environments, or both. Association studies performed on polymorphic genes coding for phase-I and phase-II enzymes (►Phase II Enzymes) that play a role in the activation of carcinogens in tobacco smoke, i.e. CYP1A1, CYP2D6, CYP2E1, and GSTM1 (►Glutathion-S Transferase), have often yielded conflicting results. However, preliminary experiments on the expression of 11β-HSD1 in human lung demonstrated that the level of this NNK carbonyl-reducing



Reductases. Figure 1 Simplified scheme of the metabolic fate of the tobacco-derived carcinogen NNK. The NNK/NNAL equilibrium is determined by the level of expression and activity of enzymes that mediate NNK carbonyl reduction. Inhibition of NNK reductases would lead to a shift to NNK activation via cytochrome P450s (CYPs), thereby enhancing the carcinogenic consequences of smoking. NNK, nicotine derived nitrosamine ketone; NNAL, nicotine derived nitrosamine alcohol; TSNA, tobacco-specific N-nitrosamines.

enzyme varied by a factor of 20 in only ten patients investigated.

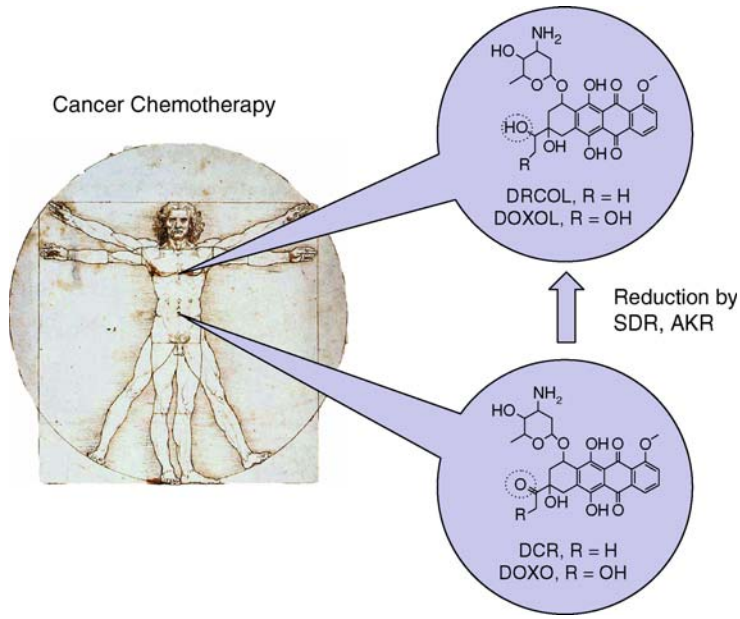
Several factors of endogenous and/or endogenous origin may influence the detoxification capacity of the NNK reductases, thereby shifting the NNK/NNAL equilibrium towards NNK and thus contributing to the interindividual variabilities observed in the response to smoking. In response to stress, elevated levels of endogenous glucocorticoids occupy the 11β-HSD1 enzyme (►Stress). High levels of cholic acids in cholestatic states, or estrogens and progesterone during pregnancy, would also affect NNK detoxification, as those steroids are substrates or inhibitors of most of these reductases. The same consequences may occur upon administration of exogenous steroids (glucocorticoid therapy), or other pharmacologic agents such as some diuretics and ►anti-inflammatory drugs which inhibit one or more of these enzymes already at therapeutic doses. A similar situation might also result upon usage of oral contraceptives, anabolic steroids, or the exposure to food constituents like glycyrrhetinic acid (GA, the principal constituent of licorice) and naringenin (a flavonoid (►Isoflavones) with high concentrations in grapefruit juice). Licorice as a tobacco additive or as a confectionery may potentiate the carcinogenic response towards cigarette smoking. Moreover, GA is known to act as an inducer of cytochromes P450. The resulting increase in NNK activation would be synergistic to NNK reductase inhibition, thereby further aggravating the toxicological consequences of smoking. The fact that chronic alcohol consumption greatly enhances the carcinogenic response to NNK might now be explained on the base that ethanol has been shown to be inhibitory for all of these enzymes.

The "Contras"

Reductases in Chemotherapy Resistance

In anti-tumor chemotherapy, the occurrence of drug resistance is a major obstacle and originates principally from pharmacodynamic or pharmacokinetic mechanisms. ►Anthracyclines like ►daunorubicin (DRC) and ►doxorubicin (DOX) are the most valuable cytostatic agents in chemotherapy, but their usefulness is limited by intrinsic or acquired resistance towards these drugs. Anthracycline resistance is not merely the result of alterations in drug uptake and retention (►Membrane Transporters) (►ABC-Transporters) (►P-glycoprotein), but also mediated by enzymatic anthracycline detoxification that is upregulated upon exposure to these drugs. The 13-hydroxy metabolites of anthracyclines, such as daunorubicinol (DRCOL) and doxorubicinol (DOXOL), are significantly less potent than the parent drug in terms of inhibiting tumor cell growth, suggesting that carbonyl reduction is an important biochemical mechanism in the detoxification of carbonyl group-bearing anthracyclines. Therefore, elevated levels of anthracycline carbonyl-reducing enzymes constitute a mechanism in the development of resistance towards DRC and DOX (Fig. 2). For example, in a variety of different cancer cell systems, including pancreas carcinoma, breast cancer, stomach cancer and ovarian carcinoma, DRC carbonyl reduction was inducible by the substrate DRC itself.

Five enzymes capable of catalyzing anthracycline carbonyl reduction have been identified in human liver: AKR1A1, AKR1B1, AKR1B10 and AKR1C2 from the AKR superfamily, and CBR1 from the SDR superfamily. Generally, increased expression levels of these reductases were observed in drug-resistant cells. In pancreas carcinoma cells, CBR1 turned out to have the highest potency. Overexpression of CBR1 lead to a sevenfold increase in DRC-resistance when IC_{50} values were taken into account. This is in accordance with DRC resistant human stomach carcinoma cells which showed strongest increase in CBR1 mRNA expression and an eightfold increase in resistance towards DRC. CBR1-deficient K562 cells gained protection towards DRC toxicity after transfection with CBR1. Therefore, CBR1 seems to be the dominant reductase in tumor cells during generation of DRC resistance by induction of phase-I metabolism. AKR1B1 was linked to DOX and ►cisplatin resistance in ►HeLa cells of ►cervical carcinoma. AKR1C2 expression levels were altered in prostate and breast tumors. In an ovarian cancer cell line, resistance to *cis*-platin chemotherapeutics correlates with the induction of AKR1C2 expression. AKR1C2 is emerging as an important cellular-stress response marker in several different cell types. Furthermore, it has been suggested that the antitumor effect of ►nonsteroidal anti-inflammatory drugs (NSAID) is mediated in part by the inhibition of certain AKR1C isoforms, in addition to inhibition of COXs. Non-MDR-resistant Chinese hamster ovary cells resistant to the calpain inhibitor (N-acetyl-leucyl-leucyl-norleucinal) overexpressed an NADPH-dependent AKR that exhibits about 70% sequence identity with AKR1B1. The enzyme was later identified as being AKR1B10 (intestinal aldose-like reductase) which is also capable of reducing DRC. AKR1B10 belongs to the aldose reductases (AKR1B subfamily) and was discovered as an enzyme being overexpressed in human lung and ►liver cancer, and even suggested as a diagnostic marker of ►non-small cell lung carcinomas. The overexpression of AKR1B10 in ►squamous cell carcinoma of the lung raises the question whether inhibition of this enzyme might be beneficial for patients, in as much as the physiological role of AKR1B10 is not yet fully understood. Recent observations suggest that its physiological substrates are retinal isomers.



Reductases. Figure 2 Carbonyl reduction is a main but undesired metabolic pathway of the anti-cancer drugs DRC and DOX. The resulting alcohol metabolites DRCOL and DOXOL, respectively, have a far less anti-tumor potency and, in addition, are responsible for the life-threatening cardiac toxicity that limits the clinical use of DRC and DOX. Elevated levels of carbonyl-reducing enzymes in cancer cells may therefore contribute to the development of anthracycline chemoresistance and affect the clinical outcome.

Cardiotoxicity

►DRC and ►DOX are highly effective antineoplastic agents, but they can produce the serious side effects of acute cardiac injury and chronic congestive heart failure. The mechanism by which they cause chronic cardiomyopathy is not fully understood. Hypotheses regarding the mechanism of cardiac toxicity include perturbation of calcium homeostasis, formation of iron complexes, mitochondrial dysfunction, and damage to cell membranes. Since the development of chronic cardiomyopathy usually coincides with an accumulation of anthracycline secondary alcohol metabolites in the heart, DOXOL and DRCOL are hypothesized to be responsible for this severe side-effect that limits the clinical use of DRC and DOX (Fig. 2).

In agreement with this, CBR1, AKR1A1 and AKR1B1 have been implicated in the development of doxorubicin-induced cardiotoxicity. For example, transgenic mice that overexpress human CBR1 exclusively in the heart show increased heart damage and decreased survival after doxorubicin treatment. On the other hand, significant cardiac protection is seen in mice heterozygous (+/−) for *Cbr1* expression with a 40–50% decrease of CBR1 protein levels. The variability of CBR1 levels in the human heart is not known. High CBR1 levels could contribute to the extreme DOX sensitivity some patients experience during treatment and also to the long-term chronic cardiotoxicity that can develop in cancer patients 10–20 years after treatment.

Clinical Aspects

The clinical consequences in chemotherapy with carbonyl group bearing anthracyclines remain to be established. Anthracycline cumulative doses upon chemotherapy of cancer patients must not exceed 500 mg/m^2, since otherwise serious side effects in cardiotoxicity can be expected. Hence, inhibition of DRC carbonyl reduction in a chemotherapeutic regimen would have a twofold benefit especially at low DRC or DOX doses: first, the preservation of the antineoplastic potency of the parent drug and second, the prevention of cardiomyopathy caused by their reduced alcohol metabolites DRCOL and DOXOL. Since several flavonoids (isoflavones) function as potent inhibitors of carbonyl-reducing enzymes, co-administration of flavonoids during anthracycline chemotherapy may therefore be cardioprotective without a loss of antineoplastic potency.

Chemical modification may lead to a decreased metabolic inactivation. In the case of the new antineoplastic agent benfluron, carbonyl reduction resulted in the rapid loss of antitumor activity. The molecule was then derivatized by the addition of two methoxy substituents, protecting the ketone from reduction, with the goal of improving the pharmacokinetic profile of

benfluron. The dimethoxy substitution indeed did protect the molecule from deactivation in incubations with human liver subcellular fractions, human hepatocytes, and purified CBR1. However, the outcome of pharmacokinetic studies with this derivative has not yet been reported.

Reduction

Definition

The chemical process involving an addition of electrons. If disulfides are reduced with two electrons, they become dithiol motifs.

►Thioredoxin System

Reduction/Oxidation

Definition

►Redox reactions properly refer to reactions in which there is a change in oxidation number. However, they can usually be considered as an exchange of electrons between two molecules, atoms or ions. Reduction describes the gain of electrons and oxidation describes the loss of electrons. Reducing agents loss electrons and oxidizing agents (also called oxidants or oxidizers) gain electrons.

►Hydrogen Peroxide

Reed-Sternberg Cells

Definition

R-S cells; Refers to a lymphoid cell and in most cases, a ►B cell. R-S cells are very large with abundant pale cytoplasm and two or more oval lobulated nuclei containing large nucleoli. Hodgkin lymphoma (synonym Hodgkin disease, HD) is a neoplastic proliferation of lymphoid cells predominantly involving lymphoid tissues. The malignant cell is the Reed-Sternberg cell. Reed-Sternberg cells are essential to the diagnosis of Hodgkin lymphoma. However, R-S cells are not unique to HD and therefores alone are not sufficient for the diagnosis of HD.

Regeneration

Synonyms

Mass recovery; Tissue proliferation

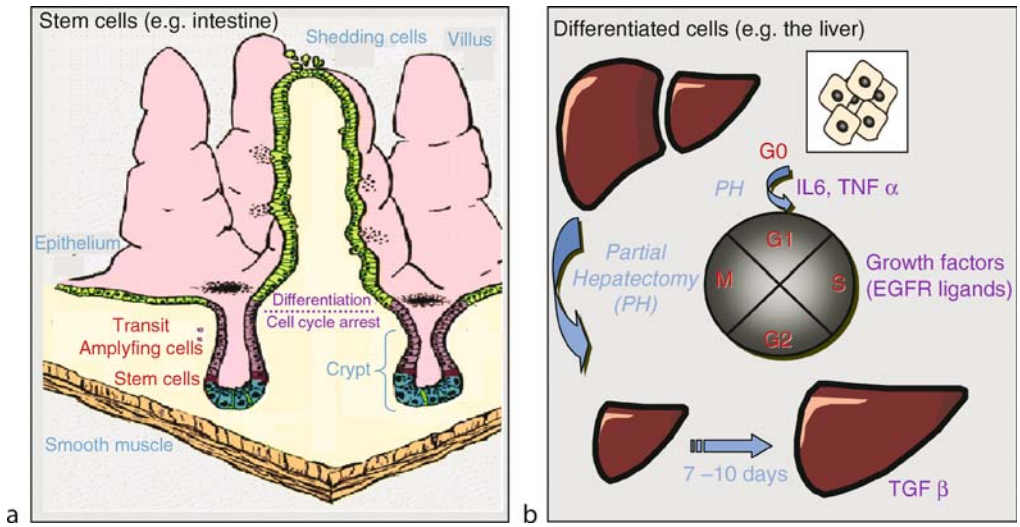
Definition

Regeneration is the recovery of cell mass of a given organ following cell loss. The balance between cell loss and cell renewal is tightly controlled. When this balance is altered, inappropriate cell growth occurs leading to the development of cancer.

Characteristics

Under normal circumstances, the processes of tissue regeneration or homeostasis are tightly regulated by several pathways to prevent excessive or inappropriate cell growth. Two kinds of cell types can participate in tissue regeneration: stem cells, which are multipotent cells that can both self-renew and give rise to more differentiated cells; and terminally differentiated cells, which are normally quiescent but are able to proliferate upon a stimulus. Some tissues regenerate from their pool of stem cells, like the intestine and the skin, and others, like the liver and the kidney, regenerate from fully differentiated cells that constitute these organs.

One classic example of tissue renewal by stem cells is the intestine (Fig. 1a). Intestinal epithelial stem cells are

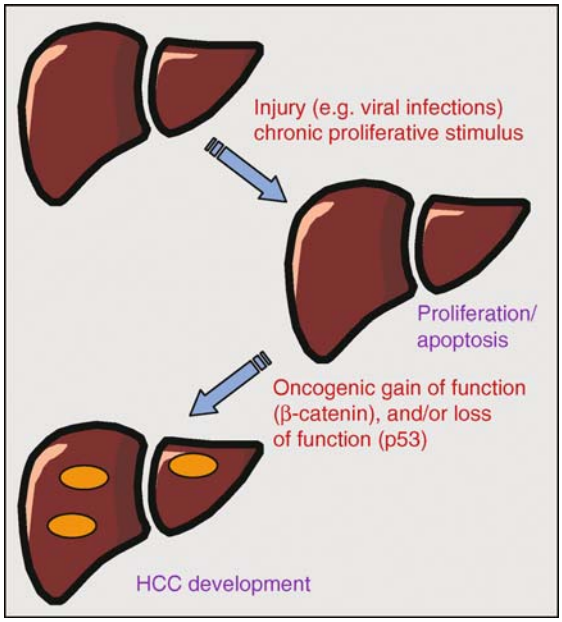


Regeneration. Figure 1 Regeneration in normal tissues. Certain tissues, such as the intestine (a), regenerate from a pool of stem cells, while others, such as the liver (b), regenerate from fully differentiated cells.

thought to be located in the crypt compartment. Gut stem cells differentiate as they migrate upwards to the surface epithelium. Before terminally differentiating into absorptive enterocytes or secretory goblet cells, progenitor cells give rise to transit amplifying cells, the immediate precursors to the effector cells. Terminally differentiated cells are eventually shed into the lumen. Wnt/ß-catenin signaling appears to be one of the major pathways controlling intestinal homeostasis. The distribution of ►APC (adenomatous polyposis coli), a gene required for degradation of ►β-catenin, is in agreement with the role of ß-catenin signaling in maintaining stem cell properties and controlling differentiation in the intestine. A gradient of APC is observed along the crypt-villus axis, where it counteracts ß-catenin signaling and allows differentiation.

The liver is the major example of fully differentiated cells that massively regenerate following injury (Fig. 1b). Following two thirds partial hepatectomy, liver regeneration is carried out by the remaining mature cellular populations composing the liver. Stem cells, although present, do not feature largely in hepatocyte proliferation. The first cells to proliferate are the hepatocytes, followed by biliary epithelial cells, ►Kupffer cells and endothelial cells. There is evidence to suggest that hepatocytes provide a certain mitogenic stimuli which initiates the other cell types to commence DNA synthesis and proliferation. The initial (priming) phase after injury/partial hepatectomy, involves the up-regulation of cytokines and pro-inflammatory proteins, like ►TNF-α and ►IL-6. This priming phase renders the liver cells receptive to the mitogenic effects of growth factors (mainly ►ERFR ►ligands). Since the size of the liver is highly regulated, once hepatocytes complete one to two rounds of division, regeneration will eventually stop. The main factors involved in the termination phase are TGF-β1 and other members of its family, such as activin.

In both systems described above, proliferation is tightly controlled, involving a careful balance between cell loss and cell renewal that keeps the normal organ homeostasis. Once this balance is disrupted, an exacerbated proliferation will occur, which can eventually lead to a tumorigenic process. Several mechanisms are involved in countering the carcinogenic process in proliferating tissues. Potentially cancerous cells can be eliminated by programmed cell death (►apoptosis) or their proliferation prevented by permanently halting their cell cycle (►senescence). However, cancer can develop if certain genes involved in these pathways are mutated or dysregulated (e.g. ►p53, ►Rb, ►p16) (Fig. 2). Different factors, both hereditary and environmental, can be responsible for the mutations leading to imbalanced growth. Environmental mutagens can vary from ultraviolet light (skin), to viral infections (liver) and dietary carcinogens (stomach and intestine). It has been demonstrated that signaling pathways involved in cancer are often the same associated with normal tissue renewal. In the kidney, for example, most genes implicated in regeneration are also involved in the tumorigenic process. Exacerbated tissue growth results indeed from dysregulation of pathways involved in regeneration/repair. Extensive evidence has pointed out two main pathways that are dysfunctional in various forms of cancer, the WNT/β-catenin and the ►Hedgehog signaling pathways.



Regeneration. Figure 2 Dysregulated regeneration during liver tumorigenesis. A proliferative stimulus triggered by injury leads to exacerbated growth. When this growth is combined with mutations inducing gain and/or loss of function of key cell cycles genes, it can lead to malignant transformation.

In normal tissues, in the absence of WNT signaling, β-catenin is phosporylated by functional interactions with glycogen syntase kinase (GSK)-3β (►GSK3), ►axin and ►APC, and subsequently targeted to the ►ubiquitin-►proteasome system. Thus, in normal adult epithelial cells, β-catenin is present in a sub-membranous location and it plays a major role in adherens junctions. Activation of Wnt signal during cell proliferation induces β-catenin stabilization and translocation to the nucleus and its association with Tcf/LEF factors causes transcriptional activation of target genes as *c*-►*myc* and ►cyclin D1. During tumorigenesis, different factors can lead to β-catenin constitutive activation. Thus, mutations in APC leading to the accumulation of β-catenin are involved in most ►colon cancers. The Wnt pathway is also constitutively activated in some types of skin and ►liver cancers, but in these cases, this activation is due to β-catenin mutations that prevent it from being degraded by the proteasome.

Three Hedgehog (Hh) genes have been isolated in humans: Sonic (SHH), Indian (IHH) and Desert (DHH) Hedgehogs. They produce secreted glycoproteins that act through several components, including the transmembrane receptors Patched 1 (►PTCH1) and Smoothened (SMOH), to initiate a complex intracellular signaling cascade that ultimately leads to the activation of the ►GLI zinc-finger transcription factors. Studies in model systems have shown that the Hh–Gli pathway controls the normal development and growth of several organs, including the skin, brain, pancreas, gut and prostate, at different stages of development. Aberrant activation of the Hh pathway in cancers is caused by mutations in the pathway (ligand independent) or through Hh overexpression (ligand dependent). This pathway has been extensively described as being dysregulated in cancers involving tissues that are renewed by their stem cells, such as pancreas, prostate and intestine. However, recent data have demonstrated that this pathway is also involved in liver cancers.

In conclusion, cancers arise when the balance between cell growth and cell loss is disrupted, and it is therefore crucial to define the precise mechanisms involved in this balance in order to develop new therapeutic tools to fight cancer.

Synonyms

Suppressive T cells; Treg

Definition

Regulatory T (Treg) cells are a specialized subpopulation of T cells that are capable of suppressing immune responses and thereby inducing immune tolerance to self and non-self. Suppressive T cells were initially described in the early 1970s and 1980s and their suppressive function was implicated in tumor-induced suppressive immunity. However, due to a lack of phenotypic markers for defining these cells, there was extensive skepticism about their existence in vivo. In 1995, Sakaguchi and colleagues showed that CD25, the ►interleukin-2 (IL-2) receptor α chain, could serve as a phenotypic marker for $CD4^+$ suppressor T cells or $CD4^+$ Treg cells. Over the past few years, several distinct subsets of Treg cells have been identified, which include (i) naturally occurring $CD4^+$ $CD25^+$ $FoxP3^+$ Treg cells; (ii) antigen-induced $CD4^+$ Treg cells such as antigen-specific $CD4^+$ $CD25^+$ $FoxP3^+$ Treg cells, IL-10-producing Tr1 cells, and TGF-β-producing Th3 cells; (iii) $CD8^+$ Treg cells; and (iv) NKT Treg cells. Recent studies demonstrate that the immunosuppressive potential of these cells can be harnessed therapeutically to treat various immune-related diseases, including autoimmune diseases, allergy, transplantation, infectious diseases as well as cancer.

Characteristics

Molecular Markers of Treg Cells

Although the expression of CD25 on T cells has been used as a useful marker of Treg cells, its expression is not necessarily associated with Treg cell function, in that it is also expressed by activated, nonregulatory effector lymphocytes. Several other molecules, including the TNF-family molecule GITR and ►cytotoxic T-lymphocyte antigen-4 (CTLA4), have been used as markers for Treg cells. However, both GITR and CTLA-4 are activation markers, they also express on activated effector T cells. Foxp3 is the best marker identified to date for $CD4^+$ Treg cells in mice and humans. Foxp3 is also expressed in $CD8^+$ Treg cells, but not in Tr1 cells. More recently, CD127 expression, the alpha chain of the interleukin-7 receptor, was found to inversely correlates with Foxp3 and the suppressive function of $CD4^+$ Treg cells. The combined use of these markers including $CD25^+$, $Foxp3^+$ and $CD127^-$ may better define Treg cell population with suppressive function.

Treg Cell in Cancer and their Antigen Specificity

Treg cells within tumor microenvironment may play a significant role in the suppression of antitumor immune responses against cancer cells. Elevated percentages of $CD4^+$ $CD25^+$ Treg cells in the total T cell population have been found in tumor tissues or peripheral blood in variety of cancers, including lung cancer, breast cancer, ovarian, melanoma, liver cancer, gastric cancer, and lymphoma. The generation and maintenance of Treg cells have long been speculated to require the presence of target antigen or tissues, but the identity of antigens recognized by Treg cells remains largely unknown. Recent efforts have led to successful identification of several ligands recognized by $CD4^+$ Treg cells, which include LAGE1 (a homolog of NY-ESO-1) and ARTC1 (*a*ntigen *r*ecognized by *T*reg *c*ells). They have potent ability to suppress naïve T cell proliferation through a cell-contact dependent mechanism. Because both LAGE1 and ARTC1 are dominantly expressed in cancer and normal testis, but not in other normal tissues tested, these Treg cells are activated only when they encounter with tumor cells, thus providing molecular basis for their specificity in the induction of immune tolerance. Since tumor cells express an array of tumor-specific antigens as well as self antigens, it is likely that Treg cells specific for tumor-specific antigens as well as Treg cells specific for nonmutated self antigens co-exist in tumor microenvironment. Overall, these tumor-infiltrating Treg cells are present at tumor sites and mediate antigen-specific, local immune suppression.

Suppressive Mechanisms of Treg Cells

$CD4^+$ Treg cells require antigen-specific activation or polyclonal ►TCR stimulation to exert their suppressive function. Once activated, they can suppress $CD4^+$ and $CD8^+$ T cells in an antigen-nonspecific manner. Several mechanisms have been proposed to explain how $CD4^+$ Treg cells inhibit $CD4^+$ effector T cells. Some investigators suggest that IL-10 and/or TGF–β are directly involved in T-cell-mediated suppression, while others contend that cell-cell contact is required for suppression. It is likely that more than one mechanism of $CD4^+$ Treg cell-mediated suppression appears to operate in vitro and in vivo. Most tumor-specific $CD4^+$ Treg cells suppress immune responses (proliferation and IL-2 secretion of naïve or effector T cells) through a cell-contact mechanism, but the precise mechanism and molecules responsible for Treg cell-mediated suppression remain to be identified.

Manipulation of the Number or Suppressive Function of Treg Cells

Successful cancer ►immunotherapy will need to manipulate the Treg cell number or their suppressive

function. One approach is to eliminate $CD25^+$ Treg cells by a specific antibody or Ontak (a IL-2-toxin fusion protein). However, because the CD25 marker is not specific for Treg cells and all activated T cells are positive for CD25 marker, this approach may not efficiently eliminate Treg cells or deplete both Treg cells and activated effector cells. Hence, more specific and effective reagents are needed to deplete Treg cells in cancer patients.

An alternative approach is to reverse the suppressive function of Treg cells. TLR signaling activation on DCs can render naïve T cells refractory to suppression mediated by Treg cells in mice, but it is not clear whether TLR activation on Treg cells can directly reverse their suppressive function. Poly-G oligonucleotides can directly reverse the suppressive function of human Treg cells in the absence of DCs. The reversal effect of Treg cell function by Poly-G oligonucleotides requires the signaling from TLR8 to MyD88 pathway in Treg cells. Future studies will focus on evaluation of the therapeutic potential of cancer vaccines in patients by reversing Treg cell function via TLR stimulation or in the combination with peptide-based vaccination.

NF-κB

Definition

Rel can refer generically to a family of structurally-related eukaryotic ►transcription factors. The vertebrate Rel family includes the proteins RelA, RelB, c-Rel, p50/p105, and p52/p100, and a viral protein (v-Rel) (Table 1). Alternatively, Rel can specifically refer to v-Rel or c-Rel. The term ►NF-κB is also often used in a general fashion interchangeably with Rel, as in Rel/NF-κB transcription factors.

Characteristics

Rel family proteins are related through an N-terminal domain of ~300 amino acids, called the Rel homology domain, which contains sequences important for the formation of dimers, DNA binding, and nuclear localization. Rel proteins must form dimers to bind to DNA and these dimers bind to a related set of DNA target sites called κB sites. The consensus sequence for the κB site is GGGRNWTTCC (where R is any purine, N is any nucleotide, and W is A or T).

Vertebrate Rel proteins can be divided into two classes based on sequences C-terminal to the Rel homology domain (Fig. 1). The C-terminal half of one class of Rel protein (including p105 and p100) contains multiple copies of a 33 amino acid repeat, called the ankyrin repeat, that causes these proteins to be inactive. However, these C-terminal inhibitory sequences can be removed to yield shorter, active DNA-binding forms (p50 and p52) that consist primarily of the Rel homology domain. A second class of Rel family protein (RelA, RelB, c-Rel) contains C-terminal sequences that function as transcription activation domains. In the fruit fly *Drosophila* there are three Rel proteins – Dorsal, Dif, and Relish – which control an early step in development and a primitive immune response to bacterial and fungal infections (Fig. 1, Table 1). Recently, NF-κB- like proteins have also been identified in marine invertabrates in the phyla cnidaria (see anemones, corals) and porifera (sponges).

Almost all Rel family proteins can form homodimers and heterodimers. The most common Rel dimer in many vertebrate cells is a heterodimer consisting of p50-RelA, which is often specifically called NF-κB. The binding of Rel dimers to DNA target sites generally activates the transcription of a large variety of cellular genes, including many whose protein products are involved in immune responses (e.g. anti-bacterial peptides), ►inflammation (►cytokines and cytokine receptors), adhesion (cell surface attachment proteins), and programmed cell death (►Bcl-2 proteins). In addition, several viral genes (including those of human oncogenic viruses such as ►Human immunodeficiency virus [HIV-1] and ►Epstein-Barr virus [EBV]) are activated by Rel/NF-κB dimers.

Cellular and Molecular Regulation

Rel ►transcription factors can be regulated at several levels. First, because there are five interacting members of the Rel transcription factor family, they can combine to form a diverse set of dimers with distinct DNA

REL. Table 1 Fly and vertebrate Rel/NF-κB transcription factors

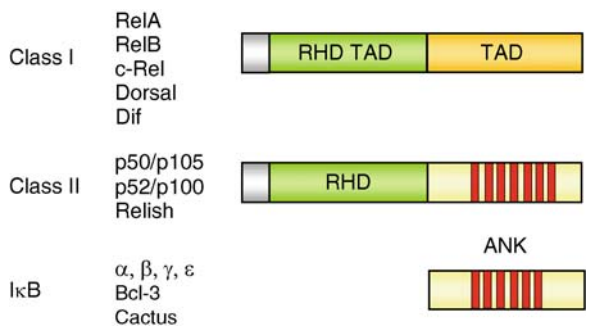
Gene	Protein	
Drosophila melanogaster		
Dorsal	Dorsal	
Dif	Dif	
Relish	Relish	
Avian Rev-T retrovirus		
v-*rel*	v-Rel	
Vertebrates		
		Human gene (chromosome)
Rela	RelA (p65)	*RELA* (11q12-q13)
Relb	RelB	*RELB* (19q13)
c-*rel*	c-Rel	*REL* (2p13-12)
nfkb1	p50, p105, or p50/p105	*NFKB1* (4q23-q24)
nfkb2	p52, p100, or p52/p100	*NFKB2* (10q24)

target site binding specificity. The composition of these dimers is determined by the affinity of specific Rel subunits for one another, by the concentration of specific subunits in a given cell, and by the post-translational modification of specific subunits. The composition of the Rel dimers in a given cell is important as it influences which genes they can control and which inhibitors (see below) can bind to the complexes.

Second, in most cell types, Rel complexes are located in the cytoplasm due to interaction with an inhibitor protein called ►IκB. IκB proteins are members of a structurally-related family of proteins (Fig. 1) that inhibit Rel complexes by masking sequences involved in nuclear localization and DNA binding. A variety of extracellular signals, including cytokines, phorbol esters, virus infection, interferon, and the bacterial outer membrane component lipopolysaccharide, can activate Rel transcription complexes by inducing their dissociation from IκB. In the best-characterized example, the p50-RelA NF-κB complex is held in the cytoplasm by interaction with IκBα (Fig. 2).

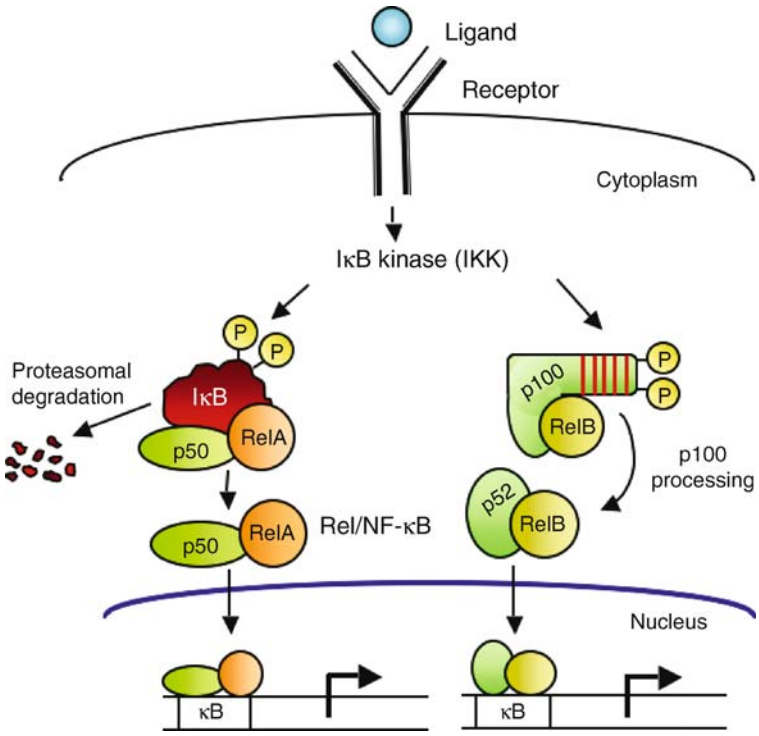
Stimulation of the cell by an appropriate signal leads to activation of an IκBα kinase (IKK), which then phosphorylates IκBα at two N-terminal serine residues. Phosphorylation of IκBα signals it for ►ubiquitination at a nearby lysine residue. Ubiquitinated IκBα is then degraded by the ►proteasome, and the NF-κB complex is free to enter the nucleus to activate transcription of specific genes. One of these genes encodes IκBα. Newly synthesized IκBα can then pull NF-κB off DNA, and export and resequester NF-κB in the cytoplasm. Thus, activation of NF-κB is a transient (~30–60 min) event in most cell types.

However, in some cell types NF-κB is continuously located in the nucleus and active. Normal cells with



REL. Figure 1 Generalized structures of Rel/NF-κB/IκB proteins. Rel/NF-κB proteins are related through the Rel homology domain (RHD), which has sequences important for the formation of dimers, DNA binding, inhibitor (IκB) binding, and nuclear localization. Dimers can form within or between Rel classes (e.g. p50-p50 or p50-RelA, etc.). Class I proteins have C-terminal sequences that are required for transcription activation (TAD). Class II proteins have C-terminal sequences with multiple copies of inhibitory ankyrin repeats (ANK, *red bars*), which can be removed by proteolysis to release the mature N-terminal DNA-binding proteins (p50 or p52). Independent IκB proteins consist largely of a series of ankyrin repeats. The protein names refer to separate proteins in each family (e.g. see Table 1 and text for details).

constitutively nuclear and active NF-κB include B cells, Sertoli cells, and some neurons. In addition, chronically active NF-κB has been documented in many cancer cell types (including ►leukemia, ►lymphoma, ►breast cancer, ►cervical cancer, ►ovarian cancer, vulva, ►prostate cancer, ►bladder cancer, ►kidney cancer, ►lung cancer, ►pancreas cancer,



REL. Figure 2 Activation of the Rel/NF-κB pathway. Many types of extracellular signals (Ligand) can initiate activation of the Rel/NF-κB signal transduction pathway by binding to a specific cell surface receptor. In most cases, these signals lead to the activation of a cytoplasmic IκB ►kinase (IKK), which phosphorylates (P) an IκB (*left*) or the C terminus of p100 (*right*). Phosphorylation of IκB targets it for degradation by the proteasome, and phosphorylation of p100 leads to removal of the C-terminal ANK repeat sequences. Free Rel/NF-κB dimers (e.g. p50-RelA or p52/RelB) then enter the nucleus, bind to specific DNA sites (κB sites), and turn on the expression of many cellular genes. Often, one of these activated genes encodes IκB; newly-synthesized IκB can remove NF-κB from DNA and resequester NF-κB in the cytoplasm. Thus, activation of NF-κB is usually a transient (30–60 min) process, which is subject to negative auto-regulation.

►oral cancer, ►larynx cancer, ►colon cancer, ►thyroid cancer, ►skin cancer, head and neck and ►neuroblastoma), and in cells infected with certain human oncogenic viruses (e.g. ►Human T-cell Lymphotropic Virus-1, ►Epstein-Barr Virus, Hepatitis B Virus). In the case of oncogenic viruses, specific viral gene products (►Tax, HTLV-1; ►LMP-1, EBV; X protein, HBV) can constitutively induce the degradation of IκB, allowing NF-κB to continuously enter the nucleus of infected cells.

Clinical Aspects

Rel transcription factors have been associated with oncogenesis in several settings. First, the avian Rev-T ►retrovirus has a single gene, v-*rel*, that encodes the v-Rel transcription factor. Young chickens infected with high titer stocks of Rev-T succumb to leukemia/lymphoma quite rapidly, often within 7–10 days, and have multiple lymphoid cell tumors, primarily in their spleens and livers. The v-*rel* ►oncogene arose by a recombination event between an avian retrovirus and the turkey c-*rel* gene, such that v-*rel* encodes a chimeric protein that has internal c-Rel amino acids and retroviral (Env) amino acids at its N and C termini. v-Rel is mutated in several ways as compared to the c-Rel proto-oncoprotein and these mutations contribute to the oncogenicity of v-Rel. It is likely that v-Rel malignantly transforms cells by forming homodimers that freely enter the nucleus, bind DNA and turn on the transcription of genes that enhance cell growth and block ►apoptosis.

Second, alterations in Rel transcription factor regulation or gene structure are found in several human cancers. As mentioned above, several cancer cell types have constitutive nuclear NF-κB activity. This chronic NF-κB activity endows the cancer cells with an unregulated proliferative capacity and an increased resistance to apoptosis. In some cases, this increased NF-κB activity is due to the production by the tumor cell of autocrine factors that continuously activate the NF-κB

pathway. In addition, genetic alterations in Rel and IκB family genes, including ►amplificational, ►point mutational, and ►chromosome translocational, have been identified in several human cancers, especially hematopoietic cell cancers. For example, the human *REL* gene is amplified in many ►Hodgkin lymphomas and ►diffuse large B-cell lymphomas. In some lymphoid cell cancers there are deletions of the 3′ region of the human *NFKB2* gene, leading to the expression of a C terminally-truncated p100 protein with altered activity. Some Hodgkin's lymphoma tumor cells have inactivating mutations in the gene encoding IκB, which enables Rel/NF-κB complexes to enter the nucleus unchecked. In addition, some ►diffuse large B-cell lymphomas and ►multiple myelomas have mutation in genes encoding upstream signaling proteins, which lead to chronic activation of nuclear Rel/NF-κB.

Pharmacologic or molecular agents that target the Rel/NF-κB signal transduction pathway have been investigated as anti-inflammatory and anti-cancer therapeutics. Many common ►anti-inflammatory drugs, including ►aspirin, ►glucocorticoids, and ►green tea (►epigallocatechin), act, at least in part, by inhibiting NF-κB. Similarly, many recent anti-cancer therapies seek to use molecular or pharmacological agents to sensitize tumor cells to chemotherapeutic agents by inhibiting the anti-apoptotic activity of NF-κB. For example, expression of a super-repressor form of IκBα, which cannot be released from NF-κB, sensitizes several tumor cell types to anti-tumor agents.

Relaxin

Richard Ivell
Head of School of Molecular and Biomedical Sciences, The University of Adelaide, SA, Australia

Definition

Is a small ►peptide ►hormone comprising two subunits, together about 6,000 Da in size. Relaxin has been identified as a locally produced factor in a number of key tissues, such as the thyroid gland, gastrointestinal tract, heart, uterus, and lung. Relaxin isknown to function in cells by activating a ►G-protein-coupled receptor on the cell surface called LGR7 or RXFP1 (relaxin family peptide 1). The main functions of relaxin are linked to uniquely mammalian traits such as lactation, viviparity, and post-reproductive survival.

Characteristics

Is a small ►peptide ►hormone belonging to the insulin family of hormones and growth factors. Its major sources in the body are in women the corpus luteum of the premenopausal ovary and the placenta, and in men the prostate gland. In humans, unlike most other mammals, there are two genes for relaxin, *RLN1* and *RLN2*. The products of these genes appear to behave identically in most bioassay systems. Since the *RLN1* gene product is

only ever expressed at very low levels in the placenta and prostate, and does not appear to contribute at all to the circulating relaxin concentration, the term relaxin is used to denote the product of the *RLN2* gene. Whereas in women relaxin can be detected in the circulation with maximum concentrations up to about 1 ng/mL during early pregnancy, in men the peptide is generally below the level of detection for most assays. Relaxin has been identified as a locally produced factor in a number of key tissues, such as the thyroid gland, gastrointestinal tract, heart, uterus, and lung. Relaxin is known to function in cells by activating a G-protein-coupled receptor on the cell surface called LGR7 or RXFP1 (relaxin family peptide 1). The principal ►second messenger system activated by relaxin involves raising the intracellular levels of cyclic AMP (cAMP), though a recent study suggests that relaxin may also be able to activate ►glucocorticoid receptors, and hence glucocorticoid responsive genes in some cells.

Relaxin is a recent development of evolution and is specific to mammals. It appears to have evolved from an ancestral peptide known as relaxin-3, which is found in the brains of all vertebrates. The main functions of relaxin are linked to uniquely mammalian traits such as lactation, viviparity, and post-reproductive survival, which are the hallmarks of a new class of regulatory factors called "►neohormones." These molecules appear to have evolved specifically to address the new needs of mammals. To achieve these novel functions, besides being expressed in specific tissues, relaxin appears to coordinate its activity via a group of specific physiological processes: most importantly ►extracellular matrix ►remodeling and ►collagen remodeling principally by the coordinate control of ►matrix metalloproteinases and their specific inhibitors; ►neoangiogenesis, involving the local induction of ►vascular endothelial growth factor (VEGF); and ►vasodilation in which both nitric oxide and endothelin appear to participate. In addition, relaxin can promote growth and/or differentiation in some cell types, for example, endometrial stromal cells.

The association of relaxin with cancer first arose as a possible link to the observation that women who have had no children have a higher risk of ►breast cancer than those who have started families at a relatively young age. The notion is that a specifically pregnancy-related factor such as relaxin might have a protective capacity in regard to breast cancer, though a recent study using a rat model appears to disallow this possibility. Nevertheless, a series of studies have identified relaxin as a product of ►breast cancer, ►endometrium cancer, ►colon cancer, ►thyroid cancer and ►prostate cancer, with increased relaxin gene expression in the neoplastic tissue compared to the healthy tissue from which the tumors arose. Secondly, a landmark study by Binder and colleagues showed that patients with ►metastatic breast cancer had significantly higher circulating relaxin levels than either a control group of healthy women, or a group of breast cancer patients of good prognosis without metastatic disease. The obvious question that then arose was whether the relaxin was causal in the context of the metastatic disease, merely an index of disease progression, or whether it was a defensive response by the body to the cancer.

To address these issues several research groups have begun to assess the role of relaxin in various parameters of tumor growth, differentiation, and the formation of ►metastases. Initially it is important to determine whether the specific relaxin receptor, RXFP1, is expressed in tumor tissues. Mostly this has made use of ►RT-PCR to detect RXFP1 gene transcripts. The difficulty is that this is a very complex gene, comprising 17 exons, with described alternative splicing giving rise to numerous variants, which may or may not have functional relevance. Very few studies have addressed this issue in the context of cancer cells and tissues, such that reported evidence of transcript expression does not necessarily imply the presence of a functional receptor. However, some studies have made use of specific and validated RXFP1 antibodies (e.g. in breast cancer), or have applied ligand-binding assays to verify the presence of potentially functional receptor protein (e.g. in ►prostate cancer). Some have assessed cell signaling and specific functional responses to relaxin using tumor-derived cell-lines.

Various cell-lines derived from ►prostate cancer, ►breast cancer, ►endometrium cancer, and ►thyroid cancer, are stimulated by relaxin to increase their invasiveness in *in vitro* ►transmigration assays. This has been shown to be due to an increased expression by the cells of metalloproteinases 2 and 9, which effectively degrade the artificial extracellular matrix in these assays. These findings would thus support the notion that relaxin could exacerbate tumor invasiveness, and assist the escape of metastatic cells.

In both ►xenograft and ►autograft mouse cancer models, over-expression of relaxin by either pure peptide delivery, by specific lentiviral or adenoviral expression, or by ►transfection of the cancer cells prior to tumor formation, in general leads to an increase in tumor size, and/or an increase in tumor differentiation, usually accompanied by an increase in tumor vascularization. The latter has been shown for a prostate carcinoma model to be due to induced expression of ►VEGF in the tumor cells. siRNA downregulation of the RXFP1 receptor blocks the effect of relaxin in the *in vitro* models. Finally, in a ►xenograft mouse model of human prostate carcinoma, application using lentiviral vectors of a relaxin receptor antagonist convincingly showed that blocking the endogenous relaxin hormone-receptor system in this way led to a reduction in tumor growth and progression. The endogenous

relaxin-RXFP1 system appears to be involved in the well-known escape of this tumor from androgen regulation. Introduction of the R273H ►p53 mutation into the LNCaP prostate cancer cell-line leads to androgen-independence by the specific induction of relaxin gene expression.

In summary, the peptide hormone relaxin appears like a key player in the growth, progression and formation of metastases for cancers of the prostate, thyroid, endometrium, and breast, and novel antagonists should soon indicate whether relaxin is an important new target for cancer therapy.

Remission

Definition

A disease state in which the symptoms or signs of a disease are abated. In leukemia, complete remission is defined by normal bone marrow, peripheral blood characteristics, and a normal performance status. The state following therapy where no disease can be detected by convention means (i.e., microscopic or radiological exam).

►Acute Lymphoblastic Leukemia
►Minimal Residual Disease
►Complete Hematologic Remission

Remodeling

Definition

Consists of a series of phenotypic changes in preneoplastic and neoplastic lesions leading to the acquisition of a normal apparent morphology. This phenomenon may indicate a ►redifferentiation of preneoplastic and neoplastic cells which, however, does not seem to be terminal.

►Preneoplastic lesions

Renal Carcinoma

Berton Zbar
Laboratory of Immunobiology, NIH – Frederick, Frederick, MD, USA

Definition

Renal carcinoma is a cancer, arising from the epithelial cells of the kidney and must be distinguished from tumors of the renal pelvis.

Characteristics

World wide about 150,000 people develop renal carcinoma each year, and ~78,000 individuals die from the disease. Most cases of renal carcinoma are sporadic, that is most renal carcinomas occur without an inherited predisposition to develop renal cancer. About 1–5% of renal carcinomas are the consequence of an inherited tendency to develop renal cancer.

Cigarette smoke (►tobacco carcinogenesis) is a recognized environmental factor that can lead to renal cancer. Exposure to high doses of trichloroethylene, an industrial solvent, may also lead to renal cancer. Renal tumors occur more commonly in men than woman. The male/female ratio for renal cancer is about 2/1.

Early Diagnosis

Currently, there are no accepted methods for the early diagnosis of renal cancer. Although population-based screening by renal ultrasound would undoubtedly detect renal tumors in asymptomatic individuals, this procedure is not considered cost effective. No serological tests are currently available for the early detection of renal cancer.

Treatment

Surgical removal of the renal cancer, usually by nephrectomy, is so far the best treatment of renal cancer. Treatment of patients with metastatic disease is difficult; there are no treatments available that consistently eradicate metastatic renal carcinoma.

Types of Renal Cancer

Renal cancer is not one disease as such. There are at least four types of epithelial renal cancer, which can be distinguished by their histological appearance (Fig. 1):

- Clear cell renal carcinoma (75% of sporadic renal carcinomas)
- Papillary renal carcinoma (15%)
- Chromophobe renal carcinoma (5%)
- Renal oncocytoma (5%)

There is evidence, suggesting a correlation between the histological type of renal cancer and prognosis.

Renal Cancer Genes

Studies of families with inherited forms of renal cancer have led to the identification of two genes that, in their mutant form, predispose individuals to the development of renal neoplasia, the ►von Hippel-Lindau (VHL) tumor suppressor gene and the ►MET proto-oncogene. Current studies are aimed at identifying a third renal cancer gene – the BHD gene, responsible for the ►Birt Hogg Dube syndrome.

The VHL and the MET gene are mutated in sporadic renal carcinomas. The VHL gene is mutated in about 50% of sporadic clear cell renal carcinomas. It is inactivated by hypermethylation in about 15% of sporadic clear cell renal carcinomas. The MET proto-oncogene is mutated in about 15% of sporadic papillary renal carcinoma.

Types of Inherited Renal Cancer

The currently recognized forms of inherited renal carcinoma are: von Hippel-Lindau disease (VHL), inherited balanced translocations involving human chromosome 3, hereditary papillary renal carcinoma (HPRC) type 1, the Birt Hogg Dube (BHD) syndrome and familial clear cell renal carcinoma.

Clinical Features of Renal Cancer Suggesting Hereditary Renal Cancer

Several characteristics of inherited renal cancers make them distinct from sporadic renal cancers. Frequently, other family members are affected with renal tumors. In general, the renal tumors are multiple and often involve both kidneys. Individuals with renal tumors need to determine whether their tumors are single or multiple and whether other family members have had renal cancer. In cases of hereditary renal cancer, it is essential to test other, apparently healthy, family members for occult renal tumors.

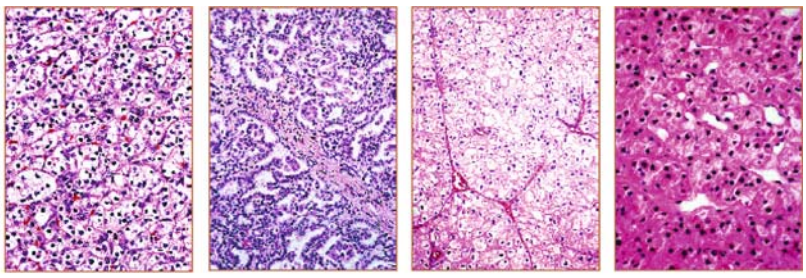
Mechanisms of Development of Inherited Renal Cancers

The VHL gene is a classic ►tumor suppressor gene. In the ►von Hippel-Lindau disease and in sporadic clear cell renal carcinoma, renal tumors develop as a consequence of the loss or inactivation of both copies of the VHL gene. The result of an inactivated VHL gene is the lack of the VHL protein in proximal renal tubular epithelial cells.

The von Hippel-Lindau disease is a rare inherited disorder characterized by a predisposition to develop tumors in multiple organs: brain, spinal cord, eye, adrenal gland, kidney, pancreas, and epididymis. There are three distinct clinical types of VHL:

- Type 1 is characterized by renal carcinoma, brain, spinal and eye tumors without tumors of the adrenal glands (►pheochromocytoma)
- Type 2A is characterized by pheochromocytoma, eye and ►brain tumors without renal cell carcinoma
- Type 2B is characterized by pheochromocytoma, renal cell carcinoma, eye and brain tumor

VHL types 2A and 2B are produced by germline missense mutations in the VHL gene; VHL type 1 is produced germline mutations that produce truncated VHL proteins.



Renal Carcinoma. Figure 1 Frequency of mutations in sporadic human renal epithelial neoplasms.

The proto-oncogene MET encodes the receptor for hepatocyte growth factor/►scatter factor. Renal tumors in patients with hereditary papillary renal carcinoma type 1 as well as a subset of sporadic papillary renal carcinomas, develop as a consequence of the constitutive activation of the MET cell surface receptor. Hereditary papillary renal carcinoma type 1 is characterized by an inherited predisposition to develop multiple, bilateral papillary renal carcinomas. Founder effects have been observed in several families with HPRC. All germline and somatic mutations, identified to date in the MET gene, were missense mutations and were located in the tyrosine kinase domain of the gene.

The Birt Hogg Dube syndrome is an inherited disorder, characterized by a predisposition to develop multiple tumors of the hair follicle (fibrofolliculomas). Usually, the fibrofolliculomas occur on the face and neck. Furthermore, a predisposition a predisposition to develop spontaneous pneumothorax and renal cancer has been described. Pathologists have had difficulty classifying the renal tumors associated with the Birt Hogg Dube syndrome, they appear to be either chromophobe renal carcinomas or renal oncocytomas.

Renal-Cell Carcinoma

Definition

Synonym ►Renal Carcinoma; Is a type of kidney cancer that involves cancerous changes in the cells of the renal tubule (epithelial cells) and composed of large, polygonal cells. Also known as clear-cell carcinoma, carcinoma of the renal parenchyma, or sometimes referred as hypernephroma.

►Birt–Hogg–Dubé Syndrome

Renal Excretion

Definition

Is the excretion of a drug through the kidney into the urine.

►ADMET Screen

Reovirus

Definition

Reo is an acronym for respiratory, enteric, orphan (of a disease). Reoviruses are apathogenic human viruses with a double stranded RNA genome that make naked icosahedral particles used in ►oncolytic virotherapy.

Reoxygenation

Definition

Is the process by which viable hypoxic cells (cancer cells living in the tumor ►microenvironment characterized by the oxygen tension below 10 mm Hg) become better oxygenated after irradiation. Reoxygenation of hypoxic tumor cells occurs between treatments during fractionated irradiation. This process is relevant to the therapy outcome, because fully oxygenated cells are three times more radiosensitive than are hypoxic cells.

Repair of DNA

Errol C. Friedberg
University of Texas Southwestern Medical Center, Dallas, TX, USA

Definition

The repair of DNA comprises a group of distinct biochemical pathways by which various types of

damage to DNA, especially damage to the nitrogenous bases A, T, C and G, is repaired. Such damage can occur spontaneously in living cells as the result of the generation of products of oxidative metabolism that interact with the bases of DNA. Base damage in DNA also transpires as the result of interactions between environmental agents, especially cancer-causing chemicals, with DNA. DNA repair of base damage can be conveniently classified as follows.

Characteristics

Reversal of Base Damage

This mode of DNA repair involves the direct reversal of selected types of base damage. A good example is the restoration of thymine dimers in DNA to their native monomeric state. Thymine dimers (T↔T) are formed by the abnormal chemical joining of adjacent thymine bases (T, T) in DNA and frequently occurs in cells that are exposed to ultraviolet (UV) radiation, such as sunlight. These lesions in DNA can interfere with normal DNA functions such as DNA replication and/or transcription. One way that thymine dimers are repaired in cells is by the action of an enzyme called DNA photolyase, which directly reverses the chemistry of the thymine dimers so that they are once again in their monomeric native state (T↔T→ T, T).

Removal of Damage

This mode of DNA repair involves the enzymatic excision of damaged bases.

- One biochemical pathway of excision repair involves the excision of damaged bases as the free base and is therefore called base excision repair. Base excision repair is employed by cells to remove simple chemical modifications such as those produced by ►oxidative DNA damage or by simple chemicals, including alkylating agents that are used to treat various cancers.
- A second biochemical pathway for the removal of damage involves the excision of a relatively large piece of one strand of the DNA duplex that includes the damaged base. This is called nucleotide excision repair. ►Nucleotide excision repair operates against thymine dimers in DNA (in addition to DNA photolyase) as well as in the removal of many other types of chemical altered bases.
- A third mode of excision repair involves the excision of bases in DNA that are incorrectly paired (mispaired bases). This type of excision repair is called ►mismatch repair.

Repair of DNA and Cancer

Defective DNA repair allows the persistence of damaged bases in the genome. When such DNA is copied during ►DNA replication mistakes are made leading to permanent mutations. Mutations that affect oncogenes or tumor suppressor genes can lead to cancer. Hence, defective DNA repair is an important cancer predisposing factor. Patients who suffer from the hereditary disease ►xeroderma pigmentosum (XP) are unable to carry out nucleotide excision repair of DNA. Hence, when exposed to sunlight, the thymine dimers generated in the DNA of their skin cells accumulate and result in a very high incidence of skin cancer. Patients who are genetically prone to ►colon cancer suffer from a disease called hereditary non-polyposis colon cancer (►HNPCC) and are often defective in ►mismatch repair. Thus, they accumulate mutations that lead to cancer of the colon.

Base excision repair often removes bases that are altered by alkylating agents used for cancer treatment. In principle therefore, inhibiting base excision repair in cancer (but not in other normal) cells would be expected to improve the therapeutic efficacy of alkylating agents. For this reason DNA repair enzymes are strategic targets for rational design of anticancer agents.

Repair of DNA Strand Breaks

Strand breaks can be produced in DNA after exposure to ►ionizing radiation (X-rays) and can also occur spontaneously in cells as a result of oxidative damage. Specialized repair pathways operate to repair both single- and double-strand breaks in DNA. The proteins encoded by the breast cancer genes ►BRCA1 and ►BRCA2 are believed to be involved in the repair of strand breaks in DNA.

Repeat Dose Toxicity Studies

Definition

Sometimes referred to as “subacute toxicity studies” or if dosing for longer periods “subchronic” for periods up to 3 months or “chronic studies” if longer, these are simply standardized studies whereby groups of animals are given daily doses of drug for different periods of time. Periods are usually 14 days or 1 month, 6, 9 and sometimes 12 months. Many parameters are usually

measured such as general clinical comportment, blood chemistry, hematology and electrocardiographic activity Full autopsies and microscopic examinations are conducted at the end of these studies. They are conducted according to ►Good Laboratory Practice.

►Preclinical Testing

Reperfusion

Definition
Restoration of blood flow.

Repetitive DNA

Definition
DNA sequences that are repeated in the genome. These sequences do not code for protein. One class consists of sequences referred to as ►minisatellites, 10–100 nucleotides, repeated thousands of times. Another class, much shorter from one to few nucleotides, is termed microsatellite (►microsatellite instability). Longer repeats, approximately 300 nucleotides in length, are ►Alu elements. A class of much longer repetitive DNA (up to 6,000 nucleotides) is represented by long interspersed nuclear elements (►LINE element).

Replication

Definition
Refers to the duplication of DNA during ►S-phase of the ►cell cycle.

Replication-Activated Adenovirus

►Oncolytic Adenovirus

Replication-Competent Adenovirus

►Oncolytic Adenovirus

Replication-Dependent Histone Genes

Definition
Are genes coding for ►histone proteins, specifically expressed in a ►cell cycle dependent manner. They differ from constitutive histone genes because they lack ►introns, and their mRNA end with a specific structure known as "stem-loop' instead of a poly-A tail. In the human genome they are located in two clusters on chromosomes 1 and 6.

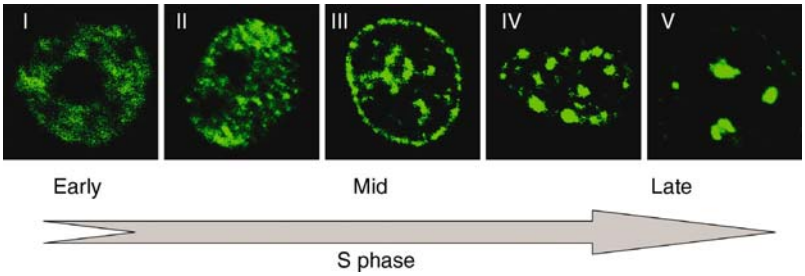
Replication Factories and Replication Foci

Alessandra Montecucco
Istituto di Genetica Molecolare CNR, via Abbiategrasso, Pavia, Italy

Synonyms
Replication sites

Definition
Are subnuclear functional domains where genomic DNA replication takes place.

Characteristics
In mammalian cells ►DNA replication takes place at discrete nuclear sites called replication foci where newly synthesized DNA accumulates. Replication foci can be revealed by pulse-labeling cells with thymidine analogues such as 5-bromo-2′-deoxyuridine (►BrdU) or biotinylated ►dUTP, which are subsequently detected by fluorescent probes. The distribution pattern of replication foci within the nucleus changes according to a precise program during ►S phase. The succession of these spatial patterns during the course of S phase of tumor HeLa cells is shown in Fig. 1. During the first 5 h



Replication Factories and Replication Foci. Figure 1 Subnuclear distribution of replication foci in different moments of the S phase. Exponentially growing HeLa cells were pulse labeled with BrdU and stained with FITC-conjugated anti-BrdU antibodies. Five patterns of replication foci (indicated by roman numbers) that are diagnostics of different moments of the S phase (from early to late-S) can be distinguished.

of S phase, replication takes place within many foci distributed throughout the nucleoplasm (type I/II patterns). Several sets of these early-replicating foci are activated over the course of the first half of S phase, each completing DNA synthesis in about 60 min. In mid-S phase, replication takes place at nuclear periphery and in perinucleolar regions for 2–3 h (type III). In the final few hours, replication occurs within a few relatively large foci that are present throughout the nucleus (type IV/V). Individual replication foci are only active for about 1 h before adjacent foci are activated and reflect the timing of firing of the ►origins of replication (►Replication licensing system). Notably, labeling with BrdU in vivo allows the distribution of ►replicons labeled during any interval of S phase to be visualized in any subsequent ►cell cycle phase and even over many cell generations. This suggests that replication foci are a general feature of ►chromatin organization (►Nucleosomes).

Colocalization on replication foci of replicative enzymes gave rise to the idea that replication takes place within factories. Replication factories assemble in response to demand and their appearance precedes DNA synthesis at specific nuclear sites. The number and size of the replication factories vary throughout S phase according to a program that reflects the replication of various portions of the genome. At the onset of S phase, the factories are associated with transcribed genes whereas the appearance of mid- and late-S phase factories coincides with the replication of silent ►heterochromatic regions. Replication factories are composed of groups of coordinately replicated chromosomal domains. Considering the number of factories, the length of the genome and the rate of a bi-directional ►replication fork, it has been calculated that an average factory in early S phase contains ~5–6 replicons spatially distributed in a small nuclear volume. Replication factories are stably anchored in the nucleus and their distribution changes through a gradual, coordinated assembly and disassembly process throughout S phase. Thus, the large replication factories in late S phase do not originate from the coalescence of several small factories but are assembled de novo during S phase.

Protein Composition of Replication Factories

Several studies have focused on identifying the constituents of the replication factories. The general approach consisted of the staining of the cells with antibodies against specific candidate proteins during S phase and observing whether these proteins colocalize with BrdU-labeled replication foci. Using this approach, several replication proteins, including ►PCNA, DNA ligase I, replicative DNA polymerases (DNA polymerase α and δ) and flap endonuclease 1, have been shown to be present at replication foci during S phase. In the last few years, the use of confocal microscope analysis has shown that, in addition to replicative enzymes, replication factories contain a still growing list of factors involved in DNA metabolism and cell cycle control (Table 1), underscoring the relevance of these functional domains in the integration and coordination of DNA replication with ►DNA repair (►Repair of DNA) and cell cycle progression. Therefore the factory model favors flexibility and crosstalk between these metabolic pathways.

Interestingly, early and late S phase factories differ not only in size but also in their composition. For instance, DNA polymerase ε colocalizes only with late-S replication factories, suggesting that this enzyme participates in DNA replication late in S phase. Also the ►histone deacetylase colocalizes with late S phase but not with early S phase replication factories. This seems functionally linked to the hypoacetylated status of the ►heterochromatin that is replicated in late S phase. The proteomic analysis (►Proteomics) of replication factories is under way and the identification of the protein composition of the factories will help to understand the mechanisms that control early- and mid/late-firing origins of replication in mammals.

Replication Factories and Replication Foci. Table 1 List of the proteins that colocalize with the replication factories

Proteins	Function in DNA replication
DNA polymerase α	Synthesis of Okazaki fragments
Flap endonuclease 1	Maturation of Okazaki fragments
DNA ligase I	Ligation of Okazaki fragments
Replication protein A	Single strand DNA binding
DNA polymerase δ	Synthesis of the leading strand
Proliferating cell nuclear antigen (PCNA)	DNA polymerase clamp
Replication factor C	Clamp loader
Minichromosome maintenance (MCM) 8	DNA unwinding
DNA polymerase ε	DNA replication? Checkpoint?
Kin17	DNA replication?
Proteins	Function in chromatin organization
DNA methyltransferase 1	Cytosine methylation
Histone deacetylase 2	Deacethylation of histone tails
Chromatin assembly factor 1	Nucleosomes assembly
Proteins	Function in DNA repair
Uracil-DNA glycosylase (UNG2)	Removal of uracil from DNA
DNA polymerase η	Translesion DNA synthesis
DNA polymerase j	Translesion DNA synthesis
MSH3/MSH6	DNA mismatch repair
MYH	DNA mismatch repair
MRE11	DNA double strand breaks repair
NBS1	DNA double strand breaks repair
Proteins	Function in cell cycle progression
Cyclin A/Cdk2	Phosphorylation of replicative factors
Rad17	Checkpoint protein

Extensive mutational analysis of human DNA ligase I and DNA methyltransferase 1 identified a short motif highly homologous in the two proteins as the determinant sufficient to target a protein to replication factories. This sequence, known as the replication factory targeting sequence (RFTS), corresponds to the first 20 amino acids of human DNA ligase I and consists of two boxes: box 1 contains the sequence IXXFF (I, isoleucine; X, any amino acid; F, phenylalanine) whereas box 2 is rich in positively charged amino acids (arginine and lysine). The identification of the RFTS opens up the possibility of disassembling the factories by targeting specific peptides. This perspective could be relevant in the search for new anti-proliferative drugs for cancer therapy.

The RFTS overlaps an evolutionary conserved binding site for PCNA, an essential component of human ►replisome. Several proteins are recruited to the factories through the same conserved PCNA-binding site, suggesting that PCNA plays a central role in the recruitment and stable association of DNA replication proteins at replication factories. Consistent with its role in the organization of the factories, PCNA, unlike replication protein A and DNA ligase I, shows only a little turnover at replication factories.

The cell cycle inhibitor $p21^{CIP1/WAF1}$ (►p21WAF1/CIP1/SDI1) binds PCNA via the same motif. Peptide mapping studies and the elucidation of the crystal structure of the PCNA-binding peptide of $p21^{CIP1/WAF1}$ complexed with PCNA identified the interdomain connector loop of PCNA as the binding site for $p21^{CIP1/WAF1}$. This implies that all the other DNA replication proteins that contain a similar PCNA-binding motif bind to the same or at least overlapping regions of PCNA. Consistent with this idea $p21^{CIP1/WAF1}$ inhibits the binding of flap endonuclease 1, DNA methyltransferase 1 and DNA ligase I to PCNA. Therefore it has been proposed that $p21^{CIP1/WAF1}$ inhibits DNA replication by binding PCNA within replication factories and causes the release of DNA replication proteins from these structures.

Regulation of the Formation of Replication Factories

Post-translational modifications of the replicative factors are involved in the dynamic program of

replication factories. For instance, two immunologically distinct DNA polimerase α-primase subpopulations have been described in mammalian cells. The two pools differ mainly in the phosphorylation status of the p68 regulatory subunit by Cdk2/cyclin A (►Cyclin dependent kinases) protein kinase. By using monoclonal antibodies selective for the two enzyme populations, it has been shown that only the phosphorylated enzyme revealed by 132–20 antibody colocalizes with the replication factories. Several pools of human DNA ligase I, differing in their phosphorylation level in vivo, have been described. Four serines phosphorylated during the cell cycle have been mapped by mass spectrometry. Substitution of these serines with the phosphoserin-mimetic aspartic acid hampers the recruitment of human DNA ligase I to replication factories, supporting the idea that phosphorylation is one of the mechanisms controlling the dynamics of replication factories during S phase.

The ordered assembly and disassembly of replication factories are monitored by the cell cycle ►checkpoints, signaling pathways that halt progression through the cell cycle until an earlier process, such as DNA replication, is complete. In the presence of drugs that stall replication forks, such as aphidicolin, the distribution patterns of replication factories are stabilized until the drug is removed from the culture medium and the dynamic program of genome replication is temporarily blocked. This requires the action of the ►ATR-dependent checkpoint pathway. On the contrary, activation of the intra-S phase checkpoint (►S-phase damage-sensing checkpoints) by ►topoisomerase II-DNA cleavage complexes induced by the anticancer drug ►etoposide causes the disappearance of active replication factories, strongly affecting the functional organization of S phase nuclei in tumor cells. Therefore the type of damage, its distribution relative to the moving fork and the mechanism involved in the ►DNA damage (►DNA Damage Responses) recognition, could determine the choice between stabilization and dispersal of replication factories in S phase.

Clinical Relevance

The clinical relevance of the replication factories derives essentially from the following aspects:

- Replication factories can be easily detected in immunocytochemistry with antibodies against several replicative proteins and selectively mark S phase cells. Thus cell staining with anti-replication factories antibodies is useful to estimate the fraction of replicating cells in a specimen. Moreover the expression level of several constituents of the replication factories strongly correlates with the rate of cell proliferation. This makes it possible to expand the repertoire of clinical ►biomarkers for the analysis of cell ►proliferation. Monoclonal antibodies against PCNA, flap endonuclease 1, Chromatin assembly factor 1 and DNA ligase I, are used in ►immunohistochemistry to analyze the kinetics of cell proliferation of neoplastic disorders and (►Preneoplastic lesions) in human pathology.
- Anticancer drugs belonging to the class of topoisomerase I and II poisons, such as ►camptothecin and ►etoposide induce the dispersal of replication factories in tumor cells. This effect is easily appreciable in staining cells with anti-replication factories antibodies. Therefore the effect on the replication factories can be considered to develop cell-based assays for screening of new potential anticancer drugs. Since the dynamics of the replication factories is controlled by cell cycle checkpoint pathways, this kind of assay could also be relevant to optimize strategies to selectively target checkpoint-deficient cancer cells.

Replication Fork

Definition

Y-shaped regions of a replicating DNA molecule at which the two daughter strands are formed and separate. Replication forks are the protein machine that translocates along double-stranded DNA, replicating both strands as it moves.

►Replication Factories and Replication Foci
►Replication Licensing System

Replication Licensing System

Julian Blow
Wellcome Trust Biocentre, University of Dundee, Dundee, Scotland, UK

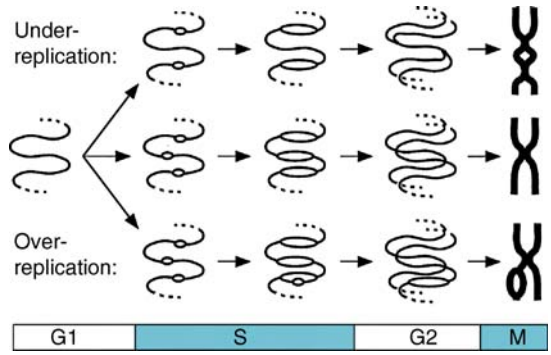
Definition

Ensures that no sections of chromosomal DNA are replicated more than once in a single ►cell cycle. It loads complexes of ►MCM/P1 proteins onto ►replication origins early in the cell cycle, which "license" the origin for a single initiation event in the subsequent S phase. As a consequence of replication, the MCM/P1 proteins are removed from the DNA, thus ensuring that re-replication of DNA does not occur in a single cell cycle.

Characteristics

In order to minimize the risk of potentially cancer-causing mutations occurring whenever a cell divides, the duplication of chromosomal DNA must be as accurate as possible. All the genome must be replicated, with nothing left unreplicated and nothing replicated more than once. This problem is made complicated by the way that eukaryotes undertake genome duplication. ►Replication forks progress along double-stranded DNA and copy both strands at a rate of 10–100 base pairs per second. However, a single replication fork would take years to duplicate a typical genome and so thousands of replication forks are used, initiated from replication origins scattered throughout the genome (Fig. 1). To ensure the complete replication of eukaryotic chromosomes, these origins must be sufficiently closely spaced so that all the intervening DNA can be replicated before entry into mitosis occurs. Failure to replicate even small sections of DNA could lead to disastrous consequences as the sister chromatids are pulled apart during mitosis (Fig. 1, "under-replication"). On the other hand, to prevent any section of DNA being replicated more than once in a single S phase, each origin must fire no more than once in each cell cycle. Over-replication of DNA is likely to be very harmful as it would represent an irreversible genetic change, potentially leading to the risk of recombination and amplification occurring in the duplicated region (Fig. 1, "over-replication"). The replication licensing system permits replication origins to be used efficiently, whilst preventing them from firing more than once in single cell cycle.

Precise chromosome duplication is achieved by separating the initiation of DNA replication into two phases (Fig. 2, left-hand panel). In the first phase, which occurs early in the cell cycle, replication origins are



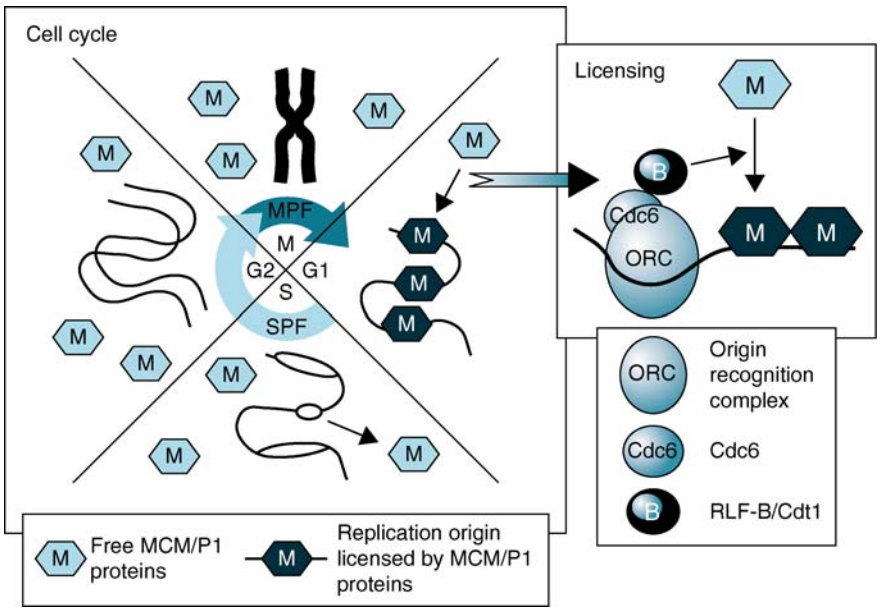
Replication Licensing System. Figure 1 Ensuring precise chromosome replication. (a) Small segment of chromosomal DNA, replicated from three origins is shown during the cell cycle. *Middle panel*: successful duplication. *Top panel*: under-replication due to the failure of one of the origins to fire. *Bottom panel*: over-replication, due to one of the origins firing a second time in S phase. The four stages of the cell cycle – G1, S (DNA synthesis), G2 and M (mitosis) – are shown below.

"licensed" by loading the RLF-M complex of MCM/P1 proteins (shown as "M" in Fig. 2). In the second phase, ►S-phase promoting factor (SPF) becomes active and promotes the initiation of a single pair of replication forks at each licensed origin. S-phase promoting factors probably consist of various ►cyclin-dependent kinases (CDKs) as well as the ►Cdc7/Dbf4 protein kinase. As each origin initiates its MCM/P1 proteins are removed, thereby resetting the origin to the unlicensed state. To ensure that no re-initiation occurs, the ability to license origins must completely cease before any replication forks are initiated; even a small amount of licensing activity present during S phase could lead to the re-replication of part of the genome. The way this regulation is achieved is currently poorly understood.

Molecular Composition

The replication licensing system consists of two components: The RLF-M complex of MCM/P1 proteins, which constitutes the license, and RLF-B/Cdt1, which is required to load RLF-M onto chromatin early in the cell cycle. Other proteins are also required on the DNA that allow it to serve as a substrate for the replication licensing system. These include the Origin Recognition Complex (ORC) and the Cdc6 protein (Fig. 2, right-hand panel). This group of proteins form the "►pre-replicative complex" present at replication origins during late mitosis and G1. All of these are potentially under cell-cycle regulation to prevent the re-licensing of replicated DNA.

There are six MCM/P1 proteins, termed Mcm2, 3, 4, 5, 6 and 7, which are in the form of a hetero-hexamer in the active RLF-M complex. However, a number of other MCM/P1 protein complexes also exist, which



Replication Licensing System. Figure 2 Left-hand panel: a small segment of genomic DNA containing three replication origins is shown during the cell cycle. The factors that drive cell cycle progress (SPF and MPF) are shown by arrows. In late mitosis and early G1, replication origins are "licensed" by binding the MCM/P1 complexes (hexagons). During S phase, S-phase-promoting factor (SPF) induces replication forks to initiate at licensed origins, and the MCM/P1 proteins are displaced. In G2 phase, all replication forks have terminated, all origins are unlicensed, and all DNA is replicated. Mitosis-promoting factor (MPF) then triggers the condensation of DNA into chromosomes and its segregation to the two daughter cells. *Right-hand panel*: the licensing reaction requires ORC, Cdc6 and RLF-B/Cdt1, and results in multiple copies of the MCM/P1 complex being assembled onto each replication origin.

are probably intermediates in an assembly/disassembly pathway. In vertebrates they are abundant nuclear proteins, and 10–20 copies of the RLF-M hetero-hexamer are loaded onto each ►replication origin. The precise role of the MCM/P1 proteins in DNA replication is currently unclear, though they have been shown to have helicase (DNA unwinding) activity. This helicase activity may be involved in allowing the replication fork proteins to load onto or move along the DNA. Various lines of evidence suggest that the MCM/P1 proteins are substrates of the Cdc7/Dbf4 kinase that is involved in activating replication origins during the cell cycle. As a consequence of MCM/P1 protein phosphorylation by Cdc7/Dbf4, other replication factors such as DNA polymerase α are then recruited to the replication origin.

RLF-B/Cdt1 acts to promote the loading of the RLF-M complex onto DNA, but thereafter does not appear to be required for the maintenance of the licensed state. Its precise molecular activity is currently unknown. RLF-B/Cdt1 is under tight cell cycle control and this regulation is likely to be important in preventing re-replication of DNA in a single cell cycle.

The Origin Recognition Complex (ORC) consists of six polypeptides termed Orc1, 2, 3, 4, 5 and 6. Binding of ORC to DNA appears necessary for that place to be defined as a replication origin. In addition to its role in establishing replication origins, ORC also appears to be involved in establishing repressive chromatin states at specific sites on DNA.

The binding of Cdc6 to chromatin is dependent on the presence of ORC. It is required for the origin to become licensed but is not for the maintenance of the licensed state once licensing has occurred. In mammalian cells, Cdc6 is exported from the nucleus at the end of G1 and does not regain access to the chromatin until the end of the subsequent mitosis. In yeast, Cdc6 is degraded at the end of G1. These features are likely to contribute to mechanisms that prevent re-licensing of DNA once S phase has started.

Regulation

Since re-replication of segments of chromosomal DNA is likely to cause very significant genetic changes to the cell, it is obviously crucial for eukaryotic cells to prevent this from happening. In order for the licensing system to operate properly and ensure that no DNA re-replicates, its activity must completely cease before S phase starts (Fig. 2). Recent work suggests that cells may possess multiple redundant mechanisms for ensuring this. One important consideration is that the components required to load the MCM/P1 proteins onto DNA (ORC, Cdc6, RLF-B/Cdt1) are not required

for the continued binding of the MCM/P1 proteins. Therefore in principle, licensing can be prevented by inhibiting the activity of either ORC, Cdc6 or RLF-B/Cdt1/Cdt1, whilst the licensed state is maintained. Although it is currently not possible to describe in molecular detail how licensing is prevented late in the cell cycle, three important themes have emerged: regulation by changes in subcellular localization, regulation by cyclin-dependent kinases and regulation by geminin.

Early experiments that characterized the replication licensing system showed that in order for replicated nuclei from the G2 phase of the cell cycle to undergo a further round of DNA replication, they had to undergo a transient permeabilization of their nuclear envelope. This suggested that re-replication of chromosomal DNA was regulated at least in part by compartmentalization of regulatory components between the nucleus and cytoplasm. Recent work has confirmed this idea, but has shown that different organisms actually regulate different components of the licensing system by this mechanism. In mammalian cells, the Cdc6 protein, which is required on the DNA for licensing to occur, is nuclear in late mitosis and G1 and is exported from the nucleus during S phase and G2. The lack of Cdc6 in the nucleus late in the cell cycle is likely to play an important role in preventing the re-licensing (and hence re-replication) of the DNA. A different version of this story is seen in the yeast *Saccharomyces cerevisiae*, where the MCM/P1 proteins, rather than Cdc6, are present in the nucleus only in late mitosis and early G1 and are exported from the nucleus at later stages of the cell cycle. Physically separating essential licensing components from their DNA substrate by nuclear export would seem to be a powerful way of preventing the inappropriate licensing of replicated DNA.

Another important aspect of the regulation of the replication licensing system involves cyclin-dependent kinases (CDK). These kinases promote the major transitions of the eukaryotic cell division cycle, including entry into S phase (SPF) and entry into mitosis (MPF) (Fig. 2). During late mitosis and early G1, however, CDK activity is low and this is the period when replication licensing can occur. Research in a number of different experimental systems have shown that CDKs, either directly or indirectly, can inhibit origin licensing. The nuclear exclusion of yeast MCM/P1 proteins and mammalian Cdc6 appears to be promoted by high CDK activity. CDKs may also have other inhibitory effects on the activity of the licensing system. For example, in S. cerevisiae, the CDK-dependent degradation of the Cdc6 protein occurs during later stages of the cell division cycle. This idea provides an elegant explanation for cell cycle regulation of chromosome replication, with an early pre-replicative phase where CDK activity is low and licensing occurs, followed by progression into S phase where CDK activity is high and licensing is inhibited. Another key licensing regulator that has recently been identified is geminin, a small protein whose abundance changes dramatically during the course of the cell cycle: it builds up in S phase and G2, but is degraded on exit from metaphase. Geminin tightly binds and inhibits the RLF-B/Cdt1 component of the licensing system, and may represent the major activity preventing re-licensing of replicated DNA late in the cell cycle of higher eukaryotes.

Clinical Relevance

When cells terminally differentiate or enter quiescence, their replication origins do not remain licensed and the MCM/P1 proteins are lost from the chromatin. The MCM/P1 proteins therefore can be used as unique markers for proliferative cells. Antibodies to the MCM/P1 proteins been shown to be useful in analyses of cervical smears and urine samples to detect abnormal proliferative cells. More speculatively, failures of the replication licensing system may underlie the ►chromosome rearrangement and gene ►amplification observed in many types of cancer. The replication licensing system as a whole also represent a potentially powerful target for anti-proliferative drugs, though this potential has yet to be explored.

Replication Origin

Definition

Is the site on DNA where ►replication forks are initiated.

►Replication Licensing System

Replication-Selective Adenovirus

►Oncolytic Adenovirus

Replication-Selective Viruses

►Oncolytic Virus

Replication Sites

►Replication Factories and Replication Foci

Replicative DNA Lesion Bypass

►DNA-Damage Tolerance

Replicative DNA Polymerase

Definition

A group of enzymes that synthesize a new DNA strand on a template strand by adding nucleotides one at a time to the 3′-OH end of DNA.

►DNA-Damage Tolerance

Replicon

Definition

Region of DNA replicated form one origin of DNA replication, replication unit.

►Replication Factories and Replication Foci

Replisome

Definition

Multiprotein complex assembled at the replication fork that carries out the synthesis of DNA.

►Replication Factories and Replication Foci

Reporter Gene Assays

Definition

Indirectly monitor the transcriptional activity of cellular genes through the production of proteins with easily measurable activities such as luciferase (►Luciferase Reporter Gene Assays), β-galactosidase (β-Gal), chloramphenicol acetyltransferase (CAT), β-lactamase (β-lac), alkaline phosphatase (SEAP or SPAP), or green fluorescent protein (GFP). They have a wide variety of uses as surrogate markers for gene transcription in cells and *in vivo*, and are valuable tools for cancer research, detection, and treatment.

Repressor Complex

Definition

A multi-protein complex that represses ►transcription. Contains three components: a DNA-binding subunit, a ►corepressor (for example SMRT, Sin3, co-REST) and a ►histone deacetylase.

Reproductive Toxicology Studies

Definition

Comprise teratology studies at examine the potential for drugs to induce structural defects to the developing fetus when the mother is being dosed with drug and studies which investigate the effects of drugs on gonads, fertility, gestation, the fetus, lactation and general reproductive performance. Such studies are usually conducted either in rabbits or rodents or both.

►Preclinical Testing

REPSA

Definition

Restriction endonuclease protection, selection, and amplification (REPSA) is a ►combinatorial selection method used to identify consensus protein, nucleic acid, and small molecule binding sites on duplex DNA. It differs from other combinatorial selection methods in that it does not require the physical separation of ligand-bound from unbound selection templates and therefore can be applied to unknown and uncharacterized mixtures of multiple, native ligands.

Reserve Cell Carcinoma

►Extrapulmonary Small Cell Cancer

Residual Disease

►Minimal Residual Disease

Resistance

Definition

The growth of cancer cells despite therapy. There are many mechanisms, but the final endpoint is that cancer cells are unresponsive to therapy.

►Minimal Residual Disease
►Multidrug Resistance

Resistance Modulation

►Chemosensibilization

Resistance Reversion

►Chemosensibilization

Respiration Rate

Definition

Synonym O_2 consumption rate or O_2 uptake rate, is the amount of oxygen consumed by a tissue or organ per unit time.

►Oxygenation of Tumors

Respiratory Burst

Definition

Synonym oxidative burst; refers to the rapid release of ►reactive oxygen species (ROS) by immune cells, such as ►macrophages and ►neutrophils. Superoxide and hydroxyl radicals as well as ►hydrogen peroxide are the most important chemicals.

Respiratory Chain

Definition

Is a series of four mitochondrial protein complexes which transport electrons from reducing equivalents (NADH, $FADH_2$) to oxygen, to form H_2O, coupled to proton extrusion. The consequent establishment of an electrochemical proton gradient drives ATP synthesis.

►Amine Oxidases

Response Elements

Definition

Are sequences of DNA within the ►promoter region of genes that are able to bind specific proteins or protein

complexes to regulate transcription of that particular gene. A particular gene may have different types and multiple response elements. This enables well-regulated and sensitive control over ►transcription.

Restenosis

Definition

Narrowing of a conduit such as a blood vessel after a blockage has been opened.

Resting Energy Expenditure

Definition

REE; Refers to the energy expended for normal cellular and organ function during resting conditions.

►Cachexia

Resting NK Cell

Definition

Are freshly isolated primary Natural Killer (NK) cells that have not been stimulated with cytokines in in vitro cultures.

►Natural Killer Cell Activation

Restriction Landmark Genomic Scanning

Christoph Plass
German Cancer Research Center Toxicology and Cancer Risk Factors, Heidelberg, Germany

Definition

RLGS; Is a two-dimensional gel electrophoresis method that is used as a genome scanning technique to survey genomes for copy number changes as well as changes in DNA ►methylation status of promoter sequences.

Characteristics

RLGS was developed as a high speed genome scanning technique for the identification of DNA ►amplification as well as DNA methylation changes. For RLGS, genomic DNA is restriction digested with a landmark enzyme, usually a rare cutting enzyme (e.g. *Not*I). The restriction ends are endlabeled in a fill-in reaction using [α-32P] labeled nucleotides. In the following second restriction digest (e.g. *EcoR*V), the DNA fragments are cut into smaller fragments suitable for separation in an agarose disc gel electrophoresis (first dimension). The next step is an in-gel restriction digestion with a third enzyme (e.g. *Hinf*I) that generates fragments with a size range between 100 and 2,000 base pairs. DNA fragments are separated in a polyacrylamide gel (second dimension). The gel is dried and exposed to an x-ray film. The resulting RLGS profile display highly reproducible patterns of RLGS fragments in which each fragment represents an end-labeled *Not*I site. Up to 2,000 end-labeled rare cutting restriction sites are displayed in a single RLGS profile. Most of the rare cutting restriction enzyme sites with GC-rich recognition sequences are located in the promoter region of genes, resulting in a selective display of gene sequences rather than random genomic sequences. The sequence of RLGS fragments can be determined through standard ►PCR-based or direct cloning procedures. An alternative to these methods is now the used of the available genomic sequences and virtual RLGS that allows to precisely predict the sequence of an RLGS fragment. If methylation sensitive enzymes are used as restriction landmarks, the method is able to provide a search for altered DNA methylation. Methylation in a *Not*I site would inhibit the restriction digest resulting in lack of endlabeling at this particular site. As a result this fragment would be missing from the RLGS profile. Since RLGS profiles are highly reproducible, this system allows the comparison of profiles derived from different tissues (e.g. normal versus diseased tissue) or between different individuals.

Application

Identification of Low Level DNA Amplification in Human Cancers

The endlabeling step in the RLGS procedure guarantees a correlation between RLGS fragment intensity and copy number of the particular sequence in the genome. The technique is sensitive enough to distinguish diploid (full intensity fragments) and haploid (half intensity fragments) copies. The majority of fragments in a human RLGS profile (about 90%) show diploid intensity, while a much smaller fraction of fragments (about 10%) have

haploid intensity. In addition, 10–15 fragments show markedly enhanced intensities (~50–200 times the intensity of a diploid fragment). It was shown that these fragments are derived from rDNA sequences, present at higher copy numbers in the genome. Such quantitative capacity allows the use of RLGS to scan tumor genomes for regions of DNA amplification. RLGS profiles established from tumor DNA are compared to profiles of matching normal tissue or blood of the patient. The tumor profile is analyzed for fragments that show an enhancement relative to the normal profile. Using this strategy CDK6 amplification in gliomas and low level amplification of MYCN and NAG was identified in medulloblastomas for the first time.

Global Scanning for DNA Methylation Changes in Human Cancers

If methylation sensitive restriction enzymes are used for the RLGS analysis, it is possible to scan genomes for differences in methylation patterns. The restriction landmark enzyme *Not*I is methylation sensitive. If a genomic *Not*I site is methylated, the enzyme does not cut and the site will not be endlabeled, resulting in a loss of this fragment in the RLGS profile. If the *Not*I site is unmethylated, the site is cut, the restriction ends are end-labeled and the fragment is present in the profile. ►CpG islands frequently contain gene promoters and/or exons and are usually unmethylated in normal cells. Since *Not*I sites are mainly located in CpG islands, RLGS is a method that allows the determination of the methylation status in thousands of CpG islands at one time. It was shown that methylation of CpG islands is associated with delayed replication, condensed chromatin and inhibition of transcription initiation in cancer. In a recent study, aberrant CpG island methylation in multiple human cancers was studied using RLGS. In this global analysis, the methylation status of 1,184 unselected CpG islands in 98 primary human tumors was tested. An estimated average of about 600 CpG islands (range of 0–4,500) of the 45,000 in the genome were aberrantly methylated in the tumors. This study also showed patterns of CpG island methylation that were common to several types of tumors together with patterns and targets that displayed distinct tumor type specificity.

Detection of Imprinted Genes

RLGS was used in two studies to identify allele specific methylation in the mouse genome. Allele specific methylation is associated with genes that show imprinted expression (►imprinting). Imprinted genes are either expressed exclusively from either the paternal or maternal allele and possess important functions during development. The screen is based on the identification of polymorphic RLGS fragments between two mouse inbred strains. Allele-specific methylation in a polymorphic fragment results in the presence of this fragment in one cross, but its absence in the reciprocal cross. RLGS was the first method that allowed a systematic screen for loci that showed allele specific methylation. The cloning of those sequences that were methylated gave access to novel imprinted loci. So far two novel imprinted genes (U2afbprs and Grf1) were identified in an RLGS scan.

Restriction Point

Definition

R-point; Represents the most important regulatory mechanism controlling ►cell cycle progression of mammalian cells in response to external mitogenic or growth inhibitory signals. The R-point is located in late G1 and is governed by the ►retinoblastoma protein pathway (►INK4 – ►cyclin D – ►CDK4/6 – ►Rb – ►E2F). Beyond the R-point, cell-cycle progression is largely independent of extracellular signals.

►Cell-Cycle Targets for Cancer Therapy

Resveratrol

Riccardo Ghidoni
Laboratory of Biochemistry and Molecular Biology, San Paolo Medical School, University of Milan, Milan, Italy

Synonyms

3,4′,5-trihydroxystilbene

Definition

Is a natural molecule belonging to the class of non-►flavonoid ►polyphenols. It exists as *trans* or *cis* isomers, both of which are present in nature, although the *trans* isomer is by far the most abundant, and commonly cited simply as resveratrol.

Characteristics

Resveratrol was first identified in 1940 in the roots of hellebore, then found to be present in grapevines in 1976 and in wine in 1992. Now it is known to be present in minor amounts in other nutritional sources, such as peanuts, blueberries and mulberries. In grape skin, where it is highly concentrated (50–100 mg/g), resveratrol is primarily biosynthesized in response to environmental stresses, such as ►UV radiation, ozone exposure, low temperature, injury or fungal infections (mainly by *Botrytis cinerea*). In wine, its concentration ranges from 0.7 to 7.7 mg/L, depending on cultivar, climate, and stress agents, red wines being approximately tenfold more enriched than white wines. Resveratrol is the active ingredient in the powder from the *Polygonum cuspidatum* root, which is used in traditional Japanese and Chinese medicine to treat various diseases. Many investigations in the last three decades have demonstrated a variety of biological properties of this molecule, including antioxidant activity, platelet antiaggregative effects, estrogen-like functions, immunomodulatory activity and chemoprevention. Resveratrol, as a wine ►polyphenol, has been claimed to be responsible for the so-called "French Paradox," i.e. the finding that the level of mortality for cardiovascular accidents is lower in France, where the consumption of wine is elevated, than in other highly industrialized Western countries with similar risk factor profile and a lower consumption of wine.

Mechanism of Action

In 1997, Jang et al. reported that resveratrol exerts anticancer effects by reducing tumor mass in rats. These authors demonstrated that resveratrol is effective in blocking *in vivo* the three stages of ►carcinogenesis: ►initiation, ►promotion and ►progression. Since this pioneer work was published, many studies employing human cancer cell lines have confirmed this observation and accepted resveratrol as a chemopreventive agent. Less convincing and still to be established is its chemotherapeutic potential.

The mechanisms underlying the antitumoral effects of resveratrol include a broad range of intracellular targets, whose modulation gives rise to overlapping responses that lead to growth arrest and death. Anyway, the efficacy of this molecule is still debated because of the multiplicity of affected targets and contradictory effects related to dose and time of treatment and to cellular phenotype, since often the specific cell molecular setting determines the response to treatment.

Since resveratrol mimics the structure of the synthetic estrogen ►diethylstilbestrol (for this it is defined also as a "►phytoestrogen"), it may compete with the growth promoting effect of estrogens. ►Breast cancer incidence among women in Western countries is sixfold higher than that among women in Asia who consume daily soy products rich in phytoestrogens.

Mechanisms of action include the inhibition of ►phase I enzymes, as ►Cytochrome P450, responsible for activating ►xenobiotics and the induction of ►phase II enzymes that conjugate these activated compounds to endogenous ligands (e.g., ►glutathione). Because of its lipophilic nature, resveratrol can cross the ►plasma membrane, be subjected to cellular metabolism and interact with ►phase 1 enzymes. Moreover, it reduces the insurgence of ►preneoplastic lesions in mouse mammary gland cultures and decreases the incidence of tumor formation in mice treated with ►DMBA used as tumor initiator. Since DMBA requires bioactivation by phase 1 enzymes, the antitumoral activity of resveratrol *in vivo* includes prevention of the initiation phase of carcinogenesis by inhibiting such enzymes. It additionally impairs the carcinogenic effect of aryl-hydrocarbons. Aryl-hydrocarbons are carcinogens acting *via* nuclear receptors to promote cytochrome P450 transcription for the enzymatic conversion of xenobiotics in carcinogen elements. Resveratrol, without binding the receptors, impairs their interaction with the promoter region of the CYP1A1 gene. Resveratrol has also been shown to induce phase 2 enzymes such as UDP-glucuronyltransferase and ►NAD(P)H:quinone oxidoreductase.

Resveratrol was first discovered in roots for its ability to inhibit the activity of ►cyclooxygenases (COXs), enzymes that catalyze the first committed steps of ►prostaglandin (PG) biosynthesis. It noncompetitively inhibits both the COX and hydroperoxidase activities of COX1 *in vitro*. This dual effect of resveratrol is unique, since classic ►nonsteroidal anti-inflammatory drugs (NSAIDs) affect only the activity of COXs. Additionally, it down-regulates COX2 transcription, likely by impairment of activation of the transcriptional factor ►NF-kB, upstream COX2 expression. ►Ornitine decarboxylase (ODC) is an additional target enzyme for resveratrol. Since both COXs and ODC are promoters of ►angiogenesis, the role of resveratrol as suppressor of tumor mass neovascularization is evident.

Resveratrol was found in a variety of cell models to arrest proliferation, mostly in an irreversible way, leading to ►apoptosis. This effect has been traced to its ability to modulate the activity of many key mediators of ►cell cycle and survival. One subject of debate is whether resveratrol-induced cell cycle arrest is reversible or is the first step of an irreversible

apoptotic program. Apoptosis-related proteins have been identified to be targeted by resveratrol, including ►p53. In a variety of cellular models, resveratrol strongly upregulates p53 and induces its posttranslational modification (phosphorylation and acetylation) required for regulating gene transcription. Thus, it imposes a checkpoint at G1/S transition and leads to the modulation of ►Cyclin dependent kinases and ►cyclins.

Resistance to apoptosis may depend on intracellular levels of prosurvival and proapoptotic factors such as members of the ►BCL-2 family and the inhibitors of apoptosis (IAP) proteins family. Resveratrol treatment up-regulates the expression of proapoptotic BCL-2 members and decreases the expression of ►survivin, a member of the IAP family.

Finally, resveratrol induces a ►ceramide-mediated apoptosis. Ceramide is a ►sphingolipid mediator of intracellular signals, present in low amounts in biological membranes. In conditions of stress and ►aging, there is an increased production of ceramide by its *de novo* synthesis and release by hydrolysis of complex sphingolipids. Ceramide interacts with a variety of intracellular targets, leading to differentiation, cell cycle arrest and apoptosis. Recently, resveratrol has been shown to promote intracellular accumulation of ceramide in breast and ►prostate cancer cells, elevating *de novo* synthesis by increasing the activity of the rate-limiting enzyme (serine-palmitoyl-transferase). This observation identifies a new important checkpoint in the actions of resveratrol. Although this polyphenol triggers multiple pathways, ceramide production may be a common step that drives cells toward irreversible death.

In addition to interfering with cell cycle control, resveratrol affects multiple targets that are involved directly or indirectly in chemotherapy responsiveness. An intriguing hypothesis is that resveratrol, like other flavonoids, is able to overcome the drug resistance of tumours that express multidrug resistance-associated proteins (►MRP).

As a polyphenol, resveratrol has an intrinsic antioxidant potential. Since the tumour initiation and progression may depend on ►DNA damage by ►Reactive Oxygen Species (ROS) generation, an antioxidant agent may prevent DNA damage, by ROS scavenging. Anyway, it appears restrictive to assimilate resveratrol to other common antioxidant agents. The large spectrum of molecular targets of resveratrol and the consequent wide range of biological effects contribute to the classification of resveratrol as a potential endogenous mediator, albeit it is an exogenous molecule for the human body. Tentatively, this concept could be enforced by the similarity of resveratrol structure to that of estrogens. Anyway, the literature does not provide convincing evidence to assign to resveratrol the role of an *in vivo* estrogen mimetic.

Clinical Relevance

Resveratrol is known to have minimal side-effects both *in vitro* and *in vivo* models. This plays in favor of resveratrol as a promising drug against many diseases, including cancer. Unfortunately, its bioavailability seems to be rather low, although the literature is confusing and contradictory in this regard. Modifications such as glucuronidation and sulphation occur in large amounts after intake and contribute greatly to diminish absorbtion and tissue distribution and increase excretion. To overcome this obstacle, attempts are currently on to develop novel strategies based on protection of resveratrol from conjugation. This may extend its half-life, thus promoting its biological activity.

Even considering these precautions, clinical attempts have been initiated to test the resveratrol efficacy in humans. Particularly, Phase 1 studies for ►colon cancer treatment are currently underway at the University of Michigan, University of California Irvine and at University of Leicester.

RET

Oliver Gimm
Department of Surgery, University Hospital, Linköping, Sweden

Definition

RET is the abbreviation for a gene that was found to be rearranged during transfection studies of ►NIH-3T3 cells with human lymphoma DNA. It is a ►receptor tyrosine kinase, for which the ligand is glial cell line derived neurotrophic factors (GDNF). It was originally detected as an oncogenic version from a ►T-cell lymphoma.

Characteristics

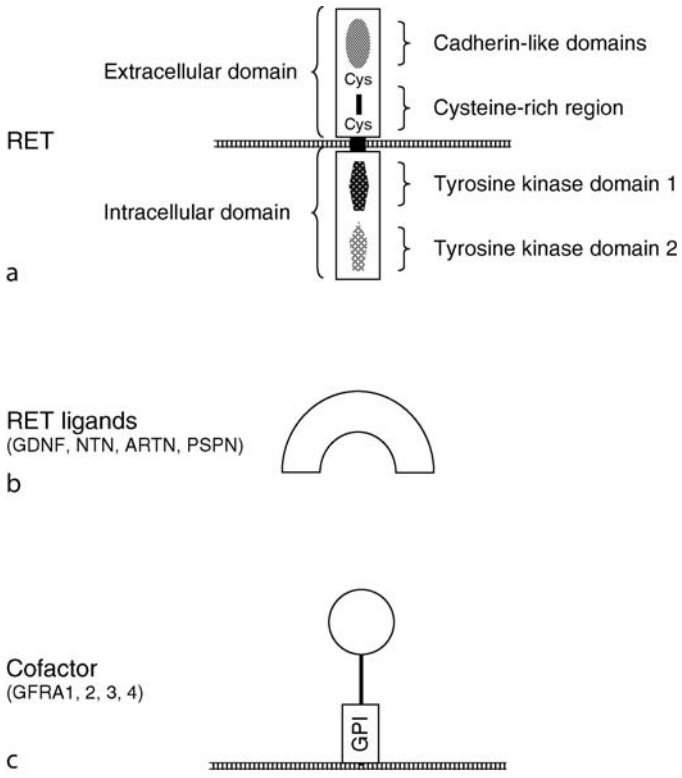
RET is located on chromosome sub-band 10q11.2 and consists of at least 21 exons. Alternative polyadenylation sites and ►alternative splicing result in different transcript sizes. RET splice variants contain the first 19 exons, followed by distinct three-prime ends. These variants produce three protein isoforms that have 9 (RET9), 51 (RET51), or 43 (RET43) distinct amino acids at their C termini. The gene encodes for a transmembrane tyrosine kinase receptor. The first ten exons, and maybe part of exon 11, encode the extracellular domain; exon 11 encodes the transmembrane domain, while the remaining exons encode the intracellular or cytoplasmic domain (Fig. 1a). The extracellular domain contains multiple cadherin-like domains and a cysteine-rich region. For the first cadherin-like domain, a surface for binding to the GDNF-GFRA (GDNF family receptor alpha)1 complex has been described. The cysteine residues are bound to each other via intramolecular disulfide bonds. Two tyrosine kinase domains have been identified in the intracellular domain.

Cellular and Molecular Regulation

RET expression is largely restricted to neural, ►neuroendocrine, and nephrogenic tissues. During embryogenesis, RET is expressed in developing kidneys, the presumptive enteric neuroblasts of the developing enteric nervous system, cranial ganglia and the presumptive motoric neurons of the spinal cord.

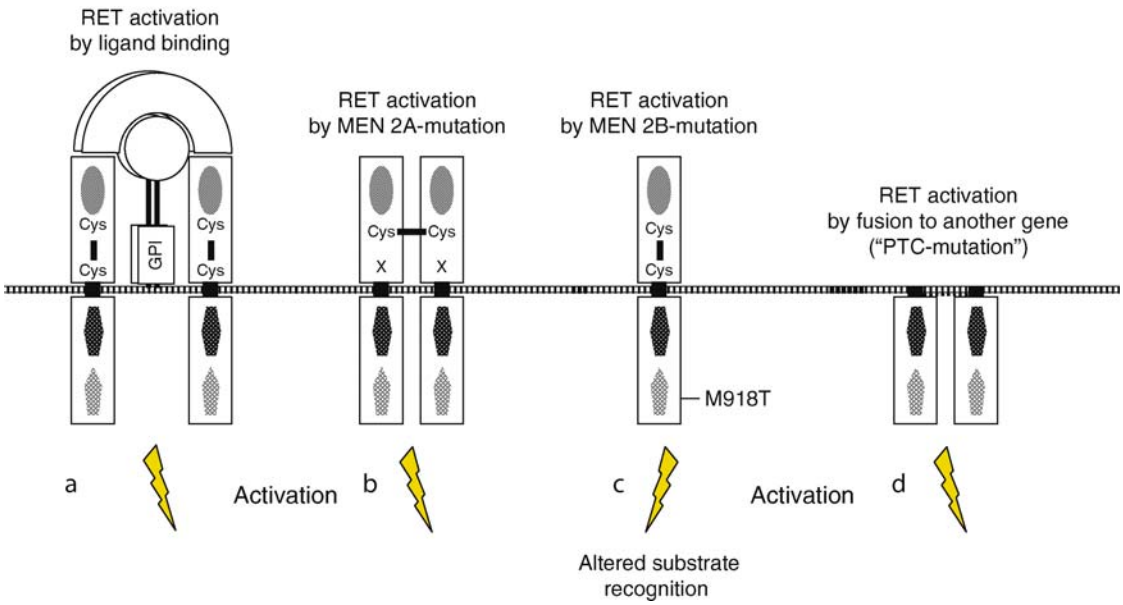
RET can be activated by binding to one of its ligands. Ligand binding leads to dimerization of the RET-receptor and subsequent phosphorylation of tyrosine residues (Fig. 2a). There are at least four ligands:

- Glial cell line derived neurotrophic factor (GDNF)
- Neurturin (NRTN or NTN)
- Persephin (PSPN or PSP)
- Artemin (ARTN or ART). (Fig. 1b and Fig. 3). A potentially fifth ligand, enovin (EVN), had been described which, however, turned out to be identical to artemin. All ligands belong to the GDNF family. The similarity among the various members is 40–60%. The ligands cannot bind directly to RET but rather require the presence of a membrane bound glycosyl-phosphatidylinositol (GPI)-linked cofactor. Four cofactors, named GFRA1–4 (also known as GFRα-1, -2, -3 and -4), have been identified (Fig. 1c and Fig. 3). GFRA1 is also known as GDNFR-α, RETL1 and TrnR1; GFRA2 is also known as GDNFR-β, NTNR-α, RETL2 and TrnR2. Each ligand preferentially binds to one cofactor; however, alternative binding has been observed in vitro (Fig. 3). The prevalence of these alternative interactions *in vivo* is unknown.

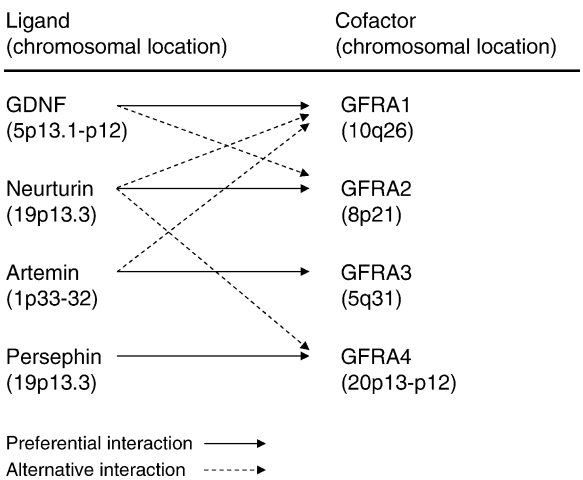


RET. Figure 1 Putative structure of RET, its ligands and their cofactors.

R



RET. Figure 2 Mechanisms of RET activation.



RET. Figure 3 Interation between various RET ligands and cofactors.

The downstream signaling pathways of RET have been investigated intensively. There is evidence that RET signals are, at least in part, transduced by intracellular serine/threonine kinases designated as ►MAPK (mitogen activated protein kinases). Other pathways involve phosphatidylinositol-3-kinase (►PI3K), Jun N-terminal kinase (►JNK), and phospholipase-C (PLC)γ.

Knockout Mice

RET −/− ►knockout mice die early after birth due to agenesis of kidneys and lack of enteric neurons distal to the stomach. In addition, RET knockout mice show depressed ventilatory response to inhaled CO2. *GDNF* −/− and *GFRA1* −/− mice also die perinatally due to the failure to develop enteric neurons and kidneys, similar to mice lacking *RET*. The GDNF-GFRA1 system has also been shown to be critical for the survival of subpopulations of sensory neurons in the dorsal root ganglion and in the nodose ganglion. Apparently the survival of neurons in the central nervous system does not depend solely on the GDNF-GFRA1 system as only a few or no deficits have been found. The critical role in kidney development emphasizes that classifying these molecules as being strictly neurotrophic is difficult. Approximately 30% of *GDNF* +/− mice lack one kidney, while *RET* +/− and *GFRA1* +/− mice have two normal kidneys. In contrast, *NTN* −/−, *GFRA2* −/− and *GFRA3* −/− mice have a relatively mild phenotype. They present with ptosis (*NTN* −/−, *GFRA2* −/− and *GFRA3* −/−), i.e. drooping of the eyelids, and deficits in the enteric nervous system, i.e. reduced density of acetylcholine esterase (AChE) fibers (*NTN* −/− and *GFRA2* −/−), parasympathetic nervous system (*NTN* −/−, *GFRA2* −/−), e.g. absence of parasympathetic innervation to the lacrimal gland, and sympathetic nervous system (*GFRA3* −/−), e.g. severe defect in superior cervical ganglion (SCG) development. *GFRA3* −/− mice and *ART* (a vascular derived neurotropic factor) −/− mice showed similar abnormalities in the migration and axonal projection pattern of the entire sympathetic nervous system. *PSP* −/− mice show normal development and behavior, but are hypersensitive to cerebral ischemia. Of note, *GFRA4* −/− mice revealed impaired thyroid calcitonin (a tumor marker produced by ►medullary thyroid carcinoma) production.

Clinical Relevance

In humans, two types of mutations have been identified in *RET*: mutations associated with ►loss-of-function and mutations associated with ►gain-of-function. The strict differentiation between mutations associated with loss-of-function and mutations associated with gain-of-function is not correct, as some mutations can cause both loss and gain-of-function depending on the time of expression, i.e. embryonic versus adult, and tissue of expression. This seemingly contradictory observation has been explained as follows. For example, the mutation C609W leads to a drastic reduction of mature RET product and subsequently reduces the level of functional receptors at the cell surface. Consequently, during formation of the enteric nervous system, the overall signal transmitted by the RET/GDNF and the RET covalent dimer complex is below the threshold required for the survival of enteric neurons. On the other hand, the ligand-independent constitutive signaling activity of the RET covalent dimer is high enough to lead to proliferation of thyroid C-cells with subsequent development of ►MTC. Biochemical analysis revealed that mutations affecting codon 618 and 620, and to a lesser extent codon 609, result in marked reduction of the level of RET on the surface.

Mutations causing loss-of-function of RET are associated with ►Hirschsprung disease (HSCR). All kinds of mutations have been found; missense mutations, non-sense mutations, frame-shift mutations, and splice-site mutations, as well as small and large insertions and deletions. Depending on the mutations, RET function may be only slightly impaired or completely lost. *RET* is highly expressed in the presumptive enteric neuroblasts of the developing enteric nervous system. Humans harboring inactivating germline *RET* mutations may lack enteric neurons and have HSCR. Interestingly, despite high levels of *RET* expression in presumptive motoric neurons of the spinal cord and developing kidneys, no clinical evidence of spinal cord involvement has been shown in patients with inactivating *RET* mutations, and renal agenesis has been reported in only a few patients with HSCR. HSCR has been reported to be associated with congenital central hypoventilation syndrome (CCHS or Ondine'e curse). Despite the fact that *RET* –/– mice show depressed ventilatory response to inhaled CO2, no *RET* mutations have been reported in patients with CCHS. Recently, mutations in *PHOX2B* have been found to be associated with HSCR and CCHS.

Mutations causing gain-of-function of *RET* have been shown to be associated with a hereditary syndrome named ►multiple endocrine neoplasia type 2 (MEN 2), with an overall life-time risk of developing MTC of about 70%, as well as with non-hereditary ►papillary thyroid carcinoma (PTC).

Mutations Found in Medullary Thyroid Carcinoma

RET has become the paradigm for molecular medicine in the management of familial cancer syndromes. Germline *RET* mutations have been found in more than 95% of all patients with hereditary MTC as part of MEN 2. The knowledge of *RET* as the disease-causing gene helps to identify individuals at risk of developing MTC.

Most mutations found in MEN 2 are almost always missense mutations. Germline *RET* mutations affecting one of six cysteines (Cys609, 611, 618, 620, 630, 634) within the cysteine-rich region (Fig. 1a) are responsible for the vast majority of two hereditary syndromes, multiple endocrine neoplasia type 2A (MEN 2A) and familial medullary thyroid carcinoma (familial MTC or FMTC), both of which are part of MEN 2. It has been shown that replacement of these cysteines by an alternate amino acid abrogates the intramolecular disulfide bonds and leads to aberrant intermolecular disulfide bonds with subsequent homodimerization and autophosphorylation (Fig. 2b).

A variety of other mutations affecting the intracellular domain have been found (e.g. E768D, L790F, Y791F, V804M, V804L, A891S). Most of them have been found in patients with FMTC but some of them have also been found in patients with MEN 2A (e.g. V804L, L790F). For some mutations (e.g. Y791F and A891S) activation of the Src/JAK/STAT3 pathway has been described.

►Missense mutations in two other codons (M918T, A883F) of *RET* affecting the tyrosine kinase domain have been found in patients with multiple endocrine neoplasia type 2B (MEN 2B), which is also part of the MEN 2 syndromes. Most often, M918T is found in most patients with MEN 2B. It has been shown that the point mutation M918T causes RET activation (Fig. 2c) but also changes the substrate specificity of the tyrosine kinase. Dimerization does not occur.

Somatic *RET* mutations have been found in sporadic MTC. Depending on the mutation analysis technique, mutations have been found in 30–70%; most often the MEN 2B-specific mutation M918T is found in exon 16. The identification of this mutation in DNA extracted from cells obtained by performing fine needle aspiration cytology can help in making the diagnosis of MTC. However, the absence of this mutation in the cytologic specimen does not exclude the presence of MTC, either hereditary or sporadic. Also, the presence of the M918T mutation does not allow determining whether the MTC is sporadic or hereditary. Additional germline mutation analysis of *RET* is required.

Mutations Found in Papillary Thyroid Carcinoma

In contrast to mutations found in MTC, specific somatic rearrangements (translocations and inversions) of *RET* have been found in PTC. The tyrosine kinase domain of

RET is fused to the 5′-terminal region of heterologous genes. The resulting chimeric molecules have been named RET/PTC. Currently, more than ten types of *RET* rearrangements have been found in PTC (RET/PTC1–8, ELKS/RET, PCM/RET, and RFP/RET). The fusion partners of *RET* are mainly *CCDC6* (coiled-coil domain containing gene 6; formerly known as H4), and *NcoA4* (nuclear receptor co-activator gene 4; formerly called *RET* fused gene (RFG)/ELE1/androgen receptor activator 70 (ARA70)) in the case of *RET/PTC1* and *RET/PTC3*, respectively. The promoter of these genes, which substitutes the *RET* promoter, is able to drive expression of *RET* in the thyroid gland. Even though the extracellular domain of RET is missing, coiled-coil domains in the fusion partners cause a constitutive dimerization (Fig. 2d). The subsequent activation of RET in this manner seems to be restricted to PTC; only one study reports RET rearrangement in one thyroid adenoma. Transgenic mice with *RET/PTC* develop PTC if driven by a thyroid-specific promoter such as the thyroglobulin promoter. The frequency of *RET* rearrangements in PTC are most often found in about 10–40% with regional/methodical differences (5–85%). Irradiation is able to cause *RET/PTC1* rearrangements in cultured cells (thyroid carcinoma cells and fibrosarcoma cells) *in vitro*. Mainly *RET/PTC1* has been found in long latency PTCs from patients following the Chernobyl nuclear accident in 1986, when a dramatic increase of PTCs was observed. *RET/PTC1* is associated with the classical variant of PTC. In contrast, *RET/PTC3* is more prevalent in short latency PTCs. *RET/PTC3* is closely associated with the solid variant of PTC.

Similar to MTC, somatic *RET* rearrangements can be diagnosed in cells obtained performing fine needle aspiration cytology in patients with PTC. However, since the frequency of *RET* rearrangements in PTC is generally low (10–40%), no conclusion can be drawn in the absence of *RET* rearrangements. The identification of *RET/PTC*, however, justifies the diagnosis of PTC. Recently, a somatic point mutation in *BRAF* (V600E; previously designated as V599F) has been identified as the most common (35–70%) genetic change is PTCs. Apparently, BRAF is required for RET/PTC-induced activation of MAPK.

Glioma retinae

Definition

Retinoblastoma (Rb, OMIM 180200) is a malignant childhood tumor of the eye that originates from neuronal cells of the developing retina. Diagnosis is based on clinical signs and symptoms and is usually made in the first 3 years of life. Development of Rb is initiated by mutations that alter both ►alleles of the ►*RB1* gene. In most patients with sporadic unilateral Rb, both mutations have occurred in somatic cells. Almost all patients with sporadic bilateral Rb are heterozygous for an oncogenic *RB1* gene mutation that was either transmitted from a parent or has occurred de novo in the germline. Germline *RB1* gene mutations

cause hereditary Rb. ►Penetrance and ►expressivity of this ►autosomal dominant trait are variable between families, which is explained in part by residual gene function of some mutant alleles.

Characteristics

Clinical Aspects

Diagnosis of Rb

The most frequent presenting sign is a white pupillary reflex (leukocoria). Strabismus is the second most common sign and may accompany or precede leukocoria. Most patients diagnosed with Rb are less than 3 years old. Age at diagnosis is earlier in children with bilateral Rb compared to children with unilateral Rb. Usually, diagnosis of Rb is established by examination of the fundus of the eye using indirect ophthalmoscopy. Magnetic resonance imaging (MRI) and ultrasonography are required for staging. Because of the high risk of tumor spread, biopsies must not be taken and, therefore, histopathology can confirm diagnosis of Rb only if therapy includes removal of the eye (enucleation).

Presentation and Family History

Most patients (60%) have Rb in one eye only (unilateral Rb). Some of these patients show multiple distinct tumor foci (unilateral multifocal Rb). The remaining 40% of patients have tumors in both eyes (bilateral Rb), which are often multifocal. More than 95% of patients with unilateral Rb and about 75% of patients with bilateral Rb have no family history of Rb (sporadic disease). Familial Rb is seen in 10–15% of patients. This includes families where retinal scars or quiescent tumors (retinomas) were identified in relatives only upon examination of the fundus of the eye.

Therapy and Prognosis

Treatment of patients with Rb depends on tumor stage, the number of tumor foci in the eye, the presence of vitreous seeding, and the age of the child. Treatment options include enucleation, external-beam radiation, cryotherapy, photocoagulation, ►brachytherapy with episcleral plaques, and ►chemotherapy combined with local therapy. Prognosis is excellent if the tumor has not invaded extraocular tissues. Metastasizing Rb often has a fatal outcome.

Second Tumors

Patients with bilateral Rb have an increased risk to develop neoplasms outside of the eye (second tumors). The spectrum of second tumors includes ►osteogenic sarcoma, ►soft tissue sarcoma, ►malignant melanoma, and ►lung cancer. The risk to develop sarcomas is significantly higher in patients with bilateral who have received external beam radiation for treatment of Rb.

Molecular Genetics

Rb is Caused by Two Mutations

Development of retinoblastoma depends on two mutations that alter both alleles of the retinoblastoma gene, *RB1* (Fig. 1). The timing of the first of these mutations is relevant for the genetic form of retinoblastoma:

- In most patients with ►sporadic bilateral Rb, the first mutation has occurred de novo in the germline of one of the parents (Fig. 1a).
- In patients with familial Rb, the first *RB1* gene mutation has occurred in an ancestor and is transmitted via the ►germ line. Family members who have inherited this mutant allele are heterozygous. Inactivation of the other, normal allele occurs in somatic cells.
- In some patients with sporadic bilateral or with sporadic unilateral Rb, the first mutation has occurred de novo during embryonal development of the patient. Consequently, these patients are mutational mosaics. Tumor development is initiated if a second mutation inactivates the normal allele in a cell that is part of the mutant sector (Fig. 1b).
- In most patients with sporadic unilateral Rb, the both mutations that are necessary to alter both copies of the *RB1* gene occur in somatic cells (Fig. 1c).

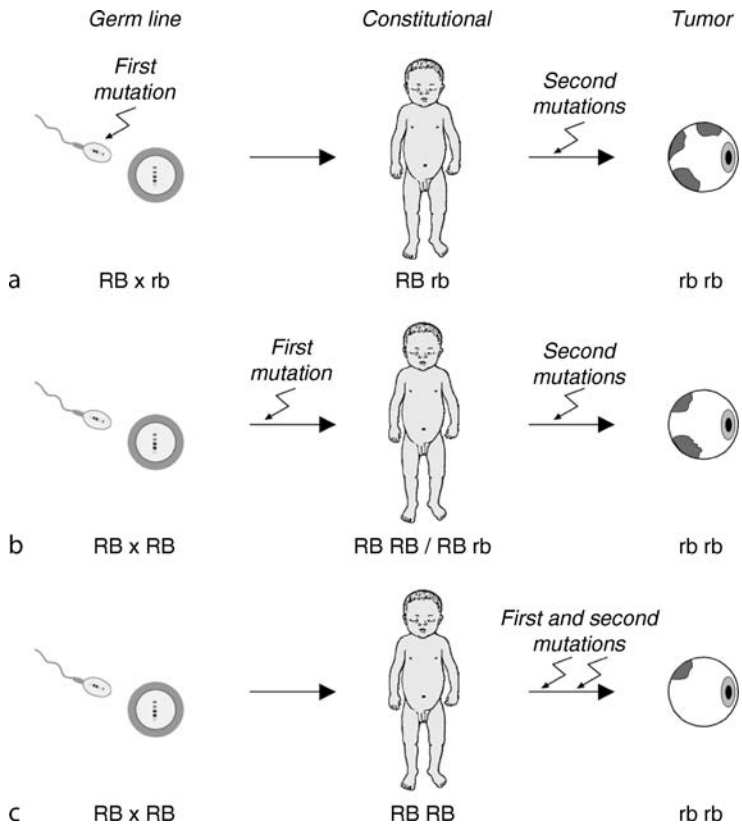
Structure of the RB1 Gene

The *RB1* gene (Acc No. L11919) spans 180 kB of genomic sequence on chromosome 13, band q14. It is composed of 27 exons and transcribed in a 4.7 kB mRNA. The 2.7 kB open reading frame starts in exon 1 and ends in exon 27 and codes for 928 amino acids. Under normal conditions there are no alternative splice forms or alternative translations start sites. The gene product is a nuclear protein which, dependent of the state of phosphorylation, enables the cell to pass to the S-phase of the cell cycle. Several other functions have been documented in addition to cell cycle regulation.

Spectrum of RB1 Gene Mutations

Mutations of the *RB1* gene are identified in constitutional DNA (e.g. from peripheral blood) of patients with hereditary Rb and in DNA from tumors (e.g. retinoblastoma):

- Large deletions: The spectrum of deletions and insertions that include all or parts of the *RB1* gene is heterogeneous. Cytogenetic deletions involving 13q14 are detected in less than 10 and 5% of patients with bilateral and sporadic unilateral retinoblastoma, respectively. Subcytogenetic gross *RB1* alterations, which can be detected by quantitative multiplex PCR or multiplex ligation-dependent probe amplification (MLPA), are present in about 10% of patients with bilateral or familial.



Retinoblastoma. Figure 1 The genetic form of retinoblastoma is determined by the timing of first RB1 gene mutation.

- ►Point mutations: More than 70% of the mutations detected in peripheral blood DNA from patients with hereditary retinoblastoma are single base substitutions and small length mutations (database of *RB1* gene mutations: http://*RB1*-LSDB.d-lohmann.de). Most point mutations result in premature termination codons as they cause of nonsense or frameshift alterations.

The following two types of mutations are identified in tumor DNA only:

- In most tumors, inactivation of one of the *RB1* alleles is accompanied by loss of constitutional heterozygosity (►LOH) at polymorphic loci located on chromosome 13. LOH can result from deletions and several chromosomal mechanisms such as mitotic recombination and nondisjunction.
- Another class of mutation only found in tumors is ►hypermethylation of the ►CpG-rich island at the 5′-end of the *RB1* gene, which is normally unmethylated. Hypermethylation is observed in about 10% of retinoblastomas.

Genotype–Phenotype Associations

The majority of *RB1* gene mutations identified constitutional DNA from patients with hereditary Rb or in DNA from tumors result in transcripts with premature termination codons (nonsense substitutions, frameshift length mutations). Available data indicate, that, at least in constitutional cells, most of these transcripts are degraded (nonsense mediated decay). With few exceptions, individuals heterozygous for mutations of this kind develop Rb (complete penetrance) and, most often, both eyes are affected.

Families with incomplete penetrance of Rb and patients hereditary unilateral Rb usually show *RB1* gene mutations that are distinct. The following types of mutation are frequently associated with incomplete penetrance and unilateral Rb:

1. Missense mutations (these account for less than 5% of known *RB1* point mutations).
2. Small deletions that keep the open reading frame intact (including skipping or deletion of in-frame exons).
3. Substitutions that affect splice signals in exons or less conserved intronic splice signals.
4. Mutations in the promoter region that inhibit binding of transcription factors and thus reduce transcription levels of the gene.
5. Deletions of the whole *RB1* with breakpoints outside of the gene.

With respect to the functional consequences it appears that mutations associated with milder phenotypic expression result in regular expression of a qualitatively altered protein (mutation types 1 and 2, see above) or in reduced levels but not loss of expression of a qualitatively normal protein (4). Within this concept, incomplete penetrance associated with some splice mutations (3) may result if some mutant pre-mRNAs are spliced normal (leaky splice mutation).

Retinoblastoma. Table 1 Risk for Rb in family members

Clinical presentation of index case	Risk to siblings	Risk to offspring
Sporadic unilateral Rb	≤1%	2–6%
Sporadic bilateral Rb	≤2%	Close to 50%
Familial bilateral Rb (one parent affected)	Close to 50%	50%
Familial Rb, incomplete penetrance type	Variable, depending on penetrance	Variable, depending on penetrance

Retinoblastoma. Table 2 Identification of the genetic cause in patients with Rb

Clinical presentation	Genetic analyses start with	Findings	Interpretation
Sporadic unilateral Rb	*RB1* gene mutation analysis in DNA from tumor. Two mutations have to be identified Testing of DNA from blood for the presence either of these mutations	In 85% of patients, neither of the two mutations is detected in DNA from blood. Sensitive methods are needed to detect patients with mutational mosaicism	Both *RB1* mutations have occurred in somatic cells (somatic mutation). The patient has not inherited a mutant *RB1* allele. Siblings have no increased risk of retinoblastoma
		In 15% of patients a predisposing *RB1* mutation is detected in DNA from blood	In patients with mutational mosaicism, both *RB1* mutations have occurred in somatic cells and siblings have no increased risk of retinoblastoma Heterozygous patients may have inherited a mutation from a carrier parent. Siblings of these patients have an increased risk of retinoblastoma unless genetic testing shows absence of the mutant allele
Sporadic bilateral Rb	*RB1* gene mutation analysis in DNA from peripheral blood of the patient or from tumor. Because of mutational mosaicism in some patients, analysis of tumor DNA is preferred	A predisposing *RB1* mutation is detected in DNA from blood	Fewer than 10% of patients are mutational mosaics. Both *RB1* mutations have occurred in somatic cells. Siblings have no increased risk of retinoblastoma
			In about 90% of patients a heterozygous predisposing mutation is detected. These patients may have inherited a mutation from a carrier parent. Siblings have an increased risk of retinoblastoma unless genetic testing shows absence of the mutant allele
Familial Rb	*RB1* gene mutation analysis in DNA from peripheral blood of family members that have inherited a mutant allele	A predisposing *RB1* mutation is detected in DNA from blood	Relatives at risk may be tested for the presence of the mutant allele

Genomic Alterations Associated with the Progression of Rb

In addition to mutational inactivation of both alleles of the *RB1* gene, retinoblastomas frequently show genomic alterations. Cytogenetic and molecular studies have shown that gains on chromosomes 1q and 6p and losses of chromosome 16q are most frequent except in tumors from very young children. It is reasonable to assume that these genomic regions contain genes that contribute to promotion and progression of this tumor. Candidate genes include the *KIF14* and *MDM4* (*MDMX*) on 1q, *DEK* and *E2F3* on 6p, and *CDH11* on 16q.

Risk Prediction and Genetic Testing

Relatives of all patients with RB are at an increased risk to carry a predisposing *RB1*-gene mutation and, consequently, tumor development (Table 1).

The genetic analyses required to identify the cause of disease in a patient depend on the clinical presentation in the index patient (Table 2).

Retinoblastoma Protein, Biological and Clinical Functions

Helen Dimaras, Brenda L. Gallie
Ontario Cancer Institute/Princess Margaret Hospital; The Hospital for Sick Children, Toronto, ON, Canada

Synonyms

Gene: *RB1* – retinoblastoma 1 (including Osteosarcoma), RB, OSRC, retinoblastoma tumor suppressor gene, *Rb1* (refers to mouse ortholog of human *RB1*); Protein: pRB – retinoblastoma susceptibility protein, Rb/p105

Definition

pRB is the protein product of the Retinoblastoma Tumor Suppressor Gene, *RB1*. Its biological functions include controlling the cell cycle, mediating differentiation, as well as protecting cells from ►apoptosis. Mutation of *RB1* resulting in functional inactivation of pRB leads to the childhood retinal tumor retinoblastoma and predisposes to osteosarcoma and other cancers. Defective function of pRB or its pathway also contributes to tumor progression in many other cancer types.

Characteristics

The RB1 Gene Encodes the pRB Protein

The *RB1* gene contains 27 exons and is located on human chromosome 13q14.2 (NCBI Entrez Gene ID: 5925). The product of *RB1* is the 110 kDa retinoblastoma susceptibility protein (pRB), composed of 928 amino acids. The protein consists of two conserved domains, named A and B. Domain A contributes to the proper folding of domain B, creating a "pocket domain" which is the site of many pRB protein interactions. The pocket domain contains an LXCXCE binding motif, which was initially found to bind oncoproteins ►Simian Virus 40 Large T-antigen, ►human papillomavirus E7 and ►adenovirus E1A.

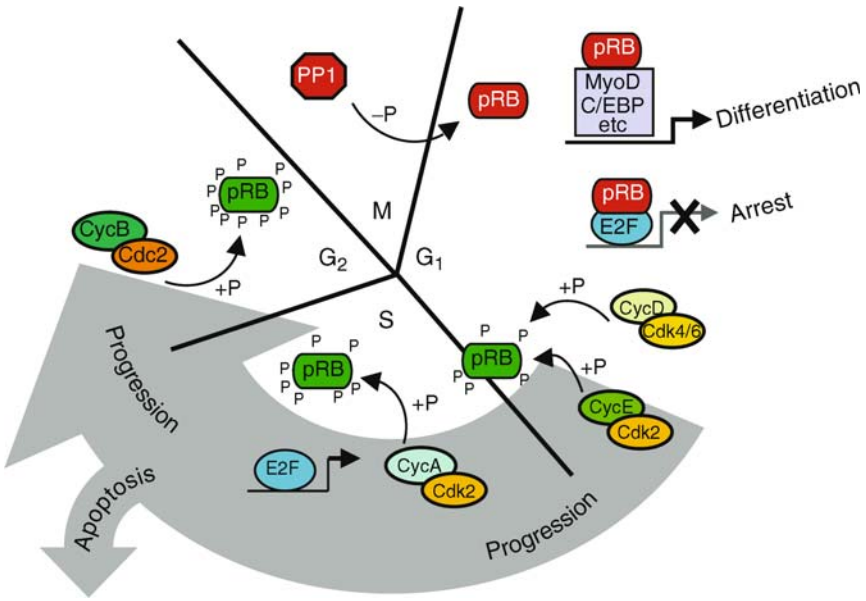
pRB is Post-Translationally Modified

Phosphorylation of pRB

The ►phosphorylation status of pRB changes with the progression of the cell cycle (Fig. 1). Key regulators of pRB phosphorylation are ►cyclin dependent kinases (Cdks), which are bound to and activated by ►cyclins; together, they phosphorylate pRB at multiple sites. The phosphorylation status of pRB affects how it interacts with its multiple binding partners. For example, hyperphosphorylated pRB is unable to bind to ►E2F transcription factors; consequently, pRB is found in its hypophosphorylated state at G_0 and G_1 stages of the cell cycle, where it effectively halts proliferation by binding to and blocking transcriptional activity of E2Fs. During the G_1 to S phase transition, Cdk4/6 and ►cyclin D or Cdk2 and cyclin E form complexes that phosphorylate pRB; as a result, pRB cannot bind E2F transcription factors. pRb continues to be phosphorylated by Cdk2-cyclin A as the cell cycle progresses from S phase through G_2, and by Cdc2-cyclin B as the cell cycle progresses into M phase, after which it is dephosphorylated by phosphoprotein phosphatase type 1 (PP1).

Acetylation of pRB

The pRB binding partners ►CBP/p300, ►histone acetyltransferases, acetylate pRB. Like phosphorylation, ►acetylation of pRB is cell cycle regulated, and can affect the protein interactions of pRB. For example, upon acetylation, pRB interacts more strongly with ►MDM2, an ►E3 ubiquitin ligase that targets proteins such as ►p53 and EID-1 for degradation. Acetylation was found to be important for the role of pRB



Retinoblastoma Protein, Biological and Clinical Functions. Figure 1 pRB Regulates cell cycle progression, differentiation and apoptosis.

in promotion of differentiation, but not in its ability to form complexes with E2F transcription factors.

Functions of pRB

The NCBI Entrez Gene database reports close to two hundred protein-protein interactions involving pRB, implicating it in a number of wide-ranging functions. The various roles of pRB likely overlap, however for simplicity we have grouped them into the following: control of the cell cycle, cellular differentiation and protection from apoptosis.

Cell Cycle Control

Unphosphorylated pRB was initially found to be essential for blocking the G_1 to S phase transition of the cell cycle. This was later attributed to its ability to bind E2F family transcription factors and effectively stop them from activating their target genes, many of which promote in G_1 to S phase transition and DNA synthesis. Transcriptional repression by pRB also involves ►chromatin remodeling, as pRB binds to and recruits ►histone deacetylase HDAC1, nucleosome modifiers BRG1 and hBRM, and ►histone methyltransferase SUV39H1, which help to maintain a repressive chromatin state, inaccessible to transcriptional machinery. In some cases, pRB can also recruit ►polycomb group proteins, a family of proteins that act as repressors.

pRB has also been implicated in E2F-independent roles for cell cycle control. In some cell types, transcription of Cdk inhibitor ►p21 can be upregulated by interaction of pRB with transcription factor Mitf. Additionally, pRB interacts and inactivates ►SKP2, part of a ubiquitin ligase complex that recognizes and marks for degradation $p27^{KIP1}$, another Cdk inhibitor. As a result of both of these potential pathways, the Cdks that normally phosphorylate and inactivate pRB are blocked, resulting in cell cycle arrest.

There is a growing body of evidence that implicates a role for pRB in the control of the ►DNA damage ►checkpoint. pRB negatively regulates a number of DNA replication factors, a function that is stimulated upon induction of DNA damage. Interestingly, even in E2F1-deficient, over-proliferating cells, presence of functional pRB prevents the accumulation of DNA ►double strand breaks, implicating a role for pRB in maintaining genomic integrity independent of its function in inhibiting E2Fs.

Differentiation and Development

Rb1 knockout mice do not develop to term, but die during gestation due to defects in many tissues including placenta, muscle, brain, blood, skin, liver and lens, suggesting that pRB is important in the cellular differentiation. It is unknown if the role of pRB in differentiation is simply an indirect result of its role as a cell cycle inhibitor, or if this reflects an additional, separate function of the protein. Certainly, only differentiated cells exhibit methylation of histone 3 at the K-9 residue (specific result of the pRB mediated function of SUV39H1) at E2F-regulated promoters, suggesting pRB contributes to differentiation by inducing cell arrest. However, study of *Rb1* mutant

mice that express pRB lacking the ability to bind E2F1-3 (and to inhibit the cell cycle) showed fewer defects in differentiation than the complete *Rb1* knockouts, indicating that the functions of pRB in cell cycle control and differentiation operate through separate pathways. Interestingly, the mutant pRB in these incompletely penetrant mice still retains the ability to bind and inhibit E2F4 and Id2, both of which act to prevent differentiation. EID-1, also a differentiation antagonist, binds to pRB in complex with CBP/p300, in an attempt to disrupt the histone acetyltransferase activity that represses chromatin. Acetylated pRB however, recruits and more securely tethers MDM2 to the complex, which then targets E1D-1 for degradation.

In addition to sequestering and inactivating inhibitors of differentiation, interaction of pRB with transcriptional activators of genes important to cell fate specification could also promote differentiation. In this respect, complexes of pRB and MyoD are thought to be essential for muscle differentiation, pRB/c-jun complexes result in differentiation of keratinocytes and adipocyte differentiation of murine embryonic fibroblasts ensues after pRB interaction with CCAAT/enhancer binding proteins (C/EBPs).

A new emerging role for pRB involves the construction and assembly of neuronal architecture, which is spatially and temporally regulated during development. It seems that the repression of E2F responsive promoters by pRB regulates not only pro-survival genes, but also those involved in laminar patterning and migration of neurons. A ►microarray study of upregulated genes in neural precursors from conditional *Rb1* knockout mice identified several genes known to be involved in interneuron migration. Of particular interest was neurogenin, an E2F-regulated gene, which regulates neuronal migration.

Apoptosis

Inappropriate entry into ►S-phase by E2F-mediated transcription can result in ►apoptosis. Thus, pRB repression of E2F factors prevents cell death; indeed, the *Rb1* knockout mice display a massive induction of cell death in several tissues. Knockout of E2F1 in conditional *Rb1* mutant mice (►knockout mice) rescues this apoptosis, indicating that E2F1 is a requirement for this cell death pathway.

Interestingly, E2F-mediated apoptosis is abolished when p53 is mutated. E2F1 can lead to the stabilization of p53 by upregulating transcription of $p14^{ARF}$, a repressor of MDM2. Now inactive, MDM2 is unable to mediate the degradation of p53, resulting in stabilization of the protein and subsequent apoptosis.

Hypophosphorylated pRB causes cell cycle arrest by inhibiting E2F-mediated transcriptional activation of genes necessary for entry into S phase, and also activates genes necessary for differentiation by binding to cell-type specific transcription factors (e.g. MyoD, C/EBP) and by recruiting ►chromatin remodeling factors (e.g. CPB/p300, not shown). Phosphorylation of pRB by Cdk4/6-cyclin D and Cdk2-cyclin E kinases in late G_1 releases E2F, allowing cell cycle progression. pRB continues to be phosphorylated in S and G_2 phases by Cdk2-cyclin A and Cdc2-cyclin B complexes, respectively. In late mitosis, pRB is activated/dephosphorylated by PP1. Inappropriate entry into S phase in the absence of pRB induces apoptosis.

Clinical Relevance

Inactivation of RB1 Initiates Retinoblastoma Development

Retinoblastoma is a childhood cancer of the retina. With the cloning of *RB1* as the first tumor suppressor gene, retinoblastoma was the first cancer to be described as a genetic disease. All retinoblastoma have mutation or loss of expression of both alleles of *RB1*. Individuals with hereditary retinoblastoma carry a constitutional mutation of one *RB1* allele (M1) and lose the second allele (M2) in the retinal cell that becomes the tumor; consequently, hereditary retinoblastoma is likely to be bilateral (affecting both eyes). Non-hereditary retinoblastoma results from somatic loss of both alleles (M1/M2) in the developing retinal cell of retinoblastoma origin, thus it is usually unilateral (affecting one eye).

Mutations in the *RB1* gene that lead to retinoblastoma are of numerous types, consisting of splice variants, missense mutations, point mutations leading to premature stop codons and deletions of all or any part of the gene. The type of *RB1* mutation generally makes no difference to the presentation of the disease, however some "low penetrance" mutations, which result in residual activity of pRB, may cause few or no tumors to be produced.

Inactivation of *RB1* is necessary, but not sufficient, for retinoblastoma tumor development. Instead, loss of *RB1* results in retinoma, a benign tumor of the retina. Subsequent genetic alterations, such as the gain of oncogenes and/or loss of additional tumor suppressor genes, lead to retinoblastoma development.

RB1 Loss in Other Cancers

Although loss of *RB1* is implicated in a wide variety of cancers, it is an initiating and rate-limiting tumorigenic factor specifically in the retina. In addition to developing retinoma and/or retinoblastoma, individuals who inherit one mutant copy of *RB1* have a 30-fold increased risk of developing osteosarcoma and other tumors. This risk is increased further by use of external beam radiotherapy to cure retinoblastoma. As a contributing factor to tumorigenesis, *RB1* mutation or pRb inactivation is observed in numerous cancers,

including but not limited to ►prostate cancer, ►breast cancer, ►lung cancer and ►bladder cancer.

Retinoblastoma Protein, Cellular Biochemistry

Ho Man Chan, Nicholas B. La Thangue
Division of Biochemistry and Molecular Biology, Davidson Building, University of Glasgow, Glasgow, UK

Definition

Retinoblastoma protein is a 110 kDa nuclear phosphoprotein (►tumor suppression). The gene locus maps to 13q14.1–q14.2. Retinoblastoma is an embryonic neoplasm of retinal origin. Young children with a ►germline mutation in one Rb1 ►allele have a 95% chance of developing a retinoblastoma tumor in their eyes. Mutation in the Rb1 allele also predisposes patients to develop other tumors, such as ►osteosarcomas and fibrosarcomas. Almost two-thirds of the secondary tumors arising in patients with retinoblastoma are mesenchymal in origin. Most mutations in Rb1 lead to premature termination of translation.

Characteristics

pRb and Its Family Members

The pRb, p107 and p130 proteins form the "pocket protein" family that is crucial in ►cell-cycle regulation. pRb and p107/p130 have five domains of high conservation. pRb shares between 30% and 35% sequence identity with p107/p130. Most of the conserved sequences lie within the so-called "pocket region" (amino acid 379–792), which is composed of two subdomains, known as the "A" and "B" box. Viral oncoproteins, such as ►SV40 large T antigen, ►adenovirus E1A and "high risk" ►human papillomavirus early protein E7, all target the pocket domain, displacing cellular proteins that interact with the pocket, thereby leading to loss of pocket protein function.

At least three distinct protein binding activities of pRb have been described to be important for its function: the large pocket (amino acid 395–876) binds to ►E2F, the small pocket (amino acid 379–792) binds to the LXCXE (L = leucine, C = cysteine, E = glutamic acid, X = any amino acid) peptide and the C pocket binds to tyrosine kinase ►ABL and oncoprotein ►Mdm2. Viral oncoproteins (e.g. E1A, E7, SV40 LT) and some cellular proteins (e.g. ►histone deacetylase (HDACs), ►cyclin D) possess an LXCXE motif in their protein sequence that enables them to bind to the pocket. The three-dimensional structure of the pRb A/B pocket bound to a LXCXE-containing peptide from E7 has been solved. The peptide binds a highly conserved groove on the B box portion of the pocket, and the A box is required for the stable folding of the B box. The A/B box interface is highly conserved, suggesting an additional protein binding region. Furthermore, both E2F and E7 peptides occupy distinct sites in the pocket. Indeed, HDACs that contain an LXCXE-like motif may form a trimeric complex with pRb and E2F. c-Abl was also reported to bind to pRB when the pocket region is occupied by E2F. Taken together, the evidence suggests a model for pRb as a "molecular matchmaker" in mediating protein complex formation.

Despite the close similarities among the family members, only Rb has been shown to be mutated in tumor cells. Neither p107 nor p130 have been found to be mutated in naturally occurring tumors. In order to study the specific cellular function of pRb, p107 and p130, knockout mice in Rb, p107 and p130 have been developed. The phenotypes indicated both distinct and overlapping functions among the family members. The absence of pRb in mice causes embryonic lethality, although p107−/− and p130−/− ►knockout mice survive to term, possibly as a result of functional redundancy between p107 and p130. This is consistent with the phenotype of the p107−/−: p130−/− mice which exhibit embryonic lethality. Rb+/− mice do not suffer from retinoblastoma, but develop tumors of the pituitary and thyroid origin. This difference may be attributed to the physiology of human and mice. Bilateral, multifocal retinal dysplasia is observed in Rb+/−: p107−/− mice. This suggests that pRb and p107 may share overlapping functions in controlling cellular homeostasis in the murine retina, and loss of both is required for tumor formation. p107−/−: p130+/− and p107+/−: p130−/− mice were developed to investigate if p107 and p130 possess tumor suppression function.

However, analysis of such animals did not reveal any obvious tumor phenotype. An alternative explanation is that, unlike the mutations in pRb, mutations in p107 and/or p130 may not be advantageous for tumorigenesis. Therefore mutations in other components of the pathway such as p16, which is frequently found to be mutated in human tumor(s), contribute to the inactivation of p107/p130 tumor suppression function, without abrogating other necessary functions of p107/p130.

Cell-Cycle Regulation of pRb

The pRb protein is ubiquitously expressed in most cycling and resting cells. pRb acts as a negative regulator for cellular proliferation, sequestering a variety of nuclear proteins involved in cellular growth. The most studied pRb target is the family of transcription factors known as ►E2F. E2F consists of a heterodimer of an E2F protein bound to a DP partner. Together, they regulate the timing and levels of expression of many genes involved in cell-cycle progression. E2F target genes encode proteins involved in DNA ►replication (for example, DNA polymerase a, thymidine kinase, dihydrofolate reductase and cdc6), chromosomal replication (for example, replication origin-binding protein HsOrc1, MCM proteins) and cell-cycle regulation (for example, cyclin A, E and D1, p107, cdc2, E2F1, 4 and 5 and p19ARF). During G0/G1, hypophosphorylated pRb binds to E2F, inactivating and thereby preventing cell-cycle progression. Cyclin D/cdk4/6 and cyclin E/cdk2 progressively phosphorylate pRb at late G1 to early S phase. In S phase, pRb phosphorylation is maintained by cyclin A/cdk2. Progressive phosphorylation of pRb results in reduced affinity for E2Fs, the release of free E2F and thereafter induction of E2F transcription.

Different pocket proteins have a preference for binding to different E2F family members. The E2F family now consists of six members (E2F-1 to -6). E2F-1, -2 and -3 exhibit high affinity binding towards pRb, but bind weakly to p107/p130. In contrast, E2F-4 and -5 show greater specificity for p107/p130, but also bind pRb. Complexes between the pRb family members and E2F form at different phases of the cell cycle. In general, p130/E2F complexes are mainly found in quiescent or differentiated cells and p107/E2F complexes predominate in S phase cells. pRb/E2F complexes are most evident during G1/S phase transition, but also exist in quiescent or differentiated cells.

pRb can modulate E2F transcription activity in at least two distinct ways: First, pRb binds to the transcription activation domain in E2F and directly inhibits E2F transcription activity. Using in vitro transcription and footprinting assays, it has been demonstrated that pRb blocks the recruitment of the transcription initiation complex by E2F. Second, pRb was shown to bind to ►HDACs, which are believed to deacetylate histones on the promoter, and actively repress transcription via chromatin remodeling. It has been shown that active repression of pRb/E2F complex is important in mediating G1 arrest triggered by ►transforming growth factor-β (TGFβ), p16 and contact inhibition.

There is evidence that phosphorylation of the pRb C -terminus by CDK4/6 causes successive intramolecular interactions between the C-terminus and the central pocket region. The initial interaction is thought to disrupt HDAC binding and therefore relieve active repression by pRb. This event then facilitates the phosphorylation of the pocket region by cyclin E/CDK2, thereby disrupting the pRb/E2F interaction. These intramolecular interactions provide a molecular basis of how phosphorylation of pRb progressively inactivates its growth suppression function.

Apart from regulating E2F transcription activity, pRb proteins also regulate E2F protein stability and apoptotic function. Overexpression of pRb family members can stabilize E2F-1 and E2F-4. E2F-1 was shown to be degraded by a ubiquitin-dependent proteasome pathway through an ►SCF-like complex. E2F-1 mutants which cannot be degraded by the SCF pathway drive cell-cycle progression into S phase followed by ►apoptosis. E2F-1-mediated apoptosis occurs independently of the transcription activation domain, but requires DNA binding. Furthermore, E2F-1-mediated apoptosis is both p53-dependent and p53-independent. Overexpression of pRb in tissue culture cells and analysis of the Rb−/− mouse embryos versus the E2F-1−/−:Rb−/− embryos indicated pRb can suppress E2F-1-mediated apoptosis. E2F-1-mediated apoptosis can, at least in part, occur through a death receptor-dependent mechanism by inhibiting activation of anti-apoptotic signals including NFκB.

Role in Terminal Differentiation

The role of pRb in differentiation was suggested from the phenotype of Rb−/− ►knockout mice, which show a pronounced defect in erythroid, neuronal and lens development. Although loss of pRb function allows the initiation of differentiation, the embryos fail to achieve a fully differentiated state, indicating that pRb is likely to play an important role in achieving and maintaining the post-mitotic state. Furthermore, the aberrant cell-cycle entry observed in the central nervous system (CNS) and the peripheral nervous system (PNS) of the Rb−/− embryo causes elevated levels of apoptosis. Again this implies that pRb may function in protecting cells from apoptosis. Indeed, Rb−/−: E2F-1−/− mice show reduced levels of ectopic cell-cycle entry and apoptosis in both the CNS and the lens at 13.5 d.p.c. as compared to Rb−/− embryos, suggesting that these defects are in part due to de-regulated E2F-1 activity.

However, this mechanism is tissue type specific, as loss of E2F-1 has less of an effect on cell-cycle entry and apoptosis in the PNS.

It is clear that pRb interacts with other non-E2F targets. This is best demonstrated in the analysis of pRb mutants that show reduced binding to E2Fs, but are still capable of augmenting MyoD transcriptional activity and inducing tissue specific gene transcription. Furthermore, these mutants still retain certain tumor suppressor functions. Therefore, at least part of the tumor suppression function of pRb correlates with its ability to promote tissue differentiation.

Although the pRb protein level does not change dramatically upon differentiation, pRb is found to be hypophosphorylated during cell-cycle exit. Hypophosphorylated pRb augments the transcriptional activity of various transcription factors important for tissue differentiation, including MyoD for myogenesis and C/EBPα for adipogenesis. Also, pRb was shown to directly bind to C/EBPα, NF-IL6 and ►AP-1 transcription factors and enhance their DNA binding activity.

Other Targets of pRb

Low ►penetrance pRb mutants, such as substitution of Trp for Arg 661 in the B pocket of pRb (661W) which are inactive in both E2F and LXCXE binding, still retain tumor suppressor activity. In cell based assays, the 661W mutant was shown to inhibit G1/S progression. Furthermore, C pocket mutations in full length pRb also reduce pRb function. Taken together, these suggest non-E2F targets of pRb contribute to pRb tumor suppression function.

It was shown that pRb can bind to the oncoprotein Mdm2 through a C-terminal region in pRb, and Mdm2 overcomes pRb-mediated growth suppression. Direct interaction of pRb and Mdm2 can overcome both the anti-apoptotic function of Mdm2 and the Mdm2-dependent degradation of p53.

The C-terminus of pRb also interacts with the c-Abl tyrosine kinase. The ►c-Abl kinase is ubiquitously expressed in both the cytoplasm and nucleus. The nuclear kinase activity of c-Abl is under cell-cycle control, being activated during cell-cycle progression. Interestingly, c-Abl can simultaneously interact with pRb when the pocket region is occupied by E2F.

The human homologue of yeast SNF/SWI2 proteins, hBrm/hBrg, can interact with pRb in a pocket-dependent manner. hBrm/hBrg has chromatin remodeling activity and co-operates with pRb in the transcriptional activation of the glucocorticoid receptor. Together with the observation that pRb also recruits HDACs, it is likely that pRb regulates transcription by altering chromatin structure.

pRb also interacts directly with the largest TATA-binding protein associated factor, TAFII250, through multiple regions in each protein. Apart from being part of the basal transcriptional machinery, TAFII250 possesses intrinsic histone acetyltransferase activity and kinase activity. Mutagenesis studies suggested TAFII250 is a cell-cycle regulated protein and its acetyltransferase activity is required for cell-cycle progression. pRb was reported to inhibit the kinase activity of TAFII250. These findings point to an additional mechanism of pRb regulating transcription by modulating the activity of the basal transcription apparatus.

Evidence exists that pRb can modulate transcription that is mediated by RNA polymerase I and III. During differentiation of U937 myeloid progenitor cells, pRb becomes localized to nucleoli, which are the major sites of ribosomal gene transcription by RNA polymerase I. Immunoprecipitation experiments demonstrated that pRb can associate with transcription factor UBF1 and this interaction compromised the transcriptional activity of UBF1, thus leading to the down-regulation of Pol I transcription activity.

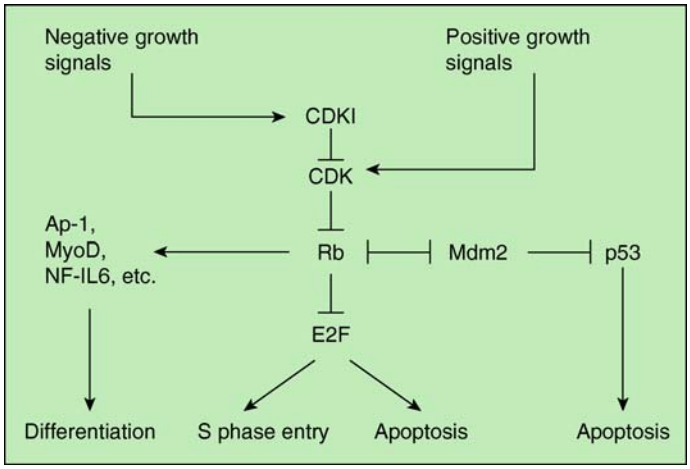
Loss of pRb function also correlated with up-regulation of Pol III transcription in tumor cells. Rb−/− fibroblasts have elevated Pol III activity compared to Rb+/+ fibroblasts. Immunoprecipitation and co-fractionation experiments demonstrated pRb interacts with TFIIIB, and TFIIIB was identified as a target of repression by pRb.

Animal Models

Rb−/− ►knockout mice fail to develop to full term, dying in utero at about 12–13 days post-coitum. The embryonic lethality is due to the failure of certain cell lineages to undergo terminal differentiation, particularly in the hemopoietic and central nervous systems (CNS). These observations suggest that pRb plays a crucial role in controlling cellular differentiation during development. Interestingly, Rb+/− mice do not develop retinoblastoma. Instead, 95% of the Rb heterozygotes die between day 300 and 400 after birth with tumors of the intermediate lobe of the pituitary (Fig. 1).

Summarizing Remarks

The RB tumor suppressor protein is an essential component of the ►cell-cycle clock, integrating both positive and negative signals for cellular growth and proliferation with the transcription machinery. The pRb protein exerts its function in tumor suppression by both antagonizing and synergizing with downstream effectors such as E2F. pRb has two modes of action: it can inactivate E2F transcription activity, and assemble an active repression complex with E2F. Apart from E2F, pRb synergies with various factors to promote cellular differentiation. The differentiation property of pRb at least contributes partly to its tumor suppressor function. The pRb-c-Abl and pRb-Mdm2 interactions also adds



Retinoblastoma Protein, Cellular Biochemistry. Figure 1 pRb integrates negative and positive signals in regulating the cell-cycle clock. Mitogenic signals activate cyclin-dependent kinase activity and inactivate pRb function by phosphorylation. In reverse, inhibitory signals, such as TGFβ and contact inhibition mobilize CDK inhibitors (CDKI) to maintain active pRb in its hypophosphorylated form. pRb has at least two distinct activities in tumor suppression: by inactivating downstream E2F activity, and by augmenting transcription activities of various transcription factors for cellular differentiation. Mdm2 acts as a mediator bridging together both the p53 and pRb pathways.

to its growth suppression function, though the mechanisms remain to be elucidated.

It is also clear that pRb is a master regulator for transcription. It can both activate and repress transcription in a context-dependent manner. pRb interacts directly with histone acetyltransferase, deacetylase and hBrm/hBrg, all of which are classes of proteins involved in chromatin remodeling. It will be important to investigate how pRb regulates transcription in a chromatin environment. Last but not the least, pRb regulates transcription from DNA polymerase Pol I, II and III, thereby integrating the cell-cycle clock with the biosynthetic capacity of the cell. pRb is indeed a bona fide master regulator of the cell.

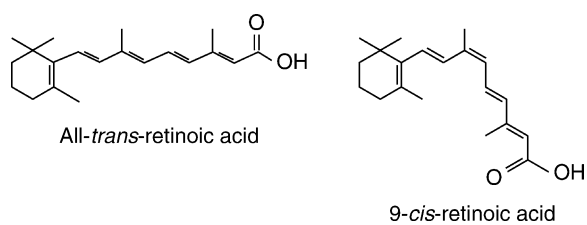
Retinoic Acid

Noa Noy
Department of Pharmacology, Case-Western Reserve University School of Medicine, Cleveland, OH, USA

Definition

Retinoic acid, a pale yellow lipid-soluble compound, is a natural metabolite of vitamin A which plays important roles in embryonic development and in adult tissues. Retinoic acid functions by activating transcription factors termed retinoid receptors, thereby regulating the expression of multiple target genes. Two isomers of retinoic acid, all-*trans*-retinoic acid and 9-*cis*-retinoic acid (Fig. 1), are transcriptionally active. All-*trans*-retinoic acid activates retinoic acid receptors (RARα, RARβ, and RARγ), while 9-*cis*-retinoic acid can serve as a ligand for both RARs and the retinoid X receptors (RXRα, RXRβ, and RXRγ). Synthetic compounds that mimic the biological activities of retinoic acid have



Retinoic Acid. Figure 1 Transcriptionally active retinoic acids.

been developed and some of these are in current use in treatment of various diseases including cancer. All-*trans*-retinoic acid and its natural and synthetic derivatives are termed "retinoids." The term "rexinoids" has been coined to describe 9-*cis*-retinoic acid and synthetic ligands that activate RXRs.

Characteristics

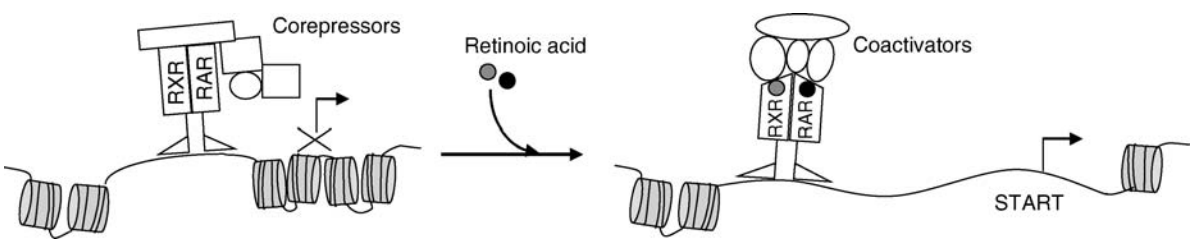
Retinoic acids regulate cellular behavior by activating RARs and RXR, ligand-activated transcription factors that are members of the super-family of nuclear hormone receptors. RAR and RXR function as a dimeric complex which binds to specific DNA recognition sequences (called response elements) in regulatory regions of target genes. In the absence of retinoic acid, the receptors are associated with accessory proteins, termed corepressors, which repress target gene expression. Binding of ligands induces the receptors to undergo a conformational change, resulting in dissociation of corepressors and recruitment of multicomponent complexes of transcriptional coactivators. In turn, coactivators modify the structure of the chromatin and facilitate the assembly of the general transcription machinery at the target gene start site (Fig. 2). Ligand-activated retinoid receptors thus regulate the expression of genes that play key roles in cellular differentiation and proliferation. Consequently, retinoic acid often inhibits cell growth and it displays antitumorigenic activities in various cancers.

Targets that mediate the antiproliferative activities of activated RAR include genes involved in differentiation, e.g. CCAAT/enhancer binding proteinε (*C/EBPε*); apoptosis, e.g. ►*TRAIL* and ►*Caspase-9*; and cell cycle regulation, as for example *Btg2* which targets ►cyclin D1. Hence, the pathways by which retinoic acid inhibits cell growth in the context of different carcinoma cell types can involve induction of ►cell cycle arrest, or differentiation, or ►apoptosis, or a combination of effects. The biological activities of 9-*cis*-retinoic acid and other rexinoids are mediated by a broad repertoire of target genes. Among nuclear receptors, RXR holds a special place because this transcription factor is an obligatory dimeric partner not only for RAR but also for other nuclear receptors. These include receptors that were reported to display anticarcinogenic activities such as the ►vitamin D receptor (VDR). The participation of RXR in numerous dimeric complexes may allow this receptor to affect carcinoma cell growth through multiple pathways that converge at the genome.

Regulation

►Vitamin A (retinol) is stored in vivo in various lipid-storing tissues, with the main pool existing in the liver. Retinol is secreted from these tissues and circulates in blood bound to retinol-binding protein (RBP). In target cells, retinol may be esterified to the storage species retinyl esters, a reaction catalyzed by lecithin:retinol acyltransferase (LRAT), or it may be converted to retinoic acid by two metabolic steps. The first, catalyzed by retinol dehydrogenase (ROLDH), leads to the formation of retinaldehyde (also called retinal). In the second step, retinal is converted to retinoic acid by a reaction catalyzed by retinal dehydrogenase (RALDH). Several isotypes of retinol- and retinal-dehydrogenases are known to exist, and these are differentially expressed in different cells and across developmental stages. Retinoic acid is degraded through the action of a member of the ►cytochrome P450 gene family termed CYP26. The several known CYP26 isotypes display a retinoic acid-4-hydroxylase activity and they catalyze the oxidation of retinoic acid to non-active metabolites. The concentration of retinoic acid in cells is thus tightly controlled by the expression levels and the activities of the enzymes that regulate its homeostasis. Cellular needs for retinoic acid are fulfilled by upregulation of expression of RALDH, and protection from excessive retinoic acid levels is provided by increases in the expression of CYP26 and LRAT.

In cells, retinoic acid is synthesized in the cytosol while its transcriptional activities are mediated by nuclear RAR. Transport of retinoic acid from the cytosol to the nucleus is mediated by a member of the family of intracellular lipid-binding proteins termed cellular retinoic acid-binding protein type II (CRABP-II).



Retinoic Acid. Figure 2 Ligand-induced activation of retinoid receptors. RXR-RAR dimers bind to response elements in regulatory regions of specific target genes. In the absence of retinoic acid, the receptors are associated with an accessory protein complex containing transcriptional corepressors. Upon binding of cognate ligands, corepressors dissociate and complexes of coactivators are recruited. These, in turn, loosen the structure of the chromatin and facilitate the assembly of the transcription initiation complex.

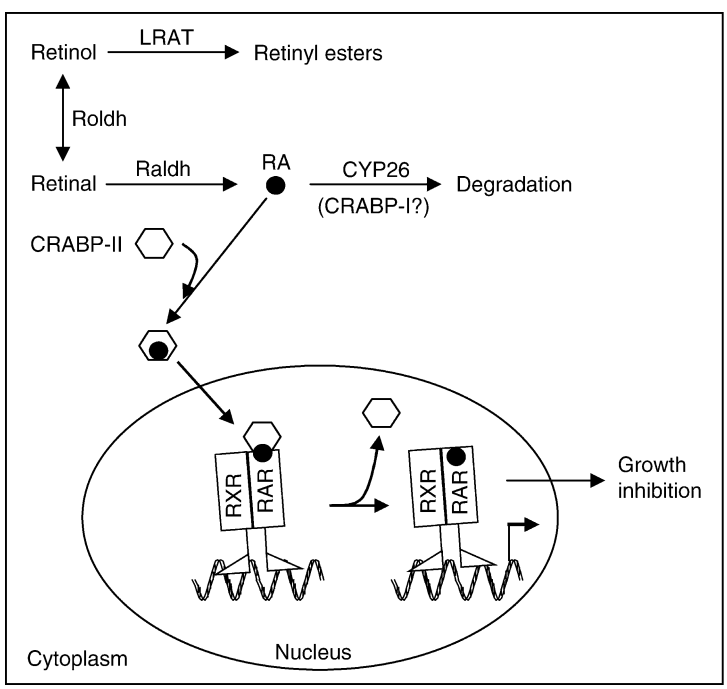
CRABP-II, which is cytosolic in the absence of retinoic acid, relocates to the nucleus upon binding of its ligand. In the nucleus, CRABP-II associates with RAR to form a complex through which retinoic acid is directly "channeled" from the binding protein to the receptor. By efficiently delivering retinoic acid from its sites of biosynthesis to RAR, CRABP-II enhances the transcriptional activity of the receptor (Fig. 3). An additional binding protein, termed CRABP-I, is involved in regulating retinoic acid biology. CRABP-I appears to dampen retinoic acid signaling, perhaps by facilitating its degradation.

Following activation by their ligands, both RAR and RXR undergo phosphorylation at specific residues, tagging the receptors for ►ubiquitination and targeting them to degradation by the ►proteasome. Receptor degradation serves as an "off-switch" for the retinoid response. Both RARs and RXRs also undergo other phosphorylation events mediated by several signaling pathways, and these modifications alter the transcriptional activities of the receptors. Various signaling cascades thus cooperate with retinoic acids in regulating the expression of retinoid target genes.

Clinical Relevance

It has been long established that vitamin A deficiency is associated with increased susceptibility to carcinogenesis both in experimental animal models and in human populations. The protective activity of the vitamin is believed to be mediated by the retinoic acid through its ability to modulate cell growth, differentiation, and apoptosis. Indeed, retinoids exhibit chemotherapeutic activities in a number of cancers. Retinoic acid is particularly efficacious in treatment of ►acute promyelocytic leukemia (APL), a malignancy caused by a ►chromosomal translocation which results in an oncogenic protein in which RARα is fused to PML. Treatment of APL patients with retinoic acid in conjunction with conventional chemotherapy results in complete remission rates as high as 90%. Retinoic acid has also been successfully used in treatment of ►neuroblastoma, ►Kaposi sarcoma, and ►cutaneous T-cell lymphoma, and it may be effective in therapy and perhaps prevention of other malignancies such as ►bladder cancer, ►liver cancer, ►lung cancer, ►pancreas cancer, head and neck, ►prostate cancer, and breast cancer. In addition to retinoic acid, several retinoids and one rexinoid are being tested for the treatment of specific cancers.

Abnormal cell growth and tumor development in various malignancies is associated with aberrations in many aspects of retinoic acid signaling. These include disregulation of the expression of RARs, most notably RARβ, deviant expression levels of enzymes and binding proteins involved in regulating retinoic acid homeostasis and action, and persistent association of



Retinoic Acid. Figure 3 Components of the retinoid signalling pathway. Retinol can be stored in the form of retinyl esters or converted to retinoic acid. Retinoic acid is mobilized to the nucleus where it activates retinoid receptors, thereby upregulating the expression of genes involved in carcinoma cell growth inhibition. Depicted are enzymes, binding proteins, and receptors involved in retinoid signalling (see text).

retinoid receptors with transcriptional corepressors. Targeting of the aberrant point(s) in RA signaling in specific cancers may allow for the improvement of current therapies and the development of novel strategies for treatment of these diseases.

Retinoic Acid Receptors

Definition

RAR; Belong to the ►nuclear receptor superfamily. Are nuclear receptors related to the ►steroid hormone receptors and ►thyroid hormone receptors, a family of proteins that function as ligand-dependent transcription factors. Several loci encoding RAR isoforms have been identified in mammals – RAR-alpha, -beta and gamma – as well as novel nuclear receptors known as RXR (Retinoid X receptor), which are distantly related to RARs and respond to high concentrations of ►retinoic acid (RA). The RARs show spatially restricted distribution patterns during embryogenesis, which have led to speculation on a variety of roles for RA in developmental processes. As with other enhancer-binding proteins, nuclear receptors act as transcription factors by binding to specific DNA recognition sequences generally located upstream of responsive genes. Although RARs can activate gene expression through binding to thyroid hormone response elements, a much more specific and potent RA response element (RARE) has been identified recently within the promoter of the RAR-beta gene. This RARE is essential for RA induction of the RAR-beta gene and, when linked to heterologous promoters, can confer transcriptional activation via all three RARs.

Definition

The process of intercellular retinoid receptors activation by another activated ►transcription factor or the alternate. It may also be considered as the cooperation among different signal transduction pathways in various normal and pathological states, whereby activation of retinoid receptors enhances the activity of other transcription factors in the absence of direct activation, thus leading in positive or negative regulation of specific target genes.

Characteristics

Retinoids

Retinoids (►Retinoic acid) comprise a group of structural and functional derivatives of ►vitamin A that are considered physiological regulators of a plethora of essential biological processes, including embryonic development, vision, reproduction, differentiation, proliferation and ►apoptosis. Pharmacologically, they have been shown to suppress ►carcinogenesis in a wide gamut of tissues (e.g. skin, respiratory epithelium) in animal models, while clinically they seem able to reverse premalignant lesions (►Preneoplastic lesions) and inhibit the development of ►second primary tumors. Until 1987 it was known that retinoids are implicated in gene transcriptional control, but the precise mechanism was still a mystery. This was the year that two research groups identified the retinoid receptors. Many scientists have now concluded that retinoids' molecular actions are mainly modulated through their receptors which are members of the ►nuclear receptor superfamily.

Retinoid Receptors

Retinoid receptors contain six domains, designated A to F. The N-terminal region (domains A and B) includes a ligand-independent activation function (AF-1). The C domain contains a highly conserved DNA-binding domain, which might also participate in protein–protein interactions with transcriptional co-factors. The D domain is involved in ligand-induced functional changes and is crucial for the binding of receptor to transcriptional co-factors. The E and F

domains, which are moderately conserved among receptors, are involved in ligand binding and include a ligand-dependent activation function (AF-2) and a dimerization surface. The ligand-binding domains of RARs and RXRs are distinct and can be pharmacologically targeted separately.

Two types of retinoid receptors have been identified: the RARs and the RXRs. There are three RAR isotypes and three RXR isotypes (α, β and γ), which are encoded by distinct genes. For each isotype, there are at least two isoforms, which differ in their N-terminal A regions and are generated by differential usage of promoters and/or alternative splicing. Isotretinoin, also known as 13-*cis*-retinoic acid (Retinoic acid), is converted to all-*trans*-retinoic acid, which activates the RARs, whereas 9-*cis*-retinoic acid (Retinoic acid) activates both the RARs and the non-classical RXRs. RARs can heterodimerize with RXRs, whereas RXRs have a pivotal role as heterodimerization partners for several other nuclear receptors, such as the thyroid hormone receptors (TRs), the vitamin D3 receptors (VDRs), the ►peroxisome proliferator-activated receptors (PPARs) and several orphan receptors. Because RXRs form heterodimers with nuclear receptors that affect lipid physiology, their effects are also being investigated in other than carcinogenesis medical conditions, including the metabolic syndrome, which is characterized by ►obesity, dyslipidemia, ►diabetes, and hypercoagulability.

Like other members of this family, retinoid receptors act as ligand activated DNA-binding gene specific transcription factors through binding, as RAR–RXR heterodimers, to *cis*-acting retinoic acid response elements (RAREs) present in cognate genes. In the absence of ligand, RAR–RXR heterodimers are bound in a complex with co-repressors that actively repress the transcription of targeted genes. Transcriptional repression occurs mainly through the recruitment of ►histone deacetylases (HDACs), which prevent the opening of chromatin that is associated with the deacetylation of nucleosomes. Upon ligand binding, co-repressors are released and several multi-protein co-activator complexes are recruited to activate transcription. ►CREB-binding protein (CBP)/p300 associates with nuclear receptors in a ligand-dependent manner and shares intrinsic ►histone acetyltransferase (HAT) activity. RAR–RXR dimers bind to RAREs, which are characterized by two half sites with the consensus sequence AGGTCA. These are usually arranged as direct repeats separated by two to five nucleotides. Other RXR heterodimers bind to similar half sites with different preferences for spacing and orientation.

Retinoid Acid Receptors (RARs)

The three RAR isotypes have similar, but not identical, sequence and structure to one another, and they are expressed in distinctive tissue specific and developmentally regulated patterns. Each RAR also performs unique functions in development and differentiation that cannot be replaced by the actions of the other isotypes. Thus, each RAR isotype exerts a mixture of overlapping and specific actions concerning target gene expression control.

The crystal structure of RARβ has only recently been completed and revealed significant differences of its ligand-binding domain compared with the other two isotypes, reflecting the size and activity of potential agonists and antagonists on RAR-mediated transcriptional control.

As do other members of the nuclear receptor superfamily, RARs possess bimodal transcriptional properties, mainly due to their association with transcriptional co-factors. One pivotal difference among RARs isotypes that might contribute to their distinct function properties is that RARβ and RARγ inefficiently interact with co-repressor complexes to represses target gene transcription in the absence of ligand, whereas they can mediate significant transcriptional activation. That means that RARβ–RXR heterodimers are more responsive to rexinoids than are RARα–RXR heterodimers. These different co-repressor interaction properties of RAR isotypes is thought to be mediated either by proximal or/and apical co-repressor docking site conformational changes. Another important distinct property of RARβ is the ability to trans-repress the transcription factor ►activator protein-1 (AP-1), reversing established tumor promotion, because anchorage-independent growth of transformed cells is efficiently inhibited. Although the exact mechanism of the anti-►AP-1 activity of retinoids remains elusive, the importance of this cross-talk (►Receptor cross-talk) for growth control is increasingly recognized and considered as a phylogenetically highly conserved function.

Rexinoid Receptors (RXRs)

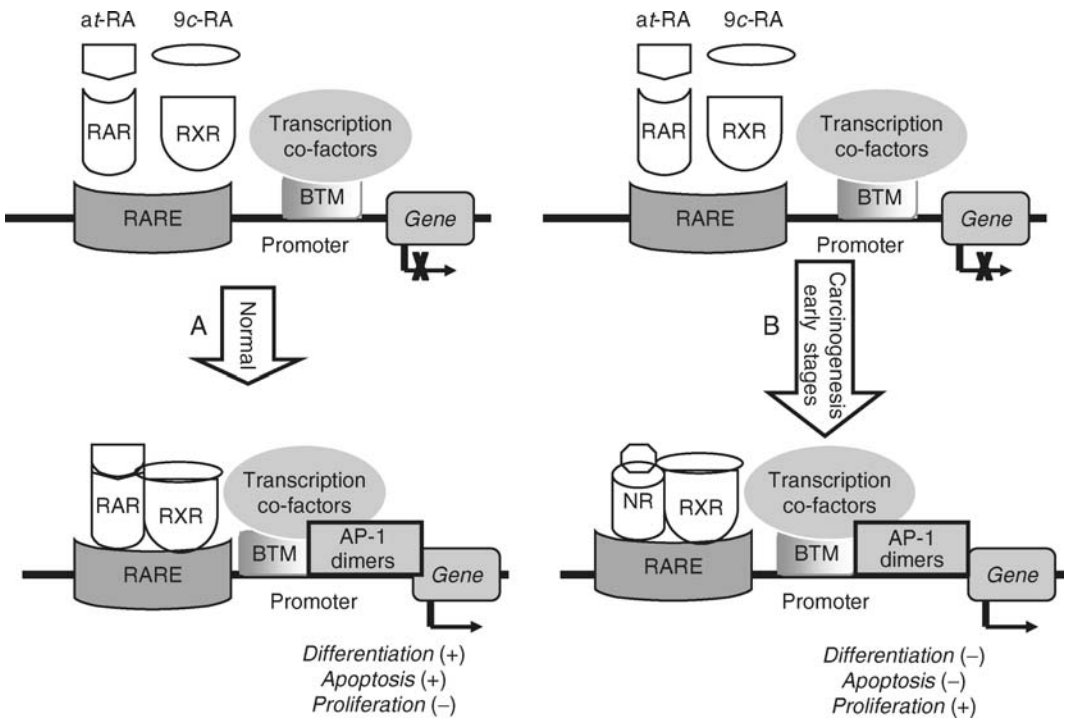
The ability of RXR to function as a ligand-dependent transcription factor is differentially regulated by its dimerization partners, which differentially control the binding of RXR ligands and the interactions of the heterodimer with transcriptional co-factors. Non-permissive heterodimers, such as those between RXRs and RARs, are characterized by the fact that the partner drastically interferes with the ability of RXR to activate transcription in response to RXR-specific ligands. However, recent studies have demonstrated that the binding of certain RXR ligands contributes to the activation of RAR–RXR heterodimers in some cell types. Heterodimers of RXRs with permissive partners have been identified and include the PPARs, Liver X receptors (LXRs) and ►Nur77 (TR-3 or NGFI-B). Recent studies suggest that nur77 is associated with trans-RA resistance in human cancer cells. The retinoic acid response element (βRARE) in the RARβ gene promoter

mediates trans-RA-induced RARβ gene expression in many different cell types and binds to both RXR–RAR and RXR–nur77 heterodimers. Gene transcriptional activation by RXR–RAR binding is mainly activated by RAR-specific ligands, whereas trans-activation by RXR–nur77 is induced by RXR-specific ligands. Thus, RARβ expression might be associated with both retinoid-induced proliferation and apoptosis processes.

Retinoid Receptors Cross-talk During Carcinogenesis

It is increasingly recognized that altered expression of RARβ protein is crucially involved in the pathogenesis of a diverse range of solid tumors, although the loss of RARα or RARγ expression has also been reported, but not consistently. Although the loss of RARβ expression is a frequent event in the early stages of carcinogenesis, the causative mechanism is still unclear and has been attributed to multiple mechanisms. However, it seems that RARβ down-regulation might be directly correlated with the sub-optimal observed clinical results of the currently used retinoids in cancer chemoprevention trials, although recent data has suggested that retinoids might also share receptor-independent anti-tumor activity. The well-recognized negative cross-talk of RARβ and AP-1 functions as a "molecular balance," thus favoring under normal conditions the RARβ mediated positive transcriptional regulatory effects regarding the induction of differentiation and apoptosis. During the very early stages of carcinogenesis this balance is disrupted by a combination of molecular aberrations, such as down-regulation of RARβ, up-regulation of AP-1 and crucial transcriptional co-factors (e.g. CBP/p300). AP-1 has the ability to enhance cellular proliferation, through cyclin D1 (►Cyclin D) enhanced expression, thus providing a developmental advantage in these gradually transformed cells in the setting of genomic instability (►Chromosomal instability).

Under normal conditions, such an aberration should trigger apoptosis intracellular feedback mechanisms to handle this imbalance. However, it seems that retinoid receptors are also implicated in the deregulation of apoptosis. The underlying mechanisms remain unknown, although the currently existing data support both the role of RARβ with its association with certain orphan receptors (e.g. Nur77) and RXRs through their complex interplay with nuclear receptors (e.g. PPARs), other transcription factors (e.g. NF-kB) as well as with important cancer-related intracellular molecules (e.g. ►Cyclooxygenase-2 (COX-2)) (►Arachidonic acid-pathway). The final outcome of these cross-coupling interactions of various retinoid receptors with other molecular pathways is differentiation inhibition, apoptosis blockade and uncontrolled cellular proliferation, namely some of the most important "hallmarks of cancer" (Fig. 1).



Retinoid Receptor Cross-Talk. Figure 1 (a) Schematic presentation of retinoid receptors activation and transcriptional activity under physiological conditions; (b) In the very earl stages of carcinogenesis the deregulated retinoid receptors cross-talk interactions with other nuclear receptors (NR) and/or other oncogenic transcriptional factors (e.g. AP-1) dictates malignant transformation of the "affected" cells.

The gradual elucidation of the paramount importance of retinoid receptors cross-talk in the carcinogenesis process has generated the notion that either more selective synthetic retinoids are warranted or/and combinatorial approaches targeting more than one crucial molecules might represent the next step in the intriguing concept of cancer ►chemoprevention.

Retinoid X Receptor

Definition

Is a member of the ►nuclear receptor superfamily which is activated by ►retinoic acid and acts as a direct regulator of transcription by binding to specific DNA sequences.

►Retinoid Receptor Crosstalk

Retinoids

Definition

Is a collective term that refers to both naturally occurring and synthetic compounds that bear structural resemblance to ►vitamin A (all-trans retinol) and/or exhibit biological activity similar to retinols, retinals, or ►retinoic acid. The main functions of retinoids include involvement in reproduction, growth and differentiation (skin differentiation, bone remodeling), and immune system functioning. They exert many and diverse functions throughout the body including roles in vision, regulation of cell proliferation and differentiation, growth of bone tissue, immune function, and activation of tumor suppressor genes.

►Carotenoids
►Nutraceuticals
►Retinoid Receptor Cross-talk

Retinol

Definition

The animal form of ►vitamin A, is a fat-soluble vitamin important in vision and bone growth. It belongs to the family of chemical compounds known as ►retinoids. Precursor in forms of retinol animal sources (liver and eggs); plants (carrots, spinach) contain pro-vitamin A ►carotenoids.

Retromer

Definition

Multiprotein complex important in recycling transmembrane receptors from endosomes to the ►trans-Golgi network.

►Wnt Signaling

Retroperitoneum

Definition

Anatomical space behind the peritoneal cavity. Retroperitoneal organs, e.g. kidneys, are relatively fixed in their location whilst intraperitoneal organs, e.g. small bowel, are generally mobile.

►Transcoelomic Metastasis

Retrospective Study

Definition

A study design that looks backwards in time and examines events that have already taken place, for example, the typical case control study that compares people who already developed disease to people who did not. Study type in which the outcome (e.g. cancer diagnosis) has occurred to the subjects before the study commences

►Mutagen Sensitivity

Retrotransposition

Definition

A still incompletely understood "copy and paste" mechanism that involves replication by reverse transcription of an RNA intermediate, mobilization and reinsertion of new cDNA copies of repetitive elements within the human genome.

Retroviral Insertional Mutagenesis

Christopher Slape, Peter D. Aplan
Genetics Branch, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA

Synonyms

Retroviral insertional tagging

Definition

Is an experimental screen performed to identify genes whose expression is linked to a ►phenotype of interest. It involves the ►infection of ►mouse models (or other model organism) with ►retrovirus, observing the mice until they develop the phenotype of interest (often a malignancy), and then identifying relevant candidate genes by determining the site of proviral insertion.

Characteristics

Retroviral ►insertional mutagenesis is an experimental approach to gene discovery that takes advantage of the life cycle characteristics of ►retroviruses.

History

Retroviruses have long been known to induce cancer. The first oncogenic retrovirus identified was avian erythroblastis virus (AEV), the existence of which has been known since around 1900. More avian and murine viruses were soon discovered. With the advent of DNA sequencing, many of these were found to contain ►oncogenes. Indeed, many of the first oncogenes were discovered in this way, including ►*ras*, ►*src* and ►*abl*. The mechanism of oncogenesis of these viruses was easily solved; expression of the oncogene contained within the virus induced the cancer. However, there were also a number of viruses that induced cancer but did not contain an oncogene. The mechanism by which these viruses induced cancer was less obvious. A study by William Hayward et al. in 1981 identified the mechanism. These authors found that insertion of the provirus in the *c*-►*myc* ►promoter led to activation of the cellular proto-oncogene *c-myc*. Even with this knowledge of the oncogenic mechanism, large-scale retroviral insertional mutagenesis projects were not feasible until a draft of the mouse genome became available. The pioneering study of this type took place in the laboratory of Neal Copeland and Nancy Jenkins in the late 1990s.

Provirus Structure

As part of their replication cycle, retroviruses are required to integrate a DNA copy of their genome into the host genome. At this stage of the replication cycle the virus is referred to as the provirus. The structure of the provirus is illustrated in Fig. 1. This represents a replication competent virus. Replication competent viruses contain genes encoding various proteins essential for viral replication, including the *gag*, *pro*, *pol* and *env* genes. At either end of the provirus are two Long Terminal Repeat regions (sometimes referred to as Long Tandem Repeats). As the name suggests, these regions contain identical, or repeated, sequence, and form the boundaries of the proviral structure. They contain sequences that are important for the transcription of the viral genes, including a promoter and an ►enhancer element, both within the U3 region. The promoter in the 5′ LTR drives expression of the proviral genes, thus facilitating viral replication. Many of the oncogene-containing viruses are replication incompetent because some or all of the required genes are replaced by the sequence of the oncogene.

Retroviral Insertional Mutagenesis. Figure 1 Elements of a retroviral provirus. The 5′ and 3′ LTRs are indicated, subdivided into the subregions U3, R and U6. E and P indicate the transcriptional enhancer and promoter respectively, with the *arrow* indicating the direction of transcription initiated at the promoter. The gag, pro, pol and env genes are indicated, along with the splice donor (SD) and splice acceptor (SA) sites.

Tumor Types

The types of tumors that can be investigated by retroviral insertional mutagenesis are limited by the types of tissues that are infected by retroviruses. Retroviral insertional mutagenesis has been used most frequently to study leukemia and lymphoma, but recent reports have used insertional mutagenesis to study ►breast cancer and ►brain tumors. A newly developed related technique, ►transposon insertional mutagenesis, offers a potential means of investigating tumors in other tissues.

LTRs Regulate Transcription of Host Genes Near the Insertion Site

The promoter in the 3′ LTR can drive expression of nearby genes in the host genome, and the enhancer element from either LTR can activate transcription of nearby host genes. It is through this mechanism that retroviral insertional mutagenesis provides an efficient cancer gene screen. Transcription of host genes that provide the cell with an oncogenic advantage lead to a clonal outgrowth and malignancy. In this way retroviral insertional mutagenesis identifies potential proto-oncogenes. There are additional mechanisms by which retroviral insertion can dysregulate host genes in such a way as to cause cancer; examples are listed below and illustrated in Fig. 2.

Promoter Insertion

Insertion of the provirus into an endogenous promoter results in replacement of the endogenous promoter with the promoter in the 3′ LTR. This results in a higher level of expression for the gene in question, as the viral promoter is very active. A frequent example of this mechanism is promoter insertion at the *c-myc* locus.

Enhancer Activation

Insertion of the provirus nearby or within the host gene can result in increased host gene expression via the endogenous promoter and proviral enhancer sequences. This is thought to be the most frequent oncogenic mechanism that occurs via retroviral insertional mutagenesis, and there are numerous examples. One common example is sp. retroviral insertion 5′ or 3′ of the *Meis1* gene.

Protein Fusion

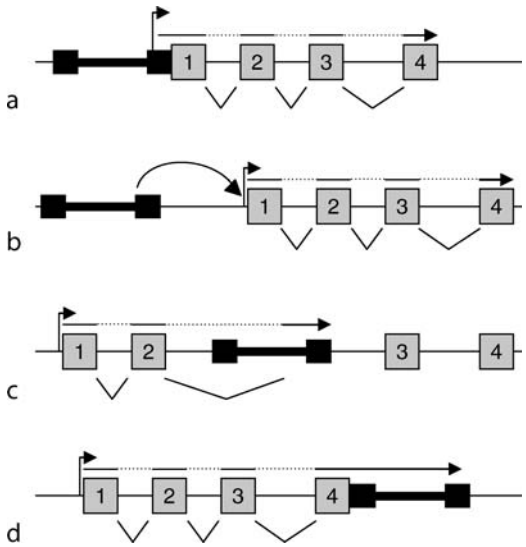
Insertion of the provirus within a gene, either within an exon or within an intron, can lead to protein truncation. In the case of an intronic insertion, this requires that the transcript splicing machinery, when splicing the endogenous transcript, take advantage of a splice acceptor site within the viral genome such that an exon of the host gene is spliced directly to the viral coding sequence. In the event of an exonic insertion, no splicing event is necessary as the coding sequence will be directly adjacent to the proviral sequence. Either of these scenarios will result in a fusion of the two proteins, which in some cases can be oncogenic. This mechanism often results in inactivation of the target gene rather than activation, and therefore occurs in ►tumor suppressor genes as well as oncogenes (as it provides a mechanism of ►dominant negative mutation). An example of a ►tumor suppressor gene inactivated by this mechanism is ►*p53*, and an example of a proto-oncogene activated by this mechanism is *c*-►*myb*.

Transcript Stabilization

Proviral integration into the 3′ UTR of a gene can result in loss of regulatory sequences that normally result in degradation of the transcript. The loss of this regulation results in an effective upregulation of the gene. An example of a proto-oncogene activated by this mechanism is *Pim1*.

Cloning of Insertion Sites

Cloning of insertion sites refers to identification of the loci into which the provirus inserted. It is important to realize that, when the organism is infected with retrovirus, many normal cells are infected and a given tissue may contain millions of insertion sites. However, even though a tissue sample may contain contaminating



Retroviral Insertional Mutagenesis.

normal, non-malignant cells, because the cell containing oncogenic insertion sites has undergone numerous cell divisions, these oncogenic insertion sites are now greatly over-represented in the tumor sample.

The most common basic strategy to identify insertion loci is one of a variety of "anchored ►PCR" techniques. One of these, inverse PCR, involves digestion of the host genomic DNA with a restriction enzyme, followed by circularization of the resultant fragments. PCR is then performed using these circularized fragments as templates and primers designed to the known proviral sequence. Several additional anchored PCR techniques exist, mostly involving the ligation of some form of adaptor to the digested fragments rather than circularization of the fragments. One primer can then be designed to the adaptor, and the other to the proviral sequence. Either approach allows specific amplification of the sequences adjacent to the provirus without prior knowledge of the identity of those sequences. The sequence obtained from the PCR product can then be compared to the genome databases to identify the exact locus of integration, and to investigate the genes known to be in the region.

One complication that arises during the insertion sites cloning process is the identification of false positive "bystander" mutations. These arise when more than one proviral integration occurs within a single cell. Not every integration within the cell is essential for tumorigenesis, but if the cell is oncogenically transformed it will produce numerous ►daughter cells, and all insertion sites within it will be represented in the final tumor sample equally. Therefore, if bystander insertions exist within a tumor sample, they are just as likely to be cloned as a genuine, biologically relevant insertion site. Therefore, individual proviral insertion site results must be interpreted carefully.

Common Integration Sites

One means of distinguishing those genes likely to be important for malignant transformation in an insertional retroviral mutagenesis screen is the identification of common integration sites. A common integration site is a region in which more than one insertion, or event, is discovered in the same cohort of mice (or other organism). This is based on the simple premise that an event that occurs in multiple cancers is much more likely to be involved in malignant transformation than one that occurs in only one cancer. However, the definition of a common integration site is complicated by several factors. Firstly, proviral integration can have biological effect on host genes over a very large distance (in excess of 100 kb, for example, in the case of enhancer activation). Secondly, the number of cancers in a given cohort increases the number of insertion sites and, therefore, insertions at a given loci are more likely to occur by simple chance. Finally, as discussed below, proviral insertion is not a truly random event, and this must also be taken into account when determining whether a site is truly a common integration site. Several algorithms have been developed to address this issue.

Randomness of Insertion

One of the early attractions of retroviral insertional mutagenesis was that it allows investigation of the whole genome without bias. However, more recent studies have suggested that proviral integration is not truly random, and that different viruses have different mechanisms of insertion that affect the frequency of their insertion at particular loci. For example, viruses in general show a preference for integration into open chromatin regions, which can vary with cell type. Viruses show different preferences for integration within transcriptional units and upstream or downstream of transcriptional units. This means that retroviral insertional mutagenesis studies are probably not truly random (although they remain approximately random), and that studies performed with different viruses may generate different results.

Retrovirus

Definition

A retrovirus, formerly referred to as RNA tumor virus, belongs to the group of RNA viruses. RNA viruses have an RNA, not a DNA genome. Following the virus entry into a cell, this RNA is transcribed by the enzyme reverse transcriptase into one single strand of DNA, which in turn serves as the template for the host cell DNA polymerase to synthesize the complementary DNA strand, eventually forming double stranded (ds) DNA. The ds DNA is stably inserted into the DNA of the host cell as a provirus, providing the source for an RNA template that is identical to the initial virus RNA genome. Viral proteins can now be synthesized. The provirus therefore behaves like any of the other normal genes within the host genome and, during cell division, is regularly passed on to the daughter cells. Synthesized viral proteins, together with the newly synthesized RNA, can be packaged and to yield new virus particles. Upon their release by the cell, in a process referred to as "budding" new cells can be infected.

Usually the retrovirus infects a somatic cell and the provirus is integrated into the genome of that particular cell. If a virus infection occurs in a germ cell (a cell destined to become a sperm or egg cell) the resulting provirus can be passed on to the progeny and is inherited like a normal gene. Such genetic elements are called endogenous proviruses; they occur and are detectable in vertebrate DNA, including that of humans. Although in some species, such as mouse, thousands of endogenous proviruses exist, they are not transcribed, a fact at least partly due to heavy methylation. Endogenous proviruses can however, be induced artificially to produce virus particles.

Retroviruses were first isolated as agents that can cause cancer in chickens, the prototypical retrovirus being the Rous sarcoma virus (RSV). Some naturally occurring cancer diseases in humans are associated with retroviruses. The ►human T-cell leukemia virus I (HTLV-I) cause a relatively rare, but invariably fatal cancer of T lymphocytes. Another retrovirus, the ►human immunodeficiency virus, HIV (also known as HTLV-III or LAV) has been identified to cause acquired immunodeficiency syndrome (AIDS). The study of retroviruses has laid the basis to identify ►oncogenes.

The analysis of the ►transduction of oncogenes has directly led to the concept of cancer as the result of a malady of genes. In pursuit of defining the role of oncogenes in cancer development, fundamental insights into the molecular basis of cancer and cellular growth control have been achieved. Retroviruses that cause, within short time after infection, cancer in animals (acutely transforming retroviruses), possess an oncogene (viral oncogene, v-onc) that is responsible for cellular transformation. Such viral oncogenes are originally not viral. Instead they but have been taken up from the host cell by the provirus, followed by their incorporation into the virus genome. Viral oncogenes therefore, have once been normal cellular genes (proto-oncogenes or cellular oncogenes). They are evolutionary conserved and are present in all mammalian cells, often even in non-mammalian cells. Alteration of these cellular oncogenes (by ►point mutation, ►translocation or ►amplification) is one of the main contributions to cancer in all mammals, including humans.

►Osteopontin
►TAT Protein of HIV

RGD, ^{18}F-Galacto-RGD

Definition

The selection of patients considered for antiangiogenic therapy may benefit from specific biomarkers defining individual angiogenetic activity in tumor tissue. ►Integrins are heterodimeric transmembrane glycoproteins consisting of different α- and β-subunits, which play an important role in cell-cell- and cell-matrix-interactions. An important member is αvβ3 which mediates the migration of endothelial cells through the ►basement membrane during blood vessel formation facilitating molecular imaging of ►angiogenesis. The pentapeptide cyclo(-Arg-Gly-Asp-dPhe-Val-) which shows high affinity and selectivity for αvβ3 can be labeled with ^{18}F. [^{18}F]Galacto-RGD represents the first PET tracer enabling imaging of αvβ3 expression.

►Positron Emission Tomography

RGS Proteins

Definition

Regulators of ►G-protein signaling inhibit G-protein-mediated signaling by activating the GTPase activity of defined G-protein α-subunits. The currently identified RGS proteins appear to predominantly interact with members of the G_i and G_q families of heterotrimeric G-proteins.

Rhabdoid Tumor

Jaclyn A. Biegel
The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Definition

A highly malignant tumor that primarily affects infants and young children. Rhabdoid cells contain large nuclei with prominent nucleoli and abundant eosinophilic cytoplasm that often contains filamentous cytoplasmic inclusions. In tumors of the central nervous system (CNS), areas of rhabdoid cells may be seen in juxtaposition to areas of primitive neuroepithelial cells resembling primitive neuroectodermal tumor, as well as mesenchymal tissue and/or epithelial tissue. The designation atypical teratoid/rhabdoid tumor (AT/RT) is used to describe the CNS tumor.

Characteristics

The true incidence of rhabdoid tumors in the population is not known due to the fact that many of these malignancies, especially in the brain, have been misdiagnosed. The most common sites of presentation for rhabdoid tumor are the kidney and brain. Rhabdoid tumors account for approximately 1–2% of childhood renal tumors and 2% of pediatric CNS tumors (►Brain Tumor). ►Extrarenal tumors are less common and may arise in a wide variety of sites, such as the liver, orbit, skin and other soft tissues. Most children are less than 3 years of age at diagnosis, and there is a slight male predominance (3:2). Rare reports of adult patients with rhabdoid tumors have demonstrated similar genetic alterations in these cases as compared to classic rhabdoid tumors of childhood. Rhabdoid tumors are highly aggressive malignancies and there have been few long term survivors.

The cell of origin for rhabdoid tumor is unknown. Variable histologic features and immunoreactivity to epithelial, neural, glial and/or myogenic markers may obscure the diagnosis of rhabdoid tumor. In the brain, the rhabdoid components of AT/RT usually exhibit positive staining for epithelial membrane antigen and vimentin, which helps distinguish it from ►medulloblastoma or supratentorial ►primitive neuroectodermal tumor. Approximately 40% of AT/RTs originate in the posterior fossa, notably in the cerebello-pontine angle. Forty percent of tumors are supratentorial, 5% are located in the pineal and the remainder are brain stem or multifocal. The tumors are highly metastatic, spreading rapidly throughout the cerebrospinal pathway.

To date, seven families have been reported in which a child with a rhabdoid tumor has had a first or second degree relative with a rhabdoid or CNS tumor. The small number of families with multiple affected individuals is likely due to the fact that few survivors have reached child bearing age. A genetic predisposition to rhabdoid tumor was originally supported by the finding that approximately 10–15% of infants with renal rhabdoid tumors had second primary tumors of the CNS. In past reports, the predominant histology of the brain tumors was consistent with a medulloblastoma or other primitive neuroectodermal tumor. It is now recognized that the brain tumors in these infants are AT/RT. Children may present with an AT/RT and rhabdoid tumor of the liver, lung or soft tissues, or with multiple primary tumors. The occurrence of two primary rhabdoid tumors (e.g. bilateral kidney tumors or rhabdoid tumors of both the kidney and brain) predicts the worst prognosis.

Genetics

The genetic predisposition to rhabdoid tumor and AT/RT is associated with a germline alteration in the INI1/hSNF5/BAF47/SMARCB1 gene. Cytogenetic and molecular studies of AT/RT, renal and extrarenal rhabdoid tumors demonstrated consistent deletions within chromosome band 22q11.2. ►Positional cloning strategies were employed to identify a candidate gene for rhabdoid tumor, which led to the identification of INI1 as a rhabdoid ►tumor suppressor gene. INI1 is a member of the ►SWI/SNF ►chromatin remodeling complex and may regulate transcription of specific target genes involved in both growth and differentiation.

Germline alterations of INI1 have been reported for patients with AT/RT, renal and extrarenal rhabdoid tumor. Germline deletions or mutations have been identified in at least 40 children. Loss of the wildtype allele or a mutation in the second allele has been documented in the tumor cells of these individuals, consistent with a ►two-hit model for a tumor suppressor gene. In several children with AT/RT and a renal or extrarenal rhabdoid tumor, the second hits arose

through different mechanisms in the two tumors, providing evidence that they were distinct primary malignancies and not metastases.

Two families in which a non-affected carrier mother transmitted a mutated INI1 gene to children diagnosed with AT/RT have been reported, suggesting that there may be ►reduced penetrance for the inherited form of this disease. Furthermore, several families with multiple affected siblings in which a carrier parent could not be identified were thought to be due to ►gonadal mosaicism.

►Biallelic inactivation of INI1 is also observed in the majority of sporadic rhabdoid tumors. ►Homozygous deletion has been documented in rhabdoid tumors from all anatomic sites, although the highest frequency appears to be among extrarenal rhabdoid tumors. ►Monosomy 22 appears to be more common in AT/RT than renal rhabdoid tumors, both in infants with predisposing germline INI1 mutations and in children with sporadic disease. Rarely, tumors demonstrate compound ►heterozygous somatic mutations in INI1, also consistent with the two-hit model.

In the majority of rhabdoid tumors, loss of one allele of INI1 is accompanied by a mutation in the remaining copy. Although some ►missense mutations have been reported, most of the mutations are ►point mutations or ►frameshift mutations that introduce a novel stop codon and thus predict premature truncation of the protein. The INI1 gene contains nine exons. The mutations are distributed throughout the coding sequence of INI1, although exons 3 and 8 are clearly under-represented. Identical mutations have been observed in rhabdoid tumors of the kidney and brain, demonstrating that most mutations are unlikely to be site specific.

The total number of INI1 mutations reported to date is approximately 200, and predictions regarding potential hot-spots or specificity of INI1 mutations may change as more data is accumulated. A single base pair deletion in codon 382/383 of exon 9 is the most frequently observed mutation in AT/RTs. To date, it has not been observed as a germline mutation or in a renal or extrarenal rhabdoid tumor. Three mutations, C157T in exon 2, C472T in exon 4 and C601T in exon 5, also appear to be present at an increased frequency. Each of these mutations has been observed as a constitutional change in patients with brain, kidney or brain and soft tissue tumors. These nonsense mutations have also been demonstrated as somatic alterations in sporadic renal tumors and AT/RTs.

The specificity of INI1 alterations for rhabdoid tumors is subject to debate. Mutations of INI1 have been reported in medulloblastoma, supratentorial primitive neuroectodermal tumor, choroid plexus carcinoma and epithelioid sarcoma. Each of these types of tumors may be included in the differential diagnosis of AT/RT in children with CNS tumors, or with rhabdoid tumor in children or adults with soft tissue malignancies. An immunohistochemistry assay for the INI1 protein was developed as an aid in the clinical diagnosis of rhabdoid tumor. Normal cells and non-rhabdoid malignant tumor cells demonstrate nuclear expression of INI1. Rhabdoid tumor cells show loss of nuclear expression of the protein. All genomic deletions and mutations of INI1 result in loss of nuclear expression of INI1. Furthermore, the loss of expression of INI1 can be observed in the 20% of rhabdoid tumors for which an INI1 deletion or mutation is not observed. The question of whether identification of an INI1 mutation is sufficient to make a clinical diagnosis of rhabdoid tumor or if there are several related tumors that may have overlapping molecular genetic alterations, will ultimately be addressed in large clinical and molecular genetic correlative studies. At present, the demonstration of an INI1 mutation is considered a poor prognostic feature and aggressive therapy is indicated.

Rhabdomyosarcoma

Janet Shipley
The Institute of Cancer Research, Sutton, Surrey, UK

Definition

Sarcomas are malignant tumors thought to be derived from mesenchymal cells and contain cells that resemble those of connective tissues in the body. Rhabdomyosarcomas (RMS) are ►sarcomas resembling developing

skeletal muscle and consist of cells showing specific stages of skeletal muscle development (myogenesis). They are a heterogeneous group of tumors and although rare, they are more prevalent in childhood than later life. Historically they are broadly divided into two major histological subtypes:

- Alveolar RMS (ARMS) – cellular architecture resembling the alveolar spaces of the lungs. Based on molecular evidence, a solid variant of ARMS has been described that does not show alveolar-like spaces.
- Embryonal RMS (ERMS) – more frequent group and classical ERMS are seen predominantly in young children. Variants include botryoid and spindle cell.

In addition, a rarer pleomorphic subtype exists that is predominant in adults and most often found in the extremities and the trunk.

Characteristics

Rhabdomyosarcoma (RMS) is the most common soft tissue sarcoma of childhood (►childhood cancer) and accounts for 4–8% of all childhood cancer cases. Males are more commonly affected, with an approximate ratio 1.3:1. The embryonal subtype accounts for around 70% of RMS cases and most frequently affects young children. The alveolar subtype is more prevalent in older children. Although RMS can arise anywhere in the body, they occur most commonly in three regions; (i) the head and neck (mainly ERMS), (ii) the genitourinary tract (botryoid) and retroperitoneum (ARMS), and (iii) the upper and lower extremities (ARMS).

Overall, more than 70% of RMS patients survive long term. Treatment of RMS usually involves two or more modalities (multi-modal therapy can include surgery, chemotherapy or radiotherapy). The survival rate depends significantly on tumor size, location, histology and whether metastasis has occurred. The outcome for the alveolar subtype is generally worse than for the embryonal cases. Accurate diagnosis of more undifferentiated RMS and tumors without distinct histological features may be difficult. ARMS are characterized by small round cells that may be difficult to distinguish from other so-called small round cell tumors, including ►neuroblastoma and the ►Ewing sarcoma family tumors. ARMS and especially the solid variant may also be difficult to distinguish from ERMS. Development of improved disease-specific therapeutic strategies, with concomitant improvements in outcome, have rendered accurate diagnosis of paramount importance. Distinctive cytogenetic and corresponding molecular changes associated with the various small round cell tumors can be useful diagnostic markers in addition to standard immunohistochemical and morphological features.

The expression of the muscle related factor family of transcription factors and the expression of the *PAX3* and *PAX7* genes in RMS is consistent with their morphological resemblance to developing skeletal muscle. The *PAX* genes are also involved in ARMS through specific translocations; t(2;13)(q35;q14) and variant t(1;13)(p36;q14) result in *PAX3-FKHR* and *PAX7-FKHR* ►fusion genes, respectively. The fusion genes encode chimeric transcription factors with the DNA binding domain from PAX3/PAX7 fused to the potent transactivation domain of FKHR (also called ►FOXO1a). The fusion proteins are more potent transcription factors than the wild type PAX3 or PAX7 gene products. The *PAX3-FKHR* fusion gene is associated with cases that have a poorer prognosis than those with *PAX7-FKHR*. Although the fusion proteins can transform ►NIH3T3 cells mice very rarely developed tumors in a knock-in *PAX3-FOXO1a* mouse model. The prevalence of tumors increased when crossed with a *INK4a/Arf/p53* deficient background. This indicates that the fusion product alone may not be sufficient to induce malignancy or that the animal models to date do not recapitulate the necessary conditions.

A number of downstream targets of the PAX3-FKHR fusion protein have been indicated through expression profiling analyses such as, *EN2, BVES, FLT1 Itam2A* and ►*MET*. *MET* encodes the HGF/SF receptor (hepatocyte growth factor/scatter factor) and silencing MET expression in both ARMS and ERMS cell lines impaired cell replication, survival, invasiveness and anchorage independent growth. Furthermore, RMS were induced in mice at a very high frequency, and with short latency, through simultaneous loss of INK4a/ARF function and disruption of MET. ►Amplification and expression of genes such as ►*MYCN*, ►*MDM2*, ►*CDK4*, and *GPC5* are also features of RMS. In addition, disruption of genes such as *ATR, PTC, P16* and ►*TP53* have been implicated in RMS development. In contrast to the *PAX-FKHR* fusion genes associated with alveolar subtype, the hallmark of ERMS is recurrent ►loss of heterozygosity, loss of ►imprinting or paternal disomy at the 11p15 locus. This loss leads to overexpression of the *IGFII* gene and is consistent with a role for the ►IGF pathway in ERMS development.

►Beckwith-Wiedemann syndrome is associated with fetal overgrowth and development of embryonal tumors including RMS and is also linked to the involvement of the 11p15.5 region. ►Costello syndrome is caused by mutation of the *HRAS* gene at 11p15.5 and children with Costello syndrome have a high incidence of ERMS. However, although sporadic

ERMS show uniparental disomy at 11p15.5, this is not driven by *HRAS* mutations. ►Li-Fraumeni syndrome involves germ line *TP53* mutations and is associated with increased risk of several tumor types including RMS.

Further understanding of RMS tumorigenesis, and in particular determining the key genes and molecular pathways involved, is resulting in novel targeted therapeutic strategies. This should lead to increased cure rates and reduce treatment associated toxicity for children with these tumors.

Rho Family Proteins

Channing J. Der
University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Synonyms

Ras homologous proteins; Ras-related small GTPases

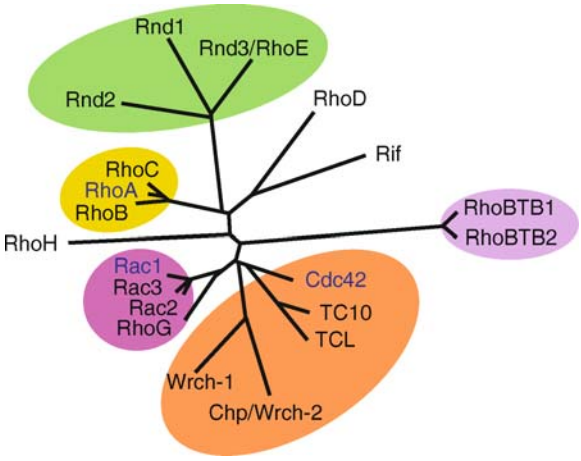
Definition

The Rho family proteins are members of a major branch of the ►Ras superfamily of small ►GTPases. Currently, 20 human members are known, with homologs present

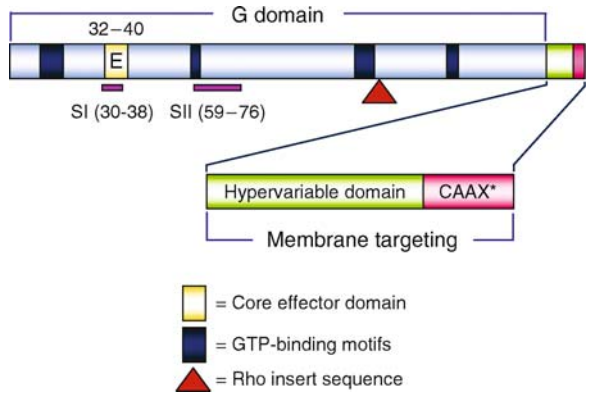
in invertebrates (S. cerevisiae (5), S. pombe (3), C. elegans (6), Drosophila (5), Dictyostelium (8), Aplysia (1), plants (2)) (Fig. 1). The best known and most widely characterized human Rho family proteins are Rac1, RhoA and Cdc42. These proteins function as GDP/GTP-regulated binary switches which regulate signal transduction pathways that control actin cytoskeletal organization, gene expression and cellular proliferation.

Characteristics

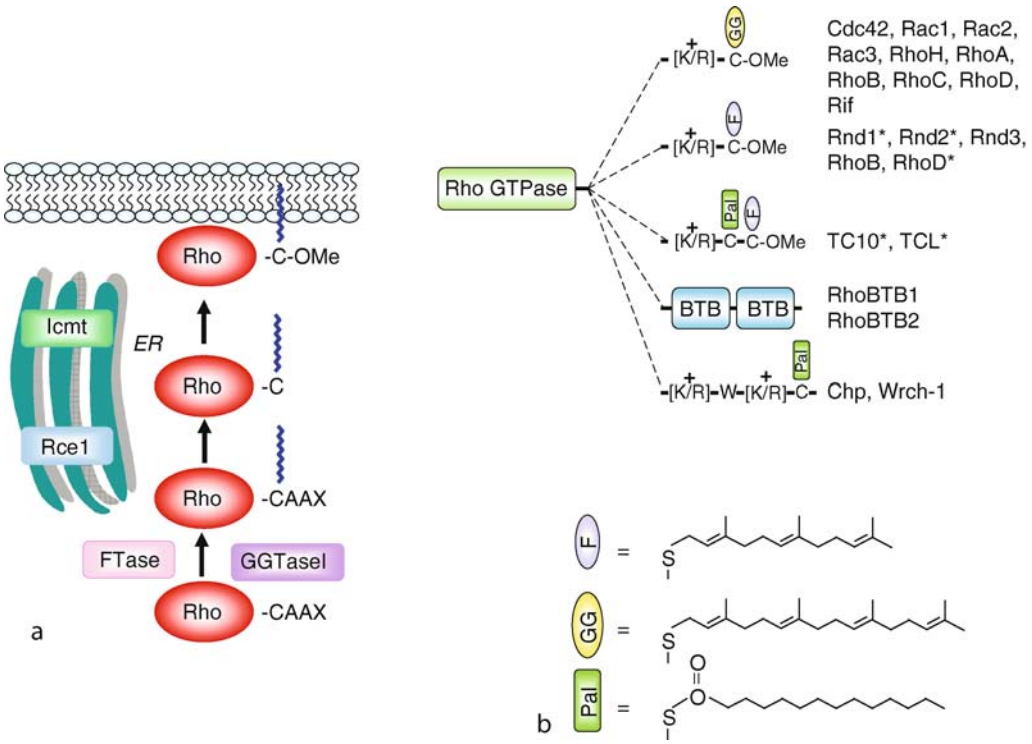
Rho family proteins are approximately 200 amino acids in length and a molecular weight of approximately 21 kDa. They share approximately 30% amino acid identity with the Ras ►oncogene proteins and between 50 and 90% identity within the family. All members share three distinct amino acid sequence elements (Fig. 2): First, they possess consensus GDP/GTP binding motifs shared with other GDP/GTP-binding proteins. Like Ras proteins, Rho family proteins possess high affinity binding for guanine nucleotides (GDP and GTP). Their biological functions are controlled by cycling between active GTP-bound and inactive GDP-bound states. Second, like Ras, 14 of 20 members terminate with a CAAX tetrapeptide sequence (C = cysteine, A = aliphatic amino acid, X = terminal amino acid). The CAAX motif signals three posttranslational modification steps; the addition of either a C15 ►farnesyl lipid (when X = M) or C20 ►geranylgeranyl (when X = L, F) ►isoprenoid lipid group to the cysteine of the CAAX motif, proteolytic removal of the AAX residues and carboxylmethylation of the now terminally prenylated cysteine residue (Fig. 3). These modifications increase the hydrophobic nature of the protein and facilitate their association with membranes. Two atypical Rho GTPases, Wrch-1 and Chp/Wrch-2, lack CAAX prenylation signals, and instead, are modified by a palmitate fatty acid essential for their membrane association. Third, sequences corresponding to Ras residues 32–40 represent the core effector domain and these sequences are involved in interaction with downstream effector targets. Sequences flanking these residues, as well as other sequences throughout Rho family proteins, are also involved in effector interactions. Finally, Rho family proteins possess a short sequence, designated the Rho



Rho Family Proteins. Figure 1 The Rho branch of the Ras superfamily. To date, 20 distinct mammalian Rho family proteins have been identified. Based on sequence and/or functional similarities, the 20 human Rho family GTPases are subdivided into the RhoA-related subfamily (RhoA, RhoB and RhoC), the Rac1-related subfamily (Rac1, Rac1b, Rac2 and Rac3), the Cdc42-related subfamily (Cdc42, TC10, TCL, Wrch-1 and Chp/Wrch-2), the Rnd subfamily (Rnd1, Rnd2 and Rnd3/RhoE) and the RhoBTB subfamily (RhoBTB1 and RhoBTB2/DBC2). The RhoD, Rif and RhoH/TTF proteins do not fall into any of these subfamilies. Generally, members of a subfamily are regulated by common RhoGEFs and RhoGAPs, and utilize overlapping effectors. However, some Rho family proteins are GTPase-deficient, constitutively GTP-bound and may not be regulated by GEFs or GAPs.



Rho Family Proteins. Figure 2 Primary structure of Rho GTPases. Rho GTPases are comprised of an amino terminal G domain that is characterized by consensus GDP/GTP-binding motifs shared with other GTP-binding proteins and a carboxyl terminal CAAX tetrapeptide sequence (C = cysteine, A = aliphatic amino acid, X = terminal amino acid). Residue numbers for the switch I (SI), switch II (SII) and core effector (E) sequences correspond to those of analogous residues of human Ras proteins. Triangle indicates Rho insert sequences positioned between Ras residues 122 and 123. The terminal X residue dictates modification by FTase (X = Ser, Met, Ala) or GGTaseI (X = Leu). While the CAAX-signaled modifications are necessary for Rho GTPase membrane association, additional sequences upstream of the CAAX motif (hypervariable region) contain sequence elements (palmitoylated cysteines or polybasic sequences) that are required for proper subcellular localization and membrane association.

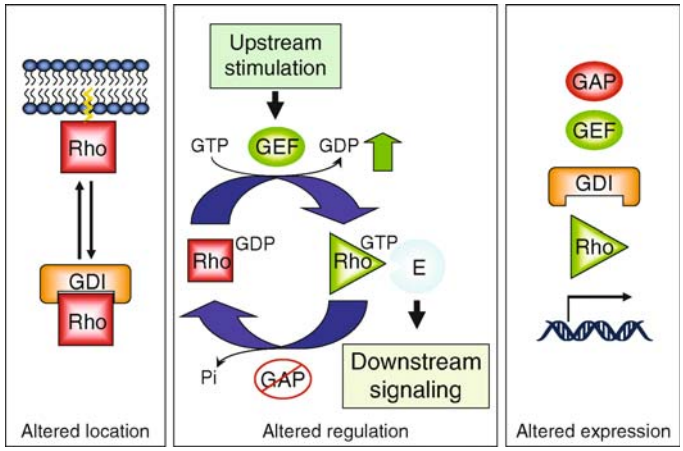


Rho Family Proteins. Figure 3 Posttranslational processing of Rho GTPases is necessary for membrane association. (a) The majority of Rho family GTPases terminate with CAAX tetrapeptide sequences that signal posttranslational processing required for membrane association and function. The first step is catalyzed by either farnesyltransferase (FTase) or geranylgeranyltransferase I (GGTaseI) stimulated covalent modification of the cysteine residue by a C15 farnesyl or C20 geranylgeranyl isoprenoid. Rce1 the catalyzes proteolytic cleavage of the AAX residues, and Icmt catalyzes carboxylmethylation of the now terminal prenylated cysteine residue. (b) Rho GTPase membrane association typically requires a second signal provided by sequences directly upstream by either palmitoylated cysteines or lysine or arginine rich sequences. RhoBTB proteins lack CAAX motifs and are not predicted to undergo posttranslational lipid modification. Shown are the verified or predicted (*) membrane-targeting and posttranslational modifications of the carboxyl terminal sequences of Rho GTPases.

insert sequence, that is not present in other Ras superfamily proteins and may also be involved in effector interaction.

Cellular and Molecular Regulation

Much of the functional information on Rho family proteins has come from studies of the three classical members, Rac1, RhoA and Cdc42. Hence, a majority of the information summarized in this article apply to the classical Rho GTPases and closely related isoforms. The GDP/GTP cycling of Rho family proteins is controlled by three distinct functional classes of regulatory proteins (Fig. 4). ►Guanine nucleotide exchange factors (GEFs) stimulate the weak intrinsic exchange activity of Rho family proteins to cause an exchange of the bound GDP for GTP to promote formation of active Rho-GTP. RhoGEFs are also called Dbl family proteins. Dbl family proteins (named after the founding member, a transforming protein identified from a human diffuse ►B-cell lymphoma) share a tandem Dbl homology (DH) domain and ►pleckstrin homology domain. The DH domain is a catalytic domain that stimulates GDP/GTP exchange. The PH domain is believed to regulate DH domain catalytic activity and can also serve to promote Dbl protein association with the plasma membrane. A number of Dbl family proteins were initially identified in gene transfer screening searches for transforming (e.g. Dbl, Vav, Ect2, Lsc) or invasion-inducing (►Tiam1) genes. Others were identified as proteins with other catalytic functions, such as the breakpoint cluster region protein (BCR). BCR is the translocation partner of the Abl tyrosine kinase present in ►Philadelphia chromosome positive human leukemias, and this genetic rearrangement causes the formation of a chimeric ►BCR-Abl fusion oncoprotein. To date, 69 distinct human Dbl family proteins have been identified. Since they function as RhoGEFs, their transforming actions are due to chronic activation of Rho GTPases. Additionally, a second structurally-distinct family of RhoGEFs, DOCK family proteins (15 human members), also serve as activators of



Rho Family Proteins. Figure 4 Rho family proteins function as GDP/GTP-regulated binary switches. In response to extracellular stimuli, RhoGEFs stimulate formation of active Rho-GTP, which in turn forms complexes with various downstream effectors (designated E) to initiate downstream signaling events. RhoGAPs serve as negative regulators of the GDP/GTP cycle and stimulate GTP hydrolysis. Deregulated Rho GTPase activity can occur by upregulated activation of RhoGEFs (e.g. fusion protein, missense mutation, phosphorylation), loss of function of RhoGAPs (e.g. deletion, promoter methylation), and altered gene expression of Rho GTPases, RhoGEFs and RhoGAPs. Deregulated expression of RhoGDIs can lead to altered membrane association of Rho GTPases.

Rho GTPases. Some atypical Rho GTPases (e.g. Rnd proteins) are GTPase-deficient and constitutively GTP-bound and active, and consequently, are not believed to be regulated by RhoGEFs.

The second class of regulators of Rho family proteins are ►GTPase activating proteins (GAPs) that stimulate the weak intrinsic GTP hydrolysis activity of Rho family proteins to promote formation of the inactive GDP-bound protein. Presently, at least 60 RhoGAPs have been identified (e.g. chimerins, BCR). The third class of regulators is the Rho guanine nucleotide dissociation inhibitory factors (GDIs). While RhoGDIs can inhibit GDP dissociation as well as GAP-stimulated GTP hydrolysis, their main cellular function involves regulation of the association of Rho family proteins with membranes. To date, three distinct Rho GDIs have been identified.

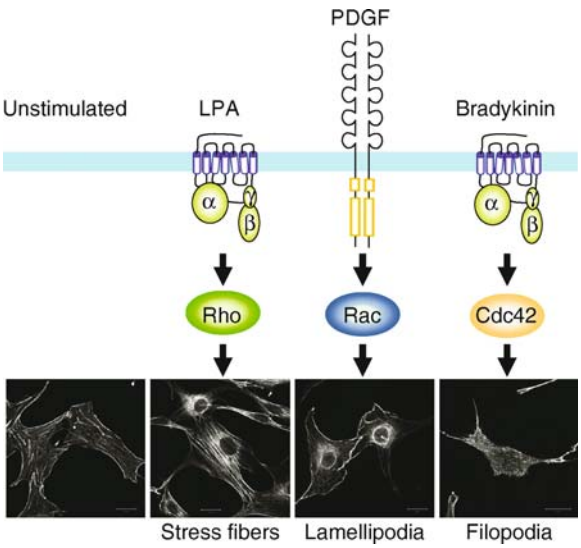
Structural analyses of Ras and Rho family proteins reveal that the GDP- and GTP-bound proteins differ in conformation in two regions, designated switch I and II (Fig. 2). The conformation of the GTP-bound protein results in increased binding affinity for downstream effector proteins. Each Rho family protein recognizes multiple effectors and some effectors are recognized by multiple Rho family proteins. Rho family protein interaction and activation of effector function leads to the stimulation of effector-mediated cytoplasmic signaling pathways that regulate the diverse functions of Rho family proteins. The effectors for RhoA, Rac1 and Cdc42 have been the most intensively studied and characterized. The multitude of effectors identified for each Rho family protein reflects the complex and diverse functional properties of these proteins.

Genetically engineered structural mutants of Rho family proteins have provided very useful research reagents to evaluate the biochemical and biological functions of Rho family proteins. The first class of mutants are ►gain-of-function mutants. Single amino acid substitutions at residues analogous to those that convert normal Ras proteins into highly oncogenic, constitutively activated proteins (at Ras residues glycine 12 or glutamine 61) also create constitutively activated mutants of Rho family proteins. These mutations render Ras and Rho proteins insensitive to GAP stimulation and thus these proteins persist in the GTP-bound state. The second class of mutants are dominant-negative mutants that contain a serine to asparagine substitution at the residue analogous to amino acid 17 of Ras proteins. These mutants can prevent activation of specific Rho family proteins, presumably by forming inactive complexes with specific Dbl family proteins. The third class of mutants are effector domain mutants that possess single amino acid substitutions in the core effector domain. These impair interaction of Rho family proteins with downstream effectors, thus leading to impairment in biological activity. Since a particular effector domain mutation leads to differential impairment of effector interaction, such mutants have been very useful reagents in establishing the specific contribution of different effector targets to Rho family protein function.

Functions

A diverse spectrum of extracellular stimuli via interaction with ►receptor tyrosine kinases (►RTKs), heterotrimeric ►G protein-coupled receptors (GPCRs) or integrins cause activation of specific Rho family proteins, most

commonly via activation of specific RhoGEFs (Fig. 5). For example, GPCRs that lead to activation of the heterotrimeric Gα13 subunit which then directly binds to the RGS (Regulator of G protein signaling) box of the p115 RhoGEF, PDZ-RhoGEF and Larg Dbl family proteins. These Dbl family proteins are specific GEFs for RhoA and related isoforms. Platelet-derived growth factor (PDGF) stimulation of the PDGF RTK causes activation of Rac1. This may be caused by activation of phosphatidylinositol 3-kinase and generation of phosphatidylinositol (3,4,5)-trisphosphate (PIP_3). PIP_3 can then bind the pleckstrin homology domain of the P-rex Rac-specific RhoGEF, leading to Rac activation. PDGF-stimulated activation of Ras can be another mechanism for Rac activation. Activated Ras binds to the Ras binding domain (RBD) of the Tiam1 RhoGEF, promoting Rac activation. Bradykinin stimulation of a GPCR causes activation of Cdc42. These various extracellular signals cause a transient increase in the GTP-complexed protein that then rapidly cycles back to the GDP-complexed form to terminate the signal.



Rho Family Proteins. Figure 5 Rho family proteins regulate extracellular stimulus-activated actin cytoskeletal organization. Extracellular stimuli that activate cell surface G protein-coupled receptors, for example, lysophosphatidic acid (LPA) and bradykinin, or receptor tyrosine kinases (e.g. platelet-derived growth factor (PDGF)) cause Rho GTPase-dependent actin reorganization. LPA activates RhoA and causes formation of actin stress fibers, whereas bradykinin activation causes formation of actin microspikes and filopodia. PDGF activates Rac and accumulation of cortical actin at the leading edge of migrating cells and formation of lamellipodia and membrane ruffling. Shown are immunofluorescence analyses of NIH 3T3 mouse fibroblasts stimulated with the indicated ligand (provided by Dr. Cercina Onesto). NIH 3T3 cells were incubated for 16 h in serum-free growth medium and the cultures were then stimulated for 15 min with the indicated ligand, then fixed and actin filaments were visualized with Alexa-phalloidin. Scale bar represents 20 μm.

Rho family proteins are regulators of diverse cellular processes. Perhaps their best characterized function involves the regulation of specific filamentous F-actin organization (Fig. 5). The ►actin cytoskeleton is a highly dynamic cytoplasmic structure that is reshaped and reformed in response to diverse extracellular stimuli. Specific Rho family proteins regulate distinct changes in actin cytoskeletal assembly and function. RhoA promotes the formation of stress fibers and ►focal adhesion, whereas RhoE/Rnd3 and Rnd1 cause the disruption of these structures. Rac1 promotes ►lamellipodia, curtain-like extensions that consist of thin protrusive actin sheets. Membrane ruffles represent lamellipodia that have lifted from the substratum at the leading edge of migrating cells. Cdc42 and related proteins (e.g. TC10, TCL, Wrch-1 and Chp) cause formation of filopodia, which are thin, finger-like cytoplasmic extensions that contain tight actin bundles and may be involved in recognition of the extracellular environment.

- Rho family proteins regulate actin cytoskeletal organization. For example, extracellular stimuli that activate cell surface GPCRs (e.g. lysophosphatidic acid, ►thrombin) or ►integrins (e.g. ►fibronectin) cause activation of cytoplasmic signaling cascades that promote the formation of actin stress fibers and focal adhesions (Fig. 3).
- A second major function of Rho family proteins involves the stimulation of cytoplasmic signaling pathways that regulate the activity of nuclear transcription factors. These transcription factors include those that regulate genes involved in the regulation of cell growth, differentiation and ►apoptosis. For example, Rac1 and Cdc42 activate the ►Jun N-terminal kinases (JNKs; also called SAPKs), and activated Jun can stimulate transcription from promoters containing ►AP-1 DNA binding motifs. RhoA, Rac1 and Cdc42 are activators of the NF-kB transcription factor. ►NF-kB regulates the expression of genes that serve an anti-apoptotic function. Rho family proteins activate the serum response factor (SRF), which forms a complex with ternary complex factors (e.g. Elk-1) at the serum response DNA element in promoter sequences of growth factor early response genes (e.g. fos).
- A third major function of Rho family proteins involves their regulation of cellular proliferation. RhoA, Rac1 and Cdc42 have been shown to be essential components required for cells to progress through the G1 phase of the ►cell cycle. Constitutively activated mutants of some Rho family proteins can promote G1 progress and DNA synthesis in quiescent cells, and

growth ►transformation of rodent fibroblasts. Extracellular signals that regulate cell proliferation cause transient activation of specific Rho family proteins. For example, ►platelet-derived growth factor is a potent growth factor for many cell types and is an activator of Rac1 function. Hence, Rho family proteins may facilitate the mitogenic actions initiated by extracellular stimuli.

Clinical Relevance

There is presently considerable experimental evidence linking Rho family proteins to cancer (Fig. 4). Unlike ►Ras, where mutational activation of Ras proteins is associated with 30% of human cancers, mutationally activated Rho GTPases are not found commonly in cancer. Instead, indirect mechanisms that include altered gene transcription or the altered function of Rho regulators are most commonly observed. For example, the Vav1 RhoGEF, normally hematopoietic cell-restricted in expression, is ectopically overexpressed and activated in pancreatic cancers. Tiam1, a Rac-specific GEF, functions as an effector of Ras and is required for Ras-mediated oncogenesis. Ras binds to and activates Tiam1, leading to persistent Rac activation. The expression of DLC-1 and related RhoGAPs are lost in a wide variety of human cancers. Since DLC-1 (►Deleted in liver cancer 1) functions as a negative regulator of RhoA, the loss of DLC-1 may promote oncogenesis by causing persistent RhoA activation. Rac1b is a splice variant of Rac1 that is preferentially expressed in breast and colon cancers. Unlike Rac1, Rac1b is persistently activated and cannot bind RhoGDI, and consequently, is a transforming variant of Rac1.

Aberrant Rho GTPase function is also associated with other human diseases. Oligophrenin-1 is a RhoGAP whose expression is lost and involved in nonspecific X-linked mental retardation. FGD1 is a Cdc42-specific RhoGEF that is mutated and inactivated in Aarskog-Scott syndrome (also called faciogenital dysplasia), which is a rare, clinically and genetically heterogeneous condition characterized by facial dysmorphic features, short stature, brachydactyly, and genital anomalies. *Salmonella typhimurium*, *Yersia pestis*, *Shigella flexneri* and other virulent bacteria have evolved mechanisms that alter the Rho GTPase function of their human host cells that facilitate their ability to promote infection and disease. *Salmonella typhimurium* causes typhoid fever, *Yersia pestis* was the causative agent for the Black Death plague which accounted for the death of approximately one-third of the European population in the fourteenth century, and *Shigella flexneri* causes dysentery. These bacteria use a type III secretion system to deliver bacterial effector proteins directly into the host cell. These function as activators or inactivators of human Rho GTPases and include proteins that act as RhoGEFs or RhoGAPs. Since bacteria do not possess Rho GTPases that are regulated by these effector proteins, these proteins exist solely for the purpose of deregulating the cellular functions of host cells.

Ribavirin

Definition

Is a synthetic 1-beta-D-ribofuranosyl-1H-1,2,4-triazole-3-carboxamide used against ►hepatitis C virus.

Ribonucleotide Reductase

Definition

Enzyme responsible for the reduction of ribonucleotides to deoxyribonucleotides for DNA synthesis. This is the rate-limiting enzyme in the biosynthesis of deoxyribonucleotides in mammalian cells.

►Chelators as Anti-cancer Drugs
►HSV-TK/Ganciclovir Mediated Toxicity

Ribosomal Protein S6 Kinase1

Definition

S6K1; A serine/threonine kinase, which is implicated in the activation of the ►mitogen-activated protein kinase cascade and the stimulation of cell proliferation.

►Programmed Cell Death 4

Ribosome

Definition
Complex structure composed of ribosomal RNAs and ribosomal proteins that associates with messenger RNA and coordinates protein synthesis.

►Funnel Factors
►Translation

Richter Syndrome

Definition
Is a rare complication of B cell ►chronic lymphocytic leukemia (CLL) or ►hairy cell leukemia (HCL). With Richter, CLL changes into a fast-growing ►diffuse large B-cell lymphoma, which is one of type of ►non-Hodgkin lymphoma. There are no obvious causes for the transformation of CLL to Richter syndrome, which can affect patients at any stage of CLL, including those in complete remission. The incidence of Richter transformation, which carries a poorer prognosis than CLL, has been reported at between three and ten percent. Richter can appear suddenly, even in patients who were in remission. The prognosis is generally poor, and aggressive treatment is usually warranted.

►non-Hodgkin lymphoma
►chronic lymphocyclic lukemia
►Rituxmab

Rigaud and Schmincke Types of Lymphoepithelioma

►Nasopharyngeal Carcinoma

RING

Definition
Really Interseting New Gene; protein motif.

►RING Finger Domain

RING Finger Domain

Definition
Really interesting new gene (RING) finger domain is a zinc-binding motif found in a variety of proteins. That of ►E3 ubiquitin ligase binds an E2 and might mediate enzymatic activity in the E2–E3 complex.

►Gankyrin

RIS

►Radiation-Induced Sarcomas After Radiotherapy

RISC

Definition
Acronym for RNA Induced Silencing Complex. RISC can assemble with short RNAs (►microRNAs or ►siRNAs) that give sequence specificity to the complex by guiding the complex to mRNAs containing a stretch of sequence complementary to the short RNAs. If the sequence complementarity is perfect or near perfect, RISC cleaves the mRNA and this is exploited by the ►RNA interference technology. If there are several mismatches between the short RNA and the target RNA, RISC does not cleave the mRNA but suppresses its translation.

►MicroRNA

Risk Factor

Definition
Is a variable (characteristic, behavior, etc.) that is associated with an increased risk of a disease. Risk factors are not necessarily causal, depending on the nature and on the way they were observed.

Rituximab

Apostolia-Maria Tsimberidou

Synonyms

Rituxan® (US), MabThera® (non-US countries)

Definition

Is a genetically engineered chimeric murine/human ►monoclonal antibody that binds specifically to the surface antigen ►CD20. CD20 is a hydrophobic transmembrane protein, which is typically expressed by pre-B, and mature B lymphocytes. It binds to lymphocytes in the thymus, white pulp of the spleen, and to most B lymphocytes in peripheral blood and lymph nodes, but not to hematopoietic stem cells, pro-B cells, or normal tissues. CD20 is involved in the initial steps of regulating the activation process for cell cycle initiation and differentiation and may also function as a calcium ion channel receptor with a key role in preventing apoptosis. CD20 is not shed from the cell surface and does not internalize upon antibody binding. Because of its human component, rituximab has low immunogenicity so that repeated administration is tolerable.

Characteristics

Rituximab is a 145-kDa monoclonal antibody, and its pH is 6.5. Its binding affinity for CD20 antigen is ~8 nanomolar. The elimination half-life of rituximab is 59.8 h (range, 11–105 h) after the first dose and 174 h (range, 26–442 h) after the fourth dose. It has been designated orphan product status for use in the treatment of ►non-Hodgkin lymphoma. Rituximab belongs to the classes of antineoplastics and immunological therapy drugs.

Mechanism of Action

The mechanism of its antineoplastic action may involve mediation of B cell lysis (seen in vitro) via binding of the Fab domain of rituximab to the CD20 antigen on B lymphocytes and by recruitment of immune effector functions by the Fc domain. The key mechanism by which rituximab exerts antitumor activity is ►antibody-dependent cell-mediated cytotoxicity (ADCC), followed by a minor role of ►complement-dependent cytotoxicity (CDC). Other mechanisms include indirect effects, such as structural changes, apoptosis, and sensitization of cancer cells to ►chemotherapy. Direct effects, including growth inhibition and apoptosis, although shown in vitro, have not been confirmed in the clinic.

Administration

Rituximab was the first monoclonal antibody approved by the United States Food and Drug Administration (FDA) in humans. The recommended dose for non-Hodgkin's lymphoma is 375 mg/m^2 via an intravenous infusion once weekly for 4 or 8 doses. The recommended dose for rheumatoid arthritis is two 1000 mg intravenous infusions separated by 2 weeks. Rituximab should not be administered by intravenous push or bolus; the initial rate of infusion should not exceed 50 mg/h. If tolerated, the infusion may gradually be increased by 50 mg/h increments every 30 min, up to a maximum of 400 mg/h.

Rituximab is an efficacious treatment option because of its non-overlapping toxicities and the ability to interrupt multiple pathogenic pathways when combined with cytotoxic agents. By virtue of its ability to target CD20, demonstrated in clinical trials initiated in 1993, rituximab conferred significant antitumor activity and minimal toxicity to patients with recurrent/relapsed indolent ►non-Hodgkin lymphoma. The ►FDA approved rituximab in 1997 based on its clinical efficacy against relapsed low-grade and follicular non-Hodgkin lymphoma demonstrated in multicenter studies.

Indications

The FDA approved rituximab for the treatment of the following CD20-positive, B-cell lymphoproliferative disorders:

1. Diffuse large B-cell non-Hodgkin lymphoma, in combination for first-line treatment
2. Follicular non-Hodgkin lymphoma, in combination with CVP (►cyclophosphamide, ►vincristine, and prednisone) chemotherapy for first-line treatment
3. Low-grade non-Hodgkin lymphoma, stable or responsive to prior CVP chemotherapy
4. Relapsed or refractory, low-grade or follicular non-Hodgkin lymphoma
5. In combination with ►methotrexate to reduce signs and symptoms in adult patients with moderate to severe ►rheumatoid arthritis, who had an inadequate response to one or more tumor-necrosis-factor antagonist therapies.

Rituximab has shown activity and is used in but not approved by FDA for the treatment of the following diseases:

1. ►Autoimmune hemolytic anemia
2. B-cell lymphoma, including ►splenic marginal zone lymphoma
3. ►Chronic lymphocytic leukemia, in combination for first-line treatment

4. Relapsed or refractory chronic lymphoid leukemia
5. ►Evans syndrome, refractory to immunosuppressive therapy
6. Chronic, ►steroid-refractory graft-versus-host disease
7. Post-transplant lymphoproliferative disorder
8. ►Systemic lupus erythematosus, refractory to immunosuppressive therapy
9. Immune or idiopathic ►thrombocytopenic purpura
10. ►Waldenstrom macroglobulinemia
11. Severe, refractory ►Wegener granulomatosis, in combination with ►corticosteroids

Adverse Events

Rituximab has a more tolerable toxicity profile than cytotoxic agents, which is particularly important for the elderly. Although dose-escalation trials were conducted, no maximum tolerated dose was established for rituximab, which is the case for various other monoclonal antibodies. The first dose of rituximab can cause an infusion reaction, which is manifested by fever, chills/rigors, nausea, urticaria, angioedema, bronchospasm, and/or hypotension. This complication can be avoided by premedicating patients with acetaminophen and an antihistamine. Infusion reactions usually respond to meperidine or hydrocortisone. Patients with a high tumor load, i.e., bulky lymphadenopathy or circulating malignant cells >25,000/mm^3 and those with renal disease are at high risk of developing ►tumor lysis syndrome (TLS). Prophylactic measures such as correction of electrolyte abnormalities, monitoring of renal function, hydration and administration of ►allopurinol or ►rasburicase usually prevent this complication, but rarely, dialysis is required.

The most common adverse events associated with rituximab are pruritus, nausea and vomiting, dizziness or headache, and pulmonary sequelae. Grade 3 or 4 lymphopenia, ►neutropenia, ►leukopenia, anemia, and ►thrombocycenia occur in the majority of patients. However, grade 3 or 4 non-hematologic toxicities are uncommon. They include angina, ►cardiac dysrhythmia, drug-induced ►pemphigus, ►lichenoid dermatitis, ►Stevens-Johnson syndrome, ►toxic epidermal necrolysis, bowel obstruction, gastrointestinal perforation, transient aplastic or hemolytic anemia, reactivation of type B viral hepatitis, immune hypersensitivity reaction, nephrotoxicity, obliterative bronchiolitis, pneumonitis, and infections. Rare cases of severe mucocutaneous reactions and progressive multifocal leukoencephalopathy have been reported.

Clinical Trials with Rituximab Monotherapy

Phase II clinical trials of rituximab therapy in relapsed or refractory, low-grade or follicular non-Hodgkin lymphoma demonstrated response rates ranging from 36% to 57% (complete response, 3–14%) and a median response duration of 7–16 months. Rituximab retreatment in patients with low-grade or follicular non-Hodgkin lymphoma who initially responded to antibody therapy and subsequently relapsed is feasible, as shown in a clinical trial, in which rituximab induced an overall response rate in 40% of patients (complete remission rate, 11%). However, in relapsed small lymphocytic lymphoma, rituximab had limited antitumor activity, probably due to a lower expression of CD20 molecules on the surface of small lymphocytic lymphoma cells. In addition, rituximab also had a shorter half-life in those patients compared with follicular lymphoma patients, raising the possibility of an "antigen sink." Subsequent studies demonstrated a soluble form of CD20 in the plasma of patients with ►chronic lymphocytic leukemia, and suggested that immune complex formation with the antigen sink may explain the shorter half-life of rituximab in that setting.

Clinical Trials with Rituximab Combination Regimens

Rituximab has been combined successfully with other active agents for the treatment of lymphoproliferative disorders (Table 1). The rationale for using rituximab in conjunction with cytotoxic agents derives from the observation that rituximab enhances the cytotoxicity of drugs, such as fludarabine and cyclophosphamide in lymphoma cell lines as well as from the principle of combining active agents with nonoverlapping toxicity profiles. The incorporation of rituximab into chemotherapy regimens for the treatment of indolent and large cell lymphoma is associated with superior clinical outcomes (response, failure-free survival and/or survival) than chemotherapy alone. For instance, the addition of rituximab to CHOP (R-CHOP; rituximab, cyclophosphamide, vincristine, doxorubicin, dexamethasone) demonstrated prolonged failure-free survival in elderly patients with diffuse large B-cell lymphoma compared to CHOP alone. In addition, survival was lengthened in elderly patients abrogating drug resistance mediated by the antiapoptotic gene ►*BCL-2*. The National Comprehensive Cancer Network (NCCN) practice guidelines for the management of patients with ►diffuse large B-cell lymphoma currently recommend ►R-CHOP as a treatment option for induction therapy.

Rituximab is being investigated in several settings, including high-dose chemotherapy with ►autologous stem cell transplantation, in which in vivo purging of CD20 cells before stem cell harvesting is being investigated. Rituximab is also used as consolidation therapy after marrow recovery and in AIDS-related and central nervous system lymphomas.

The introduction of rituximab in the treatment of lymphoproliferative and immune-mediated disorders has established a new era in the treatment of hematologicmalignancies and immunologic diseases and has generated intensive research into the development of

Rituximab. Table 1 Rituximab-containing regimens in lymphoproliferative disorders

Disease	Regimen and schedule	Acronym
►Indolent lymphoma (follicular and variants)	Fludarabine, novantrone (mitoxantrone), dexamethasone, rituximab	FND-R
	Rituximab, cyclophosphamide, vincristine, prednisone	R-CVP
	Rituximab, granulocyte-macrophage colony-stimulating factor	R-GM-CSF
►Mantle cell lymphoma	Rituximab, fractionated cyclophosphamide, vincristine, doxorubicin, dexamethasone	R-Hyper-CVAD
Large cell lymphoma	Rituximab, cyclophosphamide, vincristine, doxorubicin, dexamethasone	R-CHOP
	Rituximab, gemcitabine and oxaliplatin	R-GemOx
►Chronic lymphocytic leukemia	Fludarabine and rituximab	FR
	Fludarabine, cyclophosphamide, rituximab	FCR
	Cyclophosphamide, fludarabine, alemtuzumab, rituximab	CFAR
	Oxaliplatin, fludarabine, cytarabine, rituximab	OFAR
	Pentostatin, cyclophosphamide, rituximab	PCR
	Rituximab, alemtuzumab	N/A
	Fludarabine, cyclophosphamide, mitoxantrone, rituximab	FCM-R
	Rituximab, granulocyte-macrophage colony-stimulating factor	R-GM-CSF
►Richter syndrome	Rituximab, fractionated cyclophosphamide, vincristine, doxorubicin, dexamethasone	R-Hyper-CVAD
	Oxaliplatin, fludarabine, cytarabine, rituximab	OFAR

similar approaches for other diseases. Investigation of monoclonal antibodies comprises one of the largest growth areas in drug development.

RNA Interference

Takahiro Ochiya
Section for Studies on Metastasis, National Cancer Center Research Institute, Chuo-ku, Tokyo, Japan

Synonyms

RNAi; RNA interference; Small interfering RNA; siRNA; Short hairpin RNA; shRNA

Definition

RNA interference (RNAi) is an evolutionarily conserved gene-silencing pathway that is triggered by double-stranded RNA (dsRNA) with a short 21–23 nucleotide-long chain. Experimentally, RNAi is widely used for knocking down the expression of cancer-related genes and also provides a systematic screen to discover more about genes that trigger or inhibit cancer.

Characteristics

RNA Interference as a Research Tool

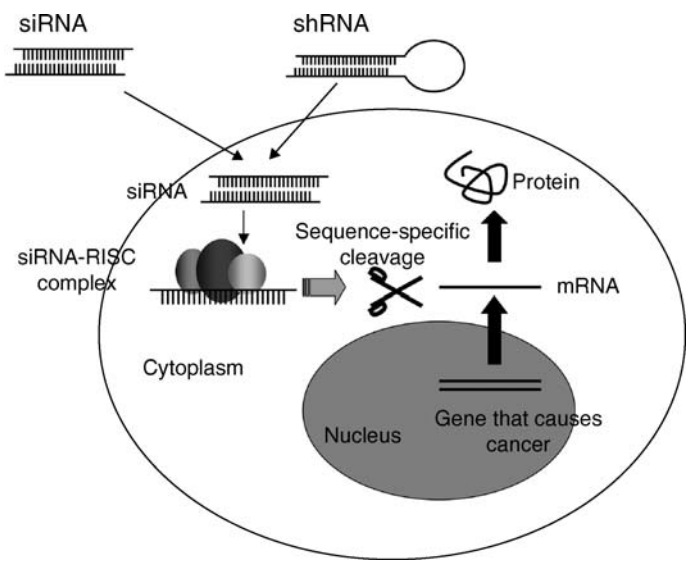
RNAi has become an extremely useful research tool because it allows genetic researchers to "knock down" specific genes, observe the consequent disruptions, and, in this way, determine exactly what a gene does. RNAi is being used as a genome-wide tool to search thousands of genes in a cell and screen for their functions. Moreover, researchers are using RNAi in

drug development, hoping that, by shutting down the genes that cause certain diseases, they will be able to cure diseases such as cancer. RNAi-mediating molecules can be chemically synthesized as a small interfering RNA (siRNA) or they can be synthesized from expression vectors as short hairpin RNA (shRNA) that can be cleaved into siRNAs by endogenous cellular dicer. They are incorporated into the RNA-induced silencing complex (►RISC), where the strands are separated. The RISC containing the guide or antisense strand seeks out and binds to complementary mRNA sequences. These mRNA sequences are then cleaved by Argonaute, the enzyme within the RISC responsible for mRNA degradation, which leads to target cancer-causing mRNA downmodulation (Fig. 1).

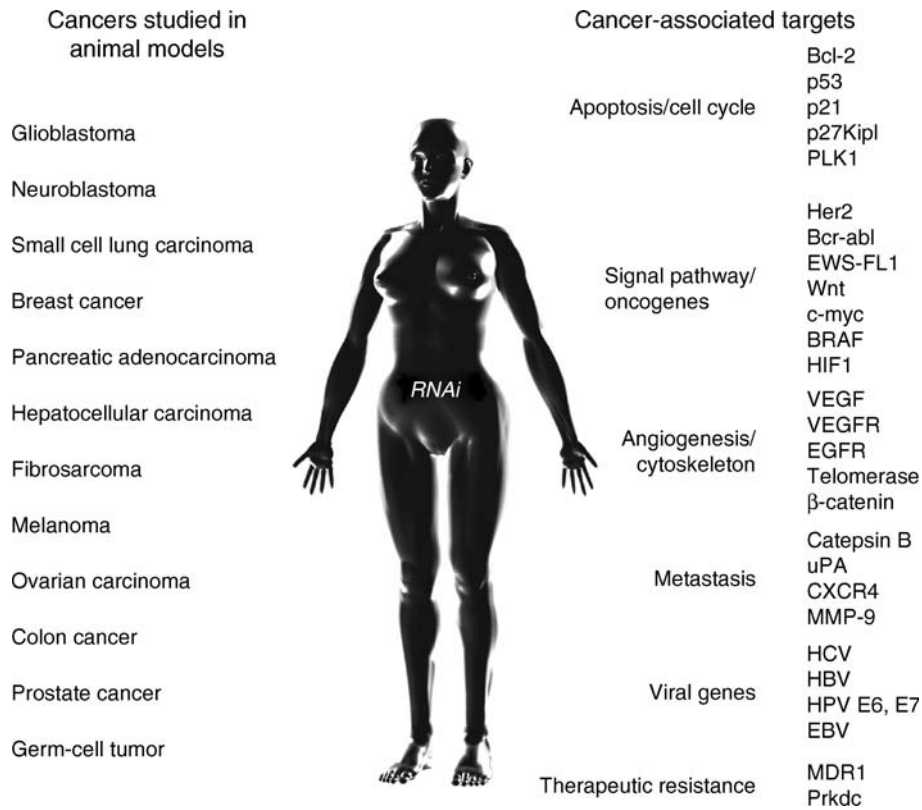
RNA Interference as a Novel Therapeutic Agent Against Cancer

The key is developing delivery strategies that are safe, specific, effective, and long lasting so that RNAi may truly become a new class of human therapeutic agent. For application to cancer therapeutics, the direct delivery of siRNAs and viral delivery of shRNAs to tumors have been successful in inhibiting ►xenograft growth in several animal models. To obtain efficient and long-lived ►gene silencing by RNAi, numerous approaches, including cationic lipid-based formulation and complexation with polyethyleneimine (PEI), cholesterol-oligoarginine, a protamine–Fab fusion protein, and biomaterials such as atelocollagen, have been shown to facilitate delivery into tumor cells. Particularly, these siRNA delivery approaches are effective with several intratumor injections of siRNA, or even a single one, at doses of 15–50 μg.

Evidence of the concept of using RNAi for cancer therapeutics in animal models is shown in Fig. 2. In mouse tumor xenograft models, the efficacy of systemic RNAi has been demonstrated using a variety of delivery strategies. Systemically delivered cationic cardiolipin liposomes containing synthetic siRNA specific for ►Raf-1 inhibited tumor growth in a xenograft model of human ►prostate cancer. ►Vascular endothelial growth factor receptor-2 (VEGF-R2)-targeting siRNAs complexed with self-assembling ►nanoparticles consisting of polyethylene glycol-conjugated (PEGylated) PEI with an Arg-Gly-Asp peptide attached at the distal end of the ►PEG accumulate in tumors and cause inhibition of VEGF-R2 expression. Intravenous administration of these complexes into tumor-bearing mice inhibits both tumor ►angiogenesis and growth rate. Simpler PEI formulations have also shown efficacy in xenograft tumor models, as have complexes of siRNA duplexes with atelocollagen. Systemic administration of atelocollagen siRNA complexes has marked effects on subcutaneous tumor xenografts as well as bone metastases of human prostate tumors. Another delivery strategy made use of a recombinant antibody fusion protein to achieve cell type-specific delivery. One attractive method is the delivery of siRNA using cancer cell-specific antibodies. In fact, the nucleic acid-binding protein protamine fused to the antibody (Fab) targeting the HIV-1 envelope protein and showed that the Fab–protamine fusion protein was able to deliver an siRNA to mouse melanoma cells expressing the envelope protein, leading to the inhibition of tumor growth in vivo.



RNA Interference. Figure 1 Targeting cancer by RNA interference. RNAi-mediating molecules can be chemically synthesized as siRNAs or they can be synthesized from expression vectors as shRNA which can be cleaved into siRNAs by endogenous cellular dicer. The strand complementary to the mRNA from target cancer-causing gene is incorporated into RNA-induced silencing complex (►RISC) then the siRNA-RISC complex degrades target mRNAs.



RNA Interference. Figure 2 Evidence of the concept of using RNAi for cancer therapeutics in animal models. In most tumor xenograft models in animals, the effectiveness of RNAi as a therapeutic tool against cancer has been demonstrated (left). An example of targeting cancer-related genes for RNAi therapy is shown (right).

The same technology was used with an antibody against ►ErbB2 fused to a protamine fragment that specifically and effectively delivered siRNAs only to ErbB2-expressing ►breast cancer cells. In another example of ligand-directed delivery, transferrin-conjugated nanoparticles were used to deliver an siRNA targeting the oncogenic EWS-FLI translocation-derived mRNA in a mouse model of metastatic ►Ewing sarcoma.

To obtain efficient and long-lived gene silencing using RNAi, several groups have used viral vectors. An ►adenovirus, despite its disadvantage, namely, that the immunogenicity of a viral vector precludes multiple administrations and results in toxicity limitations, is one of the best-known ►virus vectors for gene delivery. An intratumoral injection of an adenovirus encoding the ►HIF-1-targeted siRNA as shRNA has been shown to have a significant effect on tumor growth when combined with ►ionizing radiation. Intratumoral administration of an adenovirus siRNA vector for ►Skp-2, which is involved in the degradation of cell-cycle regulators, including p27Kip1, p21, and ►c-myc efficiently inhibited the growth of an established subcutaneous tumor of human small-cell lung carcinoma cells on NOD/SCID mice. Cre-recombinase-inducible RNAi mediated by a lentiviral vector system has been developed. As for the lentiviral vector delivery of tumor-targeting siRNAs, inhibition of ►chronic myeloid leukemia cells proliferation by a lentiviral vector-delivered anti-bcr/abl shRNA has been reported. Inhibition of the growth and invasive ability of melanoma by inactivation of mutated serine/threonine kinase ►BRAF has revealed that the lentivirus-mediated RNAi targeting for oncogenic mutations may be a promising tool for cancer therapy.

Prospects and Obstacles Regarding RNAi Therapeutics

RNAi is on a rapid pathway from its discovery to promising progress in animal studies and now preclinical and clinical trials for various types of diseases, including cancers. Despite all the enthusiasm, there are still many obstacles that need to be overcome. First, dsRNAs can stimulate innate ►cytokine responses including the ►interferon response and resulting nonspecific inhibition of ►transcription and ►translation, thereby being cytotoxic to cells. Second, although more sustained gene silencing with RNAi is achieved with the viral delivery of shRNAs, viral delivery causes virus-associated immune stimulation. Third, it is generally accepted that siRNA causes an off-target effect; therefore, when designing siRNA sequences aimed to gain insights toward improving the specificity of RNAi for potential future therapeutic applications, it is

important to minimize the sequence-specific cross reactivity by reaching a better understanding of the off-target effects of RNAi. A practical guide for siRNA selection is available elsewhere.

One possible RNAi therapy may help to defeat cancer by supporting current ►chemotherapy or ►radiotherapy. In fact, drug ►resistance is a major problem in cancer chemotherapy; it has led to the treatment failure of 30–50% of the current first-line anticancer drugs. The expression of the multidrug transporter ►P-glycoprotein (P-gp) has been reported to be one of the causes of clinical drug resistance to anticancer drugs. In this regard, targeting of P-gp by RNAi to restore the sensitivity to existing drugs is an effective strategy in RNAi-based cancer treatment.

RNA Silencing

Definition

Is the inhibition of gene expression by small sequences of RNA. These small sequences are able to cleave messenger RNA, block protein synthesis or inhibit ►transcription.

►RNA Interference

RNA Tumor Virus

Definition

Is a member of the family of retroviruses with the ability of inducing tumor growth.

►Retrovirus
►Transduction of Oncogenes

RNAi

►RNA Interference

RNP Complex

Definition

Complexes that contain RNAs and their respective RNA-binding proteins.

►pre-mRNA Splicing

Robo

Definition

Roundabout; Is the ►Slit receptor, and four *ROBO* genes have been identified. Typically, Robo proteins, including Robo1, consist of five extracellular immunoglobulin (Ig) domains, three fibronectin repeats, and a conserved intracellular region of four cytoplasmic motifs.

ROCK

Definition

Serine–threonine Rho-kinase.

►Trefoil Factors
►Rho Family Proteins

ROD-ZW10-Zwilch Complex

Definition

RZZ; Is composed by three proteins, Rough Deal (Rod), Zeste-white 10 (Zw10) and Zwilch. The RZZ

complex is responsible for both Mad1 and Mad2 recruitment to unattached kinetochores and is involved in activation of the spindle assembly ►checkpoint.

►Mitotic Arrest-Deficient Protein 1

ROI

Definition

Reactive Oxygen Intermediate.

►Reactive Oxygen Species

RON

Definition

Recepteur d'Origine Nantaise Transmembrane receptor belonging to the ►Met-receptor tyrosine kinase family.

►Macrophage-Stimulating Protein.

Ron Receptor

Macrophage stimulating 1 receptor; MST1R

Definition

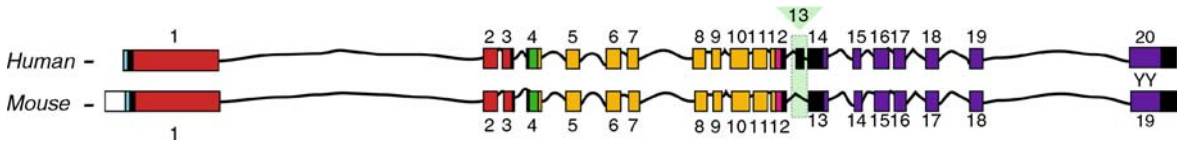
Cell surface ►receptor tyrosine kinases regulate critical signaling pathways and elicit a variety of important biological responses that contribute to tumorigenesis. The Ron receptor tyrosine kinase has been implicated in a number of human cancers. Ron belongs to a family of receptor tyrosine kinases that includes the ►*Met* proto-►oncogene. The *Ron* ►ortholog in the mouse is also referred to as *stem cell derived kinase* (*Stk*) while the chicken counterpart encodes *c-sea*. The human *Ron* gene is located on chromosome 3p21.3 and contains 20 exons with a transcript length of 4,531 basepairs (bps) and a translation length of 1,400 residues. The murine counterpart contains 75% identity to the human protein and is located on chromosome 9. The mouse *Ron* gene contains 19 exons with a transcript length 4,710 bps and 1,378 residues. A comparison of the genomic organization of the human and mouse *Ron* is depicted in Fig. 1.

Characteristics

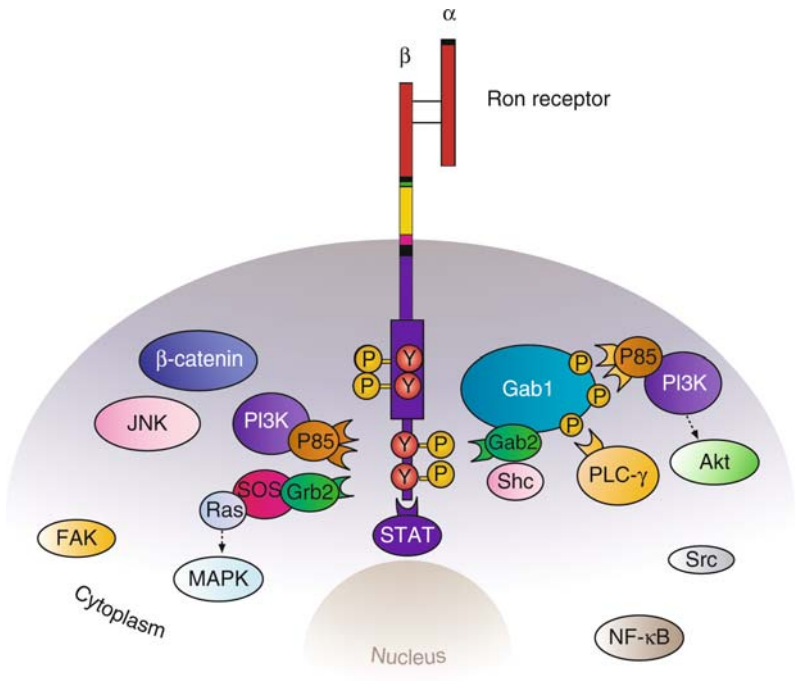
The Ron protein is a heterodimeric ►glycoprotein with disulfide linked alpha (35 kDa) and beta (150 kDa) chains. The protein is synthesized as a single chain precursor of 185 kDa that is cleaved into its heterodimeric form before exposure to the cell surface. A diagram of the domain structure of Ron is presented in Fig. 2. The protein includes a 24 amino acid signal peptide, an extracellular domain of 933 amino acids, a 25 amino acid transmembrane domain and an intracellular tyrosine kinase domain of 418 amino acids. The tyrosine kinase domain of Ron is 63% identical to the same domain in the Met receptor, while the extracellular domain is only 25% identical. The Ron alpha chain contains regions important for ligand binding while the beta chain includes an extracellular domain, a transmembrane domain and an intracellular region including the tyrosine kinase domain. Based on functional annotation of the Ron protein sequence, the extracellular domain contains a ►SEMA domain characterized by a conserved set of cysteine residues that form disulfide bonds to stabilize the protein structure. The extracellular portion of Ron also contains a plexin domain, a cysteine rich motif found in many extracellular receptors, and several IPT domains, which contain an immunoglobulin-like fold and is found in intracellular transcription factors involved in DNA binding.

Expression and Function

Ron is preferentially expressed on epithelial cells and ►macrophages. Ron expression has been detected in the central nervous system, liver, kidney, testes, bone, lung, breast, and epithelia of the digestive tract. In macrophages, Ron signaling regulates select ►cytokine and ►chemokine production in response to injury. In epithelial cells, the normal functions of Ron include a wide array of biological activities such as inducing DNA synthesis, triggering cell scattering, branching morphogenesis, and the regulation of ►apoptosis. Based on the signaling pathways elicited by Met and Ron, the activities elicited by this receptor family have been termed "invasive growth."



Ron Receptor. Figure 1 The human and mouse *Ron* gene structure. Exons are depicted by numbered boxes and introns by black lines. Red boxes code for the SEMA domain, aqua box for the signal peptide, green box for the plexin domain, yellow boxes for the immunoglobulin-like, plexins, transcription factor (IPT) domains, pink box for the transmembrane domain, and blue boxes for the tyrosine kinase domain. The Ys refer to the critical autophosphorylation sites in the kinase domain and for the docking site tyrosine residues in the C-terminal region of Ron. Note that exon 13 in human *Ron* is missing in the mouse gene.



Ron Receptor. Figure 2 Ron protein structure and signaling pathways activated by Ron. The Ron receptor is a single pass membrane spanning, disulfide-linked heterodimeric protein. The alpha chain is an extracellular glycoprotein and the beta chain spans the membrane and contains the intracellular tyrosine kinase domain. Activation of Ron leads to the phosphorylation of tyrosine residues within the kinase domain and subsequent phosphorylation of tyrosine residues that form docking sites for a number of downstream signaling proteins.

R

Ligand

The ligand for Ron is a protein termed ►hepatocyte growth factor-like protein (HGFL), and is also called ►macrophage-stimulating protein or macrophage stimulating 1 (MST1). HGFL is part of a larger family of ►plasminogen-related growth factors, which also includes hepatocyte growth factor (HGF)/►scatter factor (the ligand that activates c-Met), plasminogen and urokinase. The *HGFL* gene, similar to *Ron*, is located at chromosome 3p21.3. HGFL is predominantly produced in hepatocytes. Following synthesis, HGFL is constitutively secreted into the bloodstream, at a concentration of approximately 400 ng/ml, as a biologically inactive single chain precursor of 80 kDa. Pro-HGFL is proteolytically cleaved by membrane-associated proteins on the cell surface or by members of the kallikrein family. Proteolytic cleavage results in the formation of a disulfide-linked heterodimer containing an alpha chain of approximately 50 kDa and a beta chain of approximately 35 kDa. The beta chain of HGFL contains a serine protease-like domain and is primarily responsible for binding to Ron, while the alpha chain contains four kringle domains and appears to regulate the functional consequences of this binding.

HGFL was originally identified as a chemoattractant for macrophages, but it can also act as a motogen or mitogen for several other cell types. Depending upon cell type and context, HGFL can also induce a number

of pleiotropic effects. However, gene deletion studies in mice have shown that HGFL is not an essential gene product as HGFL ►knockout mice have limited phenotypic abnormalities.

Signaling Through Ron

Binding of HGFL to Ron leads to activation of the receptor's intrinsic tyrosine kinase activity and trans-autophosphorylation of two C-terminal tyrosine residues, creating high affinity binding sites for proteins containing Src homology 2 and phosphotyrosine-binding domains (Fig. 2). These phosphorylated tyrosine residues can bind ►phospholipase C-gamma (PLC-γ), ►phosphatidylinositol 3-kinase (PI3K), growth factor receptor-bound protein 2 (Grb2), and Shc. Ras, ►mitogen-activated protein kinase (MAPK), β-catenin, nuclear factor kappa B (NF-κB), and ►Akt mediate HGFL induced activities. Focal adhesion kinase (FAK), Src, c-Jun N-terminal protein kinase (►JNK), and ►signal transducers and activators of transcription (STAT)3 activation result from HGFL/Ron signaling. Thus, Ron activation induces pleiotropic responses through the recruitment of numerous signaling molecules.

Ron Overexpression in Multiple Tumor Types

Increased Ron expression has been documented in several tumor types including breast, colon, lung, liver, kidney, ovary, stomach, pancreas, bladder and prostate. Ron expression is also elevated in cells derived from these tumors. Clinically, high expression of Ron is positively correlated with poor prognosis in several types of human cancers including breast, prostate, colon, and pancreas. Based on gene expression analyses, in the breast, increasing Ron expression is associated with metastatic disease, and in the prostate, Ron expression is correlated with advanced, androgen-independent cancers, suggesting that Ron is important in tumor progression. Overexpression of both Ron and Met in breast and bladder cancers is associated with overall decreased patient survival.

Ron Variants

Several variants of Ron result from ►alternative splicing or alternative initiation. These variants, designated by their molecular weight, have been found in lung, colon, and breast cancers, and many are associated with increased Ron expression. Four of these variants (RonΔ165, RonΔ160, RonΔ155, RonΔ55) result in constitutive activation of the receptor and three (RonΔ160, RonΔ155, RonΔ55) have oncogenic properties. Less is known about RonΔ170 and RonΔ110.

RonΔ55, also known as Short Form (SF)-Ron, is generated from an alternative start site in intron 10 of the *Ron* gene that eliminates most of the extracellular portion of the receptor. SF-Ron is expressed in ovarian and breast cancers, and in cell lines derived from colorectal, lung and pancreatic carcinomas and several leukemias. This variant is constitutively phosphorylated, has strong kinase activity, and alters morphology, growth, motility, and anchorage-dependent growth when transduced into epithelial cells. Expression of SF-Ron can also negatively regulate E-cadherin transcription, resulting in a loss of cellular adhesion.

Mouse strains that express SF-Ron in adult bone marrow tissue are susceptible to Friend virus-induced erythroleukemia, and SF-Ron kinase activity is necessary for erythropoietin-independent expansion of erythroid progenitors in response to Friend virus. Moreover, recent studies have also suggested that SF-Ron has distinct nonredundant biological functions relative to full-length Ron in the progression of inflammatory immune responses in vivo.

Ron-Dependent Transformation

Overexpression of the full-length Ron receptor has transforming capabilities in vitro and in vivo. Mouse fibroblasts overexpressing wild-type Ron exhibit loss of contact inhibition, elongated cellular processes, and increased cellular proliferation and motility compared to fibroblasts with endogenous Ron expression. These phenotypes are augmented with HGFL. Overexpression results in tyrosine phosphorylation of the receptor, suggesting that overexpression is sufficient to elicit constitutive activation. Ron overexpression in colon epithelial cells induces cellular ►migration and invasion and is able to protect cells against apoptosis. Ron overexpression in fibroblasts and epithelial cell lines is sufficient for tumor formation in ►xenograft models.

Transgenic Mouse Models Overexpressing Ron

Important ►mouse models have been created to examine tissue-specific Ron overexpression. The mouse mammary tumor virus (MMTV) promoter was utilized to drive Ron overexpression in mammary epithelium. The female mice expressing the transgene developed *mammary tumors* with 100% incidence. The tumors were highly metastatic, with metastases observed in about 90% of the lungs and livers of all tumor bearing mice. This study demonstrates that Ron overexpression may be important in metastatic breast cancer. This data also supports the observation that Ron overexpression in human breast cancer is associated with an aggressive cancer phenotype with decreased disease free survival time and an increase in ►metastasis. In another mouse model, the surfactant protein C promoter was utilized to drive Ron overexpression in distal lung epithelial cells. Between 6 and 14 months of age, about 90–95% of the transgenic mice developed lung adenomas. These mouse models

suggest that Ron is important to tumor formation, progression, and metastasis.

Ron Loss in Murine Tumor Models

The development of a mouse model containing a targeted deletion of the Ron tyrosine kinase domain has allowed the functional significance of Ron signaling in vivo to be examined. These mice have been crossed with mice engineered to develop tumors. In a well-characterized mouse model of skin cancer, v-Ha-Ras transgenic mice were utilized in which 12-O-tetradecanoylphorbol-13-acetate (►TPA) treatment results in the formation of benign skin papillomas that progress to frank tumors. TPA-treated v-Ha-Ras mice lacking Ron signaling have a greater number of benign skin papillomas, although the papillomas are smaller in size, and have decreased cell proliferation. Importantly, the loss of Ron in this model leads to significantly reduced progression of the benign papillomas toward malignancy.

Another transgenic mouse model lacking functional Ron has been created using mice that have expression of the polyoma virus middle T antigen (pMT) under the control of the MMTV promoter. In the pMT-induced model, the mice develop mammary tumors that metastasize to the lung. The loss of Ron in this model results in a significant decrease in the rate of mammary tumor initiation, fewer tumors, a decrease in tumor size, and is associated with decreased tumor cell proliferation and increased apoptosis. Tumors lacking functional Ron also exhibit a decrease in microvessel density, suggesting that Ron may be important in regulating events impacting tumor ►angiogenesis.

Oncogenic Ron Signaling

Several signaling pathways (β-catenin, MAPK, PI3K) are activated by Ron overexpression as well as ligand binding. β-catenin is part of the ►Wnt signaling pathway and β-catenin expression has been associated with several human cancers. Mammary tumors derived from mice overexpressing Ron are associated with an increase in β-catenin and in the β-catenin target genes ►*c-myc* and *cyclin D1*. Human pancreatic cancer cells treated with HGFL also have increased nuclear β-catenin, and human colorecatal carcinoma cells lacking Ron expression have decreased β-catenin expression.

The MAPK pathway is also upregulated in a variety of cancers, and this pathway is important for many cellular processes including cellular differentiation, survival, proliferation and gene expression. In several human cancer cell lines with high levels of Ron expression, such as those derived from colon, prostate, lung, pancreas and stomach, MAPK activation can be abrogated using a neutralizing antibody against Ron. Mammary tumors from mice lacking the tyrosine kinase domain of Ron also have decreased MAPK activation. Conversely, the addition of HGFL to several cell types results in increased MAPK activation.

Similar results have been found for the regulation of the PI3K/Akt signaling pathway by Ron. Like β-catenin and MAPK, this pathway is often upregulated in various cancers. PI3K can bind directly to Ron. Akt, a serine/threonine kinase downstream of PI3K, is then activated and elicits responses decreasing apoptosis and increasing cellular survival. In colon, prostate and stomach cancer cell lines, there is a decrease in activated Akt when Ron is neutralized. In vivo, the amount of phosphorylated Akt is decreased in mammary tumors from mice lacking functional Ron. Taken together, these data suggest that Ron expression is important to the regulation of signaling pathways that are often highly associated with many human cancers.

Ron as a Therapeutic Target in Human Cancer

The mounting evidence that Ron is important in tumor initiation, progression, and metastasis suggests that Ron may be a therapeutic target for cancer treatment. Several approaches have been initiated to target Ron. Antibodies have been developed to neutralize Ron activity by preventing HGFL binding, and may be effective in treating tumors containing high Ron expression. Antibodies directed against Ron are able to inhibit MAPK and Akt activation as well as cellular migration. Moreover, in xenograft models using cancer cells that overexpress Ron, antibody neutralization is able to reduce subcutaneous tumor growth. Increased apoptosis of Ron-expressing pancreatic cancer cells was demonstrated by concurrent Ron receptor antibody blockade and ►gemcitabine treatment. In addition to neutralizing antibodies to target Ron, small molecule inhibitors have also been developed. A small peptide inhibitor containing five amino acids can inhibit HGFL- and HGF-induced cellular scattering and migration. A soluble molecule homologous to the ►SEMA domain of Ron has been shown to exhibit a ►dominant negative effect. This molecule is able to inhibit HGFL-induced phosphorylation of Ron, and has an inhibitory effect on the growth of colon cancer cells. ►Geldanamycin, a class of anti-tumor drugs that inhibit tumor cell growth by preventing proper folding and increase the degradation of oncogenic proteins, have also been identified as possible treatment modalities leading to receptor tyrosine kinase degradation, including Ron, in human cancers.

The Ron receptor participates in ►receptor cross-talk with other ►receptor tyrosine kinases and ►integrins, which may be important in regulating the therapeutic response of human tumors. Several studies have shown that Ron can interact with the epidermal growth factor

receptor (►EGFR). Moreover, treatment of one receptor can modulate the response of an interacting receptor. Targeting this interaction in cell lines results in the modulation of cellular responses including cell scattering and tumor regression. In addition to EGFR, Ron is also co-expressed with the Met receptor in bladder, breast and liver cancers, and this co-expression has been linked with poor prognosis. Combined, these studies suggest that targeting multiple receptor tyrosine kinases in these cancers might prove more effective than targeting one alone.

Although there are currently no ►clinical trials being done selectively targeting the Ron receptor, there are several ongoing clinical trials with compounds that target Met, and which cross-react with Ron. Initial data from these trials suggests that the compounds are clinically well tolerable, and show an impressive anti-tumor activity in patients with a broad range of metastatic tumor types who have failed prior treatment. In total, the data outlined suggests that Ron may be a critical factor in tumorigenesis and that inhibition of Ron, either alone or in combination therapy, may prove to be beneficial in the treatment of high-risk cancer patients.

ROS

Definition

Reactive Oxygen Species; Chemical species formed by the chemical or biochemical reduction of molecular oxygen, usually by normal metabolic processes in the cell, including energy metabolism. These consist of the superoxide radical (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radicals (OH). These oxygen species are reactive, and can react with DNA bases to cause mutations in the cells.

►Hepatic Ethanol Metabolism
►Reactive Oxygen Species

ROS Accumulation

Definition

►Reactive oxygen species (ROS) includes oxygen ions, free radicals, and peroxides. The accumulation of ROS levels can result in damage to cell structures.

►DNA Damage
►Oxidative DNA Damage

ROS Scavenger

Definition

A chemical substance added to a mixture in order to remove ►reactive oxygen species.

Rothmund-Thomson Syndrome

Definition

An autosomal ►recessive genetic disease characterized by distinctive skin abnormalities (poililoderma congenitale), juvenile cataracts, skeletal abnormalities, endocrine abnormalities, abnormal growth, and an increased propensity to develop malignant tumors.

►Bone Tumors

RT-PCR

Definition

Reverse transcriptase polymerase *c*hain *r*eaction; synonym Reverse transcription ►PCR; molecular biological technique for the in-vitro enzymatic amplification of

defined RNA sequences from as few as one copy to visually detectable levels. In a first step, RNA is transcribed into complementary DNA (cDNA) by the enzymatic activity of reverse transcriptase; the cDNA is amplified in between two oligonucleotides complementary to the ends of the region to be analyzed by the enzymatic activity of a heat stable DNA polymerase; the oligonucleotides serve as sequence specific anchors that prime the synthesis of complementary DNA strands. Serial amplification is achieved by repeated cycles of high temperature DNA denaturation separating complementary strands, annealing of oligonucleotide primers to the single stranded DNA daughter strands and de-novo DNA synthesis from precursor trinucleotides by the polymerase.

Rule of Five

Definition

Is a set of four parameters that should not be exceeded if a drug is to be orally active. The 5 refers to parameter cutoff values; MWT $\leq$ 500; Log $P \leq 5$; H bond donors $\leq$5; H bond donors $\leq$10.

Definition

The RUNX1/CBFβ heterodimeric transcription factor regulates the expression of genes required for ►hematopoiesis and is the one of the most frequent targets of chromosomal translocations associated with human leukemia.

Characteristics

Expression and Regulation

RUNX1 was originally isolated from ►acute myeloid leukemia patient samples containing the ►t(8;21) chromosomal translocation. In addition to RUNX1, mammals also express RUNX2 and RUNX3. All three RUNX proteins share homology with the *Drosophila* Runt protein and contain the 128 amino acid Runt homology domain (RHD), which mediates both DNA binding and interaction with the core binding factor β (CBFβ) protein. Through this interaction, CBFβ stabilizes RUNX-DNA binding and protects the RUNX subunit from degradation via ►ubiquitination.

RUNX1 maps to chromosome 21, spans 260 kb and contains 11 exons, with transcription proceeding from telomere to centromere along the chromosome. The expression of *RUNX* family members is highly regulated at the levels of transcription, splicing, and translation. Transcription is initiated from two distinct promoters, P1 and P2, with the resulting transcripts being processed into numerous alternatively spliced mRNAs. These transcripts can subsequently be translated either by cap-dependent or cap-independent mechanisms. RUNX activity is also tightly controlled by post-translational modifications, including phosphorylation, acetylation and ubiquitination. The multiple isoforms of RUNX1 range in size from 20 to 52 kDa. RUNX proteins localize to the nucleus and are differentially expressed in a tissue- and developmental-specific manner.

RUNX1 binds the target DNA sequence, TTG/cGGT, found in the promoters of numerous genes required for normal hematopoiesis, including myeloperoxidase, interleukin 3, the T-cell receptors (TCR), and the B cell receptors. Depending on its associated protein partners, RUNX1 can act either as a transcriptional activator or as a transcriptional repressor. Although RUNX1 binding sites alone are not sufficient for robust activation of target genes, RUNX1 can cooperate with additional factors such as ►c-Myb, ►ETS family members, and ►C/EBPα, whose binding sites lie near the consensus RUNX1 binding sites, to enhance transcription. Additionally, RUNX1 can recruit various transcriptional co-activators such as ►p300/CBP, ALY, and Yes-associated protein (YAP) to stimulate the expression of target genes.

RUNX1 also contains several domains that mediate transcriptional repression. These repression domains associate with known transcriptional co-repressors, such as mSin3A and TLE, the mammalian homologue of the *Drosophila* protein, Groucho. RUNX1 can also bind ►histone deacetylases (HDACs) and the histone methyltransferase, SUV39H1, suggesting that ►chromatin modifications are an essential feature of RUNX1-mediated transcriptional repression.

Gene knockout experiments in mice have confirmed that deletion of *Runx1* is lethal during mouse embryonic

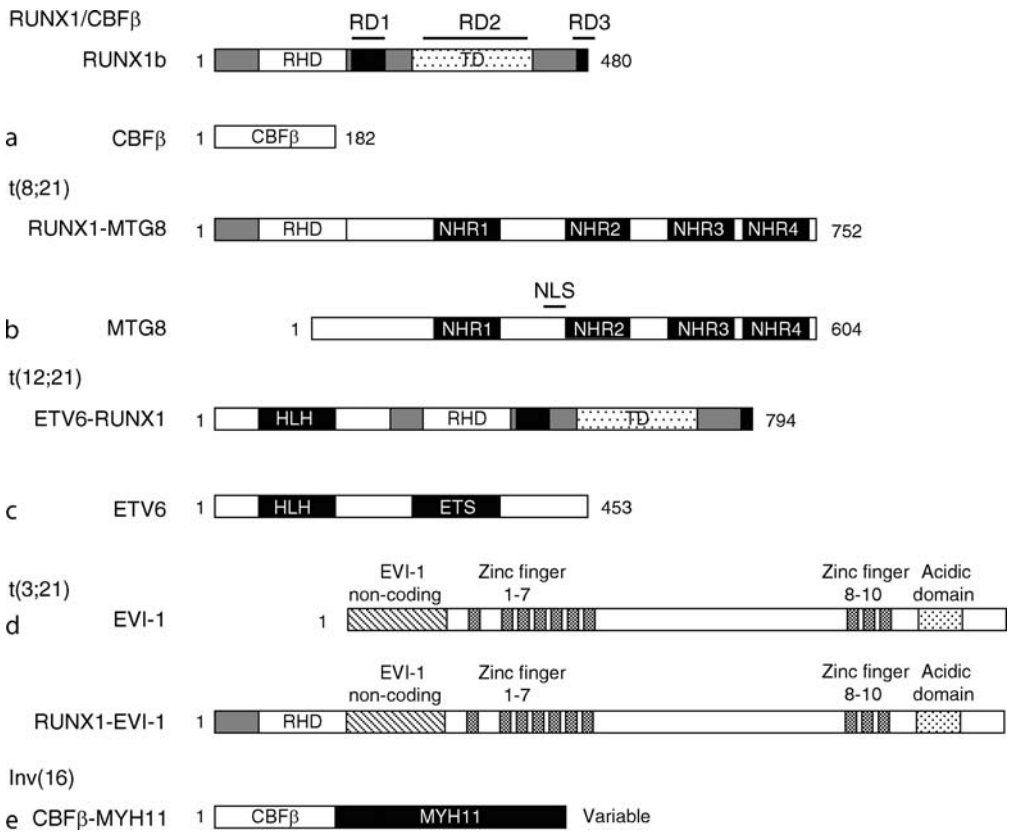
development. Although mice lacking the *Runx1* gene appear morphologically normal, they display severe central nervous hemorrhaging and die *in utero*, secondary to a complete absence of definitive hematopoiesis. A similar phenotype was observed in mice lacking *CBFβ,* suggesting that RUNX1 and CBFβ function together in the regulation of hematopoiesis.

RUNX1 in Leukemia

►Leukemia arises when the normal processes regulating the proliferation, differentiation, and survival of blood cells are disrupted. ►Chromosomal translocations have been found in up to 65% of acute leukemias. The RUNX1/CBFβ transcription factor is disrupted by at least 18 different chromosomal translocations, and is the most frequent target of translocations associated with the pathogenesis of acute leukemia. The t(8;21), t(12;21), t(3;21), and inv(16) chromosomal translocations target ►AML-1/ETO/CBFβ/TEL (Fig. 1).

The t(8;21) chromosomal translocation, which accounts for 15% of all cases of ►AML, fuses *RUNX1*, including the RHD, to a nearly full-length *Myeloid Translocation Gene on chromosome 8 (MTG8;* also known as *ETO, RUNX1T1 or CBFA2T1*). The resulting fusion protein, RUNX1-MTG8 (also known as AML1-ETO), retains the ability to bind RUNX1 target sequences on DNA to repress RUNX1-regulated genes. This ability of RUNX1-MTG8 to repress RUNX1 target genes requires the MTG8 portion of the fusion protein.

MTG8 is the founding member of a gene family that also includes *MTG16* (also known as *ETO2* or *CBFA2T3*) on chromosome 16 and *MTGR1* (also known as *CBFA2T2*) on chromosome 20. Like *MTG8, MTG16* is fused to RUNX1 by the t(16;21), a



Runx1. Figure 1 Schematic diagram of representative chromosomal translocations targeting RUNX1/CBFβ. (a) RUNX1b is shown as the predominant RUNX isoform. The Runt homology domain (RHD), transactivation domain (TD), and repression domains (RD1–3) are indicated. CBFβ is shown. (b) The RUNX1-MTG8 fusion protein, resulting from the t(8;21) translocation is shown. MTG8 contains four Nervy homology regions, NHR1–4. The MTG8 nuclear localization signal (NLS) is marked. (c) ETV6-RUNX1, generated by the t(12;21) translocation, is shown. ETV6 contains a helix-loop-helix domain and ETS DNA binding domain. (d) The RUNX1-EVI-1 fusion protein results from the t(3;21) translocation. EVI-1 contains two sets of DNA binding zinc finger domains, a proline-rich central domain, and an acidic carboxy-terminal domain. (e) The inversion 16 translocation, inv(16), is shown, in which CBFβ is fused to the smooth muscle myosin heavy chain. The length of the MYH11 portion varies in distinct fusion proteins and is thus indicated as variable.

translocation associated with therapy-related cases of AML. Though *MTGR1* is not associated with a chromosomal translocation, it is often deleted in ►myelodysplastic syndrome (MDS). Furthermore, MTGR1 was initially identified through its ability to bind the RUNX1-MTG8 protein.

The MTG proteins are homologous to the *Drosophila* Nervy protein. Like Nervy, the MTG proteins contain four highly conserved domains, called Nervy homology regions 1–4 (NHR1-4). Though the MTG proteins are unable to bind DNA directly, the NHR1 domain mediates the interaction of MTG proteins with various DNA-binding proteins, including Gfi1, Gfi1b, TAL1/SCL, TCFs, PLZF, Ldb1, and BCL6. The ability of the MTG proteins to interact with these various regulators of hematopoiesis suggests that the MTG family plays a key role in normal blood cell development. The remaining domains of the MTG proteins, including NHR domains 2–4, mediate interactions between MTG family members as well as associations with various transcriptional co-repressors, including mSin3A, N-CoR, and HDACs. Thus, the main functions of MTG proteins stem from their ability to nucleate the assembly of transcriptional co-repressor complexes.

The RUNX1-MTG8 fusion protein alters the expression of genes normally regulated by RUNX1 or MTG8. For example, by recruiting transcriptional co-repressor proteins that normally bind MTG8 to RUNX1 binding sites, RUNX1-MTG8 acts as a dominant repressor of RUNX1 target genes, including p^{14ARF} and ►Neurofibromatosis 1. RUNX1-MTG8 may also be able to recruit this transcriptional co-repressor machinery away from promoters normally regulated by MTG8, thereby indirectly stimulating expression of these genes. For example, RUNX1-MTG8 stimulates transcriptional activation of the TCF-dependent reporter plasmid, TOP-FLASH, in a manner that requires the co-repressor binding domains of the fusion protein.

When introduced into a mouse model, RUNX1-MTG8 alone is not sufficient to cause leukemia. Instead, the fusion protein causes increased ►self-renewal of adult hematopoietic progenitor cells and impairs hematopoietic differentiation. Thus, it appears that additional secondary mutations are required for development of full-blown leukemia. Consistent with this idea, clinical studies have demonstrated the presence of additional mutations affecting tyrosine kinase signal transduction pathways in patients carrying the t(8;21) chromosomal translocation. Thus, by creating an imbalance in the normal processes of hematopoietic ►stem cell self-renewal and differentiation of the various hematopoietic lineages, the main role of RUNX1-MTG8 in the pathogenesis of ►AML may be to expand the hematopoietic stem cell population and impair oncogenic checkpoints, which allows the accumulation of secondary mutations leading to the development of fully malignant disease.

Another chromosomal translocation affecting *RUNX1* is the t(12;21) translocation that occurs in 25% of pediatric cases of B cell ►acute lymphoblastic leukemia (ALL). The t(12;21) fuses the ETS family transcriptional regulator ►ETV6 (also known as TEL) with RUNX1, leading to the fusion protein ETV6-RUNX1 (also known as TEL-AML1). ETV6 contains a helix-loop-helix (HLH) oligomerization domain and Ets DNA binding domain. The ETV6-RUNX1 fusion protein contains almost all of ETV6, except for the Ets domain, fused to a nearly full-length RUNX1. Similarly to RUNX1-MTG8, ETV6-RUNX1 can still bind DNA through the RHD of RUNX1 and is able to bind transcriptional co-repressors including ►HDACs and mSin3A through the ETV6 and RUNX1 portions, respectively. Thus, ETV6-RUNX1 also acts as a dominant repressor of RUNX1 target genes. Mice expressing the ETV6-RUNX1 fusion protein show altered lymphopoiesis, but fail to develop leukemia, again suggesting that additional mutations are required for the development of fully malignant disease.

RUNX1/*CBFβ* is also involved in an inversion or chromosomal translocation event with chromosome 16. The result is a chimeric mRNA that fuses most of *CBFβ* to a smooth muscle myosin heavy chain gene, *MYH11*. The inv(16) fusion protein retains the ability to bind RUNX1 through the *C*BFβ portion, while the MYH11 portion promotes oligomerization and contains a cryptic transcriptional repression domain.

The mechanism by which the inv(16) fusion protein mediates leukemogenesis is the subject of debate. The initial model proposed that the inv(16) promotes leukemogenesis through cytoplasmic sequestration of RUNX1. This model is based on the observation that CBFβ-MYH11 co-localizes with RUNX1 in the cytoplasm upon over-expression in fibroblasts. Thus, by limiting the amount of RUNX1 in the nucleus, the fusion protein may negatively regulate RUNX1 activity. The second model proposes that the CBFβ-MYH11 fusion protein acts similarly to the t(8;21) and t(12;21) fusion proteins to dominantly repress RUNX1-regulated genes. This model is based on the observation that the fusion protein is able to bind various transcriptional co-repressor proteins, such as mSin3A and HDAC8, through its MYH11 domain and actually cooperates with RUNX1 to repress RUNX1-regulated genes. This model is consistent with the finding that RUNX1 is mostly nuclear in myeloid cells expressing the inv(16), and that expression of RUNX1 cooperates with the inv(16) to induce AML. Moreover, conditional deletion of *Runx1* does not promote leukemogenesis.

Like RUNX1-MTG8, the inv(16) fusion protein is not sufficient to cause leukemia on its own and instead requires cooperating mutations for the development of disease. For example, mice expressing inv(16) alone fail to develop leukemia after a long latency period but

readily develop disease following treatment with a mutagenic agent such as ►ENU or upon expression of the fusion protein on an *ARF*-deficient background.

RUNX1 is also involved in a translocation with chromosome 3 in therapy-related ►AML, ►MDS, and ►CML ►blast crisis. The t(3;21) results from a breakpoint between the RHD and the transactivation domain of RUNX1, causing fusion of *RUNX1* with a full-length *Evi-1* gene on chromosome 3. The Evi-1 portion of the fusion protein interacts with the transcriptional co-repressor C-terminal binding protein (CtBP). Thus, RUNX1-EVI1 may affect the expression of RUNX1 target genes through the aberrant recruitment of co-repressor complexes. Furthermore, the fusion protein also exhibits higher affinity for CBFβ, which may contribute to its dominant negative effects on RUNX1 activity. Like EVI1, the RUNX1-EVI1 fusion protein also retains the ability to induce ►AP-1 activity and repress ►TGF-β signaling, which may further contribute to its leukemogenic properties.

RUNX1 activity is also affected by point mutations or gene dosage effects. For example, point mutations in *RUNX1* have been identified in approximately 10% of sporadic cases of AML. Most of these mutations occur in the RHD of the protein and thus disrupt the ability of RUNX1 to bind DNA. Gene ►amplification of RUNX1 has also been detected in some cases of pediatric ALL, suggesting that increased dosage of RUNX1 may contribute to leukemogenesis.

Definition

Sphingosine-1-phosphate, an anti-apoptotic, angiogenic sphingolipid. A pro-proliferative sphingolipid that counteracts ceramide effects.

►Sphingolipid Metabolism

S-9

Definition

Is a cell free fraction derived from a chopped up liver that performs mostly ►phase II metabolism on a drug.

►ADMET Screen

S-Phase

Definition

Short for synthesis phase, S-phase is a period during the ►cell cycle where DNA synthesis or replication occurs. The cell cycle is divided into four phases: G1 (Gap1), S (synthesis), G2 (Gap 2) and M (mitosis). Origins of replication fire once per cell cycle allowing the entire genome to be replicated in S-phase.

Definition

Cell-cycle checkpoints function by sensing DNA damage and transmitting a signal that results in arrest at defined stages of the cycle. The ►S-phase "checkpoint" halts cells during the DNA synthetic period in response to DNA damage (►DNA Damage Responses) and is somewhat different from other checkpoints in two ways. First, in the classic paradigm, cell-cycle progression is halted at various *discrete* points in the cycle (e.g., in G_1, at the G_2/M transition, and during mitosis), and cells are usually arrested for many hours prior to re-entry into the cycle. In contrast, the S-phase damage-sensing pathway arrests cell-cycle progression for only an hour or so and seemingly at any position within the S-phase, therefore, it is difficult to think of it as a checkpoint *per se* (although we will refer to it as such in this review). As more is learned about the

molecular basis of all of the checkpoints, it is becoming clear that each may have multiple targets. Thus, the underlying strategies for mobilizing these vital damage-sensing pathways may turn out to have many similarities.

A second possible difference is that the classic G_1, G_2/M, and mitotic checkpoints are thought to serve an anticipatory or surveillance function by arresting cells *prior to* critical processes such as DNA replication or mitosis, both of which are capable of converting potentially repairable damage into catastrophic lesions, such as double-strand breaks or chromosome non-disjunction. However, there is little evidence to suggest that the classic S-phase damage-sensing pathway has an anticipatory function, and it is formally possible that the arrest of DNA synthesis in response to damage results from a competition for *trans*-acting factors between multiple DNA-templated responses (repair, transcription, and replication).

Characteristics

At what point(s) in S-phase does the S-phase checkpoint operate? It has been known for decades that when exponentially growing cells are subjected to ionizing radiation, DNA synthesis is rapidly and significantly inhibited. Compelling evidence has been obtained that damage-induced inhibition of DNA synthesis represents a *bona fide* damage-sensing signal transduction pathway, as opposed to a simple arrest of replication forks by damage in the template (i.e., a *cis*-acting mechanism). For example, a dose of 5 Gy of gamma radiation results in a single-strand break every 25 replicons on average, yet inhibits overall DNA synthesis by ~50%. Therefore, it has been presumed for years that the S-phase checkpoint is a global cellular response that functions in *trans* and inhibits initiation of DNA replication as opposed to chain elongation. Indeed, there is direct experimental evidence from studies on mammalian viruses that doses of ionizing radiation too small to damage individual viral templates nevertheless down-regulate viral replication, suggesting a *trans*-regulatory mechanism. Results from three different experimental systems also provide direct evidence that the S-phase checkpoint down-regulates DNA synthesis by inhibiting initiation ►Radiation Sensitivity. Alkaline sucrose gradient analysis of pulse-labeled DNA showed that ionizing radiation inhibits the appearance and maturation of the smallest nascent fragments to a much greater extent than the maturation of larger fragments. Secondly, DNA fiber autoradiographic analysis of the changes in the pattern of replication after irradiation suggested that initiation is preferentially inhibited. Thirdly, a ►2-dimensional gel replicon mapping approach that can distinguish between initiation and elongation of DNA synthesis, showed clearly that ionizing radiation preferentially down-regulates initiation in a defined chromosomal replicon (the amplified, early-firing dihydrofolate reductase domain). To determine whether damage-induced inhibition of initiation also occurs at origins that fire later in the S period, advantage was taken of the naturally amplified ribosomal gene cluster, in which a restriction site polymorphism distinguishes between early- and late-firing rDNA replicons. The 2-D gel replicon mapping approach showed that both the early- and late-firing origins were inhibited by ionizing radiation. By extension, it is likely that all origins in mammalian chromosomes will be inhibited in response to DNA damage, regardless of when they are activated.

An interesting recent observation suggests that there may be more than one checkpoint or pathway responsible for the overall inhibition of the rate of DNA synthesis that occurs when ionizing radiation is delivered to an asynchronous culture of growing cells. When cells are synchronized and replicate cultures are irradiated at hourly intervals during S-phase, the subsequent inhibition of DNA synthesis never exceeds more than about 25% at any time in the S-period, whereas DNA damage delivered to an asynchronous population results in 50% or greater inhibition of the overall rate of DNA replication. By careful fluorescence-activated flow sorter analysis of gamma-irradiated log cultures, it was possible to demonstrate the existence of a population of late G_1 cells whose entry into S-phase was prevented for several hours. Since this potentially new checkpoint was uncovered in CHO cells, which are deficient in p53 activity ►p53 Family, it is distinct from the well-known p53-mediated G_1 checkpoint. This pathway is therefore analogous to a G_1/S checkpoint that has been described in *Saccharomyces cerevisiae*, which acts between the cell cycle steps affected by the DBF4 and CDC7 gene products.

It is possible that down-regulation of entry into the S-phase in mammalian cells (i.e., at the G_1/S transition) functions by inhibiting the earliest S-phase origins and is therefore mechanistically related to damage-induced inhibition of late-firing origins (i.e., does not differ from the S-phase checkpoint *per se*). Since irradiation delays the entire S-period for several hours (i.e., it effectively repositions the S-phase along the cell-cycle time axis), it would have to be argued that late-firing origins cannot fire until early-firing origins have done so. Interestingly, however, cells arrested near the G_1/S boundary in either mimosine or aphidicolin (both effective inhibitors of chain elongation) are resistant to radiation-induced inhibition of DNA synthesis, lending weight to the argument that there is a unique damage-sensing pathway that operates at the G/$_1$S transition *prior to* origin firing. Since the events preceding initiation of DNA synthesis in mammalian cells are only now being characterized, it will be some time before the molecular nature of this potential new checkpoint is uncovered.

What proteins are involved in the S-phase damage-sensing checkpoint? The ataxia telangiectasia mutated (►ATM) (►ATM Protein) and the ATM Rad3-related (ATR) protein kinases are critical checkpoint factors in human cells. Both are members of the phosphatidylinositol 3 kinase-related family of protein kinases (PI3K) that play a major role in sensing damage and triggering repair of DNA lesions in mammalian cells. ATM and ATR are preferentially activated by different forms of DNA damage. ATR is activated following induction of DNA adducts by UV or by chemical crosslinking agents, whereas ATM is activated in response to double strand DNA breaks induced by irradiation, etc.

The ATM gene was cloned in 1995. Cells derived from patients with ►ataxia telangiectasia (AT) fail to inhibit DNA synthesis in response to irradiation. This phenomenon was termed ►radiation-resistant DNA synthesis (RDS), which reflects a failure of intra S-phase checkpoint control. ATM is thought to play a central role in the cellular responses (including the S-phase checkpoint) to DNA double strand breaks (DSBs) and other genotoxic stresses. ATM exists as a catalytically inactive dimer in the absence of DNA damage. In response to DNA damage, especially DSBs, ATM undergoes rapid autophosphorylation on serine 1981, resulting in dissociation of the inactive dimers to yield active monomers. However, when the 1987 site was mutated (the mouse equivalent of serine 1981) and expressed in mice as the sole ATM species, the mutated ATM kinase was activated by radiation, suggesting that an alternative mode for stimulation of the ATM kinase must exist. The fact that several different serine/threonine phosphatases type 2 (PPP2) alpha isoform and type 5 (PPP5) regulate ATM activity, raises the question whether additional phosphorylation sites exist in the ATM protein that regulate its activity. In addition to DNA damage, chromatin remodeling molecules are also able to induce rapid activation of ATM/ATR in the absence of detectable DNA strand breakage. The activation of ATM/ATR by DNA strand breakage might thus be mediated, at least in part, by a change in chromatin structure.

In 2000, the ►Seckel syndrome (an autosomal recessive disorder characterized by developmental abnormalities including growth retardation and microcephaly) gene was localized to human chromosome 3q22.1-q24 (SCKL1) by homozygosity mapping. This gene has subsequently been identified as ATR. ATR is thought to be activated by both stalled replication forks and bulky adducts produced by agents such as Mitomycin C. ATR function in cell cycle checkpoint signaling pathways is dependent on an ATR-interacting protein known as ATRIP. ATRIP contains domains similar to the ATM-binding domain of NBS1, which is required for the interaction of ATRIP with ATR. ATR and ATRIP both localize to intranuclear foci after DNA damage or inhibition of replication. ATRIP is phosphorylated by and interacts with the single-stranded DNA (ssDNA) binding protein RPA. RPA coats ssDNA at replication forks to form an RPA–ssDNA complex in response to damage. Deletion of ATR in mice mediated by the Cre recombinase causes the loss of both ATR and ATRIP expression, the loss of DNA damage checkpoint responses, and cell death. Depletion of RPA inhibits ATR association with chromatin and abrogates the aphidicolin-induced DNA replication checkpoint. Moreover, RPA is also required for activation of ATR-mediated phosphorylation of Chk1 and Rad17.

►Nijmegan breakage syndrome (NBS) is a recessive genetic disorder characterized by elevated sensitivity to ionizing radiation, chromosome instability, and a high frequency of malignancies. Since cellular features partially overlap with those of ataxia-telangiectasia (A-T), NBS was long considered an A-T clinical variant. Nbs1, the product of the gene underlying the disease, contains three functional regions: a forkhead-associated (FHA) domain, a BRCA1 C-terminal (BRCT) domain at the N-terminus, an Mre11-binding region at the C-terminus, and several SQ motifs (consensus phosphorylation sites by ATM and ATR kinases) in the central region. Nbs1 forms a multimeric complex with hMre11/hRad50, which is recruited to the vicinity of DSBs sites by direct binding to histone H2AX via the FHA and BRCT domains of Nbs1. Recent studies suggest that the Mre11/Rad50/Nbs1 (MRN) complex, and possibly other proteins, play a role in the recruitment of ATM to the region of DNA strand breaks. In addition, BRCA1 (►BRCA1/BRCA2 Germline Mutations and ►Breast Cancer Risk) appears to be necessary for recruitment of ATM to damage foci. In response to IR, ATM fails to localize to damaged sites in the cells lacking full-length BRAC1 or full-length NBS1 despite the fact that ATM is activated. Once ATM is recruited to damage sites it can phosphorylate substrates at the break, including Nbs1, 53BP1, BRAC1, H2AX, and Smc1. Smc1 is a member of the ►Structural Maintenance of Chromosomes Protein (SMC) (family of proteins) and is thought to enhance the efficiency of DSB repair. Nbs1 therefore acts both as an upstream modulator of ATM as well as a downstream target of ATM.

In response to different genotoxic stresses, ATM and ATR transduce the damage signal to checkpoint control proteins to activate checkpoints. There are multiple parallel pathways underlying the intra S-phase checkpoint. The first pathway involves the ATM/ATR-Chk1/Chk2-Cdc25A-Cyclin E(A)/Cdk2-Cdc45 cascade, which links the upstream checkpoint kinases with the core cell cycle machinery in S-phase cells. DNA-damage-activated ATM and/or ATR phosphorylate Chk1 (serines 317 and 345) and Chk2 (threonine 68). Chk1 and Chk2 inhibit Cdc25A activity by phosphorylation of its serine

123 residue followed by ubiquitin-mediated degradation. Cdc25A is a dual-specificity phosphatase, removing inhibitory phosphates from threonine 14 and tyrosine 15 from Cdk2. Thus, Cdk2 is inhibited, resulting in decreased phosphorylation of Cdc45. This prevents its association with chromatin and thereby decreases initiation of DNA replication at origins.

Another S-phase pathway involves the ATM-Nbs1-Smc1 cascade. Following IR, the MRN/Smc1 complex is recruited to sites of DSBs. Once ATM is recruited to the complex, it phosphorylates Nbs1 on serine 278 and serine 343. Mutation of these residues results in an S-phase checkpoint defect following ionizing radiation. In addition, phosphorylation of the protein Smc1 on Serines 957/966 by ATM is also necessary for activation of the S-phase checkpoint. The ATM-Nbs1-Smc1 axis is clearly distinct from the ATM/Chk2/Cdc25A pathway.

►Fanconi anemia (FA) is a recessive genetic disease characterized by cellular hypersensitivity to DNA interstrand crosslinking agents, mild sensitivity to other genotoxic agents, and clinical features that overlap with NBS, A-T, and ATR-seckel syndrome. Phosphorylation of serine 222 of Fanconi anemia protein D2 (FANCD2) by ATM is dependent on Nbs1 and is necessary for the IR-activated S-phase checkpoint. Since the ATM-FANCD2 pathway apparently acts independently of SMC1 phosphorylation, its downstream effect is presently unknown.

What are the target(s) of the S-phase checkpoint? Precise regulation of the initiation of DNA synthesis is critical, since it ensures that the genome is replicated once and only once per cell cycle. Much of what we know about the regulation of initiation at origins comes from yeast. Autonomously replicating sequence (ARS) elements were first identified in a functional assay by virtue of their ability to support plasmid replication. In *Saccharomyces cerevisiae*, it is now known that a step-wise assembly of proteins onto origins precedes origin firing. In yeast, a multi-protein complex (the ►origin replication complex (ORC)) has been isolated and shown to interact with ARS elements. ORC is comprised of six proteins and remains bound to yeast origins throughout the cell cycle. During M-phase, the cdc6 protein is recruited to ORC ►Replication Licensing System, which, in turn, recruits ►minichromosome maintenance (MCM) proteins to form the pre-replicative complex (pre-RC) on origins. An S-phase cyclin is then thought to be necessary for the association of the cdc45 protein with the pre-RC just prior to the onset of DNA synthesis. Several other proteins such as Cdt1, Gins, and MCM10 play critical but poorly understood roles in effecting initiation at origins. Origin firing is likely down-regulated through MCM2 phosphorylation, which itself is regulated by checkpoint pathways signaling through cdc45.

What is the biological significance of the S-phase checkpoint? Cell-cycle checkpoints by definition provide an adaptive cellular advantage following genotoxic stress. In the case of the S-phase checkpoint, radiation sensitivity has been uncoupled from checkpoint function, arguing that the S-phase checkpoint may not always function to enhance survival following DNA damage. However, these experiments were performed on AT or AT-like cells in which it is not possible to exclude other mutations that are epistatic to the checkpoint defect. Furthermore, ATM likely directly influences DNA repair possibly *via* SMC1. Another possibility is that the S-phase checkpoint functions to maintain genomic stability. Irradiation produces single-strand DNA breaks, and replication through single-strand breaks has the potential to produce double-strand lesions that, if not correctly repaired, can lead to chromosomal rearrangements and carcinogenesis. An interesting further possibility is that the S-phase checkpoint functions in normal cell division to cope with endogenous oxidative or other genotoxic stresses. Future work will clarify these questions.

Salivary Gland Malignancies

Militsakh Oleg, Goddard John, Ryan James, Rumboldt Zoran, Neville Brad, Sharma Anand, Gillespie M.Boyd, Skoner Joshua, Lentsch Eric, Hornig Joshua, Day Terry
Head and Neck Tumor Program, Hollings Cancer Center, Medical University of South Carolina, Charleston, SC, USA

Definition
Salivary gland tumors are an uncommon and epidemiologically diverse group of tumors. Though rare, these tumors can pose a diagnostic and treatment challenge for the head and neck surgeon.

Characteristics
Epidemiology/Risk Factors
There are three major paired glands (parotid, submandibular and sublingual) and numerous minor salivary glands which line the mucosa of the upper aerodigestive tract. The normal function of these glands is to produce saliva, which serves as a lubricant, aids in early digestion, and is important to good dental hygiene.

The incidence of salivary gland tumors is ~5 per 100,000 population, which yields ~2,500 new cases in the United States per year. They comprise less than 0.5% of all malignancies and 3–5% of malignancies of the head and neck region. Most salivary gland tumors (70–80%) arise in the parotid gland and the majority of all salivary gland tumors are benign. Of the tumors originating from the parotid gland roughly 75% are benign, while only 25% are malignant. The percentage of malignant tumors increases for other locations (37–45% for submandibular glands, 75% for sublingual gland and slightly less than 50% for minor salivary glands). The most common malignant tumor of the parotid gland is mucoepidermoid ►carcinoma, while in the submandibular gland it is adenoid cystic carcinoma. Although the most common malignancy of the minor salivary glands is mucoepidermoid carcinoma as well, when polymorphous low-grade carcinoma is found, it is virtually pathognomonic for a minor salivary gland malignancy.

The etiology of salivary gland malignancies is unknown. Several studies have demonstrated an association between exposure to ionizing radiation and subsequent occurrence of salivary malignancy. Although both alcohol and tobacco use are thought to increase the risk of salivary gland malignancies, the current literature has conflicting data. Various nutritional factors and certain diets (including those high in fruits and vegetables and low in cholesterol) are thought to lower the risk of salivary gland cancer.

Staging/Classification

Salivary gland cancers constitute a heterogeneous group of tumors with distinct histology and very diverse clinical behavior.

The World Health Organization (►WHO) has described 23 different histologic types of salivary gland cancers (Table 1), most of which are exceedingly rare. Salivary gland malignancies can further be subdivided into high and low grade tumors. Low grade tumors usually exhibit a less aggressive behavior. These include acinic cell carcinoma, cystadenocarcinoma, polymorphous low-grade adenocarcinoma and other rare tumors. In contrast, high grade tumors display a significantly more aggressive behavior. The examples of high grade tumors include salivary duct carcinomas, anaplastic and undifferentiated carcinomas and carcinosarcomas. Mucoepidermoid carcinoma, adenocarcinoma and squamous cell carcinoma of salivary glands can present with various histologic grades (low, intermediate or high) and, thus, exhibit a variety of biological behaviors (Fig. 1). Certain tumors, such as adenoid cystic carcinoma, while low-grade, exhibit very aggressive behavior due to a propensity for perineural spread (Fig. 2).

Salivary Gland Malignancies. Table 1 WHO (World Health Organization) classification of salivary gland neoplasms

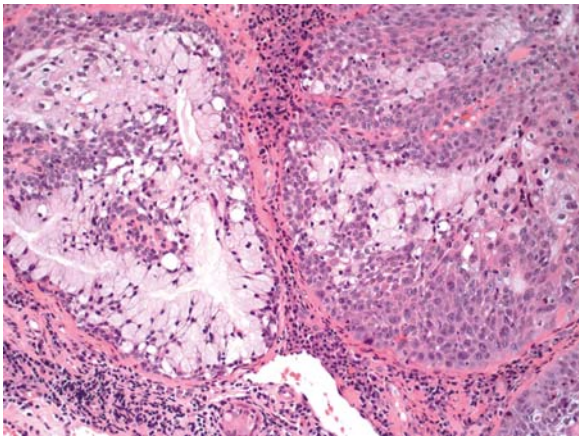
Malignant neoplasms	Benign neoplasms
Acinic cell carcinoma	Mixed tumor (pleomorphic adenoma)
Mucoepidermoid carcinoma	Warthin tumor
Adenoid cyctic carcinoma	Myoepithelioma
Polymorphous low-grade adenocarcinoma	Basal cell adenoma
Epithelial-myoepithelial carcinoma	Canalicular adenoma
Clear cell carcinoma, N.O.S	Oncocytoma
Basal cell adenocarcinoma	Cystadenoma
Malignant sebaceous tumours	Sialadenoma papilliferum
Cystadenocarcinoma	Inverted ductal papilloma
Low-grade cribriform cystadenocarcinoma	Intraductal papilloma
Mucinous adenocarcinoma	Lymphadenomas and sebaceous adenomas
Oncocytic carcinoma	
Salivary duct carcinoma	
Adenocarcinoma, N.O.S	
Myoepithelial carcinoma	
Carcinoma ex pleomorphic adenoma	
Carcinosarcoma	
Metastasizing pleomorphic adenoma	
Squamous cell carcinoma	
Small cell carcinoma	
Large cell carcinoma	
Lymphoepithelial carcinoma	
Sialoblastoma	

The current American Joint Committee on Cancer (►AJCC) staging system takes into account the extent of the primary tumor as well as regional and metastatic disease (Table 2).

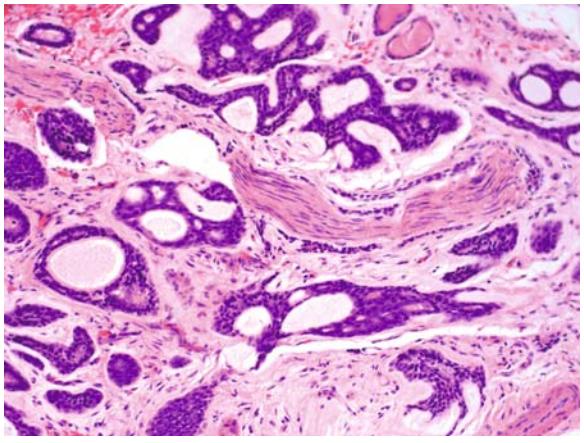
At this time, this staging system for salivary malignancies does not take into account histologic grading. Because of the wide variety of histological presentations and resultant diversity of clinical aggressiveness, the treatment of each individual cancer depends on both clinical staging and tumor histology.

Diagnosis

Detailed clinical history and comprehensive head and neck examination are critical in evaluation of salivary



Salivary Gland Malignancies. Figure 1 High grade mucoepidermoid carcinoma (hematoxylin and eosin-medium power magnification).



Salivary Gland Malignancies. Figure 2 Adenoid cystic carcinoma of parotid origin demonstrating perineural invasion (hematoxylin and eosin-medium power magnification).

gland neoplasms. Cross-sectional radiologic studies such as Computerized Tomography (►CT) or Magnetic Resonance Imaging (►MRI) are also very helpful. The real advantage of cross-sectional imaging in evaluating salivary gland masses, which primarily involve the parotid gland, is the ability to accurately reveal the location and extension of a tumor, its relationship to the facial nerve, and to assess for perineural tumor spread (Fig. 3). MRI is the modality of choice for evaluation of parotid masses and there are a few general rules that help in the differentiation of these lesions. A well-defined parotid mass of very high T2 signal is consistent with benign mixed tumor (BMT) or pleomorphic adenoma. Malignant tumors are, however, frequently also well-defined but they tend to be of lower T2 signal (Fig. 4). Positron Emission Tomography (►PET) scanning has been emerging as a new useful modality in evaluation of metastatic disease of head and neck cancers. Salivary gland tumors, however, belong to a small group of neoplasms for which PET (and PET-CT) cannot reliably distinguish malignant from benign masses, since some carcinomas do not show increased metabolic activity, while benign tumors such as BMT and especially Warthin's tumor may show very high Fluorine-18 2-Fluoro-2-Deoxy-D-Glucose (►FDG) uptake.

►Fine needle aspiration biopsy (FNAb) has been demonstrated to be a highly sensitive and specific tool in the evaluation of salivary gland neoplasms. In a review of 325 patients with salivary gland neoplasms investigated by FNAb and correlated with histologic review, the technique was found to be 85.5% sensitive and 99.5% specific. While the sensitivity and specificity may vary, especially in the smaller community hospitals, FNAb continues to help with treatment planning, providing the physician and patient adequate preparation for the necessary surgical procedure, potential for complications, and need for ►neck dissection or ►adjuvant therapy. CT-guided biopsy is the technique of choice for deep (such as in the deep parotid lobe) or poorly localized masses.

Treatment

Surgical resection has been the primary modality for treatment of salivary gland cancers. Commonly, it necessitates removal of the entire gland of origin often in conjunction with removal of involved or at risk lymph nodes (selective or modified neck dissection). In order to achieve a complete tumor extirpation without oncologic compromise, surrounding structures including cranial nerves, subcutaneous tissues, skin and muscles may require resection as well. Adjuvant radiation therapy (XRT) has long been used for achievement of better local and regional control of the disease. Frequently, it has been employed post-operatively for advanced T3 or T4 tumors. In addition, there is new limited data available in the current literature for support of adjuvant XRT even for earlier T1 and T2 cancers. In the recent retrospective review from Switzerland, the local recurrence rate was significantly lower for the group with combined treatment as compared to after surgery alone. Fast neutron-beam radiation and accelerated, hyperfractionated photon beam radiation have been reported to be more effective than conventional radiation therapy in treatment of more advanced lesions. Adjuvant XRT is typically recommended for all high grade tumors and for low grade tumors with unsatisfactory margins.

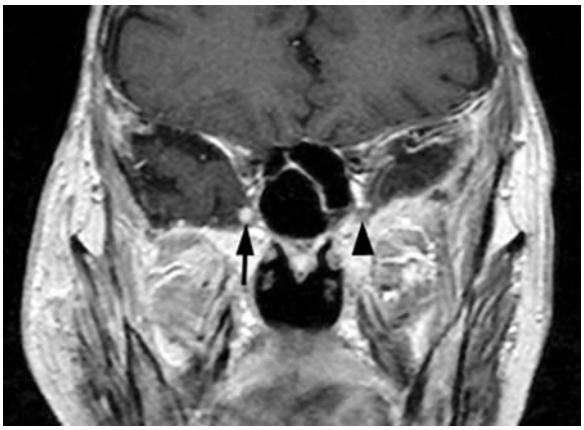
Salivary Gland Malignancies. Table 2 AJCC stage groupings for salivary gland malignancies

Stage I	$T_1N_0M_0$
Stage II	$T_2N_0M_0$
Stage III	$T_3N_0M_0$
	$T_1N_1\ M_0$
	$T_2N_1\ M_0$
	$T_3N_1\ M_0$
Stage IV	T_4 any N M_0
	Any T N_2 M_0
	Any T, any N, M_1
Primary tumor (T)	*Tx* Primary tumor cannot be assessed
	T0 No evidence of primary tumor
	T1 Tumor 2 cm or less in greatest dimension without extraparenchymal extension[a]
	T2 Tumor more than 2 cm but not more than 4 cm in greatest dimension without extraparenchymal extension[a]
	T3 Tumor more than 4 cm and tumor having extraparenchymal extension[a]
	T4a Tumor invades skin, mandible, ear canal, and facial nerve
	T4b Tumor invades skull base and pterygoid plates and encases carotid artery
Regional lymph nodes (N)	*Nx* Regional lymph nodes cannot be assessed
	N0 No regional lymph node metastasis
	N1 Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
	N2 Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
	N2a Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension
	N2b Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
	N2c Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
	N3 Metastasis in a lymph node more than 6 cm in greatest dimension
Distant metastasis (M)	*Mx* Distant metastasis cannot be assessed
	M0 No distant metastasis
	M1 Distant metastasis

[a]Extraparenchymal extension is clinical or macroscopic evidence of invasion of soft tissues. Microscopic evidence alone does not constitute extraparenchymal extension for classification purposes.

There is also a continuing effort to identify more successful systemic therapies for salivary gland cancers. There are several current trials which employ conventional chemotherapeutic agents such as taxol, or cisplatin/carboplatin combined with gemcitabine. Other medical agents have also been tried with variable success in the treatment of salivary gland cancers, though certain histologic types, such as adenoid cystic carcinoma, have consistently demonstrated resistance to systemic therapy. However, new agents that target specific tumor molecules such as ►HER2/neu tyrosine kinase and epidermal growth factor receptor (EGFR) are under active investigation.

Overall, treatment of salivary gland cancers constitutes an important component of practice for head and neck surgeons. The wide variety of clinical behaviors usually requires a multidisciplinary team approach with cooperation between otolaryngology/head and neck surgeons, medical and radiation oncologists, oral and surgical pathologists, radiologists, oral/maxillofacial surgeons and dentists, speech pathologists, dieticians and other clinical support personnel.



Salivary Gland Malignancies. Figure 3 Post-contrast T1-weighted coronal MRI showing enhancement of the right maxillary nerve within the foramen rotundum (*arrow*), consistent with perineural tumor spread of an adenoid cystic carcinoma. There is no enhancement of the contralateral nerve (*arrowhead*).

Salmonella typhi and paratyphi

Definition

Salmonella typhi and *paratyphi* are parasites, serotypes of *Salmonella enterica*. If invasive, the infections by *Salmonella typhi* or *paratyphi* lead to the development of typhoid or paratyphoid fever. The organisms can be transmitted by the fecal-oral route: it is excreted by humans in feces and may be transmitted by contaminated water, food, or by person-to-person contact (with inadequate attention to personal hygiene).

►Gallbladder Cancer

Salt Intake

Kentaro Shikata, Yasufumi Doi
Department of Environmental Medicine, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan

Synonyms

Edible salt; Sodium chloride; Salting

Definition

The composition of salt is approximately 39.3% sodium and 60.7% chloride by molecular weight. Salt regulates the water content (fluid balance) of the body, and plays an essential role in homeostasis. The nutritional requirement of salt has been estimated to be 1.25 g per day for adults.

Characteristics

Salt intake varies substantially around the world, though in developed countries, typical diets include salt far in excess of requirements. In the INTERSALT study,

daily salt intake as determined by 24-h urinary sodium excretion ranged from 5 g in Trinidad and Tobago to 14 g in Tianjin, China. The average intakes were around 8–10 g per day in most western countries and 10–12 g per day in Japan and Korea.

Epidemiological studies have shown that ►nasopharyngeal carcinoma and ►gastric cancer are associated with high salt intake.

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma is a rare malignancy, with age-adjusted incidence rates of under 1 per 100,000 person-year for both men and women in most parts of the world. In certain geographical regions, however, the incidence of nasopharyngeal carcinoma is dramatically higher. The highest rates of nasopharyngeal carcinoma have been documented among Cantonese residing in the central region of Guangdong Province in Southern China and in Hong Kong (25–30 per 100,000 person-year).

John Ho first suggested in 1971 that Cantonese-style salted fish, a common item in the local diet and a popular weaning food, may be an etiological factor in nasopharyngeal carcinoma. Since then, a large number of case-control studies conducted in various populations residing in different parts of Asia [Hong Kong, Guangzhou (Canton) and Malaysia] have confirmed the association between age at first exposure to salted fish and this type of cancer. It has been estimated that >90% of nasopharyngeal carcinomas in Hong Kong, 50% of those in Guangzhou and >60% of those in Chinese people in Malaysia are due to childhood consumption of salted fish. Animal data have further strengthened the evidence for Cantonese-style salted fish as a nasopharyngeal carcinogen. For example, rats fed this human food developed cancer of the nasal cavity in a dose-dependent manner, though this cancer rarely occurs in this species. Based on these evidences, the relationship between Chinese-style salted fish and nasopharyngeal carcinoma was determined to be "convincing" by the WHO/FAO (World Health Organization/Food and Agriculture Organization) Expert Consultation on Diet.

However, it may be that salted fish has an oncogenic action not shared by salt alone. Experimental studies have shown that low levels of several nitrosamines/precursors and ►Epstein–Barr virus-activating substances exist in preserved salted fish. Some epidemiological studies have also indicated that nitrosamines and nitrates included in preserved food play a role in the development of nasopharyngeal carcinoma if such foods are consumed during childhood. On the other hand, the antibody of Epstein–Barr virus has been found in the sera of nasopharyngeal carcinoma patients, suggesting that this virus is associated with nasopharyngeal carcinoma as well as with Burkitt's lymphoma. The consumption of salted fish may lead to the activation of Epstein–Barr virus in the sera. Further investigations are needed to examine the mechanisms through which Chinese-style salted fish increases the incidence of nasopharyngeal carcinoma.

Gastric Cancer

The incidence of gastric cancer also differs by geographic location and ethnicity. In 2002, the age-standardized incidence rates (per 100,000) of gastric cancer in Japan were 62.0 in men and 26.1 in women, and these rates as well as those in Korea (69.7 in men and 26.8 in women) were among the highest in the world. In contrast, among the white population in western countries, the incidence rate was 7.4–12.8 in men and 3.4–6.6 in women, which is clearly far lower than that in Asian countries. In the INTERSALT study, median sodium levels were analyzed in relation to national gastric cancer mortality rates. For the 24 countries studied, the Pearson's correlation coefficient for gastric cancer mortality with sodium was 0.70 in men and 0.74 in women (both $P<0.001$).

Many, but not all, results of case-control studies have shown a positive association between gastric cancer and the intake of high-salt foods such as salted fish, cured meat, and salted vegetables, or the use of table salt. However, in prospective studies among Caucasian populations, the effect of high salt intake or salted foods on the incidence of gastric cancer remains controversial. Several studies have found no positive association. Only a cohort study on 120,852 Dutch subjects and 282 gastric cancer cases showed a weak significant association between salt intake and gastric cancer incidence, though there were no clear trends. In contrast, in the Japanese population, two prospective studies have identified a significant association between dietary salt intake and gastric cancer incidence: Tsugane et al. reported that in a total of 18,684 men and 20,381 women, the quintile category of salt intake and salted food was associated with a risk of gastric cancer in men during a 12-year follow-up. Another Japanese study also investigated the relationship between the amount of dietary salt intake and gastric cancer especially intestinal-type, taking into account the effects of other risk factors such as ►*Helicobacter pylori* infection and atrophic gastritis, finding that salt intake is an independent risk factor for the subsequent incidence of gastric cancer in Japanese. Several reasons for the negative findings in Caucasian studies are proposed. The amount of salt intake in Caucasians may be lower than the threshold for incident gastric cancer. Furthermore, it may also be that the salt intake in the negative studies was not estimated accurately by detailed food frequency questionnaires. Given the lack of definitive evidence in the prospective studies, the WHO/FAO Expert Consultation concluded that salt "probably" increases the risk of gastric cancer.

Several possible mechanisms of gastric carcinogenesis induced by a high-salt diet have been discussed in the literature. High dietary salt intake is believed to alter the viscosity of the protective mucous barrier, leading to mucosal damage in the stomach and making mucosal cells more susceptible to carcinogens in food. Moreover, intragastric high salt concentrations are known to cause mucosal damage and inflammation. Persistent inflammatory changes in the stomach may promote temporary cell proliferation and increase the rate of endogenous mutation. Infection with the bacterium ►*H. pylori* is an established risk factor for the development of gastric cancer. In earlier-mentioned latter Japanese ►epidemiological study, the effect of high salt intake on gastric carcinogenesis was strong in subjects who had both atrophic gastritis and *H. pylori* infection. The synergistic promoting effects of a high-salt diet and *H. pylori* infection on gastric carcinogenesis have also been observed in an experimental study using a gerbil model. On the other hand, atrophic gastritis is thought to be a precancerous lesion of gastric cancer. Thus, the synergistic promoting effects of a high-salt diet and *H. pylori* infection may appear particularly strongly when gastric atrophy is present. It is generally accepted that gastric adenocarcinoma, particularly of the intestinal type, arises through a multistep process originating with chronic gastritis, and progresses through stages of atrophy, intestinal metaplasia, and dysplasia, eventually resulting in carcinoma. Based on these results, it is more likely that a high intake of salt is involved primarily in the latter stages of multistep gastric carcinogenesis and thereby promotes gastric carcinogenicity because atrophic gastritis is one of the morphological hallmarks of these stages. These studies suggest that salt per se is associated with incident gastric cancer directly or indirectly.

Salting

►Salt Intake

Sanctuary Site

Definition

Any location in the body that is poorly penetrated by drugs, for example, central nervous system, testes, ovary.

Sandwich ELISA

Definition

The technique of sandwich ELISA uses antibody bound to a surface to trap a protein by binding to one of its epitopes. The trapped protein is then detected by an enzyme-linked antibody specific for a different epitope on the protein's surface. This gives the assay a high degree of specificity.

Scatter Factor

Eliot M. Rosen, Saijun Fan,
Itzhak D. Goldberg
Long Island Jewish Medical Center, Albert Einstein College of Medicine, Bronx, NY, USA

Synonyms
Hepatocyte growth factor; HGF

Definition
Scatter factor (SF), also known as hepatocyte growth factor (HGF), is a multifunctional cytokine that participates in various biologic processes, including: embryonic development (►morphogenesis), oncogenesis (tumor formation), ►angiogenesis (new blood vessel formation), and the regulation of ►apoptosis (programmed cell death). SF was originally characterized as a protein secreted by mesenchymal cells (e.g. fibroblasts) that disperses (or "scatters") contiguous sheets of epithelium and stimulates cell motility. HGF was identified as a serum-derived protein that stimulates the proliferation of adult rat hepatocytes. Subsequent studies revealed that SF and HGF are identical. HGF is the ligand of a ►tyrosine kinase receptor encoded by a ►proto-oncogene (c-►Met), HGF binding causes receptor activation.

Characteristics
SF is a heparin-binding glycoprotein composed of a 60 kD α-chain and a 30 kD β-chain. The α-chain is composed of an N-terminal hairpin loop, followed by four ►kringle domains (looped structures that mediate protein interactions). The β-chain resembles protein-degrading enzymes such as trypsin, but SF lacks protein-degrading activity due to two key amino acid substitutions at the catalytic center. The binding of heparin to SF modulates its biologic activity, protects

it from degradation and allows it to be stored in the extracellular matrix. Several shortened forms of SF containing only the N-terminal loop and the first ►kringle domain (NK1) or the first two kringle domains (NK2) are sufficient to bind with high affinity to the c-Met receptor. NK1 and NK2 are produced as a result of mRNA editing, and they can function as partial agonists or antagonists of SF. However, structure-function analyses indicate that the entire SF molecule, including the β-chain, is required to generate the full spectrum of SF's biologic activity. The human SF gene maps to the long arm of chromosome 7 (7q11.2–21).

SF is synthesized as a 728 amino acid precursor (preproSF) that is converted within the cell to its secreted form (proSF) by cleavage of a short segment (►signal sequence). However, the secreted proSF is not biologically active, and must undergo an internal cleavage within the linker region between the α-chain and β-chain. Cleavage of proSF occurs outside of the cell and results in the production of the mature, two-chain biologically active SF. Thus, the cleavage of proSF to SF is a potential control point for the regulation of SF activity. Several enzymes capable of cleaving and activating SF have been identified. These enzymes include the plasminogen activators (urokinase and tissue plasminogen activator), proteins that convert plasminogen – an enzyme that circulates in blood in inactive form – into its active form, plasmin. Plasmin is the major enzyme responsible for dissolving blood clots. Another enzyme capable of converting proSF into active SF is called "►HGF activator." HGF activator is a novel protein-degrading enzyme structurally related to a blood clotting factor (factor XII, or Hageman factor). HGF activator is itself produced in an inactive ("pro-enzyme") form. It may be activated by blood coagulation factors, such as thrombin. The physiologic processes that regulate SF activation have not been fully elucidated, but there is evidence to suggest that an enzymatic cascade that results in activation of HGF activator and then SF is triggered by tissue injury.

The SF Family

SF is not related to classic growth factors (e.g., ►fibroblast growth factor or ►platelet-derived growth factor), but is a member of the kringle domain protein family, which includes blood coagulation and fibrin-degrading enzymes (e.g., ►plasminogen, prothrombin, factor XII, urokinase, tissue plasminogen activator) and a ►macrophage-stimulating protein (MSP). Within this family, SF is most closely related to the plasminogen and MSP, with which it shares a similar αβ chain structure, a similar activation mechanism (i.e. cleavage between the α and β chains), and a high degree of amino acid sequence identity (38% and 50%, respectively). MSP was formerly called HGF-like protein and is the closest relative of SF. The MSP receptor, a tyrosine kinase receptor encoded by the Ron gene, is closely related to the SF receptor, but these two proteins do not cross-activate each other's receptor. MSP circulates in the bloodstream as an inactive profactor (proMSP) which, when activated, causes macrophages to become competent and to undergo chemotaxis and phagocytosis.

SF Receptor (The c-Met Proto-oncogene Product)

The MET proto-oncogene was (c-Met) originally discovered in rearranged form as a carcinogen-induced transforming oncogene (Tpr-Met) generated by a transposition between human chromosomes 1 and 7, resulting in fusion of a powerful promoter from chromosome 1 ("Transposed promoter region") to a portion of the c-Met proto-oncogene (at 7q21–31) that codes for the intracellular region of the receptor. The Tpr-met oncogene product is a membrane-bound tyrosine kinase that is constitutively active (i.e., does not require SF for activation). The full-length c-Met proto-oncogene encodes a growth factor receptor-like tyrosine kinase that consists of an extracellular SF-binding domain, a transmembrane domain, and an intracellular portion containing a kinase domain and sites that associate with various cytoplasmic signaling proteins.

The binding of SF to c-Met triggers a molecular events similar to those triggered by the interactions between classic growth factors and their receptors. The receptor undergoes a change in three-dimensional conformation, resulting in:

- Activation of the catalytic kinase domain
- Dimerization (association of two c-Met receptors)
- Cross-phosphorylation of the two receptors on multiple tyrosines
- Initiation of a signal cascade ("signal transduction") causing transfer of information from the cell surface to the nucleus. Understanding signal transduction from c-Met will provide the key to understanding SF's biologic actions.

Signal initiation involves the interaction of phosphorylated tyrosines internal to the kinase domain of the activated c-Met with regions known as ►SH2 domains (src-homology domain-2) of proteins that act as signaling intermediaries. Most c-Met signaling involves the interaction of these signaling intermediaries with a "multi-functional docking site" involving two tyrosine (Y) residues located at amino acids 1,349 and 1,356:1349YVHVXXX1356YVNV. This unique site associates with many signaling proteins, including phosphatidyl-inositol-3′-kinase (►PI3K), phospholipase C-γ, pp60c-src, c-Cbl, and the Grb2/Sos complex, which binds p21Ras. Amino acid sequences similar to the multi-functional docking site of c-Met are found in the two related receptors: Ron and c-Sea (a tyrosine kinase receptor whose ligand has not been identified). Similar sequences are not found in the receptors for

the epidermal growth factor, platelet-derived growth factor, or other factors.

The manner in which SF binding to c-Met can result in different physiologic consequences depending upon the cell type and context (see below) is just beginning to become unraveled. For example, it was recently found that SF-induced epithelial morphogenesis (i.e., the formation of a three-dimensional network of branching tubules) specifically requires association with c-Met at cell-cell junctions and phosphorylation of a protein known as Gab1 (the Grb2-associated binder). Grb2 binds to the tyrosine-1,356 site of c-Met via its SH2 domain, while another portion of the Grb2 protein (the SH3, or src-homology-3 domain) binds to Gab1. Gab1 is a member of the family of the "multi-substrate docking proteins," which includes IRS-1 (insulin-responsive substrate-1), a cytoplasmic protein that is a major mediator of the biologic effects of the insulin-like growth factor ►IGF-I.

Cellular and Molecular Regulation

SF Producer and Responder Cell Types

In vitro studies initially suggested that SF is produced predominantly by cells of mesenchymal (connective tissue) origin, including: fibroblasts, vascular smooth muscle, endothelial cells, glial cells, macrophages, activated lymphocytes, and other cell types. However, based on subsequent in vivo studies (immunohistochemistry and in situ hybridization), it is now apparent that a variety of epithelial cell types, including keratinocytes, mammary epithelial cells, and many carcinoma cells may also produce SF. For reasons not understood, cultured epithelial and carcinoma cells lose the ability to produce SF when placed in culture, although they often retain the c-Met receptor. A variety of cell types express the c-Met receptor and are biologically responsive to SF, including (but not limited to): keratinocytes, hepatocytes, mammary epithelium, vascular endothelial cells, melanocytes, glial cells, and the corresponding malignant cell types.

Regulation of SF Production

The complexity of the regulatory mechanisms for SF production is becoming increasingly apparent as the list of known and partially characterized factors that regulate SF production continues to grow. In addition to well-known pro-inflammatory (IL-1α, IL-1β, TNF-α) or anti-inflammatory (TGF-β) cytokines that enhance or inhibit production of SF by fibroblasts, a group of partially characterized scatter factor-inducing factors distinct from IL-1 and TNF stimulate SF expression in fibroblasts and other SF-producer cell types. SF-inducing factors are secreted by various carcinoma cell lines, and they appear in the serum of rats following a subtotal hepatectomy. When co-cultured with epithelial cells, fibroblasts cease to express SF mRNA and protein, again by a regulatory mechanism that has not been elucidated. Heparin and heparan sulfate proteoglycans, which are known to bind to SF, also appear to stimulate its production. However, these molecules may simply function to stabilize the SF protein and to prevent its degradation.

Biologic Responses Induced by SF and Their Regulation

The major biologic responses induced by SF fall into four broad categories:

- Motility
- Proliferation
- Morphogenesis
- Cell survival (or more properly, protection against apoptotic cell death)

The c-Met receptor can transduce each of these biologic functions. These biologic responses may overlap (e.g., morphogenesis involves a component of cell migration through extracellular matrix); and they appear to be determined by the extracellular environment and by cell-specific programs of differentiation. For example, Madin-Darby canine kidney (MDCK) epithelial cells cultured on flat surfaces are scattered, while cells cultured in collagen gels respond to SF by forming networks of branching tubules similar to those found in the kidney.

Activation of specific pathways for motility, proliferation, morphogenesis, and/or cell survival may be determined at the receptor level or more distally. The specific pathways that activate each of these processes are only now beginning to be dissected. For example, recent studies suggest that treatment of various epithelial and cancer cell types with SF induces resistance to DNA-damaging drugs and radiation by a process that involves the sequential activation of c-Met, phosphatidylinositol-3′-kinase, c-►Akt (protein kinase B). The latter is a serine/threonine kinase that functions to protect cells against apoptotic death.

The extracellular environment plays a major role in modulating the biologic responses to SF. Studies of SF-induced branching morphogenesis of MDCK epithelial cells provides clues as to how this modulation might occur. Thus, certain extracellular matrix molecules promote forward extension of tubules (collagen I, laminin), while others promote branching (heparan sulfate proteoglycans, collagen IV). TGF-β, a component of the extracellular matrix, inhibits the entire process of branching morphogenesis. The binding of matrix proteins to integrins activates intracellular signaling processes, including tyrosine phosphorylation; and SF may induce the expression of a specific set of integrins that allows the extracellular matrix to modulate intracellular signaling. There is evidence that the extracellular matrix may modulate c-Met signaling by inducing the phosphorylation and dephosphorylation of different sites on c-Met and other signaling proteins.

SF and c-Met Participate in Various Physiologic and Pathologic Processes

Development

An important role for SF in development was suggested by the finding that homozygous deletion of either SF or c-Met results in embryonic lethality in mice. Various studies implicate SF as a mediator of mesenchymal: epithelial signaling during embryogenesis. For example, during mouse development, the SF gene is expressed in mesenchymal cells, while the c-Met gene is expressed in adjacent epithelia. This pattern is observed in multiple developing organs, and appears to be regulated with great precision in space and time. Injection of SF into the developing chick embryo induces abnormalities of the neuraxis, indicating that inappropriate exposure to SF can interfere with normal development. In addition, several studies suggest that SF and c-Met can mediate the conversion of mesenchymal cells to an epithelial phenotype, as judged by its ability to induce morphologic alterations as well as the expression of epithelial specific markers (e.g., cytokeratins and epithelial-specific junctional proteins). Mesenchymal:epithelial interconversion is commonly observed during embryogenesis, further supporting a role for the SF-c-Met ligand-receptor pair in development.

Oncogenesis

Malignant cell transformation is mediated by the Tpr-Met oncogene, which encodes a truncated and constitutively active form of the c-Met receptor. This finding raises the possibility that SF-mediated over-stimulation of c-Met has similar consequences. The idea that SF could mediate tumorigenesis in vivo is suggested by several considerations. First, SF stimulates the motility, and invasiveness of a variety of carcinoma cell types in vitro. Secondly, SF is a potent inducer of angiogenesis (new blood vessel formation), a process considered to be essential for the continued growth of solid tumors. Finally, SF can overcome apoptosis (programmed cell death) of epithelial cells which is associated with detachment of cells from their substratum. Detachment of carcinoma cells from the underlying basement membrane is an early step in tumor invasion. Studies of experimental animal models and human clinical samples further support a role for SF in tumorigenesis. Overexpression of the SF and/or c-Met genes in a variety of cell types induces or further enhances the tumorigenic phenotype in vivo, by ►autocrine and/or ►paracrine mechanisms. In studies of human breast cancer, bladder cancer, gliomas, and other tumor types, significantly higher levels of SF and/or c-Met were observed in high grade invasive cancers than in low grade non-invasive cancers. And in a study of 258 primary invasive breast cancers, a high SF content in the tumor was strongly predictive of relapse and death. Finally, recent genetic-epidemiologic studies have strongly linked activating mutations of the c-Met gene to a specific type of kidney cancer: hereditary papillary renal carcinoma.

Angiogenesis

The formation of new blood vessels from pre-existing vessels, occurs extensively during normal development and tissue remodeling, but occurs only to a limited degree in normal adults. Physiologic ►angiogenesis in adults is observed transiently during wound healing, ovulation, and placental implantation. However, persistent and inappropriate angiogenesis contributes to certain pathologic processes, including chronic inflammatory diseases (e.g., rheumatoid arthritis) and cancer. SF induces an angiogenic phenotype in cultured vascular endothelial cells (i.e., stimulates endothelial cell proliferation, ►chemotactic ►migration, and capillary-like tube formation) and induces angiogenesis in vivo in several different experimental animal models. SF may contribute to angiogenesis in AIDS-related ►Kaposi sarcoma, a cytokine-dependent neoplasm associated with extensive endothelial cell proliferation and neovascularization. The observations that both SF content and tumor angiogenesis are powerful independent prognostic indicators for breast cancer suggest a role for SF as a tumor angiogenesis factor. However, a causal relationship between SF and tumor angiogenesis is not yet proven.

Clinical Relevance

The ability of SF (HGF) is to stimulate epithelial cell growth and morphogenesis, to induce angiogenesis, and to protect cells against toxins or environmental conditions that induce apoptosis suggests a variety of potential therapeutic applications for SF. In this regard there are a number of experimental animal (mouse and rat) studies suggesting that administration of the SF protein can block or ameliorate acute and chronic injury to the liver, kidney, or lung. For example, administration of SF prevents or reduces the loss of renal function caused by toxins such as HgCl2 or ►cisplatin in mice. In a rat model, infusion of SF blocked or slowed the development of liver fibrosis and cirrhosis; and SF blocked the development of pulmonary fibrosis induced by bleomycin in the mouse lung. These findings suggest that SF is potentially clinically useful as a hepatotrophic factor for repair of liver damage or as a renotrophic factor for repair of kidney damage. The use of SF in humans presents significant challenges, such as the delivery of sufficient quantities of the factor to the sites where it is needed, in view of its short biologic half-life. Nevertheless, if reliable methods of protein or gene delivery can be developed, there may be a variety of clinical applications for SF to promote organ repair and regeneration.

Several studies suggest that the administration of other angiogenic factors (►VEGF and basic ►FGF) is

potentially useful in restoring the blood supply and preventing tissue damage, in animal models in which coronary or peripheral blood vessels are ligated in order to produce acute ischemic injury. Because of its ability to induce angiogenesis as well as its ability to protect a variety of different cell types against apoptotic cell death, it is anticipated that SF may be particularly advantageous in these settings. There is also the potential for development of small molecule inhibitors of the c-Met receptor that could be used to treat pathologic processes driven by excessive production of SF, such as certain cancers. Such inhibitors have already been developed to inhibit the function of the ►EGF receptor. A criticism of this approach is that tumor growth is driven by a variety of cytokines, growth factors, and angiogenic factors, so that the specific inhibition of a single receptor type will be insufficient to halt tumor growth. Nonetheless, combinations of receptor inhibitors may be clinically useful, and there may be situations in which inhibition of a single receptor is sufficient to inhibit tumor growth due to synergistic interactions among growth factors and cytokines.

SEA Domain

Definition

Acronym for **S**ea urchin sperm protein, **E**nterokinase, **A**grin. Is an extracellular domain of a number of proteins and associated with ►glycosylation. The common module might regulate or assist binding to neighbouring carbohydrate moieties.

Seckel Syndrome

Definition

Is an autosomal recessive disorder characterized by dwarfism, intrauterine growth retardation, bird-like facies, microcephaly, and mental retardation. ATR-Seckel Syndrome has been found in patients with mutations in ►ATR. Cell lines from patients with Seckel syndrome, who are normal for ATR, show defective ATR signaling, suggesting that Seckel syndrome can be caused by mutations in other components of the ATR pathway.

►S-Phase Damage-Sensing Checkpoints

Second Malignant Neoplasm (SMN)

►Second Primary Tumors

Second Messenger

Definition

Refers to chemical signals created within a cell in response to a hormonal stimulus from outside. Common second messengers are Calcium ions, cyclic AMP, or inositol triphosphate. Second messengers act in a cell to orchestrate metabolic or gene expression responses to a particular stimulus.

Definition

A ►second primary tumor, usually malignant, is defined as a histologically and/or clonally distinct tumor diagnosis that develops after the first cancer.

Introduction

Advances in the management of cancer have substantially improved the prognosis of cancer patients, including their life expectancy. Currently, more than 60% of cancer patients can survive over 5 years post-treatment; cancer survivors constitute 3.5% of those living in the West. However, advances in cancer management are not without adverse consequences, and long-term complications following successful treatment have become increasingly important. Second primary tumor is one of the most devastating issues facing long-term cancer survivors.

Second or higher order primary tumors account for ~6–10% of all cancer diagnoses, and are the fifth most commonly diagnosed cancer in Western countries. For instance, ~100,000 of the 1.4 million new cancers diagnosed in 2006 in the United States are second cancers. Although the aim of the management of second primary tumors assimilates that of the initially diagnosed malignancies, the diagnosis and treatment of SPTs are far more complex, especially when the effects resulting from previous therapy limit such management.

Causal and Risk Factors

Patients with one form of malignancy are known to have a higher risk of developing a second cancer.

The underlying causes and risk determinants are multifactorial; however, the majorities are related to shared etiology such as immunodeficiency, cigarette smoking and alcohol abuse. Secondly, cancer patients may possess a certain genetic predisposition to cancer. In other words, hereditary susceptibility can explain the development of some second primary cancers. Furthermore, cancer diagnosis and treatment modalities such as surgery, chemotherapy, and radiotherapy are all known carcinogenic factors. In addition, the incidence of second primary malignancy is significantly higher when the first cancer is diagnosed and treatment is delivered at early age. Survivors of ►childhood cancers and adulthood cancers have, when compared with the general population, an increased risk of 3–6 and 1.5–2 times, respectively of developing a second primary tumor. The reasons for this age effect are unknown, but might be related to a higher rate of cell proliferation, susceptibility of tissue to the carcinogenic effect of treatment, and a longer period of follow-up.

Shared Etiologic Exposure

Most second primary tumor cases are associated with some forms of shared etiologic exposure. Cancer inducing factors can be life-style or work-related. For example, ►asbestos exposure is associated with ►lung cancer and mesothelioma, while endocrine and dietary factors are associated with the development of breast, endometrial, and ovarian cancers. Patients with

S

acquired immunodeficiency syndrome (AIDS) or on immune suppression following an organ transplant are prone to develop ►non-Hodgkin lymphoma, cervical cancer, and certain forms for skin cancer, i.e. Kaposi sarcoma. Among all of the cancer-inducing risk factors, cigarette smoking is the most common and important. ►Tobacco related cancers include non-small cell and small cell lung cancers, ►squamous cell carcinomas of head and neck area, pancreatic cancer, ►bladder cancer, kidney cancer, and cancer of uterine cervix.

It has been well demonstrated that patients who have been successfully treated for squamous cell cancer of head and neck area have an increased risk of 20% in 5 years of developing a second primary cancer in the upper aerodigestive track. Studies have also demonstrated that lung cancer patients with an extended history of tobacco use are at increased risk of a second lung carcinoma, cancers of the larynx/hypopharynx, bladder, and pancreas. This indicates that tobacco use is a common causative factor.

Excessive alcohol consumption is related to increased incidence of ►esophageal cancer, liver cancer, and squamous cell carcinomas of head and neck areas. Recent clinical studies have shown that alcohol may serve as a risk factor for adenocarcinoma of the breast and ►colon. In addition, synergistic effects exist for second malignancies of the upper aerodigestive track for cigarette smoking and alcohol use.

The underlying mechanism of the development of second or higher order primary tumors due to exposure to a shared etiology is not well understood. It has been suggested that repeated carcinogenic exposure may cause "field cancerization," where the mucosa accumulates genetic alterations resulting in the induction of multiple, independent malignant lesions. This theory is now widely accepted and supported by research results in molecular biology.

Genetic Predisposition

Some types of cancers are related to hereditary genetic abnormalities, and cancer syndromes are most recognizable in familial settings. Numerous cancer syndromes and their related genetic alterations have been identified. Table 1 illustrates several more commonly diagnosed cancer syndromes, the related genetic alterations, and associated malignancies.

With the development of molecular testing technology, more genetic alterations associated with increased risk of cancer or familial cancer syndrome will be discovered.

Therapy-Related Risk Factors

As the survival of cancer patients improves following treatment, identification of long-term treatment-related complications becomes critical. Treatment-related second primary tumor is one of the most devastating side effects. Commonly utilized cancer treatment modalities including surgery, chemotherapy, and radiotherapy are all known to cause cancer. Hence, some second primary tumors are iatrogenic.

Although uncommon, cancer surgery is related to some kinds of second primary cancers. For example, radical mastectomy has been the standard primary treatment of locally advanced invasive ►breast cancer, one of the most commonly diagnosed cancers in female patients. Surgical manipulation of the axilla in order to access the axillary lymph node during mastectomy, a necessary surgical procedure, is related to the swelling of the ipsilateral arm due to lymph fluid accumulation (i.e. lymphedema) secondary to the damage to the lymph vessels. The incidence of this complication increases with the addition of radiotherapy. Arm lymphedema has been recognized as the causative factor of angiosarcoma of the affected arm or forearm, known as Stewart-Treves syndrome, named after two American physicians who initially described the cause–effect relation. Improvement in the surgical techniques involved in breast cancer treatment, including the use of lumpectomy with more limited axillar surgery and sentinel node dissection, has significantly reduced the occurrence of angiosarcoma. Some forms of colon and stomach cancer have also been described as

Second Primary Tumors. Table 1 Cancer syndromes and their associated malignancies

Cancer syndrome	Affected gene(s)	Associated malignancies
Li Fraumeni syndrome	►p53	Breast, soft-tissue, bone (osteosarcoma), brain, adrenal gland, hematological (leukemia), etc.
Hereditary non-polyposis colorectal cancer (HNPCC)	MLH1, MSH2, MSH6, CHEK2	Colon, small intestine, endometrium, ovary, stomach, kidney, ureter, etc.
Ataxia-telangiectasia	ATM	Breast
Fanconi anemia	FANC A-G, L	Breast, ovary, head and neck, cervix, esophagus, liver, brain, etc.
Retinoblastoma (RB)	RB-1	Eye, orbit, bone (osteosarcoma), soft-tissue, melanoma, brain, etc.

surgery-induced cancers. However, second primary cancer is not being considered as a substantial long-term clinical complication of cancer surgery.

Unlike surgery, chemotherapy and radiotherapy are more likely to induce iatrogenic malignancies. Second primary tumors caused by chemotherapy and radiotherapy usually develop after a lengthy latent post-treatment period. This delay, which can take years, can be partly due to the time needed for the ►DNA damage that is responsible for malignant transformation of cells to develop.

The carcinogenic effect of numerous chemotherapeutic agents has been repeatedly illustrated. The significance of chemotherapy in the development of second primary cancer was first studied in detail in a group of patients who were successfully treated for ►Hodgkin disease (HD). Researchers discovered that the cumulative risk of second primary cancer diagnosis following HD treatment during childhood was 7% at 15 years after diagnosis; the two common diagnoses of second cancer are leukemia (2.8%) and non-Hodgkin's lymphoma (1.1%). Further investigations revealed that certain agents used for HD chemotherapy, such as ►alkylating agents, were directly responsible for the increased incidence of leukemia in that group of patients. Other studies aimed at related chemotherapy drugs and cancer showed that many other agents such as ►cisplatin or cyclophosphamide are cancer-causing to various degrees.

A radiotherapy-induced primary second cancer is suggested when, after a long latency period of a minimum of 5 years but typically 15–20 years, a tumor with a histology type differs from the first tumor develops within (or close to) the irradiated field. Ionizing radiation can cause most types of cancer. The commonly known radiation-induced second malignancies include: bone or soft-tissue sarcoma, breast cancer, thyroid cancer, leukemia, and brain tumors. Some of the radiation-induced tumors, such as bone or soft-tissue sarcoma, can be more aggressive than their sporadic counterparts and respond poorly to conventional therapy.

The incidence of radiation-induced second primary tumor is related to the radiation dose exposure, but reversely related to the age of radiation exposure, i.e. the risk is higher among young irradiated patients. The underlying mechanism of this phenomenon is unknown, but it is suggested that younger patients have a larger number of dividing stem cells that are more susceptible to radiation-induced malignant transformation.

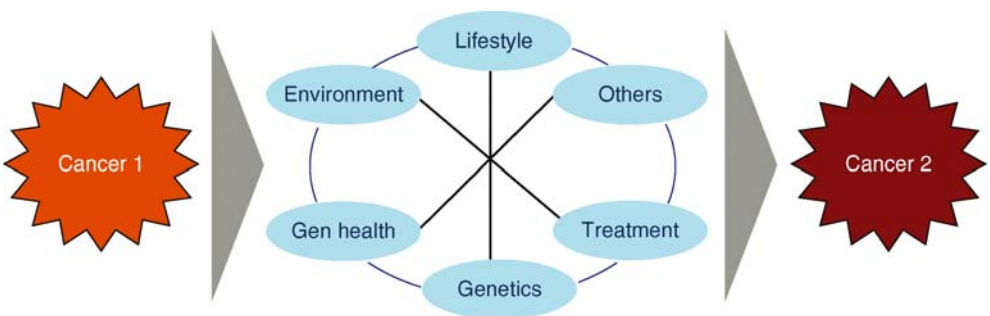
These risk factors are all associated with second or higher order primary tumors; the mechanisms of SPT development are more likely caused by more than one factor. In other words, many influences and the interactions between these influences may contribute to the development of the second primary malignancies. For example, patients with hereditary retinoblastoma, who have undergone radiation therapy, when compared to sporadic RB cases, are more susceptible to second primary cancer(s) in the irradiated field. Figure 1 illustrates the multifactorial nature of the risk factors contributing to second primary tumors.

It is important to emphasize that although surgery, chemotherapy, and radiation are related to second malignant neoplasm development, the benefits of these treatments usually surpass this complication. Therefore, second primary tumor is rarely a contraindicatory factor associated with these therapeutic modalities.

Diagnosis

Since long-term follow-up is required for most successfully treated cancer patients, the majority of second primary tumors are diagnosed during routine post-treatment follow-ups.

The diagnostic procedures utilized for second primary cancer diagnoses are no different from those used for primary malignancies. Usually, a careful history and physical examination, together with



Second Primary Tumors. Figure 1 Risk factors for second or higher order primary tumors.

pertinent laboratory and imaging tests are required for the diagnosis of any neoplasm, followed by pathological confirmation. The diagnostic process of any second primary cancer is similar; however, as local and/or distant recurrences are common following cancer treatment, especially those with more advanced disease, differentiation between a second malignant neoplasm with local relapse or distant metastasis is crucial, as the treatments of the two entities differ significantly.

The diagnosis of a second primary cancer can be confirmed if the newly discovered malignancy is histologically different from the previous diagnosis. When features of the tumor and/or cells appear similar under the microscope, a second primary malignancy is likely when premalignant changes such as carcinoma *in situ* are found within or near the specimen, as these premalignant changes indicate a *de novo* development process of a malignancy.

However, when the morphologies of the two diseases are identical under the microscope, and features that may suggest a second primary disease are lacking, further investigation with more advanced diagnostic techniques such as molecular diagnostics will be required in order to determine the difference. It is well accepted that all cancers are initiated from a single clone of transformed cell; therefore, pathological test results that can rule out monoclonal nature from the previous cancer diagnosis will be required for a diagnosis of cancer recurrence.

Treatment

The pathological diagnosis, patient's health status and preference, as well as available medical resources determine the management strategy of any type of malignancy. However, although the aim and principle of second primary tumor treatment assimilate those of the original disease, treatment of a SPT is complicated and usually restricted by previous therapy, and any associated complications.

Whenever possible, curative treatment should be considered for second primary tumors. Like their original counterparts, treatment modalities utilized for second primary cancer can include surgery, chemotherapy, radiation therapy, and/or other less commonly used methods such as immunotherapy, hormonal therapy, and molecular targeted therapy.

Usually, surgery and medical therapy can be repeatedly utilized as long as the patient's overall health condition, performance status and functionality allows. However, if the location of the SPT is within the previously irradiated field, the utilization of radiation therapy, especially external beam photon therapy, is stringently restricted by previous radiation dose, the tolerance dose of irradiated tissues and/or organs, as well as the period between the original and subsequent radiotherapy. The dose limitation of a specific tissue and organ is commonly described as TD 5/5 (the total dose equivalent that may cause severe long-term complications with 5% probability within 5 years), and any treatment dose equivalent above such limitation may cause a high incidence of substantial toxicities. Unfortunately, curative treatment for a second primary tumor usually necessitates high dose radiation that exceeds TD 5/5. Hence, patients should be provided with and fully understand the consequence of such treatment prior to re-irradiation.

The success of second primary tumor treatment depends on ►early detection. In a certain sense, early diagnosis is more critical for a second primary tumor because under many circumstances only limited treatment can be utilized due to limitations set by any previous cancer therapy. Therefore, one cannot over emphasize the importance of close follow-up after any cancer treatment.

Prevention

The development of any effective prevention methods of second primary cancers inevitably needs a thorough understanding of the mechanisms of its development. As multiple risks usually exist for the development of a second primary tumor, and the incidence of a particular type of second primary cancer is relatively low, there is currently no effective preventive approach to the development of second primary cancer. Nevertheless, some confirmed common etiologies of cancer development exist. For example, cigarette smoking has been proven as a strong risk factor of second primary cancers of aerodigestive track for patients with lung cancer or squamous cell carcinoma of the head and neck areas. Studies have shown that after successful treatment of their initial malignancies, those patients that stop smoking can reduce the relative risk of developing a second primary cancer. Therefore, while additional information and knowledge are needed in order to develop more effective prevention strategies for second primary tumors, termination of exposure to known risk factors such as tobacco and alcohol serve as the most effective preventative modality of second primary tumors.

Second-Tier/Third-Tier Lymph Node

Definition

After passing through a sentinel node, lymph fluid moves subsequently to second-tier and third-tier nodes.

►Sentinel Lymph Nodes

Secondary Amenorrhea

Definition

Absence of menstruation for >3 months.

►Menopausal Symptoms After Breast Cancer Therapy

Secondary Cancer Prevention

Definition

Prevention of tumor progression through early diagnosis of asymptomatic tumors and/or treatments against preneoplastic or early neoplastic lesions.

►Immunoprevention of Cancer

Secondary Cancer Site

Definition

The discontinuous end location where a metastatic cancer cell grows after it spreads from its primary site. For metastatic breast cancer to the bones, the secondary site is the bones.

►Metastatic Colonization

Secondary Dissemination

Definition

Dissemination following initial treatment.

►Leptomeningeal Dissemination

Secondary Hypogonadism

Definition

The failure of testicular or ovarian function caused by decreased gonadal stimulation from the pituitary/hypothalamic unit (as opposed to primary failure of the gonad itself).

►Prolactin

Secondary Lymphedema

Definition

A condition in which the lymphatic system is physically damaged by surgery (such as to remove lymph nodes) or injury, resulting in interrupted flow of lymph and blocked drainage of fluid from tissues, skin thickening and adipose tissue accumulation.

►Lymphangiogenesis

Secondary Lymphoid Organs

Definition

Secondary (or "peripheral") lymphoid organs include the lymph nodes, spleen and mucosa-associated lymphoid tissue (MALT). The secondary lymphoid structures function to survey all entering or circulating antigen and to mobilize an immune response against antigen upon its discovery. This is in contrast to the primary (or "central") lymphoid organs. These are the sites where the cells of the immune system are produced including the bone marrow and the thymus required for T cell maturation.

Secreted Protein Acidic and Rich in Cysteine

Alexandre Chlenski, Susan L. Cohn
Department of Pediatrics, Section of Hematology/Oncology, University of Chicago, Chicago, IL, USA

Synonyms
Osteonectin; BM-40; SPARC

Definition
Secreted Protein Acidic and Rich in Cysteine (SPARC) belongs to a group of non-structural proteins of the extracellular matrix (ECM), termed ►matricellular proteins, which modulate interactions between cells and their environment. It is expressed in developing and remodeling tissues, and regulates cell attachment, deposition of ECM, matrix mineralization, and ►angiogenesis.

Characteristics
SPARC is a counter-adhesive protein that induces cell rounding, inhibits cell spreading and mediates focal adhesion disassembly and the reorganization of actin stress fibers. In several cell types, it delays cell cycle in G_1 phase. It is the main non-collagenous component of bone, where binding of SPARC to

collagen can induce deposition of calcium. However, inhibition of ►hydroxylapatite crystallization suggests that SPARC prevents matrix mineralization rather than inducing it. SPARC also regulates the production, assembly, and organization of ECM, and accordingly, it is expressed at high levels in developing tissues during embryogenesis and in remodeling adult tissues, such as gut, ovary, testis, mammary gland, bone and in healing wounds. SPARC is predominantly secreted by non-epithelial cells including endothelial and smooth muscle cells, osteoblasts and platelets. Fibroblasts and ►macrophages express SPARC in healing wounds, where it is also released by platelet degranulation.

Gene Organization

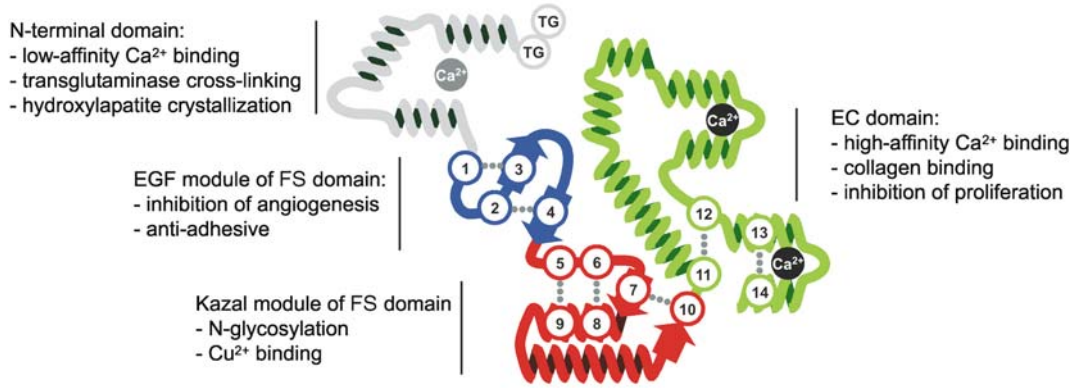
The SPARC gene spans 25.9 kb on human chromosome 5q31.3-q32. Its first non-coding exon is separated from the following coding exons by a large 10.6 kb intron. Exon 10 contains the entire 3′ non-translated region. This gene organization and the transcription start site are highly conserved in vertebrates. The major human 2.2 kb transcript contains an open reading frame from nucleotides 84 to 992, followed by 1,137 bp of 3′ non-translated region. The less abundant 3.0 kb transcript has an identical coding region, but utilizes a downstream polyadenylation signal. The SPARC promoter lacks TATA and CAAT boxes, but contains a GGA box 1 between nucleotides −51 and −120 which drives transcription. A GGA box 2 is located between nucleotides −131 and −165. Both boxes are mainly composed of a repetitive GGA motif. They are positive regulators of promoter activity, while a 10 bp spacer of low purine content has a negative impact.

Three ►Retinoid X/►Vitamin D receptor binding sites, immediately followed by an ►E-box in GGA box 1, may be responsible for stimulation of SPARC expression by ►retinoic acid and dexamethasone. Histone acetylation is essential for the activation of transcription by ►retinoid receptors. Sodium butyrate, an inhibitor of ►histone deacetylase, has been shown to stimulate SPARC expression. The activation of SPARC transcription by cAMP is consistent with several cAMP consensus sequences found in the promoter region and in the first intron. The presence of a heat shock element correlates with heat- and stress-induction of SPARC expression. Jun and ATF family members repress SPARC transcription in fibroblasts, but stimulate expression in epithelial cells, although this regulation appears to be indirect.

Protein Structure

The structure of SPARC is highly conserved among different species. All cysteine residues are found at identical positions from human to nematode, indicating that protein folding is critical for function. After the 17 amino acid signaling peptide is removed, the human protein is secreted as a polypeptide of 286 residues with a calculated mass of 32 kDa, which migrates at 40–43 kDa on SDS-PAGE due to ►glycosylation and possibly other posttranslational modifications.

The protein is divided into three distinct domains (Fig. 1). The loosely structured N-terminal acidic domain (Ala^{1}-Glu^{52}) has an α-helical character, which depends on binding several Ca^{2+} molecules with low affinity. Clusters of glutamic acid in this region resemble the γ-carboxyglutamic acid (Gla) domain of vitamin K-dependent proteins of the blood clotting system. Gln^{3} and Gln^{4} are the amine acceptor residues for tissue ►transglutaminase-catalyzed crosslinking, of which SPARC is the major substrate in maturing cartilage. This domain also mediates the interaction with hydroxylapatite, indicating that it may play role in



Secreted Protein Acidic and Rich in Cysteine. Figure 1 Domain organization of SPARC. Schematic representation of the structure of each SPARC domain. All domains and modules are shown in individual colors. Ca^{2+} ions bound with high and low affinity are respectively in black and grey. The numbers in the circles represent cysteines and TG denotes transglutaminase cross-linking acceptor residues. The N-glycosylation site is located immediately after cysteine 7.

stabilization of connective tissue. A peptide from this domain inhibits endothelial cell spreading.

The follistatin-like (FS) domain (Asn^{53}-Pro^{137}) consists of two loosely linked modules. The N-terminal epidermal growth factor-like (EGF) module is a highly twisted β-hairpin with two disulfide bonds. Peptides from the EGF module have anti-►angiogenic properties. They inhibit endothelial cell ►migration and proliferation, and promote the disassembly of focal adhesions of endothelial cells. An adjacent small hydrophobic core of mixed α/β structures stabilized by three disulfide bonds has high structural homology to the serine proteases of the Kazal family. A peptide from the Kazal module, which contains the copper-binding sequence KGHK, can stimulate angiogenesis. This module carries an N-linked carbohydrate at Asn^{99}, which causes a ~2 kDa shift in electrophoretic mobility. SPARC glycosylation is tissue-specific and has functional significance. Bone SPARC, which carries high-mannose and biantennary glycans, binds collagens with high affinity. Platelet and recombinant SPARC have bi- and triantennary structures and bind collagens with low affinity. SPARC glycosylation is apparently sensitive to neoplastic transformation, as tumor-produced SPARC has a unique hybrid pattern of glycosylation.

The C-terminal extracellular ►calcium-binding (EC) domain (Cys^{138}-Ile^{286}) folds into a compact globular and predominantly α-helical structure. It carries a canonical pair of ►EF-hand motifs, which bind Ca^{2+} with high affinity. A peptide corresponding to the second EF-hand motif inhibits endothelial cell proliferation. A long α-helix at the N-terminus of the EC domain and a short loop, which connects two EF-hand motifs, form a collagen-binding site.

This domain organization is shared by a family of proteins that have common FS/EC domain pairs, but different acidic N-termini and sometimes C-termini. Other members of the family include hevin, tsc36, testicans and SMOCs.

Functional Properties

SPARC binds and modulates the activities of structural and soluble components of the ECM, often in a Ca^{2+}-dependent manner. Ca^{2+} enhances binding to collagens, but inhibits interaction with multimeric vitronectin. In the α-granules, the major storage organelle for platelet-secreted proteins, SPARC binds to ►thrombospondin with high affinity in the presence of Ca^{2+}.

The action of various growth factors is modulated by SPARC. SPARC co-localizes with PDGF in platelet α-granules and binds with high affinity to PDGF-AB and PDGF-BB, but not PDGF-AA. This interaction results in interference of PDGF binding to its receptor on fibroblasts and inhibition of PDGF-stimulated proliferation of human vascular smooth muscle and mesangial cells. SPARC has also been shown to bind ►VEGF and antagonize its pro-angiogenic effect on endothelial cells. Although SPARC does not directly bind ►bFGF, it antagonizes its effect on the proliferation and migration of endothelial cells. SPARC can also suppress ligand-induced autophosphorylation of the bFGF receptor and inhibit both bFGF- and VEGF-induced ERK activation in endothelial cells.

►TGFβ and SPARC induce one another's expression in a reciprocal manner. In mesangial cells, SPARC binds the TGFβ/TGFβRII complex. Accordingly, in these cells, treatment with SPARC has no effect, but in combination with TGFβ it causes stimulation of ►SMAD phosphorylation, ►JNK activation, and an increase in total and phosphorylated c-jun. Treatment with SPARC stimulates SMAD phosphorylation in TGFβ-responsive epithelial and endothelial cells, but inhibits TGFβ-induced activation in fibroblasts.

Integrin-linked kinase (ILK) was identified as a SPARC binding partner. SPARC can induce Ser^{473} phosphorylation of ►AKT through ILK and ►focal adhesion kinase (FAK) in glioma cells. In contrast, in ►ovarian cancer, SPARC significantly suppresses activation of AKT and ERK signaling.

A scavenger receptor, stabilin-1, was identified as another SPARC binding partner. Binding results in receptor-mediated ►endocytosis of SPARC, followed by its targeting for degradation in macrophages.

Animal Models

In the nematode *C. elegans*, SPARC is expressed in muscle cells along the body wall and in the sex muscle, with no evidence of expression in other cell types. SPARC overexpression leads to the *Unc* phenotype consisting of a lack of coordinated movement or paralysis, accompanied by frequent disorganization of gonad and vulval protrusions. The offspring embryos are deformed and not viable.

During *Xenopus laevis* development, SPARC is expressed in the notochord and mesoderm prior to appearance of the first somites, and later in the neural tube. Disruption of normal SPARC function causes a broad spectrum of developmental abnormalities including embryonic axes deformities associated with disorganized myotomes, lack of intersomitic boundaries, and defects in eye development.

SPARC knockout mice do not have significant developmental abnormalities, but display multiple defects associated with abnormal ECM deposition. Animals develop early-onset cataracts accompanied by abnormal collagen IV deposition in the lens capsule. A reduced number of osteoblasts and osteoclasts leads to decreased bone remodeling and profound osteopenia. Animals have an enlargement of fat pads due to an increase in the number and diameter of adipocytes. The accumulation of adipose tissue compensates for

the body weight loss caused by osteopenia. The skin of adult transgenic mice has decreased tensile strength and reduced collagen content with smaller diameter collagen fibrils compared to wild-type mice. SPARC-null mice also show significant acceleration of wound healing *in vivo*.

SPARC in Cancer

The role of SPARC in tumorigenesis is complex and appears to be cell-type specific due to its diverse function in a given ►microenvironment. In some types of cancer, high levels of SPARC expression have been shown to correlate with disease progression and poor prognosis. In ►melanoma cells, high levels of SPARC expression induce ►epithelial to mesenchymal transition (EMT), and increase ►invasion and tumor progression. High levels of SPARC are also associated with invasive meningioma and ►osteosarcoma. In glioma, SPARC promotes invasion, but delays tumor growth.

In other types of cancer SPARC functions as a tumor suppressor. It inhibits the proliferation of ►breast cancer cells and induces apoptosis in ovarian cancer cells. In the majority of primary ►lung adenocarcinomas, SPARC is silenced by ►methylation, and this epigenetic aberration is associated with poor outcome. In ►non-small cell lung cancer, SPARC is not ►methylated, but its expression is frequently downregulated due to methylation of the recently identified ►tumor suppressor gene RASSF1A. Similarly, in breast and ►prostate cancers and ►neuroblastoma, the majority of neoplastic cells do not express SPARC. In neuroblastoma, high levels of SPARC are expressed in Schwannian stromal cells, which is associated with a favorable outcome.

Stroma-associated fibroblasts are commonly SPARC-positive, which in some types of cancer correlates with poor prognosis. However, other studies indicate that SPARC plays a role in creating a microenvironment that is inhibitory to tumor progression. SPARC has been characterized as a potent inhibitor of angiogenesis. It also induces the formation of tumor stroma and prevents the activation of fibroblasts. Enhanced growth of Lewis lung carcinoma and ►pancreatic cancer xenografts in SPARC-null mice is associated with altered production and organization of ECM within and surrounding the implanted tumors.

SPARC has also been found to have tumor suppressive activity in a number of animal studies. Significantly lower numbers of ►metastases are seen following injection of ►adenoviral SPARC-infected breast cancer cells compared to controls. In SPARC-null mice, enhanced tumor growth and extensive dissemination has been reported following inoculation of ovarian cancer cells. Continuous infusion of SPARC into nude mice has also been shown to potently inhibit the growth of neuroblastoma xenografts. Recent studies have demonstrated that SPARC sensitizes ►colon carcinoma cells to ►radiotherapy and ►chemotherapy. In nude mice with xenografted colon carcinoma tumors, SPARC enhances the anti-tumor effects of cytotoxic agents, resulting in improved survival.

Secretor Enzyme

Definition

A product of the Secretor gene, also named fucosyltransferase2 (FUT2), that catalyzes addition of fucose in α1,2 position onto type 1 chains. The name of the gene and enzyme stem from the presence of the gene product in secretions, namely in saliva.

►Lewis Antigens

Securin

Falk Hlubek
Department of Pathology, Ludwig-Maximilians-University of Munich, Munich, Germany

Synonyms

Human pituitary tumor-transforming gene 1; hPTTG1; Human ESP1-associated protein 1; EAP1; Tumor-transforming 1; TUTR1; Pituitary tumor-transforming gene 1; PTTG1

Definition

Securin is a 22 kDa protein that is crucial for the stability of the cells' genome. By preventing premature

►sister-chromatid separation during mitosis, securin is involved in the regulation of accurate cell cycle progression.

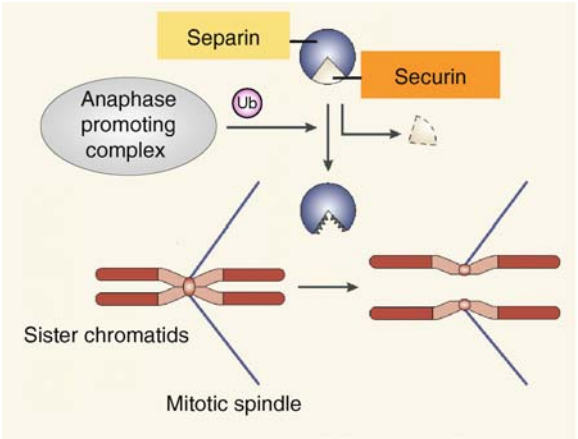
Characteristics

The protooncogene *PTTG* was first isolated from rat pituitary tumor cells. The human homolog of *PTTG*, *securin* (hPTTG1), was found to be overexpressed in Jurkat T cells (human lymphoma T cell line) and in leukocytes from patients with different types of hematopoietic neoplasms or myelodysplastic syndromes. High levels of securin protein expression have been reported for various other tumors, including tumors of the pituitary gland, adrenal gland, kidney, endometrium, uterus, and ovary as well as esophageal and colorectal cancer. Hence securin has been implicated in cell transformation and tumor development. In contrast, most normal adult tissues express little securin with the exception of tissues with highly proliferating cells, e.g., testis and thymus. Thus the level of securin expression correlates with cell proliferation in normal tissue. In fact, the securin protein is expressed in a cell cycle-dependent manner.

Securin Function

The cell division cycle (►Cell cycle targets for cancer therapy) is a tightly regulated process to ensure the correct division of the genome into the daughter cells. Low securin expression is characteristic for noncycling cells and for cells at the beginning of the cell cycle (G1-phase). As the cell cycle proceeds, the securin level rises continuously, peaking in mitosis (M-phase). During M-phase the ►sister-chromatids are connected by cohesin proteins and aligned at the metaphase plate while being attached to the mitotic spindle. In this phase of the cell cycle, securin acts as sister-chromatid separation inhibitor by binding to separin (human ESP1), which is responsible for the destruction of the cohesin complexes (Fig. 1). In late M-phase, the metaphase–anaphase transition, securin is ubiquitylated (►Ubiquitination) by the activated ►anaphase-promoting complex or cyclosome (APC/C). This triggers securin destruction by the proteolysis machinery enabling separin activation and sister-chromatid separation, followed by cell division. In addition to regulating cell cycle progression, securin is involved in processes like DNA repair, ►apoptosis, angiogenesis, and tumor development.

The multifunctional protein securin consists of 202 amino acids and contains, like many APC/C substrates (e.g., cyclins), a destruction box motif (D-box) within the N-terminus. The D-box is recognized by the APC/C complex at the end of metaphase leading to securin ubiquitylation and subsequent proteolysis. Furthermore, a central ►transactivation domain, a DNA-binding domain and proline-rich motifs representing potential Src homology 3 domain (SH3)-binding sites



Securin. Figure 1 During M-phase of the cell cycle, chromosomes are aligned at the metaphase plate with the centromers linked to the mitotic spindle. The sister-chromatids are connected in the centromeric region by cohesin proteins. Securin binds to separin, thereby inhibiting the cohesin degradation activity of the protein. In late M-phase when all chromosomes are accurately aligned, the activated anaphase-promoting complex induces securin degradation by ubiquitylation (Ub). Activated separin cleaves the cohesin proteins enabling an even distribution of the sister-chromatids to the daughter cells (Adapted from Malumbres M, Barbacid M (2001) Nat Rev Cancer 1:222–231 with permission).

(►SH2/SH3 domains) have been identified in securin. Securin (hPTTG1) is the only member of the PTTG protein family that has been studied in detail. The protein family consists of at least three members that have no significant homology to other known proteins. The different expression pattern of the *hPTTG1*, *hPTTG2*, and *hPTTG3* genes in normal and tumor tissue may suggest a tissue-specific expression and diverse functions of the encoded proteins.

Securin Function in Tumor Development

Overexpression of *securin* can transform mouse and human cells (NIH3T3, HEK293), enabling them to form tumors in ►nude mice, thus specifying securin as an oncoprotein. Mutation of the proline-residues of the SH3-binding sites abrogates the transforming (in vitro) and tumor inducing (in vivo) activity. However, securin seems to be involved in tumor development in several ways, although the precise mechanisms remain unknown. First, as securin is essential for sister-chromatid separation during mitosis, it regulates cell proliferation and chromosome stability. Loss of securin function in tumor cells increases abnormal mitosis resulting in ►aneuploidy and apoptosis. The antiapoptotic function of securin is partly mediated by the interaction with the tumor suppressor protein p53 (►p53 Protein),

blocking its DNA-binding and transactivating activity. Despite this effect, overexpression of securin can also cause aneuploidy by failure of the cells to divide the chromosomes evenly between the daughter cells. The induction of chromosomal instability in combination with the inhibition of apoptosis possibly accounts in part for the oncogenic activity of securin. Consequently securin overexpression results, depending on the degree of expression, in elevated cell proliferation and non-tumor cell transformation, which may also be mediated by the induction of *c-Myc* oncogene expression (►Myc oncogene). Recently an additional mechanism for the induction of genetic instability by securin in tumor cells has been suggested. Securin binds to DNA repair proteins (p53 and ►Ku70) and, when overexpressed, inhibits ►double-strand break DNA repair activity in colorectal cancer cells.

Second, high securin expression levels induce angiogenesis in vitro and in vivo possibly by activating the expression of basic fibroblast growth factor (►bFGF) and ►vascular endothelial growth factor (VEGF), both potent mitogenic and angiogenic factors. This activity of securin is dependent on the proline-rich domain of the protein suggesting that securin may function through SH3-signal transduction pathways.

Third, securin expression correlates with tumor cell ►invasion and has been implicated to serve as prognostic marker for poor prognosis of pituitary, thyroid, colorectal, breast, esophageal cancers, and squamous cell carcinoma of the head and neck. The proinvasive and angiogenic effect of securin may be facilitated by its induction of ►matrix metalloproteinase 2 (MMP-2) expression. Taken together, securin appears to contribute to at least three important hallmark features of cancer: cell transformation, angiogenesis, and cell invasion.

However, the regulation of securin expression in tumors is largely unknown. The growth factors ►HGF, TGFα (►Transforming growth factor), ►EGF, IGF-1 (►Insulin-like growth factors), and the hormone insulin have been implicated in securin regulation. Recently, in colorectal cancer and esophageal squamous cell carcinoma, the β-catenin/TCF-signaling pathway (►APC/beta-catenin pathway) has been found to control securin expression. In the process of tumor development, this crucial signaling pathway is deregulated, leading to the accumulation of the oncogenic protein β-catenin, which acts as transcriptional activator in the β-catenin/TCF4 protein complex. The constitutive activity of β-catenin causes at least in part the overexpression of securin and other target genes with the potential to contribute to tumor initiation and progression. Although the molecular mechanisms of securin participation in tumor development are currently poorly understood, further research will reveal whether it is relevant as potential diagnostic or therapeutic target.

"Seed and Soil" Theory of Metastasis

Chao-Nan Qian, Bin Tean Teh
Laboratory of Cancer Genetics, Van Andel Research Institute, Grand Rapids, MI, USA

Definition

A theory proposed to explain the metastatic preference of ►cancer cells for specific organs is called the "seed and soil" theory, the cancer cells being the "seeds" and the specific organ ►microenvironments being the "soil." Interaction between the "seeds" and the "soil" determines the formation of a secondary tumor.

Characteristics

Historical Development of the "Seed and Soil" Theory

►Metastasis is the spread of a cancer from its primary location to distant sites in the body, forming the secondary tumors. When cancer cells metastasize, they usually do so to preferential organs, depending on the type of cancer. For example, breast cancer cells usually metastasize to the lymph nodes, bones, lungs, liver, and brain; colon cancer cells often metastasize to the lymph nodes and liver.

The propensity of certain organs to harbor metastatic tumors was noticed in the middle of nineteenth century. When Fuchs studied the metastasis pattern of uveal melanoma in 1882, he found that a favorable site for secondary tumor development should be taken into account. Paget, a surgeon, reported the autopsy results of 735 cases of breast cancer and summarized the studies of others, and clearly proposed the "seed-and-soil" theory in 1889, pointing out that metastasis depends on interaction between cancer cells and specific organ microenvironments. The theory has had a great influence on the field of cancer research.

Recent Evidence Shows that the "Seeds" Can Even Prepare the "Soils"

A primary tumor can induce reorganization of the vasculature and lymph channels in the ►sentinel lymph node before metastasis, that is, before the cancer cells arrive. The dramatically remodeled vasculature of the sentinel lymph node can then integrate into the tumor vascular system after metastasis and nurture the fast growing metastatic tumor. The molecular basis for this pre-metastatic remodeling is not yet known.

The preparation of a pre-metastatic "niche" in bone marrow before the arrival of cancer cells has also been reported. The bone marrow-derived hematopoietic progenitor cells that express ►vascular endothelial growth factor receptor 1 are responsible for creating a favorable niche for incoming tumor cells.

Selectins

Definition

A family of cell-adhesion molecules mediating inflammatory cell arrest. E-selectin is found on activated endothelium. P-selectin (CD62-P) is expressed by endothelium and platelets upon stimulation with, e.g., thrombin. L-selectin is expressed on leukocytes. Adhesion molecules that contain a lectin-like domain that recognizes and binds carbohydrates. Relevant examples for adhesion mediated by sialyl-Lewis antigens are E(endothelial)-selectin and P(platelet)-selectin.

Selenium

Anna Batistatou,
Konstantinos Charalabopoulos
Ioannina University Medical School, Ioannina, Greece

Definition

Selenium (Se) is an essential trace element having multiple effects in many functions of the normal human organism and inducing disturbances when deficient. Thus, it has an important role in health maintenance, being furthermore implicated, when in low levels, in various chronic pathological conditions such as rheumatoid arthritis, diabetes mellitus, cardiovascular diseases, renal insufficiency, and cancer.

Characteristics

More than 10 million new cancer cases each year are recorded worldwide, with cancer being one of the leading causes of death. Much progress has been made in the quest of the etiology and pathogenesis of cancer in humans, however there are still a lot of issues to be elucidated. Identifying cancer risk factors is critical both in prevention and treatment. Epidemiological and genetic studies suggest that factors such as smoking, bioactive food components and hormones can influence the incidence and mortality of this disease. Among them a lot of attention has been drawn in those that indicate a strong relationship between low Se concentration in the serum and increased risk of various types of cancer in humans.

Trace elements such as Se, zinc, arsenic, cadmium, and nickel, found naturally in the environment, are delivered to humans from a variety of sources including air, drinking water and food. In the human body Se is absorbed by the gastrointestinal tract, skin, and respiratory system. Concentrations of this trace element in the air are low. Thus, diet and drinking water supplies are the primary sources of Se intake. Se enters the food chain through plants, which uptake it from the soil. Notably, there is a wide geographic distribution of Se in the soils varying from high concentrations in the former USSR. and USA. to low concentrations in China, and some other parts of Asia, as well as in many European countries. Se is present in a wide range of foods such as grains, meat, fish, eggs, as well as in some vegetables. Average selenium consumption from foods ranges from 71 to 152 μg daily. The suggested daily Se uptake in adults varies between scientists groups, ranging from 60–120 μg to 200–300 μg daily. Se intake from dietary sources is assessed by 24-h and weekly dietary recalls, diet histories and food frequency questionnaires. The latter is the least preferred method, since potential differences in Se absorption from the intestinal lumen, various food preparations methods and variations depending on geographical Se distribution, impair the results. In humans, high Se concentrations are detected in the thyroid gland, kidneys, genitals and liver, whilst the lowest Se concentrations are detected in pancreas and lymph nodes.

Organic Se is present in foods mainly in the form of selenomethionine, selenocysteine and selenium-methylselenocysteine, whilst inorganic Se either in the form of selenite or selenate is found infrequently and in very low amounts. Both organic and inorganic Se are utilized with similar efficacy in the human body, producing selenoproteins (SPs), although, Se enters at different points in the metabolism processes depending on the chemical form. Twenty-five SPs have been identified until now, out of a possible 50 thought to exist. Glutathione (GSH) reduces the inorganic forms (selenate and selenite) of Se. The originally discovered cytosolic glutathione peroxidase GSH-Px or GPx-1, the phospholipid hydroperoxide GSH-Px, and the secretory GSH-Px represent three isoenzymes of glutathione peroxidase. The latter, ubiquitously expressed, is the first and best characterized SP in mammals. Other selenoproteins such as thioredoxin reductase (TrxR) and selenoprotein P (SeP) also contain molecular Se in their active center and act in a similar fashion. Through all of them Se regulates the cellular antioxidant defence system, DNA damage and protein function. Se also controls cell-mediated immunity and B-cell function. TrxR is considered to be a key enzyme in Se metabolism, reducing Se compounds and controlling the intracellular redox state and SeP appears to protect endothelial cells against damage from free radicals. The varying degree of anti-carcinogenic activity of different forms of selenium, may be attributed to their metabolism in vivo. High Se concentration can lead to either cytotoxic effects or possibly to carcinogenesis, due to DNA strand breaks. Thus, in the first half of the twentieth century Se was considered an undesirable element for higher organisms. In the second half of the twentieth century the role of Se in human nutrition and biology was appreciated, since there was growing evidence that Se has multiple roles in many biological systems. Among them, Se controls cell-mediated immunity and B-cell function. Se role as an antioxidant,

as well as a cancer-preventing factor nowadays is well established by accumulating evidence. A bulk of studies strongly supports the issue that Se supplementation is effective in the reduction of cancer incidence when non-toxic doses of the element are provided with the diet, possessing thus, anticancer properties. Experimental data have shown that the chemopreventive effect of Se is due, at least partly, to its inhibitory effect on cell growth, DNA, RNA, and protein synthesis in transformed cells. Furthermore, changes in stress-related cellular proteins are widely implicated in explaining the protective role of Se. Several reports have described the inhibitory effect of Se on kinase enzyme activity. Cell cycle cyclin-dependent-kinase 2 (cdk2) and/or cell signaling protein kinases and/or some redox regulated proteins with critical transcription factors, have been proposed as targets against which Se exerts its chemopreventive actions. An increase in cyclin B expression as well as phosphorylation of the cdk2 coincidentally with the cell cycle arrest has been demonstrated. In addition, Se exerts an antiproliferative effect by modulating cellular proliferation in G1 phase in both normal and neoplastic cells and possibly impairing the expression of c-fos and c-myc oncogenes.

Furthermore, human defense mechanisms against reactive oxygen species (ROS), which induce oxidative damage are amplified by Se. Cellular oxidative damage is a general mechanism for cell and tissue injury. Selenocystein reduces the levels of hydrogen peroxide and a number of organic hydroperoxides, thereby, acting as antioxidant. Oxidative stress in the target tissue has been suggested to play an important role in carcinogenic process. Thus, Se may act as an antitumoral agent although more studies are needed to investigate the actual role of antioxidants and their possible relationships with trace elements alterations, and Se in particular, in the pathogenesis of various cancer types. It has also been shown that in colorectal cancer cells Se supplementation decreases the COX-2 protein and PGE-2 levels.

Se plasma and tissue concentration is regulated by incompletely understood homeostatic mechanisms. For estimation of the body Se amount levels, whole blood, serum, plasma, erythrocytes, urine, hair, and nails represent biological specimens suitable for sampling. Each of these differs in terms of the exposure period represented. Plasma and serum measures tend to reflect short term exposure, whilst Se levels in erythrocytes represent a long term exposure. Longer term exposure is measured by toenails samples.

Early epidemiological studies ~40 years ago suggested an inverse association between Se levels and risk of cancer. Studies from about 30 countries showed a significant inverse correlation with age-adjusted mortality for colorectal (CRC), prostate, breast, ovary and lung cancer as well as for some hematological malignancies, whilst only a weak association was found for pancreatic and skin cancer. Low Se is associated with risk of lung, colorectum, oesophagus, stomach, liver, breast, prostate, and urinary bladder cancer. Results from many chemoprevention trials strongly suggest that Se supplementation may have some protective effects against the above mentioned cancer types in populations where average dietary Se levels are low.

There are a few data regarding the association between Se and CRC or adenomas. These results depending mainly on small studies are inconclusive and probably new prospective studies with large series of individuals are needed. However, epidemiological studies have reported an inverse association between Se and CRC, cancer stage and survival, whilst some others failed to detect this association reporting null results. A pooled analysis reported by Jacobs et al. indicates that individuals with high blood Se concentration (median value 150 ng/ml) had 34% lower odds ratios (OR 0.66, 95% CI 0.50–0.87, P_{trend} 0.006) for developing a new adenoma throughout the follow up time period, in comparison with those individuals with lower plasma Se levels (median value 113 ng/ml). Thus, new prospective studies regarding Se alone or in combination with other trace elements must be designed in the near future. In breast, contradictory studies have been reported. Although there is some evidence indicating the chemopreventive role of Se in breast cancer, rigorous retrospective and prospective studies are needed to confirm this issue.

The urinary bladder mucosa differs from other tissues, being exposed to Se directly, via the urine, and indirectly, via the blood. An inverse association between serum Se levels and bladder cancer has been reported in the literature. Serum Se levels and glutathione peroxidase activity in patients suffering from transitional cell carcinoma were inversely correlated with tumor grade. Similarly, this strong inverse association has also been detected in prostate cancer. In recent reports, individuals taking Se supplementation exhibited a significant reduction in the risk of prostate cancer. Regarding the other cancer types the usual reverse association between serum Se levels and neoplastic development has been observed, although this phenomenon is not universally accepted, since there are also not confirmatory studies.

By several studies it has been indicated that the process of the underlying tumor development can lead to an uptake of trace elements by neoplastic cells explaining, thus, the increased levels of Se in tumor mass. The same phenomenon is also observed with some other trace elements such as Zn, Fe, Cu in neoplastic tissue. It is not clear whether the increased Se concentration in the cancerous tissues is responsible for the decreased serum Se levels found in these patients

or if the decreased serum Se levels precede the development of cancer.

In conclusion, Se is found naturally in the environment and is uptaken by humans through a variety of sources, including food, drinking water and air. Intake and plasma levels differ depending on geographical distribution and genetic factors. Se chemopreventive action has been demonstrated in some types of human cancers. More clinical trials are needed to investigate the role of Se supplementation in reducing cancer incidence in humans.

SEMA; Collapsin; Growth guidance cue; Neuropilin ligand; Plexin ligand

Definition

The semaphorins (abbreviated SEMA) constitute a family of genes encoding secreted and membrane associated proteins which share a common domain called the sema domain.

The name semaphorin is derived from the greek words "*sema*" meaning "signal" and "*phor*," which means "to carry." This name was given to semaphorins owing to the function of the first semaphorins in ►axon guidance.

Characteristics

Subclasses

To date, the semaphorin family comprises at least 18 different members in vertebrates and at least three different members in invertebrates. All semaphorins contain an approximately 500 amino acid extracellular sema domain and a class specific carboxy terminus that may encompass additional sequence motifs. At present the known semaphorins are divided amongst eight subclasses on the basis of these structural features and phylogenetic analysis.

Other protein families including ►plexins and the ►receptor tyrosine kinases MET and ►RON contain sema domains, but on the basis of phylogenetic analysis these proteins are only distantly evolutionary related to semaphorins.

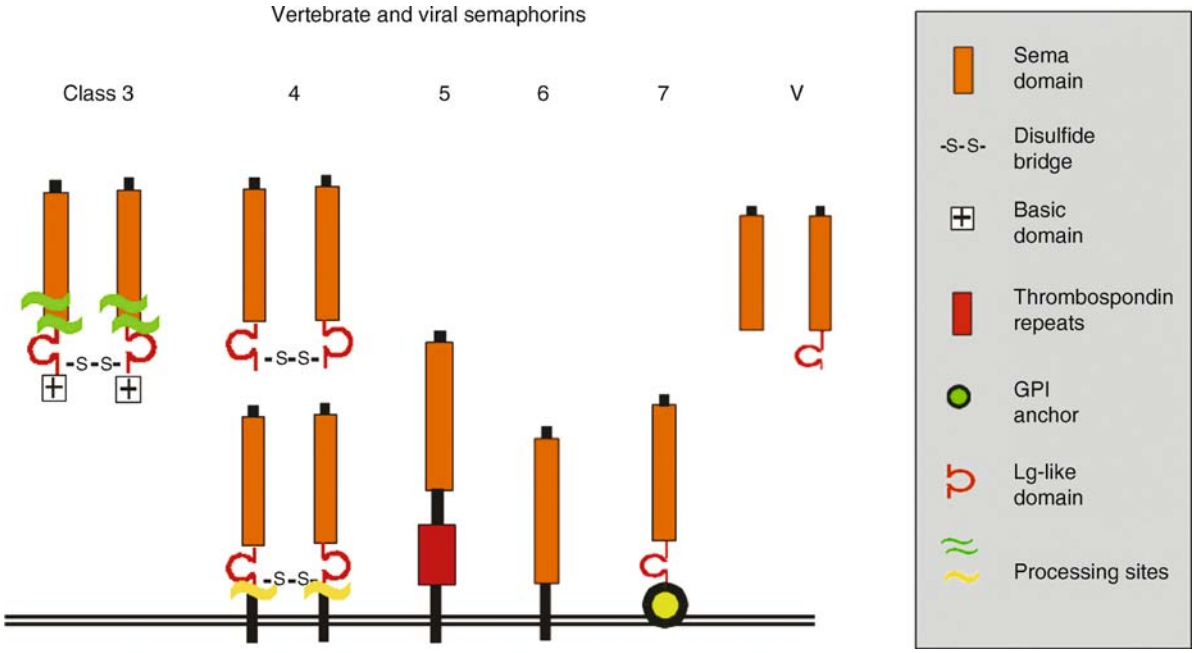
Structure and Processing

With respect to cellular localization semaphorins fall into three categories: secreted (subclass 2, 3, and V), transmembrane (subclass 1, 4, 5, and 6) and ►GPI-linked (subclass 7) (Fig. 1). Class 3 semaphorins require posttranslational modifications to gain activity. During maturation these proteins are proteolytically processed by ►furin or related serine endoproteases, possibly glycosylated (see ►Glycosylation) and they undergo dimerization. Their activity is further regulated by proteolytic cleavage of an internal RXK/RR site which separates the sema domain from the rest of the dimer. This was shown to cause a loss of the repellent activity of these semaphorins in neurobiology. However, such processing may positively add to semaphorin activity during tumor ►progression as recently shown in the case of Sema3E.

In the case of membrane-associated semaphorins, proteolytic processing may cause shedding of the extracellular domains from the cell surface, as shown for the class 4 semaphorin Sema4D.

Brief History of the Semaphorin Family

The first discoveries of semaphorins were made in 1992 and 1993 by Alex Kolodkin and co-workers in Corey Goodman´s lab at the Howard Hughes Medical Institute, Berkeley, University of California. They were attempting to identify molecules involved in the fasciculation of nerve axons in Grasshoppers and this led to the isolation of a transmembrane protein, which they first called Fasciclin IV. This protein turned out to possess a repelling activity which guided nerves in developing insect limp buds. The sequence was unique and used in the cloning of related sequences from other species including human SEMA3A. Meanwhile, in 1993, Yuling Luo and co-workers working in Jonathan Raper´s lab at the University of Pennsylvania isolated a protein from chicken brain extracts responsible for the growth cone collapsing activity observed when such extracts were added to sensory ganglion neurites *in vitro*. This protein was named Collapsin-1 and subsequently realized as the chick counterpart to human SEMA3A. Based on these sequences the



Semaphorin. Figure 1 The structure of vertebrate and viral semaphorin proteins. Semaphorins are secreted, transmembrane or linked to the surface by GPI anchor. They are found as dimers which may undergo proteolytic processing. This processing may cause shedding of the extracellular part of transmembrane semaphorins.

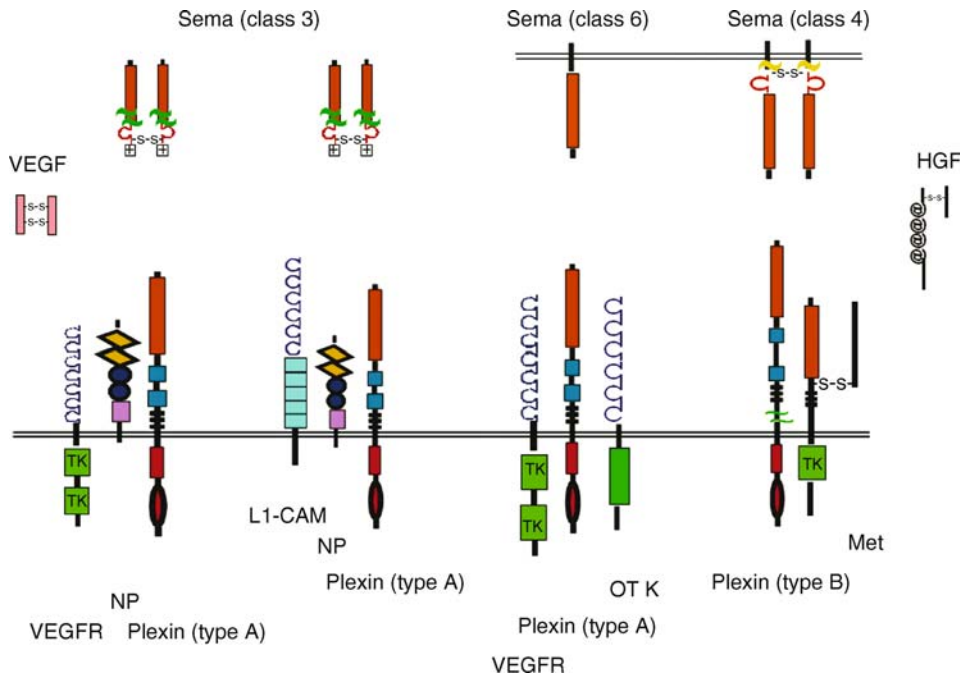
semaphorin/collapsin family was defined. The common family trait was a ~500 amino acid region, named the sema domain, constituting the better part of these proteins and containing a number of unique and highly conserved motifs (see characteristics). In the following years a number of new semaphorin members were isolated from different species. Semaphorins isolated from chick continued to be named collapsins until the nomenclature of semaphorins was changed by initiative of the Semaphorin Nomenclature Committee [1]. Evidence was rapidly mounting to suggest that the semaphorins were acting within the nervous system as ►guidance cues that guided migrating ►axonal growth cones as the complex wiring of the nervous system was established. Semaphorins were typically expressed by neighboring cells and at first considered to act primarily as repelling factors. This notion was changed in 1999 when a semaphorin was for the first time shown to be able to act as an attractive guidance cue. Today, semaphorins are considered to be bidirectional guidance factors, exerting repelling or attractive guidance depending on the composition of receptor complexes on the responding cells. Today, semaphorins are furthermore known to take part in different aspects of biology outside the nervous system including ►angiogenesis, immunobiology, and ►cancer. In cancer biology semaphorins appear to be bifunctional acting either as suppressors (see ►Tumor Suppressor Genes and ►Tumor Suppression) or promoters of tumor progression.

Semaphorins and the Composition of their Receptors

Although many different types of receptors and ►adhesion molecules are today implicated in semaphorin receptor complexes, two distinct types of receptors form the core of most of these complexes: the neuropilins and the plexins (Fig. 2). Members of the membrane-anchored class 1, 4 or 7 semaphorins bind plexins independent of neuropilins. Hence, Plexin-B1 and Plexin-C1 function as receptors for the transmembrane Sema4D and the GPI-linked Sema7A, respectively. On the contrary, the secreted class 3 semaphorins have for long been considered to require a complex of neuropilin and plexin. Hence, the earliest studies addressing this question showed that plexin-A1 combined with NP-1 and NP-2 constituted functional receptor complexes for Sema3A and Sema3F, respectively. But, this concept was challenged in 2004, when Sema3E and plexin-D1 were shown to control vascular development together independently of neuropilins. The reason for this discrepancy is currently unknown.

Neuropilins

The neuropilin family consists of neuropilin-1 (NP-1) and neuropilin-2 (NP-2), the latter existing in different splice variants. Neuropilins are transmembrane proteins that extracellularly possess two CUB (complement-binding) domains, two domains of homology



Semaphorin. Figure 2 Semaphorin receptor complexes. The core of semaphorin receptor complexes is made of plexins or plexins in combination with neuropilins (NP). Plexins bind semaphorins directly. In the case of class 3 semaphorins, it is generally so that a neuropilin is required in order to bind this class of semaphorins. Neuropilins also act as co-receptors for vascular endothelial growth factors (VEGFs). Other proteins may be involved in semaphorin receptor complexes including vascular endothelial growth factor receptors (VEGFRs), the off-track kinase (OTK), the cell adhesion molecule L1-CAM or the receptor tyrosine kinase Met. Hepatocyte growth factor (HGF) is the ligand for Met.

to coagulation factors V and VII, and an oligomerization domain, abbreviated MAM (short for meprin, A5,μ). The CUB domain is involved in the binding to class 3 semaphorins. NP-1 binds Sema3A but not Sema3F; whereas NP-2 binds Sema3F but not Sema3A. The other class 3 semaphorins Sema3C, Sema3D and Sema3E bind both neuropilins. The intracellular domains of NP proteins are very short and devoid of classical signaling motifs. Yet, they are highly conserved and bind possible adapter molecules with a ►PDZ domain.

Neuropilins may facilitate clustering of neuropilin-plexin receptor complexes but neuropilins also serve as bridges to other families of adhesion- and receptor molecules. Notably, neuropilins bind members of the ►vascular-endothelial-growth-factor-receptor (VEGF-R) family. In addition, NP-1 binds to L1-CAM, which is a member of the immunoglobulin (Ig) superfamily of ►cell adhesion molecules (Fig. 2).

Plexins

Nine plexins have been identified and they are grouped into four subclasses (plexin-A, -D). There are four A-type, three B-type, one C-type and one D-type plexin. Like semaphorins, sema domains are a characteristic of the extracellular part of plexins. In addition, plexins have two to three ►Met related sequences (PSI domains), and three IPT domains. Intracellularly plexins have two highly conserved stretches, separated by a variable linker region. The conserved domains include motifs distantly related to ►GTPase-activating proteins (►GAPs). In type-B plexins the carboxy terminus contains PDZ-domain binding motifs.

Plexin Signaling

At least some plexins may be locked in an autoinhibited configuration when not binding semaphorins. As shown for Plexin-A1 this involves the binding of the plexin sema domain to the rest of the extracellular part. It is believed that the plexins upon binding to semaphorins change configuration in a manner that allows phosphorylation of tyrosine residues in the intracellular domain as well as binding to various ►small GTPases and ►GTPase exchange factors (►GEFs).

The phosphorylation of the tyrosine residues in the intracellular part of the plexins is not because of autokinase activity inherent to the plexins but occurs because plexins are coupled to tyrosine kinases. Upon the binding of the semaphorin ligand, the plexins become phosphorylated by the tyrosine kinases with which they

interact. Hence, Plexin-B1 binds the receptor tyrosine kinase Met, and when Plexin-B1 is stimulated by Sema4D, Met causes phosphorylation of Plexin-B1. A similar interaction has been reported between Plexin-B1 and the tyrosine kinase receptor ErbB-2. Other examples of plexins interacting with tyrosine kinases are Plexin-A1 and Plexin-A2, which bind the intracellular tyrosine kinases Fes and Fyn, respectively. Plexin-A1 also interacts with the Off-track receptor, which possesses a kinase domain yet no kinase activity, as well as the VEGF receptor KDR/VEGFR-2. The binding of these two receptors to Plexin-A1 appears to have opposing effects on heart morphogenesis (Fig. 2).

The GAP-related domains in the cytoplasmic part of plexins have been shown to serve as docking sites for small GTPases such as Rac1 and Rnd1 (see ►GTPase and ►Rho family proteins). Furthermore the activation of RhoA is implicated in the axonal collapse mediated by B-type plexins. However, Plexin-B1 does not bind RhoA directly. Instead it binds to leukemia-associated Rho-GEF (LARG) and PDZ-Rho-GEF (PRG) through the PDZ-domain-binding motifs that are specific to B-type plexins. Despite the presence of a segmented GAP domain in plexins, at first plexins were considered not to have any intrinsic GAP activity. However, Plexin-B1 does exert GAP-activity when Sema4D binds to the extracellular domain and Rnd1 at the same time binds to the linker region. Under such circumstances Plexin-B1 exerts a GTPase activation activity on R-Ras (see ►RAS). R-Ras appears to function mainly in the regulation of ►integrins (see ►Integrin Signaling and Cancer).

The small GTPases Rho, Rac, and Rnd are known for their regulatory function with respect to the actin filament assembly and actin-myosin contraction, which constitute the basis for cellular structure and locomotion. Integrins couple this machinery to the extracellular matrix and provide much of the stability during ►migration (see also ►Motility). By recruiting activated forms of small GTPases or affecting integrin function plexins may influence the shape and migratory behavior of cells and axonal growth cones.

Brief History of Semaphorins in Cancer Research

The first discoveries of semaphorins in cancer biology were made in 1996 when SEMA3B and SEMA3F were located at the chromosomal region 3p21.3, which is deleted in small cell lung cancers. Today these semaphorins are thought to act as tumor suppressors through their ability to compete with ►vascular endothelial growth factors for the binding to neuropilin coreceptors. An alternative model predicts that SEMA3F acts by reducing expression of β_1 integrin in cancer cells.

Whereas SEMA3F and SEMA3B are located together on chromosome 3, the other subclass 3 semaphorins, SEMA3A, SEMA3C and SEMA3E are located on chromosome 7. The present studies of SEMA3C and SEMA3E suggest functions of these genes that promote tumor progression.

In 1997 SEMA3C was identified in cis-diaminedichloroplatinum (CDDP) (see ►cisplatin and ►platinum drugs) resistant ovarian TYKnuR cells as a gene capable of conferring chemoresistance to other cells upon ectopic expression. The underlying mechanism is presently unknown. Later SEMA3C has been shown to be upregulated in metastatic human lung adenocarcinoma cells and in malignant glioma cells.

In 1998 Sema3E was identified in murine mammary adenocarcinoma cells (see ►Breast Cancer) and reported to be expressed in a manner correlating with the metastatic potential of such cells. It was later shown to stimulate experimental lung ►metastasis when overexpressed in a nonmetastatic cell line of the same origin. The exact mechanism is currently unknown but seems to deviate from existing models since it requires proteolytic processing of Sema3E. So far human SEMA3E has also been associated with mammary adenocarcinoma, where it seems to be overexpressed in a subset of clinical samples and cell lines as seen in the case of murine Sema3E.

In 2002 Sema4D was shown to stimulate invasive growth *in vitro* through a receptor complex consisting of Plexin-B1 and Met. Later Sema4D has been shown to promote angiogenesis *in vitro* and *in vivo* in a manner that likewise requires a coupling between Plexin-B1 and Met. Experimental evidence for a role of Sema4D in tumor angiogenesis has been reported in the context of head and neck squamous cell carcinoma. Sema4D is also expressed in activated B and T lymphocytes and at a high level in lymphoid and myeloid leukemia cell lines as well as in some T-cell and B-cell non-Hodgkin lymphomas (see ►Hematological Malignancies; Hodgkin Disease and ►Malignant Lymphoma, Hallmarks and Concepts). Whether Sema4D contributes to the progression of these cancers is not known, and if so it might involve a plexin-independent mechanism since the major Sema4D receptor within the immune system appears to be CD72 rather than Plexin-B1.

In 2003, Sema5C was identified in a genetic screen for genes that would suppress a tumor phenotype in *Drosophila* that arises from inactivation of the *lethal giant larvae l(2)gl* gene. This work showed that inactivation of Sema5C blocked tumor growth in such flies and pointed to a mechanism involving a TGF-beta-like signal pathway.

Other class 5 semaphorins (SEMA5A, -5B and -5D) as well as the class 6 semaphorins SEMA6A and SEMA6B have also been associated with different human cancer cells, but the significance of these findings is unknown. Table 1 summarizes the expression and alleged functions of semaphorins in cancer according to published material.

Semaphorin. Table 1 The expression and possible functions of semaphorins in cancer. Whenever the semaphorin has been implicated with human cancer it is listed by its human name

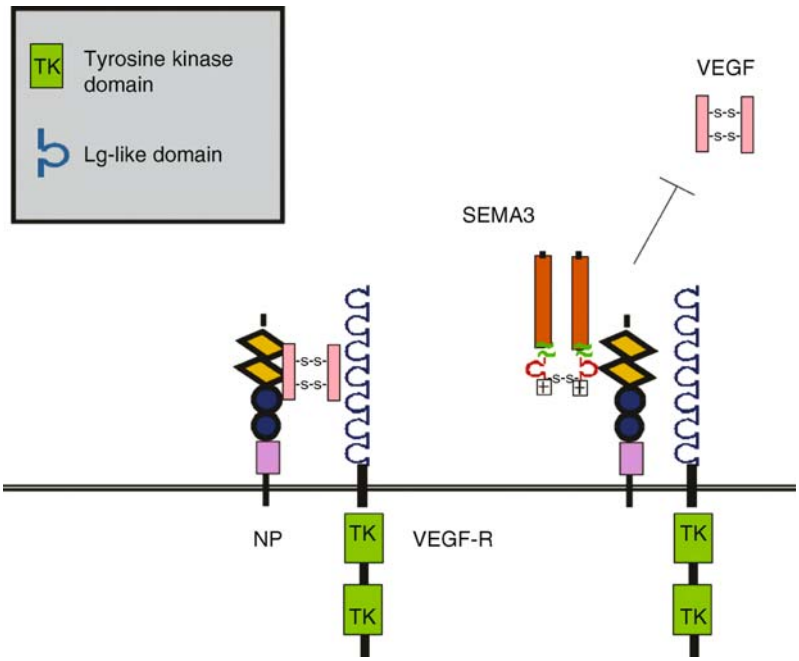
Semaphorin	Type of aberrant expression	Tumor type(s)	Function(s)
SEMA3A	Down-regulated	Mesothelioma	Inhibition of angiogenesis and migration
	Expressed	Breast carcinoma cell lines	
SEMA3B	Maps to 3p21.3 deleted in lung cancer	Lung cancer	Inhibition of angiogenesis
	Down-regulated	Lung, ovarian and breast cancer cell lines	
SEMA3C	Over-expression	Ovarian, lung, glioma cancer cell lines	Promotes cancer cell survival (chemo resistance)
	Differentially expressed (only seen in metastatic cell line)	Lung adenocarcinoma cell lines	
SEMA3E	Differentially expressed (only seen in metastatic cell lines)	Breast carcinoma cell lines	Promotes metastasis
SEMA3F	Maps to 3p21.3 deleted in lung cancer	Lung cancer	Inhibition of angiogenesis
	Down-regulated	Malignant melanoma	Inhibition of adhesion and migration
SEMA4D	Expressed	Head and neck squamous cell carcinoma	Promotes angiogenesis and invasive growth
	Differentially expressed	Lymphoid and leukemia cell lines non-Hodgkin lymphoma	Unknown
SEMA5A	Expressed	Malignant Melanoma cell line	Unknown
	Over-expressed	Uterine leiomyomata	
SEMA5B	Differentially expressed	Renal cell carcinoma	Unknown
Sema5C	Inactivation (experimentally by P element insertion)	Drosophila l(2)gl tumor model	Necessary for tumor growth
SEMA5D	Expressed	Malignant melanoma cell line	Unknown
		Ovarian cancer cells	
SEMA6A	Maps to 5q21-22 deleted in lung cancer	Lung cancer	Unknown
SEMA6B	Down-regulated when cells treated with retinoids	Glioblastoma	Unknown

Different Mechanisms may Account for Semaphorin Functions in Cancer Biology

Model I: Semaphorins may act as antagonists of Vascular Endothelial Growth Factor (VEGF) signaling.

Both class 3 semaphorins and vascular-endothelial growth factors are known ligands of the neuropilin receptors, meanwhile neuropilins exist in complexes with either plexins and VEGF receptors (VEGFR). This creates the basis for a mutually antagonistic relationship between class 3 semaphorins and VEGF ligands (see Fig. 3). Hence, NP-1 is a coreceptor of VEGFR-2 (also known as KDR) mediating the activity of certain VEGF-A isoforms in angiogenesis. However SEMA3A binding to NP-1 blocks this activity in endothelial cells. Likewise, NP-2 is a coreceptor for VEGFR-1 and VEGFR-2, and binding of NP-2 to SEMA3F or SEMA3B may influence signaling through these two receptors. Recently, NP-2 was also shown to act as a coreceptor for VEGFR-3 mediating the activity of VEGF-C and VEGF-D during ►lymphangiogenesis.

Initially, class 3 semaphorins were considered to be tumor-suppressors due to their antagonistic activity on VEGF signaling in endothelial cells (see ►Antiangiogenic and ►Antiangiogenesis). Today, the picture is made complicated by the fact that both endothelial cells and many cancer cells express class 3 semaphorins and VEGF ligands, and both cell types may express any combination of neuropilins, plexins and VEGF-receptors dependent on tumor type and localization. The effect these expressions have on the overall migratory, adhesive and proliferative capabilities of the EC and cancer cells within a given tumor may depend upon the ratio between the different receptors and between ligands. One updated model



Semaphorin. Figure 3 Model for how semaphorins may suppress tumorigenesis by blocking VEGF signaling. Neuropilins (NP) are co-receptors for both class 3 semaphorins and vascular endothelial growth factors (VEGFs). When class 3 semaphorins bind neuropilins they prevent the binding and activation of VEGF-receptors (VEGF-R) thereby blocking the pro-angiogenic signaling of VEGF.

depicts that down-regulated expression of class 3 semaphorins such as SEMA3F and SEMA3B shifts the balance in favor of VEGF ligands and their pro-migratory activity in cancer cells or pro-angiogenic activity in EC.

Model II: Semaphorins may act through complexes of receptor tyrosine kinases and plexins.

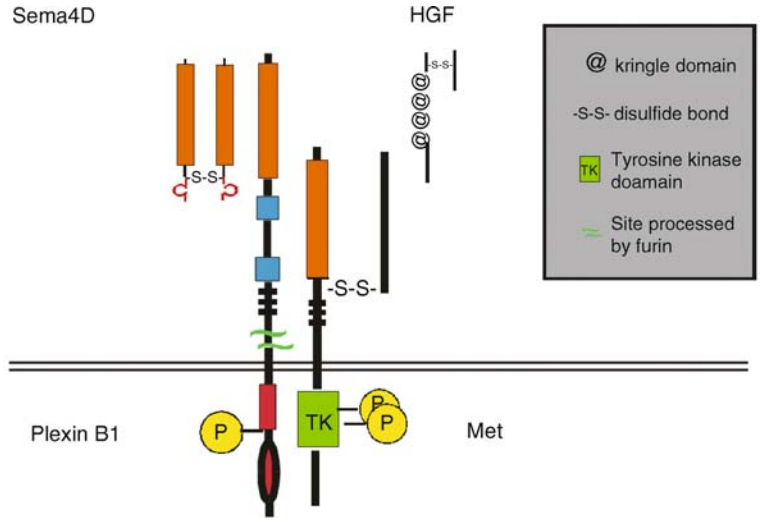
The reason for both tumor-suppressive and tumor promoting activities of semaphorins may originate from the interaction between different plexins and tyrosine kinases. The most prominent example of a potential tumor growth promoting mechanism is the interaction between Plexin-B1 and Met (see Fig. 4). The Met receptor is a known ►oncogene, and both Met and its ligand hepatocyte growth factor (HGF; see ►Scatter Factor) contribute to increased invasiveness and angiogenic activity in tumors. Sema4D and HGF have been shown to act in synergy to cause activation of Plexin-B1 and Met and facilitate invasive growth *in vitro* and angiogenesis *in vivo*. Although it remains to be shown, other semaphorins may contribute to cancer progression through similar interactions between plexins and receptor-tyrosine kinases.

Model III: Semaphorins may act through signaling to integrins.

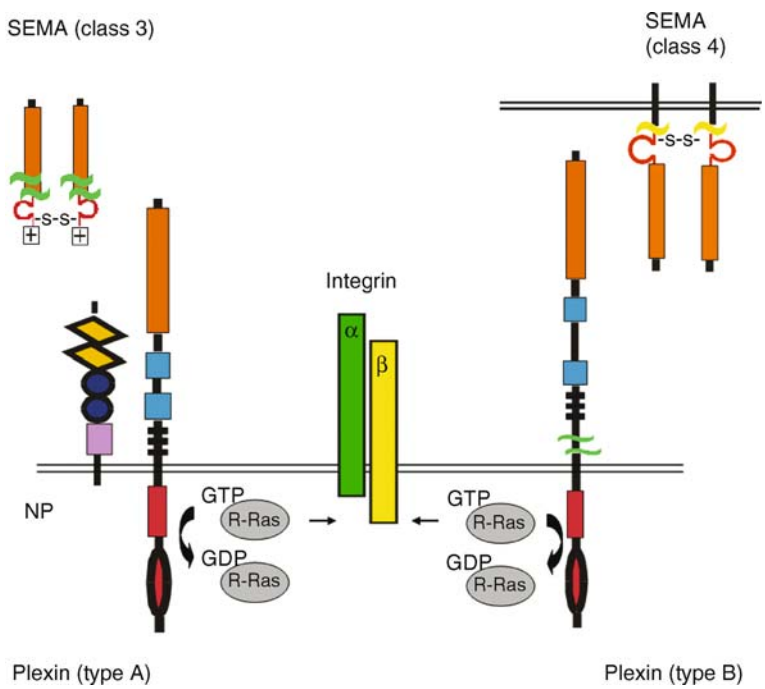
Integrins constitute a family of adhesion molecules of major importance to the migration of cells through the extracellular matrix. At the same time migration is a crucial aspect of the behavior of endothelial cells during angiogenesis as well as the behavior of cancer cells during ►invasion and metastasis. By affecting the function of integrins semaphorins may therefore affect the ability of a tumor to invade or stimulate angiogenesis. Today, compelling evidence suggests that semaphorin signaling as well as plexin activation inhibit integrin-dependent adhesion and migration of different cell types (see Fig. 5). Notably, in 2004 it was shown that SEMA3F expression in melanoma cells induces a poorly vascularized, non-metastatic phenotype, which was partly attributed to a decrease in β_1-integrin mediated migration of the cancer cells. This highlights an alternative way by which class 3 semaphorins may act as tumor suppressors.

Model IV: Semaphorins may act as suppressors of the immune system.

Semaphorins are part of the viral genomes of different ►pox viruses and the *alcelaphine* herpes virus. This has sponsored ideas concerning possible immunosuppressive functions of semaphorins. In accordance, the *Vaccinia* virus encoded semaphorin called A39R have been shown to negatively affect the migration of monocytes and phagocytosis by dendritic cells. Furthermore, the closest ancestor to the viral semaphorins is Sema7A, which seems to play a role endogenous to the immune system although its exact function is unknown.



Semaphorin. Figure 4 Semaphorins may promote tumorigenesis because of the synergistic interaction between Plexins and receptor tyrosine kinases. A prominent example of this is the interaction between Plexin-B1 (the receptor of Sema4D) and Met (the receptor of hepatocyte growth factor (HGF) Met causes phosphorylation of Plexin-B1, when Sema4D binds Plexin-B1.



Semaphorin. Figure 5 Model for how semaphorin signaling may influence the adhesion and migration of tumor cells. When semaphorins do not bind plexins, R-Ras is active (binding GTP), resulting in integrin-mediated binding to the extracellular matrix leading to higher adhesive and migratory behavior of the tumor cells. When semaphorins bind and activate plexin receptors, the GAP (GTPase activating protein) activity of plexins causes the conversion of R-Ras from a GTP-bound state (active) to a GDP-bound state (inactive). This leads to a decrease in integrin-mediated attachment and hence diminished cellular adhesion and migration. The activation of the plexin GAP activity requires the intracellular binding of the small GTPase RND1 to the plexins (not shown).

These findings make it likely that certain semaphorins expressed by cancer cells add to the ways by which the cancer cells evade the immune system.

Senescence

Definition

Is the limited capacity of cells to divide, an irreversible growth arrest state that depends on the age or cell doublings of a cell, a stage in the life cycle of a cell at which it can no longer divide. This state is dependent on the number of cell divisions and is generally brought about through the gradual shortening of the telomeres (repeat sequences at the ends of chromosomes) with each successive population doubling. Senescence is a permanent growth arrest that occurs after cells have exhausted their proliferative capacity. In normal human fibroblast, senescence takes place after approximately 60 population doublings in culture.

►Senescence and Immortalization
►Aging

Senescence Accelerated

Definition

Accelerated senescence, the process of rapid terminal growth arrest, is accompanied by phenotypic features of cell senescence (enlarged and flattened morphology, increased granularity, expression of specific biochemical and enzymatic markers such as senescence-associated β-galactosidase activity). It can be induced in normal cells by DNA damage or introduction of mutant RAS and is also induced in tumor cells by different anticancer drugs or ionizing radiation.

Senescence and Immortalization

Roger Reddel
Children's Medical Research Institute, Westmead, The University of Sydney NSW, Australia

Definition

Senescence is the permanent exit of a cell from the cell division cycle, accompanied by morphological and biochemical changes characteristic of ageing.

Immortalization is the ability of cell populations to undergo an unlimited number of cell divisions.

Characteristics

Senescence

Normal mammalian somatic cells can proliferate only a limited number of times in vitro, and the maximum

number is often referred to as the "Hayflick limit." When this limit is reached, the cells undergo various morphological and biochemical changes suggestive of ageing, so the process is referred to as senescence. Senescent cells can remain metabolically active for a long period of time, even though they have permanently exited from the cell cycle. Senescence is thus distinct from cell death (including ►apoptosis and ►autophagy). It is also distinct from terminal differentiation, where cells also exit permanently from the cell cycle and undergo changes that allow them to perform specialized normal functions. Senescent cells have been extensively studied as an in vitro model of ageing. In humans, cellular senescence appears to be a major barrier to the development of cancer.

Immortalization

It is not practicable to test whether cells are truly capable of continuing to divide forever, so cells are usually regarded as being immortalized if they have undergone many cell divisions (typically 100) beyond the Hayflick limit. Many cancers contain immortalized cells and some cancer-derived cell lines have been proliferating in vitro for many decades.

Relevance of Senescence and Immortalization to Cancer

Although the Hayflick number may be quite large (fibroblasts from an adult, for example, may divide up to 40 times before they become senescent), in most situations it is not large enough to permit tumor formation. A tumor containing 2^{40} cells would be big enough to be lethal, but there are two major reasons why 40 cell divisions does not result in a tumor of this size. The first is that cell death occurs at a very substantial rate within tumors, for reasons that include genetic instability (see chapters on ►chromosomal instability and ►microsatellite instability) and difficulties with blood supply (see chapter on ►angiogenesis) that result in cell death. The second is that the genesis of a fully malignant tumor cell requires the accumulation of a number of critically important genetic changes. Most of these changes occur at random and provide a growth advantage to the nascent tumor cell. This process consumes many more cell divisions than a normal cell is able to undergo before it becomes senescent.

Consequently, senescence forms a major barrier to carcinogenesis in humans. A cell containing some of the genetic changes required for carcinogenesis will not usually be able to proliferate sufficiently to form a clinically significant tumor while the senescence barrier is intact. Human cells become immortalized at a very low frequency (so low, that no clear example has yet been found of a normal human cell undergoing immortalization spontaneously in cell culture), so immortalization is a rate-limiting step in human carcinogenesis. In contrast, mouse cells become immortalized spontaneously at a measurable frequency and, correspondingly, the probability of a mouse cell becoming malignant is many orders of magnitude higher than for human cells. The ability to suppress tumor formation is a major selective advantage for a long lived species such as H. sapiens.

A Cell Division Counting Mechanism

The existence of a limit to the number of times a cell can divide implies that there must be a cell division counting mechanism. According to the telomere hypothesis of senescence, the counting mechanism is based on the progressive shortening of the ends of chromosomes (►telomeres) that occurs with cell division. Telomeres form protective caps that prevent the cell recognizing the ends of chromosomes as double strand breaks and repairing them, for example by fusing the ends to each other. They contain repetitive DNA (in all vertebrates the repeat unit is a hexanucleotide, TTAGGG), which ends in a single-stranded G-rich tail. Telomeres are able to fold back on themselves and form a loop structure (referred to as a "t-loop") when the single-stranded telomere invades duplex telomeric DNA and anneals to the complementary strand, thus hiding the free single-stranded telomere end. Telomeric DNA is recognized by specific binding proteins, including TRF1 and TRF2 which bind to double-stranded telomeric DNA and POT1 which binds to single-stranded telomeric DNA. The reasons for telomere shortening include the following. First, DNA replication depends on small RNA primers, which get degraded and replaced by DNA. However, there is no mechanism for replacing the terminal RNA primer required for lagging strand DNA synthesis, which results in the template for the next round of DNA synthesis being shorter. This is known as the "►end replication problem." Second, there appears to be a 5′-3′ exonuclease that shortens the C-rich strand, which creates or increases the length of a single-stranded G-rich telomeric tail.

Regardless of the exact mechanism of telomere shortening, eventually telomeres become so short that they trigger the cell to exit permanently from the cell cycle. In order for a cell to become immortalized, it must somehow prevent telomere shortening. In most cancers this is achieved by the activity of an enzyme, ►telomerase, and in a minority it is achieved by another mechanism referred to as ►alternative lengthening of telomeres (ALT). Every immortalized cell line examined to date has either telomerase or ALT activity.

Telomerase

The telomerase holoenzyme complex is normally expressed in cells of the germ-line. It is also found in some normal somatic cells, especially those that are

required to undergo extensive proliferation, but at levels that are insufficient to prevent telomere shortening. Telomerase synthesizes telomeric DNA to replace the DNA lost during cell division. The essential subunits include an RNA molecule (TElomerase RNA; TER; encoded by a gene designated TERC, which is an abbreviation of TElomerase RNA Component) that acts as the template for synthesis of telomeric DNA, the reverse transcriptase catalytic subunit (TElomerase Reverse Transcriptase; TERT) that carries out the synthesis, and dyskerin (encoded by the DKC1 gene), a protein that binds to TER. Telomerase activity can be detected in some normal human somatic cells, especially cells in highly proliferative tissue compartments such as the bone marrow, skin, mucous membranes and epithelia of the gastrointestinal tract (GIT), but not at sufficient levels to completely prevent telomere shortening. Telomerase has an important role in these tissues, because inherited mutations in any of the genes that encode one of the three telomerase components (TERT, TERC or DKC1), result in a condition called Dyskeratosis Congenita which is characterized by premature failure of proliferative capacity in tissues such as the bone marrow, skin and GIT. In contrast, at least 85% of all cancers contain sufficient levels of telomerase to prevent telomere shortening and the percentage is even higher in most types of carcinomas. The factors controlling hTERT expression are not well understood but it is known that hTERT can be upregulated by ►MYC. If TERT expression is artificially switched on by genetic manipulation in normal cells, it is usually able to induce telomerase enzyme activity, because there is usually expression of the other telomerase subunits. This prevents telomere shortening and in some types of human cells this results in immortalization. Inhibiting telomerase activity in cancer cells may cause cellular senescence or cell death, so telomerase is an attractive target for the development of new anticancer treatments.

Alternative Lengthening of Telomeres (ALT)

Some immortalized cell lines and cancers have no detectable telomerase activity and maintain their telomeres by an alternative mechanism, referred to as Alternative Lengthening of Telomeres (ALT). Overall, about 8–10% of human tumors utilize ALT to prevent telomere shortening. Although the details are not fully understood, ALT is likely to be a recombinational mechanism in which one telomere uses another telomere (or itself via looping back) as a template for synthesis of new telomeric DNA. The ALT mechanism depends on the activity of the ►MRN complex which is known to be involved in ►homologous recombination. Cells that maintain their telomeres by ALT characteristically have very heterogeneous telomere lengths, ranging from undetectably short to extremely long. They also have substantial quantities of extrachromosomal telomeric repeat DNA, that may be either linear or circular, some of which is sequestered within ►PML nuclear bodies. The presence of telomeric DNA and telomere binding proteins within PML bodies is highly characteristic of ALT-positive cells, and may be used to determine whether a tumor utilizes the ALT mechanism. Types of tumors where ALT is common include ►glioblastoma multiforme (the most common primary brain tumor in adults), ►osteosarcomas, and some types of ►soft tissue sarcomas such as ►malignant fibrous histiocytomas and ►liposarcomas.

Tumor Suppressor Genes

Immortalization is facilitated by loss-of-function of the ►p16INK4a or ►RB1 genes, and the ►p53 gene. Loss of the normal function of these genes results in a significant, but finite, increase in cellular proliferative potential. This permits the accumulation of additional genetic changes and increases the probably that activation of a telomere maintenance mechanism will occur. Cells containing an inherited p53 mutation from individuals with ►Li-Fraumeni syndrome are the only type of human cells known to undergo immortalization spontaneously.

Clinical Relevance

Treatments that reverse the immortal phenotype may be a useful form of cancer therapy. An attractive target is telomerase, but inhibitors of telomerase may need to be combined with inhibitors of ALT to prevent the emergence of drug resistance.

Definition

►A sentinel lymph node is a lymph node upon which the primary tumor drains directly.

Characteristics

General anatomy and physiology of the lymphatic system

Lymphatic capillaries are 10–50 μm in diameter, consist of a single endothelial layer with a discontinuous membrane and are supported by collagen filaments. They are filled with lymph fluid originating from the interstitial space due to an osmotic pressure gradient and fluctuating intraluminal pressures. These intraluminal pressures are caused by lymphatic flow that is generated by lymph formation, contractions of the vessel wall and external pressure. Lymph fluid absorbed by lymphatic capillaries drains into larger collecting ►lymphatic vessels. Such lymphatic vessels drain into marginal and medullar sinuses located between germinal centers within a lymph node. These centers contain large numbers of phagocytic cells that accumulate protein colloids. Then, a plexus within the lymph node drains to the efferent lymphatic vessel that joins the artery and vein in the hilum. Direct drainage of the marginal sinus into the efferent vessel also exists (Fig. 1).

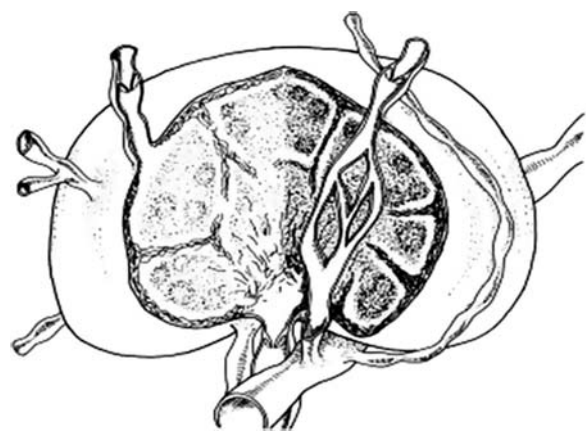
The Sentinel Node

The ►sentinel node is the lymph node upon which the primary tumor drains directly. Lymph fluid moves subsequently to ►second-tier and ►third-tier lymph nodes. Lymph from the primary tumor region does not necessarily travel to the nearest node. Two lymphatic channels originating in the primary tumor can run to two different sentinel lymph nodes (Fig. 2).

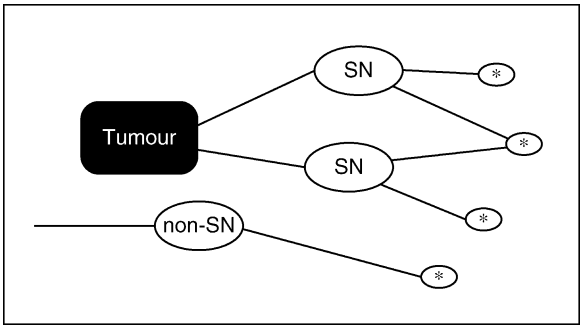
The sentinel node hypothesis implies orderly progression of ►metastases from a primary lesion through the ►lymphatic system. The concept is only relevant in tumors (►cancer) with pre-dominant lymphatic dissemination, such as melanoma and cancer of the breast, penis or colon. If the first node contains a metastasis, there is a chance of tumor spreading downstream. In case of a tumor-negative sentinel node, second-tier and third-tier nodes are generally without metastases.

Lymphatic Mapping

The lymphatic drainage pattern can be visualized by ►lymphoscintigraphy after injection of a ►radio-labeled tracer in or near the site of the tumor. The radio-labeled tracer is cleared from the lymphatic channels and accumulated by the phagocytic cells in the lymph node. ►Lymphoscintigraphic images depict



Sentinel Lymph Nodes. Figure 1 The different relations between lymphatic vessels and lymph nodes. Afferent lymphatic ducts on the left discharge their contents into the marginal sinus. One lymphatic duct runs through the node on the right and another over its surface, bypassing the germinal centers. (Illustration made by Tanis PJ; Reprinted from Tanis et al. (2001) Anatomy and physiology of lymphatic drainage of the breast from the perspective of sentinel node biopsy. J Am Coll Surg 192(3):399–409, with permission from "The American College of Surgeons").



Sentinel Lymph Nodes. Figure 2 A sentinel lymph node (SN) is the lymph node upon which the primary tumor drains directly. Two lymphatic channels originating in the primary tumor can run to two different sentinel lymph nodes. Lymph fluid moves subsequently to second-tier (*) and third-tier nodes. The SN is not always the node nearest to the primary tumor (Non-SN).

the lymph channels and the lymph node or nodes that contain the injected tracer. Dynamic scintigraphy and intraoperative ►blue dye mapping give insight in the lymphatic drainage pattern, which enables the surgeon to find the sentinel node(s).

The earliest sentinel lymph node identification techniques involved the injection of a vital blue dye, usually isosulfan blue. It was a key point in the general acceptance of ►sentinel node biopsy. The blue dye was injected intradermally at the primary tumor site in melanoma patients. An incision was made over the expected lymph node region and the lymphatic channel was visually identified. This channel was dissected and followed to the first draining lymph node.

Subsequent reports described the use of radio-labeled tracers, such as technetium-99m-bound colloids. Colloids with a small particle size can rapidly pass the openings of interendothelial junctions and allow visualization of the lymphatic channels leading directly to the sentinel node. A disadvantage of small sized particles is that some of the tracer moves on to nodes further downstream because phagocytic cells in the first node cannot trap them all. Larger colloid particles enter lymphatic channels more slowly. The tracer almost never moves on to subsequent nodes, but the channels are visualized less often.

Nowadays, the ►lymphatic mapping technique mostly used involves administration of a radio-labeled tracer into or near the primary lesion in combination with blue dye. During surgery, the sentinel node is found with the assistance of both blue dye and a ►gamma-ray detection probe. Preoperative lymphoscintigraphy is added for better specification of the location and number of sentinel nodes. Different methodologies based on these lymphatic mapping techniques are nowadays applied all over the world.

Sentinel Node Biopsy

A sentinel node biopsy is a minimally invasive technique that was initially developed as an alternative to complete lymph node dissection in patients with a melanoma. The majority of patients are spared a more complex surgical procedure with a higher morbidity rate while the same staging information is obtained.

All nodes of a complete node dissection used to be bisected and evaluated by haematoxylin-eosin staining. This way, metastases larger than 2 mm were usually identified. With the selective sentinel node biopsy, the pathologist can focus on the one or few nodes that are most likely to contain metastatic disease. The sentinel nodes are evaluated by both haematoxylin-eosin and immunohistochemistry staining, which occasionally distinguish metastases with a size of one tumor cell.

The combined procedure of lymphatic mapping and sentinel node biopsy provides prognostic information, identifies patients who may benefit from early regional therapy (►locoregional therapy) and, depending on the situation, from adjuvant systemic treatment (►adjuvant therapy). This way optimal survival rates may be realized.

Breast Cancer

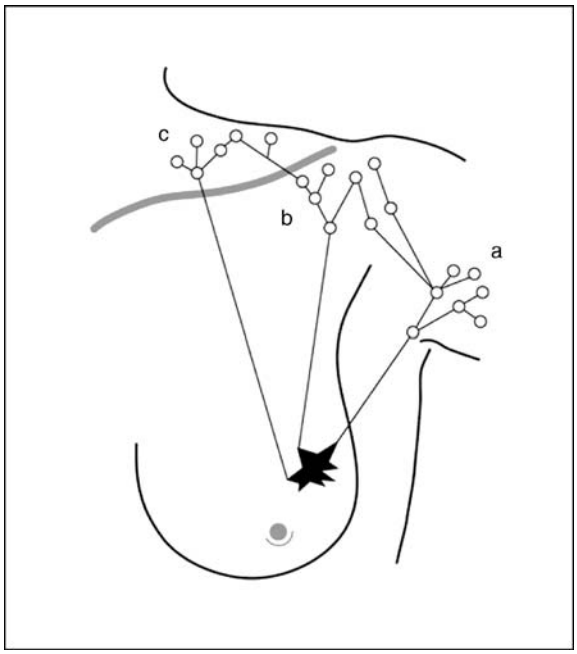
The predominant lymphatic drainage pathway from the breast is towards the axilla. Metastases initially remain localized in the lower axilla and then may travel higher up the chain to the subclavicular and the supraclavicular basins (Figs. 3 and 4).

Axillary lymph node dissection used to be performed in almost every breast cancer patient. This operation has several side effects, such as lymph oedema, pain and decreased mobility of the arm, and often no metastases were found. With the introduction of sentinel node biopsy, axillary lymph node dissection is only indicated if this node is involved. As a result, many patients are spared an unnecessary operation.

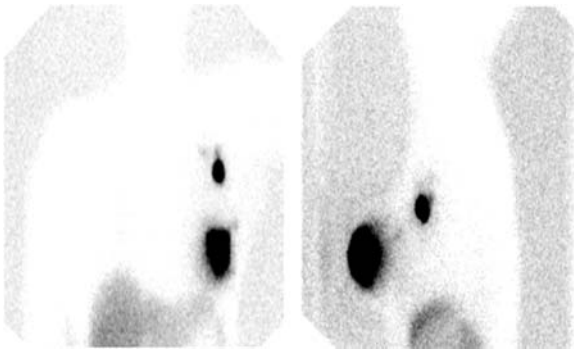
Whether the omission of routine axillary node dissection jeopardizes regional tumor control and survival is still subject of research. Large observational studies revealed excellent results in patients who did not receive axillary node dissection because of a tumor-negative sentinel node. Recurrence rates vary between 0.12% and 0.6% and these numbers do not exceed the known recurrence rates after routine axillary clearance.

Melanoma

There is consensus on the way lymphatic mapping should be carried out in melanoma patients. Preoperative lymphoscintigraphy and intraoperative use of blue dye and a gamma-ray detection probe are standard. The first large studies on sentinel node biopsy in melanoma showed a 95% sensitivity. Recent studies show false-negative rates of around 10%. False-negative means that



Sentinel Lymph Nodes. Figure 3 A tumor (black area) with lymphatic channels to nodes in the axilla (a) and to lymph nodes below (b) and above (c) the clavicula. A metastasis may be found along this lymphatic pathway.



Sentinel Lymph Nodes. Figure 4 Anterior and lateral lymphoscintigrapic images of a woman with left-sided breast cancer. A sentinel node and several second-tier nodes are visualized in the axilla.

the sentinel node is disease-free, while there are metastases in the lymph node basin.

Patients with an involved sentinel node have a 5-year survival rate of around 65% and in patients with a tumor-negative sentinel node this is 90%. A large randomized study showed that early regional node dissection based on a positive sentinel node improves survival in patients with an intermediate-thickness melanoma.

Concluding Remarks

The development of the sentinel node concept is a milestone in the understanding of dissemination of solid malignancies. The introduction of lymphatic mapping in 1989 initiated the widespread use and general acceptance of this approach. Now that the technique has been validated, many patients are spared unnecessary surgery without compromising regional control and the accuracy of staging.

Lymphatic mapping with ►sentinel lymph node biopsy has become a standard component in the management of patients with breast cancer or melanoma. This suggests potential in other tumors that spread primarily through lymphatic channels.

In the future, studies need to focus on more peripheral issues such as the prognostic significance of ►micrometastases and techniques such as molecular assays or markers. These may provide more information to optimize the staging of tumor dissemination and will enable the fine-tuning of therapy.

Synonyms

Draining lymph node

Definition

Sentinel means a lookout, and the sentinel node is defined as the first ►lymph node or nodes that are located on the direct draining lymphatic route from the area of a primary tumor.

Characteristics

The ►lymphatic system was first described in the seventeenth century by Olof Rudbeck who systematically studied the lymphatic vessels collecting extra cellular fluids from tissues emptying into ►lymph nodes. The lymphatic system is more variable then the blood system and is anatomically less well defined. The drainage from tumors seems to vary considerably, making prediction of the draining lymph node difficult without guidance. Tumor cells become metastatic either by invasive growth through basal membranes or by entering into capillaries. The endothelial cells comprising the lymph capillaries are widely fenestrated (►Fenestration) making easy access to the lymph vessel. There is also an active transport of primarily white blood cells into the lymphatic vessels but tumor cells may also use this mechanism. After entering into the capillaries of the lymphatic vessel, the metastatic cell may then enter into the draining lymph node. Thus, the tumor draining lymph node is the primary location to find lymph node metastases. If tumor cells are present in the sentinel node, the risk of systemic dissemination of the disease is high since about half of the lymphatic fluid entering a lymph node continues directly to the blood circulation via ►lymphovenous shunts.

In 1960 Gould first described a sentinel node draining a cancer of the parotid gland. Cabanas introduced the technique in 1977 for guidance of the surgical procedure for inguinofemoroiliac lymph node dissection of patients with penile carcinoma. This first study demonstrated two important principles regarding sentinel node investigations; (i) the sentinel node is the first site of metastases and may be the only lymph node involved containing metastatic cells (ii) sentinel nodes negative for metastatic cells suggest that no spreading of the disease has occurred and this finding is coupled to increased survival. Studies of prognostic factors in colorectal cancer point out the histological status of the regional lymph nodes as the most important predictor of survival and the presence of regional lymph node metastases implies a 50% reduction in 5-year survival rates. Similar observations have been reported in most solid tumors. However, the quality of the staging process of lymph node investigations are dependent on the total number of locoregional lymph nodes identified and the extent of the following histopathology investigation.

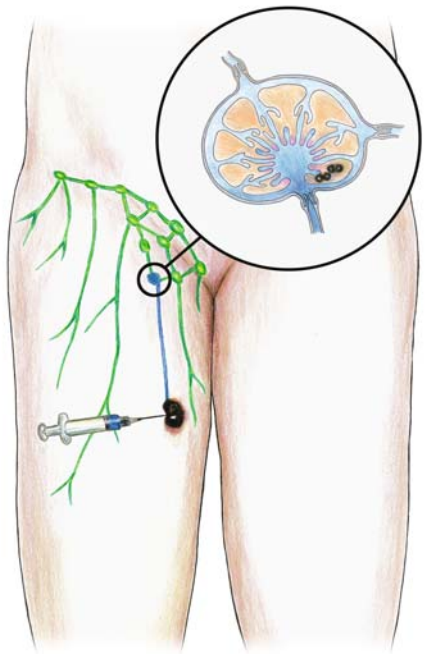
Malignant tumor often induce a peritumoral upregulation of lymphatic vessels and blood vessels by producing ►angiogenic factors such as the vascular endothelial growth factor (►VEGF), making the pathways for lymphatic drainage difficult to predict. Studies have shown that elevated levels of the cytokine cascade of VEGF-C and VEGF-D promote tumoral ►lymphangiogenesis and that inhibition of their joint receptor, VEGFR-3, suppresses the effects. Further, elevated levels of VEGF-C and VEGFR-3 correlate with presence of lymph node metastases and lymphatic invasion in human colorectal cancer. A large study of patients with breast cancer demonstrated an increased presence of lymphatic vessels in metastatic axillary lymph nodes (85%) compared to nonmetastatic lymph nodes (25%) and that intra- and perinodal lymphatic endothelial cell proliferation fractions were higher in metastatically involved lymph nodes. These discoveries underline the association of lymphangiogenesis with lymph node metastases.

Sentinel Node Procedure

The sentinel node is either located before surgery through lymphoscintigraphy or during surgery by the superficial injection of a tracer substance around the tumor (Fig. 1). When the tumor is located in the skin, the injection is usually placed around it in four places subcutaneously or intradermally. In visceral tumors (colorectal and gastric tumors) the injections should be superficial, precisely beneath the serosa whereas in parenchymatous organs (liver) the injections are preferably placed under the capsula into the parenchyma around the lesion. When approaching the tumor from the mucosal side, the injections are made through the mucosa and into the muscular wall (urinary bladder tumors). Within a few minutes the tracer has entered the ►fenestrated lymph capillaries. The tracer is then transported inside lymph vessels and accumulates through phagocytosis by ►dendritic cells in the sentinel node(s). Coal particles, dyes such as patent blue, isosulfan blue, and/or radioactive ^{99}Technetium colloid markers have been used as tracers for intraoperative ocular identification or detection using a hand held γ-counter respectively. A preoperative lymphoscintigraphy can facilitate the location of the regional lymph node basin draining the tumor and may be combined with computerized tomography for precise anatomical information in certain cases. The procedure is dependent on the surgeon's experience with the method and initial procedures are more likely to give rise to false negative sentinel lymph node, i.e., sentinel node does not contain metastatic cells whereas other regional lymph nodes are positive for tumor cells. The false negative rates in large series performed by experienced surgeons are usually as low as 3–5%.

Clinical Relevance

During recent years the importance of correct staging (►Staging of tumors) regarding lymph node metastases including presence of micro metastases has become evident for most types of human solid tumors. However,



Sentinel Node. Figure 1 The sentinel node concept. Identification of the tumor draining (sentinel) node is accomplished by peritumoral injections of Patent blue dye and/or a radioactive tracer ^{99}Technetium. The tracers enter into the lymph capillaries, which follows the lymphatic drainage and accumulation in a lymph node. During surgery the area of drainage is explored after the guidance of a γ-counter and the sentinel node is visualized by dissection. Since the tumor is in contact with the sentinel node, the sentinel node is the preferred site for metastases. When the sentinel node is investigated microscopically, it can be considered diagnostic for the whole lymph node region, guiding prognosis and therapy. In a progressively growing tumor, there is a rapid turnover of cells and disruption of normal tissue architecture, causing release of inflammatory mediators and attraction of macrophages and dendritic cells. Tumor cell debris is phagocytosed by these antigen presenting cells, which after the encounter migrate to the sentinel node, presenting peptides derived from tumor antigens to naïve T lymphocytes. Sentinel node lymphocytes mount proliferative responses and become clonally expanded against tumor antigen in an attempt to fight cancer.

the search for metastases or micro metastases among a large number of lymph nodes in a pathology specimen is time-consuming, labor-intensive, and expensive. Therefore the use of the sentinel node technique has received increasing interest since it entails detailed investigation of (in most cases) only one to three lymph nodes. Thus an increased awareness regarding an extended histopathological investigation of lymph nodes for staging and guidance for therapy has become apparent. The sentinel node concept entails the possibility of multiple drainage pathways from different parts of the primary tumor, thus a patient may have more than one sentinel node. The tumor status of this node reflects the status of the regional lymphatic field and has a strong impact on prognosis. Thus, the sentinel node procedure is increasingly used in malignant melanoma and breast cancer where it has become part of the standard staging (Staging of tumors) procedure and an important factor to consider when deciding about postoperative adjuvant therapy. In fact even insurance companies have taken the status of the sentinel node into account when determining life insurances. In a large randomized study of patients with malignant melanoma, sentinel node biopsy was compared with nodal observation demonstrating that sentinel node biopsy-guided staging provides important prognostic information and furthermore identifies patients that may benefit from immediate lymphadenectomy. In breast cancer, the introduction of sentinel node biopsy has limited the number of axillary lymph node dissections. Thus, the removal of the tumor draining sentinel node permits a smaller surgical axillary procedure and decreases the risk for different side effects including lymphoedema and nerve damage. The 5-year survival rate in patients with negative sentinel node biopsies is not different from women with breast cancer having undergone axillary lymph node dissection without the presence of metastases. Thus, sentinel node biopsy is a safe and accurate metastases screening method for patients with breast cancer. The sentinel node procedure has recently been shown to be applicable in many solid tumors including colorectal cancer, urinary bladder cancer, vulvae cancer, and gastric cancer, and the procedure may be valid for staging the majority of solid tumors.

Immunology of the Sentinel Node

According to the immune surveillance hypothesis, the immune system is continuously sensitized against developing tumors, most of which are eliminated at an early stage. Not only metastatic cells from the tumor enter into the lymphatic vessels but also antigen presenting cells, dendritic cells, which have endocytosed dying tumor cells, or debris from tumor cells containing ►tumor antigens, accumulate in the sentinel node. Since experimental evidence indicates that activation of naïve T cells (►T-cell response) occurs within the highly specialized microenvironment of secondary lymphoid organs, i.e., lymph nodes, the sentinel node may be regarded as the primary site for the immune system to encounter tumor antigens. Thus sentinel node acquired lymphocytes are clonally expanded (►Clonal expansion) T cells recognizing tumor antigens and may therefore serve as a useful source for immunotherapy.

Sentinel Node Biopsy

Definition

A minimally invasive technique to remove the first node in the draining lymphatic basin. The sentinel node is examined by the pathologist for cancer cells.

►Sentinel Lymph Nodes

Sentinel Vessels

Definition

Dilated episcleral vessels that provide nourishment to an underlying ciliary body tumor.

►Uveal Melanoma

SEP

Definition

Solitary extraosseous or extramedullary plasmacytoma.

►Plasmacytoma

Separin

Definition

A protease, also called separase, that cleaves the cohesin subunit Scc1/Mcd1 to induce sister-chromatid segregation. Its C-terminus is conserved, it.is inhibited by association with securin at the non conserved N-terminus.

Sequence Identification

Definition

Determination of the primary structure of a biomolecule (e.g. amino acids; DNA).

►Oncopeptidomics

Sequestered

Definition

In biochemistry a term, e.g., for a protein, synonymous to covered up, shielded, locked away resulting in biologically not available orphan receptor. The collective term for receptors with unidentified ligands/without known ligands.

►Arachidonic Acid Pathway

Ser/Thr-Phosphorylation

Definition

Protein phosphorylation is a post-translational modification carried out by enzymatic transfer of a phosphate group from a donor-molecule to a polypeptide backbone. The enzymes that catalyze this type of reactions are known as kinases. They transfer phosphate groups either to tyrosine residues (Tyr-kinases) or to serine or threonine residues (Ser/Thr-kinases) according to defined motifs within the polypeptide.

►Cystatins

SERCA

Definition

A pump situated in the membrane of the sarcoplasmic/endoplasmic reticulum that couples ATP hydrolysis to the import of Ca^{2+} from the cytosol to the endoplasmic reticulum lumen.

►Endoplasmic Reticulum Stress

Serex

Carsten Zwick, Michael Pfreundschuh
Klinik für Innere Medizin I, Universität des Saarlandes, Homburg, Germany

Definition

A method for identification and molecular analysis of antigens by recombinant expression cloning; Acronym for *se*rological analysis of antigens by *re*combinant *ex*pression cloning.

Characteristics

For SEREX, a cDNA library is constructed from fresh tumor specimens, cloned into λ phage expression vectors and phages are used to transfect E. coli. Recombinant proteins which are expressed during the lytic infection of the bacteria are transferred onto a nitrocellulose membrane. These membranes are incubated with the diluted serum of the autologous patients and screened for clones reactive with high-titered IgG antibodies. Positive clones are visualized by staining after incubation with an enzyme-conjugated secondary antibody specific for human IgG. Positive clones are subcloned to monoclonality, and the nucleotide sequence of the inserted cDNA is then determined.

The SEREX approach is technically characterized by several features:

- The use of fresh tissue obviates the need for culturing cells in vitro and therefore circumvents in vitro artifacts.
- The analysis is restricted to genes that are expressed by the tissue in vivo.
- The use of high-titered IgG antibodies in the initial screening procedure limits the analysis to such antigens which elicit a strong immune response in the host and imply a cognate T-cell help.
- The serological analysis covers the whole repertoire of proteins expressed by the respective tissue.
- SEREX uses polyspecific sera to scrutinize monoclonal antigens which are highly enriched in lytic plaques. This allows for a direct molecular definition of antigens, since the cDNA sequence of the antigen can be determined instantaneously.
- The specificity of the antigen, i.e. its expression spectrum is determined by the analysis of the mRNA expression pattern by Northern blots and RT PCR.
- If defined types of antigens are to be preselected for, the original SEREX approach can be modified appropriately by using biased cDNA libraries (e.g.normal testis) or modified detection systems (e.g. for IgA, IgM).

To overcome the problem of incorrect folding and the lack of posttranslational modifications, which are both inherent problems of bacterial expression systems, a eukaryotic expression system in yeast, designated as "recombinant antigen expression on yeast surface" (RAYS) has been established. For RAYS, a cDNA-library is cloned for expression as Aga2 fusion proteins on the yeast surface. After incubation with patient's sera, FACS-sorted positive clones are spotted onto 96-well-plates, re-analyzed for specific detection and the nucleotide sequence for the cDNA insert is then determined.

Cellular and Molecular Regulation

High-titered IgG responses imply a cognate T-cell help. Therefore, in an approach of "reverse T-cell immunology" antigens detected by SEREX can be used for the definition of epitopes that are presented in the context of MHC I and MHC II. Preferably, specific T-cell reactivities are looked for in patients with high serum antibody reactivity to the respective antigen, and for many SEREX antigens both CD4 and CD8 stimulating epitopes have been identified.

Clinical Relevance

SEREX allows for an unbiased search and the direct molecular definition of immunogenic proteins based on their reactivity with autologous and allogeneic patient sera. Hence, while SEREX was originally developed for the serological analysis of human ►tumor antigens, it can be used whenever antibody reactivities against tissue antigens are suspected and neither the antibody nor the antigen is known, e.g. for the identification and molecular characterization of ►autoantigens in ►autoimmune diseases. Using the RAYS approach might enable us to identify antigens that have escaped detection to date, because they elicit immune responses against post-translational modified or conformational epitopes not detectable by conventional SEREX. An international effort led by the Ludwig Institute for Cancer Research aims at defining the entire spectrum of antigens expressed by human tumors. All SEREX data are entered into the Cancer Immunome Database,

which is accessible to the public (http://www2.licr.org/CancerImmunomeDB/.)

Divisions of Public Health Sciences, Human Biology and Clinical Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA, USA

Synonyms

Matriptase: Epithin, MT-SP1, suppression of tumorigenicity 14

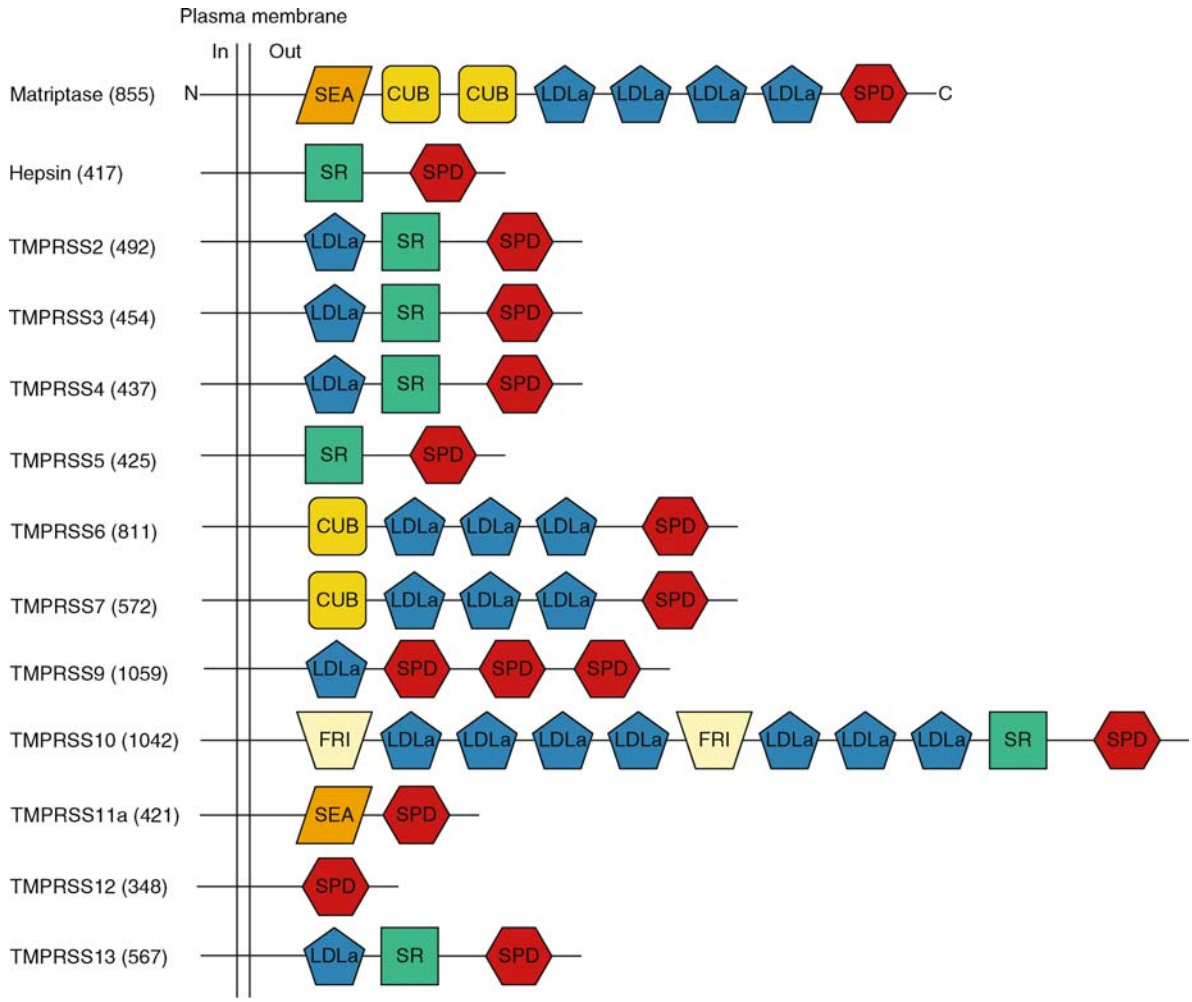
Transmembrane protease serine 1–13: hepsin (TMPRSS 1); Epitheliasin (TMPRSS 2); TMPRSS2 = TMPRSS4; Spinesin (TMPRSS5), matriptase-2 (TMPRSS6), matriptase-3 (TMPRSS7), distal intestinal serine protease (mouse only, TMPRSS8), polyserase (TMPRSS9), Corin (TMPRSS10), TMPRSS11–13 (human genes)

Definition

The family of type II transmembrane serine proteases consists of 14 members identified to date. They share a transmembrane orientation with an intracellular N-terminus and a basic, multidomain structure, which contains several individually folded protein modules in the extracellular domain (Fig. 1). Members of the family possess specific tissue and cell type distributions. For example ►Matriptase and ►Hepsin are epithelial, while ►Corin (TMPRSS10) is expressed in cardiac muscle cells. Matriptase, TMPRSS2 and Hepsin are associated with cancer development or progression.

Characteristics

The serine protease domain, which is located at the C-terminal end of all family members, encodes



Serine Proteases (Type II) Spanning the Plasma Membrane. Figure 1 Domain structures of the known type II transmembrane serine proteases. All are oriented with their amino terminal in the cytoplasm, a single transmembrane spanning domain and their carboxy terminal exposed extracellularlly. They are not drawn to scale but the total amino acid residues for each are indicated in parentheses. TMPRSS11 has known isoforms (a, b, d, e, and f) with similar domain structures and vary by only a few amino acids in length. Domains are abbreviated as; SEA: sea urchin sperm protein, enterokinase and agrin; CUB: complement C1r/C1s, Uegf and BMP-1; LDLa: low density lipoprotein receptor class A; SPD: trypsin like serine protease; SR: scavenger receptor cysteine-rich; FRI: frizzled.

the central function of the extracellular domain. The mechanism of activation, substrate specificity and physiological function of the serine protease domain are best understood for Matriptase and are described below. Hepsin is functionally related to matriptase in its ability to autoactivate, digest epithelial basement membrane proteins and activate hepatocyte growth factor/►scatter factor. Hepsin was discovered in liver and reported as overexpressed in metastatic prostate cancer cells. TMPRSS2 is preferentially expressed in the prostate under the regulation of androgen and the fusion of its promoter with genes from the family of ►ETS transcription factor plays an important role in prostate cancer development and progression (►TMPRSS2/ERG Fusions). TMPRSS2 is, itself, over-expressed in the majority of advanced prostate cancers where it often becomes mis-localized away from the plasma membrane.

Regulation of Activity

The activity of matriptase is regulated through autoactivation and is facilitated by lysophospholipids, steroid hormones and the polyanionic compound, ►suramin. For complete activation, matriptase requires glycosylation and serine protease domains to increase protein stability, an intact ►LDL receptor domain and an initial cleavage at Gly149 in the juxtamembrane

►SEA domain. In addition, the interaction of the LDL receptor domain with the serine protease inhibitor, hepatocyte activator inhibitor-1 (HAI-1) is critical for autoactivation. Active matriptase has a limited range of known substrates. These are ►HGF, urokinase plasminogen activator (►Plasminogen Activating System), ►stromelysin (Matrix Metalloproteinases), ►protease activated receptor (PAR-2) and ►extracellular matrix and cell ►adhesion proteins.

The enzymatic activities of matriptase and hepsin are inhibited by HAI-1, a membrane-associated Kunitz type-1 serine protease inhibitor. HAI-1 shares amino acid sequence homology and a similar domain structure with HAI-2 and consists of two Kunitz domains (N-terminal KD-1 and C-terminal KD-2) intersected by a low-density lipoprotein receptor (LDLR)-like domain. HAI-1 has a remarkable and unique specificity for a serine protease inhibitor and only inhibits the serine proteases matriptase, hepsin, prostasin, hepatocyte growth factor activator (HGFA) and a phosphatidylinositol (GPI)-anchored epithelial serine protease. Through regulation of matriptase, hepsin or HGFA activity, HAI-1 controls the amount of biologically active two-chain HGF on the cell surface and the activation of the Met receptor (►MET).

Biological Responses

Matriptase and hepsin have been shown to facilitate the invasion and metastasis of cancer cells through proteolysis of extracellular matrix, activation of uPA and MMP-3 and increasing in ►angiogenesis. Transgenic mice overexpressing hepsin show a defect in the epithelial basement membrane, characterized by loss and disorganization of collagen-IV and laminin-5 (►Adhesion; ►laminin signaling).

Several proteases and proteolytic cascades mediate the activation of HGF (►Scatter factor). Matriptase and hepsin are central proteases for HGF activation, since pro-HGF is their direct substrate. In addition, matriptase also activates uPA, and thereby magnifies the activity for HGF activation on the cell surface.

Studies in genetic mouse models reveal that matriptase is required for post-natal survival by maintaining the barrier function of the epidermis. Matriptase deficiency phenocopies the loss of its proteolytic target, the serine protease, prostasin/CAP1/Prss8. Matriptase also plays an important role in hair follicle development, thymic homeostasis and keratinocyte differentiation. In humans, matriptase is shed from the cell surface and is found complexed with HAI-1 in human milk.

Expression in Cancer

Matriptase is expressed on cancer cells, that originate from a variety of epithelial origins and has been implicated in cancer development, progression and ►angiogenesis. Matriptase translocates from a perinuclear reservoir to activation foci in cell-cell junctions and later moves to membrane protrusions in response to growth factor stimulation. On the cell surface, the balance between matriptase and hepatocyte activator inhibitor-1 (HAI-1) and HAI-2 regulates matriptase activity. The ratio of matriptase to HAI-1/HAI-2 expression increased with tumor grade and progression in ovarian, cervical, prostate and colon cancer. The resulting increase in active matriptase on the cell surface facilitates invasion and metastasis of cancer cells.

Matriptase and HAI-1 are indirectly regulated by ►androgens. In a ►prostate cancer cell line, treatment with ►testosterone transiently increased matriptase expression and activity and increased shedding of proteolytically cleaved HAI-1. As a result an increase in HAI-1–matriptase complexes occurred in the extracellular space. In normal human prostate glands, HAI-1 protein expression decreased after androgen suppressive therapy, however, in cancerous glands, intracellular protein expression was not affected by androgen.

Clinical Relevance

Pathologic deregulation of matriptase, hepsin or TMPRSS2 can result from increased expression, activation and from an imbalance relative to their cognate inhibitors, e.g. HAI-1. Elevated expression of matriptase and HAI-1 are associated with poor outcome in several human cancers, including node-negative breast, prostate and ovarian cancers. In a transgenic mouse model modest expression of matriptase in epidermis is sufficient to cause ►squamous cell carcinoma, and matriptase expression enhances ►gastric cancer metastasis in ►nude mice. Forced expression of Hepsin in prostate cancer stimulates metastasis while inhibiting local growth. Consistent with matriptase's role in cancer, inhibition of matriptase expression or activity by matriptase-specific small molecular inhibitors, matriptase ►anti-sense, or ►siRNA, suppresses cancer growth in cell culture and ►xenograft models.

Synonyms

hMAWD: Human MAPK activator with WD repeats; Unrip: unr-interacting protein; STRAP

Definition

STRAP is a 39 kDa protein of WD-40 family involved in probable chaperoning function during the formation of multiprotein complexes shown to be active in the ►Transforming growth factor-β (TGF-β) receptor signaling network and U-rich small nuclear ribonucleoprotein (U snRNP) assembly. ►Oncogenic STRAP is up-regulated in human cancers and may be involved in tumor progression.

Characteristics

STRAP was first cloned from mouse embryonic cDNA library while searching for novel proteins that bind the cytoplasmic region of TGF-β type I receptor (TβRI) using yeast two-hybrid screening. Later it was found that STRAP could associate with both type I and type II (TβRII) serine-threonine kinase receptors. Southern blot analyses demonstrate that STRAP is evolutionarily conserved from yeast to mammals. The importance of this conservation was revealed when STRAP knockout mice were generated using the gene-trap mutagenesis technology coupled with ►microarray in the process to identify the probable targets of ►platelet-derived growth factor (PDGF) signaling. *STRAP* was found to be a PDGF-BB-inducible gene. The gene trap insertion results in embryonic lethality between embryonic day (E) 10.5 and E12.5. Homozygous mutant embryos had defects in ►angiogenesis, cardiogenesis, somitogenesis, neural tube closure and embryonic turning. This highlights an indispensable function for STRAP during early development. Later STRAP was also identified in humans as an interacting protein with upstream of N-ras (unr) that is involved in the internal initiation of translation of human rhinovirus RNA and is implicated in cap-independent translation.

STRAP belongs to the family of WD repeat proteins that are known to have four or more repeating units containing a conserved core of approximately 40 amino acids that mostly end with tryptophan-aspartic acid (WD). Most of them are thought to form a circularized β propeller structure. Though the underlying common function is coordinating multiprotein complex assemblies, these proteins are also involved in various cellular processes like signal transduction, transcriptional regulation, programmed cell death, RNA synthesis/processing, chromatin assembly, cell cycle progression and vesicular trafficking. Other common examples of WD repeat proteins are the β subunit of the ►G proteins, TATA box binding protein associated factor II (TAFII), ►apoptotic protease-activating factor 1 (APAF-1), retinoblastoma-binding protein p48 (RbAp-48), receptor activated protein kinase C 1 (RACK1), and phospholipase A2-activating protein (PLAP) or TGF-beta receptor-interacting protein 1 (TRIP-1), which is also known to interact with TβRII.

The human *STRAP* gene is placed in chromosome 12p12.3 near the marker D12S1593. Northern blot analysis, using different tissues in mice, indicated a major transcript of 1.8 kb, though in some tissues a larger transcript was detectable. This may suggest alternative splicing of the STRAP RNA at least in some tissues. It is ubiquitously expressed in all mouse tissues with highest levels in liver and testes and less abundantly in spleen. In humans, STRAP expression has also been shown to be ubiquitous and it forms a 2 kb transcript. Both human and mouse *STRAP* genes contain 10 exons, which finally form a 350 amino acid protein migrating with an apparent mass of 39 kD on SDS-PAGE. Murine STRAP has more than 97% amino acid identity over the entire sequence with its human version. Sequence analysis indicates that STRAP contains six WD40 repeats. STRAP shows a 55% similarity in base pairs and a 19% similarity in amino acid sequence to another known WD40 protein, TRIP-1. Some of these similarities are among the conserved amino acid residues within the WD repeats. STRAP is localized predominantly in the cytoplasm but a good level is also present in the nucleus. It forms homo-oligomers probably through the WD repeats and this may be important for the multi-protein complex assembly. The physical interaction of STRAP with the TGF-β receptor complex raises the possibility that STRAP is a substrate of the receptors. Our findings showed that an increase in the phosphorylation of STRAP

requires the kinase activity of receptors in vivo, but STRAP does not appear to be a direct substrate of the receptors during in vitro kinase assays. The C-terminal 57 amino acids are important for this phosphorylation. Eukaryotic Linear Motif resource (ELM) search indicates the presence of putative phosphorylation sites in the C-terminal region for the casein kinases I and II. Multiple phosphorylation sites also seem to be present inside the different WD repeat domains for different kinases and may serve to modify the function of STRAP.

Apart from TβRI and TβRII, STRAP also binds with ►Smad2, ►Smad3, ►Smad6, ►Smad7, 3-phosphoinositide-dependent protein kinase 1 (PDK1), Ewing's sarcoma protein (EWS), hMAWD binding protein (MAWBP), unr, microtubule associated protein 1B (MAP1B), nuclear export factor (NXF) proteins, Gemin6, Gemin7, and 3 small nuclear ribonucleoproteins (SmB), SmD2, SmD3. Additionally, using ELM motif search, it also shows putative binding sites for other proteins like C-terminal Binding Protein (CtBP), protein phosphatase 1, retinoblastoma protein (pRb), TNF receptor-associated factor 2 (TRAF-2), and glycosaminoglycans and also has binding sites for domains like class II PDZ domain, ►SH2 domain and class IV WW domain. STRAP also shows the presence of multiple potential membrane targeting N-myristoylation sites, at least one of which is outside the WD repeat domains in the C-terminal region. Structural analysis of the WD repeat proteins in general shows that they act as a very rigid platform or scaffold, irrespective of the proteins with which they interact.

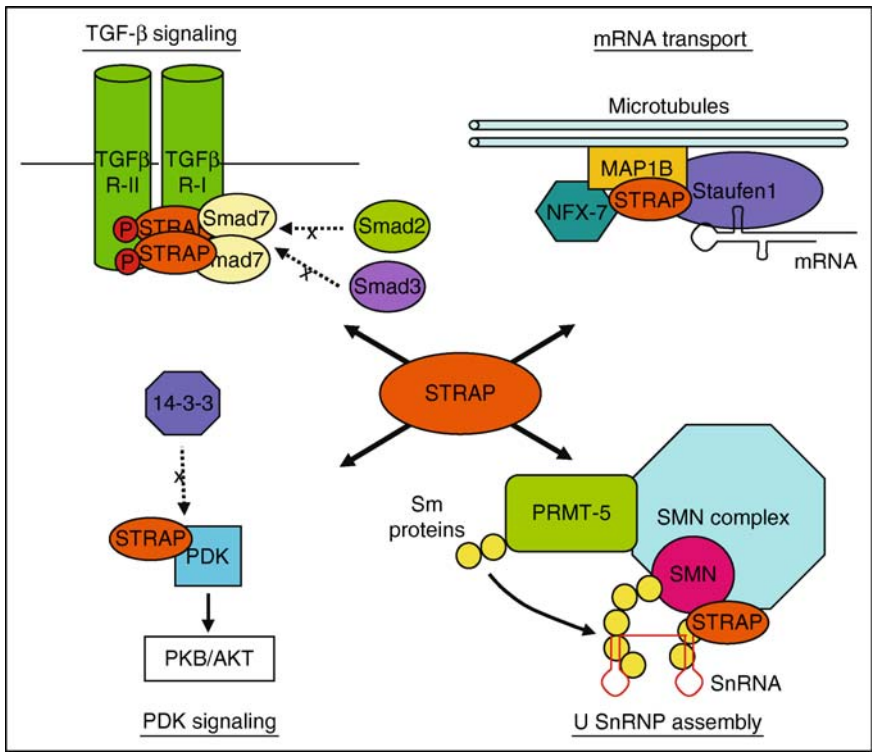
Mechanisms

STRAP binds with both TβRI and TβRII in a ligand independent manner. It synergizes specifically with Smad7, but not with another inhibitor Smad6, in the inhibition of TGF-β signaling. STRAP stabilizes the association between Smad7 and activated receptor complex, thus assisting Smad7 in preventing phosphorylation and activation of Smad2 and Smad3 by the receptor complex. Though Smad6 is also shown to interact with STRAP, this association does not seem to interfere with bone morphogenic protein (BMP) signaling in which Smad6 acts as an inhibitor. STRAP inhibits TGF-β-induced nuclear translocation of Smad2/3 and Smad4 and as a result, activation of TGF-β responsive reporter genes including *plasminogen activator inhibitor 1 (PAI-1)* and ►$p21^{Cip1}$ is abrogated. Downregulation of $p21^{Cip1}$ by STRAP leads to hyperphosphorylation of ►retinoblastoma protein (pRb). In vitro kinase assay demonstrated that overexpression of STRAP can induce extracellular signal-regulated kinase (MEK/ERK) activity in a TGF-β-independent manner. Activation of MEK/ERK pathway by endogenous STRAP was further confirmed by knocking it down using ►small interfering RNA (siRNA). Although STRAP is not a kinase, it may facilitate the activation of MAPK pathway by functioning as a chaperone for upstream kinases. Therefore, STRAP may inhibit activation and nuclear translocation of Smad2 and Smad3 by interacting with receptors and Smad7 and/or by activating MAPK/ERK pathway (Figs. 1 and 2).

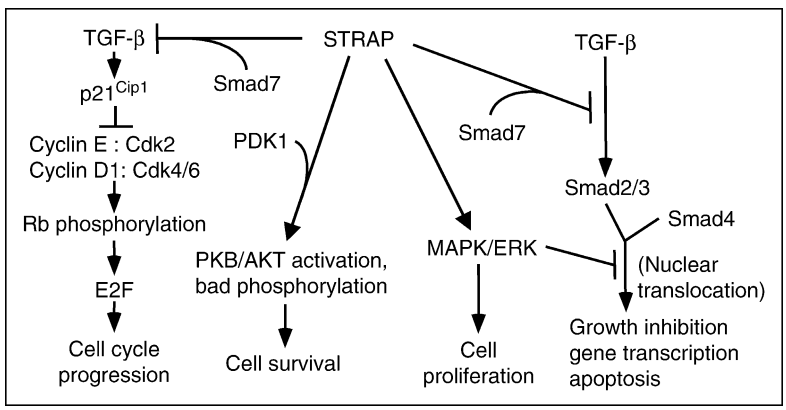
3-phosphoinositide-dependent protein kinase-1 (PDK1) has been shown to phosphorylate and activate many members of the protein kinase A, G, and C subfamily that include protein kinase B (PKB), p70 S6 kinase, protein kinase A and serum/glucocorticoid regulated kinase (SGK). STRAP interacts with the catalytic domain of PDK1 and this interaction is important for the modulation of PDK1 activity. The interaction of STRAP and PDK1 is inhibited by TGF-β and induced by insulin. This induction in binding by insulin is abrogated by wortmannin, a PI3K inhibitor. The mechanism behind PDK1 activation by STRAP is thought to be due to displacement of the 14-3-3 protein from PDK1 complex, which negatively regulates it (Fig. 1). The binding of PDK1 with STRAP also potentiates negative regulation of TGF-β mediated transcription by STRAP. This repression occurs through increased association of Smad7 with both STRAP and TβRI. Cell survival is induced by this interaction between STRAP and PDK1 probably through phosphorylation of Bad and attenuation of ►tumor necrosis factor-alpha (TNF-α) induced ►apoptosis.

STRAP is localized in both cytoplasm and nucleus. It colocalizes and associates with the oncogenic EWS protein in the nucleus through its NH_2 and COOH termini. STRAP inhibits the interaction between EWS and p300, a protein that is a transcriptional co-activator of EWS. This results in downregulation of EWS target genes like *ApoCIII* and *c-fos.* Although TGF-β has no effect on the interaction between STRAP and EWS, TGF-β-dependent transcription is inhibited by EWS.

Unr is an RNA binding protein that plays an important role in the initiation of HRV-IRES dependent translation of the animal picornavirus RNA, like the rhinoviral RNA. STRAP interacts with unr and is thought to be important during the translation stimulation activity. The macromolecular survival motor neuron (SMN) complex that helps in the assembly of spliceosomal Uridine-rich small ribonucleoprotein (U snRNP), contains the SMN protein and six additional proteins, named Gemin2-7, according to their localization (Fig. 1). STRAP seems to be involved in this assembly through its interaction with Gemin6 and Gemin7 as well as SmB, SmD2 and SmD3 components of the SMN complex. Although STRAP is localized in both cytoplasm and nucleus, it is present predominantly in the cytoplasm and may help the nuclear-cytoplasmic distribution of the SMN complex. The presence of STRAP in the SMN complexes was shown to be



Serine-Threonine Kinase Receptor-Associated Protein. Figure 1 STRAP in diverse biological functions through a role in protein complex assemblies in different signaling pathways.



Serine-Threonine Kinase Receptor-Associated Protein. Figure 2 STRAP may be involved in the progression of human cancers by activating multiple oncogenic pathways.

essential for U snRNP assembly. In contrast, STRAP was also shown not to be essential for this assembly by other groups.

STRAP along with EWS was shown to be present in the kinesin driven mRNA transport granules in the dendrites of murine neurons. In eukaryotes, the nuclear export of mRNA is mediated by nuclear export factor 1 (NXF1) receptors. As shown in mouse neuroblastoma N2a cells, NXF proteins bind to brain-specific microtubule associated proteins (MAP) such as MAP1B and also STRAP. Additionally, MAP1B also binds with STRAP. This assembly helps in the nuclear export of mRNA. In an independent setting, NXF-7 binds with MAP1B and STRAP only in the cytoplasm and colocalizes with

Staufen1 containing mRNA transport granules in the neurites of these cells (Fig. 1). As in other cases, STRAP seems to play a role in the multiprotein complex assembly required for both nuclear export of mRNA and the cytoplasmic transport of mRNA containing granules along microtubules.

STRAP is a substrate for SUMO4 (a novel member of the *SUMO* gene family) sumoylation. Although the significance of this is not yet known, SUMO4 sumoylation is predicted to have a role in the regulation of intracellular stress. It will be interesting to determine whether sumoylation of STRAP has any effect on its biological functions.

Clinical Aspects

Although STRAP seems to be involved in mutually independent biological functions, there is increasing clinical and experimental evidence suggesting that STRAP acts as an oncogene. The level of STRAP is found to be altered in different ►cancers. The protein level is elevated in 60% of ►colorectal, 78% of ►lung and 46% of ►breast carcinomas. Several lines of evidence suggest that carcinoma cells frequently lose the tumor suppressor function of TGF-β. Upregulation of TGF-β signaling inhibitors like STRAP and Smad7 and their synergistic function present a novel intracellular mechanism by which a portion of human tumors become refractory to antitumor effects of TGF-β. STRAP also exerts several other biological functions in a TGF-β independent manner that contribute to cell proliferation and inhibition of apoptosis (Fig. 2).

Ectopic expression of STRAP in different cell lines promotes cellular proliferation, induces anchorage-independent growth and increases tumorigenicity during in vitro and in vivo experiments. Downregulation of $p21^{Cip1}$, which results in hyperphosphorylation of pRb as well as activation of MAPK/ERK pathway, may contribute to the tumorigenic effects of STRAP during tumor formation and progression (Fig. 2). As noted earlier, STRAP also has an anti-apoptotic role probably through Bad phosphorylation and inhibition of TNF-α induced apoptosis. STRAP interacts with Ewing Sarcoma protein (EWS), an oncoprotein known to be involved in 80% of Ewing tumors after chromosomal translocations. Normal EWS protein is also upregulated in human cancers, which correlates with the upregulation of STRAP in 71% of colorectal cancers and 54% of lung cancers, suggesting a cooperative role of these two proteins in human cancers. In an attempt to determine whether STRAP is of prognostic value or predictive of ►chemotherapy benefit, *STRAP* gene was found to be amplified in 23% of colorectal tumors and amplification of STRAP in patients without adjuvant chemotherapy was found to exhibit better prognosis. These patients had a worse survival when treated with ►adjuvant therapy when compared with patients without chemotherapy. In contrast, patients carrying tumors with diploidy or deletion of STRAP benefited from the treatment. These results suggest that STRAP is an unfavorable prognostic marker for 5-FU-based adjuvant chemotherapy.

Taken together, STRAP appears to facilitate multiple steps in the process of tumorigenesis and possibly during ►metastasis, and it could be a potentially important drug target for therapeutic intervention in human cancers.

Serological Analysis of cDNA Expression Libraries

Definition

SEREX; A method to identify cancer-specific antigens based on screening of cDNA expression libraries with serum from cancer patients.

►Cancer-Germline (CG) Antigens

Seropositive

Definition

Indicative of the presence of an antibody to a particular antigen in a patient's blood.

Serotonin

Definition

5-hydroxytryptamine, 5-HT; Is a neurotransmitter synthesized in specific nerve cells (serotonergic) in the central nervous system (CNS) and is believed to play an important role in the regulation of mood, sleep, emesis (vomiting), sexuality and appetite.

►Fluoxetine

Serotypes

Definition

A taxonomic subgroup of a microorganism or virus determined by the antigens expressed.

►Oncolytic Adenovirus

Serpin

Definition

Serine protease inhibitor – a group of structurally related proteins, many of which inhibit proteases.

►Maspin

Sertoli Cell

Definition

Tall columnar cells found in the mammalian testis closely associated with developing spermatocytes and spermatids. Probably provide appropriate microenvironment for sperm differentiation. Its main function is to nurture the developing sperm cells through the stages of spermatogenesis. Because of this, it has also been called the "mother cell." It provides both secretory and structural support.

Sertoli-Leydig Cell Tumor

Definition

Synonym Arrhenoblastoma; Is a rare cancer of the ovaries. The cancer cells produce and release high level of the a male sex hormone testosterone, which may cause the women to develop male physical characteristics, including facial hair and a deep voice. While the tumor can occur at any age, it develops most often in young adults.

►Ovarian Tumors During Childhood and Adolescence

Serum

Definition

The clear liquid that separates from the blood when it is allowed to clot. This fluid retains any ►antibodies that were present in the whole blood.

Serum-Ascites Albumin Concentration Gradient

Definition

Is a parameter of pressure reflecting presence or absence of portal hypertension. It is calculated by subtracting the albumin concentration of the ascitic fluid from the albumin concentration of a serum specimen obtained on the same day. If the gradient is less than 1.1 g/dL, portal hypertension can be ruled out.

►Acites

Serum Biomarkers

Andreas F. Hottinger, Adília Hormigo
Department of Neurology, Memorial Sloan-Kettering Cancer Center, New York, NY, USA

Synonyms

BR 27-29; CYFRA 21-1; Hydroxybutyrate dehydrogenase; Gelatinase B; Breast regressing protein 39 Kd;

brp-39; Chitinase-3-like-1; CHI3L1; Chondrex; Human cartilage glycoprotein-39; HC gp39; 8-kDa heparin-binding glycoprotein; Gp38k; 40 kDa mammary gland protein; MGP-40

Definition

Cancer ►biomarkers are usually proteins detected in the blood, urine or other body fluids that are either produced by the tumor itself or in response to the presence of cancer. Ideally, biomarkers should allow at least one of the following: (i) early cancer detection by screening a healthy or high-risk population, (ii) help confirm the diagnosis of cancer or of a specific type of cancer, (iii) predict prognosis, (iv) monitor treatment response or (v) detect early recurrence.

Characteristics

Most biomarkers are not specific for tumors or organs and their levels may rise in other diseases. The diagnostic value of a tumor marker will depend on the prevalence of a disease in a population group and on its specificity (percentage of normal individuals without disease for whom a negative result is obtained) and sensitivity (percentage of tests which are correctly positive in the presence of a tumor). A cancer biomarker should be measured at a low cost, by a widely available assay with reproducible results in a specimen that is easy to access.

We are interested in developing biomarkers for ►brain tumors. Response to treatment of a ►brain tumor is evaluated by noninvasive imaging. This may be unreliable when assessing novel cytocidal drugs, distinguishing between disease ►progression or radionecrosis and predicting malignant transformation from low to high-grade glioma. ►YKL-40, MMP-9 and ►lactate dehydrogenase (LDH) are potential ►biomarker candidates. Monitoring circulating endothelial and progenitor cells as well as markers of this process including basic fibroblast growth factor and stromal cell-derived factor 1α may help determine treatment effect. As recent methods such as proteomics are utilized, new candidate proteins will be screened as potential biomarkers for a variety of cancers.

Alpha-Fetoprotein (AFP)

►Alpha-fetoprotein (AFP) is a fetal serum protein that shares sequence homology with albumin. It is normally synthesized during gestation by liver, yolk sac, and gastrointestinal tract. Following birth, AFP rapidly clears from the circulation. It may be elevated in patients with cirrhosis, viral hepatitis, drug or alcohol abuse as well as pregnancy, and may be used for screening of fetal spinal cord defects and placental disease.

Serum levels of AFP are elevated in up to 80% of patients with ►hepatocellular carcinoma (HCC). Changes in serum AFP levels reflect the course of disease. In patients with cirrhosis, elevation of serum AFP may be increased for up to 18 months before symptoms of HCC manifest and may be used to assist in the diagnosis. An elevation of AFP greater than 400 ng/mL is predictive for HCC with a specificity >95%. In the setting of cirrhosis and a growing liver mass, many centers use a level greater than 1,000 ng/mL as presumptive evidence of HCC and do not require a biopsy.

In men with nonseminomatous germ cell tumors (NSGCT), AFP is produced by yolk sac (endodermal sinus) tumors and, less often, embryonal carcinomas. In addition, up to 80% of mediastinal NSGCTs are associated with elevated serum AFP, regardless of histologic subtype. Whereas only 10–20% of stage I tumors express elevated levels of AFP, 40–60% of disseminated NSGCT express abnormal levels of AFP. Although these markers may be helpful for the initial diagnosis of a testicular cancer and for prognostication, their main utility is for follow-up of disease status (Table 1).

Beta Subunit of Human Chorionic Gonadotropin (β-hCG)

►Beta subunit of human chorionic gonadotropin (β-hCG) is normally produced by the placenta and human fetal tissue. Elevated serum β-hCG is most commonly associated with pregnancy, gestational trophoblastic disease and germ cell tumors. It can also be found in hypogonadal states and with marijuana use. β-hCG and AFP are elevated in up to 85% of patients with germ cell tumors, but only in about 20% of those with stage I disease. In patients with extragonadal or metastatic disease, highly elevated serum levels of β-hCG or AFP can establish a diagnosis of nonseminomatous germ cell tumor instead of biopsy. Serial measurements of β-hCG every 2–3 months for 1 year following treatment is important as elevation is often the first sign of recurrence, indicating the need to restart treatment. β-hCG is also used to diagnose and monitor response to treatment of gestational trophoblastic disease (Table 1).

Cancer Antigen 15-3 (CA 15-3)

Elevated ►cancer antigen 15-3 (CA 15-3) levels may be found in patients with ►breast cancers, and with much less specificity and sensitivity in patients with ►ovarian, ►lung, or ►prostate cancers. Increased levels may be associated with pregnancy and lactation, benign breast or ovarian disease, endometriosis, pelvic inflammatory disease, and hepatitis.

Because of a lack of sensitivity for early disease detection and lack of specificity, It has not been approved for screening of early breast cancer. However, high preoperative serum levels of CA 15-3 are associated with adverse patient outcome. CA 15-3, like

Serum Biomarkers. Table 1 Tumor markers

Tumor marker	*Primary tumor* and other cancers	Other conditions with elevated levels	Use of tumor marker	
			Diagnosis	Monitoring of treatment response
AFP	*Hepatocellular carcinoma, nonseminomatous germ cell tumor*, gastric, biliary and pancreatic cancer	Cirrhosis, viral hepatitis, pregnancy	Yes (poorly differentiated cancer of unknown origin, patients with cirrhosis and a liver mass)	Yes
β-hCG	*Nonseminomatous germ cell tumors, gestational trophoblastic disease*, gastrointestinal cancer (rare)	Hypogonadal states, marijuana	Yes (poorly differentiated cancer of unknown origin, gestational trophoblastic disease)	Yes (nonseminomatous germ cell tumor and gestational trophoblastic disease)
CA 15-3	*Breast*, ovarian, lung, or prostate cancer	Benign breast disease, benign ovarian disease, endometriosis, pelvic inflammatory disease, and hepatitis	No	No (except in selected situations, i.e. follow-up by conventional clinical procedures not possible)
CA 19-9	*Pancreatic and biliary tract*, colon, eosophagal and pancreatic cancer	Pancreatitis, biliary disease, cirrhosis	Yes (selected pancreatic masses)	No
CA 27-29	*Breast*, stomach, ovary, lung, or prostate cancer	Benign breast or ovarian disease, endometriosis, pelvic inflammatory disease, and hepatitis	No	No (except in selected situations, i.e. follow-up by conventional clinical procedures not possible)
CA 125	*Ovarian*, endometrium, fallopian tubes, pancreas, breast, colon and lung cancer	Menstruation, pregnancy, endometriosis, pelvic inflammatory disease, liver disease, pancreatitis, peritonitis and inflammation of the pleura	Yes	Yes
CEA	*Colorectal*, breast, lung, stomach, pancreas, bladder, medullary thyroid, head and neck and liver cancer, lymphoma melanoma	Tobacco, peptic ulcer, inflammatory bowel disease, pancreatitis, hypothyroidism, cirrhosis, biliary obstruction	No	Yes
PSA	Prostate cancer	Prostatitis, benign prostate hypertrophy, prostate trauma, after ejaculation	Yes	Yes
YKL-40	Glioblastoma multiforme, ovarian and endometrial cancer	Inflammatory disease	No	No

►carcinoembryonic antigen (CEA) and ►cancer associated antigen 27-29 (CA 27-29), are most useful for monitoring treatment response in women with breast cancer, especially in advanced disease. Serial determinations of tumor markers after primary treatment can detect recurrent/metastatic disease with lead times of 2–9 months over clinical symptoms. However the clinical value of this lead-time remains to be determined.

The ASCO guidelines do not recommend serial monitoring of CEA, CA 27-29 or CA 15-3 after primary therapy, except in selected situations, where patients cannot be followed by conventional diagnostic techniques.

Cancer Associated Antigen 19-9 (CA 19-9)

►Cancer associated antigen 19-9 (CA 19-9), an intercellular adhesion molecule, is an epitope of sialyated Lewis A blood group antigen. Elevated serum levels of CA 19-9 are found typically in patients with ►pancreatic and biliary tract cancers, and less often in ►gastric, ovarian, ►colorectal, lung, breast and ►uterine cancer. Elevated levels of CA 19-9 are also found in acute cholangitis, cirrhosis or other cholestatic diseases. Five percent of the population is genotypically Lewis-null blood type and will never produce CA 19-9 antigen, even in the presence of tumoral disease. The sensitivity and specificity for pancreatic cancer has been estimated to be 80–90%. These values correlate with tumor size so that CA 19-9 has limited value in identifying patients with small surgically resectable cancers (Table 1).

CA 27-29

Cancer antigen 27-29 (synonym: BR 27-29) is a normal epithelial cell mucin-1 (MUC1) apical surface glycoprotein. Elevated serum levels are highly associated with breast cancer. However they can also be found in cancers of ►colon, ►stomach, ►kidney, ►lung, ►ovary, ►pancreas, ►uterus and ►liver and in a number of noncancerous conditions, including first trimester pregnancy, endometriosis, ovarian cyst, benign kidney, liver and breast disease. Therefore, it has no role in breast cancer screening. Serum CA 27-29 levels are elevated in approximately one third of women with early-stage breast cancer (stage I or II) and in two thirds of women with stages III or IV. There is no agreement regarding the ability of CA 27-29 to detect asymptomatic recurrence after curative treatment. Serial monitoring is currently not recommended by the ASCO guidelines (Table 1).

CA-125

►CA-125 is a glycoprotein that is expressed by celomic epithelium of ovaries, fallopian tubes, endometrium and uterine cervix. Up to 90% of ovarian cancers are celomic epithelial carcinomas and overexpress CA 125. This glycoprotein can be detected in most endometroid, serous and clear cell ovarian carcinomas. Mucinous tumors however express this antigen less frequently. Serum levels of CA 125 may also be elevated in cancers of endometrium, fallopian tubes, pancreas, breast, colon and lung. Non-cancerous conditions with elevated CA 125 levels include menstruation, pregnancy, endometriosis, pelvic inflammatory disease, liver disease, pancreatitis, peritonitis and inflammation of the pleura. CA-125 is an important tumor marker for the diagnosis of epithelial ovarian cancer although it is not perfectly sensitive or specific for ovarian cancer. CA 125 can be used clinically to determine response to treatment and predict relapse and survival (Table 1).

Carcinoembryonic Antigen (CEA)

CEA is a normal mucosal cell oncofetal glycoprotein involved in cell adhesion. It is overexpressed in gastric, ►pulmonary, breast, pancreatic and predominantly ►colorectal adenocarcinomas. It may also be elevated in the serum of heavy smokers and patients with ulcerative colitis, pancreatitis and cirrhosis. Its role as a screening tool remains uncertain because of poor sensitivity and specificity. In patients with established disease, the absolute serum level of CEA correlates with disease burden and has prognostic value. After complete resection, elevated preoperative levels of CEA return to baseline and persistently elevated levels should warrant a search for residual tumor. CEA serum levels should be checked every 3 months for at least 3 years in patients with stage II or III colon cancer if the patient is a candidate for re-resection because elevated levels give a 1.5–6 months lead-time for detection of recurrence detection in comparison to other methods such as imaging. Early detection of asymptomatic recurrence increases the likelihood of a subsequent complete resection (Table 1).

Cytokeratin 19 Fragments

CYFRA 21-1 is a soluble fragment of cytokeratin 19 expressed in normal squamous cells. Elevated serum concentrations are found in tumors of squamous origin, including lung and are associated with short patient survival. The sensitivity of ►cytokeratin 19 fragments (CYFRA 21-1) depends on the histological type, being lowest for small cell lung cancer (about 16–40%). It is not used in early detection or monitoring of disease and has not been incorporated in the ASCO guidelines for patients with lung cancer.

Lactate Dehydrogenase (LDH)

Lactate dehydrogenase (LDH) is an ubiquitous enzyme that catalyses the conversion of pyruvate and lactate with concomitant interconversion of NADH and NAD+. Increased serum levels of LDH have been shown in a number of cancers, including ►melanoma, ►lymphoma, ►germ cell tumors and ►small cell lung cancer. Elevated levels of LDH can also be caused by a number of non-cancerous conditions, including heart failure, hypothyroidism, anemia, as well as lung and liver diseases.

Matrix Metalloproteinase-9 (MMP-9)

►Matrix metalloproteinase-9 (MMP-9) is a member of the zinc-dependent homologous proteinase family that degrades extracellular matrix proteins, such as cell adhesion receptors, chemokines, growth factors and their receptors and protease inhibitors. They are implicated in proliferation of endothelial and hematopoietic stem cells by inducing the release of kit ligand.

MMP-9 expression is elevated in most tumor tissues, including ovarian, thyroid, hepatocellular and gastrointestinal carcinoma. Expression of MMP-9 has been detected in both glioma and its endothelial cells. Increasing levels of MMP-9 as measured by in situ hybridization and immunohistochemistry correlate with higher grade gliomas. In GBM patients, serum levels of MMP-9 are significantly higher in patients with radiologic evidence of disease compared to patients whose disease is inactive. It is a potential future biomarker.

Placental Alkaline Phosphatase (PLAP)

Placental isoenzyme of PLAP is increased in 30% of ovarian cancer (especially serous cystadenocarcinoma), as well as cancers of endometrium, lung, breast and 40% of seminomas (75% in metastatic seminoma). Smokers may also have elevated PLAP levels.

Prostate-Specific Antigen (PSA)

►Prostate-specific antigen (PSA) is a glycoprotein that is expressed by normal prostate tissue and is overexpressed in prostate cancer. It is a sensitive and specific marker for this cancer. Levels of PSA depend upon the age and race of the patient. The predictive value for cancer is 20–30% if serum levels are greater than 4 ng/mL and 50% for values exceeding 10 ng/mL. However 20–30% of patients with prostate cancer have levels within the normal range. The American Urological Association recommends that serial PSA measurements be obtained routinely to detect early recurrence in men who have undergone primary therapy for localized disease. PSA levels should decrease and remain undetectable after radical prostatectomy or at low levels following radiation therapy and cryotherapy. The nadir serum PSA and percent PSA decline at 3 and 6 months predict progression-free survival in men with metastatic prostate cancer treated with androgen deprivation. The degree of PSA decline following second-line treatment of metastatic disease correlates with disease survival (Table 1).

YKL-40

YKL-40 is a member of the mammalian chitinase-like proteins that is highly conserved among different species. It has no enzymatic activity due to amino acid substitutions at the catalytic site. *In vitro* studies suggest that YKL-40 plays a role in proliferation and differentiation of malignant cells, by decreasing apoptosis of cancer cells, stimulating angiogenesis, and inducing proliferation of fibroblasts surrounding the tumor and remodeling of the extracellular matrix. Elevated serum values of YKL-40 have been reported in a variety of cancers, including breast, colon/►rectum, ovary, lung, kidney, glioblastoma, and melanoma. YKL-40 levels may also be increased in other diseases with an inflammatory component.

In a microarray analysis of brain tumors, YKL-40 was found to be highly overexpressed in a subset of patients with glioblastoma multiforme (GBM) in comparison to low-grade gliomas and detected in serum by ELISA. In a prospective study of 143 patients with high-grade gliomas, we found that serum levels of YKL-40 were increased in patients with active disease compared to those with absence of radiographic disease. Elevated levels of YKL-40 also correlated with shorter survival in GBM patients.

In patients with endometrial or ovarian cancer, elevated preoperative levels of YKL-40 may identify a subset of high-risk patients with worse clinical outcome. Studies in a larger sample population are underway to further evaluate its potential role as a biomarker YKL-40.

Severe Combined Immunodeficiency Disease

Definition

►SCID; ►Severe Combined Immunodeficient Mice represent a model for the human disease.

Severe Combined Immunodeficient Mice

Definition

Scid mice; Spontaneous mutant mice that lack B- and T-cells. As a consequence, scid-mice are severely immunocompromised. Scid-mice do not reject implanted human cells as would normal mice. Hence, these mice allow investigators to study the growth and progression of human tumors in an *in vivo* model.

►Cystatins

Severe Hypoxia

►Anoxia

Sex Cord Stromal Tumors

Definition

SCST; Primary ovarian neoplasms derived from the stromal component of the ovary. During childhood and adolescence, SCSTs most frequently present as juvenile ►granulosa cell tumors or Sertoli-Leydig cell tumors (synonym gynandroblastoma). Less frequent types include sclerosing stromal cell tumor, sex cord stromal tumor with annular tubules, steroid tumors and Brenner tumors.

►Brenner tumor
►Sex cord stromal tumors
►Gynandroblastoma
►Sertoli-Leydig cell tumor
►Ovarian Tumors During Childhood and Adolescence

Sex Hormone

Definition

A chemical substance produced by a sex gland or other organ that has an effect on the sexual features of an organism. Like many other kinds of hormones, sex hormones may also be artificially synthesized.

►Androgens
►Estrogens

Sex Hormone Dependent Cancers

Definition

Prostate cancer is first dependent on androgens (e.g., testosterone) for growth and may become later hormone-independent. Breast cancer is mainly sex hormone-dependent (estrogen and progesterone), but some breast tumors are hormone-independent and are more difficult to treat.

►Gonadotropin-Releasing Hormone

Sezary Syndrome

Elizabeth Knobler[1], Robert Knobler[2]
[1]Department of Dermatology, Columbia College of Physicians and Surgeons, New York, NY, USA
[2]Department of Dermatology, Medical University of Vienna, Vienna, Austria

Definition

Sezary syndrome (SS), named after the French dermatologist Albert Sezary (1880–1956), is a variant of cutaneous T cell lymphoma (CTCL), a malignancy of mature T-helper cells involving the skin and blood. It is defined by the presence of an ►exfoliative erythroderma, lymphadenopathy, and evidence of neoplastic cells in the skin and blood. "Sezary" cells refer to enlarged mature CD4+ lymphocytes with hyperconvoluted nuclei. Historically, the presence of Sezary cells in the peripheral blood was a defining criteria for SS. However, an increased number of these cells can be found in several benign dermatologic conditions and is no longer the agreed upon standard. The presence of a clonally expanded population of CD4+ cells resulting in an increased CD4/CD8 >10 in the blood is considered a more accurate measure. Immunophenotypic abnormalities which support a diagnosis of SS include decreased/absent expression of T-cell antigens CD2, CD3, CD5, and CD7. The

characteristic histologic features of involved skin seen in other forms of CTCL are often not present in SS and thus may not be a useful tool in its diagnosis. The etiology of SS is unknown.

Characteristics

SS is a rare disease making up less than 5% of all CTCLs. It occurs primarily in adults over the age of 60 with predominance in males.

Clinical features of SS include intractable, debilitating pruritus with an exfoliative erythroderma, edema, ►lichenification, thickening and fissuring of the palms and soles, nail dystrophy, hair loss, and ectropion. Malignant cell infiltrates of the skin can often lead to disfiguring features in the face (known as "leonine faces") and body.

Staging and Treatment

Staging of SS as CTCL stage III or IV depends on the degree of lymph node involvement and evidence of solid organ spread. With SS representing an advanced stage of the disease, the prognosis is usually poor with a median survival of 2–4 years. Immune compromise in these patients leads to increased bacterial infection and often to the demise of the patient.

Since SS involves both the skin and blood, systemic treatment is necessary to control the disease. The most common therapeutic tools used singly or in combination include: ►extracorporeal photochemotherapy (photopheresis), interferon alpha, bexarotene, denileukin diftitox, radiation with total skin electron beam therapy, leukeran, and gemcitabine.

sFRP

Definition

Secreted frizzled related protein; family of proteins with a cysteine-rich domain (CRD) related to the Fz receptor CRD; in most cases inhibit Wnt signals by binding to Wnt proteins; often downregulated in cancer.

►Wnt Signaling

SH2/SH3 Domains

Joseph H. McCarty
M. D. Anderson Cancer Center,
Houston, TX, USA

Synonyms

Src homology 2; SH2/src homology 3; SH3 domains

Definition

Proteins containing SH2/SH3 domains play critical roles in regulating the formation of intracellular signal transduction complexes. SH2 and SH3 domains recognize amino acid motifs containing phosphotyrosine and polyproline, respectively. Signaling pathways activated by SH2/SH3 domains subsequently lead to cellular responses including differentiation, proliferation and migration.

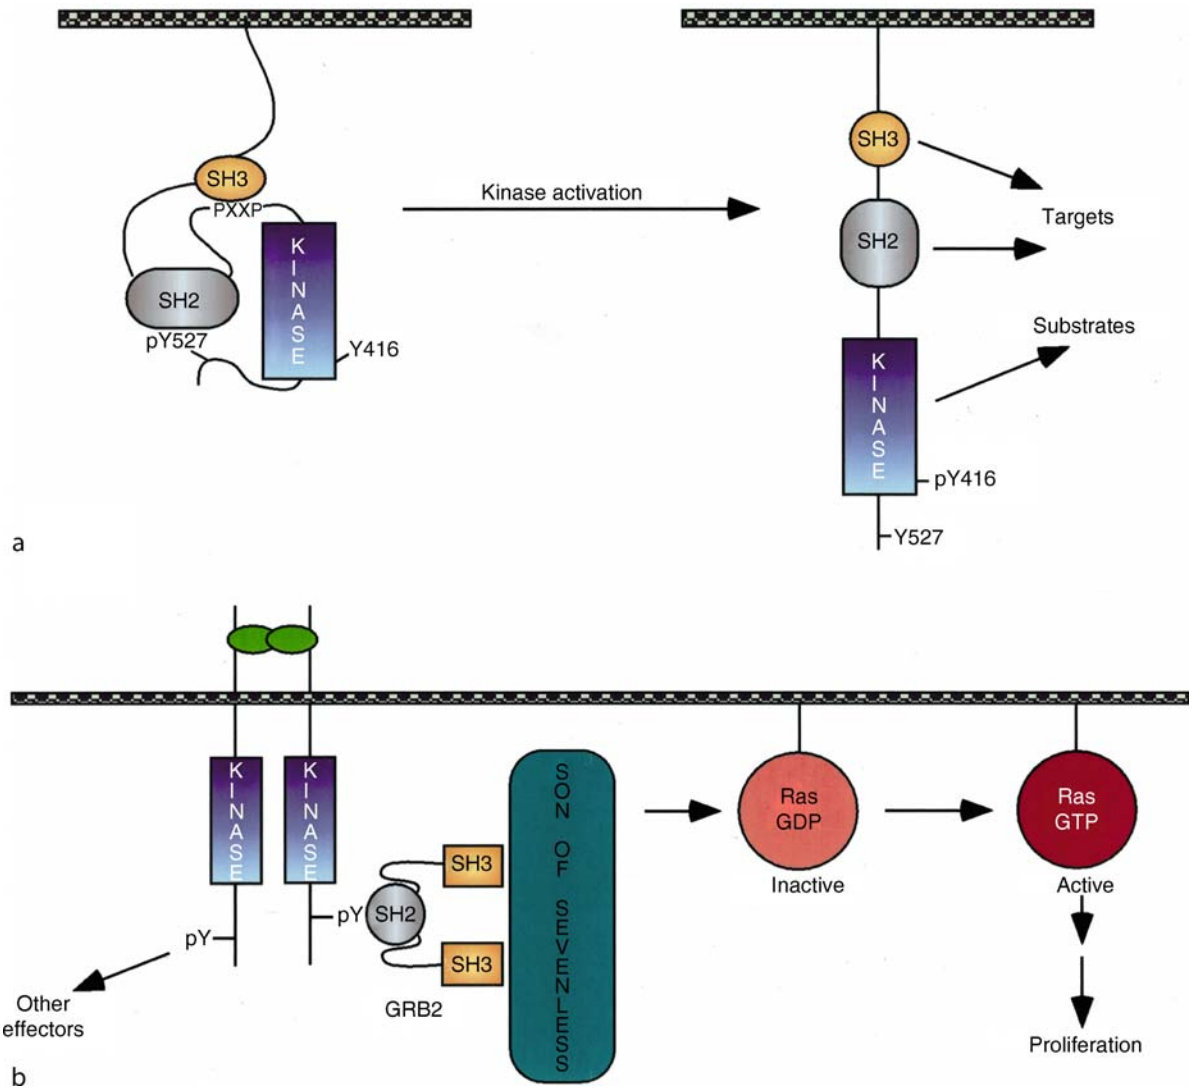
Characteristics

SH2/SH3 domains were originally identified as conserved sequences found in the Src tyrosine kinase and a variety of other proteins. These domains are now known to reside in hundreds of functionally diverse signaling molecules, ranging from tyrosine kinases and phosphatases to phospholipases and transcription factors.

- SH2 domains are composed of ~100 amino acids organized into a modular structure that recognize phosphotyrosine-containing sequences on protein tyrosine kinases and their substrates. The specificity of interaction is generally determined by the 3–4 amino acids C-terminal to the phosphorylated tyrosine position on the target protein. SH2 domain-mediated signaling events lead to cellular responses ranging from DNA synthesis to transcriptional activation.
- SH3 domains are about 50 amino acids in size and bind to target proteins containing the proline-rich consensus sequence PXXP (where P is proline and X is any amino acid). Unlike SH2 domains, SH3 domains generally remain constitutively associated with their cognate ligands, making their function less dependent on tyrosine phosphorylation. Protein interactions mediated by SH3 domains have been implicated in cytoskeletal alterations necessary for changes in cell morphology and motility.

In response to extracellular cues, SH2/SH3 domains act both intramolecularly and intermolecularly to regulate signal transduction. Their functions are well illustrated by two classical signaling cascades exemplified by the Src protein tyrosine kinase pathway and the Ras GTPase pathway.

Src is a membrane bound intracellular tyrosine kinase that contains one SH2 and one SH3 domain (the kinase domain was originally termed the SH1 domain). The post-translational phosphorylation of Src on tyrosine 527 negatively regulates kinase activity. This inhibition is the result of complex intramolecular interactions between phosphotyrosine 527 and the SH2 domain, as well the SH3 domain and a proline-rich central region (see Fig. 1). Concomitant dephosphorylation of tyrosine 527 and phosphorylation of tyrosine 416 relieves this steric block. This allows for the association of the SH2 and SH3 domains with target proteins and enhancement of Src catalytic activity. Thus, Src SH2/SH3 domains both positively and negatively regulate protein tyrosine kinase



SH2/SH3 Domains. Figure 1 Pathways exemplifying SH2/SH3 domain functions. (a) Activation of the Src tyrosine kinase domain serves as an example of both intermolecular and intramolecular functions for SH2/SH3 domains. The Src SH2/SH3 domains serve to inhibit the kinase activity. Dephosphorylation of phosphotyrosine 527 and phosphorylation of tyrosine 416 results in a Src conformational change. The tyrosine kinase is activated and the protein associates with downstream substrates via its SH2 and SH3 domains. (b) The activation of the Ras GTPase by various receptor tyrosine kinases is a classic example of SH2/SH3 domains providing an intermolecular link between critical signal transduction components. Receptor autophosphorylation leads to re-localization of constitutively associated Grb2-Sos, leading to GTP exchange and Ras activation.

activity. Various protein tyrosine kinases utilize a similar mechanism to regulate their function.

The Ras GTPase is a membrane associated growth regulator, and mutated forms are found in many human tumors. When in its GTP-bound state, Ras is considered "on" and activates multiple downstream signaling pathways. In many cases growth factor stimulation of the Ras pathway occurs via the Grb2 SH2/SH3 protein (see Fig. 1). Grb2 is an SH2/SH3 "adaptor" protein, consisting of two SH3 domains flanking a central SH2 domain. The Grb2 SH3 domains constitutively associate with various proteins, including the son-of-sevenless (Sos) GTP exchange factor. Following growth factor stimulation, phosphotyrosine motifs on the activated receptors recruit the Grb2 SH2 domain. This event in part serves to re-localize the Grb2-Sos complex from the cytoplasm to the membrane, placing Sos in proximity to membrane-bound Ras and allowing the exchange of Ras-GDP for -GTP. Based on similar observations made for other SH2/SH3 adaptor proteins, intracellular re-localization may be a common mechanism used to activate a variety of enzymatic pathways.

These examples illustrate important aspects of SH2/SH3 domain function in response to a specific stimulus. It is clear, however, that most signal transduction pathways are interconnected, and that a single extracellular cue can elicit a response involving hundreds of effector proteins. Identifying how various extracellular cues individually and combinatorally affect signaling pathways will be an important challenge for fully understanding SH2/SH3 domain functions.

Clinical Relevance

Many tumor cells possess amplifications and/or mutations in genes encoding components of the tyrosine kinase machinery. Therefore, it follows that proteins regulating cell proliferation have become central targets for drug discovery. The crystallographic structures of many SH2 and SH3 domains in complex with their various ligands has allowed for the rational design of highly specific peptidomimetic molecules. The challenge is to utilize drugs that affect only the pathological action of the specific targeted molecule, while enabling normal signal events to proceed unperturbed. For example, one can envision using SH2 and/or SH3 domain antagonists to inhibit the proliferative capacity of cells transformed due to hyperactivated or aberrantly expressed protein tyrosine kinases.

Importantly, ongoing genomic analyses will undoubtedly identify new SH2/SH3 domain-containing proteins. Characterizing the functions of these newly identified effectors and linking them to the pathogenesis of specific cancers and other disease states will be a worthwhile goal. The use of novel proteomic techniques in combination with classical cell biology will greatly aid this process.

SH2/src Homology 3

►SH2/SH3 Domains

SH2 Domain

Definition

Src homology (SH) 2 domain; Is comprised of ∼100 amino acid residues capable of binding specifically to a phosphorylated tyrosine residue in a signaling protein. Its binding specificity is determined through interactions between an SH2 sequence and a target sequence of a phosphorylated tyrosine and additional amino acid residues mainly from −1 to + 3 positions surrounding the phosphotyrosine.

►SH2/SH3 Domains

SH3 Domain

Definition

Src-homology domain 3 is a protein domain of about 50 amino acid residues that binds to specific proline-rich sequences; Modular protein interaction domain commonly found in signal transduction proteins. Binds amino acid recognition sequences that include proline-X-X-proline in target proteins. Seen often in adapter proteins that coordinate the function of macromolecular complexes with the actin cytoskeleton.

►SH2/SH3 domains

SHANK

Definition

Refers to large adaptor proteins that can self-associate and bind a variety of different proteins. Best characterized in neurons where they serve to organize receptor proteins at the synapse, shank proteins are also found in epithelia cells where their function is currently unclear.

►Cortactin

Shark Cartilage

Aditya Bardia[1], Charles L. Loprinzi[2]
[1]Department of Internal Medicine, Mayo Clinic, Rochester, MN, USA
[2]Department of Oncology, Mayo Clinic, Rochester, MN, USA

Definition

A dietary supplement derived from cartilage obtained from sharks, commonly hammerhead (*Sphyrna lewini*) and dogfish (*Squalus acanthias*) sharks.

Characteristics

Shark cartilage is a popular dietary supplement that traditionally has been proclaimed to be able to prevent and/or treat established cancer. In the early part of the twenty-first century, it has been one of the ten most common dietary supplements used among cancer patients. It has been suggested that the widespread popularity of this product has partly contributed to an increase in shark fishing, with a resultant sharp, ≥75%, decline in the world shark population in the past 15 years.

Shark cartilage is available as a capsule (taken orally), powder (for oral use when mixed with juice or as an enema), and also as an intravenous preparation. The recommended doses can vary from 500 mg to several grams per day. The adverse effects are predominantly gastrointestinal, such as nausea, abdominal pain, and diarrhea, and even hepatitis. Given its potential anti-angiogenesis properties, it has been advised that pregnant females should not consume the product.

The popularity of shark cartilage soared in the early 1990s after a book (*Sharks Don't Get Cancer*) by William Lane postulated that sharks do not get cancer due to the high proportion of cartilage in their body, suggesting that shark cartilage has chemopreventive properties. The authors predicted that "As events and research continue to unfold, shark cartilage may prove to be the first momentous step towards preventing and conquering cancer." However, subsequent research has not substantiated this prediction. Moreover, sharks do develop cancers, although the rate of cancer incidence among sharks is unclear.

A number of studies have been conducted to evaluate the potential cancer treatment properties of shark cartilage. One of the first reports of a human trial was featured on the TV show "60 Minutes" wherein results from two trials were reported, receiving considerable media coverage. In one trial, researchers from Cuba claimed that 16 weeks of shark cartilage was effective in treating cancer in 3 of the 15 patients that received the treatment. In the other trial, researchers at Simone Protective Cancer Center (NJ) claimed 4 of the 20 cancer patients consuming shark cartilage showed partial or complete response with use of the product. However, these studies had serious methodological flaws (9), the results suggested only a small response rate (20%), and the results were never reported completely in a peer reviewed PubMed indexed journal. In a well designed phase II study, involving 60 patients with advanced cancer, 1 g/kg/day of shark cartilage was reported to be ineffective in reducing the progression of disease, to have no beneficial effect on quality of life, and to have substantial gastrointestinal toxicity in about 25% of the patients. Two other phase II studies reported similar negative results with the use of shark cartilage among cancer patients.

Likewise, no suggestion of efficacy of shark cartilage was seen in a relatively small randomized placebo-controlled, double-blinded clinical trial. Among the 83 patients involved in this trial (42 receiving shark cartilage and 41 receiving placebo), there was no difference in overall survival or quality of life among the two groups. The shark cartilage and its identical smelling, tasting, and appearing placebo were not well tolerated by the study patients, with ~50% of subjects stopping the study medication within a month of initiation. Given the presently available evidence, shark cartilage has generally been considered to be an ineffective agent for cancer and promotion of its use as an anti-cancer agent has been widely criticized.

While shark cartilage supplementation has been found to be ineffective as a chemoprevention or anti-cancer agent in clinical trials, laboratory research has identified a few compounds isolated from shark cartilage that could potentially have anti-angiogenesis properties. In the late 1970s, Langer et al. first isolated a factor from shark cartilage that was found to strongly inhibit the growth of new blood vessels toward tumors and thereby restricted tumor growth. Similar findings have been reported independently by other authors. One

of the standardized extract shark cartilage products obtained from dogfish (AE-941, or Neovastat) has been reported to be a promising agent. In a phase II trial among 80 patients with lung cancer, those receiving higher doses (>2.6 ml/kg/day) of AE-941 were reported to have better survival, compared to patients receiving lower doses (median, 6.1 months vs. 4.6 months; $P = 0.026$). Neovastat is postulated to exert its anti-angiogenesis effects by multiple effects, including inhibition of tissue metalloproteinases, modulation of VEGF (vascular endothelial growth factor), and enhancement of endothelial cell apoptosis. This product was tested in a large phase III lung cancer clinical trial funded by the United States National Cancer Institute. However, the early results of this trial did not support that this agent had any benefit.

Thus, in total, currently available study data do not support the efficacy of shark cartilage as a chemopreventive or anti-cancer agent. Given the lack of established efficacy, its toxicity, and the environmental impact related to harvesting sharks, the use of shark cartilage among patients with cancer should be discouraged.

Signal Sequence

Definition

Synonym signal peptide; Is a *N*-terminal, short (18–26) amino acid sequence that acts like a zip code in nascent polypeptides and determines their subcellular targeting. A signal sequence is a protein region with which a protein can be directed to the appropriate cellular compartment within a cell, they initiate co-translational transfer through the membrane of the endoplasmic reticulum (ER). Proteins are often synthesized in an immature version (pre-protein) that is larger than the mature functional form. This is due to the presence of N-terminal amino acid stretches, referred to as leader sequences. The pre-protein is a transient precursor, since the leader sequence is cleaved off during protein processing. This signal sequence is a short stretch of 15–30 amino acids that mediates the transfer of any attached polypeptide to the endoplasmic reticulum. it provides the means for the ribosomes to attach to the ER membrane (ER regions with associated ribosomes are called “rough ER.” As soon as the first few amino acids of the protein have been synthesized, the nascent protein chain can be co-translationally transferred to the membrane.

The signal hypothesis proposes that the N-terminus of a secreted protein has a signal sequence whose presence marks it for membrane insertion. Once the protein chain is well inserted into the membrane, the signal sequence is cleaved off by a protease within

the membrane and the protein can then enter or even pass through the membrane. This principle does not hold for nuclear proteins, which are synthesized in their mature form.

Signal Transducer and Activator of Transcription

►Signal Transducers and Activators of Transcription in Oncogenesis

Signal-Transducer Proteins

Definition

Proteins function as units in signaling pathways are described as signal-transducers. They have at least two "working parts," one involved in recognition of an input signal (receptor part) and the other in generation of an output signal (generator) recognized by the downstream components. Some signal transducer molecules can respond to additional input signals that modulate their function (modulator) or could, after a short period, terminate generation of the output signal (timer).

►Signal Transduction

Signal Transducers and Activators of Transcription in Oncogenesis

Ralf Buettner, Roy Garcia, Richard Jove
City of Hope National Medical Center and Beckman Research Institute, Duarte, CA, USA

Synonyms

STAT; signal transducer and activator of transcription

Definition

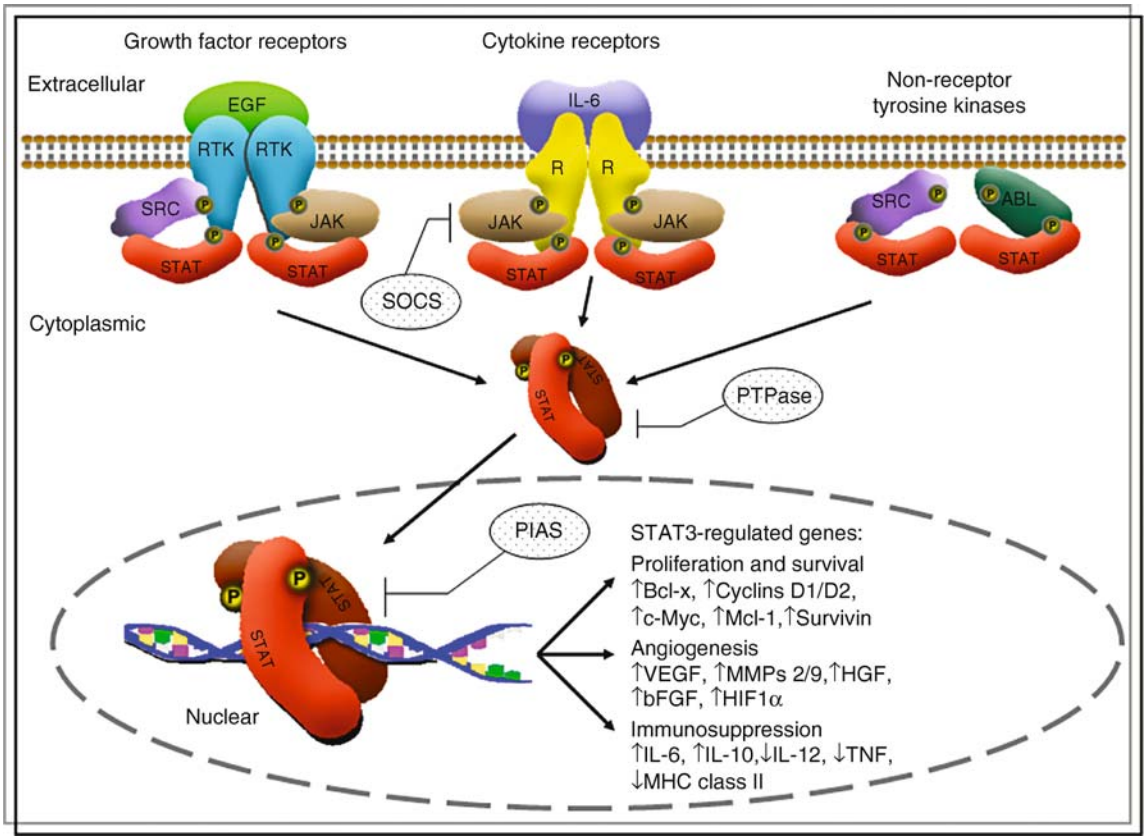
Signal transducer and activator of transcription (STAT) proteins comprise a family of latent ►transcription factors that reside in the cytoplasm and have been shown to control normal ►cytokine and ►growth factor-induced responses. In response to extracellular signals, such as cytokines or growth factors, STATs are activated through ►phosphorylation by ►tyrosine kinases. Subsequently, these activated dimers translocate (►translocation) into the nucleus where they bind to specific DNA sequences and regulate the transcription of cellular genes. Thus, STATs perform dual roles in transmitting receptor-generated signals from the cytoplasm to the nucleus and regulating cellular genes necessary for ►ligand-induced biological responses.

Characteristics

All multicellular organisms possess complex networks of molecular messengers that coordinate vital organ functions. Among the most common mechanisms used by multicellular organisms to ensure appropriate timing and duration of essential biological processes are production and secretion of cytokines and growth factors. Cytokines and growth factors control a wide variety of fundamental biological processes in diverse cell types, including immune responses, cellular differentiation, proliferation and programmed cell death (►Apoptosis; ►Apoptosis Signaling). Although differences exist between the biological processes and cell types regulated by cytokines and growth factors, these ligands possess some overlapping functions and share remarkably similar mechanisms of signal transmission. Cytokines and growth factors generally elicit a biological response by binding to receptor proteins located on the outer cell surface. Binding of these ligands to their specific receptors induces a change in the ability of the receptor to recruit and activate cytoplasmic signaling molecules that participate in signal transmission. Modulation of the activity of these cytoplasmic signaling proteins by the receptors initiates a cascade of biochemical signaling events, which ultimately lead to changes in nuclear gene expression that mediate the biological responses (►Signal Transduction). Cytokine and growth factor-induced processes are normally tightly controlled to ensure proper functioning. Aberrant functioning of these pathways results in deregulated signaling and is associated with development of a variety of pathological conditions including ►cancer.

STATs in Cytokine and Growth Factor Induced Signaling

In response to cytokine or growth factor-induced activation of signaling, cytoplasmic STATs become phosphorylated on specific tyrosine residues by receptors or receptor-associated proteins possessing tyrosine kinase activity (see Fig. 1) (►Receptor Tyrosine Kinases). Tyrosine phosphorylation of STAT proteins



Signal Transducers and Activators of Transcription in Oncogenesis. Figure 1 Constitutive activation of STATs by tyrosine kinases. Growth factors (e.g. EGF) and cytokines (e.g. IL-6) stimulate activation of receptor-intrinsic (RTK) or receptor-associated (JAK, Src) tyrosine kinases. Activated tyrosine kinases phosphorylate receptors to provide docking sites for unphosphorylated STATs. Once recruited, STATs themselves become tyrosine phosphorylated. Oncogenic tyrosine kinases such as SRC and ABL can also phosphorylate STATs independently of receptor engagement. Phosphorylated STAT dimers translocate to the nucleus, bind to specific DNA elements and regulate gene expression. In normal cells, STAT activation is transient and tightly regulated by inhibitory proteins, including PTPase, SOCS and PIAS. In cancer cells, constitutive activation of STATs, in particular Stat3 and Stat5, is associated with changes in the expression of genes that control fundamental cellular processes subverted in oncogenesis. RTK, receptor tyrosine kinase; R, receptor. See text for details. (Buettner et al. (2002) Clin Cancer Res 8(4):945–954 [2].)

allows STAT dimers to rapidly translocate into the nucleus. Once in the nucleus, STAT dimers bind to DNA and control the transcription of specific cellular genes. Under normal circumstances, the biological responses elicited by cytokines and growth factors are transient, and transmission of signaling is terminated through several inhibitory mechanisms, including (i) protein tyrosine phosphatases (►PTPase) that dephosphorylate and inactivate STATs, (ii) ►suppressor of cytokine signaling (►SOCS) family of proteins that prevent STAT activation by tyrosine phosphorylation, or (iii) protein inhibitors of activated STATs (►PIAS), a group of proteins that decrease transcription by binding to and thereby inhibiting STATs. While tyrosine phosphorylation of STAT proteins has been shown to be essential for cytokine-induced signals, activated cytokine receptors generally do not possess kinase activity and are not capable of directly phosphorylating STAT proteins on tyrosine. Cytokines induce activation of STATs indirectly through activation of receptor-associated tyrosine kinases of the Janus kinase (►JAK) family. After cytokine binding, STATs are phosphorylated by the receptor-associated JAKs, allowing signal transmission to proceed. Activation of STAT proteins has also been shown to be required for growth factor-induced cellular responses. However, the majority of growth factors that induce STAT activation bind to receptors that possess intrinsic tyrosine kinase activity, and tyrosine phosphorylation of STATs can be directly mediated by the activated receptor protein, receptor-associated JAK proteins or by additional non-receptor tyrosine kinases such as Src.

Bioactivity

Significantly, constitutive tyrosine phosphorylation and activation of STATs has been detected in cells that have undergone malignant ►transformation in response to expression of a variety of viral oncoproteins, which are often themselves constitutively activated tyrosine kinases (►Cell Transformation; ►Oncogene). Consistent with a role for STATs in oncogenesis, regulation of gene expression by one STAT family member, Stat3, has been shown to be required for induction of malignant transformation by the oncogenic Src tyrosine kinase. Furthermore, expression of a constitutively activated mutant of Stat3 can induce malignant transformation of specific cell types. These results demonstrate that, in addition to signals important to normal cellular functions, activated STATs can also transmit signals critical to oncogenic transformation.

STAT Activation During Progression of Human Cancer

Constitutive tyrosine phosphorylation and activation of STATs, in particular Stat3 and to a lesser extent Stat5, has been shown to occur frequently in a variety of human tumor types including leukemias, lymphomas, multiple myeloma, head and neck cancer, lung cancer, prostate cancer, renal cell carcinoma, colon carcinoma, melanoma and breast cancer. Frequent activation of specific tyrosine kinase signaling pathways, including activation of growth factor receptor tyrosine kinases, has also been detected in many of these tumor types. These findings suggest that constitutive activation of STAT proteins results from the constitutive activation of tyrosine kinases. Moreover, because STAT proteins control the transcription of nuclear genes involved in growth control, constitutive activation of STATs may transmit signals essential for oncogenic signaling and contribute to ►tumor progression. Among the genes that are regulated by STATs are genes involved in controlling cell cycle progression and programmed cell death (including ►Cyclins D1/D2, ►c-Myc, ►Mcl-1, ►BCL-x, and ►Survivin) (►Cyclin D; Myc Oncogene; Mcl Family; Survivin), genes that are involved in immunosuppression (interleukins-6, -10, -12, TNF, and ►MHC class II) (MHC), and genes that also participate in the regulation of angiogenesis (such as ►VEGF, MMPs 2 and 9, HGF, bFGF and HIF1α) (►Vascular Endothelial Growth Factor; Matrix Metalloproteinases; Fibroblast Growth Factors; Hypoxia Inducible Factor-1). Thus, constitutive activation of STATs – in particular Stat3 and Stat5 – in human tumors may contribute to progression of cancer by multiple mechanisms, including proliferation and survival of the tumor cell itself, induction of angiogenesis and suppression of immune cells in the tumor ►microenvironment (immunosuppression).

Targeting STATs for Cancer Therapy

Inhibition of STAT signaling has repeatedly been demonstrated to result in growth inhibition and induction of apoptosis in tumor cells harboring constitutive activation of Stat3 or Stat5. The observed dependence of certain tumors on constitutive STAT activation for survival has wide implications for cancer therapy, offering the potential for preferential tumor cell killing.

Targeting the Tumor Cell

Persistent Stat3 and Stat5 signaling within tumor cells directly participates in the development and progression of human cancers by either preventing apoptosis, inducing cell proliferation, or both. Targeting of tyrosine kinase activity upstream of STAT pathways has drawn special attention because of the recent development of tyrosine kinase-selective inhibitors. However, one potential draw-back of tyrosine kinase inhibitors is that they block multiple downstream signaling pathways in addition to STAT proteins, increasing the likelihood of undesirable toxicity. Since STAT activation is a point of convergence for many different tyrosine kinases, STATs themselves represent promising targets for the development of cancer drugs. One of the attractive features of STAT proteins for cancer therapy is that there are only two molecular targets, Stat3 and Stat5, as opposed to a multitude of tyrosine kinases. Antisense oligonucleotides and small-interfering RNA (►siRNA) that target STATs are just two of the many possibilities to interfere with aberrant STAT signaling (►Antisense DNA Therapy). Alternatively, small-molecule inhibitors are being developed to directly interfere with STAT proteins (►Drug Design). Recent progress has been made in design of short peptides, ►peptidomimetics and other non-peptide compounds that effectively block Stat3 dimerization and DNA-binding activity both *in vitro* and *in vivo*. Importantly, these compounds inhibit cell transformation mediated by activated Stat3 and provide the basis for development of novel drugs for potential cancer therapy.

Targeting the Tumor Microenvironment

Recent evidence suggests that Stat3-positive cancer cells can crosstalk with adjacent "normal" immune cells for the purpose of modifying the tumor microenvironment in favor of the cancer cell. Stat3-positive cancer cells can suppress the production and secretion of pro-inflammatory factors that otherwise would stimulate an anti-tumor immune response (►Inflammation; ►Inflammation in Cancer). At the same time, cancer cells can secrete immune-suppressive factors that act on immune cells. Some of the factors secreted by tumor cells, such as IL-6, IL-10 and VEGF, act on both tumor cells and adjacent immune cells by maintaining Stat3 activation in the tumor cell and simultaneously inducing Stat3 activation in immune cells. It has been shown

for many immune cells in the tumor microenvironment that Stat3 acts as a negative regulator of immune-stimulating molecules. Stat3 activation in immune cells has been found to inhibit the anti-tumor function of natural killer cells (NK), ►dendritic cells (DC), T-cells and ►macrophages, among other cell types (►Natural Killer Cells; Dendritic Cells; ►T Regulatory Cells; Macrophages). In the case of macrophages, for example, it has been demonstrated that ablation of both Stat3 alleles leads to increased levels of several pro-inflammatory cytokines similar to those found in cancer cells in which Stat3 signaling is inhibited. Moreover, simultaneous inhibition of Stat3 signaling in immune cells and tumor cells induces a more pronounced anti-tumor effect, demonstrating the additive nature of blocking Stat3 signaling in both tumor cells and normal cells of the tumor microenvironment. In addition to negatively regulating immune cell function, some of the factors secreted by Stat3-positive cancer cells, such as VEGF, bFGF, HGF and MMPs, are pro-angiogenic and facilitate tumor growth by increasing blood supply (tumor angiogenesis).

Summary

Because STATs play essential roles in regulation of cell proliferation and survival, the frequent activation of these proteins in human tumors suggests that they have essential roles in the malignant progression of human cancers. Furthermore, recent studies indicate that STATs also propagate signals between tumor and normal cells in the tumor microenvironment, thereby promoting tumor immune evasion and tumor angiogenesis Detection of constitutively activated STATs could provide an important marker for activation of oncogenic tyrosine kinase signaling pathways during tumor progression. Currently, characterization of the full complement of STAT-regulated genes that participate in growth regulation and tumorigenesis remains a very active and important area of investigation (►Microarray (cDNA) Technology). These studies have the potential to provide new information critical to understanding how fundamental cellular processes are subverted in tumor cells. Finally, activated STATs in human tumors provide promising targets for the design of novel therapeutics that block STAT functions involved in stimulation of proliferation, prevention of cell death, and induction of immune evasion and tumor angiogenesis. Early results in this area suggest that targeted inactivation of STAT proteins may be an effective approach to halting the growth of various types of human tumor cells. Inhibition of STAT signaling in tumors is predicted to impart therapeutic benefit by inducing growth arrest and apoptosis as well as suppressing tumor angiogenesis and immune evasion. However, targeting STAT proteins for therapeutic intervention in cancer remains to be fully explored.

Signal Transduction

David A. Frank
Dana-Farber Cancer Institute and Harvard Medical School, Boston, MA, USA

Definition

Signal transduction is the process by which information from extracellular stimuli is propagated within a cell to alter cellular function. These signals frequently modulate gene expression, but they may also directly regulate processes such as cellular survival, metabolism, and macromolecular synthesis.

Characteristics

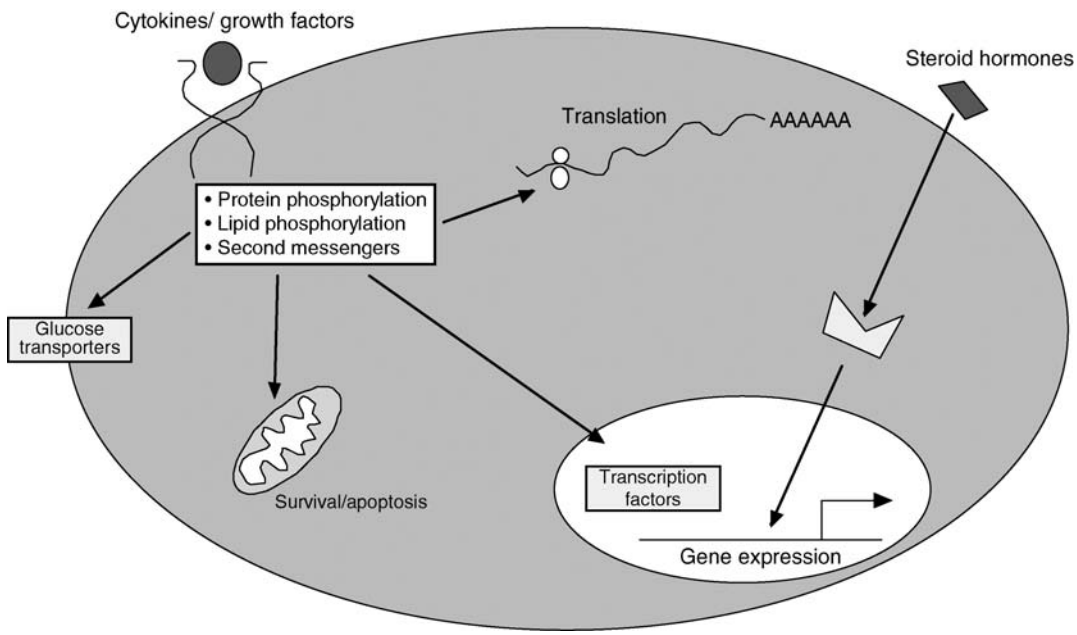
Starting shortly after fertilization, the phenotype of a cell becomes regulated largely by extracellular cues. Soluble factors such as cytokines and hormones, direct contact between cells, and interactions with the extracellular matrix all provide critical information affecting cellular morphology, proliferation, differentiation, and survival. A central question in cellular physiology is how these extracellular processes are converted into signals that can modulate the phenotype of a cell. A number of mechanisms have evolved by which such stimuli arising outside of a cell can regulate the expression of genes in the nucleus and other critical cellular processes. Several processes are used in a variety of ways by mammalian cells to transmit these signals. Each of these processes is also balanced by feedback mechanisms to modulate the cellular response. In essentially every kind of cancer, an abnormality in one or more signal transduction pathways provides a cell with signals for survival, proliferation, or self-renewal in the absence of the normal physiologic cues. Thus, elucidating signal transduction pathways is critical to understanding tumor

pathogenesis and tumor biology. Furthermore, among the most important advances in cancer therapy in recent years has been the introduction of signal transduction inhibitors that specifically target these molecular defects. These agents hold the potential to have much greater efficacy and much less toxicity than conventional cytotoxic agents.

Receptors

The ability to respond to the extracellular environment is mediated by receptors (Fig. 1). Although dozens of receptor molecules have been described in mammalian cells, from a functional perspective they can be grouped into three categories. First are receptors that are coupled to kinases. Activation of these receptors initiates the transfer of the terminal phosphate of ATP (or GTP) to an amino acid residue in a protein. Most receptor-associated protein kinases have specificity for phosphorylating tyrosine residues. This often leads to the subsequent activation of protein kinases that can phosphorylate serine or threonine residues, or lipid kinases. Thus, the interaction of a soluble ligand with an extracellular receptor can lead to the amplification of the signal through kinase cascades that can modulate cellular function through a number of mechanisms. Receptors may contain intrinsic tyrosine kinase activity, as is the case for polypeptide growth factor receptors such as the receptors for insulin, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and others (▶receptor tyrosine kinases). Receptors may lack tyrosine kinase activity of their own, but associate with cytoplasmic tyrosine kinases which become activated by the binding of a ligand. Cytokine receptors, such as receptors for interferons, interleukins, oncostatin M, and leukemia inhibitory factor (LIF) associate with tyrosine kinases of the Janus kinase family whose activation propagates the signal.

Activation of receptor-associated tyrosine kinases leads to two major effects. First, it allows the tyrosine phosphorylation of specific substrates whose activity is regulated by this modification. For example, transcription factors of the ▶signal transducers and activators of transcription (STAT) family are found inactive in the cytoplasm under basal conditions. Once phosphorylated by a tyrosine kinase, STATs form dimers, which allows them to translocate to the nucleus, bind to specific DNA regions, and regulate the transcription of target genes. The second effect of tyrosine kinase activation results from the phosphorylation of the receptor itself and associated proteins. These phosphotyrosine



Signal Transduction. Figure 1 Through signal transduction, extracellular stimuli are converted into biochemical processes that control cellular function. Steroid hormones bind to intracellular receptors which then directly control gene expression. Cytokines, growth factors, and peptide hormones interact with cell surface receptors which then initiate cascades of protein phosphorylation, lipid phosphorylation, and second messenger generation. These mediators then regulate gene expression or directly alter processes such as cellular metabolism, protein translation, and apoptosis.

residues form potential docking sites for proteins that have structural domains, such as the ►Src homology 2 (SH2) domain, that allow them to specifically bind to phosphorylated tyrosine residues. This can trigger a series of interactions with other proteins in which tyrosine phosphorylation of proteins performs a "scaffolding" function, allowing other proteins to associate, which then activates their function.

In addition to the phosphorylation of proteins, kinases that can phosphorylate lipids play a key role in signal transduction. For example, ►phosphatidyl inositol 3-kinase (PI3 kinase), which is activated downstream of many receptors, leads to the phosphorylation of lipids in the cell membrane which can serve as a docking site for proteins with the lipid-binding ►pleckstrin homology domain. The recruitment of proteins such as ►Akt to these sites then leads to their activation.

The second family of receptors do not directly modify other proteins, but rather trigger the production of small molecule mediators that diffuse through a cell and modulate cellular function. Such "►second messengers" include molecules like cyclic AMP (cAMP), cGMP, calcium ions, and lipids released from cellular membranes (such as diacylglycerol). Thus, for example, the binding of glucagon to the glucagon receptor leads to the generation of cAMP by ►adenylyl cyclase associated with the glucagon receptor. cAMP can then activate cAMP-dependent protein kinase, also known as protein kinase A, which phosphorylates a variety of substrates on serine and threonine residues. Among these is the transcription factor ►cAMP response element binding protein (CREB), which becomes activated by this phosphorylation, and mediates the expression of a cohort of target genes.

The third functional group of receptors for extracellular signals are not located on the cell surface, but rather are intracellular. The steroid hormone family of receptors makes use of the fact that the ligands with which it interacts are small lipophilic molecules that are cell permeable. For example, hydrocortisone is secreted by the adrenal glands, circulates in the bloodstream, and then directly enters cells where it binds to the glucocorticoid receptor. The receptor and its associated ligand then binds to specific regulatory sequences in the genome and activates or represses the expression of specific target genes.

Targets of Signaling Pathways

While the modulation of gene expression is a key endpoint of signaling pathways and plays a major role in the modulation of cellular behavior triggered by extracellular stimuli, other important targets of signaling pathways are present in a cell. For example, among the serine, threonine kinases activated downstream of cell surface receptors are kinases that can phosphorylate ribosomal proteins. The ribosomal protein S6 can be phosphorylated by members of the p70S6 kinase family or the ribosomal S6 kinase (RSK) family. Phosphorylation of S6 increases the rate of translation of a subset of mRNAs, which may be important for increasing cellular growth and proliferation. Kinases such as the "mammalian target of rapamycin" (mTOR) can directly phosphorylate and affect the function of proteins involved in both translation initiation and elongation.

Signaling pathways can also directly regulate cellular metabolic function. for example, the serine, threonine kinase ►Akt, which is activated by a variety of receptors, can phosphorylate the glucose transporter Glut4, which promotes its localization to the cell surface, and enhances glucose uptake in ►adipocytes.

For humans and other mammals to develop and function normally, the ability of cells to die through the process of ►apoptosis is a critical step. The development of organs such as the brain and the function of the immune system is dependent on the programmed death of large numbers of cells. While there are several mechanisms by which a cell can die, one central process involves families of proteins that regulate mitochondrial permeability. These proteins may serve to promote survival or apoptosis, and their relative levels and activity are a major determinant of whether or not a cell survives. A number of signaling pathways directly regulate these proteins. For example, the serine, threonine kinase Akt can phosphorylate the pro-apoptotic protein BAD (a member of the ►BCL-2 family of proteins), which blocks its ability to trigger apoptosis, and thereby promotes the survival of a cell.

Signal Transduction in Cancer Pathogenesis

Given the importance of signal transduction in a range of critical cellular processes, it is not surprising that inappropriate activation of signaling pathways can contribute directly to the development of cancer. Signaling pathways may be activated by a variety of mechanisms. Among the most common mutations in human cancer, and the first identified in a human tumor, are activating point mutations of ►Ras family proteins. These mutations lead to the activation of a number of downstream kinases that promote cellular survival and proliferation. Cell surface tyrosine kinases can become activated by overexpression resulting from gene amplification. This mechanism leads to enhanced production of the ►Her2 (ErbB2) protein in ~30% of breast cancers, with the consequent activation of downstream signaling pathways. Receptor tyrosine kinases can also be activated by point mutations, deletions, or internal tandem repeats, all of which can lead to enhanced

tyrosine kinase activity in the absence or presence of ligand. Another common mechanism by which tyrosine kinases are activated in cancer is through ►chromosomal translocations that lead to the formation of a chimeric gene that encodes a tyrosine kinase with enhanced activity. The prototype for this is ►Bcr-Abl, a tyrosine kinase resulting from a translocation between chromosomes 9 and 22 (forming the so-called ►Philadelphia chromosome). The tyrosine kinase c-abl is a relatively weak tyrosine kinase that localizes primarily in the nucleus and is involved in responding to DNA damage. By contrast, Bcr-Abl is a highly active kinase which is found in the cytoplasm and phosphorylates and activates a number of key signaling molecules. Bcr-Abl is found in essentially all patients with chronic myeloid leukemia (CML), and a subset of patients with acute lymphoblastic leukemia (ALL).

Most signal transduction pathways have negative feedback systems that limit their effect. However, signaling pathways can become activated during tumorigenesis by the loss of such a negative feedback component. For example, ►PTEN is a lipid phosphatase that dephosphorylates inositol phosphates, thereby countering the effect of PI3 kinase. The PTEN gene is frequently deleted in cancers which leads to unrestrained activity of the ►PI3 kinase cascade.

Signal Transduction in Cancer Therapy

Current cytotoxic cancer therapies kill cells in a largely indiscriminate manner, and thus have limited efficacy and considerable toxicities. However, increased understanding of how signaling pathways are activated in cancer has presented an opportunity to develop targeted agents which are more effective at inhibiting tumor cells while causing few side effects. Current signal transduction inhibitors generally target activated tyrosine kinases by blocking the ability of ATP to bind to the kinase. Drugs such as imatinib mesylate, which inhibits the abl kinase, have been enormously successful in treating CML, and cause few serious side effects. While much effort is going into the development of kinase inhibitors, there is also an interest in developing inhibitors for signaling proteins without catalytic function. For example, drugs that inhibit the post-translational lipid modifications of Ras might be able to overcome the effects of an activating point mutation in this protein.

siRNA

Definition

Short Interfering RNA; Refers to short double-stranded RNA molecules that can be incorporated into ►RISC. They are very similar to ►microRNAs but they are usually synthesised in vitro and not by the cells. If siRNAs are produced in cells (in lower animals or plants) they are produced from long double-stranded RNA and many siRNAs are produced from one such RNA in contrast to microRNAs that are produced from imperfect stem-loop structure precursors and only one from each precursor. SiRNAs are used to knock down the expression of genes using ►RNA interference.

►MicroRNA
►RNA Interference

siRNA

Tetsuya Nakatsura
Section for Frontier Medicine, Investigative Treatment Division, Research Center for Innovative Oncology, National Cancer Center Hospital East, Kashiwa City, Chiba Prefecture, Japan

Definition

The small interfering RNA (siRNA) transcripts are 21–25 bp long, double-stranded transcripts as a defense response to nonendogenous double-stranded RNA (dsRNA), leading to sequence-specific mRNA cleavage. This double-stranded induced cleavage was named ►RNA interference (RNAi).

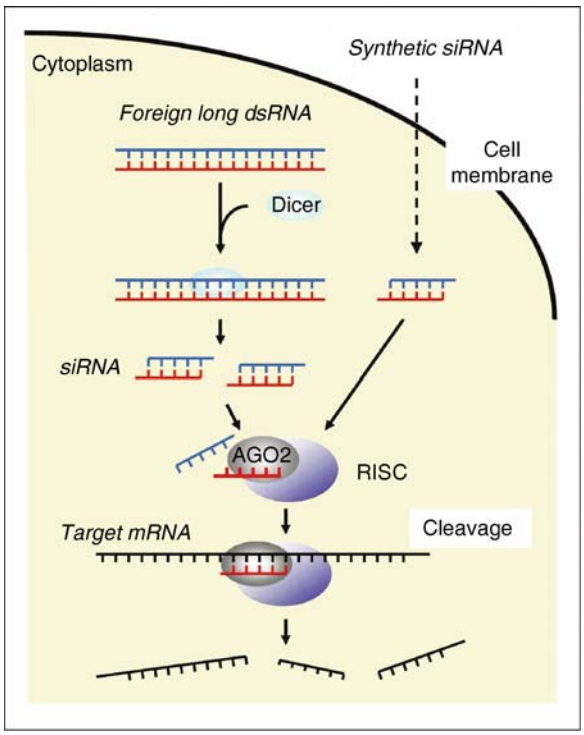
Characteristics

siRNA transcripts are 21–25 bp long, double-stranded transcripts that were found in *Caenorhabditis elegans* in 1998 as a defense response to nonendogenous dsRNA, leading to sequence-specific mRNA cleavage. This double-stranded induced cleavage was named RNAi and was soon to be found in other organisms, for example, *Drosophila melanogaster*, and in vertebrates. The main function of the mechanism is believed to a defense system against introduced viral double-stranded sequences, cutting them to pieces and thereby rendering them unable to infect the cell. The gene regulation part was not discovered until recently. RNAi was also quickly adapted for use in the laboratory as a gene-silencing tool for the silencing of specific genes by introducing the specific double-stranded sequence, and has become a common tool today for the study of gene expression and regulation due to its specificity. siRNA is generated by Dicer cleavage of long dsRNA sequences. After cleavage, the double-stranded siRNA is loaded into the RNA-induced silencing complex (RISC). During the loading process one strand is peeled off, leaving a single-stranded siRNA lodged inside RISC. This strand is then used by RISC as a template to recognize the cleavage target in the target mRNA transcript. A full match induces a cleavage in *Drosophila* RISC complexes, Argonaute2 (AGO2) has been identified as carrying the slicing action, but several other proteins are also involved in the RISC complex (Fig. 1).

Clinical Aspects

There are still unknown details regarding the biogenesis and function of siRNA, especially in mammals. The siRNA technique of using siRNA transcripts to knock down gene expression of specific genes has quickly become a popular method that is used for gene function analysis in molecular biology. The method is still being developed to improve the siRNA vectors, both the specificity and the usability of the technique, but already it exhibits a high specificity. The hope of the future is to be able to use siRNA knock down techniques to treat both genetic disorders, viral infections and, in extension, to be able to use siRNA as a cancer treatment.

The advantage of RNAi technology is that it can be used to target a large number of different genes involving a number of distinct cellular pathways. This is particularly important for a disease as complex as cancer. Most of the RNAi candidate cancer gene targets are involved in pathways that contribute to net tumor growth (either through increased tumor-cell proliferation or reduced tumor-cell death, or both). While mRNAs expressed from mutated cancer ►oncogenes can be directly targeted for RNAi intervention, RNAi can also be used to target and silence gene products that negatively regulate the function of endogenous ►tumor suppressor genes. Other gene products that can be targeted by RNAi include proteins involved in cellular ►senescence, or protein stability and degradation. Although these additional targets are not directly involved in the oncogenesis pathway, they can indirectly



siRNA. Figure 1 Schematic representation of RNA interference (RNAi). siRNA is generated by Dicer cleavage of long double-stranded RNA sequences. After cleavage, the double-stranded siRNA is loaded into the RNA-induced silencing complex (RISC). Synthetic siRNA is directly incorporated in the RISC. During the loading process one strand is peeled off by Argonaute2 (AGO2) leaving a single-stranded siRNA lodged inside RISC. This strand is then used by RISC as a template to recognize the cleavage target in the target mRNA transcript. A full match induces a cleavage.

contribute to net tumor growth, and therefore represent potential candidates for RNAi intervention.

Delivery

RNAi-mediated gene silencing in mammalian cells can be achieved by transfection, for example, using liposomes or electroporation of synthetic siRNA molecules, or by gene transfer using plasmid- or virus-based expression cassettes with RNA polymerase III promoter encoding dsRNA molecules.

The easiest way to induce RNAi is the use of chemically synthesized siRNAs. However, in addition to siRNAs produced by chemical synthesis, siRNAs may be generated by from long dsRNAs in vitro via recombinant Dicer, by in vitro transcription using T7 RNA polymerase, or siRNAs can be isolated from *Drosophila* embryo extracts. Classic transfection of siRNA molecules using different physical methods such as liposome-mediated transfection, electroporation, or single-cell microinjection has been successfully applied. Treatment of mammalian cells with siRNAs typically results in a transient downregulation of the target mRNA after 1–2 days for a duration of 3–5 days. In vivo delivery of chemically synthesized siRNAs to mice was reported by injection into the tail veins. By this approach, a downregulation of 90% of endogenous mRNA transcripts in the majority of liver cells after a single siRNA injection could be achieved. In the liver, the RNAi effect persists for several days.

Although siRNAs are readily taken up into worm and fly cells, most mammalian cells do not efficiently internalize these small molecules. This is even true of cells, such as dendritic cells and ▶macrophages, which are actively sampling their environment. Therefore, the major obstacle for using small RNAs as drugs is to deliver them into the cytoplasm of cells. An exception may be mucosal tissues. In the lung and vagina, siRNA uptake is extremely efficient and occurs even in the absence of transfection reagents. For clinical indications where siRNAs only need to be delivered to a localized region, such as the eye, pulmonary or vaginal mucosa, or superficial tumors, efficient siRNA delivery and silencing can be achieved by mixing siRNAs with cationic lipid transfection reagents used for in vitro transfection and directly injecting the siRNA–lipid complexes into the relevant tissue or instilling it into the body cavity. A similar approach is certain to apply to the skin. Mixing siRNAs with other molecules known to carry nucleic acids into cells, such as certain cationic peptides, might also be used effectively for local delivery. However, some cell types, such as lymphocytes, dendritic cells, and hematopoietic stem cells, are refractory to transfection using cationic lipids. Therefore, even when these targets might be localized, alternate delivery strategies may be needed.

The first demonstrations of the therapeutic potential of siRNAs for silencing disease-related genes delivered siRNAs systemically by rapid high-pressure intravenous injection. This method leads to transient right-sided heart failure, where elevated venous pressures somehow enable siRNAs to get into cells in highly vascularized organs like the liver, pancreas and lungs. Nonetheless, this strategy is too risky for human use. It is, however, possible to deliver siRNAs into an organ, such as the kidney, by rapid retrograde injection via catheter into the draining vein. It may be possible to use hydrodynamic injection into a peripheral vein to treat skeletal muscle by blocking venous outflow using a tourniquet. Elevated venous pressures are generated only in the targeted tissue without inducing potentially fatal heart failure. However, a minimally invasive method for delivering siRNAs requires alternate approaches. A variety of strategies that involve complexing siRNAs to cationic polymers or peptides or incorporating siRNAs into nanoparticles or liposomes have

been proposed. Alternately, siRNAs can be covalently or noncovalently linked to antibody fragments or ligands to cell surface receptors to limit the delivery of the siRNAs to cells that bear the specific receptor. These strategies probably deliver siRNAs via receptor-mediated endocytosis, although the trafficking of siRNAs into and within cells has not been well studied. The directed delivery of siRNAs into specific cells will decrease the amount of siRNAs needed for the efficient silencing of gene expression in the target organ or tissue and will reduce potential toxicity by preventing targeting of unintended cells and tissues. The optimal delivery strategy may differ between different therapeutic indications and will depend on efficiency and duration of delivery and silencing, lack of systemic toxicity, and lack of immunoreactivity, which would interfere with repetitive treatments. The first examples of effective systemic delivery have only recently been described.

Nonspecific Immune Stimulation

While there is a high degree of specificity associated with RNAi, some effects have been observed that are independent of the specific gene targeted for silencing. In general, 21 bp or longer dsRNAs can lead to a sequence-independent ►interferon response. Interferon can also activate the dsRNA-dependent protein kinase (PKR), which phosphorylates and subsequently inactivates the translation factor eIF2, leading to a global inhibition of mRNA translation. The length of the initiating siRNA clearly has some role in triggering the interferon response, with more recent data suggesting that sequences shorter than 19 nucleotides are more likely to escape the interferon antiviral response. It is anticipated that the judicious selection of siRNA sequences together with a greater understanding of their interactions with any given target gene will resolve this issue.

Similarly, evidence exists that siRNAs can activate dendritic cells and other cells of the immune system through a much more specific and restricted class of receptors, the toll-like receptors, which can recognize foreign nucleic acids including dsRNAs and when activated can send a danger signal to trigger a proinflammatory response. These findings raise the possibility that RNAi reagents may trigger unforeseen immune responses, including autoimmune diseases, in vivo.

Off-Target Interference

Nucleic acid-based gene-silencing molecules may also have effects on genes that are not considered targets, the so-called off-target effects, due to similarities in nucleic acid sequences. The degree of the off-target effect is dependent upon the mode of silencing and the stability of the nucleic acid hybrid. If siRNAs are not carefully selected, siRNAs having partial complementarity to an mRNA target can repress translation or subject unintended mRNAs to degradation. A study that compared the gene-expression profiles created by different siRNAs targeted against the same transcript revealed that in extreme cases, as little as seven nucleotide complementarity between the 5′ end of either siRNA strand to an mRNA can cause a reproducible reduction in transcript levels. Interestingly, it has been found from studies in primitive organisms that off-target effects are not observed when complete dsRNAs are introduced instead of synthetic siRNAs. This may be explained by the fact that the siRNAs derived endogenously from the cleavage of dsRNAs are generated and selected by Dicer and the RISC complex, which may have a proofreading mechanism that protects against the generation of siRNA sequences that might result in the silencing of endogenous genes. Therefore, it is possible that mammalian siRNAs generated from dsRNA precursors through the action of Dicer and the RISC complex may be less prone to induce off-target effects than synthetically designed siRNAs. Several algorithms and software are available to select siRNA target sequences with reduced off-target effects, and it will be important to select siRNA targets with relatively sophisticated sequence comparison tools to minimize potential off-target effects.

SIRS

Definition

►Systemic Inflammatory Response Syndrome.

SIRTs

►Sirtuins

Sirtuins

Olaf Witt
CCU Pediatric Oncology, German Cancer Research Center, Heidelberg, Germany

Synonyms

SIRTs; Class III histone deacetylases; Sir2-like proteins

Definition

Sirtuins are a family of protein deacetylases (►Histone deacetylases) and ADP ribosyltransferases requiring NAD+ for their enzymatic activity.

Characteristics

Biochemical Features of Sirtuins

Sirtuins are protein deacetylases and ADP ribosyltransferases that target a wide range of cellular proteins in the nucleus, cytoplasm, and mitochondria. Among the substrates are histone proteins, and therefore sirtuins are also referred to as class III ►histone deacetylases. Seven human sirtuins (SIRT1–7, see Table 1) have been identified and share a catalytic domain of 275 amino acids. As opposed to ►histone deacetylases, sirtuins require ►NAD± as a cofactor for their enzymatic activity. Therefore, NAD+/NADH ratio and metabolic status of the cell influences the activity of sirtuins. Nicotinamide is a physiological intracellular inhibitor of sirtuins.

Cellular Functions of Sirtuins

Human sirtuins (SIRTs) are structurally related to the silent information regulator 2 (Sir2) family, which are conserved from bacteria to humans and regulate lifespan in lower organisms. Sirtuins are involved in regulation of the cellular stress response, cell cycle progression, chromosomal stability and aging. SIRT1 knock-out mice show multiple developmental defects and die around birth and is thus required for normal embryonal development.

Mammals have seven sirtuins (Table 1). In addition to the intranuclear SIRT1, there is the cytoplasmic SIRT2, the three mitochondrial sirtuins SIRT3, 4, 5, and also within the nucleus the ►heterochromatin-associated SIRT6 and the nucleolar SIRT7. Based on sequence homology, the sirtuins can be grouped into four classes. SIRT1, 2, 3 comprise class I, SIRT4 is in class II, SIRT5 is in class III, and SIRT6, 7 are class IV sirtuins. Table 1 summarizes the cellular localization and functions of the 7 human sirtuins.

Among the 7 sirtuins, SIRT1 has been most intensively studied, whereas the functions and target proteins of SIRT2–6 are less well understood. SIRT1 regulates the acetylation status of histone proteins and is thereby involved in the control of ►chromatin structure and regulation of transcriptional activity. For example, SIRT1 directly deacetylates lysine 16 of histone H4, which is a mark for transcriptional inactive heterochromatin, whereas acetylated lysine 16 is found in transcriptionally active ►euchromatin. SIRT1 is a component of the polycomb group repressor complex, a multiprotein complex which controls differentiation and developmental programs in embryonic cells. In addition to its function in regulating chromatin structure, SIRT1 regulates the activity of several cellular proteins via modulating their acetylation status. For example, deacetylation of the ►tumor suppressor protein ►p53 by SIRT1 results in downregulation of its transcriptional and ►apoptosis-inducing as well as ►senescence-inducing activity. Other proteins known to be targets of SIRT1 are MyoD (a transcriptional regulator of muscle gene expression and differentiation), FOXO proteins (family of transcription factors that regulate oxidative stress response, cell cycle arrest, DNA repair, and apoptosis),

Sirtuins. Table 1 Cellular localization and functions of sirtuins

	Localization	Function
SIRT1	Nucleus	Deacetylation of histone and non-histone proteins
		Regulation of chromatin structure
		Regulation of activity of p53 and several other transcription factors (see text)
		Involved in cellular stress response, survival, senescence, cellular life span, differentiation
SIRT2	Cytoplasm	Deacetylation of α-tubulin
	Shuttles into nucleus	Mitotic checkpoint regulation
SIRT3	Mitochondria	Acetyl-CoA production
SIRT4	Mitochondria	ADP-ribosylation, suppression of insulin signaling
SIRT5	Mitochondria	not known
SIRT6	Nucleus	Guards genomic instability, target unknown
SIRT7	Nucleolus	Promotes rRNA transcription

Ku70 (a protein involved in nonhomologous repair of DNA double-strand breaks), PPAR-y (a member of the nuclear receptor superfamily that integrates energy control, lipid metabolism, and glucose homeostasis), and NF-kB (transcription factor that regulates immune response, inflammation, cell proliferation, and cell death). As a result of modulating the function of these proteins, SIRT1 is involved in cell survival, muscle differentiation, and fat metabolism and is upregulated during caloric restriction. SIRT1 plays a role in regulation replicative senescence and limit of proliferation of normal cells. SIRT1 ensures that damaged DNA is not propagated and that mutations do not accumulate in cells. In recent years, much attention has been paid to the function of SIRT1 in controlling lifespan and longevity.

Sirtuins and Cancer

SIRT1 limits proliferation capacity and induces senescence in normal, non-transformed cells exposed to chronic stress stimuli and genomic insults. Therefore, sirtuins are thought to protect against the development of cancer. Sirtuins are considered as targets for chemoprevention of age-related cancers by promoting their function in guarding genomic stability and senescence.

However, SIRT1 is also found to be overexpressed in a number of cancers such as acute myeloid leukemia (AML), skin, breast, and colon cancer, and is upregulated in chemotherapy-resistant cancer cells. High levels of SIRT1 protects malignant cells from apoptosis via deacetylation and subsequent reduction of the activity of proteins involved in programmed cell death. Among the cancer-relevant substrates of SIRT1 is the tumor suppressor protein p53. SIRT1 deacetylates p53 resulting in repression of its functional activity. Another substrate of SIRT1 is the critical B-cell lymphoma protein 6 (BCL6). Various tumor cell lines cease growth and undergo apoptosis after SIRT1 ►knockdown. SIRT1 ►overexpression blocks ►oncogene-induced senescence. At the ►epigenetic level, SIRT1 deacetylates ►histone H4 at lysine 16, a modification which is a common hallmark of human cancer. Thus, inhibition of sirtuins appear to be a promising target for certain cancers which are dependent on high levels of sirtuin activity.

Sirtuin Inhibitors and Activators

The biological activity of sirtuins can be modulated by small molecule inhibitors and activators. Nicotinamide, a natural byproduct of the sirtuin deacetylase reaction, is a general inhibitor of all sirtuin family members. Other small molecule inhibitors are sirtinol, M15, and splitomycin. The observation that calorie restriction increases life span through increase of the activity of sirtuins in animal models lead to the screening of compounds with sirtuin stimulating activity. Among the substances identified were the polyphenols quercetin and piceatannol, and resveratrol, a polyphenol found in the skin of red grapes.

Sivelestat

Kazuhiro Yoshida
Department of Surgical Oncology, Gifu University School of Medicine, Gifu, Japan

Definition

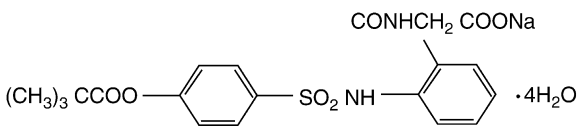
Sivelestate is a low molecular weight synthetic inhibitor of human ►neutrophil elastase (NE) (►Netrophile elastase and cancer), which was produced by Ono Pharmaceutical Company Co., Ltd., in 1991 as ONO-5046, N-[2-{4-(2,2-Dimethylpropionyloxy) phenylsulfonylamino}-benzonyl] aminoacetic acid (MW. 434.47). The structure is illustrated in Fig. 1. This is a potent, specific and intravenously active NE inhibitor and it is widely used to treat patients with lung injury diagnosed as ►SIRS (systemic inflammatory response syndrome), in Japan at a dose of 0.2 mg/kg/h for 14 days.

Characteristics

Mechanisms of Action

Sivelestat inhibits the action of NE which is a member of serine proteases produced by polymorphonuclear neutrophils and monocytes/macrophages. NE degrades a broad spectrum of extracellular matrix (ECM) (►Extracellular remodeling) and cell surface proteins, such as elastin, interstitial collagens, proteoglycans, fibronectin, laminin, and type IV collagens. Under normal physiological conditions, the proteolytic activity of elastase released by recruited neutrophils is strictly regulated by antiproteases, such as alpha-1-protease inhibitor and secretary leukoprotease inhibitor. However, under conditions of physiological disturbance, such as the presence of neoplasms, surgical stress, or inflammation, the balance between elastase and antiprotease is disrupted, and the predominant elastolytic activity causes the destruction of peripheral ECM of the lung.

NE also cleaves pro-►transforming growth factor-alpha (TGF-α) (►Epidermal growth factor receptor ligands) on the surface of human airway epithelial cells via its proteolytic activity and releases mature, soluble TGF-α on human airway epithelial cells. Release of TGF-α activates the ►epidermal growth factor receptor (EGFR) (Epidermal growth factor receptor ligands) signaling cascade (►Transduction of oncogene), resulting in mucinous secretion in the peripheral airways that might cause severe respiratory complications after major surgical stress or severe inflammatory response.



Sivelestat. Figure 1 Structure of sivelestat, ONO-5046, N-[2-{4-(2,2-dimethylpropionyloxy) phenylsulfonylamino}-benzonyl] aminoacetic acid (MW. 434.47).

Clinical Aspects

Clinical Application in Practice

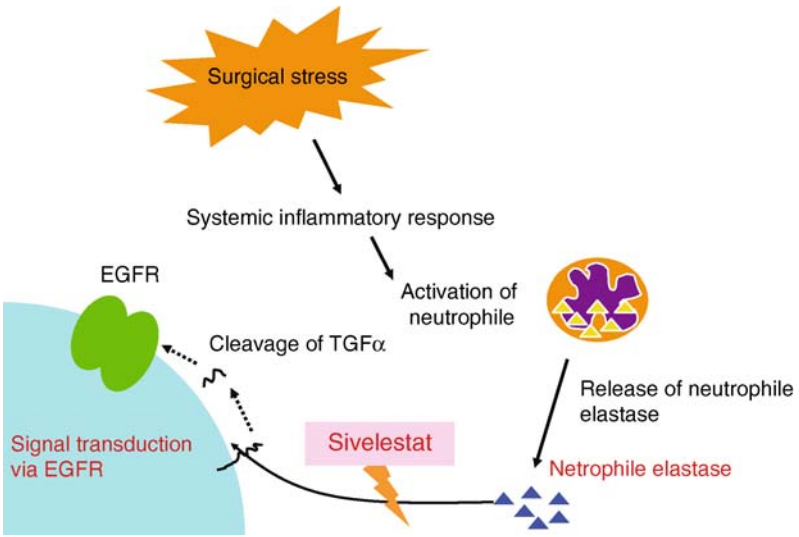
Sivelestat is prescribed clinically for the treatment of various inflammatory diseases in Japan. The anti-inflammatory effects of sivelestat are applied for the alleviation of surgical stress, and can reduce morbidity and organ dysfunction, including ►acute respiratory distress syndrome (ARDS). Considerable amount of NE is released from activated neutrophils which are induced by systemic cytokines including ►TNF-α, ►IL-8 and ►IL-6 produced by ►macrophages in the lung. SIRS is often observed after surgical injury, which influences on the function of leukocytes and endothelial cells leading to the ARDS or ►acute lung injury (ALI) with the destruction of the alveolar construction of the lung.

Application to Cancer Treatment as Molecular Targeting Therapy

Rapid recurrence or regrowth of tumors are often observed after major cancer surgery, or perioperative surgical complications with SIRS that involve the release of NE by neutrophils and also by cancer cells.

On the other hand, cancer cells have multi-►autocrine growth factor and receptor loops including EGFR- TGF-α system for the development of growth and metastatic potential.

The growth and invasion activity of cancer cells are stimulated by NE and the growth stimulation occurs via the cleaved TGF-α from the cell membrane, which activates the EGFR and then activates the subsequent intracellular signal transduction. Moreover, NE stimulates the release of several growth factors including ►PDGF (platelet derived growth factor) and ►VEGF (vascular endotherial growth factor) that are closely



Sivelestat. Figure 2 Action mechanism of sivelestat. NE released from activated neutrophils by SIRS cleaves the pro-TGF-α on the cell surface of the cancer cells, which stimulate the growth of the cell via EGFR. Sivelstat blocks the cleaveage of the TGF-α.

related to the growth and angiogenesis of tumor cells. As mentioned above, sivelestat inhibits the NE-induced release of TGF-α from cell membrane of not only neutrophils but also cancer cells (Fig. 2). Therefore, sivelestat might be a new therapeutic tool for the treatment of anti-inflammatory response and also for molecular targeting therapy (►Molecular therapy) of postoperative cancer patients by inhibiting the rapid cancer cell growth after resection of tumors accompanied with SIRS.

Sicca syndrome; Sicca complex; Dry mouth syndrome; Dry eyes syndrome; Keratoconjunctivitis sicca; KCS; Xerostomia; Xerophthalmia

Definition

Sjögren syndrome is a chronic, progressive autoimmune disorder that primarily affects the exocrine glands. The classic signs and symptoms include enlargement of the parotid and lacrimal glands, with mucosal dryness manifested by dry mouth (►Xerostomia) and dry eyes (►Xerophthalmia) (►Keratoconjunctivitis sicca). Lymphocytic infiltrates replace functional epithelium, which results in decreased exocrine secretions (exocrinopathy).

Numerous features suggest an immunologic etiology. Patients demonstrate hypergammaglobulinemia and have several types of ►autoantibodies, such as the

S

rheumatoid factor (RF), antinuclear antibodies (ANA), Ro/SS-A and/or La/SS-B, and antibodies to salivary duct epithelium.

Characteristics

Sjögren syndrome is named after the Swedish ophthalmologist Henrik Sjögren. However, the disease was addressed during the nineteenth century in a number of case reports, between the years of 1882 and 1924, describing various combinations of dry mouth, dry eyes, and chronic arthritis. Mikulicz reported in 1892 a man with bilateral parotid and lacrimal gland enlargement associated with massive round cell infiltration. Later on, the link between Sjögren syndrome and ►malignant lymphoma was described in a classic paper in 1964. More recently, a set of preliminary classification criteria was identified by a European Concerted Action in 1993 and they have been widely accepted. The triad of dry mouth (xerostomia), dry eyes (keratoconjunctivitis sicca), and a connective tissue disease, usually ►rheumatoid arthritis (►RA) or ►systemic lupus erythematosus (SLE), is termed secondary Sjögren syndrome. In the absence of a connective tissue disease, the designation primary Sjögren syndrome (or sicca syndrome) is used.

Incidence

Sjögren syndrome is the most common form of autoimmunity disorder and is seen mostly in women (female:male ratio 9:1) in the fourth and fifth decades of life. Its frequency in RA is 20% and therefore Sjögren syndrome is most commonly seen in this context.

Etiology

The etiology of Sjögren syndrome is unknown but may involve genetic and immunological factors.

1. *Genetic Factors*. ►A prominent feature of Sjögren syndrome is its genetic predisposition. The polymorphic ►major histocompatibility complex (MHC) genes are well-documented genetic risk factors for the development of ►autoimmune diseases overall. With regard to Sjögren syndrome, the most relevant MHC complex genes are the class II genes, more specifically the ►HLA-DR and ►DQ alleles. In whites of northern and western European background, including North American whites, Sjögren syndrome is one of several autoimmune diseases associated with the ►haplotypes HLA-B8, DRw52, and DR3. An association with DR2 has been reported in Scandinavians and DR5 in Greeks.
2. *Immunological Factors*. ►Immunological abnormalities include a marked hyperactivity of B lymphocytes with hyperglobulinemia and serum autoantibodies, some organ-specific such as antibodies to salivary duct epithelium, and others nonspecific such as ANA and rheumatoid factor. Impaired cellular immunity with defective suppressor T cell (►Regulatory or suppressor T cells) function has been reported in some patients but not in others. Both ►T lymphocytes and B lymphocytes have been identified in the tissue lesions and local synthesis of ►immunoglobulins has been demonstrated. Since the ►lymphocyte infiltration has been demonstrated to be initially periductular in local lymphocyte cytotoxicity directed against ►antigens on salivary gland duct cells has been postulated.
3. *Environment.* Among the possible etiologic and triggering factors involved in Sjögren syndrome, the discussion about a relationship between viral infections causing development of autoimmune reactions began some decades ago. The putative role of different ►viruses in Sjögren syndrome can be viewed in the light that salivary glands are a site of latent viral infections. Potential viral triggers include a number of viruses. Among these, ►Epstein-Barr virus (EBV) has been widely studied in relation to Sjögren syndrome. A higher prevalence of serum human herpesvirus-6 (HHV-6)-specific antibodies has also been detected in patients with Sjögren syndrome than in normal individuals (36% vs. 10%). Retroviruses are known to infect cells of the ►immune system and cause abnormalities in immune regulation. High serum titers of antihuman T lymphotropic virus type I (HTLV-1) antibodies and a high prevalence of salivary ►immunoglobulin A (IgA) class anti-HTLV-1 antibodies in patients with Sjögren syndrome were reported endemically in Japan. Hepatitis C virus (HCV) infection in some populations has been frequently (14%) detected in patients with primary Sjögren syndrome. Analysis of the association between ►chronic lymphocytic sialadenitis and ►chronic HCV liver disease showed that histologic features of Sjögren syndrome were significantly more common in HCV-infected patients (57%) compared with controls (5%). ►Lymphotropic viruses have the potential to trigger the autoimmune process. Some of the immunoreactive regions within the La/SS-B protein have been found to have sequence similarities with proteins of EBV, HHV-6, and human immunodeficiency virus (►HIV)-1. It seems reasonable that these viruses can promote autoantibody (particularly anti-La/SS-B) production through ►molecular mimicry or exposure of La/SSB homolog sequences on cellular surfaces after translocation of cryptic self-determinants.

Clinical Manifestations

Presentation

The typical case is of a middle-aged woman who developed sicca symptoms insidiously. Less commonly it presents with parotid swelling or with constitutional

symptoms such as malaise and arthralgias. Rarely the presenting feature is cutaneous ►vasculitis, a cranial neuropathy usually involving the trigeminal nerve, a peripheral neuropathy, or the hyperviscosity syndrome. Sicca symptoms tend to develop more rapidly in primary Sjögren syndrome, when episodic parotitis and involvement of other organs is more common.

Involvement of Exocrine Glands

Ocular symptoms due to reduced lacrimal secretion and dessication of the cornea and conjunctiva (keratoconjunctivitis sicca) include a gritty or sandy sensation, reduced tearing, photophobia and the presence of a ropey discharge, particularly at the inner canthus. Recurrent infections are also common. In advanced cases, the cornea may be severely damaged and complications include corneal ulceration and occasionally perforation. Decreased saliva results in dryness of the mouth (xerostomia) that leads to dysphagia, abnormalities of taste, and adherence of food to the buccal surface. Widespread involvement of mucosal glands elsewhere may result in dryness of the nose, posterior pharynx, trachea, bronchial tree, skin, and vagina. Involvement of the respiratory tract leads to an increased frequency of upper and lower respiratory tract infections and otitis media. There is parotid gland enlargement in 50% of cases (80% in primary Sjögren syndrome) sometimes accompanied by pain and fever.

Extraglandular Involvement

Extraglandular lymphoproliferation occurs in 25% of primary Sjögren syndrome, and involves the ►reticuloendothelial system, kidney, muscle, and lungs. Systemic manifestations are varied and include diffuse interstitial pneumonitis, renal tubular abnormalities, peripheral and cranial neuropathy, nonthrombocytopenic purpura, and the development of pseudomalignant and malignant lymphoid proliferation. Malignant lymphoma occurs more often than can be explained by chance alone, and Sjögren syndrome has often been considered to be a link in the spectrum between autoimmune disorders and lymphoproliferative disorders (Malignant lymphoma, Antonino Carbone and concepts).

Diagnosis

The most commonly used tests for the detection of dry eyes are the Schirmer I and the rose bengal (alternatively Lissamine green dye) and subsequent scoring according to van Bijsterveld. Schirmer I is performed using standardized tear tests strips. In the European classification criteria, ►Schirmer I test is positive ►when the wetting is less than 5 mm in 5 min. The scoring according to van Bijsterveld detects destroyed conjunctival epithelium induced by dryness. Saliva production tests are simple screening tests for salivary gland involvement in Sjögren syndrome. Saliva, which is produced by the three major and numerous minor submucosal salivary glands, exhibits great flow variations among healthy individuals and in the same individual under diverse conditions. The test should therefore be standardized; the unstimulated whole saliva collection test is performed for 15 min, and the test is considered positive when 1.5 ml or less whole saliva is collected, being well below the normal mean range. Other tests used to evaluate salivary gland involvement include parotid sialography and salivary gland scintigraphy. The sialography typically shows sialectasis in contrast to the fine arborization seen in normal parotid ductules. In the scintigraphic test, ^{99m}technetium-pertechnate is given intravenously, and in Sjögren syndrome patients, the typical finding is decreased uptake in response stimulation of the parotid and submandibular salivary glands. This test is a sensitive and valid method to measure abnormalities in salivary gland function in the hands of skilled personnel.

SS is Diagnosed on the Basis of Either European Classification

European Classification. (Preliminary criteria for the classification of Sjögren syndrome, Vitali C et al.)

1. Ocular symptoms – Positive response to 1 of 3 questions pertaining to dry eyes
2. Ocular signs – Positive Schirmer test (<5 mm in 5 min) or positive rose bengal staining
3. Oral symptoms – Positive response to 1 of 3 questions pertaining to dry mouth
4. Salivary gland involvement – Objective evidence of salivary gland involvement; salivary scintigraphy; parotid sialography; unstimulated salivary flow less than 1.5 mm/min
5. Serologic or autoantibody test results – Presence of autoantibodies to Ro (SS-A), La (SS-B), or both
6. Categories
   a. Primary SS – Presence of any of 4 of the previous 6 categories
   b. Secondary SS – Presence of potentially associated connective tissue or autoimmune disease with the first 2 categories (ocular symptoms and ocular signs) plus any 2 of the next 3 categories;

Laboratory Abnormalities

Autoantibodies to salivary duct, gastric parietal cells, thyroglobulin, mitochondria, and smooth muscle are frequently present. Rheumatoid factor is found in over 90% and ANA in ~70%. Serum antibodies to two partially characterized cellular antigens Ro (SSA) and La (SSB) are commonly found in primary Sjögren syndrome.

Anti-Ro/SSA and anti-La/SSB Antibodies

The reported frequencies of anti-Ro and anti-La (►Anti-Ro/SSA and anti-La/SSB antibodies) depend on the methods of detection and referral bias of the center performing the study. Overall, anti-Ro precipitins occur in ~60–75% of primary Sjögren syndrome and are also observed in cases of secondary Sjögren syndrome, irrespective of the association with SLE, progressive systemic sclerosis, rheumatoid arthritis, or primary biliary cirrhosis (PBC). Anti-La antibodies were initially reported to occur in up to 40% of patients with primary Sjögren syndrome. Even higher frequencies were reported when anti-La was analyzed by ►ELISA or ►immunoblotting. Further studies have shown that combined detection of anti-La and anti-Ro antibodies has a higher diagnostic specificity for primary Sjögren syndrome than does anti-Ro alone. Although the pathogenetic role of anti-Ro and anti-La in Sjögren syndrome is not established, positive serology is associated with a high frequency of palpable purpura, leucopenia, lymphopenia, and hypergammaglobulinemia, and with more severe glandular disease. Recent studies also have found salivary enrichment of anti-Ro and anti-La in patients with Sjögren syndrome, suggesting local autoantibody production in salivary glands as well as presence of Ro52, Ro60, and La autoantibody-producing cells in salivary gland biopsy samples from patients with Sjögren syndrome (SSA(Ro) SSB(La) in SS, Tsay GJ and concepts).

Anti-CENP-H Antibodies and SS

Anticentromere antibodies (ACA) have been described in patients with different rheumatic disorders including CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactly, telangiectasia), PBC, primary Raynaud's disease (PRD), and rheumatoid arthritis (RA). It is generally accepted that there is a strong correlation between ACA and Raynoud's phenomenon. An increased frequency of ACA and anti-CENP-H antibodies was found in patients with SS. SS can be subdivided serologically into two groups: group one with anti-SSA/Ro and/or anti-SSB/La antibodies, and group two with ACA and/or anti-CENP-H antibodies. In summary, ACA and anti-CENP-H antibodies are associated with SS. ACA or anti-CENP-H antibodies can be used as a serological marker for SS (Anti-CENP-H in patients with Sjögren syndrome, Tsay GJ and concepts).

Pathogenesis

Critical features of pathogenesis include: (i) association with particular class II ►histocompatibility (►HLA-DR/DQ) antigens; (ii) a pattern of particular autoantibodies, including a newly described ►antibody against muscarinic M3 receptor for acetylcholine; (iii) a high proportion of "►high endothelial venules (HEVs)" in the lacrimal and salivary gland biopsies, which express increased levels of ►cell adhesive molecules; (iv) upregulation of major histocompatibility antigens (►H antigens or histocompatibility antigens) and adhesive molecules on epithelial cells in salivary and lacrimal glands, probably in response to local production of interferon gamma (►IFN-γ); (v) expression of cell surface (►Fas, ►Fas ligand) and nuclear molecules (►bcl-2, ►bcl-x) on glandular epithelial cells and on ►lymphocytes infiltrating the glands; (vi) secretion of proinflammatory ►cytokines (such as ►IL-1, ►tumor necrosis factor-α (TNF-α), and ►IFN-γ) by lymphocytes and/or epithelial cells to perpetuate the inflammatory response; (vii) decreased secretion by the residual glandular acini as a result of their decreased neural innervation and defects in their postsignal transduction.

Immunopathology

Humoral Immunity

A large number of autoantibodies have been reported in both primary and secondary Sjögren syndrome, reflecting both B-cell activation and a loss of immune tolerance in the B-cell compartment (►Humoral immunity). Over the past few years, there has been significant progress in defining the fine specificity of these antibodies and characterizing their target ►autoantigens. In some cases, the presence of these antibodies is related to the extent and severity of disease in Sjögren syndrome. The ►B cells make up roughly 20% of the infiltrating cell population in affected glands. The B cells produce ►immunoglobulins (Ig) with autoantibody activity for IgG (rheumatoid factor), Ro/SSA, and La/SSB. A substantial number of the B cells are of ►CD5 + phenotype (►B-1 cells). Production of IgG predominates in Sjögren syndrome, whereas synthesis of IgA is more abundant in normal salivary glands. Nonorgan-specific autoantibodies anti-Ro/SSA and anti-La/SSB are diagnostically the most important and the best-characterized autoantibodies in primary Sjögren syndrome. The majority of anti-Ro-positive sera also react with the denatured from of a 52-kDa protein termed Ro52, which is structurally distinct from Ro60 and probably does not directly associate with the Ro ribonucleoprotein particle. However, the two Ro proteins colocalize to surface membrane blebs on apoptotic cells, where they may become targets of an ►autoimmune response. Human ►monoclonal antibodies reactive with continuous and conformation-dependent ►epitopes on Ro52 have recently been cloned from a patient with primary Sjögren syndrome.

Cellular Immunity

Immunohistologic analysis of lymphoid cell infiltration in exocrine glands in Sjögren syndrome shows a predominance of ►T cells or (T lymphocytes) with fewer B cells and macrophages. ►Adhesion molecules

and activated lymphocyte function-associated ►antigen type I (►LFA-I) (►Leukocyte functional antigen (LFA)) promote homing and occasionally characteristic cell clustering similar to that of follicular structures of lymph nodes. Expression of the mucosal lymphocyte ►integrin $\alpha^E\beta_7$ and its ligand E-cadherin suggest a mucosal origin of a subpopulation of the infiltrating cells. There is an increased expression of ►HLA-DR/DP/DQ molecules on acinar and ductal epithelial cells, presumably due to local production of IFN-γ by activated T cells. The majority of T cells in the lymphocytic infiltrates are CD4 + T-helper cells ►(Helper CD4 T cells) with a ►CD4/►CD8 ratio well over 2. Most of these T cells bear the memory phenotype $CD45RO^+$ and express the ►α/β T cell receptor and LFA-I, and may contribute significantly to B-cell hyperactivity. There is indication of oligoclonal expansion of certain ►TCR Vβ family-expressing lymphocytes. The peripheral blood in Sjögren syndrome has yielded findings similar to those in salivary glands, although a difference in magnitude is occasionally evident.

Immune-Mediated Tissue Destruction

Highly upregulated expression of ►HLA molecules, and the more recently demonstrated B-7 costimulatory molecules, by salivary gland epithelium in Sjögren syndrome is a potentially effective local antigen-presenting mechanism whereby HLA antigens could be involved in exocrine glandular destruction mediated directly or indirectly by $CD4^+$ T cells (►CD4 T cells). Such interaction may lead to further production of cytokines and stimulation of B-cell proliferation and differentiation. Indeed, high levels of ►interleukin (IL)-1B, ►IL-6, and TNF-α, three tissue-destructive cytokines, are produced by epithelial cells. ►IL-10 and IFN-γ are produced mainly by infiltrating T cells, whereas IL-6 and IL-10 also are produced in increased amounts in peripheral blood. A low capacity to produce ►interleukin-2 (IL-2) in Sjögren syndrome might be due to the absence of T cell ►costimulatory signals, resulting in the induction of anergy in the responding T cells population, but other explanations also are possible. Even though the mechanism(S) behind the characteristic glandular destruction of Sjögren syndrome salivary glands remains obscure, immunopathologic findings demonstrate that infiltrating ►cytotoxic T cells (►CTLs) could play a role in this event. On recognition of a proper MHC/antigen complex presented by a ►target cell, CTLs induce cell death through one of two main and independent pathways, the ►perforin-mediated pathway or the ►Fas-mediated pathway. Interestingly, expression of Fas also has been detected among infiltrating mononuclear cells in salivary glands of MRL/lpr mice, a murine model displaying features similar to those of human SLE and Sjögren syndrome.

Expression of Fas, FasL, Bcl-2, and other ►apoptosis-associated genes/proteins has been detected by reverse transcription-polymerase chain reaction (►RT-PCR) and immunohistochemical staining of minor salivary glands in patients with Sjögren syndrome. In particular, ductal and acinar epithelial cells, but to some degree also infiltrating mononuclear cells express abnormal levels of Fas and FasL, especially in cases with heavy mononuclear cell infiltration. Ductal epithelial cells expressing Fas were usually situated inside or close to a dense focus. Most in situ studies have clearly shown a low-grade or even absent apoptosis among infiltrating mononuclear cells. The presence of ►granzyme A (►Granzymes) in Sjögren glands suggests that rather than apoptosis, the ►perforin pathway of CTL-mediated killing may be involved in destruction of salivary glands. Among the salivary gland-infiltrating T cells, some express activation markers such as ►CD25, ►proto-oncogene products, and HLA-DR, but few T cells proliferate as determined by cell cycle studies. It seems difficult also to stimulate the T lymphocytes in Sjögren syndrome with the autoantigens Ro/SSA and La/SSB. These findings suggest that many cells are of memory T cell phenotype; either few of them are autoantigen-specific, or alternatively, many of them are in a state of anergy. In both cases, lack of stimulation of T cells also will hamper the apoptotic signals.

Immunopathogenesis (Summary)

The etiology and pathogenesis of Sjögren syndrome is still a matter of speculation, although several hypotheses prevail. Nevertheless, there is considerable evidence that some as-yet-unknown initiating factor(s) set against the appropriate genetic background may evoke immunologically mediated inflammatory mechanisms, which result in the chronic exocrine gland lesions. T cell-mediated autoimmune responses (►Cell-mediated immunity or cell-mediated immune response) in the glandular tissue and dysregulated apoptosis are currently considered to be of central importance in the pathogenesis. A plethora of autoantibodies has been linked to this autoimmune exocrinopathy, although their role is not always well-defined. Accordingly, B-cell activation is a very consistent immunoregulatory abnormality in Sjögren syndrome.

Treatment and Prognosis

At present, treatment for most patients is essentially symptomatic. The patient should be seen regularly by a rheumatologist as well as by an ophthalmologist and a dentist to prevent and treat the consequences of mucosal dryness, in addition to extraglandular manifestations and other associated complications.

Artificial tears often alleviate the patient's complaints, and are of importance in preventing corneal damage and conjunctivitis. The use of topical steroids is not

recommended because of a high risk of secondary bacterial and viral infections in the eye. Another treatment option for dry eye is "punctal occlusion" by using a variety of "plugs" to occlude the punctual openings at the inner aspects of the eyelids. With this procedure, the instilled artificial tears will remain in the eye for a longer time. The management of dry mouth aims to prevent and treat infections, gum disease, and dental caries. To reduce the risk of caries, it is necessary to keep good oral hygiene and use sugarless sweets and chewing gums to stimulate residual salivary flow. Artificial saliva products and special toothpaste is advocated. Eradication of oral candidiasis usually provides significant improvement of oral symptoms.

Oral ►pilocarpine has recently been shown to be a safe treatment and to provide significant subjective and objective benefits for patients with Sjögren syndrome with symptoms associated with xerostomia. Another potential therapy includes systemic use of interferon-α (IFN-α), which may be of benefit for the symptoms associated with xerostomia.

►Hydroxychloroquine may be useful as an immunomodulating agent reducing immune activation and lymphoproliferation and is sometimes used in patients with Sjögren syndrome. Administration of systemic steroids also has been suggested to improve the signs and symptoms of Sjögren syndrome, but they are mainly used for treatment of severe extraglandular complications such as pulmonary and renal involvement. Serology can be useful in predicting the subsequent outcome and complications in patients with primary Sjögren syndrome. The presence of anti-Ro/SSA antibodies may identify patients with systemic disease, and in anti-Ro/SSA/anti-La/SSB-positive patients, the relative risk of developing non-Hodgkin lymphoma has been reported as high as 49.7 after 10 years' follow-up. The development of extraglandular manifestations seems to be influenced by a number of factors including the MHC HLA B8 and DR3 expression. Spontaneous symptomatic improvement has been described in 12% of patients with primary Sjögren syndrome, especially in elderly patients with some clinical overlap with SLE.

SS and HCV

Patients with SS-HCV and B-cell lymphoma are clinically characterized by a high frequency of parotid enlargement and vasculitis, an immunologic pattern overwhelmingly dominated by the presence of RF and ►mixed type II cryoglobulins, a predominance of ►mucosal-associated lymphoid tissue (MALT) lymphomas, and an elevated frequency of primary extranodal involvement in organs in which HCV replicates (exocrine glands, liver, and stomach). Recently, there has been growing interest in the association of chronic HCV infection with both lymphoproliferative and autoimmune diseases. Several studies have found a higher prevalence of lymphoproliferative disorders in patients with HCV, although others have found no significant association. In addition, the specific tropism of HCV for many extrahepatic cell types has recently suggested a link between HCV and the development of autoimmune diseases, although this extrahepatic replication is not supported by all studies. The sialotropism of HCV may explain the close association with SS and sicca syndrome, whereas its lymphotropism links the virus with the synthesis of cryoglobulins and with lymphoma development. This extrahepatic tropism suggests the probability of the development of both autoimmune and lymphoproliferative processes in some patients with chronic HCV infection. In primary SS, lymphoma seems to be triggered by RF-secreting B cells closely associated with the 17109 and G-6 idiotypes, whereas in patients with HCV, a possible association with an antibody response to the envelope protein E2 of the virus has been postulated. The coexistence of both RF-positive processes (SS and HCV) in the same patient might enhance the possibility of developing diseases related to B-cell proliferation (cryoglobulinemia and low- and high-grade lymphoma). The most frequent type of B-cell lymphoma found in patients with SS-HCV was MALT lymphoma. The predominance of MALT lymphoma in SS-HCV and primary SS but not in HCV suggests an important role for SS in the lymphomagenesis of patients with SS-HCV (►Treatment of SS-HCV, Robert G and concepts). Two therapeutic options should be highlighted as future options. The first is the use of monoclonal agents against B cells (►Rituximab or ►epratuzumab), which have been successfully used to treat not only ►B-cell lymphomas but also cryoglobulinemic vasculitis, with the aim of controlling the marked B-cell hyperreactivity observed in patients with SS-HCV. The second is the use of antiviral agents (►Interferon and ►ribavirin), which aims to eradicate the virus as the main causative agent of this B-cell hyperactivity, and which was successfully used in some of our patients. A combination of anti-B-cell and anti-HCV agents may be a promising option for the successful treatment of B-cell lymphomas in patients with SS-HCV.

SS Cause Lymphoma?

A small percentage of people with Sjögren syndrome develop lymphoma, which involves salivary glands, lymph nodes, the gastrointestinal tract, or the lungs. Persistent enlargement of a major salivary gland should be carefully and regularly observed by your doctor and investigated further if it changes in size in a short period of time. Other symptoms may include the following: (Note that many of these can be symptoms of other problems, including Sjögren syndrome itself. Nevertheless, it is important to see your doctor if you have any of these symptoms so that any problem can be diagnosed and treated as early as possible.)

1. Unexplained fever
2. Night sweats
3. Constant fatigue
4. Unexplained weight loss
5. Itchy skin
6. Reddened patches on the skin

If you are worried that you might develop lymphoma, talk to your doctor to learn more about the disease, the symptoms to watch for, any special medical care you might need, and what you can do to relieve your worry.

SS and Lymphoproliferative Disorders

Sjögren's syndrome is a chronic organ-specific autoimmune disease characterized by lymphocytic infiltration into the salivary and lacrimal glands. About half of primary SS patients develop systemic disorders. Primary SS can be divided into three stages according to the extent of organ damage and the course of the disease. In stage I, (~45% of cases), patients have only sicca syndrome and do not experience any systemic involvement, even after 10 years. In stage II, (~50% of cases), patients experience lymphocytic organ damage, which may involve the pulmonary, renal, hepatic, hematologic, and/or dermatologic systems, among the others. Finally, in stage III, (~5% of cases), patients develop malignant ►lymphomas. Lymphomas in salivary glands are through to arise from lymphoepithelial lesions in which there are close interactions among epithelial cells, T cells, and B cells. The B cells in the lesions become activated through the interaction between CD40L and CD40. The progression from polyclonal lymphoproliferation to monoclonal lymphoproliferation, to MALT lymphoma, and finally to high-grade malignant lymphoma is regarded as a multistep process. Antigenic activation of B cells, together with oncogenic events, including ►p53 inactivation and bcl-2 activation, may play important roles in B-cells monoclonal proliferation and malignant transformation. The rheumatoid factor clone is regarded as a candidate B-cells clone that undergoes transformation (Lymphoproliferative disorders in Sjögren syndrome, Yasufumi Masaki and concepts).

Future Directions

The search for susceptibility genes in families with Sjögren syndrome is ongoing with the same approach as in the other chronic autoimmune diseases and with utilization of two major strategies: the position-independent candidate gene approach with mutation screening of suspected disease-related genes and full genome scanning (microsatellite analysis) in humans as well as in animal models to determine susceptibility chromosomal regions, which later will be used in a positional candidate gene strategy. Another challenge in Sjögren syndrome will be to stratify the disease process including genetic and environment triggers. Identification of new genetic markers and better characterization of novel autoantibodies (e.g., those directed against muscarinic receptors in exocrine glands) may lead to the development of better diagnostic and prognostic tests in Sjögren syndrome including its systemic complications. Sjögren syndrome is considered to represent an ideal disease to study the mechanisms underlying autoimmunity because its manifestations are both organ-specific and systemic. The significance of such studies is underlined by the high prevalence of Sjögren syndrome as a common but often neglected systemic autoimmune disease often found in the female and aging population.

Definition

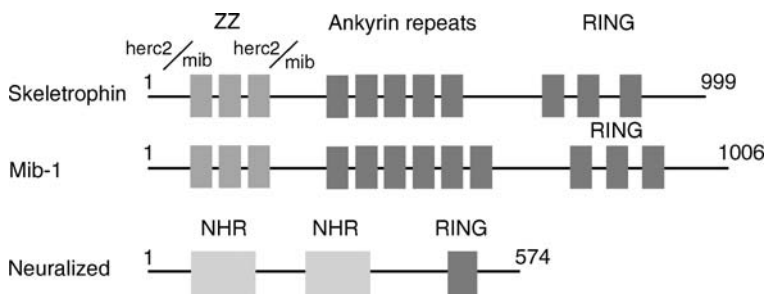
Skeletrophin is one of three ubiquitin ligases, the substrate of which is a cytoplasmic region of Notch ligands and positively regulates ligand-dependent Notch activation. The gene maps to human chromosome position 1p36.32-33, where tumor suppressor factors for neuroendocrine tumors are encoded. Although at least six alternative splicing forms have been found in the public database, the major human product, which is expressed in many tissues, is composed of 999 amino acids and is approximately 110 kDa. Skeletrophin is localized in the cytoplasm and is widely expressed in various adult tissues, with particularly strong expression in skeletal muscle, heart, and brain tissue. There are also alternative splicing forms expressed specifically in the brain, and forms expressed specifically in the developing brain.

Characteristics

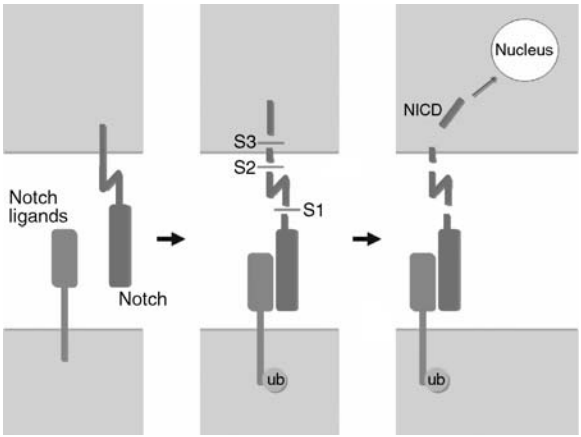
Skeletrophin has two mib/herc2 domains, a ZZ domain, ankyrin repeat domains, and two RING-HC motifs (Fig. 1). A self-ubiquitination assay revealed that a typical RING-HC motif at the C-terminal mediates ubiquitin ligase activity *in vitro*. However, both of the RING-HC motifs are believed to be essential *in vivo*. Both skeletrophin and its paralogue, mib-1 (also known as DIP-1, Fig. 1), also cause mono-ubiquitination of the intracellular domain of Notch ligands. In some tissues, including the brain, both skeletrophin and mib-1 are expressed; however, in other tissues, especially at developing tissues, skeletrophin is expressed only at low levels, with predominant expression of mib-1. Another ubiquitin ligase, termed Neuralized, also causes mono-ubiquitination of Notch ligands.

The other ubiquitin ligases, Neuralized also target intracellular region of Notch ligands. They have two neuralized homology repeat domains (NHRs) and C-terminal RING domain. NHR is believed to be important for ligand binding.

Notch ligands are internalized to the cytoplasm by mono-ubiquitination. In general, mono-ubiquitin-mediated endocytosis removes ligands or receptors from the cell surface membrane, therefore abolishing signal transmission. In contrast, endocytosis of Notch ligands positively mediates ligand-dependent Notch activation, when Notch ligands bind to Notch (Fig. 2). It is thought that endocytosis of Notch ligands may alter the moleular structure of the bound Notch molecules and expose the proteinase cleavage sites, indicated by



Skeletrophin. Figure 1 Schematic representation of molecular structures of skeletrophin and its paralogue mib-1 (mind bomb homologue-1). Skeletrophin and mib-1 have two and three RING-HC motifs, respectively. A typical RING-HC motif at the C-terminus of both skeletrophin and mib-1 mediates ubiquitination *in vitro*. Two unique herc2/mib domains are found at the N-terminus. Distinct molecular functions of herc2/mib are unclear; however, this domain is often found to coexistent with the RING motif. A novel zinc finger domain (ZZ domain), is found in dystrophin and in the first half of skeletrophin and mib-1. The ZZ domain is a putative calmodulin binding site; therefore, it is thought that skeletrophin and mib-1 may be regulated by Ca^{2+} concentration. Ankyrin repeats are a conspicuous feature of ankyrin and act as a binding site for various molecules.



Skeletrophin. Figure 2 Mono-ubiquitination of the intracellular region triggers endocytosis of Notch ligands. Ligand binding to the Notch receptor results in a conformational change, leading to the unmasking of the proteinase cleavage site, indicated by S2 in the figure. Subsequently, the extracellular domain of Notch undergoes proteolytic cleavage, then is further processed at the juxtamembrane proteolytic cleavage site to generate the Notch intracellular domain (NICD). Finally, NICD moves into the nucleus and mediates transcriptional signaling.

S1 in Fig. 2, of the extracellular domain of Notch. This process is linked to the generation of the intracellular Notch domain, which transmits the ligand-dependent Notch activation signal. Mono-ubiquitination-mediated endocytosis is generally followed by lysosomal protein degradation or recycling of surface membrane proteins. Skeletrophin may also be involved in the degradation or recycling of Notch ligands that are not bound to Notch. However, the precise mechanism that determines whether skeletrophin activates or abolishes ligand-dependent Notch activation remains largely unknown.

Clinical Aspects

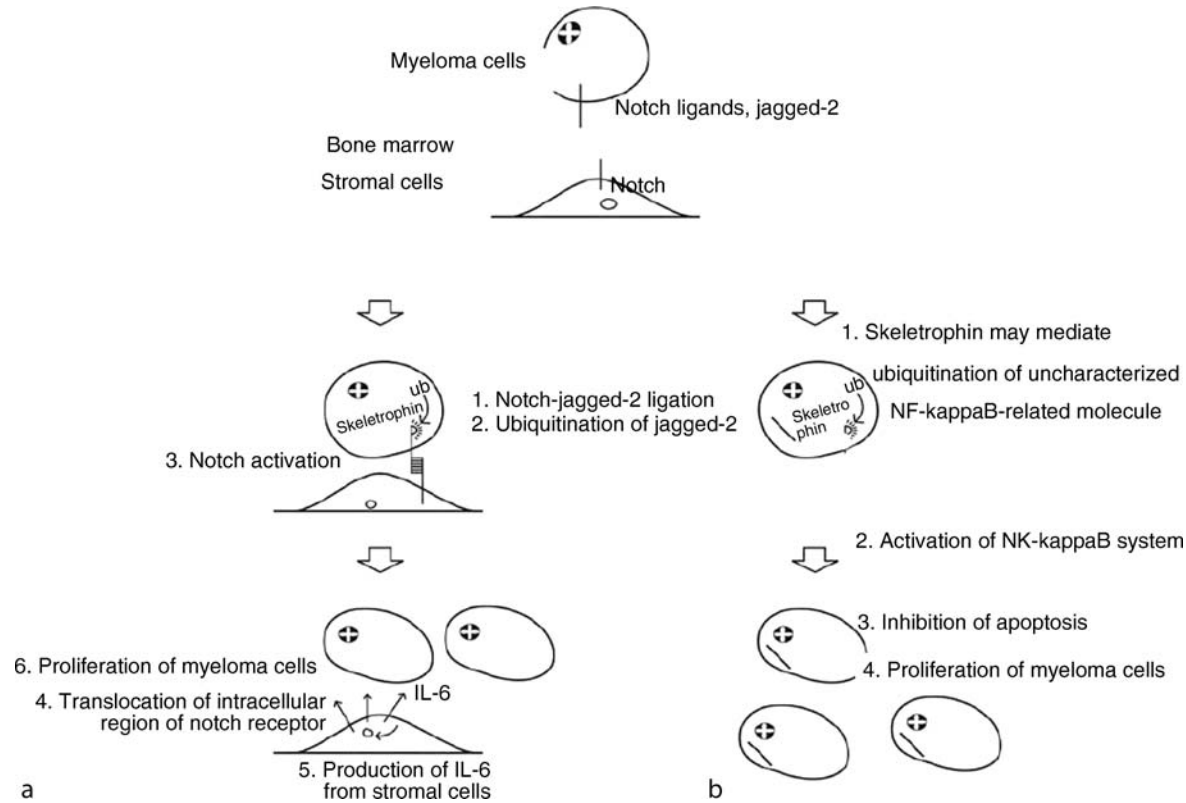
Ligand-dependent Notch activation has a dual antagonistic role in promoting and suppressing tumorigenesis. Skeletrophin also plays a role in both tumor progression and tumor suppression.

Skeletrophin is overexpressed in multiple myeloma, especially from patients whose disease is at an advanced stage and where there are osteolytic bone lesions present. In general, ubiquitin ligase and its substrate, the target molecule, are not constitutively co-expressed in a cell; however, both skeletrophin and its substrate, Jagged-2, a Notch ligand, are constantly and abundantly expressed in many myeloma cells. This aberrant co-expression of skeletrophin and Jagged-2 is caused by epigenetic molecular events in myeloma cells. Both *skeletrophin* and *jagged-2* contain a CpG-rich promoter, harboring CpG islands, which, when hypomethylated, are activated in numerous myeloma cells (Fig. 3). As a result, skeletrophin constitutively acts to cause mono-ubiquitination of the intercellular region of Jagged-2, causing ligand-dependent Notch activation in bone marrow stromal cells, which directly contact with myeloma cells. Finally, activated bone marrow stromal cells secrete cytokines, including IL-6, and create an adequate microenvironment for myeloma progression (Fig. 3a). Jagged-2 is a cell surface membrane protein with a transmembrane domain, whereas in many myeloma cells, Jagged-2 is localized to the cytoplasm, as a result of endocytosis following skeletrophin-mediated-mono-ubiquitination.

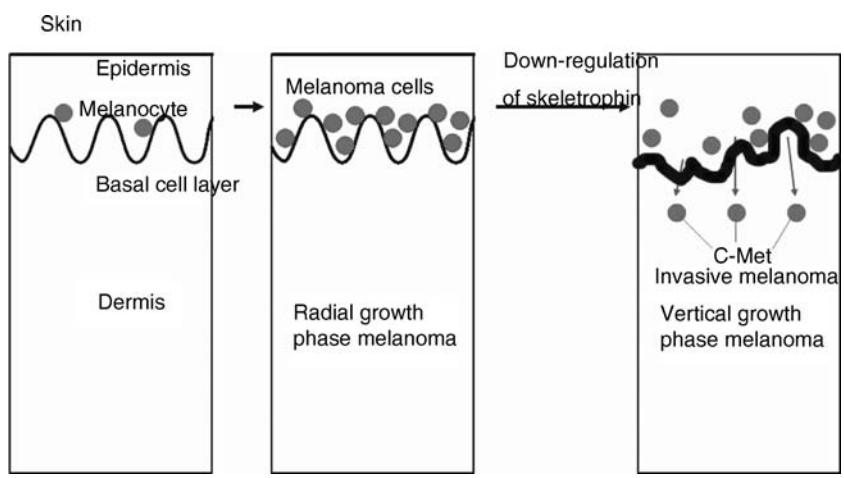
Skeletrophin is also characterized as a putative NF-kappa-B-activating protein, designated 002N. Several independent transcriptional screenings have detected skeletrophin as a powerful NF-kappa-B activator among over 15,000 clones. The anti-apoptotic effect of skeletrophin also contributes to progression of myeloma, especially in patients receiving chemotherapy (Fig. 3b). Notably, the molecular structure of the RING-HC motif in skeletrophin is very similar to that of apoptosis-mediating ubiquitin ligases, such as IAP-1, 2 and XIAP. These findings suggest that skeletrophin has an anti-apoptotic effect and promotes tumor progression by targeting an unknown molecule, other than Notch ligands.

In contrast, skeletrophin suppresses malignant melanoma progression, especially tumor invasion (Fig. 4). Skeletrophin is expressed in normal melanocytes, almost all benign nevi, and in many non-invasive melanoma cells. Skeletrophin is silenced by various epigenetic events, including hypermethylation, in many invasive malignant melanomas at the invasion stage or the vertical growth phase. Skeletrophin down-regulates transcription of the Met oncogene, which encodes the hepatocyte growth factor receptor, and plays a role in determination of the invasive phenotype of many malignant tumors. Restoration of skeletrophin in invasive melanoma has been shown to suppress tumor invasion both *in vitro* and *in vivo*.

To date, three molecular events have been determined to repress skeletrophin expression in melanoma. First, aberrant hypermethylation of the promoter region of *skeletrophin* on a CpG island is found in many invasive melanomas. Second, down-regulation of an activator protein-2 (AP-2), which is known to have a tumor-suppressor role in melanoma, also down-regulates the transcription of skeletrophin. Third, over-expression of Snail, a zinc-finger transcriptional factor, is responsible for silencing of skeletrophin by binding to an E-box in the *skeletrophin* promoter. Notably, Snail is known to be over-expressed in invasive



Skeletrophin. Figure 3 The pathological role of skeletrophin in multiple myeloma. (a) Indirect effect through bone marrow microenvironment. Myeloma cells adhere to stromal cells. Overexpression of skeletrophin and its substrate, Jagged-2, in myeloma cells facilitates ligand-dependent Notch activation in stromal cells. Activated stromal cells secrete various cytokines including IL-6 to promote myeloma. (b) Direct mechanism of skeletrophin in multiple myeloma. Overexpression of skeletrophin activates NF-kappaB signaling and protects myeloma cells against apoptosis.



Skeletrophin. Figure 4 Silencing of skeletrophin in melanoma contributes to tumor invasion. Skeletrophin is expressed in melanocytes, a normal component of melanoma, and in non-invasive melanoma cells at the radial growth phase. In contrast, various epigenetic events down-regulate skeletrophin in invasive melanoma at the vertical growth phase. The silencing of skeletrophin allows melanoma cells to express c-Met. C-met encodes hepatocyte growth factor receptor and contributes to the invasive phenotype of melanoma cells.

melanomas. In addition, as well as being one of the most common karyotypic lesion seen in melanoma, loss of alleles of 1p36 has been detected as a late event, at the invasive and metastatic phase, in melanoma progression. Therefore, loss of heterozygosity may be important for down-regulation of skeletrophin in melanoma.

It has long been speculated that a gene encoding tumor suppressor factor in invasive melanomas is located at human chromosome position 1p36.3. Recent studies indicate that this tumor suppressor factor may be skeletrophin itself. Moreover, it is believed that uncharacterized genes, which encode the suppressor molecule for various neuroendocrine tumors including neuroblastoma, are located at 1p36.3. Since melanoma is a malignant tumor of neural-crest-derived melanocytes, skeletrophin might be a tumor suppressor factor for various neuroendocrine tumors.

Ski

Definition

Was first identified as a viral oncogene from the avian Sloan-Kettering retrovirus, which transforms chicken embryo fibroblasts. Elevated levels of c-ski have been detected in several human tumor cell lines derived from neuroblastoma, melanoma and prostate cancer. Ski appears to bind to DNA and be part of the ►histone deacetylase complex.

►Smad Proteins in TGFβ Signaling

Skin Cancer

Definition

Refers to cancers involving the skin. About 80% of these skin cancer cases are ►basal cell carcinoma (BCC), 16% ►squamous cell carcinoma (SCC), and 4% ►melanoma.

Skin Carcinogenesis

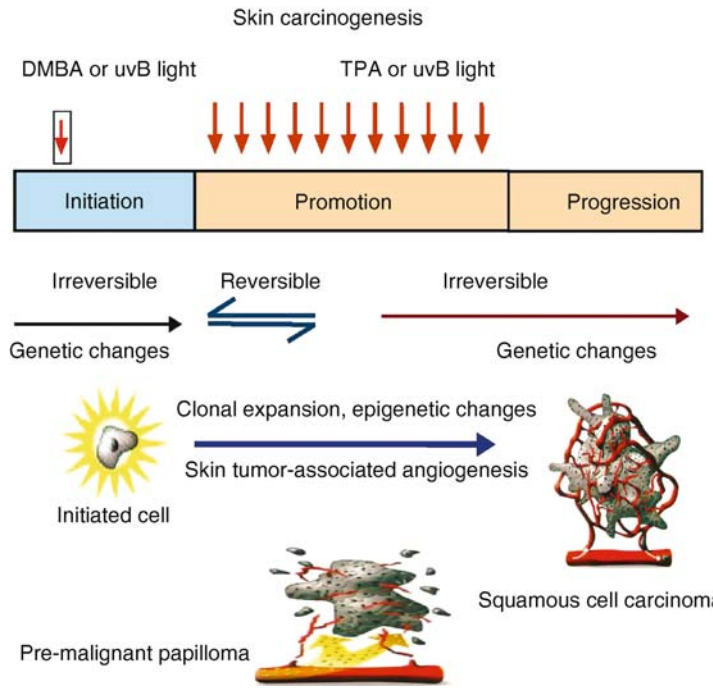
Fredika M. Robertson
The University of Texas MD Anderson Cancer Center, Houston, TX, USA

Definition

A multi-step process by which a number of distinct phases occur to form malignant skin tumors. The first step in ►skin carcinogenesis is ►initiation, which is a reversible process during genetic mutations, gene activation or inactivation occur. Examples of initiation are mutations in the v-Ha-*ras* oncogene or inactivation of the p53 tumor suppressor gene. The next phase of carcinogenesis is ►tumor promotion, characterized by a reversible phase of clonal expansion of initiated cells containing mutations/inactivated genes, with a dysregulation of apoptosis of the initiated cells, as well as by accumulation of epigenetic changes such as DNA methylation, inflammation characterized by infiltration of activated leukocytes, production of growth factors, cytokines, reactive intermediates, including oxygen free radicals and nitrogen radicals which stimulate formation of DNA damage, with inhibition of DNA repair enzymes. These alterations become irreversible and first lead to development pre-neoplastic papillomas, which are benign skin lesions. Simultaneous with tumor ►promotion, vascular permeability occurs, which is the first stage of skin ►tumor-associated angiogenesis, which is in itself a multi-step process, during which vasculature develops to provide oxygen and nutrients to expanding pre-neoplastic lesions. With continual accumulation of genetic mutations, the next stage of carcinogenesis, ►tumor progression occurs, which is characterized by the accumulation of genetic mutations leading to conversion of pre-neoplastic skin lesions to malignancy, which are primarily squamous cell carcinomas.

Characteristics

In 1775, Dr. Percival Pott, a British surgeon, made the observation that there was a high incidence of scrotal



Skin Carcinogenesis. Figure 1 Schematic of the multi-step process by which squamous cell carcinomas develop following exposure to either chemicals such as DMBA and TPA or to multiple exposures to sunlight that contains ultraviolet light in the 290–320 nm range, defined as uvB light. Note that this process includes not only proliferation but also includes genetic alterations, epigenetic changes, increased vascular permeability, and tumor-associated angiogenesis.

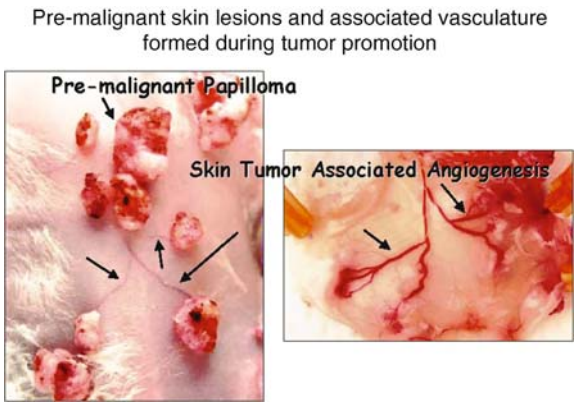
cancer in chimney sweeps compared to that of the general population. This observation is recognized to be the first report of chemical carcinogenesis, suggesting that exposure to environmental agents, such as soot and coal tar, may be directly linked to development of cancer in humans. In addition, this observation also led scientists to evaluate the carcinogenic process using a variety of different models and to identify the specific compounds and/or physical agents that are involved in growth of human tumors.

Thus began the development of rodent models to study what is now understood to be the multi-step process of carcinogenesis. The most widely used models of multi-stage carcinogenesis has been in mouse skin, which have been used over the past 70 years to identify and define distinct and sequential stages of mouse skin carcinogenesis, which is a process that includes multiple steps including tumor initiation, tumor promotion and tumor progression.

The development and use of mouse skin carcinogenesis models have led to the appreciation that the majority of tumors of epithelial origin in humans arise due to a multi-step process, with the majority of experimental models developed using the skin model as an example. There are now multiple models available that have been used to identify the genetic, molecular and cellular basis of rodent lung tumors, gastrointestinal tumors, oral and head and neck tumors, as well as hepatocellular tumors and breast tumors that are based on the commonly held view that human tumors develop as a result of a multi-step process.

There are two primary mouse skin models that have been used to define the genetic, molecular, cellular, and genetic basis of skin carcinogenesis. The first of these models is based on the topical application of a single dose of a chemical carcinogens, primarily polycyclic aromatic hydrocarbons, such as ►7, 12 dimethylbenz [a]anthracene (DMBA), followed by multiple topical exposures to an agent such as the ►tumor promoter, 12-0-tetradecanoylphorbol-13-acetate, (TPA), which is the active ingredient of croton oil, first used in multi-stage skin carcinogenesis studies.

The other model of skin carcinogenesis commonly used is based on induction of skin tumors following multiple exposures to wavelengths of light that are contained in solar radiation, primarily ultraviolet light in the 290–320 nm wavelength range of light, known as ►Ultraviolet Light B (uvB) light. Although humans



Skin Carcinogenesis. Figure 2 Photomicrographs of pre-malignant skin lesions and the dermis underlying the skin lesions which contain vasculature to each pre-malignant skin lesions which provides oxygen and nutrients. These are the classical hallmarks of the process of multi-stage skin carcinogenesis leading to formation of squamous cell carcinomas.

do develop skin tumors from exposure to chemicals, the vast majority of human skin tumors occur due to multiple exposures to solar irradiation, within an increase in skin tumors, due to the depletion of the ozone layer.

Exposure of the skin to a single dose of a carcinogen such as DMBA, a polycyclic aromatic amines derived from fossil fuel by-products followed by multiple exposures to the tumor promoter TPA or to multiple exposures of the skin to uvB light induces both genetic changes and epigenetic alterations, which significantly alters the normal organized pattern of keratinocyte proliferation and differentiation, ultimately resulting in development of skin malignancies.

Genetic Basis of Skin Carcinogenesis

These two mouse models of multi-stage skin carcinogenesis have been used to identify and define distinct and sequential stages of mouse skin carcinogenesis, which include tumor initiation, promotion, and progression. Although exposure of mice to either chemicals or to uvB light results in formation of skin tumors, these different agents induce different genetic mutations.

In the chemical skin carcinogenesis model which uses DMBA as the ►initiator and TPA as the tumor promoter to induce skin tumor formation, the first step is tumor initiation, which is accomplished by topical application of a single sub-carcinogenic dose (25–200 nmol) of DMBA to the dorsal skin of genetically susceptible mice. Exposure of the skin to carcinogen results in formation of mutations in the Harvey-ras (Ha-*ras*) oncogene at codons 12, 13, 59, and 61 of epidermal keratinocytes, which are then considered to be "initiated" cells.

Initiation

Formation of genetic mutations by either a chemical, such as a polycyclic aromatic hydrocarbon, 7,12 dimethylbenz[a]anthracene (DMBA) or benzo[a]pyrene (BP), derived from incomplete combustion of fossil fuels or as a byproduct of smoking tobacco, respectively, which induce mutations in such areas as codons 12, 13, 59 and 61 of the v-Ha-ras oncogene. Physical entities, such as solar irradiation, particularly ultraviolet light (uv) in the 290–320 nm wavelength range (uvB), induce inactivation of the p53 tumor suppressor gene by formation of mutations in specific codons including codons 151/152, 245, 248, 278, 286 within exons 5–9 of this gene.

Promotion

A process by which chemical or physical agents, such as ►12-0-tetradecanoylphorbol-13-acetate (TPA) or uvB light, stimulate clonal expansion of initiated cells and alter the differentiation pattern of specialized epithelial cells of the skin, epidermal keratinocytes. In addition to these cells undergoing tumor promotion, the stem cells of the skin located in the interfollicular "bulge region" of hair follicles in the dermis also undergo proliferation. Initiated cells undergoing clonal expansion do not undergo the normal process of terminal differentiation, which is a specialized form of programmed cell death, i.e., apoptosis, that normally occurs in epidermal keratinocytes that contain damaged DNA. In contrast to chemicals such as DMBA and BP that act primarily as initiators, uvB light acts both as an initiator as well as a tumor promoter, and is therefore considered to be a "complete carcinogen."

As an initiator of multi-stage skin carcinogenesis, uvB light induces inactivation of the p53 tumor suppressor gene due to formation of mutations primarily by formation of pyrimidine 6-4 pyrimidone photoproducts at codons 151/152. 245, 248, 278, and 286 of the p53 gene, with the frequency of photoproducts very high at codon 286. The importance of the mouse model of ultraviolet light induced multi-stage skin carcinogenesis to human tumorigenesis is based on the fact that ~50% of all human tumors contain defects in the p53 tumor suppressor gene, although the codons that are hot spots for p53 mutations may differ from those induced by uvB light, indicating that there is genetic heterogeneity in human tumors and in mouse models used to study human carcinogenesis. This clearly defines the uvB light-induced model of skin carcinogenesis as having high relevance to the genetic basis of human

skin cancer, as well as to other types of human cancers of epithelial origin.

With the development of transgenic mouse models, the genetic basis of both uvB induced skin carcinogenesis, which is p53 inactivation, and chemical carcinogenesis induced by DMBA/TPA, which is based on v-Ha-*ras* mutations/activation have been verified. Other multi-stage models of carcinogenesis have been developed based on these two mouse models of skin carcinogenesis, such as models for understanding the genetics of cervical cancer induced by human papillomas virus and the genetic basis for colorectal carcinoma using the adenosis polyposis coli gene.

Cellular and Molecular Basis

Ultraviolet light in the 290–320 wavelength range, (uvB) light is a complete carcinogen. This physical agent therefore acts as an initiator and induces mutations in specific codons of the p53 tumor suppressor gene, with clusters of p53 mutated cells formed at very early times after uvB exposure. In addition, uvB light also acts as a tumor promoter to induce clonal expansion of initiated cells, with a dysregulation of apoptosis stimulating this process. A number of different types of DNA damage have been shown to be present in skin exposed to uvB light, including cyclobutane pyrimidine dimers, pyrimidine (6-4) pyrimidone photoproducts, and formation of oxidative DNA adducts such as 8-oxo-deoxyguanine. Epidermal keratinocytes which contain these mutations in the p53 tumor suppressor gene that leads to its inactivation are resistant to apoptosis through the dysregulation of Fas-Fas ligand interactions, thereby allowing keratinocytes with p53 mutations to have a selective advantage in undergoing clonal expansion, first leading to actinic keratosis and subsequently to development of squamous cell carcinomas.

In skin carcinogenesis induced by DMBA/TPA, DMBA serves as the initiator of mutations in the v-Ha-ras oncogene and tumor promotion is accomplished by repeated topical application of a tumor promoter, such as 12-0 tetradecanoylphorbol-13-acetate (TPA), to initiated skin for 20 to 30 weeks. TPA stimulates clonal expansion of initiated *ras*-mutated keratinocytes, ultimately leading to outgrowth of pre-neoplastic skin papillomas. The changes in the skin induced during tumor promotion include epidermal and follicular hyperplasia, altered differentiation patterns of epidermal keratinocytes and interfollicular bulge region "stem cells," with an associated resistance to apoptosis and simultaneous increase in genes associated with cell survival, dermal inflammation characterized by infiltration of activated leukocytes that produce reactive oxygen and nitrogen intermediates, leading to DNA damage and alterations in DNA repair. In addition, other critical factors such as production of growth factors and their receptors, cytokines and chemokines, phosphorylation and subsequent activation of signal transduction molecules, as well as induction of immediate early genes, have been examined for their essential role in multi-stage skin carcinogenesis.

The last phase of mouse skin carcinogenesis is tumor progression, which occurs in a small subset of pre-neoplastic papillomas that acquire additional genetic mutations and subsequently undergo malignant conversion from pre-neoplastic lesions to form malignant squamous cell carcinomas.

Skin tumor-associated angiogenesis is a process that is now recognized to be essential for skin carcinogenesis. The primary growth factors involved in stimulating the vascular permeability and development of new blood vessels surrounding the developing skin lesions are in the family of vascular endothelial growth factor proteins. Further studies which better define other factors involved in skin tumor-associated angiogenesis may hold promise for development of novel strategies to inhibit survival of pre-neoplastic skin papillomas and to block their progression to squamous cell carcinomas.

Relevance to Human Disease

Skin tumors are one of the most prevalent types of tumors diagnosed in humans. Experimental rodent models of multi-stage skin carcinogenesis have been developed to define the genetic, molecular, and cellular basis of this multi-step process by which human skin tumors form. These mouse models have also provided the basis for development of rodent models for other tumors of epithelial origin. The two models of multi-stage skin carcinogenesis described above have allowed identification of the molecular pathways involved in this process and provide models for identification and development of chemotherapeutic agents for treatment of skin cancer patients. In addition, these models of skin carcinogenesis have also been used extensively to evaluate the activity of natural products and their active ingredients for prevention of skin cancer as well as are currently being used to define the role of stem cells in skin tumor carcinogenesis.

Definition

The ►Slit family of secreted proteins has been shown to function in ►axon guidance and neuronal ►migration. There are three Slit proteins in mammals, and while Slit1 expression is mostly restricted to the nervous system, Slit2 and 3 are also expressed in other organs.

Characteristics

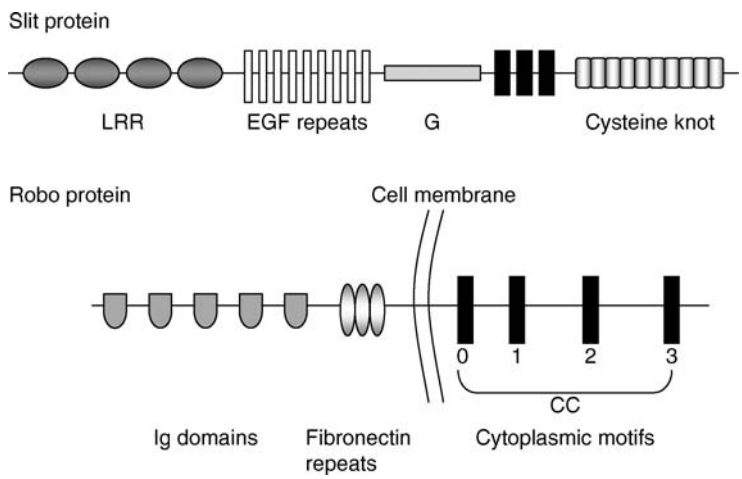
A typical Slit protein contains an N-terminal signal peptide, four leucine-rich repeats (LRRs), seven (in *Drosophila*) or nine (in vertebrates) EGF repeats, a laminin G domain, and a C-terminal cysteine knot (Fig. 1). The receptor for Slit is the transmembrane protein ►Robo (Roundabout), and four *ROBO* genes have been identified. Typically, Robo proteins, including Robo1, consist of five extracellular immunoglobulin (Ig) domains, three fibronectin repeats, and a conserved intracellular region of four cytoplasmic motifs (Fig. 1).

Slit function in the Nervous System

Expression of Robo proteins has traditionally been associated with migrating axons in the developing nervous system. Examples include expression in commissural axon growth cones after ventral midline crossing and expression in olfactory bulb axons on route from the olfactory epithelium to the primary olfactory cortex. In the *Drosophila* spinal cord, Slit functions as a short-range cue to prevent ipsilateral projecting commissural fibers from crossing the midline, and contralateral projecting commissural fibers from re-crossing the midline. A combinatorial code of Robo receptors on medial, intermediate and lateral axons helps control lateral positioning in response to a Slit gradient in the CNS. In addition, Slit proteins act as chemorepellents in axon guidance in the mouse visual system as well as in neuronal migration and axon guidance in the mammalian forebrain both *in vitro* and using knockout mice deficient in Slit1 and/or Slit2 *in vivo*.

Slit-Robo Signaling

Studies examining Slit-Robo signaling can be divided into three basic categories. The first paradigm involves



Slit. Figure 1 Schematic depicting the structure of prototypical Slit and Robo proteins. The mammalian Slit protein contains an N-terminal signal peptide, four leucine-rich repeats (LRRs), nine (in vertebrates) EGF repeats, and a C-terminal cysteine knot. A typical Robo1 receptor consists of five extracellular immunoglobulin (Ig) domains, three fibronectin repeats, and a conserved intracellular region of four cytoplasmic motifs. Robo3 (also known as Rig1) is missing one of the cytoplasmic motifs and Robo4 encodes only two Ig domains, two fibronectin repeats and two cytoplasmic motifs.

the ►RhoGTPases and the regulation of the actin cytoskeleton to generate a turning response.

Evidence has accumulated suggesting an important role for regulation of the actin cytoskeleton machinery in Slit-mediated repulsion. The ►Slit-Robo-GAPS (►srGAPs) facilitate hydrolysis of Cdc42 leading to actin depolymerization. Studies have demonstrated opposing roles for Rac in the regulation of axon repulsion in Drosophila. For example, Slit stimulation leads to recruitment of the SH3-SH2 adaptor protein Dreadlocks (Dock) and the p21-activated serine-threonine kinase (Pak) to the Robo receptor CC2 and CC3 cytoplasmic motifs. Recruitment of this complex increases Rac activity to regulate axon repulsion at the CNS midline. In contrast, Vilse, a conserved family of RhoGAPs has been shown to promote hydrolysis of RacGTP, and less efficiently, Cdc42GTP to mediate Robo repulsion in Drosophila tracheal cells and axons. The contradictory models can be explained in terms of a temporal model of Slit effectors where sequential interaction with the Robo receptors leads to a sustained turning response.

In addition to the involvement of the RhoGTPases, a role for the Abelson kinase (Abl) and its substrate Enabled (Ena) in Slit-mediated repulsion has been elucidated. Abl binds to CC3 and phosphorylates a tyrosine in CC1; whereas, Ena associates with CC2 to regulate the repulsive effect of Slit. Genetic and biochemical evidence suggests that Abl and Ena play opposing roles in Robo mediated repulsion where Abl antagonizes Slit-Robo signaling and Ena promotes the repulsive effect. In addition, Abl has also been linked with a supramolecular complex consisting of Robo and N-cadherin that facilitates inactivation of N-cadherin mediated adhesion in response to Slit. This mechanism uncouples the association of N-cadherin with the actin cytoskeleton and is accompanied by a loss of growth cone traction and axon extension.

Another mechanism associated with Slit-Robo signaling is the "silencing" of the Netrin receptor DCC. Activation of the Robo receptor leads to the silencing of Netrin1's attractive effect through direct binding of Robo's cytoplasmic domain to that of the DCC receptor without a concomitant affect on the stimulation of growth cone extension rate in embryonic Xenopus spinal axons. This hierarchical organization contributes to the finely-tuned controlled mechanisms guiding growth cones to their final targets.

Slit function Outside the Nervous System

Although the function of Slit in axon guidance and neuronal migration is well characterized, other developmental roles have been demonstrated. For example, homozygous knockout mice for the first Ig domain of the Robo1 gene frequently die at birth due to respiratory failure and inadequate lung maturation. Survivors demonstrated severe lung hyperplasia and bronchial abnormalities suggestive of early lung cancer. Human patients with horizontal gaze palsy with progressive scoliosis (HGPPS) were reported to have mutations in Rig1/Robo3, and functional studies have shown defects in commissural hindbrain projections and pontine nuclei. Furthermore, Slit2 and 3 and Robo1 and 2 expression have been detected in non-neuronal cells including pulmonary mesenchyme and airway epithelium, kidney, heart, spleen, thymus and lymph nodes. The temporal and spatial distribution of Slit and Robo mRNAs in fetal and adult tissues suggest that these genes may be associated with functional organization and cell motility during development.

Slit proteins and Cancer

Secreted proteins that guide neuronal and glial cell precursors in the developing central nervous system have also been linked with tumorigenesis. Long-range chemotropic factors including netrins, semaphorins, ephrins and the slit family of proteins are known for their roles in neuronal and glial cell migration. These molecules play an important role in neurodevelopment and it is reasonable to assume that they also influence tumor progression in the nervous system.

Slit-Robo have been shown to be involved in tumor angiogenesis and PI3K signaling has been implicated in this process. Other studies have identified Slit2 as a potential tumor suppressor gene in gliomas, lung, breast and colorectal cancer, as well as in neuroblastoma.

Slit and Medulloblastoma

Slit has also been shown to play an important role in non-neuronal cells, as an inhibitor of leukocyte chemotaxis and promoter of tumor-induced angiogenesis and endothelial cell attraction. ►Invasion of brain tumor cells has made primary malignant brain neoplasms among the most recalcitrant to therapeutic strategies. Slit2 inhibits the invasion of ►medulloblastoma, but not ►glioblastoma (multiforme) cell invasion, in a variety of *in vitro* models. For example, time-lapse videomicroscopy indicated that Slit2 reduced medulloblastoma invasion rate without affecting cell direction or proliferation. Both medulloblastoma and glioma tumors express Robo1 and Slit2, but only medulloblastoma invasion is inhibited by recombinant Slit2 protein. Downregulation of activated Cdc42 may contribute to this differential response.

A role for Rig1/Robo3 in controlling midline crossing of hindbrain precerebellar neurons and axons has been elucidated. Human patients with horizontal gaze palsy with progressive scoliosis (HGPPS) were reported to have mutations in Rig1/Robo3, and functional studies have shown defects in commissural

hindbrain projections and pontine nuclei. Furthermore, early and late stage chick cerebellar rhombic lip fragments are repelled by Slit2. Medulloblastoma cells are thought to arise from external granular layer cerebellar precursors derived from the rhombic lip, thus providing an obvious developmental parallel with Slit2 inhibition of medulloblastoma cell invasion. Slit also inhibits CXCR4-induced motility in breast cancer cells and CXCR4 antagonists have been shown to inhibit medulloblastoma tumor growth *in vivo*.

Slit2 expression has been shown to be downregulated in some gliomas with methylated SLIT2 promoter compared to gliomas and normal brain samples showing no methylation of this promoter. Slit2 and Robo1 are expressed by a variety of glioma and medulloblastoma cell lines and primary tumors. Most CNS neurons in the rat brain express at least one Robo and one Slit during their development, and that levels are maintained from the embryonic to the adult stage. Neurons expressing Robo mRNA could be unresponsive to Slit if molecules or mechanisms regulating Robo expression and function were present.

In light of the evidence demonstrating a role for Slit in leukocyte chemotaxis, angiogenesis, and now, medulloblastoma invasion, it will be necessary to further functionally characterize the intracellular mechanisms mediating non-neuronal Slit effects. The variability in the cell types and models employed will inevitably lead to differences in the intracellular mechanisms responsible for Slit-mediated effects. Selective neurodevelopmental cues such as Slit may provide significant insights into tumor invasion and outline the need for detailed assessments of how to implement this strategy for other tumor types.

Smad Proteins in TGFβ Signaling

Sylviane Dennler, Peter Ten Dijke
The Netherlands Cancer Institute, Amsterdam, The Netherlands

Definition

The Smad proteins are a family of structurally related molecules which perform a pivotal function in the transforming growth factor-β (►TGF-β) superfamily intracellular cascade. This cytokine superfamily includes TGFβ, activins and ►bone morphogenetic proteins (BMP) and regulate a broad scale of biological responses, including cell fate and ►extracellular matrix production. TGFβ superfamily members signal through heteromeric complexes of transmembrane type I and type II serine/threonine kinase receptors. Upon ligand binding, type II receptor phosphorylates type I receptor, thus activating its kinase. The activated type I receptor then propagates signals to downstream targets such as the Smad proteins. Smads (for Sma and ►Mad proteins from Caenorhabditis elegans and Drosophila, respectively) are currently divided into three classes:

- The receptor-activated Smads (R-Smads) transiently interact and become phosphorylated by specific activated type I receptor. In mammals, Smad1, Smad5 and Smad8 are specifically involved in BMP signalling, and Smad2 and Smad3 are restricted to TGFβ/activin pathway.
- The common-mediator Smad4 proteins (Co-Smad) form heteromeric complexes with either BMP or TGFβ/activin pathway-restricted Smad. These complexes then translocate to the nucleus where they control expression of target genes.
- The inhibitory Smads (I-Smads), namely Smad6 and Smad7, prevent the activation of the R- and Co-Smads through competition with R-Smads for binding to the activated type I receptor. Another mechanism has also been proposed for Smad6; this protein can compete with Smad4 for interacting with receptor-activated Smad1, yielding an apparent inactive Smad1-Smad6 complex (Table 1).

Characteristics

Smad proteins share two highly conserved domains named Mad-Homology domain 1 and 2 (MH1 and MH2) on the N- and C-terminal part of the proteins, respectively. The crystal structure of both domains has been determined. The MH1 and MH2 domains are adjoined by a divergent proline-rich linker region.

Smad proteins do not appear to contain any intrinsic enzymatic activity but rather exert their function through

protein-protein or protein-DNA interactions. The MH2 domain mediates the association with other Smads, interaction with activated type I receptors (for R- and I-Smads) and various transcription factors, for example forkhead activin signal transducer (FAST). Furthermore, the MH2 domain enables the interaction of Smad proteins with various transcription co-activators or co-repressors. The MH1 domain also mediates protein-protein interactions with transcription factors, for example ►JUN. Importantly, the MH1 domains of Smad3 and Smad4, but not of Smad2, are able to bind directly to a 5′ GTCT DNA sequence through a β hairpin motif. As Smads bind to DNA with rather low affinity and specificity, these proteins appear to need the interaction with other DNA binding partners to regulate TGFβ target gene expression. In the basal state, MH1 and MH2 domains mutually inhibit each other functions, probably because of a physical interaction. In R-Smads, cytokine-triggered C-terminal serine phosphorylation relieves this auto-inhibition. The non-conserved linker region contains several peptide motifs that participate in Smad activity regulation (Fig. 1).

Cellular and Molecular Regulation

In the absence of cytokine stimulation, R- and Co-Smad monomers are mainly localized in the cytoplasm, whereas I-Smads are predominantly nuclear. Smad anchor for receptor activation (SARA), a protein anchored to membranes, presents the unphosphorylated R-Smads to the TGFβ-activated receptor complexes. This SARA/R-Smad interaction targets the Smad proteins to the plasma membrane and promotes the cytokine intracellular cascade. The type I receptor mediated R-Smad phosphorylation triggers homo- and heteromerization with Smad4 and induces a nuclear accumulation of these proteins. Thus, the R-Smad

Smad Proteins in TGFβ Signaling. Figure 1 Structure of Smad proteins. Pathway-restricted Smads (R-Smads) are phosphorylated by the activated type I receptor on the two most C-terminal serine residues in the SSXS motif. The common-mediator Smad (Co-Smads) contains various small insertions in the MH1 and MH2 domains. The antagonistic Smads (I-Smads) lack most of the conserved MH1 domain. *Boxes in brown* indicate regions that are highly conserved between Smad proteins. *Green boxes* are regions of similarity in I-Smads only.

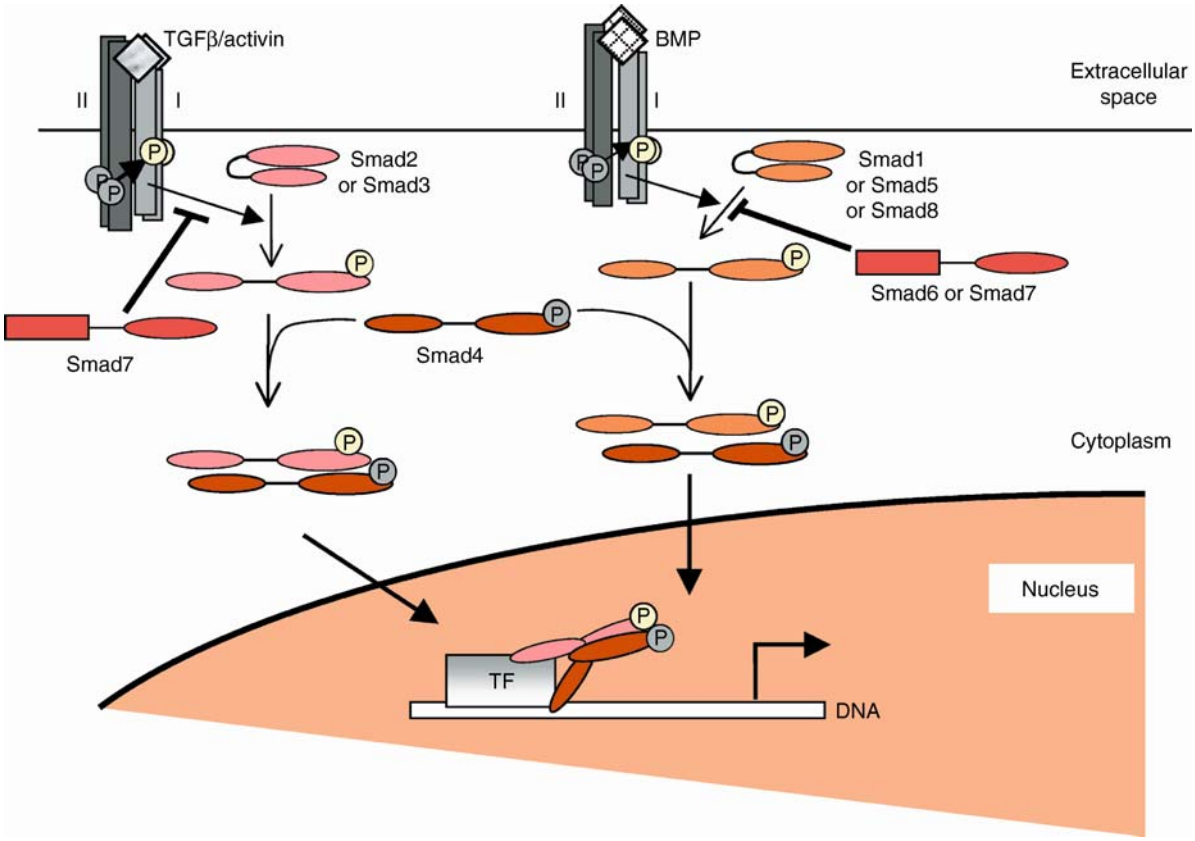
localization prior to or after activation of the pathway is an important feature of TGFβ superfamily signalling. For example, activated ►RAS induces the phosphorylation of R-Smads in their linker region through ►MAP kinase activation, thus preventing Smad translocation to the nucleus. As a result, oncogenic RAS inhibits TGFβ signalling. Interferon γ (IFNγ) also inhibits TGFβ signalling by abrogating R-Smads nuclear translocation. In this case IFNγ promotes the expression of Smad7, an inhibitory Smad that prevents TGFβ-restricted Smad activation.

Smad transcriptional activity is also regulated in the nucleus where Smad interacts with several proteins that promote or repress their activity. For example, the oncogenic ►Evi-1 protein interacts with Smad3 through its MH2 domain and abrogates Smad3 binding to DNA, thus reducing its transcriptional activity. Smads also recruit co-activators like ►CBP/p300 that promote Smad transcriptional activity or co-repressors as the oncoprotein ►Ski. These repressors recruit histone deacetylases to Smad complexes.

R-Smad are activated by phosphorylation, however, no phosphatase has yet been implicated in turning off TGFβ signalling. When R-Smad proteins enter the nucleus, they appear to activate their own degradation through ►ubiquitin-mediated proteolysis (Fig. 2).

Clinical Relevance

The gene encoding Smad4 was originally cloned as a tumor suppressor gene and called deleted in pancreatic cancers 4 (►DPC4). Smad4 appears to have a role in the late stages of a subgroup of colorectal cancers and many pancreatic cancers. In heterozygous mice carrying mutations of Smad4 and ►adenomatous polyposis coli (►APC) genes on the same chromosome, loss of heterozygosity and reduplication of the gene carrying the mutations results in intestinal polyposis



Smad Proteins in TGFβ Signaling. Figure 2 Schematic representation of the TGFβ/Smad pathway. Cytokine binding leads to the formation of a heteromeric receptor complex in which type II receptor phosphorylates and activates type I receptor. Pathway-restricted Smads are then phosphorylated by the type I receptor and form complexes with the common-mediator Smad4. These heteromeric complexes enter the nucleus where they participate, in combination with other transcription factors (TF), in the regulation of target genes. Inhibitory Smads bind to the activated type I receptor thus preventing R-Smads activation.

Smad Proteins in TGFβ Signaling. Table 2 Smad gene characteristics

Smad protein	Human chromosome	Number of exons	Mutation in human cancer
Smad1	4q28-31		
Smad5	5q31	8	
Smad8	13q12-14		
Smad2	18q21.1	11	Colorectal, lung
Smad3	15q21-22	9	
Smad4	18q21.1	11	Pancreas, colorectal, lung, ovary
Smad6	15q21-22		
Smad7	18q21.1		

with more malignant phenotypes than the simple APC heterozygotes (Table 2).

The Smad2 gene is located on the same chromosome region as Smad4 and is also frequently mutated or deleted in colon cancer. The inactivating mutations found in Smad2 and Smad4 mostly affect the MH2 domain in regions important for protein-protein interactions. However, the real role of these proteins in the cancer process has not yet been clearly defined. Mutations in other Smad proteins have so far not been found in human tumors. Nevertheless, one of the mouse Smad3-deficient strains develop metastatic colorectal cancer.

TGFβ is involved in several pathologies, however, the implication of Smad proteins in these disorders remain to be eluciated.

Small Molecule Drugs

Karl-Heinz Thierauch
Berlin, Germany

Definition

A ►small molecule drug in cancer therapy is a molecularly defined chemical entity of low molecular weight, which is applied to a patient with the intention to heal or *palliate* primary ►*proliferative disease*. Or it is directed to prevent secondary consequences of the disease, which are brought about by specific ►*secretory* activity of cancer cells or their general deleterious effect on organ and system functions. A very important aspect is the alleviation of pain.

Characteristics

Differences to Large Molecule Drugs

The molecular weight of a small molecule drug is largely found to be below 1,000 Da, as often it has to pass the cell membrane to reach the target of activity.

Large molecule drugs were often less defined as they were of biological origin e.g. due to ►*posttranslational modifications* and impurities. With the increasing power of analytical and preparative techniques and with the advent of molecularly exactly defined ►*oligonucleotides*, the distinction of exactly defined small molecule drugs from less defined large molecular weight drugs is fading, though antibodies or viruses will remain an independent class of therapeutics. Another distinction between small molecular drugs and those of large molecular weight which once was absolute now becomes relative: the possible permeation of the drug into the cell acting on intracellular targets. Whereas appropriate small molecules might diffuse or be transported by dedicated membrane proteins into the cells, for large molecules biomimetic uptake mechanisms need to be devised like the binding of a drug conjugate to receptors or toxins, followed by an internalization of the receptors toxin, respectively. In other cases viral infections might be feasible. So the natural mechanism is used as a Trojan horse or piggyback.

High Throughput Screening

Many small molecule cancer drugs were derived from natural compounds and used either directly or after some chemical modifications. A second important source came from deeper knowledge of cellular ►metabolism: ►Ligands and coenzymes were modified to obtain antagonists of the corresponding processes. These techniques were expanded with the advent of ►high throughput screening. Mechanistic targets were selected by target identification groups. Binding and functional assays interfering with the relevant mechanism were then adapted to small scale screening encompassing between 96 and 1,536 samples in a plate. Even larger scales are applied experimentally e.g. with various fluorescence read out techniques (e.g. time resolved fluorescence, fluorescence polarization). With appropriate assays up to several million compounds, contained in structurally diverse ►compound libraries, are tested for their interference with specific ►drugable targets (receptors, enzymes) in a few weeks. Also, screens using cultured cells are ongoing in a high throughput mode.

Structure Determination and Modeling

The optimization of the compounds is either at random using the intuition of the medicinal chemist or now increasingly based on the intimate structural knowledge of the respective drug target, which can be obtained from x-ray crystal structure or NMR derived structure determinations. Model calculations are performed fitting chemicals into the drug binding pocket of the target structure and preparing co-crystals of ligands with the target structure to obtain potent compounds. It is a major goal to obtain a high selectivity of a drug for the target chosen, without affecting similar cellular structures necessary for general cell functions. At this point chemical optimization efforts are key.

Physicochemical Properties and Drug Uptake

Small molecule drugs are applied according to their properties by all routes used for general drugs i.e. oral, rectal, s.c., i.m., i.v., nasal or by inhalation to mention the most important ones, and appropriate ►metabolic properties guide its availability for action at the required locus. The small molecule drugs used in cancer therapy need to have the ►physicochemical properties of general small molecule drugs, like appropriate solubility, logP values and pKB, all the metabolic characteristics like stability towards liver and gut metabolism. Physicochemical properties are predicted in model calculations, which in turn are used to predict pharmacokinetic behavior. Optimized molecules will be taken up in the gut and by cells and a useful ►distribution in the body is found. So an appropriate duration of exposure can be secured in adequate concentrations at the locus of desired activity. Depending on the target, a drug may need to pass into the cell by diffusion or an active transport process. Of special importance is their behavior towards elimination from cells by drug transporters, which may become upregulated in the gut preventing its uptake or as a means of cancer cells to acquire ►resistance towards therapy. It may also lead to an accelerated excretion in the gut or kidney. The molecular properties also govern their potential to interact with other drugs influencing their kinetics by inhibition of cytochrome P450 isoenzymes or by induction of metabolizing enzymes (►Drug drug interaction).

Drug Formulations

The drugs need to be ►formulated according to their specific use, e.g. poorly soluble agents like taxanes are formulated for i.v. application as solutions in high amounts of cremophor carriers, which themselves are not neutral to the body, but provoke reactions requiring a ►premedication for a better patient tolerability. Efforts are made to improve formulations avoiding toxic responses due to ►recipients. This is done with for example, taxanes such that the drug substance is dissolved in less awkward carriers or in vitamin E or albumin for i.v. applications permitting higher concentrations with better tolerability and thus efficacy. For others, slow release formulations are prepared to improve their efficacy through a prolongation of drug availability at relevant concentrations. This also might prevent toxicities originating from peak concentrations shortly after application, which are cut off by a slow release formulation.

Side Effects

Selectivity translates into fewer side effects. However, the aim of selectivity will sometimes be compromised by the need to affect several targets by one drug in order to obtain sufficient therapeutic efficacy. Effects which are due to the interaction with one targeted structure in different locations are ►class effects. All compounds interfering with this target will have the same side effects, as this cannot be avoided structurally. Only differential availability needs or periods of blockade may be a way to decrease such effects, if no local application is possible. The tendency to increase hypertension is, for example, a typical class effect of VEGF signal inhibitors, which is independent from the antiangiogenic effect and accompanies it, irrespective of the specific drug used. Avoidable side effects are contained in the specific structure of a molecule and are called compound specific side effects.

Some Examples for the Mechanism of Cancer Drug Action

Small molecule cancer drugs traditionally interfere with ►cell proliferation, one cardinal distinction to normal cells, through damage of DNA or the synthetic process of DNA synthesis. Examples of these drugs are bleomycin and cis-platinum, which result in ►DNA double strand breaks, or fludara, which interferes at various points with ►nucleoside metabolism. Vinca alcaloids or taxanes block tubulin modifications, which are key for nuclear division and cellular transport. With deeper knowledge of cell biology, the cell fate is blocked at very specific sites. So, certain kinases are required for ►signal transductions orchestrating the process of the ►cell cycle culminating in the separation of the chromosomes to form two new nuclei. If this process is disturbed by specific kinase inhibitors, many cancer cells will respond with a standard program resulting in self-abortion, also called ►apoptosis, thus slowing down cancer growth or even reducing its size.

The kinase inhibitors may also interfere with the activity of enzymes which are ►constitutively activated in cancer cells by mutational events e.g. bcr-abl in chronic myelogenous leukemia. Some drugs only hit specific mutants but not others, which may result in resistance, therefore, drugs are investigated for their activity against major mutants found in human disease.

In future it may be possible to discover compounds, which are specific for major mutants of the enzymes found in cancer, resulting in even higher specificity with less adverse effects as normal cells containing the same enzymes are not affected.

Some cancers depend on paracrine or autocrine growth factor signal transduction and small molecules might block protein functions in the signal chain, inhibiting signal flow downstream of that point. This is true e.g. for EGF receptor signal inhibitors at the level of the receptor kinase, e.g. gefitinib, which inhibits the growth stimulus for epithelial cells.

Antagonists of nuclear hormones, which block signaling via or down regulate nuclear receptor proteins, are effective in the therapy of breast and prostate tumor disease.

Another promising branch of small molecule therapeutics attempts to induce a more ▶differentiated and less invasive phenotype of cancer cells. This was originally applied to leukemia cells with the intention of inducing terminal differentiation and is continued with retinoids for AML and other solid tumors. Investigation is now directed towards the inhibition of the epithelial to mesenchymal transition in solid tumors. In recent years small molecule drugs have been developed against stromal components of tumors with little or no effect on tumor cells themselves, like VEGF signal interrupting and antiangiogenic tumor therapeutics.

Interference with chromatin modification like methylation or acetylation recently became an important field of drug research as appropriate test systems are now available.

Systemic Effects of Tumor Growth

Other small molecule drugs block deleterious effects of tumors secreting active products. Hormones or cytokines are discharged from neuroendocrine tumors in excessive manner, which are therapeutically antagonized by specific signal blockers to prevent a flooding of the body with the specific hormone signal. In the case of prolactinomas, treatment with dopamine might be beneficial or in the case of anorexia, a frequent companion of progressive proliferative diseases, megestrol might be helpful. Anticoagulants are advisable in some cases as the incidence of thrombi and emboli is increased in many tumor patients. Standard analgesics are administered if indicated. If they are not effective, as in the case of bone metastases in prostate cancer, antiproliferative therapy is also applied for the purpose of pain relief.

Worldwide, very many new small molecule drugs are intensively investigated with the latest available techniques in newly discovered pathways linked to cancer. They promise a breakthrough for the benefit of cancer patients, prolonging their life for a certain period of time. It is essential that such prolongation of life occurs at a decent quality of life to become a real benefit for the patient and not only one for the health industry.

[2]Department of Medical Biophysics, Princess Margaret Hospital/Ontario Cancer Institute, University Health Network, University of Toronto, Toronto, ON, Canada

Synonyms

Chemical biology screen; Chemical genetic screen; Compound screen; High throughput screen

Definition

A small molecule screen is a procedure in which small molecules (typically organic compounds with a

S

molecular weight under ~1,000 g/mol) are systematically tested for their ability to activate, perturb, or modify a target or a biological process of interest.

Characteristics

The goal of small molecule screening is to identify compounds that modulate a particular biological process, and thus, can be used as, or developed into, tools for further medical research and/or ►small molecule drugs (►molecular therapy). Typically, an assay is developed into a "►high throughput" screen, meaning that it is optimized for rapidly assaying thousands to hundreds of thousands of compounds in parallel and in an automated fashion. Large amounts of data are collected with the help of robotics, liquid handlers, and processing software. "►Hits," compounds that produce the desired assay result, are hence identified for further study.

Small molecule screening is often the starting point for identifying chemical tools. Developing a chemical probe to inhibit and study a protein, for example, offers several advantages over mutating a gene. A chemical probe can be used for rapid inhibition in different cell lines, organisms, and species, and at varying time points or at different times during the cell cycle or development. Furthermore, protein inhibition may be reversed by removing the compound, and compounds can be developed for versatile specificity (either inhibiting a specific protein or a family of proteins). In classical genetics, however, genes are not easily turned on or off at will, and mutating/deleting a gene that is essential for survival may lead to early embryonic lethality. The application of chemical tools and ideas to biological problems is known as ►chemical biology.

Small molecule screening has now become a very common method for identifying compounds that produce therapeutically desirable biological phenotypes. These compounds can be further modified to optimize their potential as drug candidates. Previously, drugs were discovered either by opportune testing or by identifying the active compounds in traditional medicines (►Chemotherapy of Cancer; Progress and Perspectives).

Types of Screens

Screens are classified into two types; phenotype-orientated or target-based. In ►phenotype-orientated screens, compounds are screened for the ability to induce a particular phenotype. Further work is usually required before the target(s) of the compound is/are known. Little *a priori* knowledge is required about the mechanism by which the desired phenotype is produced. Examples of phenotype-orientated screens include screens for compounds that alter cell division, metabolism, adhesion, viability, or protein localization. Phenotype-orientated screens are a component of ►forward chemical genetics; one may discover novel biological mechanisms involved in producing the desired phenotype by further evaluating the compounds' mechanisms of action.

►Target-based screens are performed to identify compounds that more directly alter a particular target. For example, one may purify a protein and then screen for compounds that perturb the function of this protein. The compound can subsequently be used to perturb the protein's function *in vivo*, and the consequent phenotype can be observed. This methodology is known as ►reverse chemical genetics.

In either phenotype-orientated or target based screens, counter screens or cross screens may be performed to determine if the hits from the first screen, or primary screen, will affect related targets or phenotypes. Multi-targeted compounds are often called "promiscuous" compounds.

"Small" Molecules

Screening may be performed with siRNAs, peptidomimetics, natural compounds, synthetic compounds, or other molecules. The term "►small molecule" typically refers to organic compounds with "small" molecular weights. There is no clear definition for "small," but estimates range from under 2,000 g/mol to under 300 g/mol; most commonly, "small" refers to under 500 g/mol or 1,000 g/mol. Small molecules are commonly used for screening because organic compounds are often able to cross the plasma membrane of cells, and because most marketed medicines have been derived from this class of agents.

Collections of compounds are known as libraries. Pharmaceutical companies have proprietary libraries containing millions of compounds. Only recently have collections of organic molecules numbering in the thousands to hundreds of thousands become commercially available for academic use. Example libraries include the Prestwick Chemical Library (Prestwick Chemicals; 1,120 off patent compounds, 85% marketed drugs), LOPAC^{1280} (Sigma-Aldrich; 1,280 pharmacologically active compounds), Spectrum Collection (MicroSource Discovery Systems; 2,000 biologically active compounds), Maybridge Screening Collection (Maybridge; 56,000 drug-like organic compounds), and EXPRESS-Pick (ChemBridge Corporation; over 435,000 drug-like small molecules).

In the past century, compound libraries were assembled one compound at a time during the synthesis of drug candidate variants or by purifying compounds from natural products (e.g. plants, fungi, bacteria, and other organisms). Recently, progress in ►combinatorial chemistry (the synthesis of a large number of new chemical compounds by combining various sets of compound "building blocks"), automation, and

chemical diversity has allowed for rapid diversity orientated synthesis. Novel small molecule libraries can more readily be created, increasing the rate of production from a few hundred compounds per year per chemist, to millions of compounds per year. At the current time, combinatorial libraries contain simple compounds, meaning that they have one or fewer ►stereocenters (a carbon atom with four distinct functional groups). Natural compounds are typically more complex, and it is thought that compounds with more stereocenters might provide superior target-binding specificity. Proteins, for example, are very stereochemically complex.

Screening Technology and Tools

Small molecules are typically more stable in their dry form, but must be dissolved for screening. Although there is neither a universal solvent nor any solvent proven for long-time compound storage, dimethyl sulfoxide (DMSO), a dipolar aprotic solvent, is commonly used. Dilutions of the DMSO-dissolved compounds may be performed in another solvent, such as in water or phosphate-buffered saline.

Compounds are placed in small plastic rectangular containers called "plates." Each plate contains a grid of individual open divots, called "wells," in a 2:3 rectangular matrix. Screening facilities typically have each compound created by the lab or obtained from a commercial source placed in a different well. The contents of each well and plate are carefully catalogued. Stock plates, or "mother" plates, are not used directly in experiments. Rather, these plates contain concentrated amounts of each compound for storage. "Daughter" plates are copies of the stock plates created by pipetting a small amount of liquid (often microliters) from each well of the stock plate into the corresponding well of an empty plate. The compounds in the daughter plates can be diluted and/or further aliquoted into other plates. The plates used for screening are named assay plates, and their compound contents may be either directly derived from the stock plates, or from other aliquots. Some assay plates may contain mixtures of different compounds in each well to decrease the assay time and cost. In any case, the experimental materials, such as cells or proteins, must be added to the assay plate wells.

In order to decrease the assay cost, length of time, and amount of required materials, a significant amount of effort over recent years has been placed on minimizing the assay volume. In the late 1970s, 96-well plates were used, and a few hundred microliters of assay materials were required in each well. Currently, 384-well plates are in common use, with each well requiring tens of microliters. Some screens are now being performed in 1,536-well, 3,456-well, or even 9,600-well plates, minimizing the assay volume from a few microliters to a few hundred nanoliters.

Accurate, reproducible, and rapid screening of large numbers of compounds necessitates the use of automated robotic systems. These systems are typically built around a core of one or more automated liquid handlers. In addition to a pipetting tool, robotic liquid handlers usually have a gripper tool to manipulate sample containers, assay plates, or pipette tip boxes on a work deck. The handlers are able to transfer liquids, wash tips, and move microplates without human intervention. An example of a liquid handler is the Biomek FX Laboratory Automation Workstation (Beckman Coulter). Other components of automated robotic systems may include incubators, storage containers, liquid dispensers, mixers, plate readers, or other assay equipment (such as automated digital microscopes for high content screens). One or more tracked robotic arms move the microplates from one station to another, and sophisticated software algorithms control almost every aspect of this system. Many screening centers currently have the capacity to screen over 100,000 compounds per day (depending on the assay).

Screening Assays

Numerous assays have been used in small molecule screening. Many have been designed so that hits can be detected by standard plate readers that detect changes in absorbance, fluorescence, or electrochemiluminesence (ECL). Some example screens, among the countless types and variations possible, are described below.

In vitro assays include enzymatic, fluorescent polarization, fluorescence resonance energy transfer, AlphaScreen, scintillation proximity, and biophysical assays. In an enzymatic assay, compounds that inhibit the activity of an enzyme (e.g. from cleaving a fluorogenic substrate) can be screened. In fluorescent polarization assays (FPA), a fluorescent dye is used to label a small peptide (or other molecule), and its speed of rotation is measured. When this peptide is bound to a protein (or other molecule) of equal or greater size, the speed of rotation will decrease significantly. Thus, FPA can be used to identify compounds that inhibit a fluorescently-labeled peptide, for example, from binding a particular protein. In fluorescence resonance energy transfer (FRET), a protein (or other molecule) is first labeled with a particular dye molecule, named a "donor." Then, a protein that interacts with the first protein is labeled with a dye molecule that is excited by the donor, and accordingly named an "acceptor." When the donor molecule is excited, it will in turn excite the acceptor molecule only when the interacting proteins are in close proximity. FRET can thus be used to screen for compounds that inhibit the binding of two proteins (or other molecules). In a FRET variation known as time-resolved FRET (TR-FRET), fluorescent dye signals are read in a time-resolved manner, reducing

assay interference and increasing data quality. AlphaScreen (Perkin Elmer) is similar to FRET in that donors and acceptors are used; however, the interacting proteins (or other molecules) are conjugated to beads. A laser is used to excite a donor bead which produces singlet state oxygen. The singlet state oxygen activates the acceptor bead, which has a chemiluminescer and fluorophores. Scintillation proximity assays also use beads; the donor being radiolabeled, and the acceptor containing a scintillant. Finally, biophysical techniques, such as NMR and X-ray diffraction, have been powerful *in vitro* tools for detecting compounds that bind to a particular protein.

Cell-based assays include bioluminescence resonance energy transfer (BRET), in which one protein is fused to a bioluminescent donor, and another protein, which interacts with the first protein, is fused to an acceptor fluorophore. When the two proteins are in close proximity, energy transfer can be detected; this assay is similar to FRET, but occurs in a cellular context. Cell-based assays are more commonly used for phenotype-orientated screens, such as in identifying compounds that affect cell division, metabolism, adhesion, transporters, or viability.

►High content screens are cell-based assays that utilize a combination of automated digital microscopy and flow cytometry to collect information about spatial or temporal changes in cellular processes. For example, a nuclear protein can be fused to a fluorescent tag, and an automated high content screening apparatus can be used to detect hit compounds that induce a change in protein localization (e.g. to the cytoplasm).

►Virtual high throughput screen or *in silico* screen, are being performed using advances in molecular modeling, combinatorial chemistry, and molecular biology. For example, computers are used to screen virtual libraries for their ability to bind to a model of a protein. Virtual high throughput screening is also used to identify compounds that may or may not potentially possess desirable absorption, distribution, metabolism, excretion, and/or general pharmacokinetic properties.

Screens in whole organisms, such as in bacteria, *Danio rerio* embryos, *Xenopus laevis* embryos, and *Caenorhabditis elegans* have been performed, although screens in larger animals (e.g. mice) are difficult due to the inability to maintain, treat, and observe thousands of these animals in an efficient manner. For screening a single compound on multiple cell lines, the National Cancer Institute has used the hollow fiber assay, in which different human tumor cells are placed within biocompatible hollow fibers. These hollow fibers are implanted subcutaneously or intraperitoneally in mice, and the mice are then treated with the test compound. After treatment, the fibers are removed and the compound's ability to affect different tumor cell lines and to penetrate different physiological compartments can be assessed. This assay, however, is relatively low throughput.

The Screening Epilog

Whether screening for chemical probes or for drug discovery, much research remains to be performed after the initial compound hits are identified. First, the assay is repeated under the same conditions, on the hit compounds to confirm the results. Then, ►dose-response curves may be generated using the same assay, thereby providing ►IC_{50} or ►EC_{50} values. Orthogonal testing may be performed, in which the confirmed hit is tested using a different assay. This assay is often closer to the target physiological condition. Functional assays, or secondary assays, may be performed; for example, compounds identified *via* an *in vitro* screen may need to be tested in a cellular environment, in the presence of membranes or other physical barriers. For phenotype-based screens, the target(s) of the compound(s) must be identified; an often laborious procedure. Various techniques have been developed for this purpose, including covalent labeling of the compound followed by compound-bound protein purification from cellular extracts, and peptide sequencing.

Even after compounds are tested and shown to possess the desired level of target or phenotype specificity, it is very unlikely that the process has revealed a single perfect chemical probe or drug candidate. Likely, several compounds will show some degree of activity. If these "lead" compounds share similar chemical features, one can identify a ►pharmacophore, the set of structural (electronic and steric) features in a molecule that are responsible for the molecule's biological activity. Compound analogs and structure–activity relationships (SAR) will be used to identify or synthesize new compounds that have improved activity, specificity, and ADME (absorption, distribution, metabolism, and excretion) properties.

Conclusions

Small molecule screening is a commonly used method for identifying chemicals probes and drug leads. This type of screening is a key component in the emerging field of chemical biology, with the objectives to identify a small-molecule modulator for each individual function of every macromolecule, and to translate basic research into improved clinical outcome.

Synonyms

Snail1, Snail2 and Snail3 were previously called Snail, Slug and Smuc respectively; Additional synonyms for Snail1: SnR (chick); SNAILH (human); Sna; Additional synonyms for Snail2: hSlug (human), Xslug (Xenopus), Slugh (mouse); Slu; Human symbols for Snail1 and Snail2: SNAI1,SNAI2; SNAIL-like and SNAILP both refer to a human-specific Snail1 retrogene inserted in chromosome 2

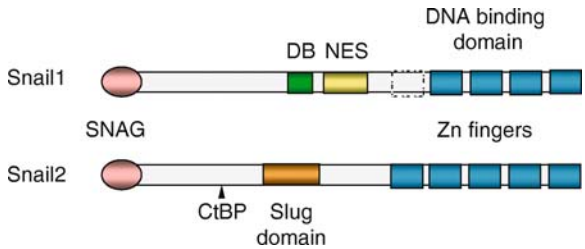
Definition

Snail genes are zinc finger transcriptional repressor of the Snail gene superfamily that participate in developmental and pathological ►epithelial-mesenchymal-transition (EMT) processes. Snail1 was initially characterized as a potent repressor of ►E-cadherin, a major anti-invasive molecule in carcinomas. Snail1 is thus proposed as a potent inductor of tumor invasion, a process that frequently occurs associated to EMT. Besides E-cadherin repression, Snail1-mediated EMT requires the set in motion of a complex genetic program leading to the downregulation of additional epithelial gene markers and to the upregulation of mesenchymal and migratory genes.

Characteristics

Structural Organization

Snail factors share a common organization: a highly conserved carboxy-terminal region, containing from four to six zinc fingers (C_2H_2 type), and a much more divergent amino-terminal region (see Fig. 1). Although three *Snail* genes (Snail1 to Snail3) and a human-specific *Snail1* retrogene (Snail-like) have been described, the vast majority of information available on their function as transcription factors and their involvement in embryonic development and tumor progression is restricted to Snail1 and Snail2. Their zinc-fingers function as the sequence specific DNA-binding domains



Snail Transcription Factors. Figure 1 Schematic representation of the main structural domains of Snail1 and Snail2 proteins. Blue boxes, zinc fingers at the C-terminal region; dotted box indicates the presence of a fifth zing finger in Snail1 protein in some invertebrates; orange box, the specific domain present in Snail2 proteins; DB (green box), destruction box; NES (yellow box), nuclear export signal; SNAG (pink box), N-terminal transactivator domain; CtBP, interacting domain of C-terminal binding protein.

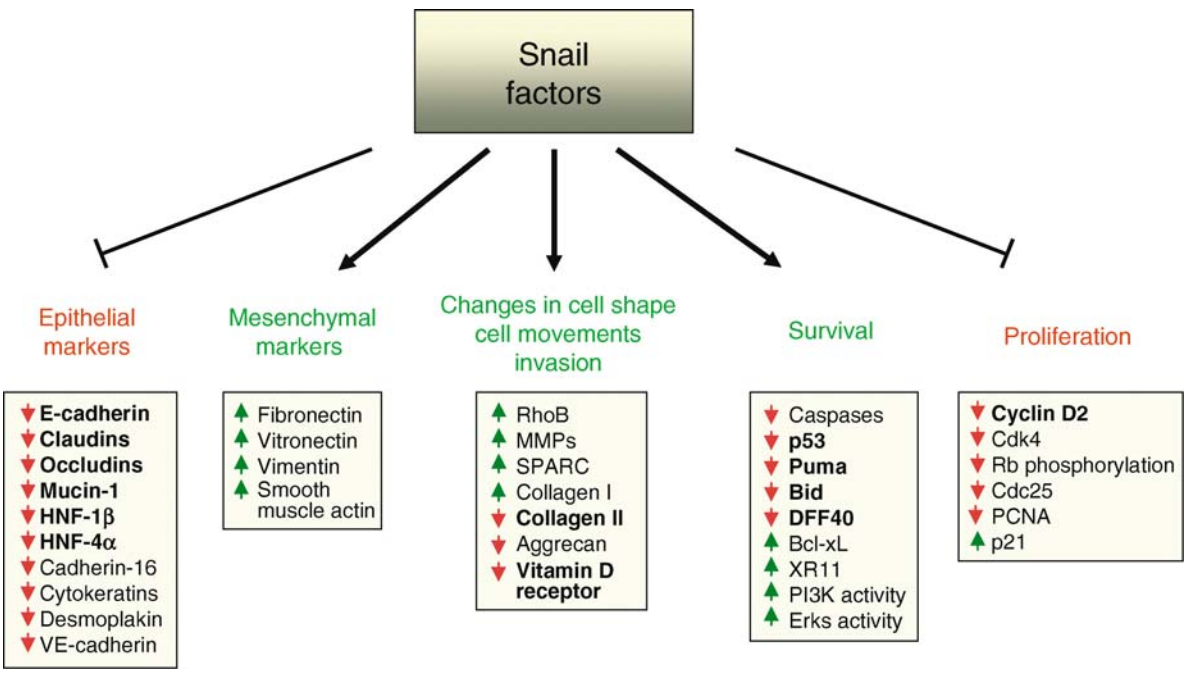
that recognize consensus ►E2-box type elements C/A (CAGGTG). The repressor domain is located at the N-terminal part in the so called ►SNAG domain, conserved between Snail/Gfi proteins. The central region of the Snail proteins is characterized by a Serine-Proline rich region highly divergent between Snail members. While Snail2 contains the so-called Slug domain in the Ser-Pro rich region, whose function remains elusive (Fig. 1b), two different functional domains have been identified in that central region of vertebrate Snail1, a ►nuclear export signal (NES) and ►a destruction box (DB) domain (Fig. 1).

Transcriptional Repression

The transcriptional repression mechanism of Snail1/Snail2 has been established for E-cadherin and many other targets (Fig. 2). In all cases, Snail mediated repression requires interaction with E2-boxes, but with different binding affinities (Snail1 > Snail2). The precise mechanism for Snail1-mediated E-cadherin repression requires the recruitment of specific corepressor complexes containing the mSin3 corepressor and histone deacetylase (HDAC1) and HDAC2. In addition, histone and DNA methylases can be recruited by Snail1 to the repressor complexes to mediate epigenetic silencing of the E-cadherin gene, and potentially of other target genes. The possibility of Snail factors acting as transcriptional activators should be also considered, since Snail2 seems to positively regulate its own promoter during embryonic development in *Xenopus* and at least human Snail2 and Drosophila snail contain a transcriptional activation domain as assayed by transfection.

Regulation of Expression and Functional Activity

Expression of Snail1/Snail2 factors is regulated by a plethora of signals, most of them actively participating in induction of developmental EMT. Among them, growth factors activating ►receptor tyrosine kinases (RTK) and ►MAPK pathways (like fibroblast growth factor (FGF), epidermal growth factor (EGF), ►hepatocyte growth factor/scatter factor (HGF/SF), or oncogenic ►Ras), ►TGF-β/BMP signals and ►Wnt/β-catenin pathways are major inducers of vertebrate Snail1/Snail2 expression. Significantly, crosstalking between distinct signaling pathways are important for Snail1 induction in different systems, particularly those involving TGFβ, Ras/RTKs, ►Notch, and/or Wnt/β-catenin pathways. Additional transcriptional regulatory mechanisms can be exerted through steroid receptors in some particular cellular systems, like in breast mammary carcinoma cells in which ligated ►oestrogen



Snail Transcription Factors. Figure 2 Snail targets. Snail induces a full EMT through the downregulation of epithelial markers, the upregulation of mesenchymal markers and the acquisition of invasive properties. In addition, Snail regulates cell division and survival. Decreased cell division favors invasion versus tumor growth. Altogether, the ability to move, invade and survive confers Snail-expressing cells a selective advantage to delaminate from the primary tumor and to form distant metastasis. Direct targets are shown in bold.

receptors downregulate expression of Snail1 gene through activation of the specific ►MTA3-NuRD correpressor complex. Significantly, Snail factors can exert an autoregulatory control, underlining the necessity of tight regulation of Snail levels.

Besides transcriptional regulation, functional activity of Snail factors can be modulated at posttanscriptional levels. Phosphorylation of Snail1 by GSK3β (►Wnt signaling) in Ser residues located at the central DB and NES domain induces Snail1 nuclear export and cytoplasmic degradation, while potential modification of neighboring Lys residues, phosphorylation by Pak1 and/or interaction with specific ►zinc transporters (like LIV1) positively control Snail1 nuclear localization, protein stability and repressor activity. Much less is known on posttranscriptional regulatory mechanisms of Snail2, except for the induction of proteasome degradation mediated by Ppa2.

Additional Snail Functions

Apart from their implication in EMT, Snail factors can regulate other cellular processes, related to cell proliferation and cell survival with important implications during embryonic development, tumor progression and other pathologies. In some particular cell/tissue contexts, Snail1 expressing cells have a low proliferative potential, exhibiting a partial G1/S cell cycle arrest, a property that may ease migration of cancer cells during tumor progression. For Snail targets related to cell proliferation see Fig. 2.

Snail factors also participate in protection against cell death induced by different external cues, thus acting as survival mediators. Significantly, the pro-survival action of Snail1/Snail2 factors has been demonstrated during embryonic development and in human carcinoma cells under genotoxic stress induced by chemotherapeutic agents and in radioresistance of hematological precursor cells. Snail1/Snail2 negatively regulate p53 (►p53 protein) -dependent (like ►Puma) and p53-independent genes (for additional targets see Fig. 2). Thus, Snail factor expression can contribute to the acquired resistance to ►apoptosis of tumor cells, a characteristic that might be crucial for the metastatic (►metastasis) process. It is very likely that the Snail-mediated pro-survival/resistance function is associated with EMT, as observed in hepatocytes in culture. Nevertheless, the different functions of Snail factors such as induction of EMT, reduced proliferation and survival can be dissociated in some cellular contexts, at least during embryonic development.

Clinical Significance

SNAIL1 expression was originally detected in several carcinoma cells associated to E-cadherin downregulation and invasiveness. Importantly, SNAIL1 expression was also detected at the E-cadherin negative invasive regions of mouse skin carcinomas (►skin carcinogenesis), human breast carcinomas and hepatocarcinomas (►hepatocellular carcinoma), supporting its in vivo implication in induction of tumor invasion. Further studies in different tumor series indicate SNAIL1 expression associated to lymph-node status and/or distant metastasis in breast and ovarian carcinomas (►ovarian cancer), colorectal tumors (►colon cancer) and squamous cell carcinomas, while SNAIL2 has been implicated in ►melanoma metastasis. SNAIL1/2 expression in different tumor series correlates with E-cadherin downregulation and/or induction of several ►matrix metalloproteinases (MMPs). The expression of specific MMPs (i.e., MMP2, MMP9) has been found to be transcriptionally upregulated by Snail1/2 in different cell model systems, further supporting the implication of Snail factors as active invasion inducers through the coordinated regulation of the molecular players of the process. The recent identification of SNAIL1 at the tumor-stroma interface of restricted tumor areas strongly support the implication of SNAIL1 at focally restricted invasion areas where the EMT processes are most likely to occur. Interestingly, SNAIL1 expression has been associated to tumor recurrence in breast carcinoma and to poor prognosis in hepatocarcinomas, while SNAIL2 has been recently associated to poor prognosis or overall patient survival in several tumor types (i.e., colon carcinomas and squamous cell carcinomas). It should be important to analyze in the near future whether the implication of SNAIL1/SNAIL2 in tumor recurrence might be related to the prosurvival function of Snail factors, or perhaps to a potential contribution of Snail factors to cell stemness.

Further studies in large tumor series using highly specific anti-SNAIL1 antibodies, recently developed, (and hopefully anti-SNAIL2 in the near future) are certainly required. This, together with additional functional studies in cellular models and, most importantly, in defined mouse model systems of tumor progression, will contribute to get a complete understanding of the clinical relevance of Snail factors in human tumors.

Solar Ultraviolet Light

Thomas M. Rünger
Department of Dermatology, Boston University School of Medicine, Boston, MA, USA

Definition

Solar ultraviolet light is ultraviolet light emitted by the sun.

Characteristics

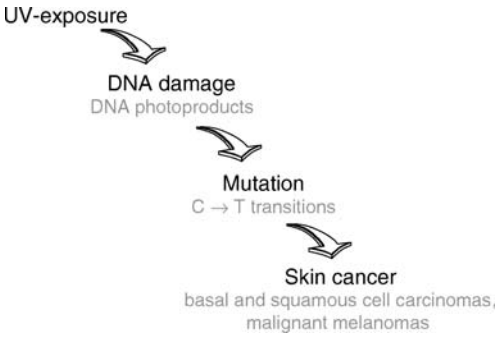
The sun emits ultraviolet radiation as part of the electromagnetic spectrum. It is usually subdivided, rather arbitrarily, into UVA (400–315 nm), UVB (315–290 nm), and UVC (200–290 nm). UVA has been further subdivided into UVA1 (400–340 nm) and UVA2 (340–315 nm). More than 95% of the sun's UV radiation reaching the earth's surface is UVA. Practically all of the UVC, and much of the UVB, is absorbed by the oxygen and ozone in the earth's atmosphere, so that ultraviolet radiation below 290 nm is virtually undetectable at ground level. Nevertheless, the remaining UV radiation can still be absorbed by biological molecules (DNA, proteins, lipids) and elicit photochemical and photobiological responses. A light-absorbing molecule is called a chromophore. Upon absorption of the radiation's energy, this chromophore is elevated to an excited state. Ensuing photochemical reactions may either change the chromophore directly, or, through energy transfer in a so-called photosensitized reaction, indirectly change a molecule other than the chromophore.

Effects of Exposure to Solar Ultraviolet Light on Skin

Exposure of skin to solar ultraviolet light has both short-term and long-term effects. Visible short-term effects are sunburning and/or tanning. Long-term effects are photoaging and induction of skin cancers (►skin carcinogenesis). Skin cancers clearly linked to sunlight exposure are ►basal cell carcinomas and ►squamous cell carcinomas, and ►malignant melanomas. An individual's tendency to develop sunburn and tanning after sun exposure correlates with the individual's susceptibility to long-term effects as well. Therefore, those individuals with higher acute sun sensitivity are generally also more at risk for developing skin cancers after chronic UV exposure.

Within the skin, the depth of penetration of UV light is wavelength-dependent – i.e. the longer the wavelength, the deeper the penetration. While UVA readily reaches the dermis, including its deeper portions, most of the UVB is absorbed in the epidermis, and only a small proportion reaches the upper dermis. UVC, if it reached the earth's surface, would be absorbed or reflected predominantly in the stratum corneum and in upper layers of the epidermis. Both short-term and long-term effects of exposure to UV light are wavelength-dependent. Previously, it was .thought that only UVB is carcinogenic, and only UVA causes photoaging. Today, however, we know that both UVA and UVB cause skin cancer and photoaging. The relative contribution of each, however, continues to be a matter of controversy.

Photocarcinogenesis involves a stepwise accumulation of specific genetic changes in a single cell, with



Solar Ultraviolet Light. Figure 1 Photocarcinogenesis chain of events.

subsequent clonal expansion. Usually, it takes decades until a tumor arises. It is commonly accepted that UV-induced skin cancers develop along a photocarcinogenesis chain of events that involves (Fig. 1):

- DNA damage formation after exposure to solar ultraviolet light
- mutation formation following DNA damage formation
- malignant transformation following mutation formation.

DNA Damage Induced by Solar Ultraviolet Light

Different wavelengths of UV light induce different types of DNA damage. UVC and UVB are capable of exciting the DNA molecule directly and subsequently generating ►DNA photoproducts. DNA photoproducts are dimers, formed by covalently binding two adjacent pyrimidines in the same polynucleotide chain. The two major types of pyrimidine dimers are ►cyclobutane pyrimidine dimers and ►6,4-photoproducts.

►Cyclobutane-pyrimidine dimers (CPDs) are the most common DNA photoproducts formed with solar ultraviolet irradiation of the skin. They are generated upon saturation of the 5,6 double bonds and formation of a four-membered cyclobutyl ring. Cyclobutane-pyrimidine dimers are observed at all possible di-pyrimidine sites, with the thymine–thymine dimer (T–T) being the most common, followed by C–T and T–C dimers. C–C dimers are the least common. The formation of CPDs is not a random phenomenon: it is influenced by the sequence and conformational context of the affected DNA sequence.

The 6,4-photoproduct is a non-cyclobutane dipyrimidine photoproduct, which is formed upon covalent linkage between the C-6 position of one pyrimidine and the C-4 position of the 3′ adjacent pyrimidine. The T–C (6–4) dimer is the most common dimer of this type, but C–C and T–T dimers are also observed after UV irradiation. Upon further irradiation with UV wavelengths between 280 and 360 nm, the normal isomers of 6,4-photoproducts can be converted to their Dewar valence isomers, which are less mutagenic than the normal isomers but may still contribute to solar mutagenesis. A few other rare DNA photoproducts have been described, such as complex purine lesions and pyrimidine hydrates, but their physiological significance in the photobiology of human skin is unknown.

The absorption maximum of DNA is at 260 nm. This makes UVC the most effective wavelength for the induction of DNA photoproducts in naked DNA. However, *in vivo*, due to the absorption of shorter wavelengths in upper layers of the epidermis, 300 nm (UVB) is the most effective wavelength for inducing DNA photoproducts in the basal layer of the epidermis, the anatomical location from which most skin cancers arise. While UVA is much less effective in generating DNA photoproducts, UVA-induced DNA photoproducts may still have a significant contribution to sunlight-induced mutation formation, because of the much higher abundance of UVA in sunlight, as compared to UVB.

UV radiation can also damage DNA indirectly. After absorption of photons by chromophores other than DNA, energy can be transferred either to DNA (type I photosensitized reaction), or to molecular oxygen, with ►reactive oxygen species in turn being able to damage DNA (type II photosensitized reaction).

UV-induced reactive oxygen species include singlet oxygen, and probably other non-radical and radical reactive oxygen species, such as hydrogen peroxide and the superoxide radical. Even the highly reactive hydroxyl radical may be formed by a reaction of hydrogen peroxide with nuclear metals through a Fenton reaction. This oxidative stress not only affects DNA, but also membranes and proteins. The relative contribution of each (oxidative membrane damage, oxidative protein damage, ►oxidative DNA damage) to the different biologic effects of UV irradiation has not been well established. Singlet oxygen and the other reactive oxygen species react predominantly with guanine and generate several DNA changes including the mutagenic and well studied 7,8-dihydro-8-oxyguanine (8-oxoG).

It remains a matter of debate, whether the mutagenic properties of UVA (in particular UVA1: 340–400 nm) are mediated by ►oxidative DNA damage or by the weak ability of UVA to form a few pyrimidine dimers.

Mutations Induced by Solar Ultraviolet Light

Cancer development requires the accumulation of numerous genetic changes in a single cell. Solar ultraviolet light induces mutations in several key genes involved in skin cancer development, e.g. ►*ras* oncogenes, *p53* (►p53 protein, histological and clinical aspects), and *PTCH* tumor suppressor genes. The *p53* tumor suppressor gene encodes a 53 kDa transcription factor that plays a critical role in cellular DNA damage responses.

Mutations in this gene can be found in most cutaneous squamous cell carcinomas and their precursors (actinic keratoses). In addition, chronically sun-exposed skin harbors many keratinocyte clones with *p53* mutations, which are undetectable by light microscopy. This indicates that *p53* mutations are an early event in the pathogenesis of UV-induced cutaneous squamous cell carcinomas.

It is well established that different types of UV-induced DNA damage can lead to the formation of a variety of different mutations, either during attempts by the cell to repair (►repair of DNA) or to replicate these lesions. Most of the *p53* mutations in cutaneous squamous cell carcinomas and its precursors are C → T single and CC → TT tandem transition mutations at dipyrimidine sites. This spectrum of *p53* mutations is very different from *p53* mutations found in malignancies of internal organs; the latter do not have the preponderance of C → T or CC → TT mutations. This, together with the fact that pyrimidine dimers most commonly cause C → T and some CC → TT mutations, provides convincing evidence for a crucial role of pyrimidine dimers in cutaneous photocarcinogenesis. Therefore, C → T, and especially CC → TT mutations have been termed "►UV-signature mutations." They are, in fact, "signature mutations" for DNA photoproducts.

Protection Against Photocarcinogenesis

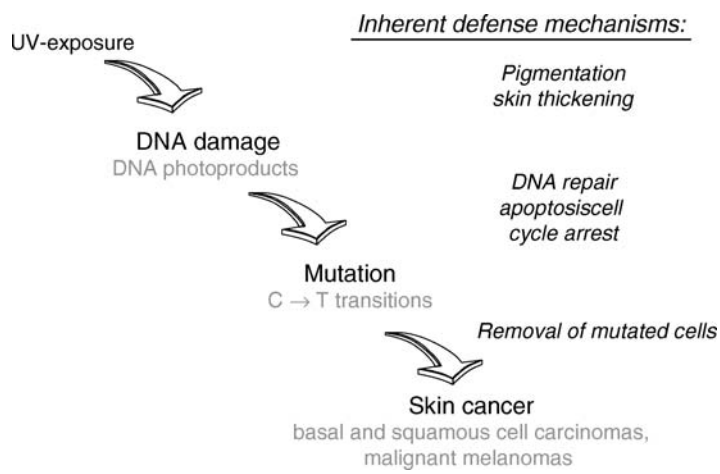
To ensure that most of the damage inflicted by sun exposure will not lead to the formation of skin cancer, UV-exposed cells have several lines of defense against the photocarcinogenesis cascade Fig. 2.

First line of defense – to avoid formation of DNA damage: In order to prevent DNA damage as a consequence of UV exposure, the human epidermis is protected by melanin, the expression of which can be increased in response to ultraviolet light (tanning response) to better protect against subsequent UV exposures. Melanin is a mixture of different polymerized pigments that absorb UV radiation. It is produced by melanocytes and transferred to keratinocytes, where it covers the upper pole of the nucleus in a microparasol to protect the nuclear DNA from the damaging effects of ultraviolet light. Skin can also increase its thickness, which reduces UV exposure of the basal layer, and it contains antioxidative enzymes, which quench reactive oxygen species and reduce the formation of oxidative DNA damage.

Second line of defense – to avoid mutation formation at sites of DNA damage: To counteract potentially mutagenic effects, UV-induced DNA damage requires excision and replacement of damaged nucleotides by DNA repair pathways. No correction procedure is absolutely exact and error-free. If it were, UV-induced skin cancers would not occur in DNA repair-proficient individuals.

DNA photoproducts (pyrimidine dimers) are mutagenic, but they can be repaired by the nucleotide excision repair (NER) pathway. As exemplified by the hereditary disorder ►xeroderma pigmentosum, a defect in this repair pathway increases UV sensitivity and UV mutagenesis in cells, and non-melanoma and melanoma skin cancers *in vivo*. The NER pathway has become well understood, in part through the identification and characterization of the different xeroderma pigmentosum genes.

Individual cancer and skin cancer risks are determined not just by a pronounced NER deficiency, as in xeroderma pigmentosum, but also by more subtle variations in DNA repair efficiency, e.g. as a consequence of polymorphism in DNA repair genes. Likewise, a decline in DNA repair efficiency with age has been linked to the increasing risk of skin cancer with advancing age.



Solar Ultraviolet Light. Figure 2 Inherent cellular defense mechanisms against the photocarcinogenesis chain of events.

Cells from patients with xeroderma pigmentosum variant have an intact NER, yet a phenotype that is indistinguishable from the other xeroderma pigmentosum complementation groups. Cells from these patients do not have a deficit in repairing DNA photoproducts, but a deficiency in what they do with unrepaired DNA photoproducts during replication in the S-phase of the cell cycle. Replicative DNA polymerases usually stall at unrepaired DNA lesions and detach from the DNA strand. For this situation, cells have a number of specialized DNA polymerases that are able to bypass different kinds of DNA damage and extend replication forks through damaged sites. Different polymerases perform this "translesional DNA synthesis" (►translesion DNA polymerases and cancer) with variable fidelity.

Due to a mutation in the pol-η gene, cells from patients with XP variant lack the particular ability of DNA polymerase-η to bypass thymine–thymine dimers with correct insertion of two A residues. This indicates that NER does not always repair all DNA lesions and that the function of a high-fidelity translesional DNA polymerase is crucial for maintaining genomic stability if cells enter S-phase with unrepaired DNA damage. In cells from patients with xeroderma pigmentosum variant, NER can remove most of the thymine–thymine dimers, but, because polymerase-η is missing, any remaining dimers are more likely to be bypassed by polymerases that insert incorrect residues. This causes a UV-►mutator phenotype. If DNA polymerase-η or any other specialized translesional DNA polymerase fails to bypass DNA damage during S-phase, the cell is faced with a stalled replication fork. In these cases, DNA recombination repair, which utilized strand invasion from the sister chromatid, can resolve the stalled replication forks.

Following formation of DNA damage by solar ultraviolet light, cells undergo significant changes. The transcription factor p53 (►p53 protein; biological and clinical aspects), which is both upregulated and activated following exposure to solar ultraviolet light, plays a pivotal role in these DNA damage responses. Genome-protecting effects of p53 in response to UV-exposure are manifold:

- it mediates a cell cycle arrest that allows for more time to repair DNA damage and prevents replication of damaged DNA;
- with overwhelming DNA damage it may induce apoptosis (an affect often seen as sunburn cells, which are apoptotic keratinocytes formed after high dose sun exposure) and thereby prevent survival of damaged cells;
- and it augments DNA repair capacity.

Loss of these protective responses with acquired inactivating p53 mutations results in a UV-mutator phenotype. This explains why p53 plays such a prominent role early in photocarcinogenesis.

Third line of defense – to prevent that cells with mutations expand clonally and form skin cancers: Even after mutations have fixed the inflicted damage for the lifetime of the affected cells, the organism still removes most of these cells, for example, through immune surveillance. However, solar ultraviolet light has several immuno-suppressive effects, which contribute to the carcinogenic properties of solar ultraviolet light. Ultraviolet light is therefore a double-edge sword with regard to photocarcinogenesis: Not only does it generate DNA damage that entails mutation formation and malignant transformation, its immunosuppressive properties and the induction of specific tolerance to UV-induced skin tumors also reduces the ability of the host immune-defense to recognize and remove malignant cells. The latter also impairs the immune-surveillance of cells infected with oncogenic viruses (such as certain HPV types commonly found in squamous cell carcinomas of transplant patients) and may thereby further promote skin cancer formation.

In addition to the intrinsic protective mechanisms against the chain of events leading to the formation of skin cancer, there are extrinsic protective agents and behaviors that can help individuals to reduce their individual skin cancer risk. In order to prevent or reduce UV irradiation of the skin, one can avoid the sun, especially around noontime, stay in the shade, wear protective clothing, and/or wear sunscreens. Sunscreens are topical preparations which attenuate UV radiation before it enters the skin by reflection, absorption, or both. Sunscreens not only protect against the acute skin injury of sunburn, but also against UV-induced immune suppression, photoaging, and skin cancer. The sun protection factors (SPF) of sunscreens, however, which indicate by what factor sunburn is prevented by sunscreen use, do not correlate well with protection factors for other non-erythema endpoints. Therefore, the SPF cannot be regarded as a reliable guide to non-erythema and chronic endpoints.

Topical application of DNA repair enzymes has been shown to increase DNA repair in skin cells and to accelerate removal of DNA photoproducts. In patients with xeroderma pigmentosum, such applications have been reported to reduce the occurrence of actinic keratoses. This indicates that it may be possible to prevent the formation of mutations after the introduction of DNA photoproducts with the use of such "enzymatic sunscreens."

Hereditary Disorders with Increased Photocarcinogenesis

Many disorders with an increased skin cancer risk after exposure to solar ultraviolet light are characterized by a deficiency in the intrinsic protective mechanisms discussed above. For example, men with androgenetic alopecia have a much higher risk of developing

S

skin cancers on the scalp than men who have retained their UV-protective hair cover. Lack of protective melanin, as in oculo-cutaneous albinism, increases the amount of DNA damage in the basal layer of the epidermis after UV irradiation and, subsequently, the risk of skin cancer.

The different DNA repair defects of xeroderma pigmentosum and the DNA damage-processing defect of xeroderma pigmentosum variant (see above) generate a UV-mutator phenotype, with an increased chance that DNA damage will result in the formation of a mutation.

Some cases of familial melanoma are caused by a germ-line mutation in the CDKN2A locus, which encodes two gene products, $p^{16INK4a}$ and $p14^{ARF}$. Intact p16 induces a G1 cell cycle arrest by inhibiting ►cyclin-dependent kinases 4 and 6, which in turn inhibit the phosphorylation of the ►retinoblastoma protein. Loss of $p16^{INK4a}$ function, therefore, entails a loss of the G1 checkpoint, leading to abnormal proliferation, unrestricted progression into S-phase, and, importantly, no cell cycle arrest after UV irradiation. $P14^{ARF}$ is an upstream regulator of p53, another important factor mediating UV-induced growth arrest. The disruption of cell cycle control with loss of CDKN2A does not, however, explain why loss of p16/p14 function predisposes mostly to malignant melanoma, and only to a much lesser degree to internal neoplasias, namely pancreatic cancer. A recent finding that loss of $p16^{INK4A}$- or $p19^{ARF}$-function also impairs the ability of affected cells to repair DNA photoproducts, leading to a UV-mutator phenotype, might be the missing link, explaining why alteration in CDKN2a predisposes mainly to UV-induced tumors.

Similarly, p53 protects against UV mutagenesis by inducing a cell cycle arrest after UV-induced damage, by inducing apoptosis in cells with overwhelming UV-induced DNA damage, and by stimulating DNA repair by directly binding to DNA repair enzymes. Consequently, loss of p53 function has been shown to result in a UV-mutator phenotype and reduced repair of UV-induced DNA damage. Li–Fraumeni syndrome is characterized by a germ-line mutation of the *p53* gene, and predisposes to malignancies of various internal organs and cutaneous melanoma.

Patients with the nevoid basal cell carcinoma syndrome, who develop multiple basal cell carcinomas, especially in UV-exposed areas, harbor germline mutations in the *PTCH* gene. PTCH belongs to the ►hedgehog signal transduction pathway that transmits extracellular growth and differentiation signals to the nucleus. While many of the *PTCH* mutations in sporadic basal cell carcinomas are UV signature mutations (C → T and CC → TT), their frequency is lower than in *p53*, and it is unclear whether sporadic *PTCH* mutagenesis is purely UV induced.

Solute Carrier Transporters

Definition

SLC Transporters; Are a large group of membrane transporters that function as secondary-active or passive transporters in the translocation of ions and small molecules, including drugs, across biological

membranes. The group comprises more than 360 members in 46 families.

►Membrane Transporters

Somatic Cells

Definition

Cells other than those of the gamete-forming germ line.

►Adult Stem Cells
►Somatic Tissue

Somatic Cross-Over Point Mapping

Definition

Is a method exploiting the fact that certain genetically unstable cells, e.g. in ►Bloom syndrome, show excessive DNA cross-overs within the BLM gene itself. This leads to restoration of BLM function in cells inheriting two different mutations in BLM.

Somatic Hypermutation

Definition

Somatic hypermutation is a process by which somatic mutations are introduced at a high rate into the variable region parts of immunoglobulin genes. This process is specifically activated in germinal centre B cells. As a result of somatic hypermutation, antibody variants are generated that differ by a few aminoacids from the original antibody. In the germinal centre reaction, B cells expressing antibodies with increased affinity due to favorable mutations can be selected. Somatic hypermutation may be involved in the generation of B cell lymphomas when non-Ig genes are targeted or when chromosomal translocations happen as mistakes of the process.

Somatostatin

Michael C. Frühwald
Department of Pediatric Hematology and Oncology, University Children's Hospital Muenster, Muenster, Germany

Synonyms

Somatotropin release inhibiting factor; SRIF

Definition

Somatostatin is a bioactive peptide that exists in the two isoforms SST-14 and SST-28, of 14 and 28 amino acids, (SST-14) and SST-28, respectively. It acts as a ►neuropeptide, (neurotransmitter), is produced by neurons and endocrine-like cells and is distributed

throughout the central and peripheral nervous system, endocrine pancreas, gut, thyroid, adrenals, submandibular glands, kidneys, prostate and placenta. Many tumor cells, immune cells and inflammatory cells produce somatostatin.

Characteristics

Somatostatin was initially isolated as an inhibitor of growth hormone (GH) release, but is now best described as a multifunctional peptide, capable of inhibiting secretory processes and cell proliferation. Hypothalamic somatostatin inhibits the release of pituitary growth hormone (GH), thyroid-stimulating hormone (TSH) and corticotropin releasing hormone (CRH). As a neurotransmitter it affects several functions such as autonomous, sensory, locomotive and cognitive. Locally produced somatostatin generally inhibits gut exocrine secretion (e.g. on insulin, glucagon, gastrin), suppresses stomach, small intestine and gall bladder motility, and mediates vasoconstriction, especially of splanchnic vessels. In the adrenals somatostatin inhibits angiotensin II stimulated aldosterone secretion and in the kidneys hypovolemia stimulated renin release. In the immune system it blocks the release of cytokines, including IFN-γ and IL-6, and limits the proliferation of lymphocytes, intestinal mucosar and inflammatory precursor cells. Furthermore, it blocks the action of growth factors such as ►IGF1, ►EGF and ►PDGF. The plasma half life of somatostatin is less than 3 min.

Somatostatin Secretion and Gene Expression

The human somatostatin gene is encoded on chromosome 3q28 in a prehormone form (►preprosomatostatin) with a mRNA of 351bp. The two bioactive forms SST-14 and the N-terminally extended SST-28 are produced by proteolytic cleavage of prosomatostatin. SST-14 is the peptide that is found predominantly. However, up to 30% of immunoreactive SST in the brain is SST-28. Somatostatin secretion is triggered by membrane depolarization, certain ions, nutrients and neurohormones/neuropeptides. Potent stimulators are glucagon, growth hormone releasing hormone (GHRH), neurotensin, corticotropin releasing hormone (CRH), calcitonin gene related peptide (CGRP) and bombesin. Somatostatin gene expression is stimulated by multiple cytokines and growth factors including IGF1 and 2, GH, IL-1, -6,-10, TNF-α, IFN-γ, NMDA receptor ligands and by steroid hormones such as testosterone, glucocorticoids and estradiol. Insulin, leptin, ►TGF-β and some glucocorticoids inhibit somatostatin expression. Transcription of the somatostatin gene is regulated by the intracellular second messengers cAMP, cGMP, NO and Ca2+ and the associated pathways involving ►CREB and ►CBP (cyclic AMP response element binding protein and CREB binding protein).

Somatostatin Receptors (sst)

Somatostatin binds to five currently known G-protein coupled seven transmembrane receptor subtypes (sst1–5) that were initially classified according to their differential binding of somatostatin analogues. The genes for sst1,3,4,5 lack introns, while sst2 contains at least three potential transcriptional start sites, one of which is located in exon 1, 50 kb upstream of the start site in exon 3. All cloned receptor subtypes contain recognition motifs for glycosylation and phosphorylation. Homo- and heterodimerization of the receptors as well as receptor internalization have been described. Upon ligand binding sst induce a multitude of intracellular effects mediated by varying G-proteins coupled to second messengers. All receptors block the formation of cAMP by inhibiting ►adenylyl cyclase and activate tyrosine phosphatases (Table 1).

Molecular Basis of Somatostatins Antiproliferative Effects

Somatostatin limits the proliferation of tumor cells in vitro and in vivo directly and indirectly. Direct regulation is by somatostatin receptors (ssts) that are localized on neoplastic cells; indirect regulation is exerted via ssts on non-neoplastic cells. Mechanistically, this is done by inhibiting the secretion of growth promoting hormones and growth factors (e.g. IGF-1), by promoting vasoconstriction (which leads to a reduced blood flow to tumor tissue), by inhibiting angiogenesis and by influencing the function of immune cells. Theblock of secretion is due to inhibition of the second messengers cAMP and Ca2+ and the inhibition of exocytosis in a G-protein dependent manner.

The direct antiproliferative effects of somatostatin appear to be largely due to the activation of protein phosphatases. Somatostatin induced protein tyrosine phosphatases (PTP) dephosphorylate tyrosine kinases of receptors for growth promoters such as insulin and possibly EGF and IGF-1. Furthermore, somatostatin inactivates MAPK activity via PTP dependent dephosphorylation (sst2), PTP-dependent Raf-1 inactivation (sst3) and inhibitionof cGMP formation (sst5). Activation of PTP is also involved in somatostatin induced apoptosis. While in CHO-K1 cells transfected with each individual sst, sst3 appears to induce apoptosis by activation of TP53, independent of G1 arrest, all other ssts prompt G1 arrest and induction of Rb.

A base pair change in the sst2 gene, found in a lung cancer cell line (COR-L103), lead some authors to the assumption of a tumor suppressor role for somatostatin receptors.

Characteristics of the five cloned human ssts and information about their distribution in human cancer. Methods that rely on tissue homogenates are unreliable since ssts are found in immune cells and veins surrounding the tumor tissue. Subtype selectivity of ligands is indicated by bold italics for IC50. Subtype expression has only been studied in a limited number of tumor types.

Clinical Relevance

Somatostatin Analogue Therapy

The demonstration of receptor subtype expression in malignancies has paralleled the creation of subtype selective receptor ligands. While the best characterized and oldest analogue, the octapeptide octreotide (plasma half life 2 h), exhibits a preference for sst2 with lower affinities for sst5 and sst3, highly specific nonpeptide

agonists for each of the five subtypes have been developed.

The longest clinical experience exists for the treatment of hormone secreting tumors with octreotide and its microencapsulated longacting release form (LAR). The classic indication for somatostatin analogue therapy is a growth hormone secreting pituitary adenoma in ►acromegaly. Furthermore octreotide and other somatostatin analogues have been used in the treatment of carcinoids, insulinomas, gastrinomas, ►VIPomas, glucagonomas and somatostatinomas, producing symptomatic or subjective responses in 30–75%, and significant reduction in tumor size in 10–15% of patients. In clinical studies octreotide and other analogues have been used as single agents or in combination with conventional cytostatic drugs with varying results in carcinomas of the breast, prostate, pancreas, colorectum, thyroid and lung, inmeningiomas, ►neuroblastomas and Non-Hodgkin-lymphomas.

Somatostatin Receptor Imaging and Radiotherapy

The in vitro detection of somatostatin receptors on a multitude of tumor tissues has led to the development of ►somatostatin receptor scintigraphy (SRS). Apart from neuroendocrine tumors expressing ssts, SRS has successfully been used in the imaging of pheochromocytomas, non small cell lung cancers (NSCLC), meningiomas, ►breast cancer, ►gliomas, ►medulloblastomas, Non-Hodgkin and Hodgkin lymphomas (►Hodgkin disease), granulomatous disease, Sjögren syndrome and rheumatoid arthritis. Binding of radioactive somatostatin analogues has been used in radioreceptor-guided surgery as an asset in the surgery of neuroendocrine gastroenteropancreatic tumors and neuroblastomas with occult metastases.

After ligand binding a fraction of receptors are internalized. This phenomenon has been used for clinical studies of in situ radiotherapy using 111Indium or 90Yttrium labeled somatostatin analogues in terminally ill patients with neuroendocrine tumors.

General Clinical Applications

In carcinoids and neuroblastomas the level of somatostatin or somatostatin receptor expression (e.g. by SRS) has been reported to correlate with tumor differentiation and therapeutic outcome of the disease.

As a therapeutic adjuvant octreotide has been used in the treatment of infectious and secretory diarrhea, L-asparaginase induced pancreatitis, symptomatic treatment of fistulas and in the management of severe pain due to neoplasia.

Spectral Karyotyping

Luba Trakhtenbrot
Head of Molecular Cytogenetics Laboratory, Institute of Hematology, The Chaim Sheba Medical Center, Tel Hashomer, Israel

Definition

Spectral karyotyping (SKY) is a multi-fluorochrome ►fluorescence in situ hybridization technique (FISH) in which all the chromosome pairs are simultaneously visualized in different colors in a single hybridization. SKY determines the unique spectral profile of each chromosome generated by specific combinations of different ►fluorochromes. At the present time, SKY can be used to analyze human, mouse and rat chromosomes.

Characteristics

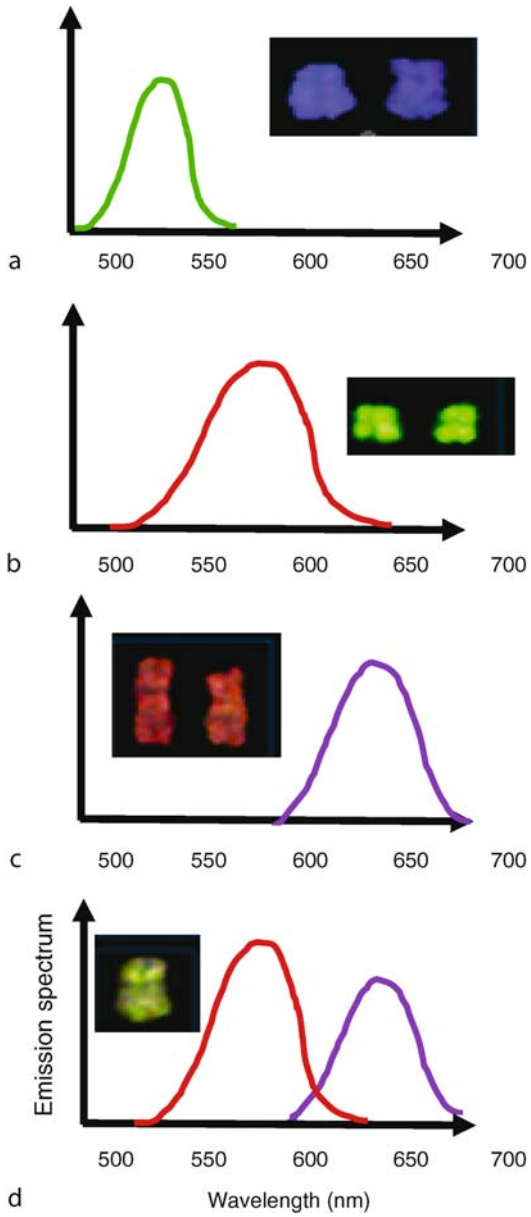
Structural and numerical ►chromosomal alterations (aberrations) are the hallmarks of malignant diseases.

Routine cytogenetic analysis based on ►G-banding techniques provides important information of diagnostic and prognostic relevance both in hematological malignancies and solid tumors. However, detection of chromosomal alterations by this method is complicated by the difficulty in routinely preparing metaphase spreads of sufficient quality and quantity, the clonal heterogeneity of the tumors and the complexity of the many ►chromosomal aberrations. In addition, homogeneously staining regions or double minute chromosomes, results of ►oncogene amplification, are impossible to characterize using G-banding analysis alone. As a result a large number of chromosomal abnormalities are described as so-called marker and derivative chromosomes instead of being precisely defined. Fluorescence in situ hybridization, a highly sensitive and specific tool for the detection of chromosomal aberrations, provides additional information to G-banding analysis clarifying particular problems. However, the ►FISH technique is unable to screen the whole ►karyotype in one experiment and therefore analysis of complex unknown chromosomal alterations requires a large panel of painting probes and several hybridizations.

The fantastic advantage of Spectral Karyotyping (SKY) is the ability to visualize simultaneously all the chromosome pairs in different colors in one hybridization. In this way, karyotype rearrangements are easily detected as a transition from one color to another at the chromosomal breakpoint region.

The SKY method involves several steps:

1. A probe cocktail (Applied Spectral Imaging Ltd, Migdal, Ha'Emek Israel) consisting of fluorescently labeled probes for each chromosome is made by labeling chromosome specific libraries generated by PCR from flow-sorted chromosomes with specific combinations of one or more of the five spectrally distinct fluorochromes (FITC, Rhodamine, Texas Red, Cy5 and Cy5.5).
2. Metaphase preparations are hybridized with this probe cocktail and then stained with 4,6-diamidino-2 phenylindole (DAPI) in antifade medium.
3. The SpectraCube® Imaging system (Applied Spectral Imaging Ltd, Migdal Ha'Emek, Israel) is used to discriminate between the different spectral characteristics of chromosomes. The system measures chromosome-specific emission spectra generated by the combinatorially labeled chromosome-specific painting probes.
4. The spectral signature of the fluorochrome combinations is analyzed using SKYView™ software. It classifies the chromosomes by comparing the acquired spectral characteristics to the combinatorial library containing the fluorochrome combinations for each chromosome. In the classified image the chromosomes appear in a Red-Green-Blue (RGB) display in which FITC is seen as blue, Rhodamine and Texas Red are seen as different shades of green and the infrared dyes not visible to the human eye, Cy5 and Cy5.5, are assigned different shades of red.

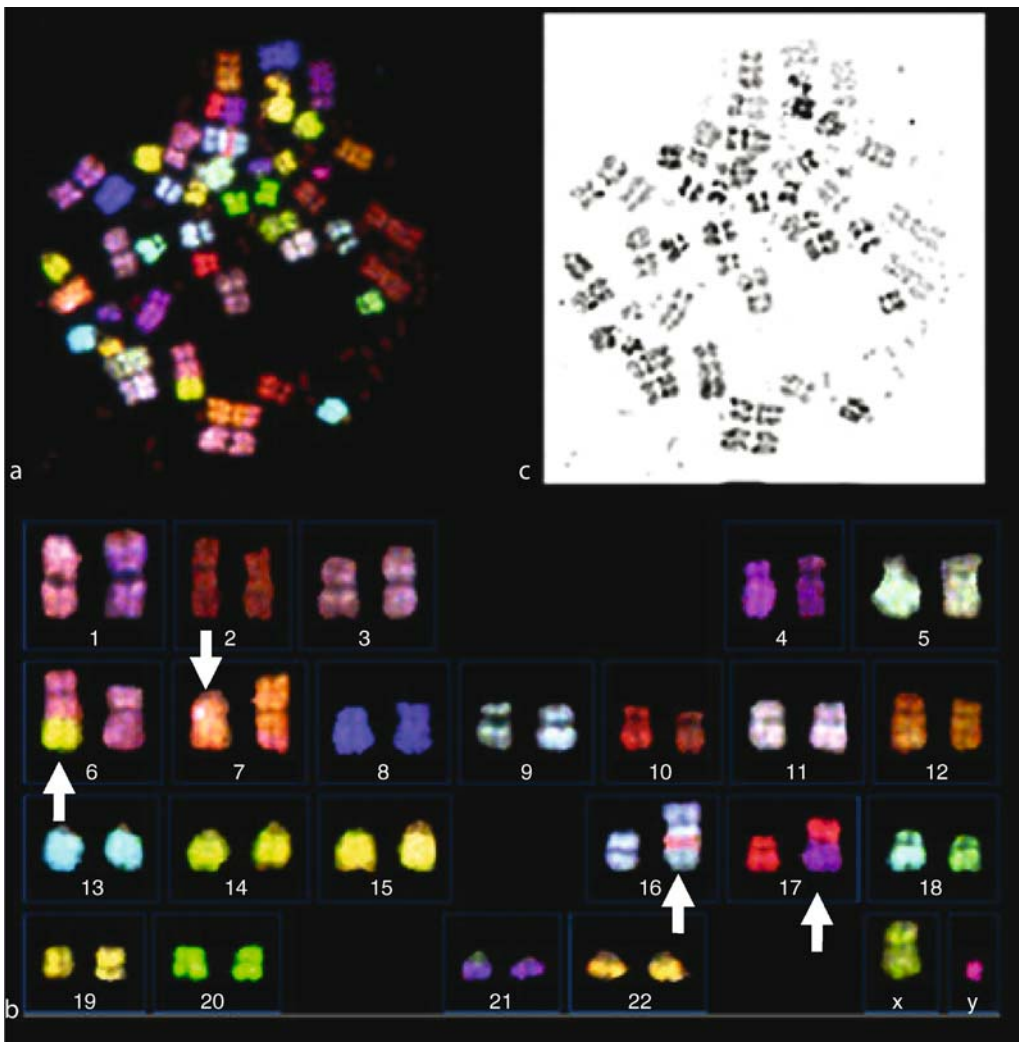


Spectral Karyotyping. Figure 1 Schematic presentation of chromosome identification according to the spectral characteristics. Each graph consists of a fluorescence emission spectra and a RGB display of the chromosome. The horizontal axis shows wavelength, the vertical axis shows relative intensity of fluorescence. (a–d) Chromosomes 8, 20, 2 and X, labeled with FITC, Rhodamine, Cy5.5 and a combination of Rhodamine and Cy5.5, respectively.

S

Figure 1 schematically presents the principle of the chromosome classification according to the spectra characteristics. Each graph consist of fluorescence emission spectra of the distinct fluorochromes (or combination of fluorochromes) and a Red-Green-Blue (RGB) display of the appropriate chromosome. Emission maximums for presented fluorochromes are: FITS – 525 nm, Rhodamine – 570 nm, Cy5.5 – 703 nm. Figure 1(a) shows chromosome 8 labeled with FITC, in the RGB display it's seen as blue color; Fig. 1(b) chromosome 20 labeled with Rhodamine, in the RGB display it's seen as green color; Fig. 1(c) chromosome 2 labeled with Cy5.5, in the RGB display it's seen as red color and Fig. 1(d) chromosome 2 labeled with combination of Rhodamine and Cy5.5, in the RGB display it's seen as specific color.

5. The chromosomes are then automatically sorted into a karyotype table according to the nomenclature rules for G-bands. Rearrangements, ▶translocations between different chromosomes and components of marker chromosomes are all easily identified because of a change in color at the point of transition (Fig. 2a and b). Finally, the software assigns a specific classification pseudocolor to each chromosome allowing chromosomal aberrations to be even more easily visualized (Fig. 2b).



Spectral Karyotyping. Figure 2 Spectral karyotyping of metaphase of a neuroblastoma tumor (a) Red-Green-Blue (RGB) display after hybridization with the SKY kit; (b) Karyotype table of spectrally classified chromosomes. Chromosomal aberrations are detected by the combination of two or more colors on the same chromosome (marked by arrows). (c) DAPI-stained separately and inverted to give a G-banding like pattern. (D. R. Betts, Department of Oncology, University Children's Hospital, Zürich, Switzerland; L.Trakhtenbrot, Institute of Hematology, Tel Hashomer, Israel).

6. The DAPI image is captured separately and inverted to give a G-banding like pattern. This image may be used to compliment the SKY analysis with chromosome banding information (Fig. 2c).

Advantages of SKY

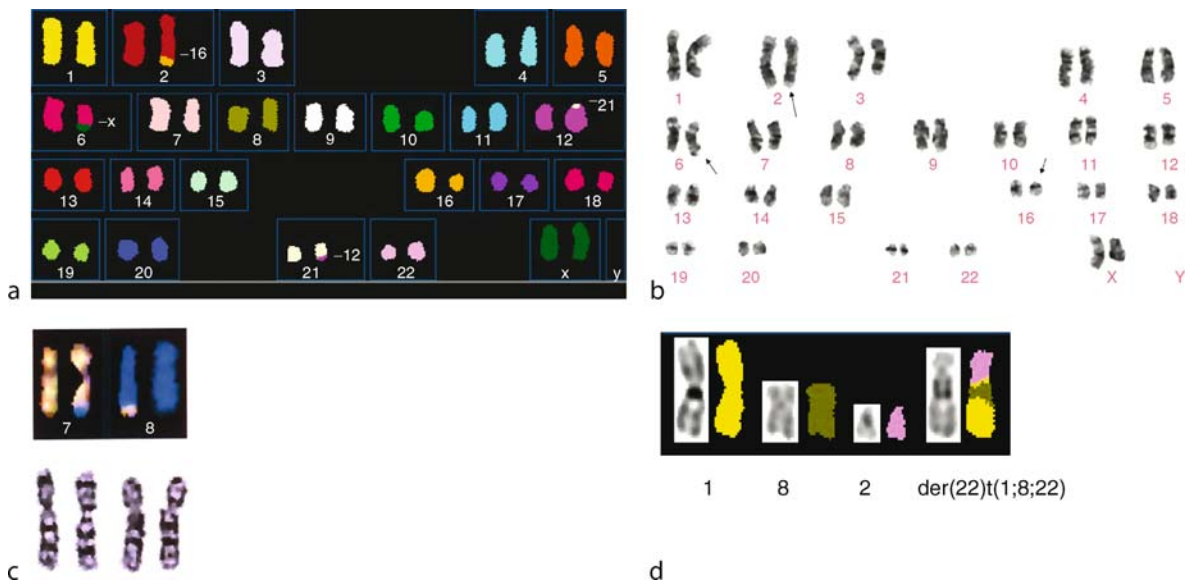
SKY analysis has revealed numerous marker and derivate chromosomes (Fig. 3a, b, d), hidden translocations (Fig. 3a, c), chromosomal ►insertions, homogeneous staining regions and double minutes unidentified or incorrectly identified by G-banding. The combination of SKY with FISH increases the accuracy of karyotype interpretation, permitting precise breakpoint mapping and the detection of small interstitial ►deletions and cryptic translocations. SKY is particularly useful in cancer cytogenetics and provides a much more detailed description of the highly abnormal karyotypes that characterize advanced tumors and cancer cell lines. The precise definition of markers by the SKY technique leads to the determination of an increased number of aberrations per tumor, identification of more chromosomal regions involved in the karyotype evolution and the analysis of more metaphases, especially polyploid. SKY enables the discovery of a larger number of subclones and the revelation of different clonal evolution pathways of karyotype alterations. In general, SKY provides an opportunity to assess the level of tumor instability that is usually associated with advanced or aggressive disease.

The flexibility of SKY permits it to be used with any genome, provided the effective flow sorting of chromosomes can be accomplished. Recently SKY has been developed for murine and rat chromosomes, the most popular species used as model systems for the investigation of tumorgenesis.

Disadvantages

Due to the nature of painting probes, SKY alone can not detect intrachromosomal rearrangements, such as paracentric or pericentric ►inversions, small ►duplications and deletions. The resolution of SKY (1–3 Mb) depends on the level of chromosomal condensation and on the combination of the fluorochromes involved in structural rearrangements. Thus, SKY should be seen as a complement, and not as a replacement, of conventional G-banding analysis.

To overcome these limitations and to elevate the accuracy of cytogenetic analysis a new method named "spectral color banding (SCAN)" was developed on the basis of the conventional SKY analysis. SCAN analyzes a single chromosome, allowing simultaneous visualization of all the chromosome bands in different colors in a single hybridization since each band is labeled with a unique combination of fluorochromes (similar to the SKY technique) with a specific spectral pattern. In this



Spectral Karyotyping. Figure 3 SKY detection of chromosomal aberrations incorrectly identified by G-banding. (a) SKY showing translocations t(12;21), t(2;16) and der(6)t(X;6), displayed in classification colors. (b) G-banding failed to recognized the cryptic translocation t(12;21), and the origin of the additional segments on chromosomes 2 and 6. (c) Translocation t(7;8)(q32;q34) is detected by SKY (RGB display), but not by G-banding. (d) SKY demonstrates a complex translocation involving three chromosomes – 1, 8 and 22. G-banding identifies this rearrangement only as a marker of chromosome 1 origin. (D. R. Betts, Department of Oncology, University Children's Hospital, Zürich, Switzerland; L.Trakhtenbrot, Institute of Hematology, Tel Hashomer, Israel).

way different bands can be distinguished from each other by different colors. SCAN analysis employs a detection system and algorithm for spectral pattern recognition identical to that used in SKY analysis.

The drawback of SCAN is its inability to detect aberrations in the other chromosomes. To overcome this shortcoming, a combination of SKY and SCAN was developed based on a probe cocktail composed of the SCAN banding probes for an individual chromosome and the SKY probe kit without the painting probe for this particular chromosome.

Clinical Significance

Since its introduction in 1996, SKY has been extensively used to elucidate chromosomal aberrations in hematological malignancies as well as solid tumors, including sarcomas, carcinomas and brain tumors. The highly important input of SKY analysis to clinical research of malignant diseases is the identification of novel recurrent aberrations with pathogenic potential and the prediction of a specific phenotype or modified response to treatment or outcome. The results of SKY analyses contribute to diagnosis, therapy decisions, and follow-up studies.

Dihydrosphingosine, the basis of the minor dihydrosphingolipids, generally inactive in cell processes.

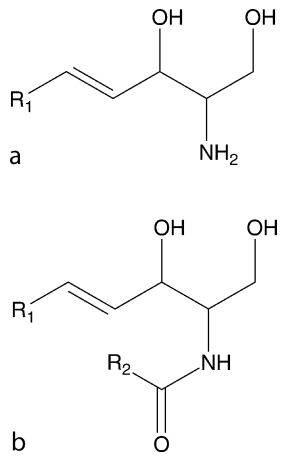
►Sphingolipid Metabolism

Sphingolipid Metabolism

Norman S. Radin
Department of Psychiatry, University of Michigan, Ann Arbor, MI, USA

Definition

►Sphingolipids (►SLDs) contain ►sphingosine (►Sph) or a similar moiety. Sphingosine (Fig. 1a) is D-erythro-*trans*-4-octadecene-2-amino-1,3-diol; R_1 is typically a C_{13} alkyl chain. ►Ceramide (Fig. 1b) is a fatty acid amide of sphingosine that plays a pivotal role



Sphingolipid Metabolism. Figure 1 Sketch (a) shows sphinogosine and (b) shows aramide R_1 represents a tridecyl alkyl chain of a saturated or monounsat urated fatty acid

in cell growth and death, in which R_2 symbolizes a saturated or monoenoic fatty acid containing 16–32 or more carbon atoms. Some fatty acids have an OH at carbon-2. Some ceramides contain phytosphingosine instead of Sph; here the double bond is replaced by an OH at C-4.

Hundreds of SLD species occur. The C-1 OH can be phosphorylated to form Sph phosphate or ►Cer phosphate, or esterified by a phosphocholine group to form ►sphingomyelin (►SM), the most common SLD. The OH can also be coupled to a sugar, usually galactose or glucose, to form GalCer or β-glucosylceramide (►GlcCer). GalCer is a major component of human brain; a portion of the lipid has a sulfate group attached to the sugar (►sulfatide). GlcCer, the primary ►glucosphingolipid (►GSL), can add other sugar moieties to the glucose, particularly galactose, N-Ac-galactosamine, and N-►acetylneuraminic acid (a characteristic moiety of the ganglioside series of GSLs).

Characteristics

Sphingolipids control the properties of cell membranes, the rate of cell growth-proliferation-destruction, apoptotic processes, the phosphorylation and dephosphorylation of proteins, the formation of reactive oxygen species (ROS), the hydrolysis of some proteins, the acetylation of nuclear histones, the binding of microbial pathogens and toxins to human cells, ►angiogenesis, telomerase, matrix metalloproteinase, cytosolic and mitochondrial ►glutathione level, and other cancer-relevant factors. Cancer cells appear to synthesize SLDs somewhat faster than normal cells and are more sensitive to SLD manipulation, even in multi-drug resistant cells. This difference in sensitivity bodes well for the design of a drug with a good therapeutic index.

Some SLDs (Cer, ►gangliosides GM3 and GD3) induce ►apoptosis – especially in cancer cells – while other SLDs (Sph phosphate, Cer phosphate, GlcCer, GalGlcCer) promote growth and proliferation and *prevent* apoptosis. Since these two types of lipids can be interconverted by the enzymes that make and hydrolyze them, it is evident that cells must maintain a balance in their concentrations and activities. One or more controlling factors are missing from cancer cells, resulting in unrestrained growth and a high rate of DNA change. Cancer cells contain unusual assortments of SLDs, with dominance of the proliferative lipids. The essence of cancer chemotheraphy appears - *from this viewpoint* – to be the targeting of these lipids, their enzymes, and the factors that control their levels in tumors.

While SLDs occur almost everywhere in cells, there are special aggregates in plasma cell membranes, called ►rafts (GSL- and cholesterol-enriched lipoid/protein ►microdomains). The rafts function as signaling platforms for important cytokines and modification of their compositions can affect many of their functions. Depletion or augmentation of cellular SLDs leads to a remarkable number of important phenomena.

►Poly-Drug Chemotherapy and Multi-Drug Resistance

Because of the unusual sphingolipid Yin/Yang, Janus-faced metabolism, which promotes *and* blocks cell death, cancer therapy calls for the use of a poly-drug cocktail that stimulates the formation of Cer, ganglioside GM3, and GD3, while simultaneously inhibiting synthesis of the proliferative SLDs. The simultaneity is important because manipulation of just one of these lipid clusters leads the cancer cell to induce changes in the other cluster and proliferative factors. This response eventually leads to renewed tumor growth and resistance to the drugs that were used initially. A similar selection occurs when the initially attacked cancer cells mutate to form cells with a more resistant imbalance in SLD composition. Thus, treating tumors with a single, first-line drug can lead to clones that are resistant to the drug and the apparent cure turns out to be illusory. Evidently a cocktail is needed to cover all or most phases of SLD metabolism in an all-out attack, to kill all the cancer clones present in each individual patient. Preliminary trials of the poly-drug approach have indicated that the dose size of each component can be lower than the single-drug approach (i.e., synergistic), so side effects can be expected to be minimized.

Chemotherapy via Ceramide Control

Cer levels can be elevated by the following approaches. Some of the drugs listed are not – or need not be – approved by the FDA.

1. *Stimulate the first step in de novo synthesis of Cer* from serine and palmitic acid, formation of 3-keto ►sphinganine, via pyridoxal phosphate as cofactor. Exogenous palmitate and serine are effective and supplementary pyridoxine may also help. Dietary carnitine, which helps mitochondria destroy the fatty acid, should be avoided. The apoptogenic effect of palmitate is augmented by etomoxir, which inhibits transport of fatty acid by carnitine. Several anticancer drugs (fenretinide, camptothecin, etoposide, paclitaxel, retinoic acid, tetrahydrocannabinol, and valspodar stimulate the de novo synthesis of Cer.

The next steps in Cer synthesis are reduction of the carbonyl oxygen, forming sphinganine, and acylation of the amine group, forming dihydroCer. This somewhat inert analog of Cer is next dehydrogenated to form Cer, producing a double bond between carbons 4 and 5. The crucial segment of Cer is the ►allylic structure, with the C-3 OH and the Δ^4 double bond. Fumonisin, a fungal toxin commonly found in significant concentrations in some foods, inhibits the acylation step and should be avoided via good food handling practices. It also inhibits acylation of free Sph (see below).

2. *Minimize the conversion of Cer to SM* (sphingomyelin), an exchange of the C-1 OH for the phosphocholine moiety of phosphatidylcholine (lecithin) with formation of diacylglycerol. A similar reaction utilizes phosphatidylethanolamine, followed by N-methylation. The enzyme, SM synthase, as well as lecithin, has been found in high concentrations in some tumors, suggesting that they protect themselves against Cer toxicity this way. It is possible to lower the body content of lecithin by restricting the intake of fatty foods. The anticancer phospholipid analog, hexadecylphosphocholine, which inhibits lecithin synthesis, also slows SM synthesis and speeds Cer synthesis. Thus, the various anticancer phospholipid analogs may owe some of their effectiveness to this mechanism. It follows from this also that drugs emulsified with the aid of lecithin should be reformulated. Tamoxifen, which inhibits diversion of Cer by glucosylation, also stimulates phospholipases C and D, thus also lowers tumor lecithin.
3. *Stimulate SM hydrolysis*, which forms Cer + phosphocholine. The major SMases, Mg^{2+}-requiring neutral SMase and an acidic SMase, are normally somewhat inhibited by mitochondrial glutathione (GSH). Thus an agent that lowers GSH levels will greatly elevate Cer level. Radiation, oxidation by ROS, condensation catalysis by glutathionyl S-transferase, inhibition of GSH biosynthesis (buthionine sulfoximine), and Michael reaction of GSH with anticancer drugs that contain allylic ketone moieties (doxorubicin, camptothecin, tetracycline, a keto metabolite of fenretinide, manumycin, actinomycin D, curcumin, quercetin, 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2, illudin, gossypolone, ciprofloxacin, 17AAG (a geldanomycin analog), and others) act this way to produce much of their anticancer activity.

Other agents lower GSH levels in tumors. Cisplatin and dietary thiocyanates (sulforaphane in broccoli) react chemically with GSH. Sulforaphane also induces glutathione S-transferase activity. Cer and many antineoplastic drugs generate ROS in cells, thus raise the sulfur atom to more oxidized states. Even modest oxidation of GSH to form disulfides and mixed disulfides with the cysteine moieties of proteins unmasks the power of SM to form Cer. Many metabolites and nutrients generate ROS in mitochondria in the normal course of oxidative metabolism. Normally the ROS are kept under control by antioxidants. GSH is needed for important enzyme reactions, so its level should not be reduced too far.

The hydrolysis of SM is stimulated by arachidonic acid, a common dietary fatty acid that is converted to prostaglandins. Thus its use would have to be controlled by the use of COX inhibitors. Thalidomide inhibits angiogenesis by stimulating the synthesis of Cer from SM.

4. *Inhibit diversion of Cer to formation of GlcCer* by treatment with D-threo-1-phenyl-2-decanoylamino-3-morpholino-1-propanol (►PDMP), ►N-butyldeoxynojirimycin, dietary glucose deprivation, chlorpromazine, tamoxifen, mifepristone, antiandrogens, ketoconazole, irinotecan, doxorubicin, dihydroxy vitamin D3, mitoxanthrone, dexamethasone, arabinofuranosylcytosine, and others. PDMP and its analogs PPMP and PPPP produce Cer in more than one way. GlcCer and its anabolite, GalGlcCer, are growth stimulators and promoters of ►P-gp (MDR1), a major cause of ►multi-drug resistance; thus inhibiting Cer glucosylation is important in several ways. It is possible that food intake reduction, which prolongs life, owes some of its effectiveness to depletion of glucose and UDP-glucose, the co-substrate in GlcCer synthesis.

In addition, GlcCer and GalGlcCer are the precursors of the gangliosides, which prevent the normal action of ►dendritic cells, the major first defense in immunological attack on cancer cells. Tumors shed a significant portion of their rapidly synthesized gangliosides into the extracellular fluid around the cancer cells. The mechanism by which these lipids inhibit dendritic cell development is not clear, possibly by inhibiting Cer glucosylation. The ►ganglioside secretion or shedding also promotes angiogenesis, a vital tool of growing tumors. Thus it seems essential to prevent GSL synthesis so that the patient's immune system can make a final clearing of cancer cells. The accumulated Cer prevents angiogenesis.

A further advantage of inhibiting GlcCer synthesis is that it depletes cell surfaces of the GSLs that act as binding sites for many microbial organisms, including viruses. Alternatively, mimics of the surface GSLs can be used to compete with the cells for binding to infective agents. Thus the complication of ►infection in cancer patients would be minimized.

Patients with ►Gaucher disease, who have a genetic deficiency in the amount of GlcCer hydrolase, are currently being treated by injection of a modified form of the human glucosidase. The enzyme lowers tissue GlcCer levels, forming Cer and glucose, thus should be helpful in cancer patients. A similar effect can be expected by injection of a small peptide that is needed for the glucosidase's activity, ►saposin C.

5. *Inhibit Cer hydrolysis*, which forms Sph + fatty acid, with D-erythro-2-(N-myristoylamino)-1-phenyl-1-propanol (►D-MAPP), N-oleoyl ethanolamine, and N-octadecylSph. Blocking ►ceramidase seems to be an effective way of elevating Cer and inducing apoptosis. Reacylation of the Sph to regenerate Cer is performed by an acyltransferase produced from the ►longevity assurance gene.
6. *Inhibit the kinase that converts free Sph* to its 1-phosphate ester (►S1P). This ester competes with Cer in controlling a cell's fate, so the *ratio* of the two lipids is critical for rebalancing the SLDs. N,N-dimethyl sphingosine, trimethylSph, and glabridin (an allylic ether in licorice) are suitable inhibitors. DimethylSph is a normal metabolite of sphingosine, but its concentration seems to be too low in tumors.
7. *Chemotherapy with dietary Cer* has shown beneficial effects in intestinal cancer. However it has to be included as part of the total poly-drug approach in order to prevent conversion of the extra Cer to pro-proliferative SLDs. Dietary SM is converted to Cer in the intestine and also has a beneficial effect; it can be considered a pro-drug. Since both lipids and GSLs occur in food, it is likely that they constitute a natural cancer-preventing mixture. SM has been used as part of a liposomal cocktail for dispersing water-insoluble anticancer drugs. A solubilizing chain of poly(ethyleneglycol), attached to Cer by a dicarboxy acid bridge, may solve the problem of administering so insoluble a lipid. It may also be useful for forming a liposomal suspension with SM.

In recent years, analogs of Cer have been synthesized that are more active than Cer in the induction of apoptosis. Adding an additional double bond, conjugated with the ►allylic double bond of Cer, improved the lipid considerably. It is significant that some antineoplastic drugs also have an allylic alcohol group that is part of a chain of conjugated bonds. A Cer analog with a pyridinium group in the fatty acid moiety was found to concentrate in tumors and prevent their growth in vivo. Its effectiveness was greatly enhanced by including gemcitabine, an antineoplastic drug that produces Cer elevation.

Immunological Attack Against Cancer Cells

Some, perhaps many, tumors consist of cells with an unusually high concentration of rare GSLs. Indeed, the ratio of Cer to GSLs decreases as the tumor malignancy increases. Unfortunately, SLDs are not potent inducers of Ab induction (see dendritic cells above) and special techniques had to be developed. Tumors of neuroectodermal origin (e.g.: melanoma and neuroblastoma) are being tested with a mouse/human chimeric ►mAb against ganglioside GD2, a prominent GSL in these cells. Promising results have also been found by active immunization with ►idiotypic peptides that mimic gangliosides. Pathogens containing idiotypes that resemble GSLs sometimes evoke neuropathological autoantibodies, as in Guillain-Barré syndrome.

α-Linked galactose in GalCer (not the usual β-GalCer) is a potent stimulator of NKT cells and a killer of cancer cells. This finding is under active study.

Mechanisms of Sphingolipid Antineoplastic Action

1. Since addition of Cer to whole cells or mitochondria produces ROS and apoptosis, the proposal has been made that the allylic OH of Cer is oxidized to an allylic ketone (keto Cer). Presumably the latter is the therapeutically active form of Cer, since it can undergo adduct formation with GSH, other thiols, and active amines. Antineoplastic drugs that contain an allylic alcohol, ester, or ether moiety may mimic Cer, forming ROS, allylic ketones, and Michael adducts. Cer – and several anticancer drugs – interfere with the mitochondrial electron-transporting oxido/reduction cycle of ►ubiquinone/ubiquinol that normally generates ATP. Ubiquinone is an allylic ketone, thus is likely to oxidize allylic alcohols.
2. Cer can generate pores in mitochondrial membranes, allowing cytochrome *c* and other components to escape into the cytoplasm where they activate the ►caspases and initiate the apoptogenic death sequence. The pores, called barrels, seem to consist of assembled Cer molecules, lined up with their polar (OH) end facing the inside. A certain minimum amount of Cer must be accumulated in the mitochondria to generate one pore. DihydroCer (lacking the double bond) is inert.
3. Cer and Sph activate *kinases* that act on important proteins (e.g.: PKC ζ involved in the control of apoptosis and many other phenomena. Cer also activates ►*phosphatases* (e.g.: PP1 and PP2A) that remove phosphate groups from many proteins (e.g.: ►Akt). These effects are seen with synthetic anticancer drugs too. Generally, sphinganine-based SLDs are inactive in these activations so the

presence of the allylic polar moiety seems to be essential. The mechanism of activation could be ascribed to binding of the active lipid to an allosteric region of the enzymes. However there is also the recently proposed idea that the SLD binds to the active site of the phosphate-transferring region, with the allylic alcohol moiety forming a transitional phosphate ester, functioning as an ►anion-transferring coenzyme for the catalytic processes.

These kinases and phosphatases control the activity of many phosphoproteins that control apoptosis and many other processes. For example, the Cer-activated phosphatase, PP2A, dephosphorylates and thereby inactivates μ- and m-calpains, leading to suppression of the migration and invasion properties of human lung cancer cells.

4. Cer is involved in other anion-transferring reactions of great importance to cancer therapy. It reduces N-acetylation of protein-linked lysine and is involved in ►histone acetylation. It binds to and activates ►cathepsin D, the acid aspartate protease that triggers the apoptotic program by activating Bid. The aspartate COOH in the enzyme's substrate may form a transient ester link with Cer during the peptide cleavage.

Sphingolipids

Definition

Are a class of lipids derived from the aliphatic amino alcohol sphingosine. The sphingosine backbone is O-linked to a (usually) charged head group such as ethanolamine, serine, or choline. The backbone is also amide-linked to a fatty acid. Sphingolipids are often found in neural tissue, and play an important role in both signal transmission and cell recognition. There are three main types of sphingolipids: ceramides, sphingomyelins, and glycosphingolipids, which differ in the substituents on their head group. Ceramides are the simplest type of sphingolipid. They consist of a fatty acid chain attached through an amide linkage to sphingosine. Sphingomyelins have a phosphorylcholine or phosphoroethanolamine molecule esterified to the 1-hydroxy group of a ceramide. Glycosphingolipids are ceramides with one or more sugar residues and are called gangliosides when they carry three sugars, however one of which must be sialic acid. Phosphorylated forms of sphingosine and ►ceramide, namely sphingosine-1-phosphate (S1P) and ceramide-1-phosphate (C1P) are involved in cell survival, angiogenesis and tumorigenesis.

►Lipid Mediators
►Sphingolipid metabolism

Sphingomyelinase

Definition

Sphingomyelin-phosphodiesterase 1 (gene symbol: *Smpd1*) hydrolyses sphingomyelin to ►ceramide. The maximum of the enzyme activity is at an acidic pH.

Sphingomyelins

Definition

Are sphingolipids that possess a phosphorylcholine or phosphoroethanolamine molecule esterified to the 1-hydroxy group of a ►ceramide.

►Lipid Mediators

Sphingosine

Spindle Assembly Checkpoint

Definition

SAC; Regulates metaphase-to-anaphase transition of the ►cell cycle in order to ensure that chromosomes do not segregate until each is properly attached by microtubules to bilateral spindle poles during mitosis and meiosis.

►Mitotic Arrest-Deficient Protein 1 (MAD1)
►Checkpoint

Spindle Pole Apparatus

Definition

Develops during the ►cell cycle. Is a highly organized structure that consists of kinetochore microtubules attached to segregating chromatids, and polar microtubules moving apart the spindle poles immediately prior to cell division. Independent changes during G2/M culminate in the formation of the spindle pole apparatus (►G2/M transition). It consists of two opposed poles each arising from one of the two duplicated centrosomes. The bisecting line at which microtubules emanating from each pole of the spindle meet is known as the metaphase plate. Pairs of chromosomes align and attach themselves along the metaphase plate and are then pulled apart from one another by motors that push and pull the separated chromosomes towards opposite poles of the cell. Formation of a spindle pole apparatus requires a change in microtubule dynamics. This is brought about by changes in the phosphorylation states of structural and motor microtubule associated proteins (MAPs); (not to be confused with mitogen activated protein kinase, MAP kinase!). Cyclin-dependent kinase 1 (CDK1) is known to phosphorylate many MAPs.

►G_2/M Transition

Spindle Pole Body

►Centrosome

Spinocerebellar Ataxia Type 1

Definition

SCA1; Is an autosomal dominant progressive neurodegenerative disorder characterized by ataxia, dysarthria, ophthalmoparesis, and variable degrees of amyotrophy and neuropathy. The disease causing mutation is an expansion of a CAG trinucleotide repeat which lies within the coding region of ataxin-1.

►Cajal Bodies

Spinophilin

Definition

synonym neurabin II; Is ubiquitously expressed and interacts with protein phosphatase 1 (PP1), an alternate reading frame (p14ARF, a 14 kDa polypeptide in humans, 19 kDa in mouse), doublecortin and actin, and synergistically suppress osteosarcoma tumor growth with p14ARF.

►Doublecortin

Spirometry

Definition
A physiologic test that measures inhaled and exhaled volumes of air independently and as a function of time.

►Chronic Obstructive Pulmonary Disease and Lung Cancer

Spleen

Definition
A lymphoid organ in the abdominal cavity that is an important center for immune system activities.

Spleen Tyrosine Kinase

►Syk Tyrosine Kinase

Definition
A large multi-protein and snRNA complex that mediates the catalytic steps of the splicing reaction.

►pre-mRNA Splicing

Splicing

Definition
The process by which introns are removed from an RNA transcript.

►Pre-mRNA splicing

Spontaneous Bacterial Peritonitis

Definition
Is characterized by the spontaneous infection of ascitic fluid in the absence of an intraabdominal source of infection involving the translocation from bacteria from the intestinal lumen to the lymph nodes with subsequent bacteremia and infection of ascitic fluid.

►Acites

Sporadic

Definition
Referring to gene mutation, a term frequently used as synonym for non-hereditary.

Sprouty

Ting Ling Lo, Graeme R. Guy
Signal Transduction Laboratory, Institute of Molecular and Cell Biology, Singapore

Synonyms

Spry

Definition

Sprouty (Spry) proteins are a family of endogenous proteins that negatively regulate the ►ERK/MAP kinase (ERK/MAPK) signaling pathway (Fig. 1) that is activated by ►Receptor Tyrosine Kinases (RTKs).

Characteristics

Sprouty was initially discovered as an inhibitor of ►fibroblast growth factor (FGF) signaling during tracheal development. It was involved in modulating branching in tracheal formation in the fly (Drosophila) and its absence led to excessive "sprouting" of tracheal tubules. As in the fly, mammalian Spry proteins work as feedback inhibitors of RTK signaling during ►branching morphogenesis of the lung, vascular system, kidney tubules and breast ducts.

To date, four mammalian Sprys (Spry1–4) have been identified with sequence similarity to the *Drosophila* protein (Fig. 2). These are expressed in the brain, heart, lung, kidney, limbs and skeletal muscle. The Spry proteins have a highly conserved cysteine-rich C-terminus. The N-terminal half of the Spry proteins are more divergent, however, except for the presence of an invariant tyrosine residue (Y) located in a short, conserved NxYxxxP motif. Many of the inhibitory functions of the Spry proteins are dependent on this residue. Of note, Spry1, 2 and 4 are tyrosine ►phosphorylated/phosphorylation in response to RTK stimulation while the ability of growth factors to induce tyrosine phosphorylation of Spry3 is unknown.

Mechanisms of Action

Various studies conducted in the mammalian system confirm Spry proteins as negative regulators of the ERK/MAPK pathway; they differ in their conclusions as to the specific point in the ERK/MAPK pathway at which Spry acts. Spry has been found to interact with regulators of MAP kinase or mainstream components of MAP kinase (Fig. 1) (a comprehensive description can be found in the review by Mason et al. (2006)).

Regulation of the Activity of Sproutys

As a negative regulator, Spry is subject to tight control through post-translational modifications and through regulation of the protein levels in the cell. The activity of Spry proteins is regulated by post-translational modifications such as serine and tyrosine phosphorylation, palmitoylation and ►ubiquitination.

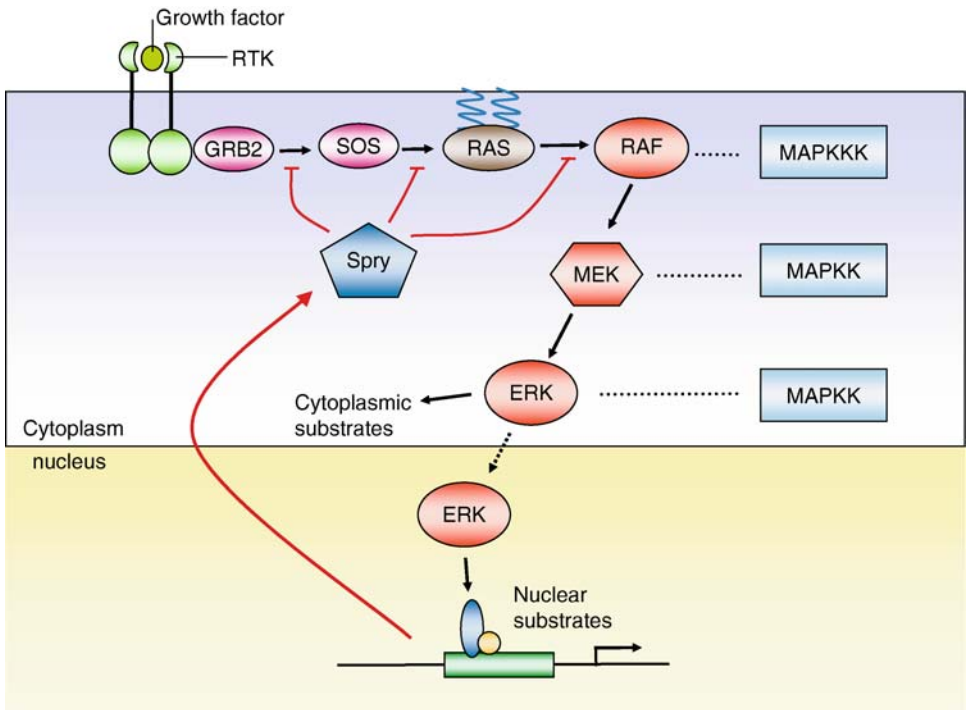
In their N-terminal domain, Spry proteins contain a conserved tyrosine residue (Tyr55 in Spry2) that undergoes phosphorylation in response to growth factor (FGF) and ►epidermal growth factor (EGF) stimulation. This tyrosine residue is necessary for Spry proteins to function as inhibitors of FGF signaling. While tyrosine phosphorylation on the conserved tyrosine on Spry is important for its functional activity, it also promotes the binding of the E3 ubiquitin ligase c-Cbl to Spry2. Tyrosine phosphorylation of Y55 on Spry2, or Y53 on Spry1, creates a consensus binding motif [NxY(S/T)xxP] which serves as a binding site for c-Cbl. The interaction of Spry proteins with c-Cbl promotes the ubiquitination and ►proteasome degradation of Sprys. This pathway has been postulated to serve as a mechanism to control the duration of Spry activity. In addition, several studies have found that serine phosphorylation of Sprys affect the activity of Sprys via influencing the stability and tertiary conformation of Spry proteins.

The activity of Spry proteins is also regulated by controlling the expression of Spry proteins in the cell. Spry proteins are induced by the same RTK signaling pathways they negatively regulate. During vertebrate development, *Spry* genes are often expressed at sites associated with FGF signaling activity. *Sprys* were also observed to be up-regulated upon activation of RTK signaling in *in vitro* cell culture.

Deregulation of Spry Expression in Cancer

The central ERK/MAP kinase pathway is deregulated in many cancers. As Spry proteins are functional inhibitors of this pathway their own regulation is likely highly relevant to the status of some cancers. There is emerging evidence that the expression of the Sprouty family of proteins is deregulated in various cancers including breast, liver, prostate, ►melanoma, ►gastrointestinal stromal tumors (GISTs) and ►lung tumors. *Spry* genes have been shown to be down-regulated in breast, liver and prostate cancers and up-regulated in melanoma, gastrointestinal stromal tumors and Ras-induced lung tumors.

The up-regulation of *Spry* expression in certain tumors (gastrointestinal tumors, melanoma, lung tumors) is often induced by the presence of ►oncogenic lesions (mutation of ►c-Kit, ►Raf kinase, ►Ras) which cause the constitutive activation of the MAP kinase pathways in these tumors. Although numerous oncogenes are also activated in breast, liver and prostate cancers, the same phenomenon of up-regulation of *Spry* genes was not observed. Instead, down-regulation of *Spry* genes was observed. The mechanisms of down-regulation of Spry genes has not been completely elucidated in these



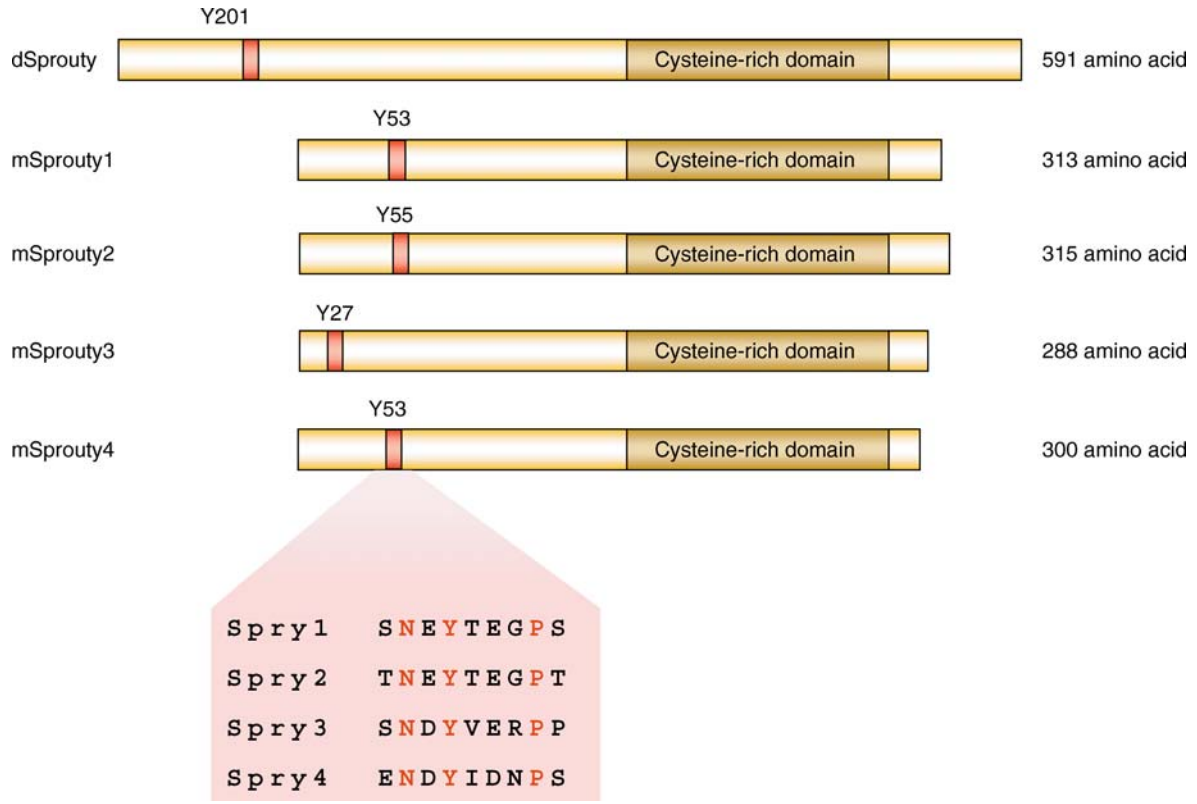
Sprouty. Figure 1 The ERK/MAP kinase pathway. The ERK/MAPK cascade is known for its crucial role in mediating the transduction of signals from Receptor Tyrosine Kinases (RTKs). Following ligand binding, growth factor RTKs such as ►VEGFR and ►FGFR become activated. This induces the binding of adapter proteins such as growth-factor-receptor bound-2 (GrB2) that bind to the activated receptors. In cooperation with Grb2, the guanine-nucleotide exchange factor, son-of-sevenless (SOS) activates ►Ras. This initiates membrane recruitment and activation of ►MAP kinase ►Raf, which leads to the activation of the ►MAP kinase kinase (MEK) and subsequently, ►MAP kinase ERK. ERK phosphorylates several cytoplasmic targets or migrates to the nucleus, where it phosphorylates and activates transcription factors that control the expression of genes that are required for cell growth, differentiation and survival. Various studies conducted in the mammalian system confirm Spry proteins as negative regulators of the ERK/MAPK pathways. Spry proteins are induced by the same RTK signaling pathways they negatively regulate and are observed to be up-regulated upon activation of RTK signaling.

cancers but at least for prostate cancers, some genetic (loss of parts of chromosomes) and ►epigenetic gene silencing by ►methylation mechanisms have been identified to be responsible for silencing of Spry genes.

As the up-regulation of Sprys in cancers is a reflection of an over-active MAP kinase signaling pathway in cancers, Sprys have the potential to be used as ►biomarkers to aid in cancer diagnosis and treatment. Up-regulation of *Spry* genes can be used concurrently with other molecular markers to distinguish between different types of tumors. When gene expression patterns of different soft tissue tumors were analyzed, *Spry* genes were found to be specifically expressed in gastrointestinal stromal tumors (GISTs) but not in synovial sarcomas, neural tumors and leiomyosarcomas. Similarly, *Spry2* expression was found to be up-regulated in melanoma cells with *B-Raf (V599E)* or N-*Ras (Q61R)* mutations but not melanoma cells with wild-type *B-Raf.* Increased MAP kinase activity in these cells was found to contribute to the higher levels of Spry2.

Up-regulation of *Spry* genes could also be potentially used concurrently with other biomarkers to aid ►prognosis or monitor the response of patients to drug treatment. However, depending on the particular type of cancer, up-regulation of *Spry* genes can either be a marker for good or bad clinical prognosis.

Spry4 is shown to be induced by aberrant c-Kit activation in GISTs. Aberrant c-Kit activity derived from activating c-Kit mutations have been shown to be important for development of GISTs. In a study that involved treating GIST cells with an inhibitor of c-Kit, ►Imatinib (Gleevec, STI-571), *Spry4* was identified and confirmed as one of the most significant Imantinib-responsive genes that were consistently down-regulated upon treatment with Imantinib. Imatinib has been shown to be an *in vitro* inhibitor of c-Kit phosphorylation and tumor cell ►proliferation while inducing ►apoptosis in a human GIST cell line. Treatment of GISTs cells with Imantinib resulted in a parallel loss of phosphorylated c-Kit, MAP kinase activation and *Spry4* levels. *Spry4* was found to be a reliable marker



Sprouty. Figure 2 Structure of Sprouty proteins. Four mammalian Sprys (mSpry1–4) have been identified with sequence similarity to the fly (*Drosophila*) protein (dSpry). Spry proteins have highly conserved cysteine-rich C-termini and invariant tyrosine (Y) residues located in a short, conserved motif. Many of the inhibitory functions of Spry proteins are dependent on this residue.

with respect to the clinical response of the patients to Imatinib treatment. In patients responsive to the drug, *Spry4* levels were dramatically decreased. However, in non-responsive patients, *Spry4* levels did not decrease. In patients who initially responded but subsequently relapsed, *Spry4* levels decreased dramatically in the tumor biopsy taken during clinical response but returned to pretreatment levels upon clinical relapse.

Spry2 was also found to be up-regulated in mouse lung tumors which are induced by oncogenic K-Ras. Individual lung tumors were isolated from the mice and examined for Spry expression. The degree of Spry2 up-regulation correlated with the histological grade of the tumor.

While Sprouty is a potential marker of aberrant MAPK signaling in the above-mentioned cancers, in other cancers it is surprisingly a marker for good clinical prognosis. In a study of the gene expression profiles of ►renal carcinoma (clear cell Renal Cell Carcinoma), 51 genes that effectively discriminate between patients with good and poor outcome were isolated. *Spry1* was found to be up-regulated exclusively in the good outcome group.

Ability of Sprys to Inhibit Cancer

Numerous *in vitro* cell-based assays demonstrated that Sprys inhibit cell proliferation, ►migration, and ►invasion as well as ►anchorage-independent cell growth by repressing RTK-induced MAP kinase activation.

Evidence from *in vivo* animal studies indicates that Spry proteins can act to suppress the tumorigenesis process. The first evidence detailing Sprys' ability to interfere with the tumorigenic process was a study where over-expression of Spry2 in an osteosarcoma cell line was found to inhibit tumor growth and metastasis, possibly via the inhibition of MAP kinase activation and cell migration. In a subsequent animal study, Spry2 was shown to inhibit K-Ras-induced lung tumors in mice. In K-Ras-induced lung tumorigenesis, mice develop lung tumors due to the presence of activated K-Ras in their lung tissue. Spry2 was found to be up-regulated in the lung tissue and was found to inhibit the tumor development. Mice with the presence of activated K-Ras in their lung tissue developed greater amount of tumors when the Spry2 expression is abrogated (deletion of Spry2 gene; Spry2 null mice). Analysis of the tumors demonstrated mild increase of

MAP kinase activation in tumors in *K-Ras; Spry* null mice compared to *K-Ras;and Spry2* wild type control mice. This evidence indicates that Spry2 functions to inhibit K-Ras-induced tumor development and that the mechanism may involve antagonism of MAP kinase signaling.

Squamous Cell Carcinoma

W. Andrew Yeudall
Philips Institute of Oral and Craniofacial Molecular Biology, Virginia Commonwealth University, Richmond, VA, USA

Synonyms

Epidermoid carcinoma

Definition

Squamous cell carcinoma is a malignant tumor arising from non-glandular lining or covering epithelia.

Characteristics

Squamous cell carcinoma (SCC) is an invasive tumor which may present at numerous body sites, including skin, ocular epithelium, ►oral cavity, alimentary tract, anogenital region, larynx and bronchial epithelium. Thus, the incidence of SCC lesions varies with site. Estimates from the National Cancer Institute indicate that over one million new cases of skin SCC (►Skin carcinogenesis) will be diagnosed in the USA in 2007, representing 16% of all types of skin cancer. Similarly, ~40,000 new cases of head and neck SCC (comprising oral cavity, pharynx, larynx) occur each year. Squamous cell carcinoma is also one variety of ►non-small cell lung cancer, the annual incidence of which is 170,000. Anogenital SCC, comprising lesions of cervix, vulva, vagina, penis and anus, are less frequent. Approximately 23,600 new cases are predicted to occur in the USA each year, of which the majority (12,000) will be ►cervical cancers.

Etiology

As squamous cell carcinomas can occur at several body sites, multiple etiological factors have been implicated in development of these lesions. Skin cancer is largely associated with exposure to ultraviolet light, with the disease affecting those areas of the body exposed to sunlight. Additionally, persons with fair skin susceptible to sunburn are at higher risk. Immunosuppressed individuals, such as transplant recipients, patients suffering from ►epidermodysplasia verruciformis (EV), or those infected with human immunodeficiency virus (HIV) are prone to develop SCC of skin, which is related to infection with ►human papillomavirus (►HPV). For ►lung cancer, the major etiological agents are carcinogens present in ►tobacco smoke (around 90% of male cancer deaths and 80% of those in females are associated with smoking); additional factors include a family history of the disease, or exposure to radon gas. Similarly, head and neck SCC is primarily related to tobacco use, particularly lesions of the oral cavity (►Tongue cancer), oropharynx and larynx. In addition to cigarette smoking, intraoral lesions may also arise in users of chewing tobacco, as well as those who use pan (a combination of areca nut and slaked lime, rolled in a betel leaf to form a quid), with or without tobacco. This practice is popular in southern Asian cultures, and in immigrant populations from this region, resulting in large, exophytic tumors. Further etiological factors for head and neck cancer include alcohol use (also important for ►esophageal SCC) and HPV infection. Anogenital SCCs are primarily caused by infection with "high-risk"

HPV (Human Papilloma Virus) types. Additional etiology includes tobacco usage and HIV infection.

Diagnosis and Clinical Features

Diagnosis of squamous cell carcinoma is based on a combination of clinical examination and histopathological assessment of a biopsy specimen. In some cases, such as ►lung and other internal tumors, clinical examination may be assisted by the use of imaging techniques, such as standard radiography or magnetic resonance imaging. SCCs of skin, oral or genital mucosa may present as exophytic, verrucous (warty) lesions (verrucous carcinoma), or as persistent ulcers that fail to heal. Typically, such ulcers have a raised, rolled border, and larger lesions may show signs of necrosis in the center.

By definition, squamous cell carcinomas arise from squamous epithelium. Histopathologically, therefore, SCCs show signs of ►invasion through the basement membrane into the underlying stromal tissue – the hallmark of carcinomas. Lesions may show varying degrees of differentiation: well-differentiated tumors will be more recognizable as squamous epithelium, forming nests of tumor cells within the stroma and may express an abundance of keratin, forming so-called "keratin pearls." Some tumors can show fewer (or no) signs of squamous differentiation, and may be graded (►Tumor grading) as moderately or poorly differentiated, or anaplastic. Highly aggressive lesions may invade adjacent muscle and bone, and enter into ►lymphatic vessels or blood vessels, thus aiding their spread to secondary sites of growth (►metastasis).

Squamous cell carcinomas may develop through a series of well-defined premalignant stages, during which the epithelium shows increased disruption of normal growth and differentiation and loss of tissue architecture. The epithelium progresses through ever more advanced stages of ►dysplasia, in which some (or all, depending of the degree of dysplasia) of the following ►cellular atypia may be observed:

- Hyperchromatic nuclei
- More frequent mitoses
- Aberrant mitotic figures
- Mitoses in suprabasal cell layers (in stratified epithelia)
- Pleomorphic nuclei, altered nucleus/cytoplasmic ratio
- Loss of cellular polarity
- Dyskeratosis – keratinization deep within the epithelium
- Loss of ►adhesion
- De-differentiation and loss of tissue architecture

Typically, premalignant lesions are described as mildly, moderately, or severely dysplastic depending on the number of cellular atypia observed upon histopathological examination. The most severe cases (but where invasion has not yet occurred) may be referred to as carcinoma-in-situ (CIS). Cervical dysplasias are generally graded as cervical intraepithelial neoplasia (CIN) grade I, II or III, or as CIS, representing increasing severity.

Clinically, potential premalignant lesions may also be noted. ►Actinic keratosis is a well-recognized condition seen on areas of sun-exposed skin which presents as scaly, erythematous patches. Similar lesions on the lip are known as actinic cheilitis. These lesions may range from mild to severe, depending on the degree of cellular atypia present histologically. Full-thickness cellular atypia (CIS) is known as ►Bowen disease. Pre-neoplastic lesions are also recognized at other body sites. In the oral cavity, white patches (►leukoplakia) may be dysplastic, although the majority does not progress to invasive cancer. Red, atrophic areas of ►erythroplakia should be regarded with much more suspicion, as they have a greater propensity for malignant change. A combination of these two lesions – "speckled leukoplakia" or leuko-erythroplakia – are also more likely to undergo malignant transformation. Less frequently, lichen planus (particularly the erosive form) may develop into squamous cell carcinoma. In cervical epithelia, suspicious areas are identified by application of a dilute solution of acetic acid to the area under investigation, producing acetowhite lesions, the histological condition of which is then determined by biopsy. In the development of lung SCC, one of the intermediate histological events is the onset of squamous metaplasia, where the normal respiratory epithelium assumes squamous characteristics. This change may be reversible if exposure to the initiating agent (most commonly tobacco smoke) ceases.

Disease Management

Therapeutic modalities for squamous cell carcinomas include one of (or more commonly a combination of) surgical excision, chemotherapy or radiotherapy. Typically, smaller well-localized lesions are excised with a wide surgical margin of normal tissue. The "normality" of the margin is generally based on clinical and histological assessment. However, this is complicated by the phenomenon known as ►field cancerization. This hypothesis proposes that histologically normal fields or patches of cells are present which have developed from genetically altered stem cells and, thus, are predisposed to undergo malignant ►progression. This underlies the propensity of squamous cell carcinomas to recur following excision or for patients to develop multiple second primary lesions. The likelihood of future tumor occurrence makes preventive strategies appealing. In this regard, the use of ►retinoids has been explored in several clinical trials. However, the success of this is still under debate as,

in some trials, provision of beta-carotene actually increased the incidence of lung cancer. Novel chemotherapeutic drugs that target mutant epidermal growth factor receptors present on the tumor cells are being used for treatment of some ►lung cancers and head and neck SCC. The central role for HPV in cervical ►carcinogenesis has led to the development of a vaccine to prevent viral infection.

Molecular Aspects

A considerable body of research has documented the molecular genetics and biochemical features associated with squamous carcinogenesis. While distinct differences have been noted between tumors arising at specific body sites, there are many common genetic aberrations that are shared amongst SCCs. ►Loss of heterozygosity (LOH), indicative of inactivation of ►tumor suppressor genes, has been reported to occur at multiple chromosomal locations including chromosomes 1, 3p, 4, 5q, 6, 8, 9, 11q, 13q, 14q, 17p and 19q. Two of the most actively studied are the ►*CDKN2A* gene on 9p21 and ►*TP53* on chromosome 17p13 which, respectively, encode p16/►INK4A, an inhibitor of ►cyclin D-dependent kinases, and ►p53, a multi-faceted regulator of cell cycle progression, genomic damage and programmed cell death (apoptosis). Loss of p16/INK4A has been shown to occur through chromosomal loss or deletion, as a result of promoter hypermethylation and, less commonly, through intragenic mutation. The net effect of such a loss is to deregulate the activity of ►cyclin dependent kinases (CDKs) 4 and 6, which are normally active in the G1 phase of the cell cycle. This leads to the hyperphosphorylation of pocket proteins, such as the ►retinoblastoma protein pRB, and more rapid progression through the cell cycle, thus contributing to the enhanced proliferation seen in cancer cells. Loss or mutation of *RB1* is observed less frequently in SCC which may be ascribed, at least in part, to the loss of p16/INK4A, increased expression of cyclin D1 as a result of gene amplification of a locus on chromosome 11p, and the action of the HPV E7 (►Early Genes of Human Papilloma Viruses) oncoprotein.

Loss of expression of a functional ►p53 protein is a common feature of SCC, in some cases through chromosomal loss or deletion. More commonly, however, intragenic mutations result in expression of ►p53 proteins harboring amino acid substitutions that disrupt normal function, or in expression of truncated proteins. The biological consequences of p53 loss can be wide-ranging, given the many functions of this protein, and include failure to activate cell cycle checkpoints in the event of genotoxic stress and failure to execute programmed cell death. C-to-T transition mutations are found commonly in skin cancer, with CC-to-TT changes present at high frequency. These are indicative of ultraviolet irradiation-induced damage, consistent with the known etiology of SCC at this site. Similarly, mutations found in head and neck and lung SCCs are frequently ascribable to the actions of carcinogens present in tobacco smoke, such as the occurrence of G-to-T transversions. The presence of mutation in the *TP53* gene may also be useful to identify clones of genetically altered cells that have arisen during the process of field cancerization.

Deregulation of cell growth by human papillomavirus contributes to the genesis of the majority of cervical cancers. Additionally, HPV has been linked with other anogenital tumors as well as head and neck (primarily pharyngeal), skin and lung cancers. The E6 and E7 (►Early Genes of Human Papilloma Viruses) oncoproteins encoded by "high-risk" HPV types deregulate cell cycle progression by targeting p53- and pRB-dependent pathways. E6 (►Early genes of human papilloma viruses) targets p53 for degradation by the ubiquitin-proteasome pathway (►Ubiquitination). Additionally, E6 (►Early Genes of Human Papilloma Viruses) targets PDZ-motif-containing target proteins such as Dlg, MAGI-1 and MUPP1, each of which has also been shown to suppress cell growth. The E7 (►Early Genes of Human Papilloma Viruses) protein is well-recognized for its ability to bind the retinoblastoma protein and the related p107 and p130 pocket proteins, targeting them for degradation and, hence, also deregulating proliferation. E7 (►Early Genes of Human Papilloma Viruses) also inhibits the function of the transcriptional coactivator FLH2 which may further enhance cellular transformation, while E6 and E7 (►Early Genes of Human Papilloma Viruses) also upregulate expression of the cellular inhibitor of apoptosis protein cIAP2, leading to apoptosis resistance.

Inactivation of the fragile histidine triad gene, ►*FHIT*, located at chromosome 3p14 is another important ►tumor suppressor gene loss that is observed in squamous cell carcinomas. Studies have documented reduced expression in ►oral SCC and in oral premalignant lesions, as well as in esophageal, lung and ►cervical carcinomas. In addition to gene loss, ►epigenetic gene silencing by promoter hypermethylation contributes to reduced transcript levels, and may be attributable to exposure to tobacco smoke. Decreased expression is also reported to be an early event in tumor progression and may be associated with a worse prognosis. Conversely, studies of skin SCCs (non-tobacco etiology) do not provide evidence of altered FHIT expression.

Mutations in the ►*HRAS* gene are reported in only 10–20% of skin tumors, in contrast to initial studies. However, *NRAS* mutations are found with higher prevalence in patients with xeroderma pigmentosum, an inherited condition in which there is a defect in DNA

repair processes. Mutations in *KRAS* are reported in up to 30% of lung cancers. Genes encoding ►Ras proteins are infrequently mutated in head and neck cancers, except for lesions associated with a pan or betel quid chewing habit.

Disruption of growth factor signaling pathways is also common in many squamous cell carcinomas. Overexpression or mutation of the epidermal growth factor receptor (►Epidermal growth factor receptor inhibitors/ligands) is seen with high frequency in head and neck, lung, alimentary and anogenital tumors, and helps to drive proliferation as well as ►motility and ►metastatic spread of tumor cells. Loss of the negative regulatory effects of transforming growth factor beta also contributes to deregulated cell growth, as well as the transition from an epithelial to a mesenchymal (►Epithelial to mesenchymal transition) phenotype that is seen in some advanced cancers. Additionally, the role of ►inflammation is becoming increasingly recognized in squamous cell carcinogenesis, as well as in other tumor types. Notable players in this area include members of the ►chemokine network which can modulate immune function, induce tumor neovascularization (►angiogenesis) and stimulate proliferation and metastasis of tumor cells.

SR Proteins

Definition

A family of RNA binding proteins that are characterized by one or more amino-terminal RNA-recognition motifs (RRM), a glycine rich region, and a carboxyl terminal region that is rich in the amino acids arginine and serine which are largely arranged as dipeptides. Individual members of the SR family of proteins are able to complement non-splicing competent cytoplasmic extracts to gain splicing function. SR proteins are important for constitutive ►splicing and have also been found to be important for regulation of alternative splicing. SR proteins facilitate alternative splicing by binding to elements within the pre-mRNA called splicing enhancers and recruiting other components of the ►spliceosome

Src

Sarah J. Parsons
University of Virginia, Charlotteville, VA, USA

Synonyms

c-Src; v-Src; $pp60^{c\text{-}Src}$; $pp60^{v\text{-}Src}$

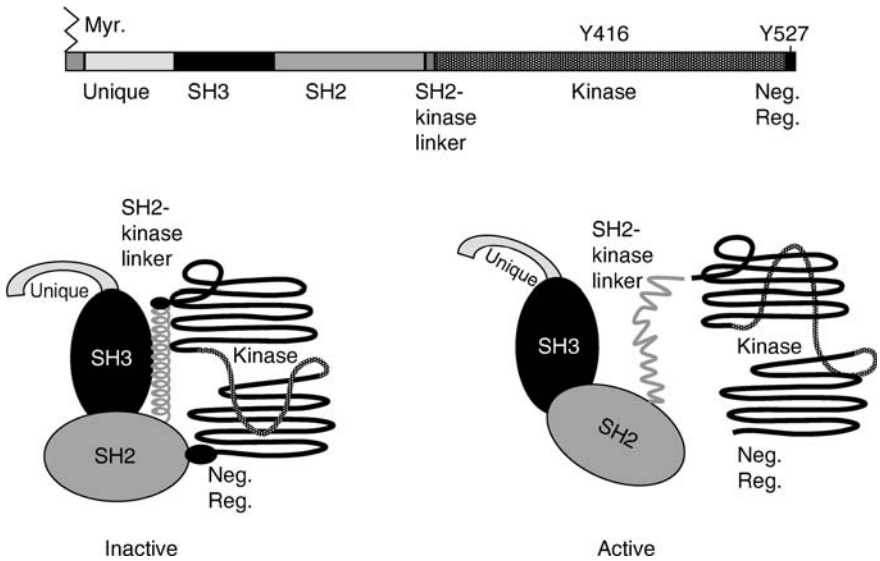
Definition

v-Src (or viral Src) is a 60 kDa protein encoded by the oncogenic retrovirus, Rous sarcoma virus. The protein derives its name from its ability to induce sarcomas in experimental animals and malignantly transform cells in tissue culture. c-Src, or cellular Src, is the normal cellular progenitor of v-Src. c-Src is non- or weakly transforming when overexpressed in tissue culture cells. Both v- and c-Src are cytoplasmic tyrosine kinases that transfer phosphate from ATP to tyrosine residues within specific protein substrates. The resulting phosphotyrosine either conformationally activates the enzymatic activity of the recipient molecule or functions as a docking site for other molecules that transmit growth signals to the nucleus in a chain of events involving multiple phosphorylation and binding reactions. c-Src contains a carboxy-terminal region that maintains the molecule in a mostly inactive state. In v-Src, this 12 amino acid region is deleted, rendering the molecule constitutively active.

Characteristics

Domain Structure

Each molecule of Src contains seven domains that are involved in targeting the protein to cellular membranes (the myristylation domain), in binding other proteins (the Unique, ►SH3 and SH2 domains) and in regulating the catalytic activity (Fig. 1). Src is one of a family of at least nine proteins that have a similar overall structure, including Fyn, Yes, Fgr, Hck, Lck, Blk, Yrk, and Lyn. Some of the family members are present only in certain cell types, such as cells of the hematopoetic



Src. Figure 1 Structure of c-Src. As a linear molecule, c-Src consists of an N-terminal membrane association domain that contains the site of myrisylation, a Unique domain that exhibits the widest sequence divergence among family members, an SH3 domain, an SH2 domain, an SH2/kinase linker, the catalytic domain, and a negative regulatory domain that contains Tyr 527 (531 in human c-Src). When c-Src is activated, Tyr 416 (Tyr 419 in human c-Src) in the kinase domain becomes phosphorylated. How all the domains of c-Src relate to one another in a three-dimensional context to generate the inactive and active states of the enzyme is also shown and explained in the text.

lineage, while others are ubiquitously expressed. c-Src is one of the latter family members.

Subcellular Localization

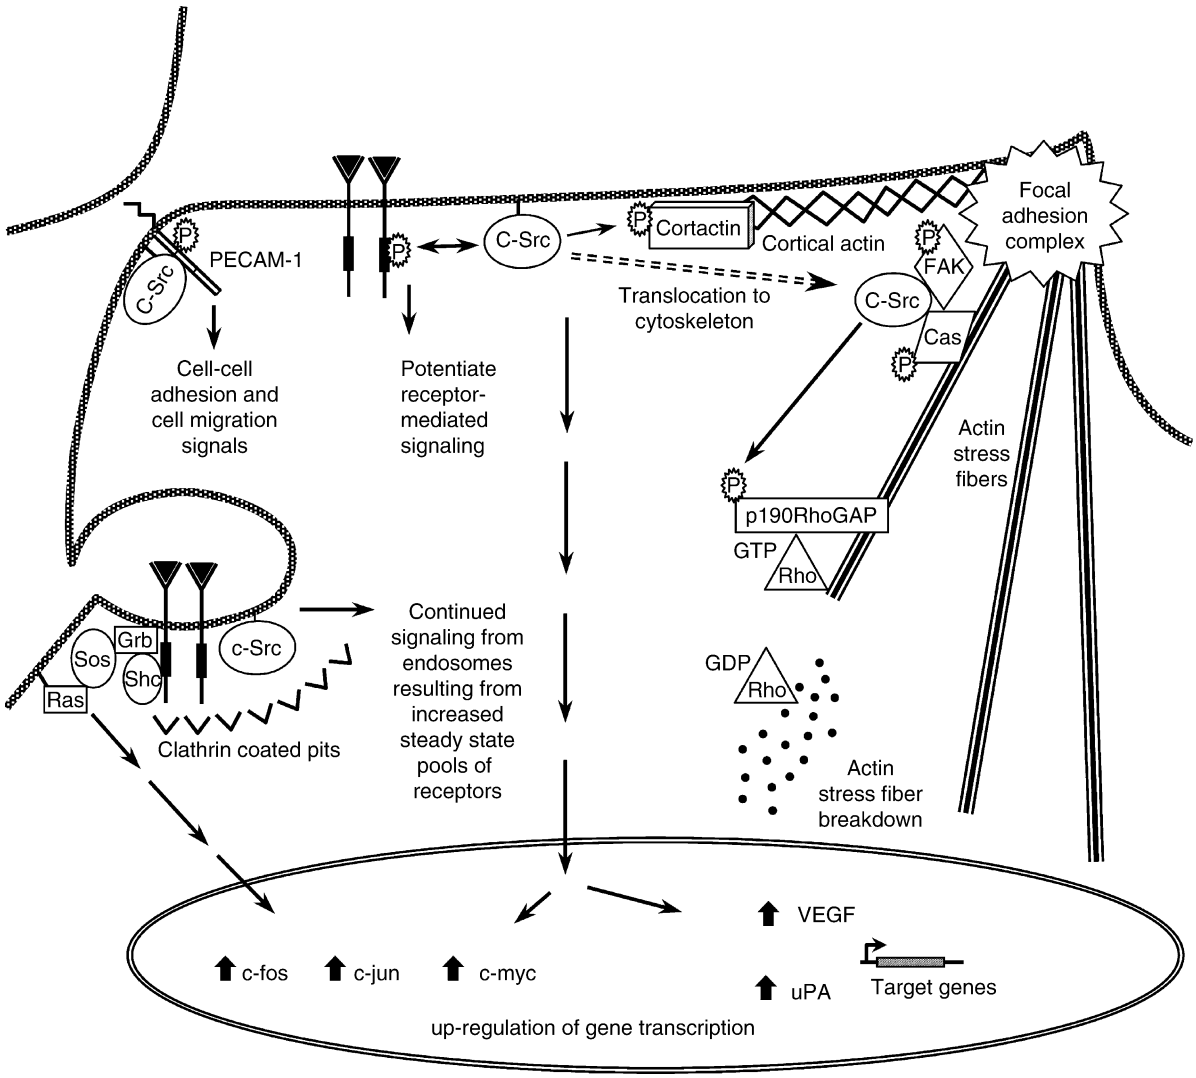
The myristate fatty acid modification on the amino terminus of Src targets it to intracellular membranes, including the plasma membrane and membranes of intracellular organelles, especially those of the endocytic pathway. c-Src has also been found to associate with ►centrosomes in interphase cells.

Interacting Proteins

Src forms complexes with a variety of intracellular signaling molecules via its Unique SH2 and SH3 domains (Fig. 2). These proteins include, but are not limited to, polypeptide growth factor receptors such as the ►epidermal growth factor (EGF) receptor, intercellular ►adhesion molecules such as PECAM and ►E cadherin, gap junction proteins such as connexin 43, and several proteins found in focal adhesions such as focal adhesion kinase (►FAK) and p130CAS. While most of these binding proteins are also substrates of Src, Src can phosphorylate proteins that do not form complexes stable enough to extract from the cell, such as the cortical actin binding protein, ►cortactin, p190RhoGAP (a GTPase activating protein for ►Rho family GTPases) and clathrin, a component of endocytic vesicles.

Cellular and Molecular Aspects

The extreme C-terminal domain of c-Src contains a tyrosine residue (Tyr 527 in chicken c-Src and Tyr 531 in human c-Src) that when phosphorylated binds its own SH2 domain in an intramolecular fashion (Fig. 1). This binding, together with the coupling of the SH3 domain to a pseudo-polyproline sequence in the SH2 kinase linker, renders the protein inactive. c-Src becomes activated when these intramolecular interactions are disrupted by competition with other signaling molecules that contain either phosphotyrosine or polyproline regions that bind the SH2 and SH3 domains, respectively, of c-Src. Such events occur, for example, when the c-Src SH2 domain binds phosphotyrosine 397 of FAK or phosphotyrosines of activated and tyrosine phosphorylated polypeptide growth factor receptors. Full activity is achieved upon dephosphorylation of Tyr 527/531 and autophosphorylation of Tyr 416/419 in the activation loop of the catalytic domain. Antibodies specific for phosphorylated Tyr 416/419 are frequently used to assess the activation state of c-Src in human tumors. c-Src activity has been reported to increase following integrin engagement of extracellular matrix (and subsequent activation of FAK) or upon stimulation of cells with growth factors, such as EGF, PDGF and FGF. v-Src is constitutively activated by deletion of the C-terminal phosphotyrosine 527/531 and mutations within the SH3 domain that reduce interactions with the pseudo-polyproline region.



Src. Figure 2 Examples of c-Src targets and their potential roles in transformation.

S

Clinical Relevance

c-Src is overexpressed or activated in multiple human tumors, particularly in ►glioblastomas and ►carcinomas of the breast, lung, colon, prostate, cervix, stomach and ►ovary. In ►breast cancers, the frequency of tumors overexpressing c-Src approaches 70%. Although analyses of other tumor types are not as extensive as those of breast cancers, existing data suggest the frequency of c-Src overexpression in lung and colon tumors may be similar to that in breast malignancies. Members of the EGF receptor family are also overexpressed in many of the same types of tumors that overexpress c-Src. Recent studies indicate that c-Src and EGFR synergistically promote tumor growth. This enhanced growth is accompanied by an EGF-induced association between c-Src and the EGFR, phosphorylation of EGFR by c-Src on several novel sites, and activation of signaling pathways that are required for EGF-induced mitogenesis and cell survival following genotoxic stress. These findings are providing the impetus for discovering novel therapeutics that disrupt both the physical and functional interactions between c-Src and EGFR family members.

c-Src's involvement in the formation and turnover of focal adhesions and cell-cell contacts also suggests a role for this protein in cell ►migration and ►metastases. Regulation of ►vascular endothelial growth factor (VEGF) expression in response to hypoxia implicates c-Src as a modulator of angiogenesis, further underscoring its potential importance as a target for anti-tumor therapy. To that end, numerous pharmaceutical companies have developed inhibitor compounds

that target c-Src kinase activity, and several of these are being tested for treatment of solid tumors in clinical trials, including AZD0530 (AstraZeneca), BMS-3554825 (Bristol Myers Squibb), and SKI-606 (Wyeth Research).

St. John's Wort

Definition

Synonym hypericum, goatweed. The flowering tops of St. John's Wort are used to treas and tablets with concentrated extracts. Although St. John's wort is not a proven therapy for depression, there is some evidence that St. John's wort is useful for treating mild to moderate depression. It is also used for anxiety and/or sleep disorders. St. John's wort can influence the clearance of specific drugs known to be metabolized by CYP3A (►Cytochrome P450) or excreted via ►ABC drug-transporters.

►Irinotecan

Stage

Definition

Referring to tumors, is an internationally agreed index which objectively measures the extent of tumour growth and progression. Common criteria include tumour size, extent of local spread, and presence of lymph node or visceral metastasis. Each tumour-type has its own staging system, with variations in the common criteria, which correlates with prognosis.

►Transcoelomic Metastasis

Staging of Tumors

Fang Fan
Department of Pathology, University of Kansas School of Medicine, Kansas City, KS, USA

Synonyms

Determination of tumor extent and spread; Tumor staging

Definition

Tumor staging is a clinical procedure aimed at documenting the anatomic extent of a malignant tumor at a specific site, and the extent of its spread locally, regionally, or to distant sites. Upon completion of

the clinical staging procedures, the tumor under consideration is assigned to a particular *stage* (stadium in Latin), i.e. given a semiquantitative designation summarizing the data about the size of the tumor and the extent of its spread.

Characteristics

Purpose

The staging of cancer is used to document the extent of the neoplastic disease in a standardized and consistent manner that will allow clinicians to compare the features of a particular tumor with other similar tumors. The main reasons for staging of tumors have been summarized by the American Joint Committee on Cancer as follows:

- Selection of the most appropriate therapy for each individual patient
- Formulation of prognosis for each cancer patient, i.e., prediction of the natural course of the neoplastic disease and its outcome with or without treatment
- Objective and measurable assessment of the effects of therapy
- Objective performance of clinical cancer studies within a single institution or geographically distant institutions

Clinical staging of tumors is of paramount importance for the proper selection of treatment of each particular cancer patient. Many univariate and multivariate studies have shown that the tumor stage at the time of diagnosis is in most instances the most powerful predictor of outcome of a neoplastic disease and cancer patients' survival with or without treatment. It is also essential for organizing multi-institutional cancer treatment studies and other forms of clinical cancer research.

Methods

Tumor staging is typically based on a multidisciplinary effort including oncologists, surgeons, radiologists, pathologist and even other clinicians. The data may be collected by biopsy, during surgical exploration, during definitive cancer surgery, laparoscopic surgery, and radiologic examination of the patient. The material collected during these procedures is usually submitted for macroscopic and microscopic pathologic examination. Additional studies, such as molecular biologic analysis of the tumor material may be undertaken in research institutions, but it is not routinely included in the staging of most tumors.

The most widely used tumor staging system is called the TNM system. The TNM system is based on analysis of three parameters: the size or extent of the untreated primary tumor (T), the absence or presence of spread to the regional lymph nodes (N), and the presence or absence of distant metastasis (M). For the sake of uniformity and consistency the following standardized definitions are used:

Primary tumor (T)	
TX	Primary tumor cannot be evaluated
T0	No evidence of primary tumor
Tis	Carcinoma in-situ (early cancer that has not invaded into the surrounding stroma)

Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be evaluated
N0	No regional lymph node involvement

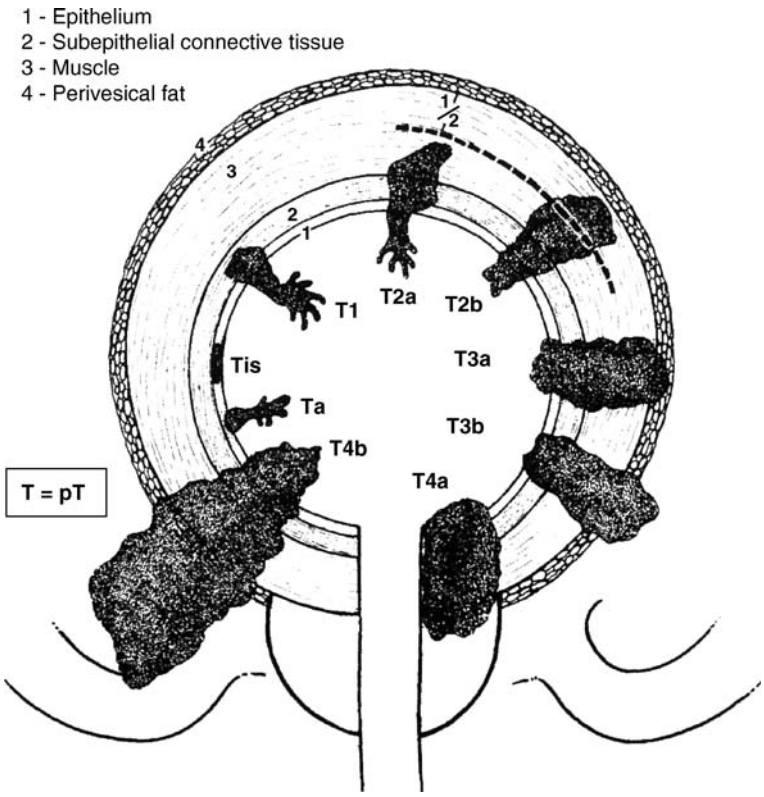
Distant metastasis (M)	
MX	Distant metastasis cannot be evaluated
M0	No distant metastasis (cancer has not spread to other parts of the body)

The staging based on the TNM data typically includes five categories, corresponding to stages 0 and stages I–IV. Each of these stages may be subdivided into subcategories labeled a, b, or c. Stage 0 denotes *carcinoma in situ*. Stage I, II and III tumors are localized to the organ of their origin or have spread regionally. Stage IV tumors have metastasized to distant sites.

The criteria for T, N, and M and for stages 0–IV vary from one anatomic site to another. For example, bladder cancer T3N0M0 is stage III, while colon cancer T3N0M0 is stage II. For specific staging of tumors in various anatomic sites one must refer to specific staging manuals. Figure 1 illustrates the definition of T classifications for bladder cancer.

Perspectives

Staging of tumors has been standardized to a great extent but still many problems remain to be solved. The older staging systems such as the staging of colonic carcinoma according to Dukes are not used any more and are thus only of historical interest. New staging classifications are constantly being proposed and the merits of new approaches are discussed in medical literature. The same holds true for the new studies on the molecular biology techniques or new imaging techniques, which are used in



Staging of Tumors. Figure 1 Tumor staging. Extent of primary bladder cancer (T classification).

experimental protocols in many leading research centers. Overall, one can predict with confidence that the current protocols for staging of tumors will be improved by the introduction of newer technology, but all these modifications will require extensive independent confirmation and validation before they become widely accepted.

Ta	Non-invasive papillary carcinoma
Tis	Carcinoma in-situ: "flat tumor"
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades muscle
pT2a	– Superficial muscle (inner half)
pT2b	– Deep muscle (outer half)
T3	Tumor invades perivesical tissue
pT3a	– Microscopically
pT3b	– Macroscopically (extravesical mass)
T4	Tumor invades any of the following: prostate, uterus, vagina, pelvic wall, abdominal wall

Statins

Leonidas C. Platanias
Robert H. Lurie Comprehensive Cancer Center and Division of Hematology-Oncology, Department of Medicine, Northwestern University Medical School, Chicago, IL, USA

Definition

Statins are synthetic agents that inhibit HMG-CoA reductase, the rate-limiting enzyme that controls cholesterol biosynthesis. Currently, there are several statins in use for the treatment of hypercholesterolemia in humans. It is well established that these agents induce their therapeutic effects by decreasing low density lipoproteins (LDL). Such effects have been associated with a decrease in the rate of progression of atherosclerotic lesions in patients with coronary artery disease, and it is now well established that the use of statins has changed the natural history of coronary artery disease in humans. Beyond their ability to lower cholesterol, statins have important additional biological effects in vitro and in vivo, including anti-inflammatory and antitumor properties.

Characteristics

There has been substantial experimental evidence establishing that statins inhibit the growth of malignant cells and induce programmed cell death in vitro. Moreover, statins exhibit chemopreventive effects towards certain types of tumors in vivo when administered to humans. The ability of statins to generate such responses in vitro and in vivo is of high interest and may prove to be of clinical value in the future.

Cellular Effects of Statins in Vitro

Statins induce apoptosis of different types of malignant cells in vitro. These include cells of leukemia origin as well as cells originating from a variety of solid tumors, including colon, prostate, breast, thyroid, pancreatic, small and non-small cell lung cancers, as well as malignant melanoma, osteosarcoma, glioma and medulloblastoma. Although the mechanisms by which statins induce apoptosis have not been fully elucidated, there is evidence that distinct cellular events are involved in the induction of statin-dependent pro-apoptotic responses. Blocking protein ►geranylgeranylation correlates with ►lovastatin-induced apoptosis of human leukemia cell lines. In addition, statins activate the pro-apoptotic JNK ►MAP kinase pathway in malignant cells, and the activation of this pathway is essential for statin-dependent programmed cell death. Beyond activation of the JNK pathway, statins inhibit the MEK/ERK signaling cascade, which is associated with increased cell proliferation, and this constitutes another major mechanism contributing to their antineoplastic properties. ►Atorvastatin and ►fluvastatin also induce differentiation of NB4 leukemic cells that are of acute promyelocytic leukemia (APL) origin. Such effects also occur in cell variants that are refractory to the differentiating effects of all-trans-retinoic acid (ATRA). Atorvastatin and fluvastatin exhibit also similar in vitro effects on primary leukemic blasts that have developed resistance to the differentiating effects of ATRA and appear to reverse such ATRA-resistance.

Statins in the Prevention and Treatment of Cancer

There is accumulating evidence from epidemiological studies indicating that statins exhibit chemopreventive effects against certain solid tumor types, including colorectal cancer, lung cancer, prostate cancer, and pancreatic cancer. On the other hand, statins do not seem to exert such chemopreventive effects against

breast cancer. Extensive preclinical evidence has also suggested that statins may have therapeutic effects against certain malignancies. This has led to the recent initiation of clinical trials to examine the clinical activity of statins in certain malignancies. A recent phase I study assessed the combination of high doses of pravastatin with chemotherapy in the treatment of acute myelogenous leukemia patients. Such combination was found to be safe and well tolerated, while a high number of complete responses was seen. Altogether, there is a substantial amount of evidence raising the possibility that statins may eventually find a role in the prevention and/or treatment of certain tumors and hematologic malignancies. Several epidemiological and clinical studies are currently ongoing to address this issue.

Staurosporine

Molliane Mcgahren-Murray,
Khandan Keyomarsi
Department of Experimental Radiation Oncology, Department of Surgical Oncology, Unit 66, University of Texas, MD Anderson Cancer Center, Houston, TX, USA

Definition

Staurosporine is a natural product originally isolated from the bacterium *Streptomyces staurosporeus* from a soil sample obtained in Japan (Iwate Prefecture) in 1977 during a search for new alkaloids present in actinomycetes and given the name AM-2282. The term alkaloid refers to a naturally occurring amine produced either by a plant, animal or fungus. Actinomycetes are a group of Gram-positive bacteria that had previously been shown to produce the alkaloids pyrindicin, NA-337A and TM-64.

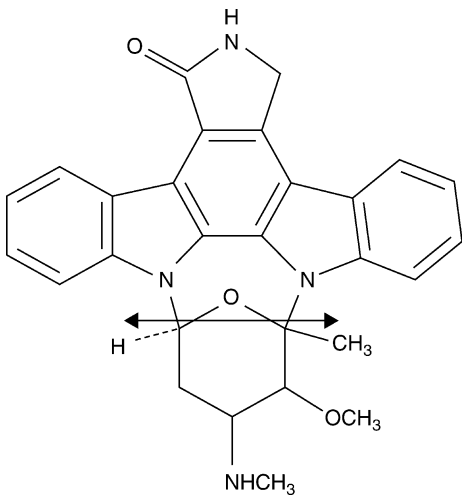
Characteristics

The initial studies on AM-2282 focused on the taxonomy of the producing strain, fermentation, isolation, and physico-chemical and biological properties of this new alkaloid. Besides being identified as a new species, they also discovered that AM-2282 had antimicrobial activity. The term antimicrobial is given to any type of chemical compound that can suppress the growth of, or aid in the death of microorganisms, such as bacteria, yeast and mycoplasma. AM-2282 had antimicrobial activity against fungi and yeast, but no significant effects on bacteria.

The structure of AM-2282, which herein will be referred to as staurosporine, is shown in Fig. 1. Staurosporine was the first of over 50 alkaloids to be isolated with this type of chemical structure, which was elucidated through X-ray analysis. In Fig. 1, the portion of the structure above the arrow, is known as an indole carbazole sub-unit, while the lower part of the structure is a sugar molecule. Although staurosporine was isolated in 1977 and, its X-ray crystal structure was determined in 1978, it was not until 1996 that the first total chemical synthesis was achieved. Part of the challenge to the synthesis of staurosporine was the joining together of the sugar and indole carbazole groups and establishing the sugar stereochemistry. In 1992, the indole carbazole group known as staurosporine aglycon was isolated. Aglycon is the non-sugar compound remaining after replacement of the glycosyl group with a hydrogen atom.

Kinase Inhibition

The anti-microbial activities of staurosporine were initially thought to be via its role as a potent inhibitor



Staurosporine. Figure 1 Structure of staurosporine (AM – 2282).

S

of protein kinase C (PKC). These initial studies revealed that staurosporine was able to inhibit PKC from rat brain. Using other inhibitors such as trifloperazine, chloropromazine, and polymixin B, staurosporine was a more potent inhibitor of PKC than other known inhibitors. Furthermore, PKC inhibitors trifloperazine, chloropromazine, and polymixin B appeared to compete with phospholipids, whereas, the inhibition by staurosporine was not released by increasing the concentration of phosphatidylserine. Studies with cultured cells showed that staurosporine has very potent growth inhibitory activity.

In addition to being an inhibitor of PKC, staurosporine also inhibits several other kinases, such as tyrosine kinases. The in vitro activity of staurosporine was analyzed by investigating the autophosphorylation of $p60^{v\text{-}src}$ in chicken embryo fibroblasts (CEF) that were infected with the rous sarcoma virus (RSV), revealing staurosporine was able to inhibit the autophosphorylation. This was evidence as staurosporine could inhibit tyrosine specific protein kinases similarly to serine and threonine specific kinases such as PKC. Together, staurosporine is a more potent inhibitor of protein-tyrosine kinase than other known inhibitors.

Staurosporine can also inhibit the myosin light chain kinase. Myosin light chain kinase plays a critical role in smooth muscle contraction as well as in the activation of non-muscle cells, by catalyzing the transfer of the γ-phosphate from ATP to the myosin light chain, which is dependent upon Ca^{2+}/calmodulin. The phosphorylation of the light chain is necessary for the activation of actomyosin ATPase, which is a prerequisite for tension development in both smooth and non-muscle cells. Inhibition of the myosin light chain kinase is ATP-dependent.

Other kinases that can be inhibited by staurosporine include the insulin receptor tyrosine kinase activity non-competitive with ATP and the platelet-derived growth factor (PDGF) receptor tyrosine kinase.

Besides having inhibitory activity on these kinases involved in signal transduction pathways, staurosporine was also shown to block cells in different phases of the cell cycle. Staurosporine can block the G1 to S transition at low concentration (1–10 ng/ml) and block cells in late G2 phase at higher concentrations (100–200 ng/ml). There have been several reports showing that the retinoblastoma protein is important in the ability of staurosporine to arrest cells in the G_1 phase of the cell cycle. For example, staurosporine can be used to protect normal cells from the toxic effects of chemotherapy at subnanomolar concentrations, to allow for a reversible G1 arrest through inhibition of the retinoblastoma protein, followed by treatment with camptothecin. Such sequential treatment (with staurosporine first) results in a protection of cells against the toxic affects of chemotherapy. Tumor cells, however, appear unaffected by staurosporine, and are sensitive to low amounts of camptothecin.

The cell cycle associated kinase that is inhibited by staurosporine is Cdc2 (also known as CDK1) which is important in the G2/M transition of the cell cycle. Staurosporine also inhibits the cdk2 and cdk4 kinases which are involved in G1 and S phases.

Collectively, these findings suggest that staurosporine is a non-specific kinase inhibitor because it can inhibit kinases of several different functions with similar efficiencies. This is due to the fact that the serine/theronine kinases conserve the amino acid sequence and 3-D structure of the ATP binding domain. Additionally, staurosporine inhibits the activity of both the insulin receptor tyrosine kinase and of Ca^{+}/calmodulin-dependent protein (CaM) kinase II in a non-competitive manner with ATP. This suggests that staurosporine can interact with other catalytic domains distinct from the ATP binding site.

Staurosporine in Apoptosis

Staurosporine has been a useful tool in analyzing apoptosis because it has been able to induce apoptotic cell death in cell lines that are normally resistant to chemotherapeutic drugs and death-inducing ligands. One of the death-inducing ligands, TRAIL ((TNF)-related apoptosis-inducing ligand), can normally induce apoptosis in two-thirds of melanoma cell lines examined. Staurosporine, however, is able to induce apoptosis in all melanoma cell lines tested, including those resistant to TRAIL.

Although staurosporine was shown to have a strong cytotoxic effect on the growth of several mammalian cell lines, it did not show anti-tumor activity in any in vivo models tested. However, a naturally occurring analog of staurosporine, UCN-01 showed anti-tumor activity in vivo. UCN-01 was also isolated from the same culture broth *Streptomyces* sp. No. 126 that produced staurosporine. UCN-01 differs structurally from staurosporine with a hydoxyl group at the C-7 carbon. Adding this hydroxyl group causes UCN-01 to be specific for PKC inhibition. UCN-01 also shows apoptotic effects in vitro on the cell lines HeLa S3 and MCF-7 similar to what was observed with staurosporine.

Similar to staurosporine, UCN-01 can also inhibit cell proliferation by arresting cells in different phases of the cell cycle. The growth inhibitory affect of UCN-01 is often used to modulate the affects of radiation and chemotherapy. When cells are treated with radiation, which arrests cells in the G2 phase of the cell cycle, in the presence of UCN-01, the cells are no longer able to accumulate in G_2 leading to early mitosis and subsequent apoptosis. UCN-01 also abrogates the S phase of the cell cycle. For example, in p53 mutant cells, treatment with chemotherapeutic drugs such as camptothecin results in S and G2 arrest of

the cells. When cells are subsequently treated with UCN-01, it leads to an abrogation of the camptothecin-mediated arrest resulting in mitotic catastrophe and cell death.

Anti-tumor Activity

Since UCN-01 shows anti-tumor activity in vivo with much less cytotoxicity than staurosporine, UCN-01 was used for further pre-clinical studies. Using a xenograft model system with several tumor cell lines (breast and renal carcinoma, and leukemia cells) and with either intravenous or intraperitoneal injections, UCN-01 was shown to have an anti-tumor effect.

The first case of using UCN-01 to treat patients was in 1996 with a 72 h infusion in the United States (Bethesda, MD) and in Japan as a 3 h infusion. These initial studies showed an unusual pharmacological effect that was not observed in the animal models. The concentrations of UCN-01 in the human plasma were considered abnormally high compared to animal models. Furthermore, the half-life in humans was over 500 h, which was 100 times longer than in the animal models. Eventually it was discovered that in humans, UCN-01 binds strongly to the plasma α_1-acidic glycoprotein resulting in its lack of plasma clearance. Although the initial schedule called for 72-h continuous infusion every 2 weeks, based on the low clearance and prolonged half-life of UCN-01, this was modified to 36-h continuous infusion every 4 weeks. This study has lead to several follow-up studies in which UCN-01 is given as 1–3 h infusions every 4 weeks along with several combinatorial trials. For example, a phase I/II trial of gemcitabine followed by UCN-01 for a 72-h infusion was recently initiated at the National Cancer Institute. Among some of the other agents that are being examined in combination with UCN-01 are cisplatin and 5-fluorouracil. Other ongoing studies with UCN-01 are to use this agent to protect normal cells against the toxic affects of chemotherapy. Since the concentration of UCN-01 required to reversibly arrest normal cells in the G1 phase of the cell cycle is much lower than those required to mediate a toxic affect in tumor cells, this rationale provides a promising alternative to chemotherapy alone. These pre-clinical and ongoing clinical studies provide a novel and potent target that can be used to biologically modify the mechanisms of deregulation of cancer cells and as such provide a novel class of anti-cancer agents.

Stefins

Janko Kos
Faculty to Pharmacy, University of Ljubljana, Ljubljana, Slovenia

Synonyms

Type I cystatins; Cystatins A, B

Definition

►Stefins are members of the ►cystatin superfamily of cysteine proteinase inhibitors localized in the cytosol and thought to protect cytoskeletal proteins from degradation by ►cysteine proteases released from lysosomes.

Characteristics

Type-1 or Family-1 of the cystatin superfamily of cysteine protease inhibitors includes human stefins A and B and their homologues in other species such as ►cystatins α and β in rat, bovine thymus stefin C, porcine thymus stefins D1 and D2, mouse stefins A (1–4) and others (see MEROPS subfamily I25A). The genes for human stefins A and B have been mapped to chromosomes 3q21 and 21q22.3, respectively. The lack of a signal sequence and disulfide bonds makes stefins distinct from other members of the cystatin superfamily. Stefins are single chain proteins consisting of 98–103 amino acid residues, with a molecular mass of 11–12 kDa. Human stefin A is an acidic protein with pI values between 4.5 and 5.0, whereas stefin B is neutral, having pI values in the range of 5.9–6.5. Their tissue and cellular distribution are different, stefin A being localized mainly to epithelial and lymphoid tissue, while stefin B is evenly distributed in various cells and tissues.

Like other members of the cystatin superfamily, stefins are reversible and competitive inhibitors of cysteine proteases. The structural basis of the inhibition

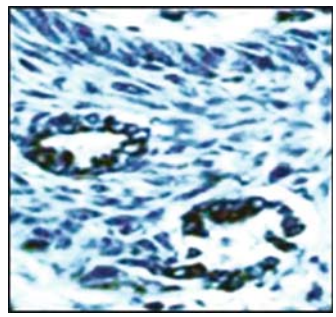
has been elucidated from the X-ray crystal structure of ►papain-stefin B complex and NMR structure of stefin A. Stefins are potent inhibitors of ►cathepsins L and S with Ki values in the picomolar range, whereas cathepsin B inhibition is weaker (Ki 10^{-8} M for stefin A and 10^{-7} M for stefin B).

Physiological and Pathological Roles

Besides protection of cytosolyc and cytoskeleton proteins from degradation by cysteine proteases accidentally released from lysosomes, several other functions have been suggested for stefins. For example, stefin A may be important in the control of normal ►keratynocyte proliferation and differentiation. Also, it has been proposed that it plays a role in ►apoptosis, since apoptotic bodies consistently stain for inhibitor, which also correlates with p53 activation. Stefin A should also protect epithelial and lymphoid tissues from cysteine proteases produced by pathogens invading the body. Increased levels of stefin A were found in inflammatory skin samples, psoriatic epidermis, and in inflamed gingival tissue homogenates from patients with periodontal inflammatory diseases. Decreased levels of stefin B mRNA were detected in patients with ►progressive myoclonus epilepsy (PME) and associated with excessive activity of cathepsin B. Besides protease inactivation, stefin B could bind other proteins in a multiprotein complex that has a specific cerebellar function, which might contribute to the disease in patients with progressive myoclonus epilepsy. Recent genetic studies have also identified mouse stefin A to be involved in a control of ►ovarian follicular growth and maturation.

Stefins in Cancer

Cysteine proteases, the targets for stefin's inhibitory activity, have been implicated in multiple steps of tumor ►progression, including processes of cell transformation and differentiation, ►motility, ►adhesion, ►invasion, ►angiogenesis, and ►metastasis. In most tumor types their levels of expression, protein concentrations and enzymatic activities, in particular of cathepsins B and L, have been demonstrated to be significantly higher than in their control tissue counterparts. The increased levels of cathepsins are usually not accompanied by an equal increase of the cystatins, which was suggested as the main cause of harmful cysteine, cathepsins-dependent proteolytic activity in tumor tissue. However, the balance is selectively altered for type II cystatins, which are in most cases downregulated in tumors, whereas type I cystatins, i.e. stefins A and B, have been found up-regulated in a majority of cases when compared to control tissue counterparts. Higher levels of stefins A and B in tumors have been determined in lung, ►breast, head and neck and ►prostate cancer, as well as in murine lymphosarcomas, ►hepatomas and Lewis lung carcinomas (Fig. 1). These



Stefins. Figure 1 Stefin A immunostaining in lung adenocarcinoma (*Kindly provided by B. Werle*).

higher levels, up to a certain level, may counter-balance the excessive activity of cysteine cathepsins, associated with matrix remodeling, resulting in the progression of the disease. On the other hand, high cytosolic levels of stefins may be relevant for regulation of apoptosis, when initiated via lysosomal cell death pathway inhibiting cathepsin B, which was proposed as a dominant execution protease in the lysosomal apoptotic pathways, induced in a variety of tumor cells by tumor necrosis factor alpha (►TNF-α). In some studies lower levels of stefins in tumors have been reported. For example, stefin A immunoreactivity was lower in lymphomas and in tumors of squamous epithelial cell origin, as well as in prostate and ►brain tumors. Lower mRNA levels of stefin A or B have been reported in breast and ►esophagus tumors as compared to adjacent control tissues.

Although stefins are cytosolic proteins, they have also been detected in body fluids of cancer patients. Stefin A and stefin B have been detected in ascitic fluid from patients with ovarian carcinoma and in bronhoalveolar fluid of lung cancer patients. Increased serum levels of stefin A in patients with ►hepatocellular carcinoma and liver cirrhosis have been correlated with tumor size and with a number of neoplastic lesions. Stefin A, but not stefin B, levels were moderately increased also in patients with ►colorectal or lung cancer.

Increased levels of cysteine protease activity, not being balanced by a corresponding increase of cysteine protease inhibitors, are associated with the progression of malignant disease and patients' poor prognosis. Enhanced expression of stefins is expected to diminish the tumor-associated proteolytic activity and indeed, there is evidence of a suppressive role of stefins in various cancer types. Moreover, higher levels of stefin A and stefin B in tumor tissues have been shown to correlate with a favorable prognosis for cancer patients. A significant prognostic value of stefin A and stefin B was determined in patients with lung and head and neck cancer. In the latter, high stefin A tumor levels were found as a strong factor for prediction of prognosis also in multivariant analysis when correlated with

established clinical parameters. In prostate tumors higher cathepsin B/stefin A ratios were associated with a more aggressive behavior of prostate cancer.

Animal models with excluded expression of particular cystatin did not support a suppressive function for cysteine protease inhibitors in cancer. In stefin B as well as cystatin C ►knock-out mouse, a significantly lower metastatic spread was detected than in wild-type animals. Similarly, higher levels of stefin A and stefin B in body fluids have been associated with a poor prognosis in cancer patients. Alterations in secretion may result in higher extracellular and lower intracellular levels of stefins and, therefore, a reverse correlation with patient survival is to be expected. However, cysteine proteases, and consequently their inhibitors, are involved in various physiological processes, including those which may act in a manner opposing tumor progression, such as apoptosis, activation of T-cell immune response, cell ►migration, seeding, and drug resistance processes. Thus, besides their concentration, cell and tissue localization of stefins, and a number of extrinsic and intrinsic factors, could make a critical switch between harmless and harmful.

Stem Cell

Definition

Is a founder cell that exists in all multicellular organisms and shows self-renewal ability through mitotic cell division and can differentiate into a wide range of lineage-committed cells. Upon division, each new cell has the potential to either remain as a stem cell or become another type of cell with a more specialized function. There are three kinds of stem cells: embryonic stem cells, germinal stem cells, and adults stem cells that have different developmental potentials: totipotent, pluripotent, multipotent, or unipotent.

►Adult Stem Cells
►Stem Cell Markers
►Stem Cells

Stem Cell Factor

Definition

SCF; Is a glycoprotein that acts as both a positive and negative regulator of hematopoiesis. The cell surface receptor for SCF is KIT, a cancer stem cell marker. SCF is also involved in mast cell development, gametogenesis, and melanogenesis.

►Stem Cell Markers
►Kit/Stem Cell Factor Receptor in Oncogenesis
►Mastocytosis

Stem-Cell Harvest and Purging

Definition

Following stimulation with growth factors, chemotherapy or both, CD34+ stem cells can be mobilized to the blood and harvested via a central vein catheter. In case of malignant bone marrow involvement, tumor cells may be mobilized as well. By in vitro ►purging the stem cells may be selected (e.g., CD34+ cell selection) or the tumor-cells depleted. By in vivo purging of the patient with monoclonal antibodies (e.g., CD20 antibodies in B-cell lymophomas), the amount of tumor cells in the stem cell product may be reduced to undetectable (by ►PCR) levels.

►Mantle Cell Lymphoma

Stem Cell Hypothesis in Cancer

Definition

Tumors arise from cells termed cancer ►stem cells that have properties of ►adult stem cells, particularly the

abilities to self-renew and differentiate into multiple cell types, and that these cells persist in tumors as a distinct population that likely causes disease relapse and metastasis. They are the only cells capable of, by themselves, giving rise to new tumors.

►Pancreatic Cancer Stem Cells

Stem Cell Markers

Gail M. Seigel
Department of Ophthalmology, University at Buffalo, Buffalo, NY, USA

Definition

Stem cell markers are molecules used for the identification of unspecialized, undifferentiated cells, and in the case of malignancy, presumptive ►cancer stem cells.

Characteristics

There is increasing evidence that subpopulations of neoplastic cells demonstrate heterogeneity with respect to proliferation, differentiation, and expression of cellular proteins characteristic of ►stem cells. Subpopulations of cells that express stem cell markers that can also be shown to contribute to tumor progression and resistance to chemotherapy are termed cancer stem cells. Cancer stem cells are found in very small subpopulations within tumors, in the range of 0.1-1% of the total cell number. Microscopically, cancer stem cells outwardly appear the same as any other tumor cell. Therefore, in order to identify these rare subpopulations, a number of stem cell markers have been identified and developed as a means of distinguishing stem-like cells from other cells within a cancer population. Unique expression patterns of stem cell markers provide a means for scientists to identify as well as isolate stem-like cells from heterogeneous tumor populations.

Stem cell markers are generally cell surface proteins with the ability to selectively bind to, or activate other signaling molecules. In some cases, stem cell markers are transcription factors that maintain stem cell properties of ►pluripotency and/or ►self-renewal. Stem cell markers are often designated by short-hand terms, based on their cellular function and/or the molecules to which they bind. As yet, there is no unanimously agreed-upon universal stem cell marker. Therefore, multiple markers are used in combination for verification of stem cell identity.

Stem cell markers have been assigned to embryonic, hematopoietic, and neural categories based upon the original location(s) in which they were discovered. These categories work fairly well for embryonic and adult stem cells; distinctions blur in cancer, where, for example, embryonic and/or hematopoietic stem cell markers can be found in tumors of neural origin. Some examples of commonly used stem cell markers with applications in cancer biology include:

ABCG2 (72,300 kDa) (also known as ATP-binding cassette superfamily G member 2, BCRP, BCRP1, BMDP, MXR, MXR1) defines a ►Hoechst-33342-negative phenotype of ►side population (SP) cells. ABCG2 is expressed in cancers of the blood, ►breast, ►prostate, ►lung, germ cell, and retina. ABCG2 may be a potential marker for positive selection of cancer stem cells from a wide variety of tissues.

Bmi-1 (44–46 kDa, murine viral ►oncogene homolog) is a ►polycomb group gene. In addition to its role in development, Bmi is also a tumor-associated antigen, expressed in cancers of the blood, ►brain, lung, oral mucosa and gastrointestinal tract.

CD44 (80–95 kDa) is a ►cluster of differentiation (CD) molecule that functions as a receptor for hyaluronic acid. It is involved in cell/cell and cell/matrix interactions. Overexpression of CD44 has been associated with the development and spread of a range of different types of malignancies. CD44 is found in cancers of the blood, breast, prostate, germ cell and lung.

CD133 (120 kDa), also a cluster of differentiation molecule, was first identified as a hematopoietic stem cell marker. It is a glycosylated protein which recognizes a CD34 + subset of human hematopoietic stem cells. CD133 expression has been demonstrated in human leukemias, prostate cancer, germ cell tumors as well as in ►brain tumors.

CD164 (80–90 kDa), also known as ►sialomucin, is a cluster of differentiation molecule expressed on CD34 + hematopoietic progenitor cells. CD164 has been detected in prostate cancer.

►c-kit (145 kDa, CD117) is the membrane receptor for ►stem cell factor (SCF). It is an oncogene expressed in cancers of the blood, prostate, germ cell, lung and gastrointestinal tract.

Musashi-1, 2 (39 kDa) are RNA binding proteins associated with ►asymmetric cell division (asymmetric cytokinesis) in neural stem cells. Musashi-1 has been detected in cancers of the breast, brain and retina, while Musashi-2 is rearranged in chronic myeloid leukemia.

Nanog (34 kDa) is a human embryonic stem cell marker and transcription factor also found in osteosarcomas, breast cancers, ►retinoblastomas and germ cell tumors.

Nestin (177kDa) is categorized as a neural stem cell marker. It is a class VI intermediate filament protein

primarily expressed in stem cells of the central nervous system, including brain tumors.

Oct-4 (also termed Oct-3 or Oct3/4) is an embryonic stem cell marker. It is a ►POU transcription factor that confers self-renewal and pluripotency to embryonic stem cells. Oct 4 is expressed in both embryonic stem and germ cells, as well as in germ cell neoplasias, ►bone tumors and retinoblastoma.

Sca-1 (18 kDa) is a mouse-specific stem cell marker (stem cell antigen 1, Ly-6A/E), and a member of the ►Ly6 antigen family. Sca-1 is expressed in cancers of the blood, prostate, lung, breast, and retina.

Sox2 (34 kDa) is a transcription factor important in maintaining self-renewal properties of neural progenitor cells. Sox2 is an acronym for "SRY-related HMG-box gene 2." SRY refers to "sex-determining region Y," as the first Sox gene was found to be important in sex determination of developing gametes. HMG refers to ►"high mobility group (HMG group)," which is the DNA binding domain of Sox2. Sox2 has been localized to cancers of the brain, lung and gastrointestinal tract.

A summary of stem cell markers with applications in cancer biology is shown in Table 1. Note that the field is changing rapidly, as new markers and tissue locations are added constantly. Therefore, this is not an exhaustive list, but rather a representative list of the most common stem cell markers to date that are applicable to cancer.

Methods Used to Detect Stem Cell Markers in Cancer Biology

Antibodies directed against stem cell markers can be used to identify and isolate stem cells. Fluorescently-labeled secondary antibodies directed against primary antibodies bound to stem cell proteins identify specific populations of stem-like cells.

Fluorescence-activated cell sorting can isolate rare stem cells from a heterogeneous tumor population. In this technique, a suspension of labeled cells passes by a laser, one at a time, and then through an electric field. The fluorescent cells become negatively charged and can be directed, based on charge, to a separate collecting tube for further analysis. In this way, a very small population of cells expressing stem cell markers can be isolated from a heterogeneous tumor population.

Magnetic beads linked to secondary antibodies also allow for the isolation of rare cell populations based on expression of stem cell markers on the cell surface. Magnetically-beaded cells expressing stem cell markers can be separated based on magnetic attraction while the non-expressing cells are washed away. Once the beaded cells are isolated, the cells of interest can be freed from the magnetic beads for further analysis.

Fluorescent antibodies can also be used to visually assess cells as they exist within the tissue of origin or within mixed cell cultures. Fluorescently-labeled stem-like cells will emit light at specific wavelengths that can be visualized by fluorescence microscopy.

Polymerase chain reaction (PCR) can be used to detect the presence of genes coding for stem cell markers that are expressed in putative stem cells. This method is not as useful for isolating stem cells, but can be used to screen populations for stem cell markers and test isolated cell populations for expression of stem cell genes.

Clinical Applications

The hypothesis that a subpopulation of cancer stem cells drives tumorigenesis and chemo-resistance may

lead to new approaches for cancer prognosis and therapy. Expression patterns of stem cell markers may indicate the differentiated or undifferentiated state of a tumor, and may correlate with a favorable or an unfavorable prognosis in the clinical setting. Once cancer stem cells are identified and characterized using stem cell markers, they can be targeted, using specific stem cell markers for immunologically-based therapies. New stem cell markers will continue to be discovered and are certain to play an important role in the rapidly emerging field of cancer stem cell biology.

Stem Cell Niche

Definition

The local ►microenvironment that houses the stem cell population in a tissue or organ. Made up of cells, blood vessels and extracellular matrix, ►stem cells adhere to the niche through ►cell adhesion molecules and receive signals e.g. Wnt glycoproteins, that regulate their behavior.

►Stem Cell Plasticity

Stem Cell Plasticity

Malcolm R. Alison
Centre for Diabetes and Metabolic Medicine, Queen Barts and the London School of Medicine and Dentistry, Institute of Cell and Molecular Science, London E1 2AT, UK

Synonyms

Transdifferentiation; Metaplasia

Definition

Stem cell plasticity refers to the ability of some ►stem cells to give rise to cell types, formerly considered outside their normal repertoire of differentiation for the location where they are found. Included under this umbrella title is often the process of "transdifferentiation" – the conversion of one differentiated cell type into another, and ►metaplasia – the conversion of one tissue type into another. From the point of view of this essay, some metaplasias have a clinical significance because they predispose individuals to the development of cancer. Circulating bone marrow-derived cells (BMDCs) that usually generate all blood cell lineages, can switch cell lineage commitment and contribute to the regeneration of several damaged non-hematopoietic tissues, and some carcinomas may even have their origins in BMDCs. The bone marrow origin of some tumor stromal cells and vasculature is now widely acknowledged, but since this pathway was not formerly recognized, it too can be considered a further example of plasticity, which, importantly, has significant biological and therapeutic implications for cancer.

Characteristics

Most adult tissues have *multipotential* stem cells (►Adult stem cells), cells capable of producing a limited range of differentiated cell lineages appropriate to their location, *e.g.* small intestinal stem cells can produce all four indigenous lineages (lysozyme-secreting Paneth cells, mucin-producing goblet cells, absorptive columnar cells and enteroendocrine cells). However, tissue-based stem cells may be more versatile than previously thought, particularly those of bone marrow, and these cells may generate unexpected cell types when engrafted in a damaged non-hematopoietic tissue or organ. This so-called plasticity is being exploited in the field of regenerative medicine where it is hoped to produce new cell therapies for currently intractable diseases such as diabetes and congestive heart failure. Other sources of malleable stem cells include ►umbilical cord blood, ►mesenchymal stem cells (MSCs) from many sources including liposuction waste (fat), skin fibroblasts and spermatogonia.

Stem cell plasticity has been questioned by some investigators who have been unable to reproduce some of the claims: "blood to brain," "brain to blood," "bone marrow to oocytes," "bone marrow to cardiomyocytes." Other instances of plasticity have now been attributed to cell fusion between bone marrow cells (or their macrophage descendants) and cells of the recipient organ. Cell fusion may have implications for tumorigenesis. Such a process could endow differentiated cells with stem cell properties such as infinite self-renewal, while at the same time result in genetic instability with obvious tumorigenic potential.

From the viewpoint of cancer, we should note that while a scattering of engrafted cells of hematopoietic origin (but with a phenotype appropriate to their new location) is often observed in damaged parenchymal organs, these cells appear to have engrafted not as stem cells but either as ►transit amplifying cells or ►terminally differentiated cells, thus their long-term significance for cancer development is highly questionable. If BMDCs did engraft as stem cells in a new location, it is not inconceivable that they could be the founder cells of tumors at these sites. Indeed in a murine model of gastric cancer, BMDCs repopulate the gastric mucosa and over time contribute to metaplasia, dysplasia and cancer in response to chronic infection with *Helicobacterfelis* (►Gastric cancer, ►Helicobacter pylori). BM-derived gastric glands are seen after 20 weeks of chronic infection, leading to a final replacement of 90% of the gastric mucosa with BMDCs after 1 year. Upon progression to epithelial dysplasia and gastric adenocarcinoma, the majority of the dysplastic glands were of BM-origin, most likely from MSCs. Chronic inflammation led to atrophic gastritis, probably ablating the ►stem cell niche of numerous indigenous gastric glands, and the vacant niches were then occupied by BMDCs that subsequently behaved as gastric gland stem cells (Fig. 1) (►Stem cells and cancer).

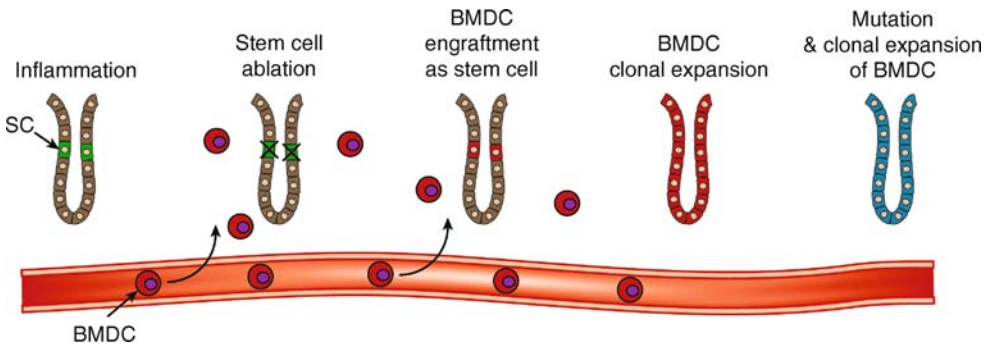
An origin of carcinoma from BMDCs has also been suggested for one case of skin basal cell carcinoma arising in a female recipient of a male kidney transplant. In this case, most of the cytokeratin-positive tumor cells were male, and since BCC rarely if ever metastasizes (so no occult metastasis in the transplanted organ), it is likely that donor BMCs in the graft had migrated to the skin, either fusing with or differentiating into keratinocytes, before undergoing malignant transformation. On a cautionary note, it has been observed that in some murine and human cancers there are occasions when BMDCs incorporate into the tumors, phenotypically mimicking the cancer cells, but of course not actually initiating them.

Metaplasia

Metaplasias are major switches in tissue phenotype, invariably they occur in tissues subjected to chronic trauma, and are likely to represent epigenetic reprogramming of tissue stem cells – *in-situ* stem cell plasticity. Cancers can arise in areas of metaplasia, and we often have a metaplasia – dysplasia – carcinoma sequence. For example, the esophagus is normally lined by squamous epithelia, but due to acid reflux it can become lined by glandular tissue (Barrett's esophagus) and adenocarcinomas usually arise in areas of dysplastic Barrett's esophagus. In the airways of the lung, chronic irritation by tobacco smoke can lead to a switch from columnar to squamous epithelia, and squamous carcinoma of the lung usually arises from patches of squamous epithelia. Metaplasias may well be caused by misexpression of homeotic genes, a good example being intestinal metaplasia in the stomach caused by overexpression of the intestine-specifying *CDX* genes; here too, metaplasia predisposes to gastric cancer.

The Bone Marrow and Tumor Stroma: Clinical Relevance

BMDCs may indirectly influence tumor behavior by contributing to the ►desmoplastic response and to the tumor vasculature, lineages not formerly considered to have arisen from bone marrow (►Desmoplasia, ►angiogenesis). ►Myofibroblasts are a distinguishing feature of pathological fibrosis, normally regarded as having originated by activation of local organ



Stem Cell Plasticity. Figure 1 Stem cell plasticity could provide an alternative pathway for cancer development as seen in experimental gastric carcinogenesis. Continued inflammation and tissue damage leads to eradication of the indigenous stem cell compartment and its replacement by bone marrow derived cells (BMDCs), whose progeny subsequently repopulate the whole gland. Mutation in a BMDC engrafted as a stem cell can then lead to a dysplastic gland and subsequent gastric cancer. Key: indigenous normal epithelial cells are brown, indigenous stem cells are green, BMDCs are red and mutated BMDCs are blue.

fibroblasts, but there is clear evidence that many are generated from bone marrow cells. These BMDCs can contribute to organ fibrosis, including the fibrosis surrounding many cancers – the desmoplastic response. Thus, BMDCs may be useful for the local delivery of anticancer agents such as interferon.

►Endothelial progenitor cells (EPCs) are mobilized endogenously in response to tissue ischaemia or exogenously by cytokine therapy to augment neovascularization. The development of a vascular supply to a tumor is a prerequisite for tumor survival – allowing for the provision of oxygen and nutrients as well as the disposal of waste products. New vessel formation is also required for tumor metastasis. Previously, tumor vasculature was thought to develop exclusively *via* endothelial cell migration and proliferation – *angiogenesis*. However, the creation of new blood vessels by EPCs is known as *vasculogenesis*, and such a process is a significant event in tumorigenesis. This opens the possibility of using bone marrow cells as a vehicle for transporting antiangiogenesis molecules directly to the tumor vascular bed, in effect using BMDCs as Trojan horses.

Stem Cell Telomeres

Eiso Hiyama
Natural Science Center for Basic Research and Development, Department of Pediatric Surgery, Hiroshima University Hospital, Hiroshima University, Hiroshima, Japan

Synonyms

Telomeric repeats of stem cells; Guanine-rich tandem DNA repeats of chromosomal ends

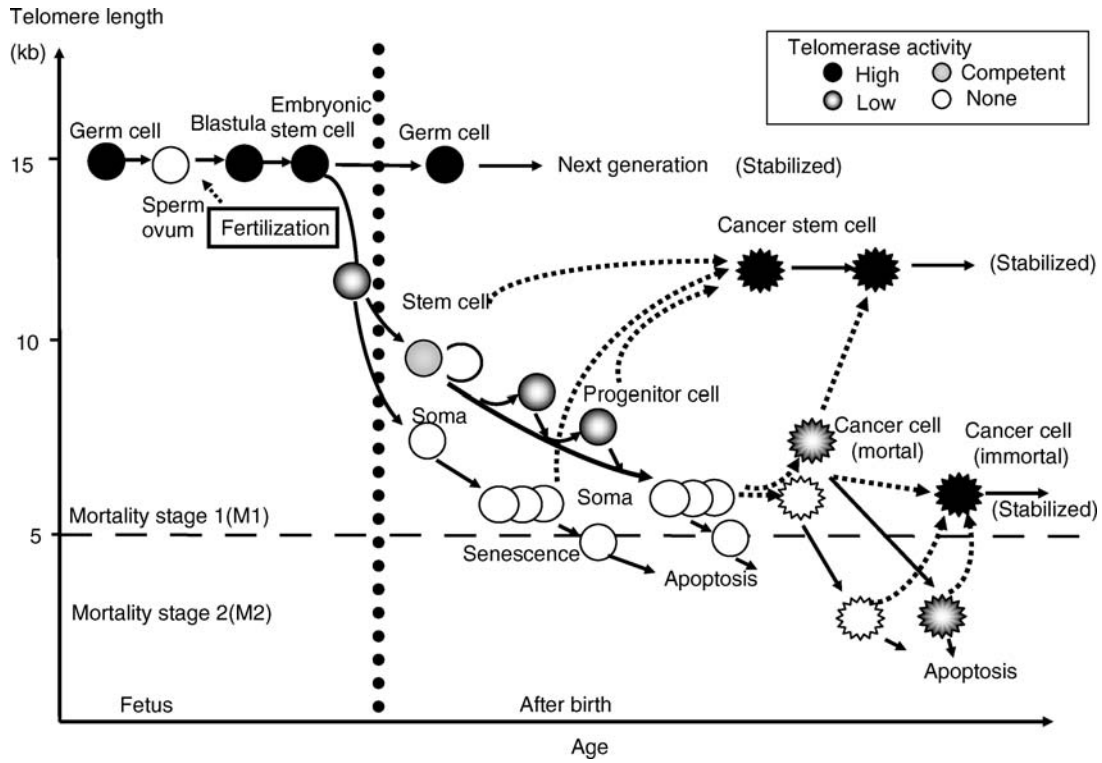
Definition

►Telomeres are guanine-rich tandem DNA repeats that cap the ends of eukaryotic chromosomes. Their primary function is to prevent chromosomal degradation, fusions and instability. During cell division, telomeres shorten as a result of the incomplete replication of linear chromosomes. The slow rate of cell turnover in stem cell compartments means a longer period of ►telomere length stability in stem cells versus somatic cells. Nevertheless, stem cell telomeres do gradually shorten with age.

Characteristics

Human ►telomeres consist of tandem repetitive arrays of the hexameric sequence TTAGGG, with overall telomere sizes ranging from ~15 kb at birth down to <5 kb in ►senescence cells or in some chronic disease states. The end of telomere forms a 3′ overhang of the G-rich strand, which is generate by the postreplicative processing of the C-rich strand, folds back into the duplex telomeric DNA to form a protective t-loop. During the process of cell division, telomeres shorten as a result of the incomplete replication of linear chromosomes, the so-called "►end-replication problem." This progressive telomere shortening is one of the molecular mechanisms underlying aging, since critically short telomeres trigger chromosome senescence and ►apoptosis. A critical length of telomere repeats is required to ensure proper telomere function and avoid activation of the DNA damage pathways that result in replicative senescence or cell death.

The ends of telomeres are protected and regulated by telomere-binding proteins and form a special lariat-like structure called the ►t-loop that prevents degradation by exonucleases or processing as DNA damage signal caused by exposure of DNA ends. A human telomere needs >5 kb of its length to form the t-loop. When the length shortens to <5 kb, cells fall into senescence (►mortality stage 1 (M1)). In immortal cells, telomere length is maintained by ►telomerase, a reverse transcriptase, or another mechanism such as ►alternative lengthening of telomere (ALT). In most human somatic cells, except for stem cells and lymphocytes, telomerase activity is diminished after birth, such that telomere length shortens with each cell division (Fig. 1). Most malignant tumors must have a mechanism for bypassing M1, a cell-cycle checkpoint. The overcome of this checkpoint leads to an extended lifespan but continued telomere losses, eventually producing a crisis or the ►mortality stage 2 (M2) of replicative senescence caused by ►chromosomal instability, unless some mechanisms that escape this stage are activated. To escape M2, the telomeres in immortalized cancer cells must be stabilized by reactivation or up-regulation of telomerase activity.



Stem Cell Telomeres. Figure 1 Telomere dynamics in human stem cells.

Germ cells and ►embryonic stem cells maintain telomere length between each generation with high levels of telomerase activity during rapid proliferation. In the developmental stage, telomerase activity gradually decreases and diminishes in most somatic cells after birth and falls in senescence (M1 stage). Thus, the telomere length of somatic cells is one of the limiting factors of cell division. In ►adult tissue stem cells, the level of telomerase activity is low or undetectable. Activity is up-regulated in committed progenitor cells which have high reproducible activity in each tissue, but it is insufficient to maintain telomere length. On the other hand, most cancer cells bypass M1, which leads to an extended lifespan but continued telomere losses. Eventually, the consequence is crisis or entry into the M2 stage of replicative senescence. ►Cancer stem like cells and cancer cells are immortalized with stabilized telomeres by escaping M2.

Stem cells are capable of karyotypically stable, prolonged self-renewal. They are also characterized by their potential to generate a very large number of committed progenitors and descendants during a small number of self-renewal divisions. Since stem cells have elongated proliferative capacity, they must have a mechanism that maintains telomere length through many cell divisions. In human stem cells, telomere length is maintained for many cell divisions and telomere length remains in longer than somatic cells by telomerase or ALT. The former mechanism is at work in ►hematopoietic stem cells (HSCs) while the latter functions in ►mesenchymal stem cells (MHCs). The mechanism of telomere maintenance in human stem cells is different in each type of stem cell, but telomeres are not completely maintained in human stem cells except for embryonic stem cells. Thus, human ►adult stem cells have an intermediate existence between somatic cells and immortal cells, showing aging-related changes concomitant with telomere shortening. The temporary activation or low expression of telomerase in adult stem cells may partially account fot the resistance to telomere erosion of stem cells in general bu the telomere lengths of these cells were gradually eroded, consequently yielding the ageing of stem cells. The gradual loss of telomeres is interpreted as a regulator for cell life span and is considered a cancer prevention mechanism, because prolonged replications and longevity would subject cells to the accumulation of mutations leading to transformation of stem cells to cancerous cells. If these stem cells are immortalized, they are no longer human stem cells but may become "cancer stem like cells." Recently, the important role of telomeres in human illness has been highlighted by studies of the rare genetic disorder "►dyskeratosis congenita (DKC)." This essay shows the role of

telomeres and telomerase in the function and regulation of the stem cell compartment, and their importance in ►stem cell failure diseases.

In the hematopoietic system, low telomerase is detectable in stem cells with self-renewal potential and their early descendants, but age-dependent telomere loss is observed in both lymphocytes and neutrophils. In bone-marrow transplant patients, the length of telomeres in blood leukocytes was shorter than that in germline cells from the same donor. A subset of stem cells isolated from adult bone marrow showed shorter telomeres than in fetal cord blood, suggesting that a progressive decline in telomere length with age occurs in hematopoietic stem cells. Thus, transplanted HSCs derived from aged donors may reach their proliferative limit during the lifetime of the recipient, resulting in graft failure after HSC transplant. The regulation of telomere length and telomerase activity is a complex and dynamic process that is tightly linked to cell cycle regulation. Therefore, individual stem cell turnover at any given point would be minimal and the up-regulation of telomerase activity in stem cells could be minimal. It is, however, up-regulated in lineage-committed progenitor cells that undergo rapid expansion, such as committed hematopoietic progenitor cells, and activated lymphocytes. In more mature cells, repression of telomerase activity is independent of proliferation. These findings suggest that one important function of telomerase in stem cells is to reduce the rate of telomere loss during cell division, preventing premature critical shortening of telomeres and loss of telomere function. Such a role of telomerase would be critically important in the case of increased proliferative demand, such as infection and regeneration.

In T and B lymphocytes, telomerase activity appears to be up-regulated in response to mitogenically activated proliferation and progressively down-regulated in more mature subsets. Telomerase is also essential for the lifelong maintenance of telomeres in normal memory lymphocytes that have a high rate of turnover in clonal expansion. Loss of the ability to up-regulate telomerase in an antigen-specific highly differentiated memory cell leads to replicative senescence, resulting in a reduced response to reinfection. Low levels of telomerase activity have been found in some non-hematopoietic stem cells, including neuronal, skin keratinocytes, intestinal crypt, mammary epithelial, pancreas, adrenal cortex, and kidney stem cells (Fig. 1). However, some controversial data remain in telomerase activity and TERT (telomerase reverse transcriptase) expression in non-hematopoietic stem cells. The difference of the levels of telomerase activity in the their components of various organs is likely derived from the difference of their cellular turnover among organs. It has been shown that hepatocytes enter senescence due to telomere shortening in the cirrhotic stage of a wide variety of chronic human liver diseases. The replicative senescence in hepatocytes is probably in part the result of continued proliferation during 20–30 years of chronic liver disease. Chronic inflammation, the presence of growth factors, and DNA-damaging agents such as reactive oxygen and nitrogen species may also play a role in this process.

Recently, the critical importance of telomerase activity in some human stem cells has been highlighted by the discovery of the etiology of dyskeratosis congenital (DKC), stem cell failure disease. In this disease, dysfunction of the telomerase RNA template gene causes the absence of telomerase activity and premature telomere shortening, resulting in bone marrow failure, intestinal disorder, or malignancy, at <50 years of age. Positional cloning associated the affected gene in many patients with X-linked DKC, termed *DKC1*, that encodes the dyskerin protein. The association of the telomerase complex with dyskerin suggested that the DKC phenotype may be the result of altered telomerase activity. The subsequent discovery of a 3′ deletion in the gene encoding TERC in a single large family with autosomal dominant DKC confirmed that telomerase deficiency is important to the etiology of DKC, and that telomerase is important for the maintenance of telomeric cellular lifespan and replicative potential in the stem cells of human organs.

In *Terc* knockout mice complete absence of telomerase activity is tolerated without abnormality in the first few generations; however, after the fourth generation, they begin to exhibit abnormalities similar to the phenotype of human DKC. Wild-type mice derived from late generations of *Terc* +/− mice with short telomeres and positive telomerase activity also displayed a similar phonotype of DKC. These findings indicated that short telomeres are the cause of stem cell failure. In addition, the observation that the *Cdkn1a* deletion improves the stem cell function and lifespan of mice with telomere dysfunction indicates that up-regulation of ►p21 (WAF1/CIP1/SDI1) in response to shortened telomeres impairs repopulation capacity of stem cells in age-related diseases and senescence.

Aplastic anemia is generally thought to be the result of HSC damage or loss resulting in the failure of bone marrow stem cells to produce sufficient quantities of all hematopoietic lineages. Telomere length was significantly shorter in the peripheral blood granulocytes and monocytes of patients with aplastic anemia or related disorders. An inverse correlation between age-adjusted telomere length and peripheral blood counts was also observed in aplastic anemia. As in DKC-associated aplastic anemia, a report found mutations in the *TERC* gene of patients with aplastic anemia. Data from congenital disorders, like DKC and aplastic anemia, suggest that disturbed telomere maintenance may play a

role in replicative exhaustion of the stem cell pool *in vivo*, again highlighting that the disturbance of stem cell telomere maintenance is an important etiology of "stem cell failure diseases," which are age-related diseases and premature senility syndromes.

Another mechanism of telomere maintenance in human stem cells is ALT. Mesenchymal stem cells (MSCs), which can be derived from bone marrow, can differentiate into multiple mesoderm-type cell lineages including fibroblasts, adipocytes, osteoblasts, chondrocytes, and endothelial cells, as well as into non-mesoderm-type lineages including neuronal-like cells. In human MSCs (hMSCs), replicative senescence reportedly sets in rather early. Without growth factors, cells cease dividing around 40–50 population doublings, telomere length gradually shortens by 30–120 bp/PD, and telomerase activity is undetectable. However, hMSCs maintain long telomeres without the up-regulation of telomerase activity for more than 100 population doublings in culture with basic FGF. Even using highly sensitive assays, no telomerase activity has been detected in hMSCs so far, and there may be a mechanism of telomere maintenance other than telomerase, such as ALT, in hMSCs. A recent observation of subtelomeric DNA hypomethylation facilitating telomere elongation in mammalian cells suggests that such epigenetic modification of chromatin may occur in hMSCs. However, in hMSCs, overexpression of telomerase indeed resulted in the elongation of telomeres, and *TERT*-transfected cells continued proliferating when untransfected control cells ceased growth. Furthermore, the potential of telomerase-overexpressing cells to form bone *in vivo* was greatly enhanced.

Embryonic stem (ES) cells, primitive stem cells, are likely immortal and are characterized by indefinite self-renewal and the potential to differentiate and contribute to the germ line. To maintain telomere length completely, ES cells display high levels of telomerase activity and hTERT expression, both of which are rapidly down-regulated during differentiation and are much reduced or absent in somatic cells, including stem cells, in self-renewal tissues (Fig. 1). The down-regulation of telomerase activity in differentiating ES cells is reportedly tightly correlated with histone deacetylation and DNA methylation of the *TERT* gene. High telomerase activity or the expression of TERT can, therefore, be regarded as a marker of undifferentiated ES cells.

In cloned animals originating from adult nuclei with shortened telomeres, telomere length in somatic cells has been found to be comparable with that in age-matched normal animals originating from a fertilized egg with long telomeres. This finding indicates that the enucleated oocyte has the ability to reset the telomere length of the nucleus derived from a donor adult somatic cell by the elongation of telomeres. How this mechanism is "reset" remains unknown in oocytes in cloned animals. Solving this mystery would be a technical breakthrough in developing cloned animals.

In summary, because of lifelong cell turnover of stem cells, telomere length in these cells is maintained longer than in somatic cells but gradually shortens due to aging. Insufficiency of telomere maintenance mechanisms in stem cells causes "stem cell failure diseases" such as DKC.

Stem Cells

Andrew G. Renehan[1], Christopher S. Potten[2]
[1]School of Cancer and Imaging School, University of Manchester, Department of Surgery Christie Hospital NHS Foundation Trust, Manchester, UK
[2]Epistem Ltd and School of Biological Sciences, University of Manchester, Manchester, UK

Definition

With the exception of hemopoietic stem cells, morphological criteria do not exist to identify stem cells in most tissues, and therefore, they are generally defined in terms of their properties. *Stemness* is not a single property but a number of properties that a cell has the capability to perform depending upon circumstances. In adult steady state renewing tissues, a stem cell is a relatively undifferentiated cell capable of proliferation and self-maintenance, producing a variety of cell lineages and capable of tissue regeneration following injury. Probably the most important property of stem cells is that of *self-renewal*.

Characteristics

Tissue Renewal and Models of Cellular Hierarchy

Many tissues in the adult undergo self-renewal, and accordingly, establish a life-long population of relatively pliable stem cells – the ▶adult stem cell. The different capacity of tissues to proliferate is the basis for conventionally categorizing tissues in adulthood into three categories:

- Those that are constantly renewing (e.g. bone marrow, intestine)
- Those that proliferate slowly but may renew their population in response to injury (e.g. lung, liver)
- Those that are more static (e.g. nerve, muscle)

Tissues are renewed by cell division and differentiation from a small number of stem cells, which have a high capacity for cell proliferation, but their actual rate of cell division is usually slow in the absence of injury or demand.

Between the stem cell and the mature cell of a particular tissue, a number of different stages of differentiation may be recognized, of which some retain a degree of stemness. Potten and Loeffler classify cells within a system into three types on the basis of their replicative potential as *actual stem cells, potential stem cells*, or *committed cells*. Actual stem cells are defined as undifferentiated cells capable of (i) proliferation; (ii) self-maintenance; (iii) production of large numbers of differentiated progeny; (iv) regeneration of the tissue after injury; and (v) flexibility in the use of their options. The potential stem cells are latent or reserve counterparts of actual stem cells, which may be reactivated to become functioning stem cells. The essential properties of *stemness* may be retained by some proliferating cells located distally in a lineage. This is referred to as the *compartment model of cellular hierarchy* and is illustrated for the intestinal crypt in Fig. 1.

Stem Cell Division

It has been proposed that a specific type of mitosis occurs in the functioning stem cells, which is responsible for the self-maintenance of this cell type. In general, normal stem cell mitosis will proceed by *asymmetrical division* to produce one daughter stem cell and one daughter that continues to divide, mature, and differentiate. However, mathematical modeling suggests that about five percent of the time, a stem cell may undergo *symmetrical division* to produce either two stem cells or two maturing cells. In the former case, a stem cell is lost from its niche by differentiation, displacement or apoptosis to ensure constancy in numbers. Promoting this form of division could be an approach to deplete mutated stem cells (probably the earliest step in carcinogenesis – see below) and may constitute an alternative strategy to inducing cell death to treat early neoplastic lesions.

Stem Cell Markers and Identification Problems

The development of a stem cell specific marker for each tissue of origin is the "holy grail" of stem cell research. Several markers and approaches have been suggested; examples are listed in Table 1, but to-date, (with the exception of hemopoeitic stem cells), there is no ideal stem cell marker for adult stem cells.

In attempting to measure stem cells, one may find oneself in a circular argument. In order to answer the question whether a cell is a stem cell, we have to alter its circumstances, and in doing so inevitably lose the original cell, and one may only see a limited spectrum of responses. This situation has a marked analogy with *Heisenberg's uncertainty principle* in quantum physics – which states that the very act of measuring the properties of a certain body inevitably alters the characteristics of that body.

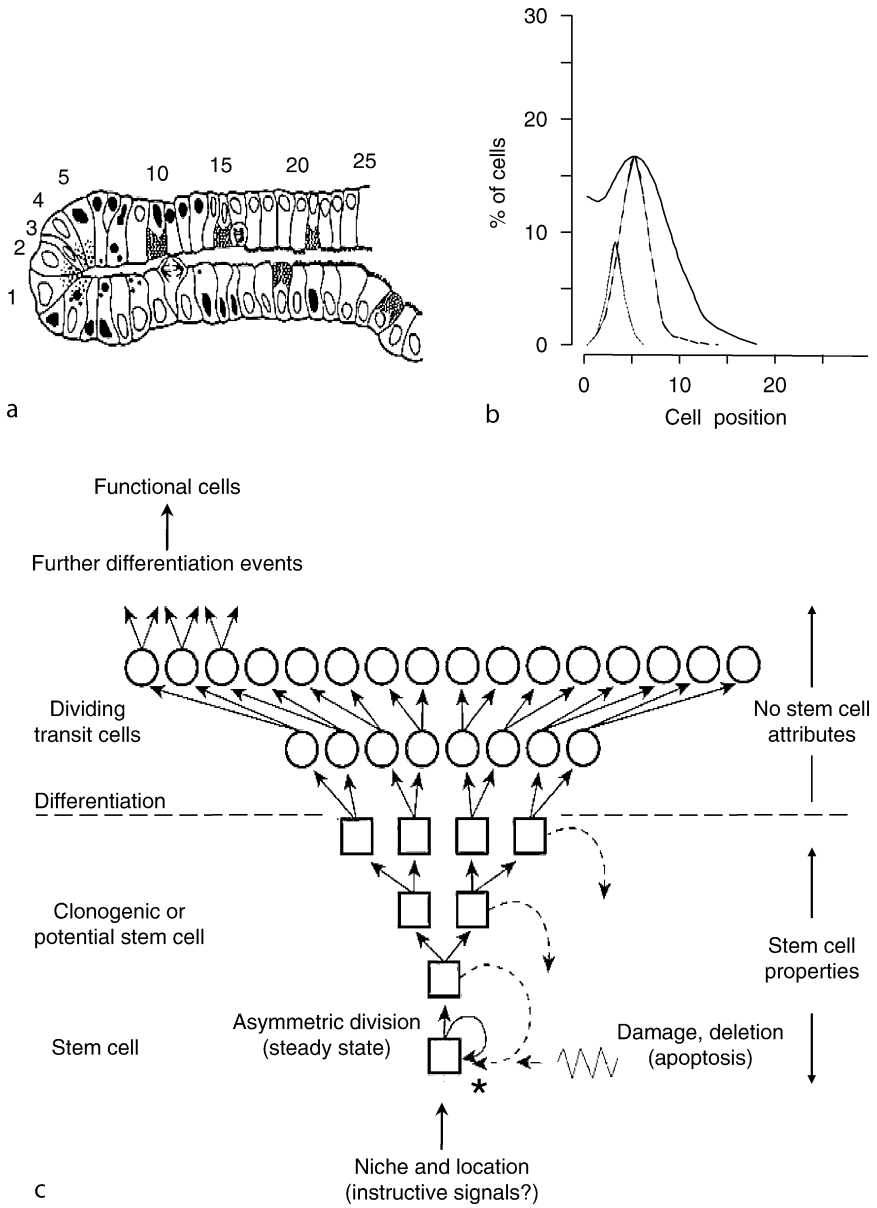
Stem Cell Location and the Niche

Adult stem cells are often localized to specific environments or *niches*. For a number of systems, these niches correspond to specific histologically identifiable locations, but these have not been determined for all tissue. Within each niche, the stem cells are influenced by neighboring cells and extra-cellular matrix. For each tissue, the stem cells in specific niches are *pluripotent* for the cell population of that tissue. Thus, for example, five different cell types (Paneth cell, goblet cell, enteroendocrine cell, M cell, enterocyte) are derived from the intestinal stem cell. Some stem cells give rise to a particular phenotype but there is heterogeneity in the cellular characteristics depending on the microenvironment – for example, blood vessels present in renal carcinoma metastases to the brain display the typical fenestrated morphology of renal vessels and not the continuous morphology of endothelial cells in invading brain vessels. Further studies demonstrated that transplanted bone-marrow cells (in sex-discordant transplant patients) may give rise to new hepatocytes in the livers of the recipients raising the possibility that human stem cells may be reprogrammed to express dormant areas of the genetic code, and thereby regenerate physically distinct phenotypes.

What remains unclear is whether stem cells are intrinsically different from daughter cells or whether they are instructed to be different by their microenvironment. In other words, could any cell behave as a stem cell if given the appropriate niche and signals – a phenomenon referred to as *plasticity*? This has implications for tumorigenesis and clinical situations such as tumor seeding and implantation. It is conceptually possible to manipulate any cell *in vitro* to behave like a stem cell but this is an unlikely scenario *in vivo*. The very early mammalian embryo (less than four cells) – the ultimate stem cells – is strong evidence favoring the argument that stem cells are intrinsically different.

The Concept of Stemness and "Immortal" DNA Strands

A recurrent theme in stem cell biology is whether stem cells are long-lived progenitors with the intrinsic capability to self-perpetuate their pluripotency, or whether "stemness" is not an intrinsic property, but rather a



Stem Cells. Figure 1 (a) Diagram of a longitudinal crypt (large intestine) section showing the cell positions. (b) The apoptosis frequency plot (radiation-induced: *solid line*) can be compared with the theoretical distribution of actual stem cells (*dotted line*), clonogenic or potential stem cells (*dashed line*) based on mathematical modeling. All these are centered round cell position four. The *continuous grey line* represents the distribution of rapidly proliferating cells which are predominantly determined by the committed dividing transit cell. (c) The current model for a three-tiered hierarchical stem cell compartment is also illustrated. There are from 4 to 6 actual stem cells per crypt, but many more cells (potential stem cells) that are capable of stem cell function. When a stem cell undergoes a commitment to differentiation, it often first enters a transient state of rapid proliferation. Upon exhaustion of its proliferative potential, the transiently amplifying cell withdraws from the cell cycle, and executes its terminal differentiation. *Approximately 5% are symmetrical divisions.

non-autonomous feature. The latter model suggests that in every adult tissue with renewal capabilities there must be a niche that determines the stem potential of cells within. Owing to the general lack of specific markers, epithelial stem cells have been traditionally identified by their ability to retain radiolabeled thymidine for long periods of time. More than 25 years ago, John Cairns proposed that stem cells selectively retain old (that is, labeled) replication error-free DNA strands while donating newly synthesized strands to their descendents

Stem Cells. Table 1 Examples of potential stem cell markers and techniques for stem cell isolation

Marker/techniques	Tissue example	Comments
CD34	Bone marrow	A $CD34^+/CD38^-$ cell surface phenotype is found in Acute Myeloid Leukemia stem cells and in normal primitive hematopoietic progenitors
►CD44	Breast	$CD44^+/CD24^-$ cell phenotype isolated from human breast tumors cause breast cancer in SCID mice
CD133 (prominin)	Liver	A transmembrane protein on stem cells from several organ sites
	Bone marrow	
	Neural	
EpCAM (CD326)	Liver	Present on hepatic stem cells but also hepatoblasts and committed progenitors. Overexpressed in many cell lines
NCAM	Liver	Present on hepatic stem cells but not any progenitor cells thereafter
	Neural	
Musashi-1 (Msi-1)	Intestinal crypts	Musashi-1 gene encodes an RNA-bind protein that is required for asymmetric divisions. It may mark intestinal stem cells but also has broader expression in the crypt.
Hes-1	Intestinal crypts	Like Msi-1, Hes1 may be expressed outside the stem cell region of the crypt
SOX2	Neural stem cells	SOX2 is expressed in multipotent neural stem cells at all stages of development
Stem-cell antigen (Sca-1)	Breast	Sca-1 positive cells demonstrate enhanced regenerative potential
^{3}H-thymidine retention	Breast Intestine	Stem cell retain DNA synthesis incorporated label over a long period (see Fig. 2)
Electron microscopy	Breast	Identification of large light cells (ULLC) and small undifferentiated light cells (SLC) justaposed suggest they result from an asymmetric single mitotic event
Hoechst dye side population (SP)	Breast	SP mammary cells are similar to SLC cells and are highly enriched for Sca-1 expression
Laser capture micro-dissection (LCM)	Intestinal crypts	LCM was followed by DNA microarray analyses, which demonstrated increased expression of cell proliferating genes
Gene profiling	Skin	Examples include Wnt inhibitors (sFrp1, Dkk2, Wif1); cell cycle inhibitors (Gas1, Ak1, Inhbb), and TGF-β signaling components

EpCAM, epithelial adhesion molecule; NCAM, neural cell adhesion molecule; Hes-1, a homeobox gene expressed by murine embryonic stem cells; SOX2, a homeobox gene transcription factor derived from murine embryonic stem cells.

which will be lost from the tissue after a short time. Although this has long been controversial, recent work demonstrates asymmetric segregation of chromatids in stem cells of small intestine using specific labels for new and old chromatids (Fig. 2). Retention of old chromatids by stem cells has also been demonstrated using *in vitro* models and in *in vivo* breast stem cell systems. The existence of "immortal" DNA strands has implications for understanding the lifespan and mutagenesis dynamics of stem cells, but it also implies that certain stem cell properties are maintained or inherited autonomously throughout adulthood.

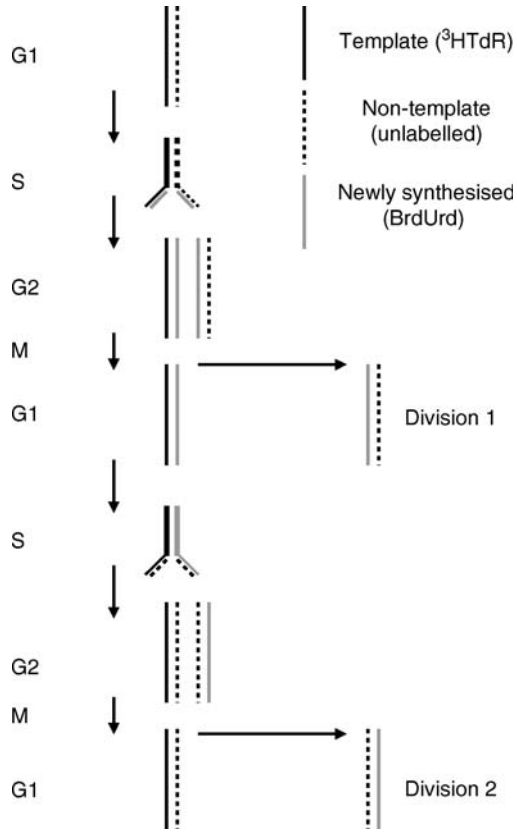
Regulation of Stem Cell Numbers

Until recently, little was understood about the molecular regulation of stem cells. Over the past 5 years, several genes and signaling pathways have been shown to have important regulatory functions for some stem cells. Three key gene systems are ►*Wnt* (Wingless), *Shh* (Sonic ►Hedgehog), and ►*Notch*, and their associated tissue stem cells are listed in Table 2. However, as these genes frequently operate in other cell types, they cannot be called "stemness" genes.

Properties of Stem Cells Which Favor Tumorigenesis

There is a general hypothesis in cancer biology that most cancers arise from a mutated stem cell and are there are a number of characteristics of stem cells which support this hypothesis. These are as follows:

- Capacity for self-renewal and progenitor production via asymmetric cell division



Stem Cells. Figure 2 Diagram showing the segregation of template and newly synthesized DNA strands in one chromosome. The Cairns' hypothesis proposed that all the chromosomes would behave in this way. The template strands are selectively retained by the stem cell daughter of a cell division, whereas the newly synthesized strands are segregated to the daughter cell destined to enter the dividing transit compartment and be shed from the tissue after a few days, thus removing any replication-induced errors. Label introduced into the newly synthesized strands takes two divisions to be removed from the stem cells. Label in the template strand would persist in the stem cell line.

Stem Cells. Table 2 Signaling pathways that regulate stem cells

Signaling pathway	Stem/progenitor cell self renewal	Implicated in tumorigenesis
Wnt	Hematopoietic	Colon carcinoma
	Epidermal	Epidermal tumors
	Intestinal	
Shh	Hematopoietic	Medullablastoma
	Neural	Basal cell carcinoma
	Germ line	
Notch	Hematopoietic	Leukemia
	Neural	Mammary tumors
	Germ line	

Wnt, wingless; Shh, Sonic hedgehog.

- Regulated by a niche – conceivably, disruption of this host control may lead to aberrant expansion of the stem/progenitor cells and cancer initiation
- Long-lived allowing time to accumulate multiple mutations
- Ability to generate multiple lineages via downstream differentiation
- Active telomerase expression
- Activation of anti-apoptotic pathways (high ►BCL-2 and inhibitors of ►apoptosis (IAPs) proteins)
- ►Anoikis resistance allowing survival during dissemination
- Ability to undergo ►migration
- Increased membrane transporter activity, which may in turn be a mechanism of drug resistance
- Distinct signaling pathway patterns including Wnt, Notch, Snail, Twist, and Hedgehog

Evidence that Human Tumors Arise from Stem Cells

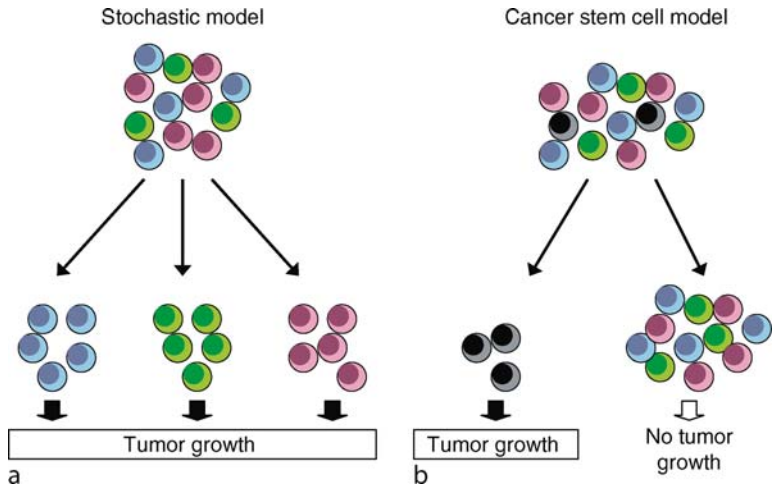
Additional evidence that most tumors arise from stem cells comes from the following:

- Many cancers arise in tissues where self-renewal is essential (e.g. skin, gut, bone marrow).
- For the most part, human tumors are monoclonal, suggesting that they arise from a single transformed cell.
- Tissue-specific differentiation – most human tumors contain cell types consistent with an origin from the stem cells of that tissue.
- Changes in stem cell regulation mechanisms occur commonly and early during tumorigenesis.
- Bio-mathematical modeling supports the concept that tumors arise from mutated stem cells.

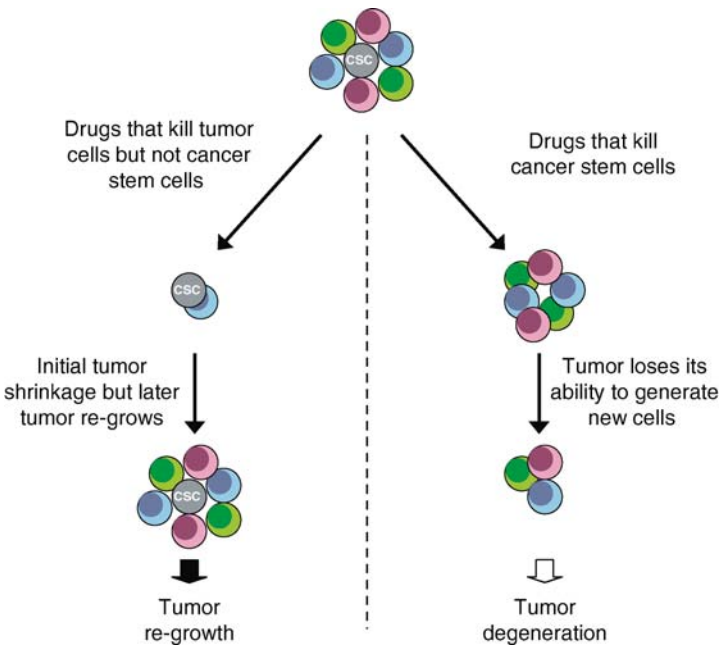
Cancer Stem Cells

Through increased understanding of the molecular biology of embryonic organ development and self-renewing adult tissues, a clearer idea is emerging that a unique population of stem cells – cancer stem cells (CSC) – may be responsible for the maintenance of tumor growth (Fig. 3), and that these cells are inherently resistant to standard treatments. These concepts are not new, being first promulgated by Cohnheim in 1875. However, recently, a number of investigative teams have been able to successful isolate subpopulations of human cancer cells with dramatically enhanced tumorigenic capacity when transplanted into immuno-deficient mice.

S



Stem Cells. Figure 3 Cartoon of two common models of tumor growth. In the stochastic model (a), tumor cells are heterogeneous with every cells having a low but equal probability with time of proliferating and forming new tumors. According to this model, the genetic changes leading to cancer development and progression are operative in all cells within the tumor. In the cancer stem cell model (b), tumor cells are heterogeneous but most cells have only limited potential to proliferate and only a small subset – the cancer stem cells (*grey/black shaded* cells) – have the ability to initiate new tumors.



Stem Cells. Figure 4 Conventional therapies (*left-hand side* of panel) may shrink tumors by killing mainly cells with limited proliferation potential. If the putative cancer stem cells (CSC) are less sensitive to these therapies, then they will remain viable after therapy and re-establish the tumor. By contrast, if therapies can be targeted against cancer stem cells (*right-hand side* of panel), then they might more effectively kill the CSC, rendering the tumor unable to maintain themselves or grow.

This has now been successfully demonstrated for ►acute myeloid leukemia, ►breast cancer, ►colon cancer, ►brain tumors and ►pancreatic cancer. However, we do not know with certainty whether or not CSCs are derived from normal stem cells.

As an extension of the CSC model, recent studies have postulated that migrating non-proliferating stem cells, located at the tumor invasion front, exhibit ►epithelial to mesenchymal transition, which may contribute to tumor ►metastases.

Clinical Implications of Cancer Stem Cells

The emergence of a molecular understanding of CSCs will have major implications for how we view conventional anti-cancer treatments, and how we develop novel anti-cancer strategies (Fig. 4). Conventional therapies may shrink tumors by killing mainly cells with limited proliferation potential. If the putative CSCs are less sensitive to these therapies, then they will remain viable after therapy and re-establish the tumor. By contrast, if therapies can be targeted against CSCs, then these might more effectively kill the CSCs, rendering the tumor unable to maintain themselves or grow. Thus, even if cancer stem cell-directed therapies do not shrink tumors initially, they may eventually lead to cure.

A fascinating question, at present, is whether or not stem cells express the molecules that clinicians are currently targeting such as estrogen receptors, ►HER-2, and ►Epidermal Growth Factor Receptor (EGFR). The major signaling pathways so far identified in stem cells are often mutated in cancers but they are not, by and large, the focus of current molecular treatments. Stem cell regulatory pathways (as outlined above) are thus the potential unexploited anti-cancer targets of the future.

Stem-like Cancer Cells

Dean G. Tang
Department of Carcinogenesis, The University of Texas M. D Anderson Cancer Center, Science Park-Research Division, Smithville, TX, USA

Synonyms

Cancer stem-like cells; Cancer stem cells; CSC; Tumor progenitors; Tumor-initiating cells; TIL; Tumor-reinitiating cells; Tumor-repopulating cells

Definition

Cancer stem cells (CSC) are functional rather than having a fixed definition. ►The least stringent definition would be that the prospectively purified CSC population is more tumorigenic than the bulk or the marker-negative tumor cell population(s) in a suitable tumor development assay. Using ►the most stringent definition, a cancer stem cell should be a cell that, at the single-cell level, can reconstitute, in a recipient animal, a tumor that is identical to the parental patient tumor and that can be serially xenotransplanted indefinitely. Therefore, in a strict sense, none of the CSC thus far reported can be truly classified as CSC and should more appropriately be called tumor-reinitiating cells. In reality, it will be very difficult to identify a tumorigenic cell that can fulfill the most stringent definition of a cancer stem cell mentioned above. Firstly, a tumor, especially a solid tumor, is made of numerous cell types. To expect one cell or even a population of cells, when transplanted into a foreign host (i.e., mice) in an exotic environment, to fully reconstitute an original patient tumor in its complete composition is very difficult and essentially impossible to prove. Secondly, when such experiments are actually done, the best one can do is to coinject the putative tumorigenic cell population with stromal components (e.g., fibroblasts, carcinoma-associated fibroblasts or CAFs, urogenital sinus mesenchyme or UGM, etc.) in an extracellular matrix (e.g., Matrigel or collagen) into an "orthotopic" animal site such as brain, mammary fat pad, or prostate lobes. These so-called orthotopic sites are considerably different from their human counterparts and tumor establishment would inevitably require the recruitment of various host (i.e., mouse) cells by the tumor-reinitiating cells. Such "reconstituted" tumors could never be identical to the original patient tumors. Thirdly, during the purification process, the majority of cells are often discarded to obtain marker-positive and -negative populations. These discarded cells would be important in the original tumor composition but they would be very difficult to reconstitute in tumor development assays. Altogether, one can say, at the very best, that the experimental tumor reconstituted from the presumptive CSC histologically "resembles" the (patient) primary tumor.

Therefore, we probably have to seek a middle ground when making the claim to a cancer stem cell. A ►functional definition of CSC is as follows. First, the presumptive CSC (i.e., the cell population enriched in putative CSC) must be prospectively purified from, e.g., cell cultures, xenografts, and/or primary tumors. When purifying candidate populations of CSC from tumors, lineage selection must be performed to remove "irrelevant" cells such as stromal and blood cells that may contain other ►stem cells (SC) including mesenchymal and hematopoietic SC, which might have the ability to undergo transdifferentiation. Second, in vivo

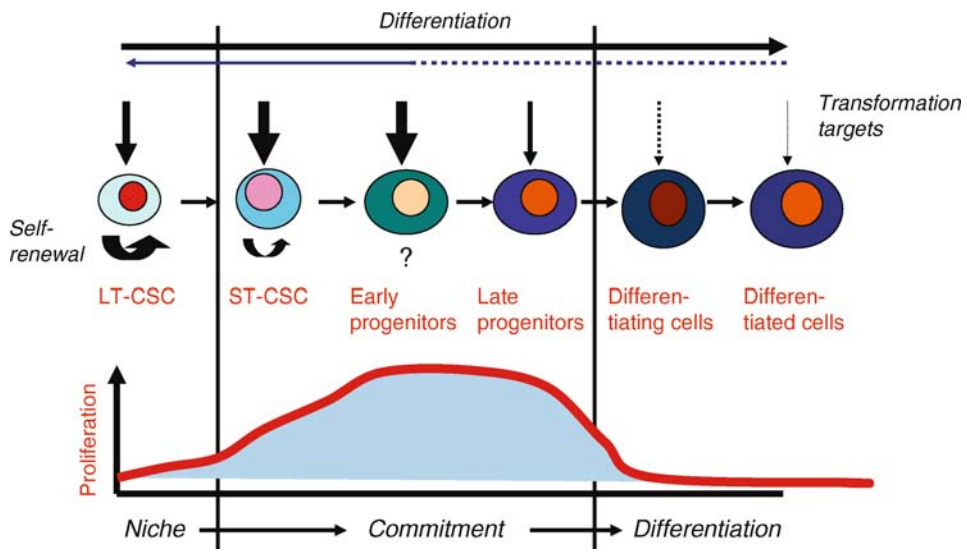
tumorigenicity experiments must be done to show that such cell populations are enriched in tumor-reinitiating cells. When feasible, serial tumor xenotransplantation should be carried out to determine whether the tumors derived from the putative CSC can be transplanted for multiple generations. Histologically, the reconstituted as well as serially xenotransplanted tumors should resemble the original tumor. Third, importantly, the presumptive CSC population, or a subpopulation within, has to be studied to show that they possess certain intrinsic biological properties normally associated with SC elaborated below. Only when these conditions are fulfilled can one confidently claim that the candidate population of tumor cells under investigation is enriched in potential CSC or tumor-reinitiating cells. Importantly, even such tumorigenic populations are likely heterogeneous with true CSC representing perhaps only a very small fraction.

Characteristics

CSC identified in different types of tumors or the same type of tumor but from different patients may manifest very different biological and functional properties. On the other hand, all CSC are expected to share certain common properties such as relative dormancy but with extended proliferative capacity, significant clonogenic potential, preferential expression of stem cell-related genes (e.g., self-renewal genes), the ability to undergo asymmetric cell division, and enhanced in vivo tumorigenic and ►metastatic potentials.

Theoretically, tumor cells in any cancer, depending on the differentiation status, may be organized as a hierarchy that can be roughly classified as long-term CSC (LT-CSC), short-term CSC (ST-CSC), early and late tumor progenitors, and differentiating and differentiated tumor cells (Fig. 1). The LT-CSC should possess indefinite self-renewal and ST-CSC some self-renewal properties. The early tumor progenitors may or may not possess any self-renewal activities. The LT-CSC, localized in putative CSC niche, likely proliferate slowly although these cells possess the highest proliferative potential. By contrast, the cell types that constitute the bulk of the proliferating cell compartment in a tumor are mostly tumor progenitors and ST-CSC (demarcated by two vertical lines, Fig. 1). Differentiating and differentiated tumor cells, which should express tissue-specific differentiation markers, are hypothesized to lack proliferative capacity and self-renewal in vivo. In theory, both CSC (LT- and ST-CSC) and tumor progenitors should have the ability to regenerate tumors in tumor development assays. In principle, however, tumors initiated by CSC should be able to be passaged indefinitely whereas tumors initiated by tumor progenitors can only be propagated for a limited number of times.

Putative CSC are often thought to derive from normal SC, which may or may not be the case. In fact, because normal progenitor cells are the major proliferating cells in a tissue or an organ and they may possess certain self-renewal abilities or they may acquire self-renewal abilities by the transforming events (e.g., silencing of p16, mutations of ►PTEN, etc.), these cells are more likely the targets of initial tumor transformation (Fig. 1). In other words, transformed tissue progenitor cells may



Stem-like Cancer Cells. Figure 1 This figure presents a hypothetical model of tumor cell hierarchy. LT-CSC localized in putative niches make the commitment to develop into ST-CSC and tumor progenitors, which in turn differentiate into "functional" cell types such as PSA-producing prostate cancer cells. In most tumors, tumor progenitors and ST-CSC may constitute the bulk of proliferating cell compartment and their normal counterparts may represent the major transformation targets. See text for more descriptions.

actually be the real CSC. Alternatively, the initial tumor transformation may occur in normal SC but further genetic mutations and/or epigenetic alterations take place in more mature tumor progenitor cells, which thus represent the real CSC that drive tumor formation, ►progression, and recurrence. Both of these concepts have been recently born out in acute and chronic myelogenous leukemia (AML and CML). Finally, although most differentiated cells are thought not to be able to "dedifferentiate" (i.e., going back along the lineage development; Fig. 1), some somatic cells such as hepatocytes and endothelial cells are known to be able to replicate themselves. Therefore, some differentiated cells may also become transformation targets and subsequently become CSC.

Identification

Putative CSC have now been reported in multiple human tumors including AML, CML, multiple myeloma (MM), ►brain tumors (glioblastoma, medulloblastoma, etc), ►breast tumors, ►melanoma, and ►prostate cancer, ►colon cancer, and ►gastric cancer. In principle, CSC can be identified by several experimental strategies.

1. *Marker-Based Analysis*. A variety of adult tissue SC are found to express relatively specific markers, which can be cell surface or intracellular such as nuclear. Interestingly, many reported CSC also seem to express the cell surface markers that identify their normal counterparts. This observation provides a relatively simple enrichment procedure utilizing either flow cytometry-based cell sorting or microbeads-based affinity purification. For nuclear markers, a marker promoter-driving reporter construct such as GFP-tagged retroviral or lentiviral vector system can be developed to track down putative CSC and then purified by flow cytometry. The disadvantages associated with using predetermined marker(s) to identify CSC include that the marker proteins frequently change during cell development in vivo and cell preparation in vitro and that in most cases the functions of "stem-cell" markers in both normal SC and stem-like cancer cells are unclear.
2. *Side Population (SP) Analysis*. Mouse hematopoietic SC are found to preferentially express multidrug resistance (MDR) family proteins such as MDR1 and other membrane transporters such as ABCG2 (also called BCRP for breast cancer resistance protein). This property allows the HSC, in an experimental setting, to pump out the Hoechst 33342 dye. Therefore, on dual-wavelength flow cytometry, the HSC-enriched cell population is identified as a "side" or tail Hoechst^{dim} population at the lower left quadrant of the histogram. By contrast, the major population of cells, devoid of HSC, is displayed as Hoechst^{hi} cells called as non-SP or main population (MP). Recent work reveals that multiple adult tissue SC can also be enriched by the SP protocol and that the SP from several cancer types are also enriched in stem-like cancer cells. The major advantage of this technique when used to identify putative CSC is its simplicity. The potential problems associated with the technique are that chronic accumulation of Hoechst dye in non-SP cells may be cytotoxic (thus invalidating suitable controls) and that SP cells isolated from some normal tissues seem to be enriched in progenitor cells rather than SC.
3. *Sphere-Formation Assays*. Many normal SC such as neural, hematopoietic, and mammary SC, when maintained under special culture conditions, can form three-dimensional spheres, which are like miniorgans that can differentiate into multiple cell types. Putative CSC identified in brain and prostate tumors as well as in melanoma also have the ability to form anchorage-independent spheres. The advantage of using sphere-forming assays to enrich for CSC is its initial independence of specific markers. The disadvantages include the empirical nature of finding culture conditions suitable for sphere formation and the necessity of finding ways later to identify and purify the real CSC from the spheres.
4. *Label-Retaining Properties*. Mammary SC and normal keratinocyte SC in interfollicular epidermis and hair follicle bulges are quiescent and can be identified with a pulse label with the thymidine analog BrdU (bromodeoxyuridine) followed by a long-term "chase" (i.e., removal of the label). Fast-proliferating progenitor cells dilute out the BrdU label after several cell divisions whereas the slow-dividing SC retain BrdU and thus identified as "label-retaining cells" or LRCs by either immunohistochemistry or flow cytometry analysis. Recently, the LRCs purified from the bulge regions in transgenic mice indeed are found to be enriched in SC based on both gene expression profiling and functional assays. Interestingly, the LRCs in human breast tumors coexpress mammary epithelial SC markers and seem to have certain SC properties. Human prostate cancer cell spheres and xenograft tumors also possess slow-cycling LRCs. These tumor LRCs are yet to be prospectively purified out to show that they indeed represent slow-cycling CSC.

Clinical Implications

CSC are thought to have high levels of prosurvival mechanisms such as heightened expression of anti-apoptotic ►Bcl-2 family proteins (including Bcl-2, Bcl-xL, and Mcl-1), ►telomerase, and antioxidant and detoxifying enzymes. In addition, they preferentially express cell surface pumps such as ABCG2 and MDR1. Furthermore, they generally proliferate much slower

than the progenitor cells. Most current anticancer therapeutics targets fast-proliferating tumor progenitor cells. All these together lead to relatively transient therapeutic efficacy as CSC will most likely survive therapeutics due to their relative dormancy, increased survivability, and enhanced capacity to efflux therapeutic agents. CSC, once mobilized to the cell cycle, may regenerate a less differentiated tumor with expanded CSC and tumor progenitor cell compartments and result in drug-resistant tumor progression and ►metastasis. There is emerging evidence that CSC are more resistant to therapeutic regimens.

CSC, due to their different genetic makeups and signaling requirements than in their normal counterparts, might be preferentially targeted. For instance, leukemia SC seem to show some differences in the expression of surface marker repertoire compared to normal hematopoietic SC. Therefore, these different markers may be taken advantage of for the antibody-based therapeutics. CSC with mutant ►p53 and PTEN tumor suppressors may be particularly more sensitive to apoptosis induction induced by restoration of p53 and PTEN expression/functions. Leukemic SC are recently shown to be extremely sensitive to cell death triggered by BH3 mimetics, presumably because of their heavy reliance on Bcl-2 and Mcl-1 for their survival. Finally, normal neural and mesenchymal SC have been employed alone or as vehicles to carry cytotoxic cytokines or gene products to specifically target CSC in certain tumors such as ►glioblastoma multiforme.

Stent

Definition

A synthetic (usually plastic or alloy mesh) tube inserted into a blood vessel, ureter or segment of intestine to prevent or treat blockage.

►Desmoid Tumor

Steradian

Definition

The SI unit (international system of units) for solid angle.

►Bioluminescence Imaging

Stereocenter

Definition

A carbon atom with four distinct functional groups.

►Small Molecule Screens

Stereotactic Radiosurgery

Definition

A radiation therapy procedure that uses special equipment to position the patient and precisely deliver a large radiation dose to a tumor and not to normal tissue. Synonym radiation surgery, radiosurgery, stereotactic external-beam radiation and stereotactic radiation therapy.

►Glioblastoma Multiforme

Sterile-α-Motif

SAM domains are a class of protein modules characterized by a globular structure consisting of five a-helices and can mediate interactions with other proteins, RNA, and lipids.

Steroid Hormone Receptor Coactivators

Definition

Are defined as cellular factors that do not bind DNA directly but are recruited to the promoters by steroid hormone receptors. These promoters enhance agonist-dependent transcriptional activation by facilitating transcription initiation through interaction with components of the basal transcription machinery. Coactivators also enhance transcriptional activity of SHR by other mechanisms such as modulating alternative RNA ►splicing.

►Progestin

Steroid Hormone Receptors (SHR)

Definition

Members of a superfamily of nuclear receptors that function as ligand- or hormone-dependent transcription factors. The term superfamily defines a set of genes derived from a single progenitor gene that has diverged to produce the unique functions of its members.

►Progestin

Steroid Receptor Coactivator-3

►Amplified in Breast Cancer 1

Steroid-Refractory Graft-Versus-Host Disease

Definition

A potentially fatal bodily condition that results when T cells from a tissue or organ transplant, especially a bone marrow transplant, react immunologically against the recipient's antigens, attacking cells and tissues (refractory to steroids).

►Rituximab

Steroid Sulfatase

Paul Foster
Department of Endocrinology and Metabolic Medicine, Imperial College Faculty of Medicine, St. Mary's Hospital, London, UK

Synonyms

Aryl sulfatase C; Steroid sulfohydrolase; Steryl sulfohydrolase; STS

Definition

Steroid sulfatase (STS) is an enzyme which is virtually ubiquitous throughout the human body and its activity is implicated in a range of physiological processes and pathological conditions. Its prime responsibility is for the hydrolysis of alkyl (e.g. dehydroepiandrosterone sulfate (DHEAS)) and aryl steroid sulfates (e.g. estrone sulfate (E1S)) and therefore plays an essential role in regulating the formation of steroids such as DHEA and E1 which can be converted to biologically active steroids (e.g. androstenediol (Adiol) and ►estradiol (E2)).

Characteristics

The activity of STS was first discovered in rat liver microsomes. Now it is known to be active in a plethora of tissue types, including testis, ovary, placenta, skin, lung, brain and bone. Therefore it is thought to be found in small quantities throughout the body. It is a member of a superfamily of 12 different mammalian sulfatases. The gene for the human STS is located on the distal short arm of the X-chromosome. The actions of this enzyme make a large contribution to the in situ estrogen production in hormone-dependent malignant tissues. Little is known about the regulation of STS gene expression or enzyme activity. However, the expression levels of mRNA and enzyme activity are increased in cancerous breast and endometrial tissue compared to normal tissues. During the last decade there has been a significant amount of research carried out to elucidate the role that STS plays in the conversion of steroid sulfates, such as DHEAS and E1S, and the consequent formation of biologically active steroids, such as androstenediol and E2.

The highest incidence of breast cancer occurs in postmenopausal women after the cessation of the production of ovarian estrogens. However, estrogens are still produced by the local conversion of androstenedione to E1, a reaction that is catalyzed by the ►aromatase enzyme. A major proportion of the estrogens that are formed are available for conversion by estrone ►sulfotransferase into E1S which is biologically inactive because it is unable to bind to the ►estrogen receptor (ER). However, steroid conjugates, because they bind to albumin, have a much longer half-life in the plasma (about 9 h) compared to the unconjugated estrogens and are also found in circulating blood at greater concentrations. This acts as a potential reservoir for the formation of biologically active estrogens, e.g. E1, via the actions of STS (see STS figure). The E1 thus formed is further metabolized by 17β-hydroxysteroid dehydrogenase (17β-HSD) type 1 to E2 which is the most biologically active natural steroid that can interact with the estrogen receptor (ER) and stimulate tumor cell growth. In postmenopausal women, the production rates of E1 and E2 are ~40 μg/day and 6 μg/day respectively.

There is another route via which STS may influence the growth of some tumors. There is evidence that

DHEAS and its unconjugated metabolite DHEA, stimulate cancer development. These steroids are able to act as precursors for the formation of steroids with estrogenic properties, such as Adiol. Furthermore, various studies have shown that DHEAS, DHEA and Adiol all have the ability to increase proliferation of breast cancer cells in vitro and are capable of stimulating the growth of carcinogen-induced mammary tumors in vivo. The most abundant of these steroids is DHEAS which is secreted by the adrenal cortex. Removal of the sulfate group on DHEAS by STS results in the formation of DHEA which can undergo a further reduction to make Adiol (see STS figure). In postmenopausal women, a significant proportion of Adiol produced comes from DHEAS and DHEA in the peripheral tissues. The importance of Adiol becomes evident when it is known that it can bind to the ER, albeit with a slightly lower affinity than E2. However, as Adiol plasma concentrations are reported to be about 100-fold higher than those of E2 in postmenopausal women, its significance in the development of cancer should not be underestimated.

Regulation of STS

There has been little research carried out as to how the STS enzyme is regulated in situ. It is thought that the cytokines ►interleukin (IL)-6 and tumor necrosis factor (TNF)-α can act synergistically to increase STS activity in some breast tissue and cancer cells. Conversely, IL-1β, an inflammatory cytokine, is capable of reducing STS activity and mRNA levels in human endometrial stromal cells, vascular smooth muscle and human aortas. The presence of these cytokines in breast cyst fluid may explain the differential regulation of STS in breast cancer cell lines by breast cyst fluid. Also, basic ►fibroblast growth factor and ►insulin-like growth factor type I (IGF-I) are known to increase STS activity in some breast cancer cells. This indicates that these growth factors, which are released by malignant breast tissue, can elevate local estrogen levels.

Other steroids are also thought to influence the expression of STS mRNA and subsequent activity. The use of exogenous testosterone treatment in the male mouse causes an induction of STS. The uteri of pregnant guinea pigs have greater levels of STS activity compared to fetal or mature females which implies an estrogenic regulation. The substrate for STS, E1S, is thought to increase STS activity in the liver of ovariectomized rats. Conversely, a reduction in STS mRNA levels was found when breast cancer cells were treated with the ►progestagen, Promegestone. However, exposure to the same cells with a different progestagen stimulates STS activity in these cells. Therefore, it seems likely that STS expression and activity can be regulated by other steroids suggesting various feed-back mechanisms, which are still poorly understood, are active.

STS in Hormone-Dependent Breast Cancer (HDBC)

There is increasing evidence to support the importance of STS in human breast cancers. Breast tumor tissue of postmenopausal women can have as much as ten times the estrogen levels than are seen in the plasma of the same patients. Furthermore, STS activity has been shown to be at least 50 times greater in both pre- and postmenopausal breast tumors compared with normal breast tissue. STS expression is detected in 90% of breast tumors, whereas aromatase expression is only found in 60–70%, and activity of STS in breast tumors is much higher than that of the aromatase complex. This increased STS activity could account for as much as a tenfold greater amount of E1 originating via the STS route than via the aromatase pathway.

Real time RT-PCR experiments have demonstrated that STS mRNA expression in malignant breast tissue is significantly higher than that in normal tissue. Clinical studies have now shown that STS mRNA expression may be a predictor of recurrence in breast cancer patients and that this association and prognosis only applies to ER +ve tumors. Significantly, elevated STS mRNA expression is associated with a poor prognosis in both pre- and postmenopausal women. This indicates that even in premenopausal women intra-tumoral estrogen synthesis could play a major role in the growth of breast tumors. The over-expression of the aromatase enzyme has also been examined as a potential prognostic marker as it is also supposed that its actions are pivotal in regulating tumor estrogen synthesis. However, it was found to have no prognostic value. Therefore, it is possible that the STS pathway may be more important than the aromatase pathway for the production of biologically active estrogens in the tumor. STS mRNA levels have been shown to correlate with tumor size and to be elevated in some tumors exhibiting metastasis compared to non-metastatic cancers.

STS Inhibitors

The importance of STS in the development of various cancers has led to the design and synthesis of a range of STS inhibitors. The main therapeutic focus for these compounds has been targeted on breast cancer in postmenopausal women. These patients are initially treated with standard endocrine therapy, such as antiestrogens, or more recently, aromatase inhibitors. Unfortunately, many breast tumors will fail to respond to these therapies making the use of STS inhibitors a potential option for therapeutic intervention. STS inhibitors come under three main categories:

1. *Alternative substrates*. These compounds (e.g. DHEAS, pNPS, MUS, flavone and isoflavone

sulfates), which contain at least one sulfate group in the structure, are designed to compete with E1S for binding to the active site of STS and, as a consequence, impede the hydrolysis of the natural substrate to E1. However, they are in principle alternative substrates for STS and hence the value of using these agents clinically in the treatment of HDBC is limited.

2. *Reversible inhibitors.* Reversible STS inhibitors are mainly E1 derivatives that are designed to compete with E1S for the enzymes active site but remain metabolically stable by not acting as potential substrates.
3. *Irreversible inhibitors.* The majority of STS inhibitors reported to date belong to this class of inhibitor. EMATE (estrone-3-*O*-sulfamate), the very first highly potent STS inhibitor, inhibits STS in a time- and concentration-dependent fashion. Its sulfamate group (OSO_2NH_2) was originally designed to mimic the sulfate group of E1S. However, despite EMATE being orally active and highly potent, it is not considered as a suitable agent for HDBC therapy because it was found to be strongly estrogenic in rodents. As a result, non-steroidal STS inhibitors were developed, of which STX64 (BN83495, 667COUMATE) has shown excellent efficacy in various in vivo tumor models and also, promising results in a recent Phase I trial in patients with advanced breast cancer. This "proof of concept" provided by STX64 strengthens the role of STS inhibitors in the treatment of HDBC.

There is still a considerable amount of research to be done on establishing the roles of STS in hormone-dependent cancer, mainly in the breast and prostate. The availability of many structurally diverse STS inhibitors may further assist in this work. While STX64 is the first and most advanced development STS inhibitor to date, the considerable therapeutic benefit of STS inhibitors on patients with hormone-dependent malignant tumors should further encourage the development of second-generation inhibitors.

Department of Haematology, Royal Liverpool University Hospital, Liverpool, UK

Synonyms

CGP57148; Gleevec; Glivic; Imatinib; Signal Transduction Inhibiotor-571

Definition

STI-571 is an oral drug marketed by ►Novartis, and is currently used for the treatment of certain types of

►cancer(s), including chronic myeloid ►leukemia (CML) and gastrointestinal stromal tumors (GISTs).

Characteristics

Physicochemical Properties

STI-571 is a small compound belonging to the phenylaminopyrimidine class of compounds (Fig. 1). It is chemically designed as 4-[(4-methyl-1-piperazinyl) methyl]-N-[[[4-(3-pyridinyl)-2-pyrimidinyl]amino]-phenyl]benzamidine methanesulfonate, with a molecular formula of $C_{29}H_{31}N_7O{\cdot}CH_4SO_3$. Its molecular weight is 589.72.

Pharmacology and Pharmacokinetics

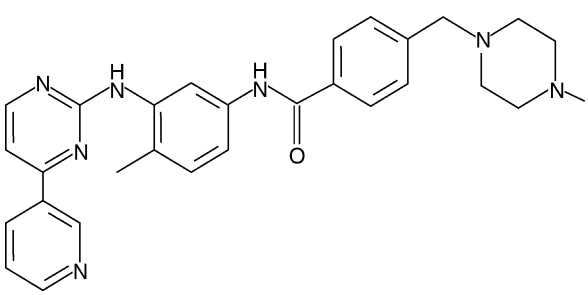
Protein kinases are an important group of ►enzymes that activate a range of substrates through phosphorylation. According to the nature of the phosphorylated –OH group in their substrates, they are classified as protein-serine/threonine kinases, or protein-►tyrosine kinases; in addition, a small group of dual specificity kinases catalyze phosphorylation of both threonine and ►tyrosine. Mutation or dysregulation of these enzymes is a frequent cause of the excess proliferation and/or reduced ►apoptosis of cancer cells. Therefore, protein kinases have become important therapeutic targets.

In humans, at least putative 518 protein kinase genes have been identified, with 385 coding serine/threonine kinases, 90 coding tyrosine kinases and 43 coding tyrosine kinase-like proteins.

STI-571 selectively inhibits certain types of protein-tyrosine kinases, including ►stem cell factor receptor (KIT), ►platelet-derived growth factor receptors (PDGFRs) (PDGFRα and PDGFRβ), ABL and its oncogenic form ►BCR-ABL. These tyrosine kinases catalyze the following reaction by binding adenosine triphosphate (ATP) and transferring phosphate from ATP to tyrosine residues on various substrates:

$$\mathrm{MgATP}^{1-} + \mathrm{Protien} - \mathrm{OH} \rightarrow \mathrm{Protein} - \mathrm{OPO}_3^{2-} + \mathrm{MgADP} + \mathrm{H}^+$$

STI-571 functions by competitively blocking the ATP binding site in these tyrosine kinases, thereby inhibiting their activities. The drug has either no or minimal effects on more than 30 other intensively studied protein kinases.



STI-571. Figure 1 Structure of STI-571.

Data from pharmacokinetic studies in healthy subjects and over 900 patients have shown that STI-571 is well-absorbed after oral administration. Following a single 400 mg dose of STI-571, a peak plasma concentration of 1.9 ± 0.4 μg/ml is reached within 3 h. After multiple dose administrations on a once-daily schedule, the plasma peak concentration reaches a level of 4.4 μM (2.6 ± 0.8 μg/ml). The steady-state plasma trough concentration 24 h after administration of 400 mg daily is over 1 μM. This trough concentration exceeds that required for inhibition of the cellular tyrosine phosphorylation activities of Kit, PDGFs and BCR-ABL in *in-vitro* assays (50% inhibitory concentration of STI-571 ranges from 0.1 to 0.25 μM). When the daily dose is increased to 600–800 mg, a steady-state plasma peak concentration as high as 13 μM can be reached. Mean absolute bioavailability is 98%.

Following oral administration in healthy volunteers, the half-lives of STI-571 and its major active metabolite (the N-desmethyl derivative) are ~18 and 40 h respectively. At clinically relevant concentrations, ~95% of STI-571 binds to plasma proteins (mainly albumin and α_1-acid glycoprotein).

CYP3A4, a ►cytochrome P450, is the major enzyme responsible for metabolism of STI-571. The main circulating active metabolite in humans is the N-demethylated piperazine derivative which has an *in-vitro* potency similar to that of the parent STI-571. Elimination is predominately via bile, mostly as metabolites (75%). After an oral ^{14}C-labeled dose of STI-571, ~81% is eliminated within 7 days, with a faecal to urinary excretion ratio of 5:1. Of the unchanged STI-571, 20% is excreted in urine, and 80% in feces.

Clinical Applications

Chronic Myeloid Leukemia (CML)

CML is a ►clonal hematopoietic malignancy, with an annual incidence of 1–1.5/100,000. The median age of onset is 45–55 years. The disease typically has three phases. Most patients present in chronic phase but, in an average of 3–5 years, the disease progresses to an accelerated phase with increased tumor loads and additional chromosome aberrations. This usually progresses relatively quickly to the blast-crisis phase where the disease comes to resemble acute leukemia. Treatments, including chemotherapy and stem cell transplantation, are usually effective only in the chronic phase of the disease.

More than 90% of cases of CML are caused by the BCR-ABL fusion protein, resulting from a translocation between the bcr gene on chromosome 9 and the abl gene on chromosome 22. This ►cytogenetic abnormality causes the non-receptor tyrosine kinase, ABL, to

become constitutively active, and is necessary and sufficient to induce the malignancy via increased proliferation, reduced apoptosis, and perturbed interactions between CML cells and bone marrow stroma. Therefore, this oncogenic ABL tyrosine kinase has become an ideal therapeutic target in CML.

In 1992, STI-571 was synthesized at Ciba-Geigy Pharmaceuticals (now Novartis) as an effective tyrosine kinase inhibitor. Four years later, the inhibitory effects of STI-571 on *in-vitro* growth of BCR-ABL-positive leukemic cells was confirmed and reported. Phase I clinical trial studies with STI-571 started in June 1998 and phase II trials were initiated in 1999. These trials confirmed that STI-571 is safe and effective in the treatment of chronic-phase CML. In 2001, STI-571 was approved in both the USA and Europe for the treatment of CML.

Large scale, phase-III multi-centre trials have now shown that STI-571 is superior to conventional interferon-α-based therapy in previously untreated chronic-phase CML, with an initial complete hematological response (CHR) rate of 95% versus 55% and a complete cytogenetic response (CCgR) rate of 76% versus 15%. The expected 5-year overall and progression-free survival for STI-571-treated patients has reached ≥90%. Therefore, STI-571 is now used as first-line treatment for CML.

In addition, STI-571 has some activity in the accelerated and blast crisis phases of the disease. Thus, around 40 and 20% of patients in accelerated phase can achieve a CHR and a CCgR respectively. The 3-year progression-free survival has been reported to be as high as 40%. For patients in blast crisis, the rate of response to STI-571 (including CHR, partial hematological response and hematological improvement) is also higher than that in historical controls treated with cytarabine-containing regimens (52% vs. 29%). However, the response of patients with blast crisis is usually temporary, with a median progression-free survival of ≤10 months and a 3-year survival of only 7%.

The standard dose of STI-571 for CML is 400 mg daily. A higher dose, 600–800 mg daily, has also been used, particularly for cases previously treated with conventional chemotherapy. However, whether such increased doses of STI-571 will achieve better responses remains to be determine in prospective studies.

Gastrointestinal Stromal Tumors (GISTs)

Gastrointestinal stromal tumors are a rare type of soft tissue sarcoma, with an annual incidence of 0.68–1.45/100,000 according to epidemiological data from North America and Sweden. More than 90% of GISTs occur in the stomach or small intestine, but they can occur anywhere along the length of the digestive tract. Although the exact causes of GISTs are unknown, most have a constitutively activated ►receptor tyrosine kinase (RTK) pathway. This occurs through mutations in either the KIT (in more than 80% cases) or the PDGFRα (in about 5–7% cases) gene. The abnormally increased activity of either of these two receptor tyrosine kinases is responsible for mediating the signals which stimulate the proliferation and survival of the tumor cells.

The most common treatment for GISTs is surgery to remove the solid tumour. However, GISTs have an extraordinarily high rate of recurrence after surgical resection and are very resistant to radiation and standard chemotherapy. Since STI-571 targets both of these oncogenic tyrosine kinases (as well as ABL), its effects were soon tested in GISTs. The agent was found to have activity, and is now standard therapy for advanced tumors which cannot be removed by surgery alone and for metastatic and recurrent disease.

Since 2000, thousands of patients worldwide with metastatic or recurrent GISTs have been treated with STI-571, and it has been found that a partial response or stable disease is achieved in 80% of cases. Furthermore, survival is prolonged with improvement of quality of life. Seventy percent cases with metastasis now have an expected survival of over 24 months compared to 15 months before the introduction of STI-571. Studies of STI-571 in both the neoadjuvant (STI-571 used both prior to and post surgical resection) and adjuvant (STI-571 used post surgery) settings are now being conducted to evaluate whether the low rates of cure obtained with surgical resection alone can be improved.

A daily dose of 400 mg with or without surgery is the recommended first-line treatment for recurrent or metastatic GIST; a higher dose (600–800 mg) may be considered in patients who progress, develop secondary resistance or present with specific genotypic characteristics. Treatment should be continued until there is progression or adverse effects become intolerable.

Other Diseases

STI-571 is now being used as experimental treatment of other diseases, including BCR-ABL-positive ►acute lymphoblastic leukemia. KIT-positive small-cell lung cancer, and PDGFR-positive ►prostate cancer.

Side Effects

Common side effects include oedema, rash, nausea, diarrhea and fatigue. Anemia, neutropenia and/or thrombocytopenia can develop in some patients, especially those with advanced disease. Almost all of these side effects are dose-dependent and controllable.

Resistance to STI-571

In CML, resistance to STI-571 more frequently develops in advanced disease, although it can be seen in chronic phase, usually after initial response. This resistance can be caused by multiple mechanisms.

Among these mechanisms, mutations in the BCR-ABL kinase domain are the most important. They are detected in more than 90% of cases with resistance to STI-571, and may be acquired during treatment, or may exist in a mutated clone present before therapy. Other mechanisms include BCR-ABL overexpression or amplification, reduced intracellular drug concentrations (e.g. caused by low expression of the drug influx transporter HOCT1 gene and/or high expression of the efflux transporter MDR1 gene), and abnormalities downstream of BCR-ABL, e.g. defects in the pro-apoptotic proteins BAD and Bim.

In GISTs, primary resistance is rare and only seen in <15% of cases. More often, resistance is acquired after more than 1 year of STI-571 therapy. Several groups have shown that such resistance is due to mutations in KIT.

Low Concentrations in the Central Nervous System (CNS)

STI-571 has limited activity against CML in the CNS because of poor penetration of the blood-brain barrier. This results in an 88–100-fold lower concentration of STI-571 in cerebrospinal fluid, compared to that in plasma. Case reports have shown that CNS relapse of CML can occur in patients who have maintained major cytogenetic remission with STI treatment. Although this late CNS disease is still rare, it may become more common over time as more patients are treated successfully with long-term STI-571.

►Imatinib

Sticker Sarcoma

Definition

Synonym Canine transmissible tumor (CTVT); a contagious veneral tumor found in the domestic dog and potentially in their social canids, such as the gray wolf and the cyote. The tumor cells themselves, rather than another agent such as a virus, constitute the contagious agent of the disease. CTVT is passed through the population by ►allografts, with the tumor cells from one animal directly seeding tumor formation in the next, usually during coitus. The tumor cells carry a particular marker, common to all tumors in the different host animals, which consists in a diagnostic long interspersed nuclear element (►LINE-1) near the ►*MYC* gene. The cells of any canine host do not have this diagnostic LINE-1 insertion. Thus, all tumors represent a single cell lineage that has been propagated over long time. The mechanism for tumor cells to evade the host immune system is not clear.

Stress

Corinna Bergelt
Institute of Medical Psychology, University Medical Center Hamburg-Eppendorf, Hamburg, Germany

Definition

There are different ways to investigate the phenomenon of "stress". From the biologist's point of view, stress can be defined as the unspecific biological response of the body to any ►stressor. The biological ►stress response includes the activation of the sympathetic nervous system and the release of several hormones (most prominently adrenaline and cortisol) and is among other reactions associated with an increased heart rate, increased blood pressure, altered immune system response and suppression of the digestive system.

From the psychological point of view, stress is a transactional process which depends on the meaning a person attributes to a stressor. In terms of the transactional stress model which was developed by Lazarus and Folkman, stress results from the subjects' appraisal that a certain stressor or situation is perceived as threatening (as opposed to challenging or harmless or irrelevant) and that the demands of the stressor exceed the individual's resources to deal successfully with the situation. In this model the same situation can lead to severe stress in one person while another person might not even recognize the situation as a potential stressor, depending on a variety of factors, including life experience, personality, coping resources or social environment of the subject.

Generally, there are two main approaches in social research on stress. One approach to define stress is the concept of ►daily hassles. Following this approach, stress is a result of an accumulation of minor stressors in daily life (e.g. misplaced keys or overcrowded public transport). However, the majority of research related to stress and cancer occurrence defines stress as the experience of ►major life events (or synonymical: ►stressful life events).

Major life events are defined as events which cause major changes in the life of the individual and are stressful to almost everybody regardless of individual coping capacity or social environment. In the social sciences, exposure to major life events is often measured by a checklist, the most prominent of these being a checklist which was constructed in the 1960s by Holmes and Rahe as a rank scale of life events. In a reanalysis of this scale in the 1990s, the five most stressful events in the list of 43 events were (in descending order) 'death of a spouse', 'divorce', 'death of close family member', 'marital separation' and 'fired from work'.

Characteristics

The assumption of an association between stress and cancer occurrence is common among cancer patients. Many patients believe that their cancer disease was caused or at least influenced by personal factors such as personality traits, coping strategies, depressive mood or stress. Likewise, many clinicians believe based on their own clinical observations that stress or emotional trauma are associated with cancer risk. Since these beliefs persist among clinicians, researchers, patients and the lay public, the topic has received intensive research attention in the past and many studies have addressed the question if stress is associated with cancer risk.

Possible Pathways of an Association of Stress and Cancer Risk

Different possible pathways for an association between stress and cancer risk have been postulated: The stress reaction of the body includes the release of several hormones and studies on the effects of stress on the immune response have shown that severe or chronic stress can adversely affect the immune system. It has been hypothesized that these changes can directly increase the risk for cancer. A competing theory of a relationship between stress and risk for cancer is based on the assumption that severe stress can influence behavioral factors and thus subsequently increase the risk for cancer. Studies on health behavior have shown that the experience of stress is associated with unhealthy behavior such as smoking, unhealthy diet and lack of physical exercise. These behavioral factors themselves are risk factors for several cancers and an increase in cancer risk in the context of stressful living conditions might be ascribed to an increase of these unhealthy behaviors.

Methodological Problems

Research on the association between stress and cancer risk is methodologically challenging, because stress is difficult to conceptualize and cancer is a multifactorial disease. Any interpretation of research findings must take the methodological basis of the respective study into account, especially with regard to study design, different approaches in the measurement of exposure to stress, outcome measurement (development of a cancer disease) and the consideration of confounding variables.

Many studies on the association of stressful life events and cancer risk which have postulated a link between the two show methodological weaknesses. Some of them are based on small sample sizes and especially many early studies used a retrospective approach and were designed as case-control studies. In a ►case–control study, patients who are diagnosed with cancer are matched with healthy controls and both groups are asked about the experience of stressful events in the past (mostly referring to a period of two, five or ten years before the study). Naturally, a patient who was (maybe even recently) confronted with a cancer diagnosis might recall things differently (and might overreport the exposure to stress retrospectively) than a person who does not have to deal with a potentially life threatening disease. This phenomenon is called ►recall bias and represents a fundamental problem in case-control studies which investigate past events.

The methodologically strongest solution to avoid the problem of recall bias is the ►prospective study design. In prospective studies on stress and cancer risk, only subjects who have not yet been diagnosed with cancer are included in the study. At the beginning of the study, all participants are investigated about their experience of stress and then followed up for a long period of time. The outcome of interest is cancer incidence and the analyses address the question if the subjects who develop cancer during follow up had initially reported more stress (e.g. stressful life events) than the subjects who do not develop cancer.

In addition to study design, the assessment of exposure and outcome plays an important role with regard to the methodological quality of a study. Although it is likely that most people recall especially major events in their life correctly, there is no means to assure that their recollection represents the true exposure. One way to address this problem is the unbiased exposure assessment based on register data. Likewise, the strongest approach to assess the outcome (in this case: the development of a cancer disease) is the

use of register data rather than self-report. Exposure in studies of stressful life events and cancer risk can be ascertained either from register data or from self-reports, which often comprises a checklist.

Another important factor in the examination of an association of stress and cancer risk is the adjustment for other risk factors for cancer. Since it is well established that behavioral factors such as smoking, alcohol consumption, diet, and exercise increase the risk for several cancers, these factors should be taken into account in order not to ascribe a potential finding to stress when it is in fact based on e.g. higher alcohol consumption in the exposed group.

Findings

Positive associations between severe stressors (i.e. stressful life events) and cancer risk have frequently been reported from case-control and ►retrospective studies. Since these studies suffer from the above described methodological problems, this essay focuses on the results of studies which utilized a prospective approach.

Several prospective population-based studies which assessed both exposure and outcome with unbiased data sources such as administrative data from population registers and cancer registers investigated stressful life events such as death of a spouse, divorce, death of a child or serious illness in a child. Most of these studies were conducted in Scandinavia where the availability of complete population registers and cancer registers enable ►cancer epidemiology researchers to link these data and investigate for example thousands of parents whose child died or whose child was diagnosed with a severe illness. Overall, these prospective population-based studies have shown no association between the investigated stressful life events and subsequent cancer risk.

Two studies found a slight increase in the risk for specific cancers though: one study on cancer risk in about 20,000 parents who had lost a child showed that bereaved mothers had a slightly increased risk for all cancers, which was confined to a slightly increased risk for smoking-related cancers. Likewise, a study of the cancer risk of about 20,000 parents of children in whom schizophrenia was diagnosed found that the mothers had an increased risk for ►lung cancer. However, elevated cancer rates were only found for smoking related cancers and since these studies where based solely on administrative data there was no means to adjust for smoking behavior. Therefore these findings seem to support the hypothesis that stress does not directly influences cancer risk, but alters health-related behavior (such as smoking patterns) which in turn might increase cancer risk.

Two other studies utilized a more sophisticated approach by combining administrative data for the unbiased assessment of the outcome with personal information from the participants with regard to potential confounding variables in a prospective study design. Therefore, as opposed to many previous prospective studies, the analyses in these studies could be adjusted for a number of lifestyle factors known to be associated with cancer risk (e.g. smoking patterns and alcohol consumption):

A large prospective study of breast cancer in Finland took exposure to potential confounding factors into account and assessed the outcome on the basis of information in a population register, while experience of stressful life events was assessed from a checklist. It was found that experience of divorce or separation or death of a husband, a close relative or a friend increased the risk for breast cancer. However, a Danish study which used a similar approach (assessment of stress by checklist, assessment of outcome by register data, adjustment for behavioral factors) and investigated all cancer sites did only show that the accumulated experience of stressful life events was associated with an unhealthy lifestyle but was not associated with an increase in cancer incidence.

Conclusion

Although the topic of the presumed association between stress and cancer risk received intensive research attention in the last decades, methodologically advanced studies on the subject are still rare. Due to methodological limitations, many previous studies contribute little to the question of the influence of stressful life events on the development of cancer. Concurrently lay theories on such an influence are widespread among cancer patients and the general public. Only prospective, population-based studies provide reliable information that may support a more evidence-based discussion of these issues.

Based on the repeated results of the prospective studies which have been conducted so far we can conclude that there is no convincing evidence that stress is an independent risk factor for cancer. This conclusion does not only imply that cancer patients have no reason to blame their psychological condition for the occurrence of the disease. The findings might also assist health care professionals working with cancer patients or their relatives since they can reassure patients that there is no scientific proof that stress or the experience of stressful events such as bereavement or divorce causes cancer.

Stress Response

Ze'ev Ronai
Signal Transduction Program, Burnham Institute for Medical Research, La Jolla, CA, USA

Synonyms

Immediate early stress response; Damage response

Definition

Stress response is a process that occurs in response to an altered balance of endogenous homeostasis following altered external and internal stimuli.

Characteristics

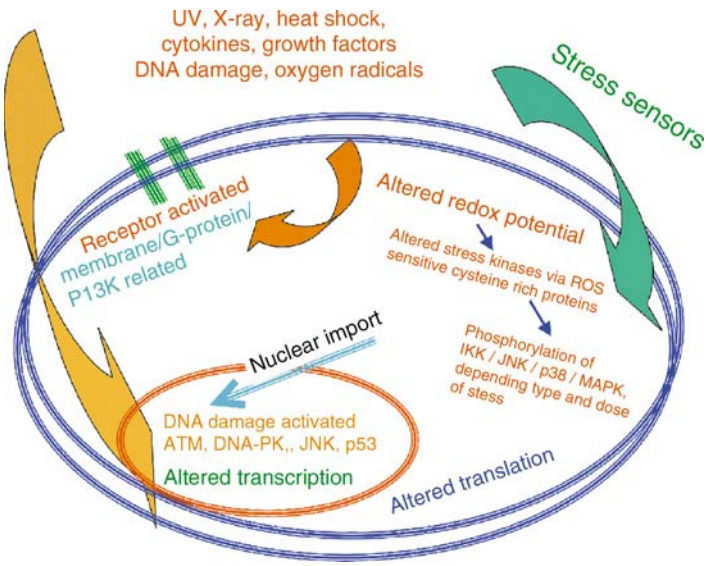
A cellular stress response consists of cellular changes required to accommodate internal or external insult. It can be induced following change in ►ROS which can take place in response to ►DNA damage, ►inflammatory cytokines, ►growth factors and irradiation, as well as osmotic or heat shock. Exposure to anti-cancer drugs or deprivation of survival factors also results in the activation of a stress response. A large set of cellular sensors, which include redox sensitive proteins, cell surface receptors, and proteins that recognize changes in ROS, ►ER stress or DNA damage regulate the activity of stress kinases and their respective substrates. Depending on the type and degree of stress, the combined activation of stress kinases and their corresponding substrates dictate the cellular fate (survival or death) in response to the stress administered (►Apoptosis). The activation of one or more stress activated kinase pathways allows the cell to determine whether DNA repair and growth arrest will prevail over the initiation of programmed cell death or cellular differentiation. The nature of the cellular stress response is therefore dependent on cell type, expression pattern of cell surface receptors and stress kinases in concordance with respective phosphatases and kinase inhibitors.

Cellular Regulation

Recognition of cellular stress can be attributed to one of the following (as well as to any of their combinations):

- Altered organization of cell surface receptors, including changes in the oligomerization of EGFR, PDGFR and IGFR as well as altered localization and conformation of membrane anchored proteins including phosphoinositol 3 kinase (PI3K).
- Change in the redox potential within the cell, primarily due to an altered balance of reactive oxygen radicals (as a result of impaired activity of detoxification and homeostasis maintaining enzymes among which are thioredoxin and glutathione S-transferase π which were shown to inhibit, under non-stressed growth conditions, the activities of ASK1 and JNK, respectively).
- DNA damage which results in the activation of DNA-PK, JNK, and other kinases that sense changes in the presence of DNA lesions (Fig. 1) Each change, or the combination of these changes, has been implicated in the activation of a selective subset of stress kinases and in the subsequent activation of their respective substrates.
- ER stress, which results in activation of ►Unfolded Protein Response (UPR) degradation of misfolded proteins (ERAD) with possible trigger for programmed cell death.
- Change in ubiquitin-mediated signaling that impacts cell cycle progression, activation of protein kinases and DNA damage responses.

Among key stress signaling pathways are the IKK, MAPK, JNK and p38 cascades. Interestingly, the upstream regulatory components that include TRAF2, MEKK1, ASK(1–2), TAK(1–2), MEK(1–4) often share regulation of downstream components of the stress kinase pathways (Fig. 2) The interplay between signaling pathways is controlled through organization via scaffold proteins, which facilitate contact between selective members of a given stress-signaling pathway. Requirements for scaffold proteins were shown for IKK, JNK and MAPK family members. The activation of stress kinases leads to the phosphorylation and/or stabilization of their substrates and to their transcriptional activities. Growing evidence



Stress Response. Figure 1 Outline of major stress sensors. Cell exposure to stress, as exemplified in the list of DNA damage and stress inducing treatments listed, affects one or more of the major cellular stress sensors. Those sensors include cell surface receptors, membrane anchored proteins and cysteine rich proteins which are sensitive to the formation of reactive oxygen radicals, and DNA lesions which are sensed by nuclear-residing protein kinases. The activation of one or multiple sensors depends on the type of stress, its dose and duration. In turn, respective changes in the activities of stress kinases (Fig. 2) will determine cell fate.

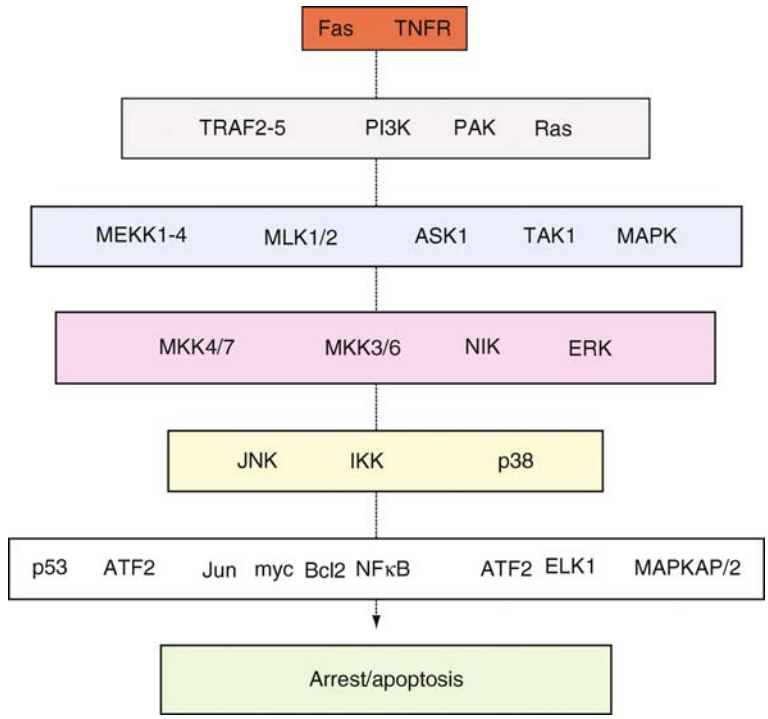
points to re-wiring of signal transduction pathways in human tumors and pathological disorders. Among the four major stress signaling pathways are:

- IKK, a family of kinases implicated in the regulation of IκB phosphorylation and subsequent ►ubiquitination and degradation. Consequently, ►NFκB is free to enter the nuclei to mediate its transcriptional activities. NFκB has been associated with the cellular ability to cope with stress through its positive effect on proteins that antagonize the apoptotic cascade, including IAPs, TNFα, Fas and Bcl2.
- MAPK, which is responsive to Ras and PI3K signaling, has been implicated in the cellular response to ROS and elicits the activation of p42/p44 ERKs.
- JNK and p38 which are activated by the upstream kinases MKK4/7 and MKK3/6, respectively. The latter are tightly regulated by ASK1 and MEKK1 signals. c-Jun/ATF2 are phosphorylated by JNK and p38, which represents divergent signaling cascades that result in transcriptional output that is often shared by the heterodimer ATF2/Jun. Other members of the p38 families are expected to play a role in the phosphorylation of substrates that are not modified by JNK and vice versa, thereby conferring selectivity for the stress response.
- ATM and DNA-PK represents enzymes that recognizes DNA damage and contributes to cellular stress response via phosphorylation of key regulatory proteins including the tumor suppressor protein p53.

Activation of p53 is a good paradigm for stress response as this tumor suppressor stress inducible protein is phosphorylated by multiple stress kinases resulting in the dissociation of proteins that otherwise target its ubiquitination and degradation. Phosphorylation of p53 depends on the nature and degree of damage and stress and is carried out by ATM, DNA-PK, p38, and JNK. Phosphorylation on multiple residues (including 15, 20, 37, 46, 81, 389) depending on the type and dose of damage results in p53 that is able to elicit growth arrest or a signal triggering apoptosis.

Clinical Relevance

The interplay between stress-activated kinases, ligases and other regulatory components appears to play a key role in the type of cellular response to stress. Changes in the expression, activation or in the duration of stress kinase output are expected to result in an altered cellular response to stress. Tumors were found to harbor such changes, which conferred greater resistance to radiation or chemotherapy, with the example of TRAF2/GCK in human melanoma. Mutations in stress kinases are rarely found, although cases reported an MKK4 mutation in certain human tumors. Changes in the activation



Stress Response. Figure 2 Stress kinases. Several stress signaling cascades are based on their affinity to upstream and downstream components. Among the major stress kinases are ERKs (extracellular signal regulated kinases), IKK (inhibitory κ kinase), JNK (Jun kinase) and p38. Each of these signaling cascades is activated at different kinetics and with diverse affinities in response to stress. Thus, various types of stress can activate different subsets of stress signaling cascades. Activation of the upstream stress components results in the phosphorylation of respective downstream targets. For example, TRAF2 (tumor receptor associated factor 2) can elicit the activation of NIK (nuclear factor κ B inducing kinase), MEKK1 (MAP/ERK kinase 1), ASK1 (apoptosis signal-regulating kinase 1), mitogen activated protein kinase (MAPK), which in turn phosphorylates IKK, MKK4/7 (mitogen activated kinase kinase 4/7), p38 or ERKs, respectively. Organization of these signaling cascades via "scaffold" proteins maintains their close contact and the high affinity for related family members. These kinases will in turn phosphorylate their transcription factors substrates. Depending on the combination of activated transcription factors and apoptosis regulatory proteins, the cell can undergo growth arrest, allows proper damage repair or can undergo programmed cell death.

of stress kinases were also reported in heart and neurological disorders.

Our greater understanding of mechanisms underlying the regulation of stress kinases and their substrates is expected to allow the design and use of reagents that would specifically target the selective kinase to alter its activities, which will determine the ability of the cell to cope better (or worse) with the type of stress and DNA damage.

Stroma

Definition
Meaning mattress or support for parenchymal cells; Is the connective tissue of an organ or a gland. Historically, stroma was recognized as a supportive or scaffolding component. The stroma is believed to "sense" and "react" to paracrine and autocrine physiological or pathological disturbances, thus attempting to maintain the homeostatic balance. In the malignant process, refers to non-malignant cells and connective tissue that surround and support a tumor.

►Desmoplasia
►Stromagenesis

Stromagenesis

Synonyms
Stromatogenesis; Stromal progression; Tumor-associated stromal progression

Definition
Stromagenesis, from the Greek term *stromatogenesis* (υστρώμα ►stroma = mattress and γένεσις genesis = creation or birth), is used to describe the progressive changes that stroma undergoes during the process of ►epithelial tumorigenesis. Specifically, the term describes tumor-associated changes in fibroblasts and fibroblast-derived ►extracellular matrix, as opposed to the formation of new stromal endothelial blood vessels, identified as ►angiogenesis.

Characteristics
Although the term "►stromagenesis" has only recently entered the scientific literature (2002) describing ►melanoma-fibroblast cross-talk, the process of stromagenesis has been investigated for more than a century. Early publications from several pathologists in the late nineteenth century (e.g. Theodor Langhans in 1879), used the word "stroma" to refer to connective tissue and vessels associated with tumors. They thought of these areas as purely mechanical and nutritional supports with only mild insinuation of their active roles in ►tumorigenesis. The first meaningful hint that the stroma can influence tumor cell behavior was published in 1889, when Stephen Paget presented his "seed and soil" hypothesis. Paget reported that upon autopsy of 735 breast cancer patients, metastases were preferentially distributed to particular organ beds. He proposed that although randomly scattered throughout the vasculature, tumor cells, regarded as "seeds," could only generate viable metastases in specifically permissive territory, or "fertile soil." He further postulated that during cancer progression, tumor cells actively contribute to formation of a pro-metastatic microenvironment. Almost one century after Dr. Paget's theory, in 1975, Dr. Beatrice Mintz, from the Institute for Cancer Research at Fox Chase Cancer Center in Philadelphia, reported that normal host cells could restrict the neoplastic growth of ►teratocarcinoma cells microinjected into blastocysts. The injected blastocysts resulted in ►mosaic yet normal, healthy, and fertile mice. Dr. Mintz's work was the first to show that cancer cells are totipotent (e.g. stem cells) and that a "normal" microenvironment restricts tumorigenic processes, while a tumor-associated stroma promotes tumor development.

Today, it is believed that tumor cells can both influence and be influenced by their stromal microenvironment, and that some stromas are genetically and/or epigenetically more suitable than others to support tumorigenesis and metastases. Some radical theories such as the "tissue organization field theory," propose that stroma is the sole tumorigenic component. This theory describes cancer as a problem of tissue organization comparable to organogenesis, and proliferation as the default state of a cell. Even though the

term "stroma" applies to both connective tissue's endothelial and fibroblastic cells, the term "stromagenesis" is often specifically used to describe the changes that tumor-associated fibroblasts (also known as cancer-associated fibroblasts) and their extracellular matrices undergo during tumorigenesis, while the term angiogenesis is used to describe the endothelial progression manifested as development of new vasculature in the vicinity of the tumor. Finally, the term "tumor-microenvironment" collectively includes stromagenesis, angiogenesis and cells arising from the host inflammatory immune responses to the tumor, which recruits macrophages and lymphoid cells to the tumor milieu.

It is believed that stromagenesis involves a mechanical process whereby the stroma is stiffened due to changes in protein composition, which increases in intrinsic forces proximal to the tumor, inducing the tumor to progress. Stromagenic changes can be observed at the immediate vicinity of a developing tumor, as an integral part of the tumor, as well as at secondary tumor-site (e.g. at the site of a metastasis). Investigators have attempted to describe stromagenesis by recounting its progression in at least three stages: (i) normal or repressive, (ii) primed or inductive and (iii) tumor-associated or activated stroma. The best described stromagenic reaction, known as ►desmoplasia, is regarded as fibrotic or scar-like by pathologists. Oncofetal stroma, less well-described, presents a less organized stroma that is positive for the oncofetal fibronectin isomer and has been associated with, among others, aggressive oral ►squamous cell carcinomas, as well as some breast and colorectal cancers. Since the two described phenotypes share some markers, it is not yet clear whether they are entirely distinct or whether they are dynamically interchangeable, thus emerging as desmoplastic or oncofetal stroma at different times during tumorigenesis. Oncofetal stromal-reactions have been observed relatively far from the primary tumor site (e.g. in the skin of a variety of cancer patients), while desmoplasia has only been reported in direct association to neoplastic lesions. Nevertheless, a clear stroma reaction often represents more than 50% of the total tumor mass such as in the case of pancreatic cancers.

Activated fibroblasts are frequently characterized as myofibroblastic cells expressing ►alpha-SMA. Various tumor-stroma specific markers have been described, e.g. the fibroblast activation protein (►FAP). This protein has been shown to be expressed in the tumor-associated stroma but not in normal stroma or epithelial cells, or in cancerous tissues with the exception of melanoma. Antibodies against FAP were the first used to investigate the possibility of developing an effective chemotherapy by specifically targeting the tumor-associated stroma. Other stroma specific markers include extracellular matrix components such as tenascin-C, hyaluronic acid, and SPARC (also known as osteonectin).

It is now well-recognized that both direct and indirect interactions between cancer cells and their stroma are critical for promoting the growth and invasiveness of tumors. Nevertheless, the mechanisms by which tumor cells promote stromagenesis are not well defined, but some important triggers such as the cytokine TGF-beta have been identified. ►TGF-beta is produced and secreted as a latent molecule by normal epithelial cells, tumors, and stromal fibroblasts. It is activated by extracellular proteases (including metalloproteinases ►MMP-2, MMP-9, ►MT1-►MMP) and receptors (including integrins) on the surface of fibroblasts or early stage tumor cells. TGF-beta suppresses the growth of an emerging population of tumor cells. However, at later stages of tumorigenesis, TGF-beta is indirectly tumor supportive, because during tumor development TGF-beta receptors are often down-regulated on the tumor cell surface causing a loss of TGF-beta responsive growth inhibition in tumor cells. However, because tumor cells continue to produce TGF-beta and stromal fibroblasts maintain high levels of its receptor(s), TGF-beta continues to drive fibroblastic responses (e.g. type I collagen fibrillogenesis), promoting the differentiation of stromal fibroblasts into myofibroblasts (myofibroblasts are also believed to be actively recruited to the tumor site from the circulation). Alpha-SMA also actively promotes stromagenesis and mechanical force is generated by the myofibroblast through the isometric contraction of stress fibers containing alpha-SMA. This force is transmitted by integrin-dependent adhesion-structures, which connect stress fibers with the modified stromal extracellular matrix. It has been shown that TGF-beta induces desmoplastic differentiation of normal fibroblasts into alpha-SMA expressing and collagen type I assembling myofibroblasts *in vitro*. Moreover, it is known that induction of connective tissue growth factor and a specific differential splice form of fibronectin known as ED-A enhance the pro-fibrotic effects of TGF-beta.

The vital interplay between tumor and stroma means that, in principle, it is possible to target signaling pathways that regulate tumor-induced stromagenesis and, thereby, contain tumorigenesis.

Definition

Stromelysin-1 (EC 3. 4. 24. 17), a secreted proteolytic enzyme whose gene maps to 11q23, is a member of the ►matrix metalloproteinase (►MMP) family. Like the other MMPs, it is characterized by its ability to degrade the extracellular matrix (►ECM) components and its dependence upon Zn^{2+} binding for enzymatic activity. Stromelysin-1 is produced by fibroblastic cells and by normal and transformed epithelial cells in culture and *in vivo*. It plays a pivotal role in the degradation and remodeling of the ECM during a variety of normal and pathological processes. Besides digesting ECM components, stromelysin-1 modulates the activity of biologically active molecules by direct cleavage and release from bound stores, thus influencing many cellular functions.

Characteristics

Enzymatic Properties of Stromelysin-1

Human stromelysin-1 is secreted from cells as an inactive ►zymogen (M*r* latent 57,000 Da) and comprises four distinct structural domains: (i) an N-terminal propeptide that maintains the enzyme in latent form, until it is removed, owing to the interaction of a cysteine residue in this peptide with the zinc ion in the active site, (ii) a catalytic domain containing the active site with the catalytic zinc moiety, (iii) a linker or hinge region, and (iv) a C-terminal hemopexin-like domain that is believed to play a role in the recognition of certain substrates and influence the binding of macromolecular inhibitors. Active enzyme (M*r* active 45,000 Da) is produced by cleavage of the propeptide that can be induced by proteinases like plasmin or *in vitro* by thiol-modifying agents, chaotropic agents and heat, which destabilize and activate the molecule by dissociation of the zinc and the cysteine residue. Once activated, stromelysin-1 is susceptible to inhibition by tissue inhibitors of metalloproteinases (►TIMPs).

Stromelysin-1 has one of the broadest substrate spectra of the MMPs and can degrade most ECM components, but not fibrillar collagens. In addition, stromelysin-1 activates a number of proMMPs, and acts on non-matrix substrates including cell-surface and

matrix-bound growth regulators, releasing them from stores (Table 1).

Regulation of Stromelysin-1

Stromelysin-1 is involved in ECM remodeling during physiological processes such as morphogenesis, growth and wound repair. It follows that a tight and spatiotemporal regulation of its expression is critical for cell and tissue homeostasis. Stromelysin-1 expression is mainly controlled at the transcriptional level. A number of specific DNA elements in the human stromelysin-1 promoter have been shown to be important in the regulation of its transcription. They enable the gene to integrate through binding the transcription factors, which are a large number of stimuli from the different cellular signaling pathways. The specific DNA elements that have been well characterized are: (i) A proximal ►AP-1 site at –70 which binds the transcription factors of the ►Fos and ►Jun families. This site is necessary for the basal level of expression but is not sufficient on its own for activation by numerous inductors as the epithelial growth factor (EGF), the ►platelet-derived growth factor (PDGF), phorbol esters or the proinflammatory cytokine IL-1β. Nevertheless, this site must not be underestimated because it is important for combinatorial regulation by the different members of the Fos and Jun families. (ii) Palindromic head to head ►Ets-binding sites (EBS) at –216/–201, which are not present in the promoter of the other MMPs. These sites bind the oncoproteins of the Ets family, which are transactivators such as Ets-1, Ets-2 or Pea-3 and repressors such as Tel. This EBS palindrome is important for the transcriptional regulation of the stromelysin-1 promoter in response to the oncoproteins ►Ras, Mos and ►Src, phorbol esters which are tumor inducers such as ►PMA and IL-1β. (iii) An upstream regulatory sequence which is composed of an EBS and a NIP (Nuclear Inhibitory Protein) site at –94/–80. It cooperates with the EBS palindrome and the AP-1 site in response to IL-1β and PMA. (iv) A stromelysin IL-1 responsive element (SIRE) at –1614/–1595, which is a distal negative response element to IL-1β responding also to the tumor necrosis factor α (TNFα), another proinflammatory cytokine. This element can present a single nucleotide polymorphism (►SNP) 5A/6A.

Stromelysin-1. Table 1 Stromelysin-1 substrates (Adapted from ref. 1 and completed)

ECM substrates	Bioactive substrates	
Aggrecan	MCP-1 (« monocyte chemoattractant protein-*1* »)	Partial inactivation
Laminin	MCP-2	Agonist > > antagonist
Fibronectin	MCP-3	Agonist > > antagonist
Collagens III, IV, V, IX, X, XI	MCP-4	Agonist > > antagonist
Gelatin	SDF (« stromal cell-derived factor »)	Inactivation
Entactin	Pro-TNFα	Soluble active TNF-α
Perlecan	L-selectin	Shedding
Decorin	Pro-HB-EGF (« heparin binding-EGF »)	Active HB-EGF
Tenascin	Pro-IL-1β	Active IL-1β
Vitronectin	Perlecan	FGF2 release
Fibrin/fibrinogen	Decorin	TGF-β release
LP (« link protein »)	CTGF (« connective tissue growth factor »)	VEGF release
Elastin	SPARC (« secreted protein acid rich in cysteine »)	Angiogenic peptides
	Plasminogen	Angiostatin
	E-cadherin	Soluble ectodomain
	IGFBP-3 (« IGF binding protein-3 »)	Active IGF release
	Pro-MMP-1	Active MMP-1
	Pro-MMP-3	Active MMP-3
	Pro-MMP-7	Active MMP-7
	Pro-MMP-8	Active MMP-8
	Pro-MMP-9	Active MMP-9
	Pro-MMP-13	Active MMP-13
	α1-proteinase inhibitor	Inactivation
	α1-antichymotrypsin	Inactivation
	α2-macroglobulin	Inactivation

The additional adenine in the 6A allele increases the binding of a NF-κB p50/p50 dimer leading to a lower level of stromelysin-1 transcription. This polymorphism has been associated with disease severity in diverse pathologies including ►cancer. (v) A stromelysin-1 PDGF response element (SPRE) at –1584/–1571 which binds the stromelysin-1 PDGF response element binding protein (SPBP). SPBP transactivates the stromelysin-1 promoter in response to PDGF through a κ/ι ►PKC-dependent pathway requiring cooperativity with the AP-1 site. (vi) A nerve growth factor response element (NGFRE) at –241/–229, which binds the interferon response element binding factor-1 (IREBF-1). The transcription of stromelysin-1 was shown to be increased by IREBF-1 in response to the nerve growth factor (NGF).

Besides these well defined responsive elements, variation in the levels of stromelysin-1 transcription by other compounds has been reported: (i) ►oncostatin M, which induces stromelysin-1 in human chondrocytes, (ii) protein synthesis inhibitors such as cycloheximide and anisomycin, which induce an increase in levels of stromelysin-1 messenger RNA in human fibroblasts, (iii) ►transforming growth factor β (TGF-β), which is able to repress the activation of the stromelysin-1 transcription by EGF, Ras and Src in fibroblasts, and (iv) hormones, which are also inducers or repressors of stromelysin-1 transcription. Glucocorticoids are able to inhibit the increase in stromelysin-1 messenger RNA induced by EGF, PMA and IL-1β in fibroblasts. On the one hand, ►retinoic acid, like glucocorticoids in fibroblasts, is able to repress the stromelysin-1 expression and on the other hand to increase its induction by NGF in pheochromocytoma cells. Oestradiol and progesterone inhibit stromelysin-1 expression during the menstrual cycle. Androgens have been reported to decrease the expression of stromelysin-1 induced by PMA in prostate carcinoma cells. Unfortunately, the mechanism whereby all these compounds exert their effects remains unclear. A post-transcriptional regulation of stromelysin-1 was also described. Indeed, activation of p38 alpha mitogen-activated protein kinase (►MAP Kinase) enhances stromelysin-1 expression by messenger RNA stabilization.

All the different responsive elements and effectors listed above point out the complexity and the sensitivity of stromelysin-1 regulation. It reflects more particularly the equilibrium found at every control level between positive and negative signals. This is a strategy required for all the MMPs to obtain a very subtle-tuned expression in response to various stimuli in different cellular types and biological events.

Stromelysin-1 and Cancer

It would be simplistic to consider stromelysin-1 just as a proteolytic enzyme hydrolysing components of the ECM. Stromelysin-1 is able to generate and release numerous active and latent molecular signals or regulate pre-existing molecular signals. In this way, stromelysin-1, like other MMPs, can modulate the cellular environment at different levels and is therefore able to influence the behaviour and the future of the cells. It can be easily understood that misregulation of such a gene is associated with severe erosive and invasive pathologies such as tumor growth and invasiveness.

Stromelysin-1, like numerous other MMPs, is expressed in different tumors and its presence correlates with their aggressiveness. Its expression has been shown *in vivo,* notably in carcinomas: mammary carcinoma, colorectal carcinoma, lung carcinoma, prostate carcinoma, pancreatic carcinoma, oesophageal carcinoma or cutaneous carcinoma. It is noteworthy that stromelysin-1 has been often shown to co-express with the oncoprotein Ets-1, which is considered, among all the other Ets proteins, as an independent marker of poor prognosis in various cancer types. During the earliest stages of tumor development, stromelysin-1 is predominantly localized at the level of the fibroblasts of the ►tumor stroma.

Stromelysin-1 induces, by its proteolytic activity towards numerous compounds, the release of growth factors which act directly on tumor cells and other surrounding cells, including fibroblasts, inflammatory cells and endothelial cells. Stromelysin-1 in degrading perlecan releases FGF2 (or basic ►fibroblast growth factor) which in the setting of cancer is known for its potential to induce ►angiogenesis and might be involved in desmoplasia in tumors, owing to its role in fibrosis. In degrading decorin, another proteoglycan, stromelysin-1 releases TGF-β, a growth factor implied in cell growth and proliferation. Stromelysin-1 is able to cleave extracellular proteins sequestering growth factors such as ►insulin-like growth factor binding protein 3 (IGFBP-3) which binds to insulin-like growth factor II (IGF II). Stromelysin-1 can also release active ►heparin-binding EGF-like growth factor (HB-EGF) from cell surfaces by cleaving it at a site just outside the cell membrane. ►Chemokines are known targets of stromelysin-1 and other MMPs. For example, stromelysin-1 has been shown to transform, by partial proteolysis, the precursor of IL-1β in an active molecule, influencing tumor-infiltrating inflammatory cells. Stromelysin-1 is also involved in the loss of cellular adherence and the phenotypic modification of epithelial cells, which occur during the early stages of carcinomatoid tumor development. Thus, stromelysin-1 cleaves the extracellular domain of the ►adherens junction protein ►E-cadherin. The soluble fragment of E-cadherin which is released prompts cells to disaggregate and promotes tumor-cell ►motility in a paracrine manner, by interfering with the function of other full length E-cadherin

molecules. Cleavage of E-cadherin also triggers the ►epithelial-to-mesenchymal transition (►EMT), promoting cancer cell invasiveness. Acquisition of an invasive phenotype by the tumor often goes with a gain of MMP expression by the tumor itself. Indeed, stromelysin-1 expression is associated with invasive carcinomas. Some ►squamous cell carcinoma (SCC) tumor cells can express stromelysin-1, providing further activity for a tumor-driven proteolytic cascade, in which MMP-13 can be activated by stromelysin-1 expressed by tumor cells. In addition, many compounds secreted by tumor-infiltrating inflammatory cells as well as by tumor or stromal cells are capable of modulating MMP expression. Tumor cells can also secrete factors, such as extracellular matrix metalloproteinase inducer (EMMPRIN), which enhances the expression of several MMPs, including stromelysin-1 by fibroblasts.

Stromelysin-1 has also a role in tumoral neoangiogenesis. Inhibition of the stromelysin-1 activity decreases neovascularization drastically in a murine model of ►colon cancer. In addition, the release of proangiogenic factors by stromelysin-1 is also in agreement with its known role in angiogenesis: (i) release of FGF2; (ii) release of vascular endothelial growth factor (VEGF) isoform $VEGF_{165}$, as a consequence of degradation of its natural inhibitor, the connective tissue growth factor (CTGF); (iii) release of active HB-EGF; (iv) production of an angiogenic polypeptide, owing to the cleavage of a matricellular protein, ►SPARC (secreted protein acid rich in cysteine). Nevertheless, stromelysin-1 can also generate ►anti-angiogenic factors. Indeed, stromelysin-1 generates angiostatin by cleaving plasminogen and might be involved in the generation of ►endostatin, a C-terminal fragment of the basement-membrane collagen type XVIII. It indicates that expression of stromelysin-1 in the tumor periphery might also serve to limit or regulate angiogenesis induced by the tumor. Another role of stromelysin-1 as a negative regulator of tumor expansion might exist. In fact, stromelysin-1 is able to cleave and inactivate ►CXCL12, a ligand for CXC chemokine receptor 4 (CXCR4) on leukocytes. ►Breast cancer cells express CXCR4 and it has been shown that inhibition of the binding of CXCL12 to CXCR4 by blocking antibodies reduces ►metastasis *in vivo*. Therefore, cleavage of CXCL12 by stromelysin-1 might inhibit metastasis.

Stromelysin-1 can act as a natural tumor promoter. It can induce premalignant lesions and favor tumor emergence on its own. These observations come from using transgenic mice overexpressing stromelysin-1 specifically in the mammary glands. Mammary tissue of these transgenic mice presents the characteristics of stroma reaction with collagen accumulation, neovascularization, tenascin-C expression and upregulation of endogeneous stromelysin-1. These changes are hallmarks of cancer ►progression and may even predispose towards neoplastic epithelial transformation. Thus, overexpression of stromelysin-1 gives rise to changes that could potentially promote mammary ►carcinogenesis. This is confirmed in older animals from 6–24 months of age, which develop with an important incidence, spontaneous premalignant lesions and mammary cancers. A recurrent genomic instability has been shown by array comparative genomic hybridization (►ArrayCGH) in these different premalignant and malignant lesions. In addition, stromelysin-1 plays an active role in EMT. Thus, overexpressing this enzyme in normal mammary epithelial cells leads to an important morphological change with a loss of cell-cell adhesions and vimentin synthesis revealing EMT. This was confirmed *in vivo* using transgenic mice overexpressing stromelysin-1. A recent study indicates that stromelysin-1-mediated EMT is due to the expression of Rac1b, an isoform of Rac1 GTPase, which causes an increase in cellular ►reactive oxygen species (►ROS). This increase in the ROS stimulates the expression of the transcription factor ►Snail, promotes EMT and causes oxidative damage to DNA and genomic instability. This may represent a key event in the stromelysin-1-induced phenotypic and genotypic malignant transformation in normally functioning cells.

These results are supported by studies in human cancers where the 5A allele of stromelysin-1 (see above, regulation of stromelysin-1) corresponding to higher levels of stromelysin-1 transcription may represent an unfavourable prognostic feature in breast cancer patients associated with more invasive disease. The 5A allele might also be associated with the increased susceptibility to non small cell lung cancer among smokers and a risk of development and lymphatic metastasis in oesophageal squamous cell carcinoma.

On the contrary, other studies using stromelysin-1 transgenic animals showed a reduction in the number of mice developing mammary tumors following treatment by a chemical carcinogen. An ►apoptosis induction of mammary epithelial cells in transgenic animals overexpressing stromelysin-1 (possibly by degrading laminin) has been reported. In addition, in stromelysin-1-deficient mice, topical applications of carcinogens resulted in skin tumors that grew at a faster initial rate than did carcinogen-elicited tumors in wild type mice. This enhanced tumor development was correlated with a reduction in the tumor inflammatory cell infiltrate. Thus, the presence of stromelysin-1 appears to be a protection by an increased influx of inflammatory cells to the area of carcinogenesis.

All these data point out that the proteolytic activity of stromelysin-1 and other MMPs towards an always growing number of matrix and non-matrix substrates renders it difficult to predict the effect of cleavage in a complex biological context. This is all the more

real in cancer progression which involves a continuous interplay between tumor cells, stroma cells, and inflammatory cells. It becomes clear that the biological consequences of this activity can lead to either stimulation or inhibition of tumoral development. Validation of true substrates *in vivo* and a better understanding of the biological properties of the cleavage products is required to find an efficient therapeutic use for the inhibitors of stromelysin-1 and other MMPs.

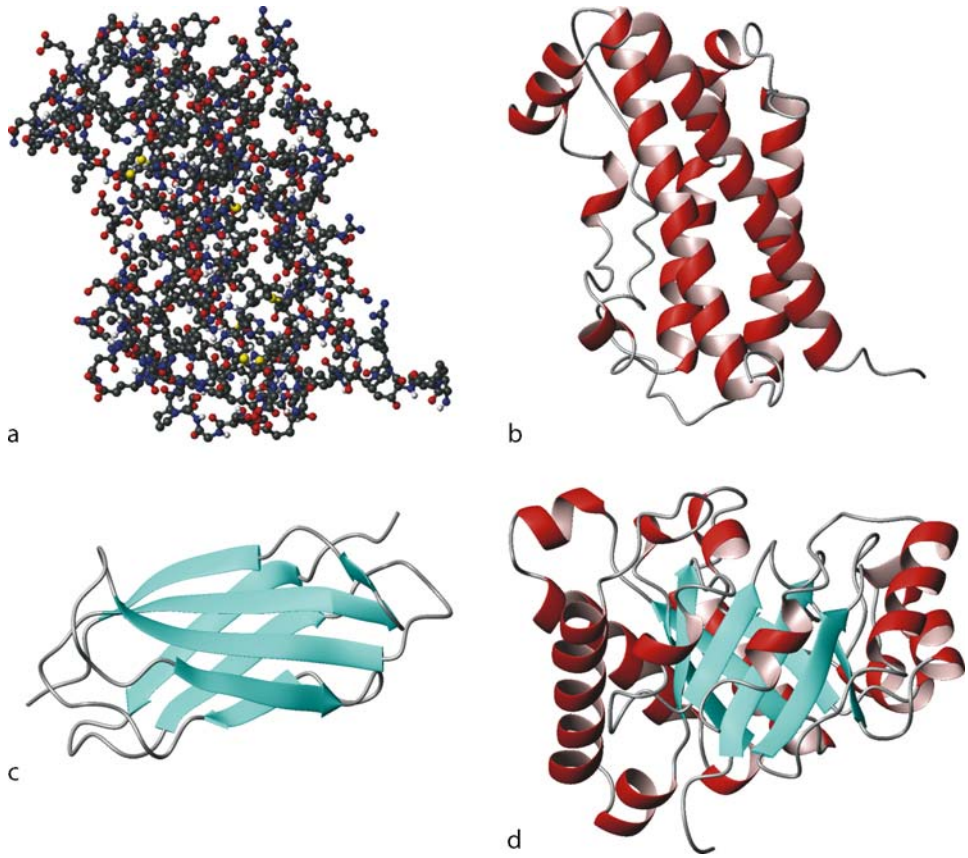
Definition

Structural biology involves biophysical methods that can determine the three-dimensional structure of macromolecules. These structures can lead to an understanding of the molecular basis of cancer and identify the atomic details necessary for drug design, optimization, and development.

Characteristics

The two methods that can elucidate atomic-level structures of biological macromolecules – e.g., proteins, DNA, RNA, and complexes between/among these molecules – are ►X-ray crystallography and ►nuclear magnetic resonance spectroscopy (►NMR). For X-ray crystallography, crystals are necessary for determining structures. In contrast, NMR is used to determine structures of molecules in solution. In crystallography, X-rays are diffracted by the crystal creating the data necessary to determine the structure. NMR experiments are based on the property of nuclear spin, inherent to specific nuclear isotopes such as ^{1}H, ^{13}C and ^{15}N. A majority of NMR-derived structural restraints are derived from magnetic couplings between nearby nuclei. Structures of the same macromolecule determined by each method are essentially identical. However, each technique presents its own advantages and disadvantages and, together, the two techniques are highly complementary. In practical terms, NMR spectroscopy is limited in the size of the protein investigated, with structures <30 kDa being relatively routine and structures up to around 100 kDa anticipated. On the other hand, X-ray crystallography has been successfully utilized to determine the structures of very large macromolecular complexes such as a virus or the large ribosomal subunit. A final important difference involves static versus dynamic views of protein structure. X-ray crystallography excels at providing high resolution detail of the equilibrium, or most stable, state of a macromolecule. NMR structures are normally more dynamic and indicate regions of the structure that have multiple conformations. While this is also possible in crystallography, the end result of an X-ray structure looks more like a static macromolecule. Together, these two views are highly complementary in that knowledge of both the preferred molecular conformation and the possible dynamic excursions around this low energy state are important to understanding molecular function.

The final output of a structure determination project consists of a set of Cartesian coordinates for every atom in the macromolecule, i.e. a listing of their relative positions in the commonly named X, Y and Z geometric axes. Armed with an understanding of the covalent connections between protein atoms, these spatial coordinates allow construction of three-dimensional visualizations of the overall molecular structure. Whereas the "ball and stick" representation (Fig. 1a), localizing each atom (ball) and covalent bond (stick), provides the greatest wealth of detail about the molecular structure, it fails to convey important patterns about the overall structural topology. The simpler "ribbon diagram" (Fig. 1b–d) illustrates only the backbone secondary structural elements, which together assemble into an overall topological pattern. The basic elements of protein ►secondary structure include alpha-helix, beta-sheet, loop and coil regions. Initially produced as a linear chain of amino acid residues, the secondary structure folds to form the ►tertiary structure of the protein. Two or more linear chains or subunits are sometimes necessary to form the final ►quaternary structure. Despite the evolution of tens of thousands of different proteins in the human genome, it appears that far fewer structural topologies are required to carry



Structural Biology. Figure 1 Graphical depictions of protein structures. (a) "Ball and strick" representation of human growth hormone (PDB code 3HHR) compared to (b) a bockbone "ribbon diagram" of the same protein, which more clearly demonstrates its four helical bundle structural topology. Also illustrated are two additional examples of protein structural topologies: (c) the beta-sandwich from human fibronectin (PDB code 1FNF) and (d) the alpha-beta barrel, represented by human triosephospate isomerase (PDB code 1HTI).

out all the necessary functions of human biology. Examples of these fundamental three-dimensional topologies are the four alpha-helical bundle (Fig. 1b), the beta-sandwich (Fig. 1c), and the alpha-beta-barrel (Fig. 1d). Additional examples of experimentally determined protein structures can be found in the ►Protein Data Bank (PDB, http://www.pdb.org), a centralized, public database of nearly all published macromolecular structures. The PDB is a powerful resource for researchers, students and teachers alike, providing graphical tools for visualization of protein structures along with a variety of accompanying genetic, structural and functional data on each submitted molecule.

Macromolecules serve as the cell's machinery and are responsible for a vast majority of the biological activities necessary for life. The atomic level description of macromolecules derived from structural biology provides the framework for defining the fundamental mechanisms by which these molecular machines function. Oftentimes, a newly determined structure of a long-studied macromolecule provides critically needed explanation of previous experimental results. Other times, structural analyses of newly discovered proteins provide important insights into their potential biological functions and serve as a powerful guide for future investigations. The catalytic mechanisms of protein enzymes or nucleic acid ribozymes can be aided by observation of the chemical groups located in the active site of the macromolecule, generally in a series of structures with separately bound reactants, products and intermediates of the reaction. Similarly, the molecular basis of allostery, such as occurs for the binding of multiple ligands to hemoglobin, can be elucidated by comparison of multiple, differently ligated structures. Analysis of transmembrane-spanning and membrane-associated receptor proteins reveals the structural basis of cell-cell communication.

One of the most illustrative case studies of the important role played by structural biology in cancer

research involves the tumor suppressor ►p53 protein. Inactivating mutations in p53 are seen in over 50% of all tumors, highlighting its central function as a cell cycle regulator and tumor suppressor. The p53 polypeptide contains four distinct domains, which vary in their structural stability and their degree of conformational mobility. The most stable region is located in the central portion of the chain and folds into a DNA-binding domain (DBD). A vast majority of inactivating mutations are located in this domain and a combination of X-ray crystallographic structural models of the DBD complexed to nucleic acid along with complementary NMR studies have revealed the precise molecular interactions involved in transcriptional activation. Inactivating mutations directly interfere with DNA-binding, structurally destabilize the DBD, or disrupt critical protein-protein interactions required for cooperative binding of p53 oligomers to DNA. The first 100 residues in p53 are natively unfolded, as demonstrated by NMR and other complementary biophysical techniques. However, portions of this unstructured region are believed to undergo disorder-to-order transitions upon binding various regulators of p53 function. For example, co-crystallization of the p53-binding domain of MDM2, a critical regulator of p53, with its recognition sequence located in the p53 N-terminal domain reveal a helical structure for these residues. Lastly, a large body of structural studies on the "tetramerization domain," located C-terminal to the DBD in p53, have elegantly demonstrated the importance of p53 oligomerization in its function as a transcriptional activator. The tetramerization domain forms a four helical bundle with pairs of beta strands connecting adjacent helices, in what is often referred to as a "dimer of dimers" arrangement. In solution, p53 exists as mixture of dimeric and tetrameric forms in equilibrium, with the tetrameric form preferred for recognition of its DNA consensus sequence. Hence, knowledge of the structural properties of p53 has contributed to a better understanding of its function and has aided the rational design of potential anti-cancer agents, which function by enhancing the tumor suppressing activities of p53.

In the remaining portion of this essay, we will review how the three-dimensional structure of a target involved in cancer, whether a protein or nucleic acid, can be used in a variety of ways to contribute to the development of an anti-cancer drug. We will consider three different methods: (i) the screening of a target by libraries of small molecules using computational techniques, also called *in silico* design, (ii) the use of "molecular fragments" or small molecules in crystallography or NMR, respectively, to design novel compounds, and (iii) optimization of a lead compound or the study of a known therapeutic to meet unmet clinical needs.

If no small molecule inhibitors are initially available, the functional site involved in inducing cancer can directly reveal important properties – such as the volume of the functional site, the electrostatic potential of the macromolecule, atoms that can act as hydrogen bond donors or acceptors, and the overall hydrophobicity of the site – that are important for identifying a drug. Sophisticated software has been developed for ►small molecule screening of millions of compounds into this site and score the best fit of each molecule with respect to all molecules in the library. The molecules predicted to bind most tightly can then be experimentally screened against the target protein. If any of these predicted compounds have the desired chemical or biological effect, they can be used to develop a molecule that goes into clinical trials against a specific tumor or cancer.

An alternative experimental approach is to use either organic solvent molecules (in crystallography) or multiple molecules that bind to adjoining sites (in NMR) to design specific, novel molecules that bind to the active site. The crystallographic approach is known as multiple solvent crystal structures (MSCS) and attempts to find functional groups (such as amides, various alcohols, demethylformamide, acetone, etc.) to create a chemical map of where these functional groups can bind in the active site. The information gained from this approach is used by chemists to design small molecules that incorporate the functional groups in the exact position to create a new therapeutic agent. An analogous approach in solution is known as SAR by NMR. In this case, larger molecules can be used that bind to adjoining regions and can be chemically linked to create a specific compound for the molecular target.

When the structure of an approved drug is studied in complex with its molecular target, it reveals how it binds and what would be necessary to improve potency, if it becomes necessary. A perfect example of this is the ►small molecule drug Gleevec, which is used to specifically target a specific protein that causes chronic myelogenous leukemias. In some patients, mutations occur in the protein that leads to resistance to Gleevec. To overcome this problems, the three-dimensional structure of Gleevec bound to its target, ►bcr-abl, and mutants of this protein have been determined, which has led to both an understanding of how the mutants avoid binding Gleevec and the development of new compounds that are effective against the mutant protein.

Structural Maintenance of Chromosomes Protein

Definition

SMC; Protein complexes consisting of structural maintenance of chromosomes (SMC) are critical for the accurate segregation of chromosomes during cell proliferation cohesion and condensin are two members of this family. Cohesion is required to hold sister chromatids together during mitosis while condensin is required for proper organization of mitotic chromosomes to allow segregation.

Definition

The preferred local utilization within a protein complex of a locally synthesized substrate by shielding the nascent substrate from a molar excess of the same moiety in the surrounding bulk solution. The converse also occurs where that moiety is preferentially drained by an intracomplex "substrate steal" mechanism depriving the complex of essential substrate. The direction of the flux also depends on the accessibility of the relevant precursor pools. Membrane-linked multienzymes in the glycolysis pathway attached to red cell transporter proteins and the fatty acid synthase multienzyme assembly are key examples. Reference [1] and its recent update from the same group (J Biol Chem in press) provide a good example.

The relationship to cancer follows a newly discovered example that utilizes a protein–protein shield that includes one isoform of the first metastatic suppressor ever to be discovered, nucleoside diphosphate kinase (NDPK, nm23, awd) in a complex that can also include ►G proteins. This is described in reference [2] and a comprehensive set of reviews in reference [3]. Briefly, depending on the subcellular site of the complex, the isoform of NDPK and cell type, interacting components (effectors) may include an ion channel in the membrane (e.g., potassium channels). Mitochondrial examples are also known that may maintain *trans*-matrix flux across the inner/outer membranes to/from the cytosol during high demand. Substrate channeling makes it possible to repeatedly create local shielded products and arranges their flux toward or away from a process or organelle without local substrate build-up or deficiency.

Characteristics

Molecular collisions in a liquid such as a cytosol or in a semiliquid lipid membrane typically occur at over one billion per second, which generates a problem for the fidelity of precursor–product relationships in protein–protein-based reactions. These reactions require repeatedly identical products from a pair of substrate reactants say, for example, small ligands at millimolar levels collide in the surrounding water phase that itself exists at a concentration of 55,000 times excess over solute. These solute concentrations are assumed to be even throughout the cell cytoplasm. Substrate channeling challenges that notion.

The Key Features

1. A multiprotein complex contains one or more effector proteins controlling function(s) essential for cell viability (critical nodes of interacting proteins – viability interactomes) that bind one or more interacting regulatory partners involved in sensing some substrate flux. The idea posits a subspace environment (microcytosol) in the interstices of the interface between the protein components forming a shield against the bulk phase 55M water. See latest work from Sariban-Sohraby's group (in press 2007).
2. A relay signal may or may not link to feed the complex of proteins that reflect the prevailing bulk cytosol status. However, small molecules dissolved in water outside the complex do not have unfettered access to the interstices of the multiprotein complex (restricted gate).

The Prototypical Paradigm

Individually, one such protein component (NDPK) of one such complex has been repeatedly linked to the spread of different cancers either by mutation of specific residues that are either (i) known to be permissive for binding/phosphorylation interactions (protein kinase CK2 and NDPK) or (ii) by virtue of altered absolute levels of each component (disordered concentrations of either NDPK or CK2 are linked to cancer). The exact partner protein stoichiometries are unknown but examples exist in cytosol and membrane with different effectors constituting the complex such as ion channels. Thus the proposed sensor complex has the potential to utilize more than one effector protein (ion channel, G protein etc.).

Each effector (output enzyme) shares the property of slotting into some unknown surface of interaction between complexed protein kinases. One kinase is constitutively active when isolated from cells – a necessary prerequisite for a sensor! This cancer-related kinase is CK2 (formerly casein kinase 2); the second is the above dual serine–histidine kinase NDPK (NDPK-A or nm23-H1). In vitro data suggest that AMP activated kinase is also present with NDPK but the function is unknown. AMPK is occasionally misnamed by some authors as AMP-dependent kinase but AMPK was deliberately given the name AMP activated kinase by DG Hardie because of its substantial AMP-independent activity. These three kinases are always active to some degree in a resting cell replete with ATP.

Details

Epithelial Membrane. CK2 also controls the lipid transporter ABCA2 and the efflux pump function of another ABC protein (the MDR protein). Heterotrimeric G proteins receive histidine phosphate on their beta subunits directly from the high energy phosphohistidine on one isoform of NDPK. This idea is similar to control of potassium channel function by direct transfer of phosphohistidine to the target potassium channel, for example, and its removal by a local phosphohistidine phosphatase.

Mechanisms

NDPK not only transphosphorylates nucleoside diphosphates using a high energy phosphohistidine

intermediate (38 kJ/mol, compared with 8 kJ/mol for phosphoserine or phosphotyrosine) but can make this energy available for transfer to a G protein or a K channel. The key authors in the field may be found at www.dundee.ac.uk/mchs/ndpk.

Sulforaphane

Fung-Lung Chung
Department of Oncology, Lombardi Comprehensive Cancer Center, Georgetown University Medical Center, Washington, DC, USA

Synonyms

4-Methylsulfinylbutyl isothiocyanate; (-)-1-Isothiocyanato-4(R)-(methylsulfinyl) butane

Definition

Sulforaphane belongs to the isothiocyanate family. It is a hydrolysis product of glucoraphanin, a glucosinolate found in broccoli. Its molecular formula is $C_6H_{11}NOS_2$, and its molecular weight is 177.29 Da. Glucoraphanin is also known as 4-methylsufinylbutyl glucosinolate. Sulforaphane is the aglycone breakdown product of glucoraphanin, also known as sulforaphane glucosinolate (SGS). Glucosinolates are beta-thioglucoside-N-hydroxysulfates and are primarily found in cruciferous vegetables (cabbage, broccoli, broccoli sprouts, brussels sprouts, cauliflower, cauliflower sprouts, bok choy, kale, collards, arugula, kohlrabi, mustard, turnip, red radish and watercress). Young broccoli sprouts and young cauliflower sprouts are especially rich in glucoraphanin. The enzyme ►myrosinase present in cruciferous vegetables converts glucoraphanin to sulforaphane upon damage to the plant (such as by chewing).

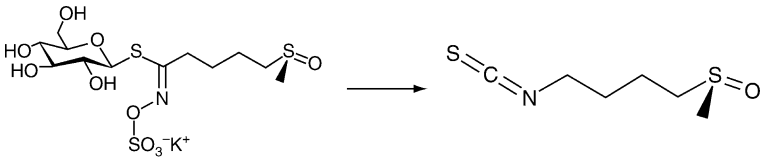
Characteristics

Actions and Pharmacology

Sulforaphane has anticarcinogenic activity in laboratory animals that are exposed to chemical carcinogens. It inhibits mammary gland carcinogenesis in rats induced by ►dimethyl benzoanthracene, colon tumorigenesis in rats induced by ►azoxymethane, and lung carcinogenesis in mice exposed to tobacco carcinogens, ►benzo(a)pyrene and ►4-(methylnitrosamino)-1-butanone (►NNK) (►Carcinogenesis, ►carcinogen metabolism, ►chemical carcinogenesis). It appears to be effective during both initiation and post-initiation (progression) stages. In addition to other cell lines, for example human colon cells, studies have also shown that in prostate cancer cells, sulforaphane can induce ►cell cycle arrest and ►apoptosis, suggesting its potential in preventing prostate cancer. However, so far no tumor bioassays in animals have been reported to test its chemopreventive activity for prostate cancer. It also has anti-bacterial activity as consumption of broccoli sprouts is effective at inhibiting *Helicobacter pylori* growth with sulforaphane being at least one of the active agents.

Mechanisms of Action

Several possible mechanisms have been studied for the chemopreventive activity of sulforaphane, notably inducing phase II detoxification enzymes, such as glutathione S-transferase and quinone reductase [NAD(P)H: (quinone-acceptor) oxidoreductase] (►Detoxification). These enzymes may confer protection against certain carcinogens and other toxic electrophiles, including reactive oxygen species. In addition to phase II enzyme induction, the induction of apoptosis and cell cycle arrest and enhancement of the transcription of tumor suppressor proteins are also likely mechanisms. Numerous studies have shown that SFN activates multiple signaling pathways in various cell lines involving protein kinases. Chief ones among them are the mitogen-activated protein kinase (MAPK) family of serine/threonine kinases, including ERK1/2, JNK1/2 and p38 that play an important role in cell proliferation and apoptosis in response to stimuli and ERK activation mediates PEITC or SFN-induced apoptosis in PC-3 cells. SFN has been shown to induce apoptosis via a p53-dependent or – independent



Glucoraphanin (–)-(R)-sulforaphane

Sulforaphane. Figure 1 Hydrolytical conversion of glucoraphanin to sulforaphane mediated by myrosinase.

pathway. Together, these studies show that ITCs can modulate the kinase pathways and transcription factors, often in a cell-specific manner. As an electrophile, sulforaphane can covalently modify thiols in proteins. The binding to cystein residues in critical proteins has been suggested to underlie its functions as a phase II enzyme inducer and may be one mechanism by which it induces apoptosis. However, detailed molecular mechanisms for the apoptosis induced by sulforaphane remain to be investigated.

Metabolism and Pharmacokinetics

Few studies have been conducted in humans on sulforaphane or its glucosinolate, glucoraphanin. However, broccoli is a rich source of sulforaphane, containing 44–56% of glucoraphanin. It has been used as a substitute of sulforaphane in several human studies to understand how it is metabolized. Like other ITCs, a major route of metabolism of sulforaphane is via the mercapturic acid pathway, involving first conjugation with glutathione (GSH) followed by enzymatic degradation to subsequent cysteinylglycine, cystein and finally N-acetylcysteine. The N-acetylcysteine conjugate is then excreted in urine as a major metabolite of sulforaphane. The bioavailability of sulforaphane from fresh broccoli is approximately three times greater than that from cooked broccoli, in which myrosinase is inactivated. Considering the cancer-chemopreventive potential of ITCs, cooking broccoli may markedly reduce its beneficial effects.

Summary

Results from cell culture and animal studies indicate that sulforaphane can inhibit chemical-induced carcinogenesis (chemical carcinogenesis), however, little direct evidence is available to support its role in protecting against cancers in humans. Epidemiological studies have shown an association of broccoli intake with a reduced risk of colon cancer. Although the active ingredients responsible for the protective effect were not identified, based on results of the animal and cell culture studies, sulforaphane may be involved.

Sulfotransferases

Hansruedi Glatt
German Institute of Human Nutrition (DIfE)
Potsdam-Rehbruecke, Nuthetal, Germany

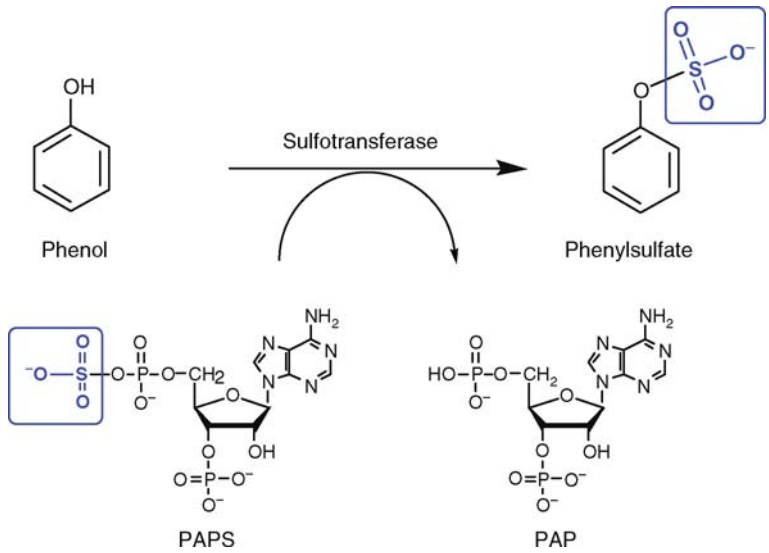
Synonyms

Sulfokinases

Definition

Sulfotransferases transfer the sulfo (SO_3) group from a donor substrate to a nucleophilic site of an acceptor substrate (Fig. 1). Whereas 3′-phosphoadenosine-5′-phosphosulfate (PAPS) serves as the sulfo donor for all eukaryotic sulfotransferases studied, the acceptor substrates are highly variable (small endogenous and ►xenobiotic molecules as well as various macromolecules) depending on the individual sulfotransferase enzyme. Sulfotransferases must not be mistaken for ►sulfatases. The latter enzymes hydrolyse sulfo conjugates. Together with sulfotransferases they regulate local and systemic levels of various hormones and the sulfation state of glycan structures.

S



Sulfotransferases. Figure 1 Sulfotransferase reaction illustrated for phenol as the acceptor substrate. In this case the sulfo group is transferred to an oxygen atom, generating a sulfooxy (sulfate) group. Other possible acceptor sites are amino and – rarely – thiol groups, leading to the formation of sulfoamino and sulfothio groups, respectively.

Characteristics

Sulfotransferases can be classified on the basis of the sulfo acceptor: (i) glycan structures of proteoglycans; (ii) carbohydrates of glycolipids; (iii) tyrosine residues of proteins; (vi) small molecules. The amino acid sequences and the gene structures are very different between these four classes.

Proteoglycan carbohydrate sulfotransferases modify sugar and aminosugar residues of glycoproteins. Nearly 30 forms are present in the human. Most forms are localized in membranes of the Golgi apparatus. Some classes of products, such as the glycosaminoglycans (heparan, chondroitin, dermatan and keratan sulfates), are modified in many different positions. This complex and variable modification requires several different sulfotransferases (including combined *N*-deacetylases/*N*-sulfotransferases). *O*-Sulfonated (sulfated) and/or *N*-sulfonated glycoproteins are important components of the cell surface and the extracellular matrix. The negative charges introduced by sulfo transfer affect interactions with other molecules, such as receptors and proteases, and can modulate their function (e.g. as co-receptors or protease inhibitors).

Protein tyrosine sulfotransferases (two forms in the human) modify tyrosine residues of proteins. The tyrosine sulfation motif is identical to the tyrosine phosphorylation motif, and both modifications involve the same increase in mass (80 Da). Nevertheless, there is no competition between these post-translational modifications, as they occur in different cellular compartments. The protein tyrosine sulfotransferases are integral membrane proteins of the Trans Golgi Network. Most tyrosine-sulfated proteins are secretory, others are incorporated into lysosomal and plasma membranes. Protein tyrosine sulfation is irreversible.

A glycolipid sulfotransferase localized in the Golgi apparatus catalyses the formation of various sulfated glycolipids, such as cerebroside sulfate (a major component of myelin) and seminolipid (found in testis).

The fourth class of sulfotransferases modifies small molecules. These enzymes are soluble proteins and are usually localized in the cytoplasm. However, some forms are enriched in cell nuclei in some tissues. Most are present as homodimers with subunit masses of 30.5–41.3 kDa (human forms). Monomeric and heterodimeric proteins may also occur. These sulfotransferases are members of a single superfamily, termed ►SULT. Using the degree of amino acid sequence identity as a guide, the SULT superfamily is further classified into families (SULT1, 2, 4 and 6 in humans), subfamilies and individual forms of subunits (13 in humans). Some SULTs play an important role in the regulation of local and systemic levels of endogenous compounds: SULT1A3/1A4 (identical protein encoded by two different genes) for catecholamines, ►SULT1E1 for estrogens, and SULT2 enzymes for various alcoholic steroids, bile acids and cholesterol (hydroxysteroid and alcohol sulfotransferases are trivial names for the SULT2 enzymes). However, all these forms also metabolize certain xenobiotics with high efficiency. ►SULT1A1, the most abundant SULT form in humans, is characterized by very broad substrate tolerance

towards xenobiotics and a moderate catalytic efficiency for various endogens substrates (estrogens, iodothyronines and catecholamines), for which it may serve as a backup enzyme in the absence of more specific SULT forms. The primary functions of the remaining human SULT forms is less clear, although a number of endogenous and xenobiotic substrates have been identified, except for SULT4A1, a form specifically expressed in brain. Not only no substrate has been found for this form; it also lacks the ability to bind PAPS, the common co-substrate of sulfotransferases. The amino acid sequence of SULT4A1 is conserved to an unusually high extent between different mammalian and other vertebrate species, suggesting an important, hitherto unknown function. Other forms may also have undetected functions in addition to their sulfo transfer activities.

With the striking exception of SULT4A1, the SULT superfamily shows high evolutionary dynamics. While a single SULT1A gene has been detected in all non-primate species investigated, four genes occur in the human. The non-primate enzymes (SULT1A1) metabolize both xenobiotics and catecholamines; they are supported in these functions by SULT1D1. On the contrary, humans have SULT1A enzymes specialized for catecholamine metabolism (encoded by the *SULT1A3* and SULT1A4 genes), and other forms with enhanced xenobiotic-metabolizing activity but strongly decreased affinity for catecholamines (SULT1A1 and SULT1A2); moreover, the SULT1D1 gene is degenerated to a pseudogene in humans. An opposite situation is found for the SULT2A subfamily, which comprises a single form in humans, but at least three different forms in mice and rats. Sexual dimorphism of hepatic expression is another species-dependent characteristic of many SULTs. This dimorphism is dramatic in young adult rats, with Sult1c1 and Sult1e1 exclusively expressed in males and the various Sult2a enzymes exclusively or predominantly expressed in females. Such sexual dimorphisms are absent or minute in humans, much below the interindividual variations within the sexes.

Sulfotransferases and Cancer

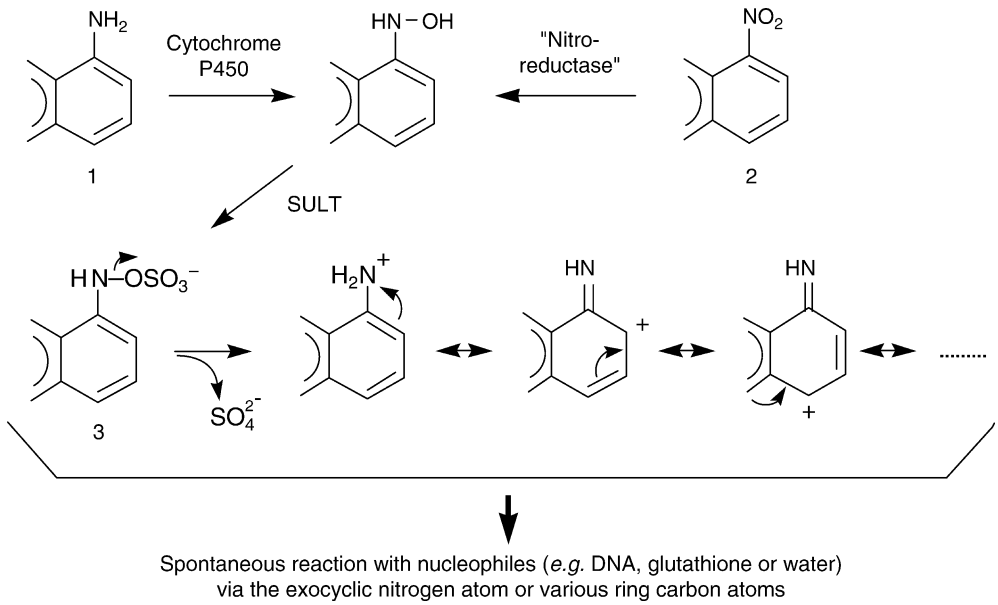
The expression of many sulfotransferases strongly depends on the type and the differentiation state of cells. Changes in levels and patterns of proteogylcan carbohydrate sulfotransferases, glycolipid sulfotransferases and SULTs have often been reported between normal, preneoplastic and neoplastic cells, but without elucidation of the causal relationships. In principle, sulfation-dependent alterations in cell-cell, cell-matrix and protein-protein interactions on the plasma membranes could trigger the process of carcinogenesis. More specific connections with carcinogenesis can be made for SULTs, as they metabolize hormones, carcinogens and anti-cancer drugs.

Estrogen-dependent tissues are major sites of the expression of SULT1E1, which probably is used for tuning the estrogen responsiveness. In the endometrium, SULT1E1 expression strongly varies during the menstrual cycle, roughly in an anti-parallel manner to the expression of the ►estrogen receptor, and is up-regulated in pregnancy. SULT1E1 is present in normal mammary cells, but not in tumor cells. This difference may lead to an increased local level of active estrogen hormones in tumor cells.

Numerous chemical carcinogens require metabolic activation to electrophilically reactive intermediates that can covalently bind to DNA and induce mutations. 2-Acetylaminofluorene was the first carcinogen for which an activation pathway was elucidated. It involved *N*-hydroxylation followed by sulfo conjugation. The *in vitro* findings were corroborated *in vivo*: inhibition of SULT or PAPS deficiency abolished, or drastically decreased, the hepatocarcinogenicity of 2-acetylaminofluorene and *N*-hydroxy-2-acetylaminofluorene in mice and rats. Meanwhile it is evident that SULTs are involved in the formation of reactive, mutagenic and potentially carcinogenic metabolites from many compounds. The reason is in the fact that sulfate is a good leaving group in certain chemical linkages, e.g. when the resulting cation is resonance-stabilized (Fig. 2). Thus, SULT- or *N*-acetyltransferase-mediated esterification usually represents the final activation of various homo- and heterocyclic nitro-, amino- and amidoarenes (Fig. 2). The relative importance of the various SULTs and *N*-acetyltransferases in this activation strongly depends on congener, species and tissue. Other rodent carcinogens that can be activated by SULTs to mutagens include some alkylated polycyclic aromatic hydrocarbons (e.g. 1-methylpyrene), alkenylbenzenes (e.g. safrole), nitroalkanes (e.g. 2-nitropropane), steroidal drugs (e.g. cyproterone acetate), schistosomacidal drugs (e.g. hycanthone) and anti-estrogens (e.g. ►tamoxifen).

SULT-mediated activation is not detected in standard *in vitro* mutagenicity tests, as these systems are SULT-deficient. Addition of an external SULT system is not a reliable remedy for this shortcoming, as sulfo conjugates are charged and may not penetrate into the target cells. cDNA-mediated expression of SULTs within the target cells is a more appropriate alternative. In general, a given promutagen is only activated by a small number of SULT forms, which vary for different promutagens.

In the rat, SULT expression is strongly concentrated to the liver. This is true in particular for those forms that are capable of activating many different promutagens. Indeed, SULT-dependent carcinogens usually induce liver tumors in the rat. The kidney is a potential target for those reactive sulfo conjugates that are sufficiently stable to be transferred via the circulation to this site. Various human SULTs have a much wider tissue distribution than rat SULTs. Thus, it is important to



Sulfotransferases. Figure 2 Metabolic activation of aromatic amines (1) and nitroarenes (2) to reactive sulfuric acid esters (3). In general, these esters are very short-lived in water ($t_{1/2}$ < 1 s). Note that the heterolytic cleavage is not a reversal of the SULT reaction, as the leaving sulfate group contains an additional oxygen atom. "Nitroreductase" is not a specific enzyme in mammalian cells, but a side activity of various enzymes primarily catalyzing other reactions (such as xanthine oxidase, cytochrome P450 reductase and quinone reductase).

consider other candidate target tissues in humans beside the liver and kidney.

Human SULT1A1 is able to activate a particularly wide range of diverse promutagens. However, it also forms stable sulfo conjugates from a much larger number of other xenobiotics and thus may contribute to their detoxification. SULT1A1 shows a common polymorphism, involving a ^{213}Arg/His exchange, which affects enzyme expression and activity. Furthermore, this polymorphism is genetically linked with another functional polymorphism in the neighbouring SULT1A2 gene. The incidence of various tumors significantly differed between SULT1A1 genotypes in epidemiological studies. The high-activity genotype was associated with a reduced risk in some cases and an elevated risk in other cases. Possibly, these findings reflect the dual role of SULT1A1 in detoxification and toxification of xenobiotics.

►Aminoflavone, an aromatic amine, is a new cytostatic drug entering clinical trials. It requires bioactivation by ►cytochromes P450 and SULTs (pathway 1–3 in Fig. 2). The growth-inhibiting activity of aminoflavone in 60 human tumor cell lines was primarily determined by the level of expression of SULT1A1.

The anti-estrogenic activity of tamoxifen, a drug used in the treatment of mammary tumors, is mainly due to its metabolite 4-hydroxytamoxifen, which has much higher affinity for estrogen receptors than the parent drug. 4-Hydroxytamoxifen is a good substrate of SULT1A1. Surprisingly, the high-activity genotype of SULT1A1 was associated with an increased survival time in tamoxifen-treated women with breast cancer; among patients who did not receive tamoxifen, there was no association between survival and SULT1A1 genotype. Thus, it appears that sulfation of 4-hydroxytamoxifen provides a benefit whose mechanism remains to be elucidated.

In conclusion, SULTs are involved in the metabolic activation and inactivation of carcinogens, the regulation of hormones interacting with tumors, and the activation and inactivation of some anti-cancer drugs. Sulfotransferases that modify macromolecules might also play a role in carcinogenesis, as sulfated and *N*-sulfonated macromolecules are major constituents of the plasma membrane and the extracellular matrix, which are important for cell-cell interactions.

SULT

Definition

Acronym for the gene superfamily encoding soluble sulfotransferases.

►Sulfotransferases

SULT1A1

Definition

Most abundant soluble sulfotransferase in the human organism. It facilitates the excretion of numerous drugs and other ►xenobiotics. It also catalyses the final activation step of various carcinogens and the anticancer drug ►aminoflavone.

►Sulfotransferases

SULT1E1

Definition

Sulfotransferase form with high affinity for estrogens, primarily expressed in estrogen-dependent tissues (for tuning estrogen responsiveness) and in human small intestine (for inactivating dietary estradiol/estrone) and liver. A small number of promutagens are activated by SULT1E1 with much higher efficiency than by other sulfotransferase forms.

►Sulfotransferases

Sumoylation

Definition

Is the reversible, covalent attachment of SUMO, a ubiquitin-like protein (Ubl). Many proteins, such as transcription factors, are regulated by sumoylation. Often sumoylation acts antagonistic against ►ubiquitination, preventing proteins from being degraded. Sumoylation is important for the regulation of DNA damage repair and for the maintenance of genome integrity. There is evidence that sumoylation is involved in cancer metastasis.

Sun Light Induced Cancer

►Photocarcinogenesis

Sunbeds

Definition

The device used for tanning with an artificial source of ►UV radiation may be referred to as a sunbed, a sunlamp, artificial UV, artificial light, a tanning bed, among other terms. Also, a number of terms are used to define a place where indoor tanning may occur: solarium, tanning salon, tanning parlor, tanning booth, indoor tanning salon, indoor tanning facility. In addition, indoor tanning may take place in private, non-commercial premises.

Sunitinib

Definition

Is a small molecule that blocks the ►vascular endothelial growth factor receptor as well as other receptors. It has antiangiogenic and anticancer properties.

►antiangiogenesis

Superantigens

Definition
A class of antigens, including certain bacterial toxins, that unleash a massive and damaging immune response.

Supercooled Phase

Definition
Phase without ice formation, which occurs firstly when tissue is subjected to a constant lowering temperature.

►Cryosurgery in Bone Tumors

Supercooling

Definition
In cryosurgery, pure water with a subzero temperature.

►Cryosurgery in Bone Tumors

Superoxide Dismutase

Definition
SOD; Is an important intracellular antioxidant defense mechanism that catalyzes the dismutation of superoxide into oxygen and hydrogen peroxide. The three mammalian types of enzyme differ with respect to their intracellular localization and the metal atom within their active center (Cu, Zn, or Mn). Overexpression of SOD in cancer cell lines induces an increase in H_2O_2 production and reduces tumor growth.

►Oxidative Stress
►Photodynamic Therapy

Superoxide Radical

Definition
Chemically, an oxygen molecule to which one extra electron has been added, giving it a negative charge. O_2^-

►Nickel Carcinogenesis

Supervised Classification

[2]Department of Theoretical Bioinformatics, German Cancer Research Center, Heidelberg, Germany

Synonyms
Supervised (machine) learning

Definition
Supervised classification is the process in which an artificial system (usually a computer program) is used to generate a predictive model (►Classifier) based on numerical feature descriptions of real-world observations (samples) that are grouped in at least two different categories (classes). The objective of this process is to establish a classifier that predicts with a minimal error the class of new samples that have not been used for construction of the classifier.

Characteristics
Clinical management and basic research of heterogeneous diseases, such as cancer, increasingly covers sophisticated technical systems and laboratory assays that may generate large volumes of high-dimensional data. A prominent example from the field of cancer research is genome-wide expression analysis using ►microarray technology, an approach that may yield tens of thousands of data points (gene-expression levels) for a single biological sample. These comprehensive analyses may reveal important information on the underlying biological phenotype of the sample and are frequently applied to identify novel ►biomarkers for disease outcome or response to therapy. However, processing, analysis and interpretation of this high-dimensional data is not trivial. Deriving

proper conclusions from such complex measurements therefore requires sophisticated computational methods in order to reliably classify the phenotype of each sample. The process in which a computational method is applied to generate or apply a diagnostic or prognostic tool for phenotype classification of a biological sample is called supervised classification.

The techniques applied in supervised classification have their origin in machine learning research and have been developed for the task of learning by examples: Certain real-world observations of interest (samples) can be grouped in different categories (classes). The attributes (features) of the samples can be described, e.g., by numerical quantification through a measurement. The central question addressed by supervised classification approaches is: "Given the features and class labels of an exemplary set of samples (training set), can a pattern of feature values be derived that is indicative of a certain class and is therefore able to accurately predict the class of new samples that were not used for learning (test set) based on their feature description?" Different techniques have been contrived for the task of learning by examples, however, the general framework for the process of supervised classification typically follows a certain standard: A learning machine (a computer program) is confronted with a data set of training samples for which the class affiliation is known and derives a predictive model. This subprocess is known as ►model selection. The predictive value of the derived model is then determined by its ability to generalize from the given set of training samples, i.e., to predict with minimal error the class of new samples that have not been used for classifier generation. This subprocess is also referred to as ►model testing.

Clinical Relevance

In cancer research, techniques for supervised classification have been used particularly for data from molecular and cell biology endeavoring to identify novel biomarkers from ►DNA microarray experiments for gene-expression profiling or comparative genomic hybridization (►ArrayCGH), ►microRNA expression analyses, mass spectrometry or ►proteinchip profiling. The endpoints predicted in such studies usually either cover the classification of disease subtypes, the prediction of patients' outcome or the prediction of response to a certain therapy. With growing experience in dealing with high-dimensional data from these techniques it has become evident that a universally best method for classifier creation does not exist. Therefore, an abundance of strategies and algorithms have been described that may be successfully utilized for supervised classification. Some of the more frequently used learning algorithms are: Linear Discriminant Analysis, Decision Trees, Support Vector Machine (SVM) Learning, Artificial Neural Networks (ANN), and the Nearest Shrunken Centroid Analysis (also known as "Prediction Analysis of Microarrays," PAM).

Caveats and Recommendations

Before tools derived from supervised classification approaches can be used in a clinical setting, it is mandatory that they are both highly accurate and reproducibly applicable. Studies that propose novel predictors by supervised classification should therefore mind the following recommendations:

1. A classifier is not sufficiently characterized by a list of its features. Therefore, a detailed description of the algorithm used and the parameters of the derived predictive model is mandatory. Only a thorough description of the application of supervised classification techniques guarantees reproducible results.
2. Proper evaluation of generated predictive models is mandatory before these models can be introduced into a clinical setting. With high-dimensional data, the number of measured features exceeds that of available samples for classifier construction by far (the feature to sample ratio is high). As a consequence, there is a big threat for "overfitting" classifiers to the unique set of samples from which they have been derived. In this context, overfitting means that although the classifier performs good results on the training set of samples (and therefore seems to "fit" this set quite well) its predictive power might turn out to be poor in an independent data set. To avoid the problem of overfitting, stringent evaluation of a generated classifier should be performed by proper (cross) validation. This implies the use of large sets of samples that have not been used for classifier generation (independent samples).

   In principle, it is advisable to follow the recommendations of Simon and Altman, who suggest classifying studies that promote new diagnostic or prognostic tools into one of three phases. Studies showing an association of a new prognostic factor with real outcome or an improved prognostic performance in comparison to established markers are categorized as phase I or II. Studies investigating the hypothesis that a newly created prognostic tool emanating from phase I and II studies can be independently validated on a large cohort of new patients are of phase III. Only classifiers that successfully pass all three study phases should be considered for utilization in the clinical setting.
3. High classification accuracy of a predictor does not imply biological relevance of its features. A big caveat needs to be put to this fact as even predictive

models with extraordinary accuracy will comprise neither all nor only features that are functionally related to the phenotype of the disease. Deducing biological importance from high discriminative power of features will be misleading in the vast majority of cases. Furthermore, utilizing different algorithms will lead to distinct predictive models, all of which may classify a given set of samples with similar accuracy although they are composed of varying sets of features.

Abiding by these recommendations may save from many of the pitfalls of supervised classification. When applied and evaluated properly, supervised classification approaches will undoubtedly play an important role in the development of improved cancer diagnostics, optimized risk stratification and more individualized, patient-tailored therapy.

Supportive Care

Sanchia Aranda
School of Nursing, The University of Melbourne, Carlton, VIC, Australia; Peter MacCallum Cancer Centre, Melbourne, VIC, Australia

Synonyms

Palliative care

Definition

Supportive care refers to those services, both specialist and generalist, that might be required by people affected by cancer (patients and family members) to meet the many needs associated with cancer and cancer treatment. Thus supportive care is provided across the continuum of the cancer journey, from the point when the possibility of cancer is first raised, through diagnosis and treatment and into palliative care or survival.

Characteristics

Supportive care has been referred to as an 'umbrella' term to describe the many services involved in assisting people affected by cancer and their families to live well and manage the many needs that arise from having cancer and receiving cancer treatment. There is growing evidence that the needs of people with cancer are numerous and that despite increased awareness by health professionals about these needs they frequently remain unmet. Needs relate to many domains but are often classified as informational, physical, psychological and existential. There is also growing recognition that these unmet needs affect both short and long-term outcomes for people with cancer and their families and require more formal approaches to ensure support outcomes are improved. The increasingly organized approach to supportive care in cancer is notable in the formation of the Multinational Association of Supportive Care in Cancer (MASCC) in 1990. MASCC recognizes supportive care to encompass all aspects of care beyond those involved in direct cancer disease management and as involving a range of disciplines and specialists including doctors, nurses, social workers, psychologists, dentists, researchers, educators and others.

Supportive care encompasses many common elements of care provision such as symptom control, rehabilitation, psychological support, self help, information provision, patient education, complementary therapies, spiritual care and palliative care. High quality supportive care assists patients to continue potentially curative cancer treatment, to live well with advanced disease, to manage the return to "normal" as a cancer survivor and to focus on quality living at the end-of-life. Supportive interventions can range from pharmacological interventions such as antiemetics through to psychological interventions such as cognitive behavioral therapy. All health professionals involved in cancer care delivery will be involved in the delivery of supportive care to people affected by cancer and their families and thus such care requires a team approach.

Perhaps the most important related term is palliative care as in many ways the term supportive care seeks to widen the commonly understood elements of palliative care to aspects of cancer care not traditionally understood as requiring palliative care involvement.

Palliative care, as distinct from ▶palliative therapy (as defined elsewhere in this collection) aims to improve the quality of life of people facing life-limiting and terminal illness through provision of pain and symptom relief and attention to the broader psychosocial and existential needs. While many aspects of palliative care are applicable earlier in the course of cancer many people affected by cancer, their families and health providers find the close association between palliative care and end-of-life care a barrier to earlier engagement of these services in meeting non end-of-life support needs. Palliative care is also not recognized as extending beyond cancer treatment into survivorship. Examples of support needs where palliative care services might usefully be included in earlier parts of the illness trajectory include the management of symptoms associated with cancer treatment such as pain from chemotherapy induced mucositis and the psychosocial support of patients and families who face a crisis of meaning following the diagnosis of cancer. However it is more difficult to define other supportive needs as being palliative care, such as pre-chemotherapy education, learning to talk after a laryngectomy or managing issues such as return to work following successful cancer treatment. The rise of modern palliative care has been the catalyst for increased attention to the wider supportive care needs of people with cancer and their families but the term supportive care captures this broader focus of meeting these other support needs.

Supportive care services rely on several key elements for success: assessment of supportive care needs, discussion with patients and families about their priorities for support, referral to appropriate specialist services including the possibility of self-referral and access to appropriate health and support information to enable to patient to understand what is happening to them, to engage in self-care and to participate fully in health related decision making.

Four key principles appear to drive the development of supportive care services internationally in that they are commonly featured in the literature on this topic:

- Supportive care needs require an individualized approach
- Patients and carers are critical members of the supportive care team
- A multidisciplinary and coordinated approach is essential
- The development of an evidence base for interventions to improve supportive care outcomes

Supportive Care Needs Require an Individualized Approach

While supportive care needs are able to be identified, classified and measured amongst groups of patients with similar cancers or receiving similar cancer treatments, to be effective approaches to supporting people with these needs must take account of the person's unique situation. Providing information and support that is tailored to a person's expressed needs improves outcomes. Tailoring of supportive care services to the individual's situation means taking account of their life orientation, values, response to illness, existing support system and goals for care. What is a major problem and cause of distress for one patient or family member might be of only minor concern to another. Thus central to the provision of supportive care services is an ongoing dialogue with the person affected by cancer and their family to ensure appropriate responses to the needs they experience.

Patients and Carers are Key Members of the Supportive Care Team

Importantly supportive care is not the sole domain of qualified health professionals, as is the case in disease related treatment. Indeed patients and their families are considered to be an important component of supportive care delivery. The premise is that supportive care services should allow care to be delivered in home and community settings and that people affected by cancer should be involved in service design and in the development of novel interventions for testing in robust clinical trials.

For many people affected by cancer being at home is made possible through personal and family/friend involvement in supportive care delivery. Supportive care provided by patients and their family/friends can range from technical care such as the management of medications and central venous access devices, through instrumental and daily living care such as assistance with hygiene, mobility and household chores through psychosocial support to cope with the emotional demands of a cancer diagnosis, its treatment and ongoing adverse side effects. Cancer treatment is now largely delivered in the ambulatory setting and thus supportive care interventions increasingly focus on improving the capacity of patients and their significant others to undertake self-management of the many demands of cancer treatment.

A Multidisciplinary and Coordinated Approach

The supportive care needs expressed by people affected by cancer are varied and often complex; this complexity often requiring the input of multiple health professionals. For example, the management of the oral mucosa during chemotherapy might involve a dentist to undertake a pretreatment check and correction of caries, a dental hygienist to remove plaque build-up, a nurse to assist with daily oral hygiene reinforcement and oral assessment to minimize oral complications, enable early detection, and manage oral analgesics, a palliative care physician to manage severe pain and a dietician to assist with maintenance of the patient's nutritional

status. No one discipline will successfully manage these support needs alone.

Supportive care also often requires the involvement of several settings of care such as acute, primary and home care. Coordination of care becomes a key feature of supportive care delivery with a high need for attention to information flow and the avoidance of gaps and/or duplication of care.

In reality many of the disciplines required to be involved in supportive care, such as dieticians, physiotherapists and clinical psychologists, are not well established as specialist disciplines in cancer care in many parts of the world and are also poorly captured in the systems that fund cancer services. This means that the burden of paying for supportive care services, such as those involved in return to work programs or long-term enteral feeding, are part of the large out-of-pocket expenses faced by many people following cancer treatment.

The Development of an Evidence Base to Interventions to Improve Supportive care Outcomes

As the multiple supportive care needs of people affected by cancer have become better recognized so has the need for an evidence base to guide clinicians in how to best address these needs. The increasing focus on supportive care highlights the paucity of evidence to guide interventions to prevent or reduce supportive care needs. In the United Kingdom national guidance has been developed for supportive and palliative care but is largely based on levels of evidence from consensus or descriptive studies with few randomized controlled trials. As a result in many western countries there is an emerging emphasis being placed on the development of research capacity in supportive care. Governments, such as in Canada, the United Kingdom and Australia, recognize that appropriately used *Supportive Care Interventions* can reduce time in hospital, improve quality of life and increase patient satisfaction with health services.

One of the most critical areas of supportive care where there is a growing evidence base is in meeting the psychosocial needs of people affected by cancer, with a specific emphasis on evidence-based communication. Guidelines in this area establish a strong mandate for enhancing the training of health professionals in good communication skills, particularly around the delivery of health information and in eliciting and responding to the patient's concerns. However, even in this area much of the research has focused on women with breast cancer and may miss some of the subtleties of providing for the psychosocial needs of men and individuals with other cancers.

The increasing attention on research is evidenced by the development of specialist journals on supportive care such as Supportive Care in Cancer and The Journal of Supportive and Palliative Care and the creation of a WHO Collaborating Center for Supportive Cancer Care at the MD Anderson Cancer Center in Houston Texas. However, there remain many gaps in the knowledge on how best to prevent, minimize, manage and recover from the many adverse effects of having, receiving treatment for, living with, dying from or surviving cancer.

Conclusion

Supportive care is becoming recognized as a key component of cancer management, standing alongside medical, surgical and radiation treatments to ensure best physical, psychological and social outcomes for people affected by cancer and their families. However there are many barriers to best practice in supportive care including funding, the lack of a strong evidence base in many areas and shortages of specialist services in many disciplines. It is imperative that cancer control programs work to capture the supportive care needs of people affected by cancer and foster research into the best interventions to prevent and minimize these needs is established.

Suppressors of Cytokine Signaling

Zoran Culig
Department of Urology, Innsbruck Medical University, Innsbruck, Austria

Synonyms

SOCS

Definition

Suppressors of cytokine signaling (►SOCS) and the cytokine-inducible SH2 protein CIS regulate the responses of various cells to ►interleukins and other cytokines. They are rapidly induced after treatment with a cytokine. SOCS prevent prolonged activation of the signaling pathway of Janus kinase (►JAK)/►signal transducer and activator of transcription (►STAT).

Characteristics

The SOCS/CIS family has eight members: SOCS-1, -2, -3, -4, -5, -6, -7, and CIS. They are composed of an amino-terminal domain of variable length, central ►SH2 domain, and a carboxy-terminal 40-amino-acid module known as SOCS box. Expression and function of SOCS-1, -2, -3 and CIS were characterized in most studies.

SOCS-1 and SOCS-3 downregulate JAK tyrosine kinase activity due to the presence of an inhibitory region in their amino-terminal domain. SOCS-1 could bind directly to JAK kinase through its SH2 domain, whereas SOCS-3 SH2 domain binds the signal-transduction subunit gp130 of a cytokine receptor. The SOCS box is important for interaction with the ubiquitin-transferase system. It suppresses oncogenic activity of the TEL gene fused to JAK2 and STAT phosphorylation in hematopoietic cells. This part of the molecule is involved in the degradation of the nucleotide exchange factor Vav and the papilloma virus oncoprotein E7. SOCS-1 and -3 are major negative regulators of signaling of ►interleukins (IL), in particular ►IL-6, through inhibition of prolonged activation of the JAK/STAT pathway. Mice deficient of SOCS-1 die due to a myeloproliferative disorder caused by uncontrolled ►interferon-gamma and ►tumor necrosis factor-alpha signaling. Deletion of SOCS-3 is associated with polycythemia, a premalignant form of erythroid ►leukemia.

SOCS proteins also interact with either ►insulin-like growth factor or ►insulin receptors thus diminishing the effect of these antiapoptotic molecules. Both regulators of cytokine signaling degrade insulin receptor-substrate-1 and -2 thus inhibiting action of the ►insulin-like growth factors in target tissues.

CIS and SOCS-2 bind to phosphorylated tyrosine residues on activated cytokine receptors. Cytokines which induce ►STAT5, such as ►prolactin, ►erythropoietin, IL-2, -3, and growth hormone signal via upregulation of CIS. Similarly, SOCS-2 acts as a ►negative feedback regulator of growth hormone signaling. SOCS-2-deficient mice present with liver hypertrophy, increase in serum levels of ►insulin-like growth factor-I, and weight.

Role of SOCS-1 in Cancer

SOCS proteins are considered tumor suppressors in most human malignant neoplasms on the basis of expression and functional studies. The expression of SOCS-1 and SOCS-3 is reduced in several tumors in which IL-6 acts as a pathogenetic factor. Mice with haploinsufficiency of the *SOCS-1 gene* develop severe liver fibrosis. In these animals, the development of ►hepatocellular carcinoma was accelerated. Expression of SOCS-1 is decreased in hepatocellular carcinoma because of frequent hypermethylation of CpG islands. It was found in 65% of analyzed liver carcinoma samples. Transfection of hepatocellular carcinoma cells with SOCS-1 cDNA resulted in a reduced growth rate and anchorage-independent growth.

►Epigenetic changes in the *SOCS-1 gene* promoter were also observed in tumors derived from gastrointestinal tract, ►lung cancer, ovary, pancreas, as well as myeloma and chronic lymphoid leukemia. SOCS-1-deficient animals increasingly develop ►colorectal tumors. Decreased SOCS expression because of changes in ►epigenetic mechanisms or increased

degradation leads to continuous activation of JAK2 and STAT thus promoting tumor growth.

JAK activation in cancer could be caused not only by IL-6 and related cytokines but also by ►Src kinase. SOCS could inhibit JAK/STAT activity induced by the cytokines of the IL-6 family but not that induced by ►Src. SOCS-1 is a negative growth regulator of cells transformed by the Kit receptor tyrosine kinase or the v-Abl oncogene. Tumorigenicity and metastatic activity of Tel-JAK2 and Bcl–Abl cells were diminished by expression of SOCS-1. Tumors that overexpress v-Abl may bypass the inhibitory effect of SOCS-1 through phosphorylation, disruption of its interaction with ►elongin, or inhibition of proteasomal (►Proteasome) targeting of JAK.

SOCS-1 expression increased in human ►melanoma in comparison to melanocytes in normal skin and melanocytic nevi. In contrast to several solid neoplasms, SOCS-1 expression correlates with tumor invasion and could be considered a progression marker in melanoma. SOCS-1 mutations were frequently detected in primary mediastinal B-cell and ►Hodgin lymphoma and are associated with increased nuclear phospho-STAT5 accumulation. Thus inadequate action of SOCS-1 in cancer leads to a hyperactivation of signaling through the STAT pathway.

SOCS-3 in Human Cancer

The role of SOCS-3 in human cancer is similar to that of SOCS-1. Its expression is decreased in lung, head and neck, and liver cancer. SOCS-3 promoter hypermethylation was frequently observed in these tumors. Deregulation of the ►STAT3 pathway was reported in cutaneous lymphoma cells in which constitutively active STAT3 and SOCS3 are simultaneously expressed. SOCS-3 levels in lymphoma were reduced by transfection of the dominant-negative STAT3. Under these experimental conditions, the cells became more sensitive to an effect of ►interferon-alpha.

SOCS-1, -2, and -3 and CIS transcripts and immunoreactive proteins are elevated in in situ ductal and invasive ►breast cancer. It seems that SOCS exhibit their action in regulation of STAT3 in tumors in cooperation with other proteins such as ►caveolin. These interactions may be critical for the outcome of STAT3 phosphorylation in breast and ►prostate cancer. Estrogenic induction of SOCS3 in breast cancer cells was blocked by the pure estrogen receptor antagonist ICI 182,780.

IL-6 causes a variety of biological effects in prostate tumors. They may include inhibition of proliferation but also promotion of survival of tumor cells and stimulation of ►angiogenesis. In prostate cancer, the expression of SOCS-3 was investigated in a number of cell lines. SOCS-3 mRNA and protein were found in cells in which there is no expression or phosphorylation of STAT3. In contrast, SOCS-3 was not detectable in LNCaP cells in which treatment with IL-6 induces STAT3 phosphorylation, growth inhibition, and terminal ►neuroendocrine differentiation. Loss of SOCS-3 in that cell line is a consequence of gene promoter hypermethylation. SOCS-3 expression is higher in samples of prostate cancer compared with those obtained from benign tissue. Upregulation of SOCS-3 in prostate and pituitary cancer cell lines was observed after treatment with an AMP derivative. Agents that elevate intracellular ►cAMP cause an inhibition of proliferation and stimulation of ►apoptosis in prostate cancer cells. siRNA approach revealed that SOCS-3 acts as a negative feedback regulator of action of hormones that induce increased cAMP levels.

SOCS-2 in Malignant Diseases

Compared with SOCS-1 and -3, there is a more limited evidence supporting global role for SOCS-2 as a tumor suppressor or promoter. SOCS-2 levels are elevated in BCR–ABL tyrosine kinase-positive in comparison to BCR–ABL-negative chronic myeloid leukemia cell lines. They also increased in patients with chronic myeloid leukemia in blast crisis. SOCS-2 is a component of a BCR–ABL-►negative feedback mechanism. It could inhibit some of its effects in leukemia cells. Leukemia cells, however, develop a resistance to inhibitory effects of SOCS-2. SOCS-2 is induced by estrogen and growth hormone in hepatoma and breast cancer cells.

In short, SOCS proteins are involved in regulation of cellular events in cancer tissue. In most tumors, their expression decreases because of epigenetic changes in respective gene promoters. SOCS reexpression in some of the cancer cell lines leads to retardation of tumor growth. In breast and prostate cancer, SOCS elevation may prevent oncogenic signal transduction through the JAK/STAT signaling pathway.

Suramin

Definition

Is a polysulfonated naphthyl urea, inhibiting ►heparanase with an IC_{50} of 48 μM. Suramin inhibited B16 melanoma cell invasion (IC_{50} = 10 μM) through reconstituted basement membrane, but had no effects on melanoma cell growth. Suramin has not been widely used because it has significant toxic effects in humans, including neurotoxicity, renal toxicity, adrenal insufficiency and anticoagulant-mediated blood dyscrasias. In efforts to avoid these side effects, analogs of suramin have been synthesized and are undergoing evaluation. Compounds NF 227, NF 145 and NF 171 are three such analogs, all of which possess heparanase inhibitory activities more potent than that of suramin (the IC_{50} values were 20–30 μM). These compounds effectively inhibited heparanase-mediated ►angiogenesis in an animal model.

Surface-Enhanced Laser Desorption/Ionization Time of Flight Mass Spectrometry

Definition

Time-of-SELDI-TOF MS; Is an approach that combines two powerful technologies, retentate chromatography and MS. The core of the SELDI-TOF MS platform is the proteinchip arrays, which have varying chromatographic properties, such as anion exchange, cation exchange, metal affinity, and reverse-phase. The SELDI-TOF MS provides on-chip separation as well as the capability to perform enzymatic reactions directly on the chip. Various complicated biological materials can be uniformly captured, concentrated, and purified on the small chemical surface of the chip. To be able to identify the proteins, the complexity of the sample was reduced by fractionation approaches. A complex mixture of proteins from cells or body fluids can be reduced to sets of proteins with common properties by binding the sample to chips with differing surface chemistries in parallel and in series.

Surface Plasmon Resonance

Bong Hyun Chung, Moonil Kim, Yong-Beom Shin
BioNanotechnology Research Center, Korea Research Institute of Bioscience and Biotechnology, Yuseong, Daejeon, Republic of Korea

Definition

►Surface plasmon resonance (SPR) is one of several optical phenomena known to occur on two-dimensional metal surfaces (typically gold or silver films) when a total internal reflection of incident light occurs at the interface of two different substances, one with a high refraction index and the other with a low refraction index. The SPR ►biosensor, which exploits the SPR phenomenon, is a label-free and surface-sensitive spectroscopic system, which utilizes measured changes in the local refraction index upon adsorption. This sensor may be applicable to disease diagnostics and ►high-throughput screening (HTS) in drug discovery, as well as to studies of biomolecular interaction.

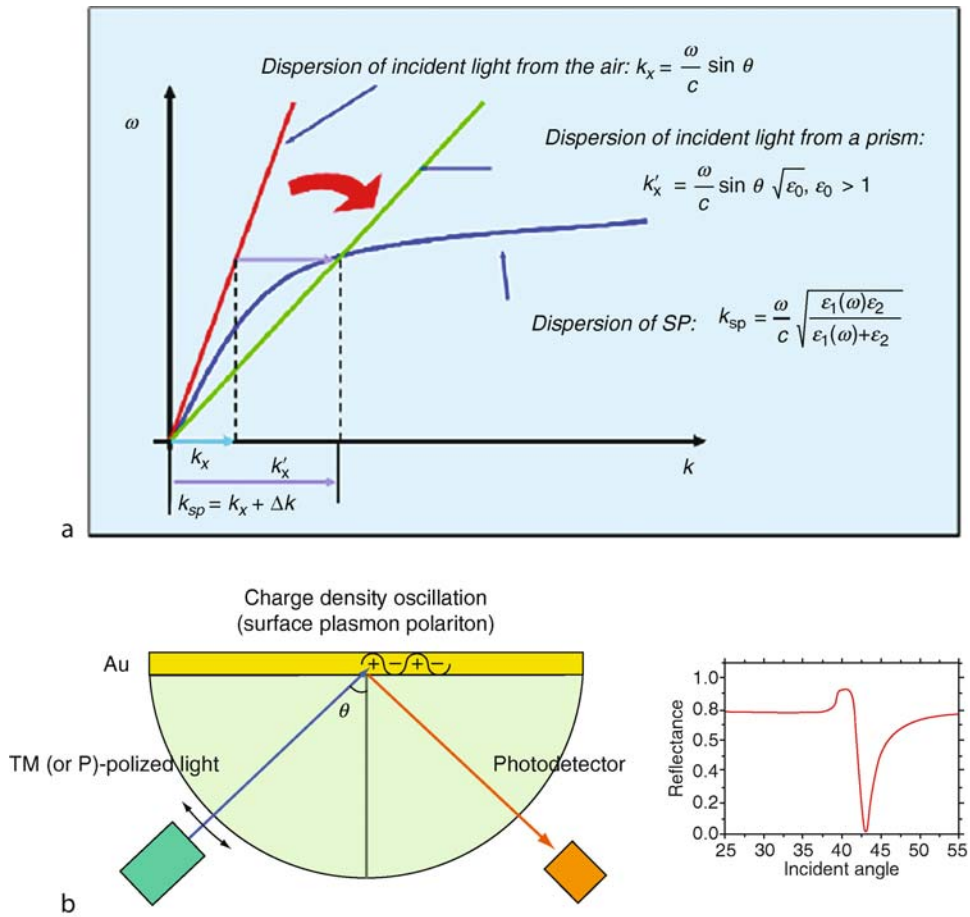
Characteristics

Detection Principle of SPR Biosensor

Surface plasmon polaritons (SPPs), which are also referred to more simply as surface plasmons (SPs), are longitudinal and collective oscillations of electrons occurring on a metal-dielectric interface. The frequency of these longitudinal oscillations are linked to the wave vector (k_{sp}) by a dispersion relation. The incidence of light can induce the excitation of the SPs when the momentum of the SPs matches that of the incident light. In such cases, the well-characterized surface plasmon resonance phenomenon occurs. As SP waves are inherently longitudinal, the waves can be coupled only with the transverse magnetic (TM) mode of electromagnetic waves, the polarized direction of which is parallel to the incident plane. It has been determined that this wave-matching condition can be quite readily disrupted by even miniscule changes in the interface conditions. Hence, in cases in which the light excitation condition is fixed, the SPR technique not only allows for the precise measurement of changes in the refractive index or the thickness of the medium adjacent to the metal film, but also enables the detection of changes in the adsorption layer on the metal surface. As is shown in Fig. 1a, the surface plasmons have a larger wave vector than do light waves of the same energy $\leq\omega$. In order to excite the SPs with photons, the wave vector of the photons must be increased. Thus far, two basic apparatus can be utilized to achieve this: (i) a prism coupler; (ii) a grating coupler. The Kretschmann geometry of the ATR method, using a prism, is currently the approach most often employed in SPR sensors. This is a special case of ATR, in which a thin metal film exists at the ATR interface. As can be observed in Fig. 1b, the light wave is reflected completely at the interface, and excites the SP via the evanescent field. Detection is thus accomplished by recording the changes in the resonance angle or the wavelength.

Properties of the SPR Biosensor

As has been thoroughly documented, the SPR biosensor is a versatile optical spectroscopic system, and represents a promising technology for the real-time, ►label-free analysis of affinity-based measurements in the fields of analytical biochemistry, experimental biology, and medicine. Following the introduction of the SPR biosensor by Jonsson et al. in 1991, the applications of SPR technology have expanded significantly, coming to encompass a wide-ranging field of topics. However, the applications of SPR technology in biomedical science are particularly salient; as many as 5,000 review and research articles concerning SPR have been published over the last 15 years. SPR-based biosensor technologies remain a subject of intensive research, and technical advances in the approach are continually opening new opportunities for the application of the general method. Numerous SPR apparatus are being developed and exploited on the basis of theoretical developments. One such promising approach is the coupling of SPR to mass spectrometry (SPR-MS), an approach that may prove to be extraordinarily useful in the field of functional proteomics. This hybrid SPR-MS system has shown itself to be a rapid and effective method for the identification of interaction partners in complex biological mixtures. The other principal SPR-associated technology involves the application of the technique to imaging systems. With regard to SPR imaging (SPRI), this system detects the change in the reflectivity of incident light, due to the binding of biomolecules to chip surfaces at a fixed angle of incidence, in contrast to SPR systems involving the detection of shifts in the SPR angle or wavelength. SPR imaging using optical array detectors appears to constitute a promising new direction in parallel or multi-channel biosensing, and thus may allow for high-throughput drug screening. Additionally, SPRI technology may also be applicable to the diagnosis of different types of disease including human cancers in the near future. Currently, commercially obtainable SPR instruments are large and expensive, and are therefore inappropriate for applications requiring portability and affordability, such as point-of-care technology (POCT). For this reason, miniaturization efforts that render the development of a portable system feasible have recently been undertaken in parallel with other components of research into more advanced SPR instrumentation.



Surface Plasmon Resonance. Figure 1 (a) The dispersion relation of non-radiative SPs, and (b) the configuration of the ATR method. See text for details.

Biomedical Applications

The most extensively employed application of SPR sensor technology is the monitoring of affinity scale in the study of biomolecular interactions. The many SPR-based affinity analysis applications currently available have become extremely significant in biomedicine and other fields. Biomedical applications of SPR can be categorized into 3 general fields; (i). Biomolecular interaction analysis, (ii). High-throughput screening, and (iii). Proteomics research.

Biomolecular Interaction Analysis (BIA)

The most common application of SPR biosensors is biomolecular interaction analysis (BIA), a critical component of protein function research. SPR technology has been applied to the monitoring of a variety of biological events, including kinetic analyses of ligand–receptor interactions, kinetic analyses of DNA binding to proteins with captured DNA, interaction analyses of enzymes with their substrates, dynamic analyses of antigen-antibody binding, epitope mapping, DNA hybridization, and real-time monitoring of DNA manipulation. In addition, the spectral SPR profile has been shown to be influenced by changes in the optical thickness of the sensor metal film, as well as by changes in the refraction index occurring near the metal surface (within ~200 nm). Because these optical indicators can be affected by structural transitions in proteins, SPR has also been utilized in the characterization of the conformational alterations of immobilized proteins upon binding to small molecules or in a variety of environments.

High-Throughput Screening (HTS)

SPR-based biosensors can be employed not only for the real-time monitoring of the kinetics of ligands with their receptors, but also in the development of pharmaceuticals, as SPR can be employed in drug screening procedures for single molecules in drug discovery studies. The application of SPR technology to high-throughput screening (HTS) is another recent trend in drug screening. SPR systems have been configured into a variety of formats, including array format, multi-channel unit format, and SPR imaging (SPRI)

format, which allow for simultaneous real-time measurement in the range of hundreds to thousands of binding reactions on the surface of a chip. Despite the profound versatility of SPR technology, SPR biosensors are also known to have a significant drawback that makes them inappropriate for high-throughput screening, as this system does not allow for the analysis of many samples in parallel. By way of contrast, SPR imaging technology using optical array detectors not only allows for high-throughput multiplex analysis, but also provides a sensitivity almost identical to that of classical SPR. Therefore, SPR imaging systems are more appropriate for high-throughput label-free detection than any other optical technique. SPR imaging methods allow for the quantitative characterization of biomolecular interactions, including DNA-DNA duplexes and DNA-drug interactions, in an HTS manner. Furthermore, the targeting of single-base mismatches in the alteration of DNA-DNA hybridization properties has been achieved in DNA arrays, using SPRI biosensors. Another technology that uses the SPR imaging system has been applied to the monitoring of real-time interactions of proteins to a DNA-patterned chip surface in a high-throughput manner. For example, this approach has been used for the high-throughput analysis of interactions occurring between the ►p53 protein and multiple DNA sequences. Recently, a novel SPR imaging-based HTS system for anti-cancer drug discovery was developed by Ro et al. in 2006. In the research, in order to determine whether the SPR imaging system was capable of screening for small molecules that inhibit protein-protein interactions, the interaction between the retinoblastoma tumor suppressor ►RB protein and the ►human papillomavirus (HPV) E7 protein was selected for use as a model system. The RB-E7 interaction was challenged by the spotting of the RB protein in the presence of the RB binding peptide (PepC). The SPR imaging results showed that PepC inhibited the RB-E7 interaction in a concentration-dependent manner, thereby indicating that SPR imaging-based HTS technology could potentially provide a versatile tool for the selection of small molecule inhibitors, via the targeting of protein-protein interactions.

Proteomics Research

One powerful method by which the biological function of most proteins can be anticipated is the identification of the interaction partners of "bait" proteins, which results in the discovery of protein biomarkers for disease diagnosis and drug screening. These functional proteomics studies, including "ligand fishing" from complex biological mixtures, can be performed efficiently using SPR biosensors coupled with mass spectrometry (MS). This combined SPR-MS system, when utilized as a tool for ligand fishing, allows for the identification of interaction partners with the desired drug candidate characteristics, biomarkers in a variety of therapeutic areas, epitopes or antibody binding sites on protein antigens, and enzyme inhibitors in extracts constructed from diverse organisms. Conventional SPR-MS approaches can be used to characterize unknown proteins that have been captured on the sensor surface, both via SPR technology and by exact direct mass measurement with ►matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) MS. As SPR detection is non-destructive and non-labeling, the combination of these two systems is quite relevant to possible approaches to the identification of binding partners directly after interaction analysis, followed by mass spectrometric assays. Recently, a new analytical protocol, in which SPR is coupled to ►electrospray ionization (ESI) MS, has created a new opportunity for the identification and secondary characterization of interaction partners. This system is, potentially, an extremely effective method for the identification of novel binding partners. Therefore, the combined SPR-MS system is expected to become a powerful tool in the area of quantitative analysis of functional proteomics, a field which includes large-scale "ligand fishing" assays.

Surgical Trauma and Cancer Recurrence

Wilhelmin M. U. van Grevenstein,
Casper H. J. van Eijck
Department of Surgery, Erasmus MC, Rotterdam, The Netherlands

Definition

Surgical trauma occurs after every surgical procedure by using traumatic tools, gauzes, and by rubbing the tissue. This causes an inflammatory response during which loads of cytokines and growth factors are produced. These factors will create an outstanding environment where tumor cells can adhere and flourish into a tumor lesion. Understanding the specific mechanism of tumor cell adhesion can lead to develop specific tools to prevent local and distant recurrence in the future.

Characteristics

The process of cancer metastasis could be compared to an exhausting obstacle race, during which the tumor cell has to pass a series of sequential interrelated steps to become a clinically relevant lesion. In distant metastasis, the tumor cell must succeed in invasion, embolization, survival in the circulation, adhere to a distant capillary endothelium, followed by extravasation and multiplication in another organ. Locoregional tumor recurrence after intra abdominal seeding or spill of tumor cells seems to be less complicated, the tumor cell has to adhere, after which it can flourish and grow out as a lesion.

Although the process of locoregional tumor recurrence gives the impression to be highly comprehensible, peritoneal and local recurrence is a persistent hurdle after curative resection of colon or pancreatic tumors. The resection site is preferable and recurrence to locoregional sites is common. Several theories on local tumor recurrence have been advocated. The most feasible theory is the development of local recurrence after resection of locally advanced disease, which already penetrates the peritoneal surface or adjacent organs. Another source for local recurrence is the presence of cancer cells in the abdominal cavity prior or during surgery. Peritoneal washings, before manipulation of the tumor, are positive in 20–30% of the patients with colorectal cancer. Furthermore, extensive manipulation of the tumor during surgery will cause leakage of tumor cells out of the dissected lesion or out of the transected lymphatic channels or veins. The free floating tumor cells or tumor emboli will precipitate on raw tissue, followed by an inflammatory response during which an outstanding environment for the tumor cells will be created.

Approximately 40% of the patients with colorectal cancer, who underwent surgery for local or locally advanced disease, develop recurrent disease. The intra-abdominal recurrence rate after curative resection for pancreatic cancer is even more deplorable. Methods of prevention and treatment of locoregional metastasis, like neoadjuvant radiotherapy, brachytherapy, adjuvant chemotherapy, photodynamic therapy, (hyperthermic) intraperitoneal chemotherapy and peritonectomy, are developed and implemented in daily surgical practice. The benefit of adjuvant chemotherapy on overall survival for patients with node-positive, locally advanced colon cancer is well established. The adjuvant therapy regimen in pancreatic cancer has not been elucidated yet. The ESPAC-1 randomized controlled trial showed no survival benefit for adjuvant chemoradiotherapy after R0 resection, however, it revealed a potential benefit for adjuvant chemotherapy. However,

a study from Smeenk et al. showed that adjuvant chemoradiotherapy, after irradical resections of pancreatic cancer, gives a significant improvement of local control, nevertheless treatment with chemoradiotherapy does not improve survival.

These (neo)adjuvant treatment strategies are mainly based on diminishing advanced disease. An adequate understanding of the pathophysiology of the tumor cell adherence is needed to clarify the initial step of implantation.

Trauma and Inflammation

Since Virchow's studies in the mid-nineteenth century, the role of inflammation and wounding as an initiator and promoter of tumor development has been implied. Virchow indicated that cancers tended to occur at sites of chronic inflammation.

The investigation aiming to clarify the relationship between inflammation and cancers first led to the determination, whether the reactive oxygen species (ROS) and nitrogen species generated by inflammatory cells, such as leucocytes recruited to the inflammatory foci to kill infectious agents, may cause mutagenic assaults and result in tumor initiation. Nowadays, it has been realized that the development of cancers from inflammation might be a process driven by inflammatory cells as well as a variety of mediators, including cytokines, chemokines, and enzymes, which altogether establish an inflammatory microenvironment.

Inflammation is a process in response to tissue damage caused by microbial pathogen infection, chemical or mechanical induced wounding. At the very early stage of inflammation, neutrophils are the first cells to migrate to the inflammatory sites under the regulation of molecules produced by rapidly responding macrophages and mast cells present in tissues. As the inflammation progresses, various types of leucocytes, lymphocytes, and other inflammatory cells are activated and attracted to the inflamed site by a signaling network involving a great number of growth factors, cytokines, and chemokines.

Surgical trauma induces an acute phase response, during which tissue damage will be controlled, infective organisms will be killed and the repair process will be induced. The acute phase response is initiated by macrophages and monocytes entering the surgical traumatized site, which release proinflammatory cytokines, tumor necrosis factor alpha (TNF-α), and interleukin-1 beta (IL-1β). TNF-α and IL-1β stimulate the production and release of other cytokines, like interleukin 6 (IL-6). These cytokines are potential directors of the expression of cell adhesion molecules (CAMs) and regulating in that way the adhesiveness between leucocytes and the endothelium. Parallel to the endothelium, the inflammatory cascade following surgical trauma in the peritoneal cavity, creates an outstanding environment for residual or spilled tumor cells to adhere to mesothelial cells.

Laboratory Investigations

The process of tumor recurrence can be separated into tumor cell adhesion and tumor growth. Initially the tumor cells have to adhere before they nurture and develop into a metastatic lesion. To study the specific pathways of tumor cell adhesion we developed an in vitro model, in which we investigated the interactions of different human colon and pancreatic tumor cell lines on mesothelial monolayers and the endothelium. Our study focuses on the influence of surgical derived inflammatory factors on tumor cell adhesion. IL-1β and TNF-α are crucial enhancing factors of tumor cell adhesion to the mesothelial monolayers and the microvascular endothelium. In addition, IL-1β and TNF-α significantly upregulated the expression of adhesion molecules ICAM-1, VCAM-1, and CD44 on mesothelial cells and endothelial cells.

These cytokines are produced during the acute inflammatory response, which is induced by peritoneal trauma and has to initiate the wound healing process. IL-1β, TNF-α, and IL-6, produced by activated leukocytes, are the major mediators of inflammation and tumorigenesis. Together they generate the production of adhesion molecules, growth factors, nitric oxide, and the activation of the NF-κB pathway. In that way the proinflammatory cytokines will stimulate tumor adhesion, growth, and invasion. Furthermore mesothelial cells have additional active participation in the inflammatory response by producing proinflammatory cytokines and in that way stimulating the expression of adhesion molecules. TNF-α has a dominant function in the abdominal cavity and might modulate the production of ILs from mesothelial cells. Production of IL-1 and IL-8 by mesothelial cells is enhanced after stimulating the cells with TNF-α. In malignant disease, high dose local TNF-α selectively destroys tumor blood vessels and thereby induces apoptosis, but when chronically produced this cytokine may act as an endogenous tumor promoter. It contributes to the modulation of the cell, i.e., CAMs, necessary for tumor spread and growth. The influence of IL-1β on tumor cell metastasis is inevitable as well. In mouse metastasis models, treatment with an IL-1 receptor antagonist significantly decreased tumor development. Additionally, IL-1β-deficient mice are resistant for developing metastases.

During the inflammatory response, PMN are attracted to the site of injury, which is mediated by chemotactic factors and proinflammatory cytokines. PMN are known to aggravate an overwhelming burst of ROS to destroy invading organisms and inducing additional tissue destruction. Furthermore this oxidative burst can be induced by TNF-α, which causes an

upregulation of the FMLP receptors (N-formyl-methionyl-leucyl-phenylalanine) on PMN. In our studies, FMLP-stimulated PMN induce a significant enhancement of tumor cell adhesion. Moreover, the ROS producing system (X/XO) exhibits an even superior enhancement of adhesion of tumor cells and this enhancement was inhibited by antioxidant scavengers.

Clinical Applications

Notwithstanding that surgery remains the treatment of choice in colorectal and pancreatic cancer, local recurrence after curative surgical resection is an incessant drawback. Different pathways of local tumor recurrence have been unraveled, nonetheless in what way can these investigational results be implemented in clinical practice?

Peroperative diminishing surgical trauma, by using less traumatic tools, gauzes, and techniques, seems to be an adequate option. The study done by Bouvy et al. showed in a rat model that laparoscopic surgery is associated with less tumor growth stimulation compared with conventional surgery, due to reduced surgical trauma. Additionally laparoscopic surgery is correlated with less immunological alterations and this may imply less local tumor recurrence as well. Lacy et al. showed that laparoscopic-assisted colectomy was associated with a significantly lower probability of tumor recurrence and a higher probability of overall and cancer-related survival in stage III cancer. Although the recent publication of Law et al. is not a randomized controlled trial, this study put forward a significant survival benefit for patients, who underwent a laparoscopic resection in stage I to III colon cancer. The two randomized controlled trials, in which laparoscopic-assisted colectomy was compared with open surgery, could not reveal this benefit concerning tumor recurrence in the laparoscopic group.

Since the expression pattern of adhesion molecules on tumor cells is tremendously divers, it is not feasible to use single monoclonal antibodies to confront spilled tumor cells. The development of cell adhesion peptides (i.e., RGD peptide) provides promising results by blocking the adherence of tumor cells to the components of the extracellular matrix. The use of RGD peptides has been expanded with preliminary results by using the RGD peptides for delivering drugs to tumor cells that express certain integrin types after which an internalization process takes place of the integrin adhesion complex.

Interfering with the inflammatory process during and after surgery is a reliable option to prevent tumor recurrence, however, wound healing is depending on this process. This interference should be very selective, otherwise the healing process will be disturbed. Interference with the inflammatory response might be accomplished by inhibiting the influx of PMN into the peritoneal cavity with antineutrophil serum (ANS) after curative resections of gastrointestinal tumors. An in vivo study showed a significantly decrease of peritoneal tumor recurrence after intraperitoneal injection of ANS.

Another pathway of interest is the influence of ROS on tumor cell adhesion. Accumulation inhibitors of ROS are superoxide dismutase, catalases, glutathione peroxidases, vitamins C and E, these antioxidant enzymes and nonenzymatic systems are engineered during stress. Since the release of ROS is enormous following surgical trauma, additional exogenous administration of antioxidants might be a therapeutical option.

An antioxidant with potential is melatonin. Melatonin, produced mainly in the pineal gland, possesses a wide spectrum of biologic activities, including its function as a naturally occurring oncostatic neurohormone by inhibiting cell proliferation, inducing apoptosis and reducin metastatic spread. Regarding the scavenger function of melatonin, a synthetic form might be of interest in prevention of tumor recurrence.

Since the discovery of NF-κB in the mid-1980s, this transcription factor has been a subject of intense investigation. The NF-κB transcription factor complex is a pleiotropic activator that participates in the induction of a wide variety of cellular and viral genes. Binding sites for NF-κB are present in the promoter region of many CAMs, cytokines, and growth factors. Antisense inhibition of NF-κB activity causes a block of cellular adhesion to the extracellular matrix, inhibition of in vivo growth of adherent cells, and inhibition of in vivo tumorigenicity in nude mouse models. Recent investigations also showed that ROS is engaged in a unique reciprocal cross talk with NF-κB. The exact mechanism has not been unraveled yet, however, remarkable is that the induction of NF-κB is abrogated by overexpression of ROS scavenging enzymes.

A promising NF-κB inhibitor is pentoxifylline (trental). The inhibition of the transcription of NF-κB might cause a suppression of CAMs and in that way a potential decrease of lung metastasis. In addition, pentoxifylline may reduce the TNF-α induced oxidative burst by reduced binding of FMLP to PMN surface receptors.

Interference with the invasion of tumor cells through the extracellular matrix is another therapeutic option. Matrix metalloproteinases (MMPs), a group of zinc-dependent endopeptidases, play an important role in the growth and invasion of colorectal and pancreatic cancers by degradation of the extracellular matrix. The levels of certain MMPs can be used to estimate the metastatic capacity and recurrence of disease as well as prognosis of patients. However, for effective therapy using MMP inhibitors, highly selective administration may be required. Since MMP-7 is the most critical MMP for colorectal cancer progression, developing

selective inhibitors against this protease and their administration in the early stage of disease may be worth trying.

The inflammatory sequelae enhance tumor cell adhesion the mesothelium in vitro. The pathways involved are orchestrated in a meticulous way by proinflammatory factors produced peroperatively in response to surgical trauma. Interference with the inflammatory sequelae (i.e., cytokines, PMN, ROS, adhesion molecules, NF-κB) produced peroperatively must be well balanced, without disturbing the wound healing process and the systemic immune response. Interference with these pathways may lead to specific tools to conquer the adhesion and growth of spilled tumor cells in vivo.

Surrogate Endpoint

Stuart G. Baker[1], Barnett S. Kramer[2]
[1]Biometry Research Group, National Cancer Institute, Bethesda, MD, USA
[2]Office of Disease Prevention, National Institutes of Health, Bethesda, MD, USA

Synonyms

Intermediate endpoint; Surrogate endpoint biomarker; Surrogate outcome

Definition

A surrogate endpoint is an outcome observed prior to a health outcome of interest (called the true endpoint) that is used to make conclusions about the effect of intervention on the true endpoint.

Characteristics

Role of Surrogate Endpoints in Cancer Research

The role of surrogate endpoints in cancer research depends on the purposes of the analysis. The main roles are to (i) shorten the length of time needed to evaluate a new treatment for clinical use and (ii) quickly and cheaply evaluate interventions at an early phase of development as a prelude to more rigorous evaluation.

Ideally these roles require the surrogate endpoint to be validated. As with so many terms used in the medical literature, the meaning of the term "validation" can vary among medical scientists. We define validation of a surrogate endpoint as a formal process of data analysis for determining how well the surrogate endpoint can be used to make conclusions about effect of treatment on true endpoint. Some authors use the term surrogate endpoint to mean the early outcome has been validated, based on the literal definition of a surrogate as a substitute; here we use the term surrogate endpoint to refer to an outcome that is considered as a possible substitute for the true endpoint but that still requires validation. If a surrogate endpoint is validated it can, with reasonable confidence, be used to evaluate a new intervention, but subject to very important caveats.

Surrogate endpoints can take a variety of forms related to characteristics of genes, proteins, cells, tissues, or individual health status. Surrogate endpoints have been proposed to shorten the time needed to evaluate a new cancer treatment or preventive intervention. For example three-year disease free survival has been evaluated as a surrogate endpoint for 5-year overall survival in patients in colon adjuvant ▶clinical trials and ▶prostate-specific antigen (PSA) has been proposed as a surrogate endpoint for prostate cancer recurrence but its validation has been questioned. Although adenoma occurrence has been used as a surrogate endpoint for colorectal cancer occurrence in cancer prevention trials, it has not been validated. The validation methods that are discussed below primarily refer to this use of surrogate endpoints to shorten the time to evaluate a new intervention for clinical use.

Surrogate endpoints are also frequently used to evaluate possible treatments to identify those agents that are the best candidates for more rigorous evaluation using a true endpoint. Examples of these surrogate endpoints are markers of cell proliferation and apoptosis. The use of these surrogate endpoints involves much smaller sample sizes than with a true endpoint of cancer incidence which is a major reason (besides shortening the time for evaluation) they are so attractive to researchers. The smaller sample size for the surrogate endpoints arises because the surrogate endpoint is more common than the true endpoint. The more common the endpoint, the smaller the sample size needed to detect a given percentage decrease in probability of endpoint. However the fact that the sample size is much smaller

with the surrogate endpoint than the true endpoint is an indicator that these surrogate endpoints can almost never be validated as currently used in drug development. In this situation, the underlying problem with validation is that a common outcome is not a good substitute for a rare outcome because most subjects with the common outcome do not develop the rare outcome, leading to a large amount of noise. Basically the only way to adjust for the extra noise is with a sufficiently large sample size to reliably predict the effect of treatment on true endpoint. Nevertheless, because selection of candidate ▶chemoprotectants (often termed "chemopreventive agents") is needed, these un-validated surrogate endpoints are used in cancer prevention research. Recently developed schema for assigning levels of evidence may be useful for ranking surrogate endpoints for preliminary evaluation of chemoprotectants.

A third use of surrogate endpoints is for clinical decision-making for individual patients. In this setting, the clinician measures a biomarker on a patient after the start of treatment and uses this marker to predict outcome and inform possible changes in therapy. Validation of surrogate endpoints for this use is not well developed. It is important to realize that most of the literature on validating surrogate endpoints applies to use of surrogate endpoints for evaluating the effect of treatment on true endpoint among a population. Importantly this type of validation does not necessarily imply validation for clinical decision-making.

Methods of Validation

This discussion of validation focuses on the role of surrogate endpoints to shorten the duration of cancer trials used to make a clinical recommendation. At the onset of this discussion, it is important to dispel a common misconception that a high correlation between a surrogate endpoint and a true endpoint implies the surrogate endpoint has been validated. It has been shown mathematically that even perfect correlation between a surrogate and a true endpoint does not guarantee a validated surrogate endpoint. The reason is that the relationship between the surrogate and the true endpoint can differ in different arms of the trial while still being perfectly correlated within each arm. This difference in relationships between arms could lead to incorrect conclusions about the effect of the treatment on the true endpoint when using only information about the effect of treatment on the surrogate endpoint.

When validating a surrogate endpoint it is preferable to use data from randomized trials rather than from observational studies. When data are collected from a randomized trial, each of the two key components, the effect of treatment on surrogate endpoint and the effect of treatment on true endpoint, are not biased from unmeasured baseline covariates. This is not the case when data are collected from an observational study.

There are two major approaches to validation of surrogate endpoints. One approach involves only a single randomized trial with data on a surrogate and a true endpoint. The other approach involves data from multiple randomized trials with surrogate and true endpoints. Once a surrogate is validated it would be applied to a new trial with only a surrogate endpoint.

Many early methods for surrogate endpoint validation were based on data from a single trial and relied on the Prentice criteria. The Prentice criteria, named after the criteria formulated by Ross Prentice in an influential 1989 article on surrogate endpoint validation, were developed to ensure that rejection of the null hypothesis under the surrogate endpoint implies rejection of the null hypothesis under the true endpoint. The main criterion, sometimes called the Prentice criterion, is that the distribution of the true endpoint conditional on the surrogate endpoint does not depend on the intervention. In other words, the Prentice criterion says that, for all treatments under consideration, there is a single pathway from treatment to true endpoint that goes through the surrogate endpoint, so once the surrogate endpoint is known, no other information is needed to determine the distribution of the true endpoint. With data on a surrogate and true endpoint in a single trial one can statistically test if the Prentice Criterion holds. If one statistically rejects the Prentice Criterion, the surrogate endpoint is poor. If one cannot statistically reject the Prentice Criterion, further investigation is needed because lack of rejection of a null hypothesis does not automatically imply that the null hypothesis can be accepted. One approach for validation when the Prentice Criterion is not rejected is to compute the proportion of treatment effect explained by the surrogate endpoint. This computation involves fitting two regression models: (i) a model for the effect of treatment on true endpoint and (ii) a model for the effect of both treatment and surrogate endpoint on true endpoint. The proportion of treatment effect explained equals one minus the ratio of the coefficient for treatment effect in model (ii) to the coefficient for treatment effect in model (i). For a perfect surrogate endpoint, the proportion of treatment effect explained equals one, because the surrogate endpoint captures all the information about the true endpoint. Despite the popularity of the proportion of treatment effect explained, it has many drawbacks including wide confidence intervals. However the major drawback is the difficulty in reaching any consensus as to the proportion needed to validate a surrogate endpoint. Opinions vary, and the "acceptable" threshold may differ from early phases of drug development to definitive testing for drug approval. The acceptable level may also vary among diseases.

Another approach for single-trial validation with a binary surrogate endpoint involves constructing a model for two levels of the surrogate endpoint: (i) the level observed based on the actual assignment of the randomization group and (ii) the level inferred if, contrary to fact, the person were assigned to the other randomization group. While this validation approach has attractive mathematical and conceptual underpinnings, it has not been applied in practice. Also the assumptions required for estimation are very stringent, and may not hold in many situations.

Validation methods based on data from single trials are inherently limited because they do not account for variability over trials in the mechanism by which treatment affects the outcome. This was a major criticism of a single-trial validation of prostate specific antigen as a surrogate endpoint for survival among patients with prostate cancer.

Validation methods based on data from multiple trials of surrogate and true endpoints are becoming more popular. These surrogate endpoint validation methods are sometimes called meta-analytic because, like standard meta-analyses of true endpoints in randomized trials, they combine data over multiple trials although the techniques and purpose differ. A variety of meta-analytic methods for validating surrogate endpoints have been proposed, and there is no consensus as to best approach. In fact some investigators advocate multiple approaches to meta-analytic validation.

Many meta-analytic validation methods are based primarily on two statistics for each trial, the effect of treatment on surrogate endpoint and the effect of treatment on true endpoint, which are often plotted as a set of points. A regression line is then fit to these points to construct a model relating the effect of treatment on the surrogate endpoint to the effect of treatment on the true endpoint. The simplest model is a linear regression based on least squares. More complicated regression models account for additional variability by specifying that the coefficients in the regression vary over trials according to a specified distribution. Different versions of these complex regression models are needed for different types of data (binary, survival, continuous) along with special software. Sometimes there are numerical problems when fitting these models. To apply the results to a new trial, the effect of treatment on surrogate endpoint in the new trial is plugged into the regression model to yield the predicted effect of treatment on true endpoint in the new trial. Alternatively an investigator can compute a surrogate threshold which is the minimum effect of treatment on surrogate endpoint that corresponds to a statistically significant effect of treatment on true endpoint.

Another meta-analytic approach has been recently developed for use with binary surrogate endpoints. This approach has been applied to survival data where the binary endpoint is cancer recurrence at an early time and the true endpoint is probability of overall survival to a later time. The basic idea is that each arm of each trial in the meta-analysis has information relating the surrogate and true endpoints. The same relationships can be applied to the surrogate endpoint in the new trial to obtain an estimate of the predicted effect of treatment on true endpoint in the new trial based on data from each previous trial. These estimates are averaged over predictions from all previous trials to obtain an average estimate of the surrogate-based predicted effect of intervention on true endpoint in a new trial.

Meta-analytic methods are most straightforward when each trial involves two randomized groups, with subjects in one group receiving a control treatment and subjects in another group receiving an experimental treatment that is never used as a control.

Special considerations arise when a trial has more than two randomization groups, when it is not clear which treatment is the control, or when a treatment applies to the control group in one trial and the experimental group in another trial.

There are various approaches for using regression type meta-analytic models to summarize the quality of the surrogate endpoint. One summary measure is an individual-level association, which is the squared correlation between surrogate and true endpoints after adjusting for trial and treatment effects. (Unlike the other validation measures discussed, this measure could be useful for clinical decision making for individual patients.) Another summary measure is a trial-level association, which measures the association between the effect of treatment on surrogate endpoint versus the effect of treatment on true endpoint. Related summary measures based on information theory have also been developed. Sufficiently high values of the summary measure indicate a surrogate endpoint is validated, but more guidance is needed to determine the threshold level.

Another summary measure for the quality of the surrogate endpoint in a meta-analysis is the average prediction error. To compute this measure, one trial is removed from the meta-analysis and treated as a new trial. The other trials are used to predict the effect of treatment on the true endpoint in the "new" trial. The error is the absolute value of the difference between predicted and true effects of intervention on true endpoint in the "new" trial. This procedure is repeated over all trials with a different trial selected as the "new" trial on each iteration. The error is averaged over all trials to obtain the average prediction error. The average prediction error is compared with the average clinically meaningful difference that each trial was designed to detect (which can be inferred based on the sample size of the trial and variability of the true endpoint). As a

rule of thumb, a ratio of average prediction error to clinically meaningful difference of 1/10 indicates a good surrogate endpoint (because errors due to the use of the surrogate are relatively small compared to the difference one hopes to detect), while a ratio of 1 or greater indicates a poor surrogate endpoint. Again this may vary according to how much tolerance one has for making a mistake. This in turn may vary with phase of drug development, lethality or stage of the disease, and toxicity of the intervention.

Caveats in the Use of Validated Surrogate Endpoints

Regardless of the method of validation, there is no guarantee that in a new study the validated surrogate endpoint will in fact yield the correct conclusion about the effect of treatment on a true endpoint in a new trial.

One reason for caution with validated surrogate endpoints is that the treatment under study in a new trial may have different mechanisms for affecting true endpoints than the treatments in previous trials. For example a new treatment to reduce adenomas may have a different impact on the fraction of adenomas that develop into ►colon cancer than would previous treatments. A different mechanism for the effect of treatment on true endpoint could mean that the extrapolation from previous trials, even accounting for extra variability, may be incorrect. To avoid this problem, the intervention in the new trial is often restricted to being in the same "class" as the intervention in the trials used for validation, although this is still no guarantee that the surrogate endpoint will yield the correct conclusions in a new trial. In fact even the same drug could have a different spectrum of mechanistic actions at different doses. For example beta-carotene is likely an antioxidant at low concentrations but a pro-oxidant at high concentrations and acetaminophen is a safe antipyretic drug at low doses, but is a potent liver toxin at higher doses.

A validated surrogate endpoint should also be viewed with caution when the presence of the surrogate endpoint necessitates additional treatments that could affect the true endpoint. For example a surrogate endpoint of cancer recurrence will often lead to secondary treatments designed to alter the true endpoint. If a new type of secondary treatment is adopted in a new trial, results from previous trials using the older secondary treatment will no longer be applicable.

Another caution in using a validated surrogate endpoint is that it applies only to one particular endpoint, usually the primary health benefit. In many trials harmful side effects are a serious consideration. It is possible that in the interval between the surrogate and true endpoints, the intervention can cause serious adverse effects unrelated to the true endpoint. In such circumstances reliance on the biomarker for decision-making can miss a net harm. In essence this is what happened with celecoxib for the prevention of colon cancer. In a clinical trial, celecoxib decreased the risk of incident adenomatous polyps in patients with prior polyps; but an excess of cardiac deaths occurred prior to the average time interval between polyp formation and cancer development. In summary, if a trial is terminated at the time the surrogate endpoint is observed, it may not have continued sufficiently long enough to provide information about harmful side effects.

Survivin

Csaba Mahotka
Institute of Pathology, Heinrich Heine Universität, Düsseldorf, Germany

Synonyms

BIRC5; baculoviral IAP-repeat containing protein 5; API4; apoptosis inhibitor 4

Definition

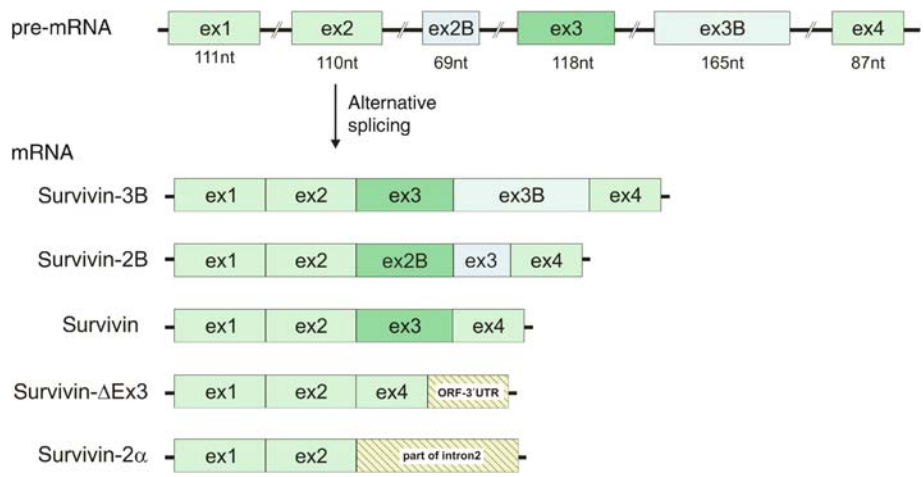
As a structurally unique member of the ►inhibitor of apoptosis protein (IAP) family, survivin is highly expressed in fetal tissues, but not in most adult tissues. Most human cancers return to the fetal pattern of survivin overexpression, thus suggesting a pivotal role of survivin for tumor cell survival.

Characteristics

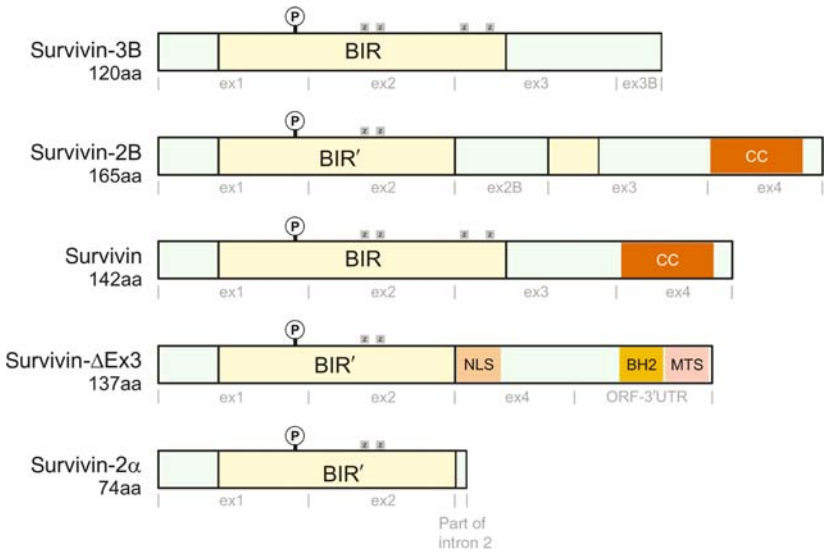
The human survivin gene is located on chromosome 17 (band q25) and encompasses 14.796 base pairs that comprise six exons. The coding strand is preceded by a TATA-less promoter and a GC-rich region corresponding to a ►CpG island. The coding sequence of survivin is largely complementary to the coding strand of the ►effector cell protease receptor-1 (EPR-1) gene. This suggests that survivin and EPR-1 transcripts originate from duplicated genes that were arranged in opposite orientations. The human survivin gene encodes five different splice variants, which may contribute to the fine-tuning of survivin actions (Fig. 1):

- Survivin is the first of five transcripts identified and consists of exon 1 (111 bp), exon 2 (110 bp), exon 3 (118 bp) and exon 4 (87 bp).
- Survivin-2B is characterized by the insertion of an additional exon 2B (69 bp) between exon 2 and 3.
- survivin-ΔEx3 shows a loss of exon 3 as well as a frame shift with extension of the open reading frame into the 3′ untranslated region.
- Survivin-3B contains an additional exon 3B derived from a 165 bp long part of intron 3.
- Survivin-2α is characterized by an addition of 197 nt of intron 2, of which 195 nt are non-coding.

The structure of the corresponding survivin proteins is unique as compared to other IAPs. Thus, most mammalian IAPs contain a carboxy-terminal RING finger domain, a caspase recruitment domain (CARD) and, most importantly, two or three copies of a baculovirus IAP repeat (BIR), a zinc finger domain essential for the inhibition of apoptosis by IAPs. In contrast, survivin proteins exhibit only a single BIR domain, an extended carboxy-terminal α-helical coil that forms a bowtie-shaped homodimer, and lack both the RING finger and the CARD region. The splice variants survivin-2B, survivin-ΔEx3 and survivin-2α exhibit pronounced structural alterations that also affect



Survivin. Figure 1 Structural organization of the alternatively spliced transcripts of the survivin gene. Abbreviations: ex, exon; ORF, open reading frame; UTR, untranslated region; nt, nucleotides.



Survivin. Figure 2 Protein domains of functional divergent survivin splice variants. Abbreviations: P, phosphorylation site at Thr34; z, zinc finger ligand; BIR, baculoviral IAP repeat; BIR′, truncated BIR domain; NLS, nuclear localization signal; BH2, bcl-2 homology domain 2; CC, coiled coil motif; MTS, mitochondrial targeting sequence; aa, amino acids; ex, exon.

their single BIR domain (Fig. 2). The BIR domain in survivin-3B is not impaired by alternative splicing. Survivin is a 16.5 kDa protein (single chain) and can act as a homodimer, while heterodimerisation with its splice variants are also described. To date, research has been mainly focused on the functional properties of the survivin protein, whereas little is known about the four different survivin variants.

Transcription of survivin shows a marked cell cycle-dependent pattern with a pronounced up-regulation in the G2/M phase (►G2M-transition). This cell cycle periodicity has been related to the presence of two Sp1 sites in the proximal promoter region. They might interact with zinc finger transcription factors of the Sp family that are also implicated in the control of other cell cycle-related genes. Suppression of survivin transcription in the G1 phase may be further regulated by a cell cycle homology region (CHR) and by three cell cycle-dependent elements (CDE) of the promoter that are also known from other G2/M-expressed genes.

Functional and Cellular Characteristics

In accordance with other mammalian IAPs, survivin antagonizes a broad range of apoptotic stimuli by inhibiting caspase-3, -7 and -9. Survivin-dependent inhibition of caspase-9 has is restricted on phosphorylation at Thr34. Other mechanisms of action in a cell cycle dependent manner are the association to the ►p53 network, as well as the binding to CDK4, and moreover, the activation of survivin by CDK1-dependent phosphorylation at Thr34 has been demonstrated. Survivin has been reported to interact with several other apoptotic factors, such as XIAP and smac/DIABLO. Moreover, many other proteins are known to also interact with survivin: HBXIP, INCENP, ►Aurora B kinase, tubulin, ►HSP90 *et alii*.

Survivin is abundantly expressed in fetal tissues as revealed by immunohistochemistry in lung alveolar epithelium, proximal tubule epithelium of the kidney, pancreatic islets, endometrial glands, intestinal crypt epithelium, thymic medulla and neurons of the spinal cord. Survivin is predominantly localized in the cytoplasm, whereas survivin-ΔEx3 is found exclusively in the nucleus.

In contrast to other mammalian IAPs, however, survivin expression is not detectable by Northern blot, in situ hybridization and immunohistochemistry in normal adult tissues, with the exception of thymus and placenta. The predominantly restriction of survivin expression to fetal tissues suggests a key role of this IAP protein for the regulation of developmental apoptosis. Of note, several highly proliferating adult cells and tissues could express increased levels of survivin possibly to escape from cell death (e.g. T lymphocytes).

Survivin actions have been located to the microtubules of the mitotic spindle apparatus. Survivin binding to the polymerized microtubules is mediated by a carboxy-terminal ►coiled-coil domain. The increased levels of survivin expression during the G2/M phase of the cell cycle might protect the mitotic apparatus from degradation. Therefore, survivin has been suggested to be an active component of the G2/M

checkpoint control that preserves chromosomal ploidy and genetic stability by induction of apoptosis in aberrant cells. The down-regulation of survivin expression in adult tissues may lower the threshold for apoptosis in replicating cells harboring genetic defects.

Clinical Relevance

Many types of human cancer, such as carcinomas of the lung, stomach, colon, breast, prostate, skin as well as non-Hodgkin lymphomas, neuroblastomas and melanomas, return to the fetal pattern of survivin expression. Survivin reexpression may be an early step of malignant transformation, as evident from its presence in precancerous lesions such as colorectal adenomas and Bowen's disease of the skin. The exact molecular mechanisms involved in the reactivation of the survivin gene in human cancers are currently unknown. Nevertheless, the overexpression of survivin in many histogenetically distinct tumor types indicates a strong selection advantage from survivin-related resistance to apoptosis. This selection advantage may result from the loss of an effective G2/M checkpoint control that permits ►progression of genetically unstable tumor cells through mitosis. Moreover tumor cells may profit from the increased resistance to many different pro-apoptotic stimuli, including – inter alia –hypoxia and death signals from immunocompetent cells.

The clinical implications of survivin-related resistance to apoptosis are profound. First retrospective studies on gastric, colorectal and bladder carcinomas as well as neuroblastomas suggest that survivin may be a prognostic factor, helping to identify patients with an increased risk of rapidly progressive disease.

The presence of survivin in urine may also act as a biological marker for bladder cancer. Different expression patterns of the alternative splice variants of survivin, such as survivin-2B and survivin-ΔEx3, are defined as ►biomarkers on mRNA level for tumor staging and progression in certain tumor entities.

Because survivin also confers increased resistance to certain anticancer drugs, e.g. ►paclitaxel and methotrexate, the level of survivin overexpression may be used as a predictive parameter for anticancer-drug sensitivity. Finally, the disruption of survivin-related antiapoptosis may become an attractive therapeutic target, selectively increasing the susceptibility of cancer cells to apoptosis-based treatment strategies without affecting the viability of non-neoplastic tissues that do not express survivin. Survivin is proposed to play a central role in the progression and resistance to therapy of diverse tumor types. The clinical utility of survivin and its variants as a diagnostic tumor marker can be profoundly improved if the marker is also a therapeutic target. Many studies suggest that an inactivation of survivin prevents tumor progression.

SV40

Michele Carbone, Haining Yang
Cancer Research Center of Hawaii, University of Hawaii, Honolulu, HI, USA

Synonyms

Simian virus 40

Definition

A DNA tumor virus (genus Polyomavirus) found to be a contaminant of Salk and Sabin poliovaccines (1955–1961) that propagates naturally in kidney cell lines of

Asian macaque species, specifically the rhesus and African green monkey. SV40 in these species, and related primates, produces no cytopathic effects upon the animals, but the virus injected into hamsters and other rodents causes ependymomas, lymphomas, osteosarcomas, sarcomas and ►mesotheliomas. Subsequent research has shown a possible correlation between SV40 (Fig. 1) and human mesotheliomas.

Characteristics

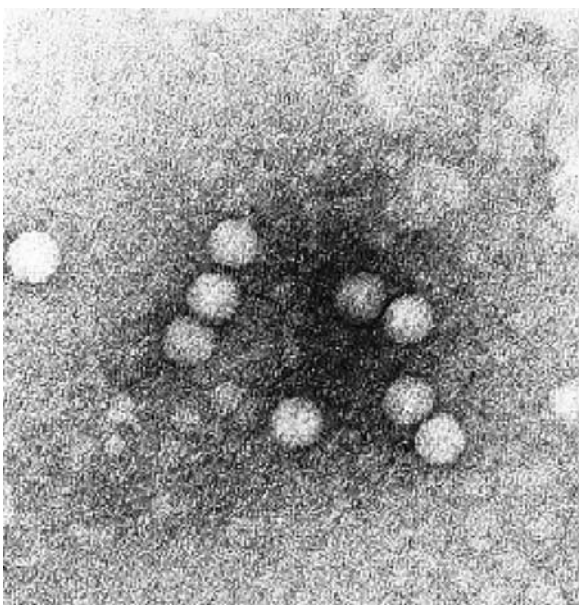
SV40 particles lack a lipid envelope and have a diameter of ~40–50 nm with spherical icosahedral symmetry. The molecular mass of the SV40 virion has been estimated to be 270 kDa. The icosahedral capsid contains three viral proteins (VP1, VP2, VP3), with VP1 being the major protein and VP2/VP3 being minor proteins. Along with the viral proteins, the SV40 virion contains cellular histones (H2A, H2B, H3, H4) that aid in condensing the viral DNA. The SV40 genome comprises of a closed circular dsDNA (5,243 bp) that associates with the various histones to achieve condensation, similar to that of cellular DNA in the form of chromatin. Nucleosomes that number between 24 and 26 on the viral DNA are made from the assembly of the histone-DNA complexes.

The genome of SV40 is numbered in a clockwise direction beginning at the origin (Ori) and continuing around until the site of Ori is reached again, marking the end of the genome. SV40 genome is responsible for coding six genes, synthesizing VP1, VP2, VP3, LP1, and the large (T-ag) and small (t-ag) t-antigens. SV40 large T-ag is comprised of 708 amino acids, while the small t-ag contains 174 residues. The initiation of viral DNA synthesis is mediated by the essential replication protein large T-ag, which in turn is regulated by phosphorylation. The transformation of cells and induction of tumor formation by SV40 is another function of the large T-ag, which causes the inactivation of products made from several tumor suppressor genes, including ►p53, ►pRb, p107, p130/Rb2, p300 and p400. One of the crucial consequences of binding large T-ag to p53 is the inactivation of an essential checkpoint that halts the process of mitosis if DNA damage is present, causing the cell to continue cycling. The small t-ag protein is not an essential mediator in SV40 replication, but it does play a significant role by causing an increase in the production of large T-ag and aiding in inactivating p53.

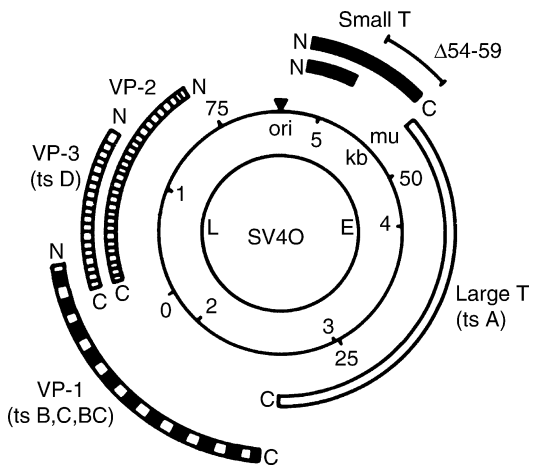
Different regions of the SV40 genome, designated "early" and "late," are expressed at different times during the stages of infection. The early region codes for the large T-ag, the small t-ag, which are the SV40 oncogenes, and for a 17 kDa protein of uncertain biological significance. The late region codes for the capsid proteins VP1, VP2, VP3, and for LP1, a protein involved in the process of SV40 particle assembly late in infection (Fig. 2).

Replication

The early and late regions of the SV40 genome distinctly separate the replication process into two events: Similar to other viruses, SV40 virions come into



SV40. Figure 1 Electron micrograph (250,000×) of SV40 virions (kindly provided by Dr. R. Fresco).



SV40. Figure 2 Genetic map of SV40. *Outer circular* segments represent specific proteins (Tag/tag, VP1, VP2 and VP3). *Inner circle* represent the direction of transcription and region of origin.

S

contact with the outer membrane surface of the host cell and attach to receptors located throughout the outer cell surface. These receptors are thought to represent the major histocompatibility complex class I molecules (MHC class I). Upon being transported into the cell, SV40 virions are moved to the cell nucleus. Once inside the nucleus, the virion capsid disassembles and the viral DNA is released.

At this point in replication, the early region of the SV40 genome is transcribed first, synthesizing the small t-ag/large T-ag proteins. This causes the cells to enter S phase. The SV40 72-bp enhancer elements help positively regulate transcription in the early region of the genome.

It has been identified that there are SV40 strains with either one 72-bp enhancer (archetypal) or two 72-bp enhancers (non-archetypal). Nonarchetypal SV40 replicates more rapidly compared to archetypal SV40. Three G + C-rich domains, also referred to as 21-bp repeat regions, are binding sites for cellular factors. Upon the initiation of S phase, the viral DNA replication and transcription can now begin from the late region, causing the production of necessary structural proteins (VP1, VP2, VP3, LP1). After the necessary proteins and DNA replication is complete, the various viral particles assemble together forming the next generation of SV40 virions. When a high number of virions accumulate in the cells, the cell is lysed and infectious SV40 is released. Infected mesothelial cells, however, can release infectious SV40 without undergoing lysis.

Clinical Relevance

Poliomyelitis was a devastating disease that swept throughout the western world until 1955 when the Salk vaccine began to be used against this crippling disease. Poliovaccines made from monkey kidney cell cultures between 1955 and 1961 and sold until 1963 were found to have been contaminated with numerous supposedly harmless viruses. Knowledge of this contamination was well known, but there was no evidence to suggest any tumorigenic properties of any viruses present in the vaccines. In 1960, Sweet and Hilleman established that an unknown percentage of poliovaccines produced from monkey kidney cell lines was contaminated with SV40. In 1962, Eddy and colleagues produced investigations showing that newborn hamsters injected with rhesus monkey kidney cell cultures developed sarcomas. The resultant sarcomas were attributed to the DNA tumor virus SV40.

It was shown that SV40 was able to successfully replicate, produce infection, and spread throughout humans by oral and respiratory routes. In 1964, when SV40-transformed human cells were injected subcutaneously into volunteer terminally ill patients, those cells were found capable of growth. Vaccines that were produced after 1961 were required by federal law to be tested for SV40, but by that time it has been estimated that ~98 million people, both adults and children, had already been exposed to SV40 through a contaminated poliovaccine. SV40 was able to transform both human and rodent cells in tissue culture. However, epidemiological studies suggested that SV40 was not oncogenic in humans, because the overall incidence of cancer in cohorts injected with contaminated poliovaccines was similar to that of cohorts who had not been exposed to SV40 contaminated poliovaccines.

Subsequent investigations in 1993, showed that when hamsters were injected with SV40 into the pleural space, all of the animals developed mesotheliomas within 3–6 months. Mesotheliomas are tumors that have increased from almost zero to 3,000 cases per year in the USA during the past 50 years. In the USA mesotheliomas are mostly caused by ►asbestos, the finding that SV40 caused mesothelioma in hamsters prompted investigations into the possibility that some mesotheliomas in humans could be attributed to SV40 infection directly or with SV40 acting as a co-carcinogen with asbestos. Mesothelioma samples studied in 1994 showed that 60% of the samples contained SV40 DNA and expressed the SV40 large T (tumor) antigen. The results were confirmed by numerous laboratories using a variety of techniques such as PCR, in situ hybridization, Western blot, immunohistochemistry, Laser dissection/PCR, etc., but the percentage of positive samples varied from 6 to 83%, and a few studies were completely negative. Technical and geographical differences may count for these variances. Significant geographical differences in exposure to SV40 were confirmed by a recent study showing that the poliovaccines used in the former USSR and in the countries under its influence contained infectious SV40 until at least 1978. These findings supported a previous conclusion of the Institute of Medicine of the National Academy of Sciences that the epidemiological data were flawed and therefore it was not possible to accept or reject a causal association between SV40-containing poliovaccines and cancer. In fact, it was not possible to clearly distinguish exposed from non-exposed cohorts. Although the epidemiological data are not available, mechanistic experiments in human mesothelial cells, and animal experiments strongly support a pathogenic role of SV40 in mesothelioma. More recently, SV40 has been shown to be a co-carcinogen in causing mesothelioma in animals and malignant transformation of mesothelial cells in tissue culture. In addition, the data showed that in the presence of SV40 lower amounts of asbestos were sufficient to cause mesothelioma. Co-carcinogenesis was mediated through the activation of the ►extracellular signal-regulated kinases (ERKs) and ►activator protein-1 (AP-1) activity that led to cell proliferation and stromal invasion.

Synonyms

Spleen tyrosine kinase; Syk

Definition

Syk ►tyrosine kinase activity was originally recognized in spleen, thymus and lung and was later cloned from spleen. A 72 kDa protein, Syk contains 635 amino acids and the human gene maps to chromosome 9q22. It contains two N-terminal, ►SH2 domains in tandem and a C-terminal tyrosine kinase domain. Interdomain A separates the tandem SH2 domains and interdomain B links the kinase domain to the tandem SH2 domains. An alternatively spliced site in interdomain B deleting 23 amino acids gives rise to a short form of Syk that can be differently expressed according to the tissue. Syk together with the related Zap70 (zeta-activated protein of 70 kDa) constitute a separate tyrosine kinase family.

Characteristics

Distribution and Function

Syk is critical to immune cell signaling where it promotes ►proliferation, survival, ►phagocytosis,

and ►differentiation and is required for lymphocyte development. Syk also influences angiogenesis and lymphangiogenesis. Animals lacking Syk die around birth from a failure of blood and lymphatic vessel separation. Although Syk is now studied as a target for therapeutic control of asthma, allergy and autoimmune disease due its function in immune cells such as mast cells, there are several indications that Syk is potentially a target for cancer therapy. Syk seems to be involved either positively or negatively in tumor formation and ►progression, depending on the cell type. In hematopoietic malignancies, Syk can be constitutively activated or overexpressed. The TEL-Syk gene fusion resulting from a ►chromosomal translocation identified in a myelodysplastic syndrome patient was found to result in constitutively autophosphorylated Syk that promoted growth factor independent growth in a hematopoietic cell line. Syk may also promote cancer growth in B cell lymphomas since inhibitors of Syk suppresses lymphoma growth. Syk overexpression has been reported in anaplastic lymphoma kinase-positive tumors, and in splenic marginal zone and mantle cell lymphomas, however its direct responsibility in lymphoma development is not known. In contrast, loss of Syk has been reported in ►Reed–Sternberg cells of classical Hodgkin disease, and in ►chronic lymphocytic leukemia and ►acute lymphocytic leukemias.

It is now appreciated that Syk, unlike Zap70, is found not only in hematopoietic cells, but also in many other cell types including mammary, gastric, and lung epithelia, and in hepatocytes, melanocytes, neuronal, muscle and endothelial cells and in some fibroblasts. And, Syk appears to behave as a ►tumor suppressor in a growing list of tumors, including ►breast cancer, ►gastric cancer, ►hepatocellular carcinoma, and ►melanoma in which its expression is lost compared with normal cells. In breast, Syk is progressively lost from normal to hyperplastic to ►ductal carcinoma in situ to invasive cancers.

Experimental Evidence for a Tumor/►Metastasis Suppressor Role of Syk

Animal studies using breast or melanoma cells have shown that re-expression by gene transfer of Syk in tumor cells that are Syk negative, blocks primary tumor growth when tumor cells are injected into the mammary fat pad or in the skin of mice, respectively. Conversely, inhibition of Syk function in breast cancer cells that express Syk is accomplished by gene transfer of a kinase-defective, dominant-negative Syk. This results in more efficient tumor initiation and increased tumor growth when cells are injected into mice. An ►experimental metastasis model reveals that re-introduction of Syk potently blocks lung metastasis of breast and melanoma tumors. In keeping with its role in blocking metastasis, in vitro studies correlate Syk loss in breast cancer cells with invasive growth of cells in a three dimensional extracellular matrix culture system. Re-expression of Syk in Syk-negative cells blocks this invasive growth, as well as inhibiting directional cell ►migration due to ►chemotaxis by tumor cells, and ►anchorage-independent proliferation, processes that are associated with the ability of tumor cells to metastasize. Thus, Syk can behave not only as a tumor suppressor, but also as a metastasis suppressor in non-hematopoietic tumors.

Mechanism of Syk Activation and Signaling

Activating receptors on hematopoietic cells contain one or more cytoplasmic ►immunoreceptor tyrosine-based activation motifs (ITAM) that, following activation of the receptor and phosphorylation on tandem tyrosine-containing motifs by Src family kinases, form binding sites for the Syk tyrosine kinase. This occurs via tandem SH2 domains contained in the N-terminus of this molecule. Syk then phosphorylates itself on multiple tyrosine residues, thereby creating binding sites for its substrates and downstream effectors. Amongst these one can distinguish intermediates of the major intracellular signaling pathways (e.g. ►MAP kinase and ►PI3 kinase) and final effectors (e.g. alpha-tubulin and ►cortactin). These signaling cascades finally affect a complex series of cellular responses such as cell proliferation, differentiation, ►adhesion and migration, ►apoptosis, and phagocytosis. Signaling in hematopoietic cells requires immune cell receptors that are lacking in epithelium and other Syk positive cell types raising the question of the mechanism of Syk activation in epithelial cells. However, Syk can also be activated by transmembrane ►integrin receptors in hematopoietic cells. There is some evidence for β1 integrin-mediated activation of Syk in epithelial cells. ►Integrin signaling is involved in cancer and most particularly in the ►invasion and metastasis processes. In epithelial cells, Syk can also be activated when membrane-bound ITAM motifs are introduced into cells either experimentally, or, associated with ►Epstein-Barr virus (EBV) infection. Relevant to EBV infection in ►nasopharyngeal cancer, Syk activation is required for increased cell migration. Oppositely, in breast cancer and melanoma cells, Syk suppresses chemotaxis when re-expressed following gene transfer experiments. Downstream, following Syk activation, a number of pathways can be activated or inhibited depending upon the cell type and microenvironment. Thus, across the spectrum of cancers, Syk function likely depends on the cellular and molecular context, which varies widely between hematopoietic cells and other cell types.

Syk might also influence cell behavior via its differential subcellular localizations in breast epithelial cells. Syk possesses a nuclear targeting sequence that is absent in the alternatively spliced short form, and nuclear localization is associated with suppression of tumor cell invasion and alteration in expression of transcription factors via interaction with SP1 transcription factor in breast cancer cells. Syk also negatively regulates SP1 activation during hypoxic stimulation as occurs during tumor cell growth in areas of low oxygen abundance. An early observation was that re-introduction of Syk into Syk-negative breast cancer cells results in abnormal cell division and cytokinesis. Correspondingly, Syk was found to be present also at the centrosome, the major microtubule organizing center of the cell. This localization is dependent upon its tyrosine kinase activity, and its presence there is tightly regulated during cell cycle progression suggesting a potential to regulate cell proliferation. In other epithelial cells, such as lung, the role of Syk may be more closely aligned with its function in immune cells, since Syk activation is required for production of inflammatory molecules induced by tumor necrosis factor.

Clinical Studies of Syk Expression and Activity

Clinical pathology studies of tissues from breast and gastric cancer patients reveal that the loss of Syk is associated with poor outcome such as reduced overall survival and increased metastasis risk. Syk nuclear localization was significantly associated with improved outcome in gastric cancer. Loss of Syk protein in cancer cells is an independent prognostic marker of poorer overall survival in hepatocarcinoma cells revealed by multivariate statistical analysis but Syk has not been found to be an ►independent prognostic factor in breast or gastric cancers to date.

Loss of Syk is at least partially due to ►epigenetic gene silencing caused by the ►hypermethylation of a ►CpG island in the promoter portion of the SYK gene. This has been documented in breast, transitional cell carcinoma of the bladder, hepatocellular carcinoma, gastric, melanoma, and ovarian cancers; and in T-lineage acute lymphoblastic leukemia. Hypermethylation of the SYK gene is an independent prognostic factor of poorer overall survival in hepatocellular carcinoma. Microarray comparison of genes previously shown to be altered by hypermethylation revealed differential Syk expression in normal versus prostate cancer cells. And, Syk methylation is associated with ►histopathological grade in transitional cell carcinoma of the bladder, loss of Syk being associated with the most invasive tumors. Overall, Syk expression appears to be primarily regulated at the transcriptional level, but presently no transcription factors regulating Syk expression have been identified.

Sympathetic Ganglia Neurons

Definition

Nerve cells that make-up the sympathetic nervous system.

Symptom Management

Definition

Treatment of the symptoms caused by cancer disease

►Leptomeningeal Dissemination

S

Synaptic Vesicle Recycling

Definition

A specialized class of small vesicles (synaptic vesicles, ~50 nm diameter) in nerve cells store neurotransmitters and releases them upon the arrival of an action potential at the nerve terminal. Neurons can fire in excess of a thousand times per second, which would rapidly lead to depletion of synaptic vesicles. Thus, synaptic vesicles

are efficiently internalized, after their fusion with the plasma membrane by a molecular machinery that is largely overlapping that of ►endocytosis.

Synaptopodin

Definition

A gene expressed in renal podocytes and neurons and interacting with actin.

►Myopodin

Synchronizer

Definition

The regular alternation of light and darkness over 24 h, social time cues, and feeding schedules periodically reset the endogenous bodily rhythms and hence, they are called synchronizers. The light–dark synchronization displays species specificity. Thus, mice or rats that are used for preclinical tests of cancer therapeutics rest during the light span and are active at night, while the reverse is true for humans.

►Circadian Clock Induction

N-Syndecan

Definition

Is a member of the syndecan family of transmembrane heparan sulfate proteoglycans that was cloned initially from neonatal rat Schwann cells and is the principal syndecan expressed during early postnatal development in the central and peripheral nervous systems. Purified N-syndecan binds in vitro with high affinity to several extracellular regulatory ligands, including basic fibroblast growth factor, pleiotrophin and a novel collagen-like protein secreted by Schwann cells that bind to the heparan sulfate chains of N-syndecan. It is suggested that ligand-regulated dimerization of N-syndecan represents a mechanism for regulating downstream signaling activities.

►Pleiotrophin

Syndecans

Definition

Are a diverse group of type I transmembrane heparan sulphate ►proteoglycans with a wide array of ligands and distinct cell signaling capabilities. Four mammalian syndecans have been identified: syndecan-1/CD138, syndecan-2/fibroglycan, syndecan-3/N-syndecan, and syndecan-4/ryudocan. The heparan sulphate glycosaminoglycan chain of syndecans binds a number of extracellular proteins, including growth factors, ►chemokines, extracellular matrix components, cell adhesion molecules, proteases, and protease inhibitors. Although in some cases the family members have overlapping functions, syndecans and their heparan sulphates can bind distinct ligands and produce cellular responses unique to each syndecan. Moreover, the in vivo expression pattern of each syndecan can differ greatly from the others.

►Pleiotrophin

Synergism

Definition

Is opposite to antagonism, i.e., two or more agents create stronger effect than the predicted sum of their individual effects.

►Xenobiotics

Synergistic

Definition

Interaction of two or more agents that results in a combined effect greater than the sum of their individual effects.

►Nilotinib

Syngeneic

Definition

Genetically identical or closely related, so as to allow tissue transplant, immunologically compatible.

Synovial Sarcoma

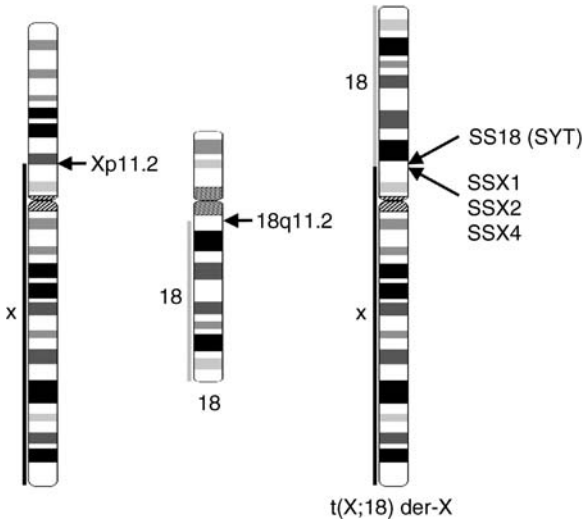
Diederik de Bruijn, Ad Geurts van Kessel
Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands

Definition

Human synovial sarcomas are soft tissue tumors that account for up to 10% of all human sarcomas and mainly affect children and young adults. These tumors display relatively high rates of local recurrences and metastases (►metastasis) and are therefore regarded as high grade tumors. Five- and ten-year survival rates of 60–80% and 40–50%, respectively, have been reported in several large retrospective studies. The tumors occur most frequently in the extremities (often associated with the large joints), but may also be encountered in a wide variety of organs. The name synovial sarcomas is misleading since it has become clear that they do not originate from synovial tissue. Instead, synovial sarcomas are thought to be derived from progenitor cells that are capable of differentiating into mesenchymal and/or epithelial structures. A very recent study indicated that these progenitor cells may, in fact, be primary myocytes. Histopathologically, synovial sarcomas can be subdivided in four subtypes: (i) biphasic (with an epithelial and a mesenchymal component), (ii) monophasic (either mesenchymal or epithelial), (iii) calcifying and (iv) poorly differentiated tumors.

Characteristics

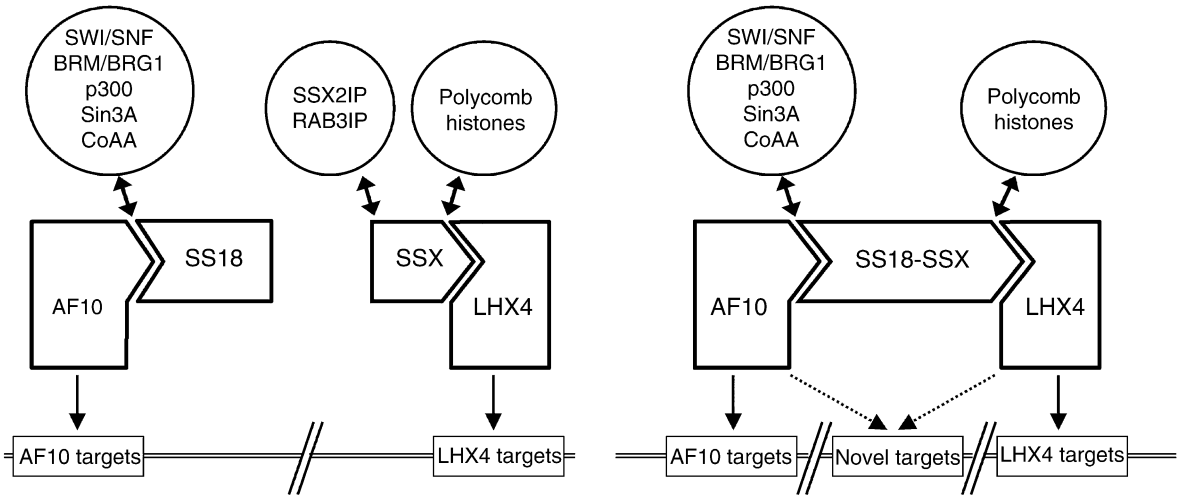
Cytogenetically, the tumors are characterized by a specific chromosomal translocation, t(X;18)(p11;q11) (Fig. 1), which leads to a fusion of the SS18 (previously known as SYT or SSXT) and SSX genes. In the far majority of SS18-SSX fusion proteins identified to date, the C-terminal eight amino acids of the SS18 protein are replaced by the C terminal 78 amino acids of one of the SSX proteins. The SSX genes constitute a family of at least nine (highly related) X-chromosomal genes. Of these, three were found to be involved in the SS18 fusions: SSX1, SSX2 and SSX4. SS18-SSX fusion genes have been detected in almost all synovial sarcomas, but not in any other tumor type examined so far. Clinically, synovial sarcomas display a variable response to common treatment protocols, such as radiation and chemotherapy (►adjuvant Therapy). Over the years, many investigators have reported adverse prognostic factors, such as tumor size (>5 cm), high tumor grade, advanced (metastatic) disease and (higher) patient age. Treatment with chemotherapy (ifosfamide, either alone or in combination with doxorubicin) has been reported to increase the overall survival rates, also



Synovial Sarcoma. Figure 1 The synovial sarcoma specific t(X;18)(p11;q11) chromosomal translocation. The normal chromosomes X and 18 with the respective breakpoints are shown to the *left*. The derivative-X chromosome, with the breakpoint-associated genes (*SS18*, *SSX1*, *SSX2* and *SSX4*) is shown to the *right*.

of patients with high grade tumors and metastases. Despite these findings, there is ample room for further improvement and optimization of the (differential) diagnosis and treatment of human synovial sarcomas. To enable this, detailed information about the molecular mechanisms underlying synovial sarcoma development is of imperative importance.

The tumorigenic nature of the SS18-SSX fusion protein has been established in vitro and in vivo (►oncogene). Further, functional, analysis of the SS18 and SSX genes has revealed that they encode nuclear proteins that exhibit opposite transcriptional regulatory activities. The SS18 protein functions as a transcriptional co-activator which interacts directly with the transcription factor AF10, the co-activator CoAA, and several members of the epigenetic chromatin remodeling (BRM and BRG1) (►chromatin Remodeling in Cancers) and modification machineries (p300 and SIN3A) (►p300/CBP Co-Activators). In contrast, the SSX proteins function as transcriptional co-repressors which interact with the RAB3IP and SSX2IP proteins and the transcription factor LHX4, and are associated with histones and several Polycomb group repressor proteins. The domains involved in these apparently opposite transcription regulatory activities are retained in the SS18-SSX fusion proteins. Therefore, these may function as "activator-repressors" of transcription, which can bind to target DNA through the AF10 and LHX4 transcription factors (Fig. 2). This notion implies that the SS18 and/or SSX protein functions may be impaired in the SS18-SSX fusion protein. Alternatively, the fusion



Synovial Sarcoma. Figure 2 Model depicting the synovial sarcoma associated SS18, SSX and SS18-SSX (fusion) proteins and their respective interactions. In normal cells (*left)* the SSX proteins and their interactors SSX2IP and RAB3IP may associate with the Polycomb repressor complex and histones and in addition, through interaction with the LHX4 protein, bind to cognate DNA sites and affect target gene expression. The SS18 protein can interact with several members of the SWI/SNF chromatin remodeling complex (BRM and BRG1), but also with proteins involved in covalent chromatin modifications (p300 and Sin3A) and the co-activator CoAA. In addition, through interaction with the transcription factor AF10, SS18 may bind to cognate DNA sites and affect target gene expression. In synovial sarcoma cells (*right*) the SS18-SSX fusion proteins have lost the interaction domains for SSX2IP and RAB3IP, but have retained the interaction/association domains for both the SWI/SNF and the Polycomb complexes. Through these interactions, the SS18-SSX fusion proteins may anomalously affect the regulation of these target genes and/or affect the regulation of other (novel) target genes, either through AF10, LHX4, or both.

protein may have gained novel functions. A recent functional analysis revealed that the SS18-SSX fusion protein influences the process of ►epithelial to mesenchymal transition (EMT) which is commonly observed in tumor cells. This example of a SS18-SSX gain-of-function may underlie the above-mentioned histologic differences among synovial sarcomas. A recent study has indicated that novel treatment options for synovial sarcoma patients may include so-called "epigenetic" drugs (►epigenetic Therapy). Synovial sarcoma cell lines were shown to be extremely sensitive to the histone de-acetylase inhibitory drug Romidepsin (also known as FK228 or depsipeptide), both in vitro and in vivo. As yet, the exact mode of action of this broad spectrum "epigenetic" drug on synovial sarcoma growth is unknown. However, it is to be expected that detailed knowledge on the molecular mechanisms underlying synovial sarcoma pathogenesis will be instrumental for obtaining insight into its mode of action and, thus, the development of more targeted therapies.

Synuclein

Julia M. George
Department of Molecular and Integrative Physiology, University of Illinois at Urbana-Champaign, IL, USA

Definition

Synucleins are small cytosolic proteins of uncertain function, normally expressed at high levels in the vertebrate nervous system. Increased expression of synuclein proteins, especially γ-synuclein, is associated with progression of a variety of tumors.

Characteristics

The precise function of the synuclein proteins is not well understood. All family members (α-synuclein, ►SNCA; β-synuclein, ►SNCB; and ►γ-synuclein, ►SNCG) share a conserved domain related to the lipid-binding domains of the ►exchangeable apolipoproteins, the major lipid transporters in blood. This conserved domain mediates reversible interactions with lipid membranes. α-Synuclein regulates the uptake and incorporation of fatty acids into phospholipids, and mutations in α-synuclein alter the composition of cellular membranes.

Each of the synuclein isoforms possesses a unique tail domain, which may mediate distinct physiological actions. α- and β-synuclein are normally expressed in the ►central nervous system, while γ-synuclein expression is found throughout the central and ►peripheral nervous systems, and at lower levels in some non-neural tissues. Synuclein family genes have so far been identified only in vertebrate species.

Synuclein Expression in Cancer

The first synuclein family member to be associated with cancer was γ-synuclein, which was originally named ►breast cancer-specific gene 1 (►BCSG1), due to its specific expression in infiltrating breast carcinoma as compared to normal breast tissue. The other synuclein proteins are also somewhat associated with certain cancers. For example, 87% of ►ovarian cancers display increased expression of one or more synuclein family members, while 42% express all three. The γ-synuclein isoform is particularly associated with cancer. Overexpression of γ-synuclein is observed in a large percentage of tumors from varied tissues of origin, but not in adjacent non-neoplastic tissues. Expression of γ-synuclein in cancer increases in a stage-specific manner, with moderate expression in stage I tumors, and very high expression in stages III-IV.

Increased expression of γ-synuclein in tumor cells apparently results from deregulation of normal expression, as no γ-synuclein mutations or gene amplifications have been associated with cancer. Tissue specific expression of γ-synuclein is mediated by methylation of ►CpG islands in exon 1, and ►hypomethylation at these sites has been observed in γ-synuclein overexpressing tumor cells. The increased expression of γ-synuclein observed in advanced cancer is mostly likely the consequence of a loss of ►epigenetic gene silencing of γ-synuclein expression during tumor progression, rather than a primary event in tumor initiation.

Misfolding of α-synuclein protein is associated with both familial and sporadic ►Parkinson's disease (PD), and mutations in α-synuclein that alter its sequence or increase its expression cause early-onset PD. PD patients have an increased risk of both ►melanoma and breast cancer, as compared to the general population, but a decreased risk for many other cancers. This may reflect the involvement of common genes in PD and cancer.

Role in Tumor Progression

γ-Synuclein expression in breast cancer cell lines increases cell proliferation. It interacts with the mitotic spindle checkpoint control protein ►BubR1, promoting its degradation by the proteasome and overriding mitotic arrest. Loss of spindle checkpoint control can result in ►aneuploidy, the state of having the wrong number of chromosomes. γ-Synuclein augments proliferative signaling through the ►estrogen receptor pathway, by acting as a molecular chaperone to increase ►estradiol binding to the receptor. γ-Synuclein also alters signaling via the ►MAP kinase pathway, which plays a key role in the regulation of cell proliferation.

γ-Synuclein enhances cell motility and invasiveness, and its overexpression in established tumors may drive malignant tumor progression. γ-Synuclein promotes production of ►matrix metalloproteinases, secreted

proteases that break down the extracellular matrix and allow tumors to invade surrounding tissues and blood vessels, thereby facilitating ►metastasis. γ-Synuclein expression also increases resistance to certain chemotherapeutic agents that trigger ►apoptosis via MAP kinase and/or ►JNK signaling pathways, e.g. ►taxol, vinblastine, and ►paclitaxel.

Overall, γ-synuclein expression in a tumor correlates with a poor clinical prognosis. Its expression in primary tumors is associated with the presence of distant metastases. This protein may prove to be a useful ►biomarker for detecting cancer, ►staging tumor progression, and evaluating metastatic potential.

Tamoxifen

V. Craig Jordan
Fox Chase Cancer Center, Philadelphia, PA, USA

Definition
Tamoxifen is a nonsteroidal antiestrogen used for the treatment and prevention of ►estrogen receptor (ER) positive breast cancer. Tamoxifen is the most studied anticancer agent.

Characteristics
Background
Tamoxifen (ICI 46,474) was first described as an effective postcoital contraceptive in rats but the drug induces ovulation in subfertile women. The compound was subsequently reinvented throughout the 1970's as an agent to be targeted to OER positive breast cancers for use as a long-term adjuvant therapy with potential use for the chemoprevention of breast cancer (►Estrogenic hormones and cancer, ►hormones and ►cancer).

Adjuvant Therapy
Studies throughout the 1980's and 1990's demonstrated that long-term adjuvant tamoxifen therapy (5 years) produced dramatic increases in disease-free survival and overall survival. These data were observed in patients who were classified as Stage I and Stage II breast cancers and the compound is effective in both pre and postmenopausal women. Tamoxifen is cheap and effective with availability in generic form in countries throughout the world. Tamoxifen is credited for increasing survivorship and saving the lives of 500,000 women. The appropriate use of tamoxifen as the gold standard for the endocrine treatment of breast cancer throughout the 1990's, is credited in contributing to the decrease death rate from breast cancer observed in the United States and other countries around the world. However, concerns about side effects (see below) and the development of drug resistance has led to the development of the aromatase inhibitors as a substitute

for tamoxifen in the adjuvant treatment of breast cancer in postmenopausal women. Current studies demonstrate that aromatase inhibitors have an improved side effect profile compared to tamoxifen and improved disease-free and overall survival.

Chemoprevention

Laboratory studies first showed that tamoxifen could prevent the development of carcinogen-induced rat mammary tumors. Randomized clinical trials around the world have demonstrated that tamoxifen can reduce the incidence of breast cancer by 50% in high risk pre and postmenopausal women. High risk refers to the mathematical model (Gail Model) that is available on the internet through the National Cancer Institute in the United States that will determine the 5 year and lifetime risk of a woman developing breast cancer. Some of the risk factors used in the Gail Model are age, start of menses, termination of menses, age when the woman had children, if the woman had children, breast biopsies, ductal hyperplasia, and first degree relatives developing breast cancer.

Concerns about the side effects of tamoxifen (see below) have focused the use of tamoxifen in the premenopausal population where the risk/benefit ratio is high. In other words, tamoxifen effectively reduces the incidence of breast cancer but the side effect profile is low. Most importantly, after women take a 5 year course of tamoxifen during their premenopausal years, the beneficial effects of tamoxifen in preventing breast cancer may last for up to another 10 years but the side effects of hot flashes, etc. will disappear. Recent studies of a related compound, Raloxifene that is used for the prevention of osteoporosis, shows that this selective estrogen receptor modulator or (SERM) will prevent breast cancer in women taking raloxifene to prevent osteoporosis. A recent clinical trial in the United States called the Study of Tamoxifen and Raloxifene (STAR) demonstrated in postmenopausal women that tamoxifen and raloxifene were equally effective in preventing an increase in invasive breast cancer but raloxifene had a superior side effect profile.

Mechanism of Action

Tamoxifen is lipophyllic and well absorbed from the gastrointestinal tract. Patients accumulate tamoxifen over the first 4 weeks of treatment when they reach steady-state. The drug has a long biological half-life so that even if treatment is stopped, the drug can be detected in the blood for up to 6 weeks. Tamoxifen is a prodrug that is metabolically activated by the CYP2D6 enzyme system to the compounds 4-hydroxytamoxifen and endoxifen both of which have a high affinity with the OER. It is important to note that CYP2D6 enzyme system can be blocked by certain selective serotonin reuptake inhibitors (SSRIs) and this may impair the antitumor actions of tamoxifen. Patients often take SSRIs to reduce the incidence of hot flashes in patients taking tamoxifen.

Tamoxifen binds to the ligand binding domain of the OER in the breast tumor and causes a conformational change that is distinct from the natural estradiol OER complex. As a result, tamoxifen is unable to cause gene activation and completely mimic estrogen action. However, tamoxifen is not a complete antiestrogen. The tamoxifen estrogen receptor complex retains estrogen-like actions which can switch on and switch off target sites around a patient's body. For example, tamoxifen is an antiestrogen in the breast but has estrogen-like properties in bones and in the uterus. Tamoxifen is classified as a selective estrogen receptor modulator.

Side Effects

Tamoxifen exhibits specific estrogen-like effects and also antiestrogenic effects. Tamoxifen is sufficiently estrogenic to stimulate the uterine endometrium and enhance the growth of OER positive ►endometrial cancers. Tamoxifen causes a fivefold increase in endometrial cancer compared with women not taking tamoxifen. In other words, if a thousand 60 year postmenopausal women were followed for endometrial cancer, one woman per year would develop endometrial cancer. In contrast, if those same women were taking tamoxifen, five women would develop endometrial cancer (low grade, early stage) per year. Additionally, the estrogen-like effects of tamoxifen are reflected in an increase in thromboembolic disorders in postmenopausal women. It is important to note that endometrial cancer and blood clots are not elevated in premenopausal women. There is also a significant rise in the diagnosis of cataracts and cataract operations. The STAR trial demonstrated that raloxifene does not increase the risk of endometrial cancer. There were fewer hysterectomies, fewer cataracts, fewer cataract operations and a lower overall incidence of blood clots.

Tamponade

Definition

The accumulation of a fluid (blood or serous exudate) in thepericardial sac, leading to compression of the chambers of the heart and leading to increasing heart failure.

►Cardiac Tumors

Tankyrase-2: TNKL, TNKS2, TANK2

►Tankyrases

Tankyrases

Hiroyuki Seimiya
Division of Molecular Biotherapy, Cancer Chemotherapy Center, Japanese Foundation for Cancer Research, Koto-ku, Tokyo, Japan

Synonyms

TRF1-interacting, ankyrin-related ADP-ribose polymerases; There are two closely related homologues: Tankyrase-1: TNKS, TNKS1, TANK1; Tankyrase-2: TNKL, TNKS2, TANK2

Definition

Tankyrases are members of the poly(ADP-ribose) polymerase (►Parp) family that regulate telomere length in ►telomerase-positive human cells. There are two related homologues, tankyrase-1 and tankyrase-2. Tankyrase-1 is a protein of 1327 amino acids and 142 kDa. The gene maps to 8p22-p23. Tankyrase-2 is a protein of 1166 amino acids and 127 kDa. The gene maps to 10q23. Tankyrase-1 is relatively abundant in reproductive tissues (i.e. testis and ovary), whereas tankyrase-2 exhibits rather ubiquitous expression.

Characteristics

Structure

Tankyrase-1 has four characteristic domains: HPS, ANK, SAM, and PARP. The N-terminal HPS domain is a homopolymeric run of histidine, proline, and serine residues, the functional significance of which is unknown. The ANK domain is composed of a long stretch of 24 ANK repeats, providing a platform for protein-protein interactions. Distinct from those of ankyrins, tankyrase-1's ANK domain is further divided into five, well-conserved subdomains, ARC (ANK repeat cluster) I-V. Each ARC works as an independent, ligand-binding site. The SAM (sterile alpha motif) domain is another module for protein-protein interaction and contributes to self-multimerization of the protein. The C-terminal PARP domain catalyzes ►poly (ADP-ribosyl)ation of acceptor proteins by using NAD as a substrate. This post-translational modification gives drastic negative charges to the acceptor proteins and often disrupts interactions between the acceptor proteins and their target DNA.

Tankyrase-2 is a closely related homologue of tankyrase-1. Amino acid identities between ANK, SAM, and PARP domains of tankyrase-1 and tankyrase-2 are 83, 74, and 94%, respectively. The most striking feature of tankyrase-2 is the absence of an N-terminal HPS domain. Tankyrase-1 and tankyrase-2 can associate in intact cells via their SAM domains to form a multimer.

Intracellular Distribution

Tankyrase-1 is found at various intracellular loci, including telomeres, mitotic ►centrosomes, Golgi apparatus, and nuclear pore complexes. Telomeric localization of tankyrase-1 is mediated by its interaction with a telomeric repeat-binding factor 1 (TRF1), which directly binds the double-strand telomere DNA, $(TTAGGG)_n$. During mitosis, tankyrase-1 concentrates around the pericentriolar matrices. This accumulation depends on tankyrase-1's interaction with nuclear/mitotic apparatus protein (NuMA), which plays an essential role in organizing microtubules at the spindle poles. In the Golgi apparatus, tankyrase-1 is peripherally associated with the Golgi membranes. In adipocytes and myocytes, it is colocalized with GLUT4 (glucose transporter 4) storage vesicles in the juxtanuclear region of the cells, where it specifically binds to insulin-responsive amino peptidase (IRAP).

The intracellular localization of tankyrase-2 has been characterized less often than tankyrase-1. So far, it has been reported that tankyrase-2 localizes predominantly to a perinuclear region, similar to the properties of tankyrase-1. Upon subcellular fractionation, both tankyrase-1 and tankyrase-2 are predominantly recovered in the low-density microsomal fraction, which contains vesicular ►endosomal compartments.

Binding Partners

To date, various tankyrase-1- and tankyrase-2-binding proteins have been reported with a consensus RXX(P/A)DG motif as a canonical tankyrase-binding site. Such proteins include TRF1, NuMA, IRAP, Grb14 signaling adaptor protein, tankyrase-binding protein of 182 kDa (TAB182), Mcl-1 apoptotic regulator, and Epstein-Barr

virus nuclear antigen-1 (EBNA-1). TRF1, NuMA, IRAP, TAB182, EBNA-1, and tankyrase-1 and tankyrase-2 themselves have been shown to be poly(ADP-ribosyl)ated by tankyrases. PARP inhibitory compounds, such as 3-aminobenzamide, PJ-34, and 4-amino-1,8-naphthalimide, block this poly(ADP-ribosyl)ation.

Functions

Depending on the binding partner and subcellular localization, tankyrase-1 is involved in several distinct biological events, including telomere elongation, cell division control, and insulin-stimulated glucose uptake. Also, the coexistence of multiple ARCs and an oligomer-forming SAM domain is implicated in the master scaffolding function of tankyrase-1 (and tankyrase-2), which could work as an intracellular "molecular lattice."

Telomere Elongation

Classical DNA replication machinery cannot replicate the very ends of linear DNA; ►end replication problem. Accordingly, native capping structures at the ends of chromosomes, telomeres, gradually erode after each round of the cell cycle in somatic cells. Most immortalized cells, including germ cells and 80–90% of cancer cells, maintain their telomere length by activating telomerase. Telomere elongation by telomerase requires its enzyme activity and accessibility to the substrate, 3′-overhang of telomere DNA (also called as the telomeric G-tail). Telomere access to telomerase is repressed *in cis* by the telomeric protein TRF1. Thus, TRF1 directly binds an array of double-strand telomere DNA, $(TTAGGG)_n$, and recruits additional telomere-binding proteins, such as TIN2 (TRF1-interacting nuclear factor 2), TPP1 (originally designated PTOP (POT1- and TIN2-organizing protein), PIP1 (POT1-interacting protein 1) or TINT1 (TIN2-interacting protein 1)), and POT1 (protection of telomeres 1), to the chromosome ends. The resulting TRF1-TIN2-TPP1-POT1 complex diminishes accessibility of telomerase to the telomeres. According to this mechanism, longer telomeres provide more binding sites for TRF1 and therefore become a less reactive substrate for telomerase. Conversely, shorter telomeres provide fewer binding sites for TRF1 and become a more reactive substrate for telomerase. This balance between open and closed states of the telomeres stabilizes the length of telomeric TTAGGG tracts at each chromosome end of telomerase-positive cells.

Tankyrase-1 enhances telomere access to telomerase and contributes to telomere elongation: tankyrase-1 binds to the N-terminal acidic domain of TRF1 via its ANK domain. As described above, the ANK subdomain, ARC, plays a role in association with TRF1. While each of five ARCs can independently recognize TRF1, ARC V, the one closest to the C-terminal, is the most important for telomeric function of tankyrase-1. Interaction between ARC V and TRF1 enables tankyrase-1 to poly(ADP-ribosyl)ate TRF1. This post-translational modification eliminates telomere binding of TRF1, resulting in dissociation of the TRF1-TIN2-TPP1-POT1 complex from telomeres. Telomere-unbound TRF1 is degraded by ubiquitin-dependent proteolysis; ►ubiquitination. These alterations induce a telomere open state and facilitate telomere elongation by telomerase. It is notable that tankyrase-1 enhances telomere access of telomerase but does not increase the enzyme activity of telomerase. Indeed, tankyrase-1 overexpression induces telomere elongation in a telomerase-dependent manner.

Tankyrase-1 can form a ternary complex with TRF1 and TIN2. In this complex, poly(ADP-ribosyl)ation of TRF1 is prevented by TIN2. So far, however, when and how tankyrase-1 is activated or inactivated is not fully understood. Like tankyrase-1, tankyrase-2 also can recognize and poly(ADP-ribosyl)ate TRF1. However, the extent of functional redundancy and specificity between tankyrase-1 and tankyrase-2 are largely unknown.

Cell Division Control

Since ►siRNA-mediated knockdown of tankyrase-1 causes mitotic arrest of multiple cell types, tankyrase-1 is thought to be required for proper cell division. In normal cell division, each pair of sister chromatids is equally divided into two daughter cells. In some tankyrase-1 knockdown cells, however, sister chromatids can separate at the centromeres and arms but not at the telomeres. Accordingly, cell division is interrupted and abnormal chromosome distribution and spindle morphology occur. In other tankyrase-1 knockdown cells, mitotic arrest occurs with intact sister-chromatid cohesion (arrest at the metaphase). Tankyrase-1 is also required for the assembly of bipolar spindles. It recognizes a centrosomal protein NuMA via its ANK domain, and poly(ADP-ribosyl)ates NuMA in intact cells. Consistently, these two proteins are co-localized at the mitotic centrosomes. Meanwhile, tankyrase-1 is phosphorylated during mitosis by glycogen synthase kinase 3 (GSK3). GSK3 inhibitors, such as lithium chloride and indirubin, inhibit this phosphorylation. Currently, the functional significance of NuMA's poly(ADP-ribosyl)ation and tankyrase-1's phosphorylation during mitosis remain unknown.

Insulin-Stimulated Glucose Uptake

The GLUT4 vesicle is an endocytic compartment within adipocytes and myocytes. This storage vesicle contains the glucose transporter protein, GLUT4, and it regulates glucose uptake upon stimulation with insulin; major fractions of the GLUT4 vesicles usually reside in the trans-Golgi reticulum. Insulin stimulation induces exocytic translocation of the vesicles towards the cell surface, where GLUT4 facilitates glucose uptake. In adipocytes, insulin-stimulated translocation of GLUT4

is mediated by IRAP, another GLUT4 vesicle-resident protein.

Tankyrase-1 is implicated in regulation of GLUT4 translocation. As mentioned, tankyrase-1 directly binds IRAP via its ANK domain and can poly(ADP-ribosyl) ate IRAP. Tankyrase-1 knockdown by siRNAs attenuates the insulin-stimulated translocation of GLUT4 vesicles and subsequent glucose uptake. This inhibitory effect of siRNA is reproducible with PJ-34, a PARP inhibitor that is effective against tankyrase-1 (and other PARPs). Tankyrase-1 knockdown does not attenuate the upstream insulin signaling, such as phosphorylation of the ►insulin receptor, IRS-1 (insulin receptor substrate-1), Akt; ►AKT signal transduction pathway in oncogenesis, GSK3, and p42/p44 ERKs (extracellular signal-regulated kinases; ►MAP kinase).

Clinical Aspects

Telomere synthesis by telomerase is the Achilles' heel of unlimited proliferation of most cancer cells. Continuous treatment of cancer cells with telomerase inhibitory drugs (►Small molecule drugs) shortens telomeres and eventually induces cellular ►senescence, ►apoptosis, or both. Thus, telomerase inhibitors have the potential to benefit cancer patients; ►molecular therapy. One concern is that telomere shortening *per se* compromises the effect of telomerase inhibitors since shorter telomeres have fewer TRF1 and therefore allow easier access to residual telomerase activity. This phenomenon results from incomplete shutdown of telomerase activity.

In addition to enzyme activity, accessibility to telomeres could be a rational target for telomerase inhibition. In fact, tankyrase-1 modulates the impact of telomerase inhibitors on human cancer cells. First, tankyrase-1 overexpression, which removes TRF1 from telomeres, confers resistance to telomerase inhibitors. PARP inhibitors, such as 3-aminobenzamide and PJ-34, reverse this drug resistance. Second, even in cells that do not overexpress exogenous tankyrase-1 (but do express endogenous tankyrase-1) these PARP inhibitors enhance telomere shortening by means of telomerase inhibitors, such as MST-312. Accordingly, the cells undergo earlier crisis. Telomerase inhibitor-resistance caused by telomere shortening *per se* is also reversed by 3-aminobenzamide. These observations suggest that tankyrase-1 could be a target for cancer therapy; ►chemotherapy of cancer, progress and perspectives. Pathologically, tankyrase-1 gene expression is elevated in some tumors but not in others.

Tarceva

►Erlotinib

Target Cells

Definition

The functions of effector T cells are always assayed by the changes that they produce in antigen-bearing target

cells. These cells can be B cells, which are activated to produce antibody; macrophage, which are activated to kill bacteria or tumor cells; or labeled cells that are killed by cytotoxic T cells.

Target-Based Screen

Definition

A procedure in which molecules are systematically tested for their ability to activate, perturb, or modify a particular biological molecule.

►Small Molecule Screens

Targeted Deletion

Definition

The process used in generation of a mouse embryonic stem cell (ES cell) with a portion of a specific gene deleted on one allele; embryonic stem cells are transfected with a DNA carrying the deleted gene flanked by regions exactly matching the endogenous allele to be targeted, and in some ES cells the transfected DNA recombines with the homologous endogenous allele, replacing the endogenous allele with the deleted allele.

Targeted Drug Delivery

Duxin Sun
Division of Pharmaceutics, College of Pharmacy, The Ohio State University, Columbus, OH, USA

Synonyms

Drug targeting; Site-specific drug delivery

Definition

Targeted drug delivery is to site-specifically deliver or activate the therapeutic compounds in tumor. Thus, the targeted drug delivery is expected to enhance drug efficacy by increasing local active drug concentration in tumor, and to decrease side effect by minimizing drug exposure in normal tissues.

Characteristics

Anticancer drugs possess a greater potential of toxicity and much narrower therapeutic index than any other categories of medication. ►Chemotherapy is often dose- and toxicity-limited. A delicate dose regimen is usually required to balance drug efficacy, drug toxicity, and drug resistance; a high dose might cause toxicity while a low dose might induce drug resistance. In addition, anticancer drugs are usually designed to act on the fast proliferating ►cancer cells. However, rapid proliferation is also the feature of some normal cells such as bone marrow, hair follicles, and intestinal epithelium. Although tremendous effort has been explored to improve the protocol of chemotherapy, the success is very limited to enhance drug efficacy and to reduce drug toxicity.

Several targeted drug delivery technologies have been studied to improve chemotherapy by enhancing drug efficacy and reducing drug toxicity, which have achieved certain degree of success.

Intratumoral Drug Administration

The simplest form of targeted drug delivery is local intratumoral drug administration. The therapeutic compounds can be directly injected into tumor tissues to transiently increase local drug concentration with minimal or no exposure to normal tissues. However, this method may not be applicable for many cancers. It is also difficult to maintain effective drug concentration in tumors for a prolonged time, and thus repeated dosing may be required.

Liposomal Drug Delivery

Chemotherapeutic compounds can be encapsulated in liposome. Liposomal drug formulation achieves passive drug targeting in tumor by enhanced permeability and retention (EPR) effect. Tumor tissues have abnormal vasculature. Since these vasculatures are hyperpermeable with no lymphatic drainage, the liposome will be delivered to the tumor tissues by blood circulation and trapped in the tumors. The drug in the liposome will be gradually released to achieve anticancer efficacy. Therefore, liposomal drug formulation will passively enhance drug accumulation in tumor and decrease exposure to susceptible healthy tissues. The successful liposomal formulation of doxorubicin has been used clinically for cancer treatment. Several generations of liposome formulations have been tested. First generation of liposome passively enhances drug accumulation in tumors and decreases the exposure in normal tissues, but it is rapidly cleared in blood (within minutes). Second generation of liposomes (PEGylated long-circulating

liposomes and ►immunoliposome) increase half-life in blood circulation and tumor targeting.

Tumor-Activated Prodrug Therapy (TAP)

The first strategy in TAP therapy is site-specific prodrug activation. Prodrug is an inactive form of a therapeutic compound by chemical modifications. The inactive prodrug can be activated by an overexpressed enzyme in tumor to achieve site-specific activation, while the prodrug remains inactive or less activated in normal tissues to reduce toxicity. The site-specific activation of the prodrug in tumor increases the anticancer efficacy. The clinically used anticancer drug Xeloda (Capecitabine) provides a best example for this strategy. Xeloda is the first oral chemotherapy drug for the treatment of metastatic colorectal cancer. Xeloda is a ►5-fluorouracil (5-FU) prodrug, which is orally administered. Three enzymes (carboxylesterase, cytidine deaminase, and thymidine phosphorylase) activate Xeloda to produce active 5-FU. Xeloda is hydrolyzed by carboxylesterase into 5′-deoxy-5-flurocytidine (5′-DFCR). Subsequently, 5′-DFCR is converted by deaminase to 5′-deoxy-5-flurouridine (5′-DFUR). Finally, 5′-DFUR is converted into 5-FU by thymidine phosphorylase. Due to the high level of thymidine phosphorylase in tumor, more activation of xeloda is observed in tumors than in normal tissues to exhibit better anticancer efficacy than 5-FU.

The second strategy of TAP is to directly link the prodrug to a targeting moiety (antibody or other ligands) for targeted drug delivery. The antibody-prodrug conjugate binds to the antigen on the tumor cells. The drug–antibody–antigen complex is rapidly internalized into the cancer cells to achieve high drug concentration in targeted cells. For example, anti-CD33 antibody can be conjugated with calicheamicin to target acute myeloid leukemia cells due to the high level of CD33 on the cell surface. Antibody trastuzumab-taxane conjugate shows 55–200-fold more potent than Taxol. Daunorubicin and methotrexate have been linked to anti-MM46 antibody or anti-EL4 monoclonal antibody for treatment of human melanoma. Most of those TAP therapies show better efficacy in vitro and targeted drug delivery in animal model. It is still very challenging in many aspects of TAP therapy such as rapid clearance in blood, low potency, inefficient internalization of conjugates, poor penetration, and premature release of the drugs.

Antibody-Directed Enzyme Prodrug Therapy

Antibody-directed enzyme prodrug therapy (ADEPT) is a two step process. In the first step, a drug-activating enzyme is targeted to tumors by a tumor targeting antibody. In the second step, a nontoxic prodrug is administered systemically and converted to the active drug with high local concentration in tumors by the localized antibody-enzyme conjugate. Meanwhile, the prodrug remains inactive (without drug-activating enzyme) in normal tissues and thus decreases its nonspecific toxicity. ADEPT provides many advantages: (i) Amplification effect: each localized antibody-enzyme molecule converts a large number of nontoxic prodrugs to potent active drugs and increases the local active drug concentration in tumor. (ii) Bystander effect: the locally activated drug molecules with high lipophilicity diffuse into the cancer cells regardless of the heterogeneous antigen expression. The bystander effect addresses the issues of poor tumor penetration of the antibody-enzyme conjugate. (iii) The antibody-enzyme conjugate does not need to be internalized into each cancer cell for prodrug activation. The enzymes in ADEPT could be a bacterial enzyme without mammalian homologs to minimize nonspecific prodrug activation in normal tissues, such as carboxypeptidase G2, cytosine deaminase, beta-lactaminase, penicillin G amidase. Other bacterial enzymes with mammalian homologs or mammalian enzymes with low expression in normal tissues can also be used, such as beta-glucuronidase, alkaline phosphatase, and alpha-galactosidase.

Gene-Directed Enzyme Prodrug Therapy

GDEPT is also a two step process. First, a gene that encodes a drug activation enzyme is delivered to tumor cells. The delivered gene will express the drug activation enzyme in the tumor only. In the second step, a nontoxic prodrug is delivered and is converted into active drug in tumor cells by the expressed enzyme. Many enzymes and drugs can be used in this system. For instance, cytosine deaminase for 5-florocytosine prodrug activation, thymidine kinase for ganciclovir, and arabinonucleoside prodrug activation, carboxypeptidase G2 for benzoic acid mustard prodrug activation, carboxypeptidase A for methotrexate-alanine prodrug activation, galactosidase for daunorunbicin-galactose prodrug activation, glucuronidase for epirubicin-glucuronide prodrug activation, alkaline phosphatase for doxorubicin phosphate prodrug activation, cytochrome P-450 for cyclophosphamide and isofamide prodrug activation.

Folate-Targeted Drug Delivery

Many cancer cells overexpress folate receptor on the cell surface. For example, 80% of metastatic breast cancer and 90% of ovarian cancer are folate receptor positive. Folate is absorbed by its carrier, and can also be taken up by cells through folate receptor mediated endocytosis. Folate-drug conjugate can bind to folate receptor to achieve targeted drug delivery. Many compounds can be delivered by folate conjugates such as small molecules of chemotherapeutic agents, protein complexes, radioimaging agents, genes, and antisense oligonucleotides.

Transferrin Targeted Drug Delivery

Tumor cells have been reported to have high level of transferrin receptor. Transferrin-drug conjugates can bind to transferrin receptor and be internalized inside the cancer cell. This strategy has advantages for tumor tissue distribution and prolonged half life. Fro instance, transferrin-doxorubicin has the potential to circumvent cardiotoxicity. Transferrin-diphtheria toxin selectively killed brain tumor cells with high level of transferrin receptor, although this conjugates also show neurological side effects due to low level of transferrin receptor in normal brain endothelial cells.

Albumin-Drug Conjugate for Targeted Delivery

Distinctive characteristics of tumor tissue with lack of lymphatic drainage leads to accumulation of plasma albumin. Thus albumin-drug conjugate can achieve targeted drug delivery. for instance, methotrexate (MTX): albumin (1:1 molar ratio) was accumulated at higher level (14% accumulation) in xenograft tumors compared to MTX alone (0.4% accumulation), and thus showed better efficacy.

Targeted Therapy

Definition

Therapy directed to a specific molecular target present in the cancer cell, which explains the efficacy of the drug. Targeted therapy has been discovered by exploiting the genetic differences between normal and tumor cells. New agents have been specifically developed to target the gene expression and signaling pathways deregulated in the ►cancer cells. For example, the treatment of ►chronic myeloid leukemia has been revolutionized by ►imatinib, a small molecule inhibitor of tyrosine kinases, including ►BCR-ABL, PDGFR, and KIT. Recent studies have also confirmed the effectiveness of ►herceptin in ►breast cancer. Testing for the presence of ►*HER-2/neu* gene mutation to select patients for ►herceptin treatment is rapidly becoming common practice in the health system that can accommodate the cost of treatment.

Targeted Viruses

Definition

Viruses used in oncolytic virotherapy that have been genetically modified to achieve selective replication in tumor cells.

►Oncolytic Virotherapy
►Oncolytic Virus

Targeting, Active

Definition

Active targeting is one of the mechanisms by which drugs or drug delivery vectors can be preferentially delivered to target cells *in vivo*. With this method, vectors that possess tissue-specific molecules, such as antibodies, peptides, and sugar chains, actively recognize target cells by molecular interactions.

Tat

Definition

HIV Transactivator protein product of the HIV *tat* gene.

►TAT Protein of HIV

TAT Protein of HIV

Adriana Albini[1], Douglas Noonan[2]
[1]IRCCS Multimedica, Milano, Italy
[2]University of Insubria, Varese, Italy

Definition

Tat is a small viral protein that is encoded by the spliced two-exon tat gene in the HIV genome, responsible for transactivation of the HIV genome.

Characteristics

The HIV Tat protein gets its name from its principal activity, Tat stands for Transactivator, which means that it binds to DNA and activates the transcription of DNA into RNA. The Tat protein has an important role in controlling the transcription of the lentivirus HIV genome from its built-in "promoter," known as the long terminal repeat (which refers to its structure) or ►LTR, to make the RNA that forms new HIV virus particles. In addition to this major role, Tat has also been implicated in a wide variety of pathologies encountered in persons infected with HIV. How does this small (about 101 amino acids) Tat protein do this? Tat has a capacity to bind a striking number of different proteins, nucleic acids and even polysaccharides. It is this combination of binding to different partners that has linked Tat to numerous events in AIDS and intrigued many researchers, making Tat one of the most extensively studied HIV proteins.

Transcriptional Regulation: Control of HIV Replication

The HIV LTR acts as a gene promoter. The gene promoter is a portion of DNA that mediates the binding of RNA polymerase (usually through a series of other proteins that bind to the promoter DNA as well) at the beginning of the gene to be transcribed into RNA. This interaction of proteins with DNA controls the transcription of each gene so that it occurs at a certain moment. In the absence of Tat, very little RNA is transcribed from the HIV LTR promoter. When Tat is present, the rate of transcription shoots up several hundred fold, making the transcription of the HIV genome efficient.

After HIV infects a cell, it is reverse transcribed into DNA, which is then integrated into the genome of the cell (similar to ►retroviruses). The viral DNA is then packaged along with the rest of the cellular DNA by winding onto the histone proteins. In this state, the HIV LTR promoter is rather inactive. In fact, in order to be transcribed, the promoter region of any gene must be unwound from these histones. The HIV DNA is bound to the histones in a very specific manner, with one histone group just prior to, and another just after, a site which binds DNA binding proteins of the cell known as SP1 and NFκB. The activity of these proteins may be enough to allow the binding of an RNA polymerase, known as RNA polymerase II or RNAP II, to the HIV LTR.

The binding of RNAP II to the LTR alone is not enough for efficient transcription. In the absence of Tat it does not appear to be able to advance forward to synthesize RNA beyond the first 44 nucleic acid base pairs. The major role for Tat is to unleash this machinery and send it to work. When Tat is present, it binds to a segment of this short initially polymerized RNA, which forms a peculiar loop known as the TAR (TransActivation Responsive) element. The TAR-bound Tat then brings in a series of other proteins that allow the transcription process to proceed.

Tat has been demonstrated to play a key role in the unwinding of HIV DNA from histones, which is one key for allowing RNA transcription. To do this, Tat binds to a group of proteins known collectively as Tat-associated histone acetyltransferase (TAH). The TAH complex can be formed by different cellular proteins such as p300 or is close relative CBP, along with P/CAF and/or TAF250. These TAH proteins have an enzymatic activity that transfers an acetyl group to histones and are known as histone acetyltransferases. The recruitment of the TAH complex to the HIV LTR region by TAR-bound Tat leads to acetylation of the histones that bind to the LTR, causing changes in their conformation that facilitate RNA transcription. In fact, in cells where p300 and P/CAF are limiting, addition of Tat increases transcription only about sevenfold, while addition of both Tat and p300-P/CAF allows increases transcription about 80-fold.

The TAH complex also appears to acetylate the Tat protein itself. This appears to lower the binding of Tat for the TAR, but increases the binding of Tat to another complex of proteins known as the Tat-Associated Kinase (TAK) or positive acting transcription elongation factor complex (P-TEFb). This complex of proteins consists of cyclin-dependent kinase 9 (cdk9) and one of the cyclin T isoforms (T1, T2a, T2b). This protein complex can directly bind Tat. More importantly, the kinase activity of the TAK complex phosphorylates (adds a phosphate group to) the RNA polymerase RNAP

II. This phosphorylation appears to alter the activity of the RNAP II, improving its ability to transcribe the HIV genome. Together, the TAH and TAK complexes brought in by Tat unleash the RNAP II to finish the job it started, giving the 100-fold improvement of transcription, and therefore HIV replication, observed when Tat is added to HIV infected cells.

Tat also transactivates several cellular genes in addition to the HIV LTR. The activation of these genes is also thought to contribute to the pathogenesis of HIV. The genes include the cytokines IL-6, TNF and IL-1, which are known to be increased in AIDS patients and may have detrimental effects on the overall function of the immune system.

AIDS-Associated Pathologies: A Direct Contribution by Tat

One of the most striking properties of Tat is its ability to exit from cells, where it is released into the extracellular environment. Several studies have shown that the HIV-1 Tat protein can exit from cells, including HIV infected cells. As the Tat gene does not encode a signal peptide, the release of HIV-Tat has been suggested to occur via an alternative secretion pathway, like that demonstrated for some cytokines. It may also come from cells dying due to HIV. The Tat that is found extracellularly appears to be intact and active, and substantial levels of Tat protein have been observed found in the serum of many HIV patients. Antibodies can be made against Tat in AIDS patients, indicating that it is released, and interestingly an inverse correlation between anti-Tat antibodies and patient survival has been reported in some studies. These data suggest that extracellular Tat may favor HIV replication, and have spawned tests on the possibility of using Tat as part of an AIDS vaccine.

A wide range of activities have been attributed to the Tat protein released extracellularly. Several studies have demonstrated that the HIV Tat protein, or peptides based on Tat, are capable of entering cells cultured in vitro. The Tat that enters cells is capable of transactivating the HIV LTR. Tat and Tat peptides have even been used to deliver other proteins into cells, and a peptide based on Tat may find use as a signal to move drugs into cells.

In addition to getting into other cells, the Tat that is released also appears to bind to several cell surface proteins, including specific receptors. These activities of Tat have been linked to many of the pathological alterations found in HIV infection. For example, some groups of AIDS patients frequently have ►Kaposi sarcoma, an otherwise rare, benign vascular tumor. Unlike most Kaposi, the Kaposi sarcoma associated with AIDS is very malignant and could be life-threatening for many of these patients. Tat was first linked to Kaposi sarcoma when Kaposi-like lesions were found on mice genetically engineered to express Tat. Soon after, Tat was shown to be a growth factor for Kaposi cells, but the reason for this was not known. Later studies showed that Tat could bind to KDR (VEGFR2), a receptor for the growth factor ►VEGF, on the surfaces of endothelial and Kaposi sarcoma cells. VEGF (vascular endothelial growth factor) is important in the formation of new blood vessels, as is its receptor KDR. The ability of Tat to bind and activate KDR means that Tat could stimulate the formation of vessels found in Kaposi tumors, as well as the growth of cells of the tumor itself. We now know that Kaposi sarcoma is due to an infection with a herpesvirus, HHV8, that occurs when the immune system is unable to control this virus. All Kaposi cells, whether from aggressive AIDS or benign sporadic of iatrogenic (post-transplant), have KDR, however the Tat stimulation of KDR and perhaps other receptors appears to make AIDS Kaposi potentially lethal.

Many Tat proteins have an RGD sequence, three amino acids found in many proteins of the extracellular matrix. Through this RGD sequence Tat can bind to cell surface integrins, proteins that are normally involved in binding to extracellular matrix molecules. Studies have shown that several integrins bind the Tat protein. Tat-integrin binding has been shown to trigger events typical of integrin-extracellular matrix ligand interactions, including activation of p125 Focal Adhesion Kinase. The binding of Tat to these receptors has also been linked to Kaposi sarcoma and other activities of HIV Tat.

The immune suppression seen with AIDS appears to affect cells that are not infected with HIV aside from those harboring the virus. Several studies have shown that there is immune suppression of non-HIV infected cells from AIDS patients, and that the number of immune suppressed cells seems to exceed that of the potentially HIV-infected cells. Proteins released from HIV-infected cells are clearly potential candidates for mediating this immune suppression. Tat has been linked to induction of T-cell anergy (lack of activity), T-cell ►apoptosis (programmed death), but also to a T-cell hyper-activation that appears to prime cells for infection by HIV. These events are probably all closely linked to the same phenomenon. The potential receptor system(s) involved in these activities of Tat include CD26. CD26 is a dipeptidyl peptidase that is known to cleave and alter the activities of chemokines, molecules whose receptors are very important cell surface receptors for HIV and that can regulate HIV infection. Tat has been shown to significantly increase the expression of two key chemokine-HIV receptors, CXCR4 and CCR5, by monocytes and T-lymphocytes, potentially increasing HIV infection.

The Tat protein has been reported to act as a growth factor and protect transfected cell lines from apoptosis. Tat has been consistently found to up-regulate the expression of CD95-►Fas, a protein that signals cells to

die. The increase in apoptosis is typical for partially activated T-cells, as is entry into anergy resulting from an incomplete stimulation of T-cells. Tat may be capable of partial, but incomplete, T-cell activation. HIV does not readily infect resting T-cells, T-cell activation is a key requisite for HIV infection of these cells. A partial T-cell activation may be sufficient for HIV infection yet detrimental to the host immune response, a potential role that Tat may fulfill.

Extracellular HIV Tat has been shown to have wide ranging effects on lymphatic cells such as monocytes, macrophages, dendritic cells and even natural killer cells. Tat has been reported by several groups to be a strong chemoattractant for monocytes. This activity could contribute directly to the recruitment of potentially "infectable" cells toward an HIV-infected cell producing and releasing Tat protein, an activity which may have a direct affect on establishment and spread of HIV infection in the host. Tat has been shown to bind to and activate several chemokine receptors (including CCR3 and CKCR4) and mimic the chemoattractant properties of chemokines. Chronic inflammation is frequently associated with cancer and inflammatory cells can promote tumor growth and tumor angiogenesis, thus Tat may influence the AIDS-associated tumor microenvironment through direct and indirect mechanisms. Tat can even inhibit HIV infection in high doses by binding chemokine receptors, although the physiological relevance of this observation is not yet clear.

The Tat protein appears to inhibit dendritic cell phagocytosis and natural killer cell function, apparently by blockage of certain calcium channels. Finally, Tat has been linked to AIDS associated dementia. Tat has been shown to excite neurons, which is associated with neurotoxicity. The molecular identity of the Tat receptor(s) on neural cells is not yet known. However, the neuroexcitory properties of Tat were blocked by lowering extracellular calcium, suggesting that interference with calcium channel function may be involved.

Conclusion

Tat is known to have a major role in HIV replication through a complex series of interactions with nuclear proteins. In addition, Tat outside the cell appears to be able to stimulate through, or interfere with, several cell surface receptors, sending signals that may be a root cause of many pathologies found in HIV-infected patients.

TATA Box

Definition

Synonym Goldberg–Hogness box; Is the core promoter sequence (5′-TATAA-3′) of most genes. In eukaryotes, it represents the DNA binding site of the TATA binding protein during the process of gene transcription. Promoters lacking a TATA box were first found in housekeeping genes and have more recently been found in various gene promoters involved in cell-specific transcription.

TATI

Definition

Tumor-associated trypsin inhibitor (TATI) is a low molecular weight protein used as a tumor marker, e.g. ovarian cancer.

►Ovarian Cancer

Tau

Definition

Is a ►microtubule-associated protein (MAP) that is functionally modulated by phosphorylation and that is hyperphosphorylated in several neurodegenerative diseases. Tau proteins interact with ►tubulin to stabilize ►microtubules and promote tubulin assembly into microtubules.

Taurodont

Definition
Unusually large tooth with an unusually large pulp chamber and either multiple roots or a large single root.

►Dental Pulp Neoplasms

Tax

Definition
Is a viral oncoprotein encoded by the ►human T-cell leukemia virus 1 (HTLV-1). HTLV-1 is the causal agent of a human leukemia, adult T-cell leukemia (ATL). During HTLV-1 replication, Tax transcriptionally activates the viral long terminal repeat (LTR). Several major cellular signal transduction pathways including the transcription factors NF-kB, CREB, SRF and AP-1 are induced by Tax. During cell division, Tax binds MAD1 directly to repress its function.

►Mitotic Arrest-Deficient Protein 1 (MAD1)

Tax Binding Protein-181

Taxane

Definition
Are diterpenes synthesized by plants of the genus *Taxus* (yews). A class of naturally-occurring or synthetic chemicals containing a characteristic 15-member ring system, the latter composed of four isoprene units with the molecular formula $C_{20}H_{32}$. Drugs that inhibit microtubule formation resulting in cell cycle arrest and apoptosis, used in cancer chemotherapy. Microtubules are essential to cell division, and taxanes therefore stop this action by freezing the mitosis process.

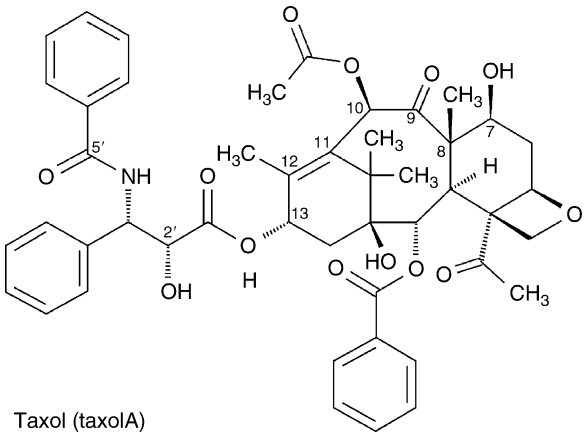
Taxol

Spyros D. Georgatos,
Panayiotis A. Theodoropoulos
Department of Basic Sciences, The University of Crete, School of Medicine, Heraklion, Crete, Greece

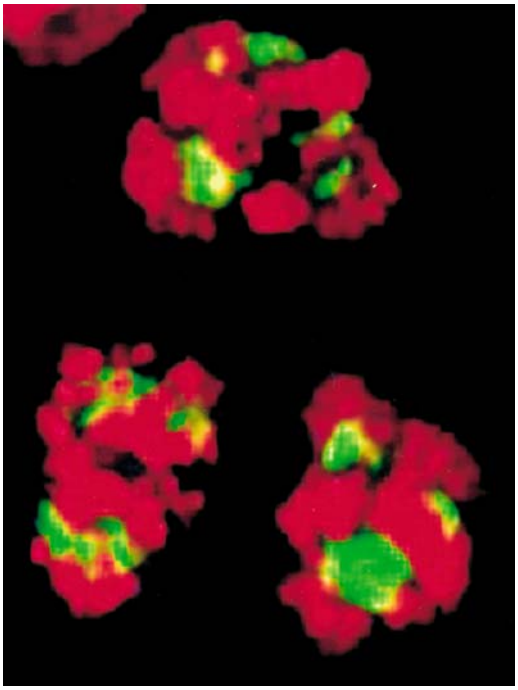
Definition
Taxol (Paclitaxel) was first isolated in 1971 from a crude extract of Taxus brevifolia, a scarce, slow growing yew plant found in the forests of the Pacific Northwest. It is a diterpenoid containing the characteristic taxane ring (Fig. 1). Total chemical synthesis of this compound was achieved in 1994, opening the way for the production of various analogues. Currently, taxol is commercially prepared by hemisynthesis, in which a synthetic side chain is attached to natural products isolated from the needles of Taxus plants. Enzymatic conversion of various taxanes to 10-deacetylbaccatin III (a precursor for taxol hemisynthesis) has been reported.

Characteristics
Mode of Action
Due to its hydrophobic character, taxol readily crosses the ►plasma membrane. Once in the cytoplasm, the drug binds with high affinity to the β-subunit of ►tubulin, modifying and stabilizing ►microtubules. When modified by taxol, these cytoskeletal structures exhibit decreased dynamic instability and increased rigidity. As a result, the function of the microtubule-based machines (e.g., ►mitotic spindle) is compromised and the cells cannot divide properly. Taxol also binds to ►Bcl-2, a protein involved in the process of programmed cell death (►apoptosis).

The cellular effects of taxol vary depending on dose and treatment scheme. In the range of nanomolar concentrations it induces sustained mitotic arrest (Fig. 2), inhibits protein prenylation and triggers apoptosis. At micromolar doses it promotes synthesis and release



Taxol. Figure 1 Chemical structure of taxol.



Taxol. Figure 2 Confocal microscopy image, showing human cervical carcinoma cells in mitosis. Cells were treated with 10 nM taxol for 20 h. Immunostaining was done with anti-tubulin antibodies and counter-staining was done with propidium iodide. Chromosomes are shown in *red*, the mitotic spindle in *green*.

of cytokines, such as ►tumor necrosis factor (TNF) and ►interleukins (IL1 and IL8), increases tyrosine phosphorylation by ►MAP kinases, induces early response genes and stimulates production of ►nitric oxide.

How taxol exerts its cytotoxic action remains elucive. Structure-activity studies differentiate microtubule stabilization from other effects, supporting a direct effect on the genetic and signal transduction machinery. However, other studies suggest that the drug acts by inducing cytoskeletal damage.

Recent observations show that taxol activates Raf-1 kinase and induces phosphorylation of Bcl-2. Phosphorylation of the latter may, in turn, lead to dissociation of Bcl-2/►Bax complexes, unleashing Bax into the cell and thus triggering apoptosis. Although these hypotheses are intuitively attractive, neither of them could fully account for the cell killing action of taxol: programmed cell death is also induced by other microtubule-stabilizing drugs which are free of genomic side-effects (e.g., ►Taxotere), while apoptosis can still occur independently of Raf-1 phosphorylation, or after Bcl-2 is dephosphorylated by cellular phosphatases.

Taxol and other microtubule-acting agents affect dramatically the architecture of the cell nucleus. It is widely known that cells treated with nanomolar amounts of taxanes or ►vinca alkaloids develop lobulated nuclei or multiple micronuclei and missort key cellular constituents. Also, taxol affects the nuclear envelope. Even at nanomolar concentrations, the drug induces focal unraveling of the nuclear lamina and extensive clustering or ectopic localization of nuclear pore complexes (Fig. 3). Cells that possess a defective nuclear envelope and which are treated with taxol remain alive for at least 24 h after the end of the treatment, but are unable to import karyophilic proteins, such as the transcription factor ►NFκB, into the nucleus. It has been proposed that inhibition of NFκB import may render the cells prone to programmed cell death.

Clinical Pharmacology

Antitumor Activity

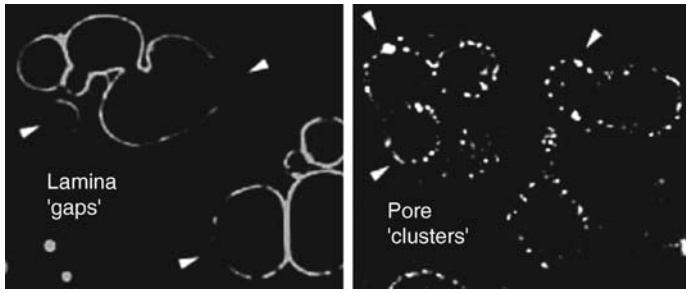
Taxol as a single chemotherapeutic agent has been proven effective against a variety of tumors, including ovarian, breast, head and neck, esophageal, bladder and lung carcinomas. In addition, several schedules of combination therapy have been developed as alternatives for patients with advanced cancer. Pilot studies show that taxol can enhance radiation sensitivity of tumor cells, potentiate tumor response and increase the therapeutic ratio of radiotherapy.

Absorption and Excretion

The drug is administered as a 3-h or 24-h infusion. It undergoes ►cytochrome P450-mediated metabolism to 6-OH derivatives and other products. Less than 10% of a dose is excreted intact from the urine.

Toxicity

The principal toxic effect of taxol is neutropenia. Several other toxic effects, such as myalgias, mucositis,



Taxol. Figure 3 Nuclear lamina and pore complex lesions after treatment of human endometrial carcinoma cells with 10 nM taxol. *Left*: indirect immunofluorescence using anti-lamin B antibodies. *Right*: indirect immunofluorescence using anti-nucleoporin antibodies. The interruption of the nuclear lamina and the formation of large pore clusters is evident in these images.

hypersensitivity reactions, stocking-glove sensory neuropathy and disturbances of the cardiac rhythm, have also been encountered.

Structurally and Functionally Related Compounds

Structurally Related Compounds

- ►Docetaxel (taxotere), produced by semisynthesis (1986) from 10-deacetyl baccatin III, a taxoid precursor. It is the second member of the taxane class to reach clinical use.
- Several chemically synthesized taxoids bearing substitutions or modifications.

Nontaxane, Microtubule-Stabilizing Agents

- Estramustine, a conjugate of estradiol and nor-nitrogen mustard.
- ►Epothilones A and B, two macrolides isolated from myxobacterium, Sorangium cellulosum.
- A family of marine-derived compounds extracted from sponges (discodermolide and laulimalide) or corals (sarcodictyins A - F and eleutherobin).

Taxotere

Edward L. Schwartz
Department of Oncology, Albert Einstein College of Medicine, Bronx, NY, USA

Synonyms

Docetaxel

Definition

Taxotere is a widely used ►cancer chemotherapeutic drug with well-documented clinical anti-tumor activity against a range of human cancers, including ►breast, ►lung, ►prostate and ►ovarian cancers. It is a semi-synthetic molecule belonging to the ►taxane family, and is closely related chemically and pharmacologically to the naturally occurring drug ►Taxol (►paclitaxel). Taxotere binds to the β-►tubulin component of ►microtubules, a key ►cytoskeletal protein in cells, and stabilizes the structure of the microtubule polymer, prevents its disassembly, and suppresses microtubule dynamics. These actions interfere with a number of cellular functions in which the microtubules are involved.

Characteristics

Chemistry

The anti-tumor activity of the taxanes was first observed in preclinical models using a crude extract of the bark of the Pacific yew tree *Taxus brevifolia*, and Taxol was subsequently (1971) identified as the active constituent. Both Taxotere and Taxol are diterpenoid compounds consisting of a 15-member taxane ring system linked to an unusual 4-member oxetan ring. Limited supplies of bark from the *T. brevifolia* tree prompted the search for alternative derivatives and sources of starting material.

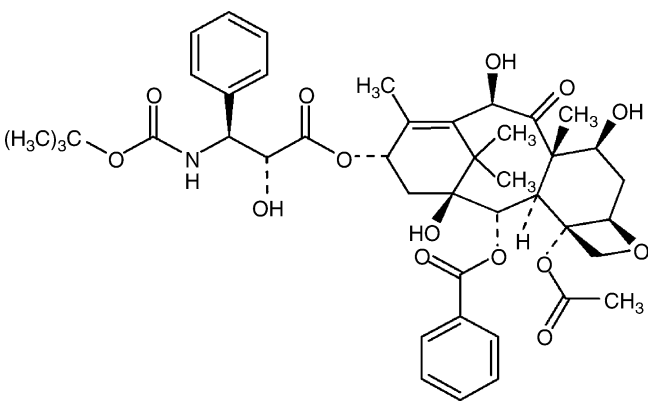
An inactive compound, 10-deacetylbaccatin III, found in the needles (which are more abundant and also are a renewable source) of several yew species, was used as starting material for the synthesis of Taxotere, which was first reported in 1986. Taxotere and Taxol differ in the nature of the substitutions at the C-10 position of the taxane ring and on the ester side chain attached to C-13, and these differences are the basis for the increased water solubility and greater potency of Taxotere, compared to Taxol (Fig. 1).

Mechanisms of Action

Microtubules are a component of the cell's ►cytoskeleton, and form a well-organized network of hollow tubes in which one end is anchored at the ►centrosome (the microtubule-organizing center), and the opposite, free end extends out into the cytoplasm. Microtubules are composed of noncovalent ►heterodimers of α-and β-tubulin, which are arranged head-to-tail to form helical polymers. There is an exchangeable GTP/GDP binding site on β-tubulin which mediates the rapid assembly and disassembly of the microtubules. The free ends of the microtubules undergo frequent periods of slow growth and rapid shortening, a process called dynamic instability, and microtubules also exhibit treadmilling, in which the loss of tubulin at one end is matched by the addition of tubulin at the opposite end. This dynamic behavior is required for the proper functioning of the microtubules. During mitosis, microtubules capture and are responsible for the alignment of the chromosomes and for their subsequent separation to the two daughter cells during anaphase. Properly functioning microtubules are required for the migration of most cell types, and they also play an important role in cell signaling and the intracellular transport of proteins, vesicles, and mitochondria.

Much of the early work on the binding and effect of the taxanes on microtubules was done using Taxol. Taxol preferentially binds to the microtubule polymer, rather than to unassembled tubulin, at a site that is distinct from the GTP/GDP site and which also differs from the sites at which colchicine, vinblastine and podophyllotoxin bind. Studies suggest that in their interactions with purified microtubules, Taxotere and Taxol are qualitatively indistinguishable. Although Taxotere and Taxol have the same apparent binding site on tubulin, Taxotere binds with a 1.9-fold greater effective affinity.

The taxanes promote microtubule assembly, even in the absence of added GTP, by altering the tubulin dissociation constants at both ends of the microtubules. The taxanes reduce the critical concentration of tubulin required for microtubule assembly, with the required concentration 2.1-fold lower in the presence of Taxotere than with Taxol. In addition to promoting both the nucleation and elongation phases of polymerization, they also produce microtubules that are extremely stable and are resistant to depolymerization. The effects on microtubule assembly are maximal at Taxol or Taxotere concentrations that are equimolar to that of tubulin, and evidence indicates that they bind with a stoichiometry of 1 per αβ tubulin dimer. In cells treated with stoichiometric concentrations of taxanes, there is an increase in the microtubule-polymer mass along with the formation of abnormal polymers and a characteristic intracellular "bundling" observed. While these concentrations of the drugs are obtained clinically, it is only for brief periods of time after drug administration. At substoichiometric concentrations, the taxanes effects on microtubule dynamics are more prominent than are their actions on microtubule mass, and the suppression of mitotic spindle dynamics plays a central role in their cytotoxic actions. By interfering with the ►mitotic spindle, the taxanes block cancer cell proliferation by causing cell cycle arrest at the metaphase/ anaphase boundary. The resultant blocking or slowing of mitosis



Taxotere. Figure 1 Chemical structure of Taxotere (docetaxel).

leads to cell death via the induction of the intrinsic mitochondrial pathway of apoptosis.

Taxotere is transported out of cells by the ABC-transporter class of membrane transport proteins, which include P-glycoprotein, MDR1 and MDR2. Overexpression of these pumps and the accompanying multi-drug resistance (MDR) phenotype can lead to profound cellular resistance to the taxanes. Microtubule-related determinants may also confer resistance to the taxanes, and these include the levels of expression of microtubule-associated regulatory proteins, the extent and nature of posttranslational modification of tubulin, and the varying levels of expression of different tubulin isotypes. Interestingly, cancer cells made resistant to Taxol do not necessarily show the same degree of resistance to Taxotere, and this may be due to the observation that Taxotere is retained intracellularly longer than is paclitaxel.

In addition to effects on tumor cell proliferation and apoptosis, Taxotere is a potent inhibitor of angiogenesis, and this is likely due to its direct effects on ►endothelial cells. While it inhibits endothelial cell proliferation at concentrations comparable to those which inhibit cancer cells, it also inhibits endothelial cell motility, invasiveness, and tubule formation *in vitro* at concentrations substantially (10- to 100-fold) lower than required to cause cell cycle arrest or apoptosis. Based on pharmacokinetic analyses of Taxotere, cancer patients are exposed to these anti-angiogenic concentrations of drug for extended periods of time. Taxotere also has anti-angiogenic activity in several *in vivo* preclinical models, and these *in vivo* anti-angiogenic actions were probably not directly due to the anti-proliferative or cytotoxic activities of the drug, as other agents that inhibited endothelial cell proliferation *in vitro* did not affect angiogenesis *in vivo*. The mechanisms for these actions are not fully understood, and may include effects on signaling pathways, including those mediated by cell surface ►integrins and cell surface receptors for the angiogenic factor ►vascular endothelial growth factor (VEGF). The effects of the taxanes on microtubule dynamicity at the low concentrations that inhibit angiogenesis appear to be qualitatively different from those at concentrations that block cell proliferation.

Clinical Use

Taxotere is a highly effective drug with a spectrum of anti-cancer activity that is virtually identical to that of Taxol. Taxotere initially received regulatory approval for use in patients with metastatic or locally advanced ►breast cancer who had failed other drug therapies. In addition to increasing survival when used as second-line therapy in patients with advanced disease, subsequent studies showed it was active in the adjuvant treatment (►adjuvant therapy) of patients with local breast cancer after definitive local treatment. It has been shown to increase survival in unresectable metastatic ►non-small cell lung cancer, and is one of the most effective agents in the treatment of ovarian cancer and in hormone-refractory ►prostate cancer. The wide spectrum of activity that Taxotere was found to have in pre-clinical models has been confirmed in the clinic, and anti-tumor activity has been noted in ►bladder, ►endometrial, ►esophageal, ►gastric, head and neck, and small cell lung ►carcinomas, and in lymphoma and ►melanoma.

Taxotere is often used in combination with other chemotherapeutic drugs, including ►cisplatin, cyclophosphamide, doxorubicin, and prednisone. In addition to being evaluated in a large number of drug combinations, a range of doses and schedules of Taxotere have been studied in clinical trials over the years. The drug is usually administered once a week or once every 3 weeks as short (1 h) intravenous infusions at doses ranging from 60 to 100 mg/m^2. ►Neutropenia is the primary toxicity observed at these doses, with a significantly reduced neutrophil count typically first observed on day 8 after treatment. Complete resolution occurs by days 15–21, and the severity of the neutropenia is related to the dosage of the drug and the extent to which the patients bone marrow function has been compromised by the concomitant or prior use of other myelosuppressive (►myelosuppression) drugs. The neutropenic effect of Taxotere generally is more severe, but shorter in duration, than that of Taxol.

A number of other toxic effects have been associated with Taxotere use. Hypersensitivity reactions (►dyspnea, bronchospasm, and hypotension) can occur acutely with drug administration, and a unique fluid retention syndrome (peripheral edema, pleural and peritoneal fluid) can occur chronically with multiple courses of therapy. In both instances, the frequency and severity of these toxicities are substantially reduced by premedication with a corticosteroid and H_1 and H_2 histamine antagonists. Skin toxicities occur frequently, although these are also attenuated by premedication, with the most common manifestation being an ►erythematous pruritic macropapular rash on the arms, hands and feet. Taxotere causes mild to moderate neurosensory and neuromuscular effects (numbness, ►paresthesia), and although common (up to 40% of patients), these occur less frequently and are less severe than in patients receiving Taxol.

The relative water-insolubility of Taxotere requires it to be formulated for clinical use in the nonionic surfactant polysorbate 80 (Tween 80). Both the hypersensitivity and fluid retention side-effects of the drug have been attributed to the use of this vehicle. A number of different alternatives to the use of Tween 80 have been evaluated in pre-clinical studies, with the objective of developing a less-toxic, better-tolerated formulation, and the

identification of ways to better target Taxotere to malignant tissue. These include polyethylene glycol (PEGylated) liposomal Taxotere, immunotargeted-liposomal Taxotere conjugates, Taxotere-fibrinogen-coated olive oil droplets, Taxotere-encapsulated nanoparticle-aptamer bioconjugates, and submicronic dispersion formulations. Some of these formulations have entered early clinical trials.

Refers to cells derived from a single progenitor T cell.

T-Cell Hybrids

Definition

T-cell hybrids are formed by fusing an antigen-specific, activated T cell with a T-cell lymphoma. The hybrid cells bear the receptor of the specific T-cell parent and grow in culture like the lymphoma.

T-Cell Receptor

Definition

TCR; consists of a disulfide-linked heterodimer of the highly variable α and β chains expressed at the cell membrane as a complex with the invariant CD3 chains. T cells carrying this type of receptor are often called α:β T cells. An alternative receptor made up of variable γ and δ chains is expressed with CD3 on a subset of T cells. Both of these receptors are expressed with a disulfide-linked homodimer of ζ chains, which carries out the intracellular signaling function of the receptor.

T-Cell Response

Periasamy Selvaraj
Department of Pathology, Emory University School of Medicine, Atlanta, GA, USA

Definition

Expansion of antitumor T cells in response to growth of cancer or to a ►cancer vaccine or a cancer immunotherapy.

Characteristics

In living organisms, the growth and division of cells is a tightly controlled and highly regulated process that maintains the integrity of cellular architecture and survival. Cell growth can occur in our body to replace a dead cell, to heal a wound, to maintain normal homeostasis, or to generate immune cells during an immune response. The number of divisions that cells undergo during these processes is highly controlled and the cells stop dividing when they receive signals either through contact inhibition or other means. Deviations from normal regulatory mechanisms may result in uncontrolled cell growth and the development of various types of cancers in our body. Many genes in the human body play pivotal roles in regulating the normal metabolic and growth patterns of cells. Mutations in these genes lead to the production of altered proteins that may result in the uncontrolled cell growth that is observed in cancer.

Role of ►*immunosurveillance* in *antitumor immunity*: Gene mutations occur constantly through the life span of a living organism, resulting in the occasional production of abnormal cells. Most mutant cells with defective metabolism die of a process called apoptosis. The mutant cells that are able to survive with altered proteins will be recognized by the immune system and destroyed by a process termed immunosurveillance. There is strong evidence for the existence of such immunosurveillance against cancer. Cancers develop in high frequencies in people with immunodeficiency diseases associated with immune system defects such as AIDS, or in animals that have an incomplete immune system, suggesting that cancer specific immunity is a major mechanism for elimination of cancers from the body. This immunity is provided by the cytotoxic activity of tumor specific T cells that recognize tumors and destroy them. However, there are many ways that cancer cells circumvent this immunosurveillance. Some cancers secrete immunosuppressive factors such as TGF-β, which attenuates T cell immune response. Down regulation of MHC class I molecules that stimulate the immune system or upregulation of molecules that induce T cell apoptosis are other mechanisms cancers use to inactivate antitumor T cell immune responses.

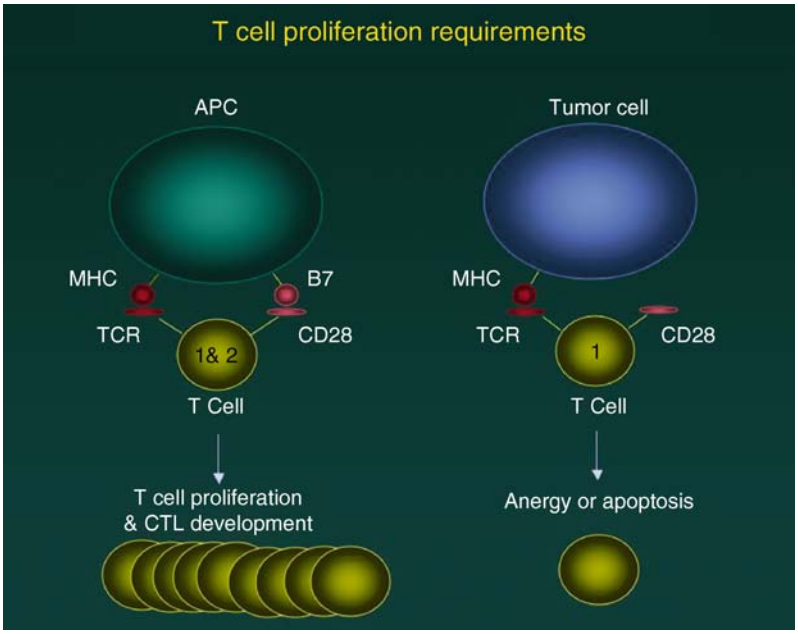
Molecular requirements of T cell responses. T cells are divided into two major subsets. CD4 antigen-expressing T cells are termed "helper T cells" whereas CD8 antigen-expressing T cells are termed "cytotoxic T cells." It has been shown that $CD4^+$ T cells provide help by secreting cytokines for the generation of robust $CD8^+$ T cells that can kill tumor cells. Since T cells play a crucial role in the development of antitumor immunity, most cancer immunotherapy is designed to directly or indirectly activate tumor-specific $CD4^+$ and $CD8^+$ T lymphocytes and induce immunological memory against tumors. Studies have shown that both subsets of T cells play an important role in the antitumor immune response. Recent advances in understanding the molecular and cellular requirements for antigen-specific immune responses have led to a number of promising immunotherapeutic strategies for inducing antitumor T cell responses for the treatment of cancer. Many of these strategies include vaccination with ►dendritic cells (DCs) engineered to express tumor antigens, cytokine transduced tumor cells, peptide vaccines, DNA vaccines, heat shock proteins, hybrid tumor cells, and tumor cells transduced with costimulatory molecules.

The rationale for the vaccination strategies mentioned above is that antigen-specific T cells can be stimulated effectively by providing stimulatory signals arising from either tumors themselves (direct priming) or through ►antigen-presenting cells (APCs) of the host (indirect priming). Normally, T cells are educated in the thymus to react against cells expressing MHC molecules that display peptides derived from foreign or altered proteins. Since tumors express altered proteins, the peptides derived from these altered proteins are associated with MHC molecules and presented to T cells that are specific to the altered protein. For an optimal immune response, antigen specific T cells

require at least two specific signals. One of the signals is provided by engagement of the T cell receptor (TCR) with peptide bearing MHC molecules on the APC. The second signal (costimulatory signal) can be delivered by the interaction of various adhesion molecules on the surface of T cells and the APC, one of which is the interaction of CD28 expressed on T cells and B7-1 (CD80) expressed on APCs such as DCs. The absence of a second signal results in T cell clonal anergy, thus preventing the development of tumor specific T cells (Fig. 1). Tumor cells, which lack costimulatory molecules such as B7-1, are poorly immunogenic since they fail to deliver the costimulatory signal necessary for the generation of an anti-tumor T cell immune response. Therefore, one approach to improve the ►immunogenicity of tumor cells has been to introduce costimulatory adhesion molecules such as B7-1 onto the tumor surface by ►gene transfection. This B7-1 expression results in the induction of T cell mediated antitumor immunity and subsequent tumor rejection in animals. These studies also demonstrated that ►costimulation is required only for the initial stimulation and expansion of tumor specific $CD8^+$ cytotoxic T cells (CTLs) and not required for the killing of tumor cells by CTLs. This basic understanding of the role of T cell immunity in eliminating tumors has given rise to many immunotherapeutic approaches focused on expanding tumor specific T cells in a tumor bearing host using vaccination and other immunotherapy approaches.

Pathways of tumor antigen-specific T cell stimulation in vivo: Tumors transduced with the B7-1 molecule have been suggested to prime T cells directly, whereas DNA vaccines, peptide vaccines, and cytokine transduced tumors may stimulate T cells indirectly through host APC. However, recent studies suggest that tumors transduced with B7-1 molecule use both priming pathways to induce an antitumor immune response. The indirect pathway could occur through host APCs, mainly by DCs taking up the tumor antigens and processing and presenting them to $CD8^+$ T cells through ►cross-priming. B7-1 gene transfected tumor cell vaccines, once thought to work only by activating $CD8^+$ T cells directly, have now been shown to activate T cells indirectly through cross-priming by professional APCs. The enhancement of cross-presentation by tumors expressing B7-1 has also been attributed to the enhanced recognition of these tumors by ►natural killer ►cells. NK cells have been shown to express CD28 and cross-linking of CD28 on NK cells by B7-1 results in the release of factors such as TNF-α and IFN-γ, which subsequently stimulate DCs. Recently it has been shown that activated human NK cells can also directly interact with $CD4^+$ T cells and costimulate TCR-induced proliferation, suggesting a possible cross-talk between $CD4^+$ T cells and NK cells during antigen specific immune response.

Many studies have shown that antigen-specific $CD8^+$ CTLs can be generated without $CD4^+$ T cell help. DCs have



T-Cell Response. Figure 1 T cells require two signals to enpand and become effective cytotoxic T cells. In the absence of second signal of tumor specific T cells and undergo energy or apoptosis. Thus, tumors by not expressing the second signaling. Molecule can prevent generation omtitumor T cell response.

been shown to play a major role in this $CD4^+$T cell independent expansion of $CD8^+$ CTLs. Antigen-specific $CD8^+$ CTLs developed in the absence of $CD4^+$ T cell help are capable of providing protective antitumor immunity in mice. However, recent studies show that $CD4^+$ T cells play a major role in maintaining the CD8 T cell memory developed during antigen exposure. The $CD8^+$ memory T cells developed in the absence of $CD4^+$ T cell help are defective in responding to antigens in a secondary challenge with antigen, suggesting that for induction of an optimal antitumor immunity, both $CD4^+$ T cells and $CD8^+$ T cells are required. These observations demonstrate that interaction of immune cells such as DCs, NK cells and T cells that are activated by direct and indirect pathways cooperate to produce an optimal antitumor T cell immune response during vaccination.

Thus, the introduction of ►immunostimulatory molecules directly into the tumor by gene transfer offers an attractive approach to improve the immunogenicity of tumor cells. Accordingly, the expression of costimulatory molecules such as B7-1 or cytokine molecules by gene transfer results in the induction of tumor immunity capable of inducing wild-type tumor rejection in animals. Apart from these vaccine strategies, it has been shown that adoptive transfer of *ex vivo* expanded and activated ►tumor infiltrating T cells reduced tumor burden in animals and humans. Recent studies have also shown that $CD4^+$ $CD25^+$ regulatory T cells (Tregs) (►T regulatory cells) play an important role in suppressing antitumor immunity in a host. The depletion of Tregs has been shown to increase potency of many antitumor immunotherapeutic methods.

Methods to detect antitumor T cell responses: Studying T cell immune responses during vaccination or other type of immunotherapies is valuable in understanding the nature of the immune response. Moreover, identifying a correlation between characteristics of antitumor T cell response and clinical efficacy of a treatment modality will be useful in predicting clinical outcome of a therapy at an early stage. For example, T cell populations carrying longer telomeres will be the dominant population in mice that are treated with the most potent vaccine since it has been shown that the presence of this T cell population is a predictive indicator of robust antitumor immunity. Similarly, better therapeutic efficacy was observed when a T cell population expressing TCR containing specific Vβ was expanded during a vaccine administration.

Tumor antigen specific $CD8^+$ T cells can be quantified by CTL assays and intracellular IFN-γ staining of cells obtained from blood in humans or the spleen in the case of mice. Limiting dilution assays or CD8 and IFN-γ staining can be used to determine the frequency of activated $CD8^+$ T cells. Increase in IFN-γ has been shown to occur during antigen-specific $CD8^+$ T cell activation. If the frequency of IFN-γ staining cells is too low to be detected by the intracellular cytokine staining method, then the ELISPOT assay to determine IFN-γ secreting cells can be carried out. Alternatively, expansion of tumor antigen specific T cells can be monitored using MHC tetramers. Although measuring antigen specific T cells using MHC tetramers is a very sensitive assay, it indicates the mere physical presence of an antigen specific T cell but does not indicate whether the expanded antitumor T cells are functionally active or not. Therefore, MHC tetramer assays are normally combined with functional assays such as CTL assay or intracellular IFN-γ staining to determine the antitumor efficacy of an immunotherapeutic method.

Lessons from human immunotherapy: Based on the knowledge obtained from *in vitro* experiments and animal models of antitumor T cell responses and vaccines, many clinical trials have been conducted. Both cell-based and vaccine-based therapies have been employed. In cell-based therapies, patients were administered *ex vivo*-expanded tumor infiltrating T cells or DCs loaded with tumor antigens. In vaccine-based therapies, cancer cells or cellular fragments or tumor-associated antigens were modified with adjuvants such as cytokines or other immunostimulatory molecules and administered to induce expansion of tumor antigen-specific T cells. Some of the trials showed moderate success whereas some of them were not as effective as observed in animal models. Interestingly, in many patients, although vaccination produced strong antitumor T cell responses, the regression of the tumor did not occur, suggesting there is a disconnect between the expansion of antitumor specific T cells and efficacy of a cancer vaccine. This could be due to the lack of homing of antitumor T cells to tumor site, or tumors may secrete immnuosuppressive factors that lead to the inactivation of cytotoxic T cells. Also, comparison of the results of T cell response, as measured by MHC tetramer assays and functional assays, showed that not all the tumor antigen specific T cells expanded during a vaccination are functionally active, suggesting aberrations in the development of T cells during vaccination. These results emphasize the need for further studies on the nature and mechanisms of T cell responses during various therapeutic approaches. A careful manipulation of the induction of antitumor T cell immune responses and homing of T cells to tumors will lead to the development of effective therapies to treat various types of cancer.

TCL1

Giandomenico Russo
Istituto Dermopatico dell'Immacolata, Istituto di Ricovero e Cura a Carattere Scientifico, Roma, Italy

Definition

The TCL1 gene is involved in the generation and/or manifestation of mature forms of leukemias, mainly in the T-Prolymphocytic leukemia (T-PLL) and in chronic lymphocytic leukemia (B-CLL).

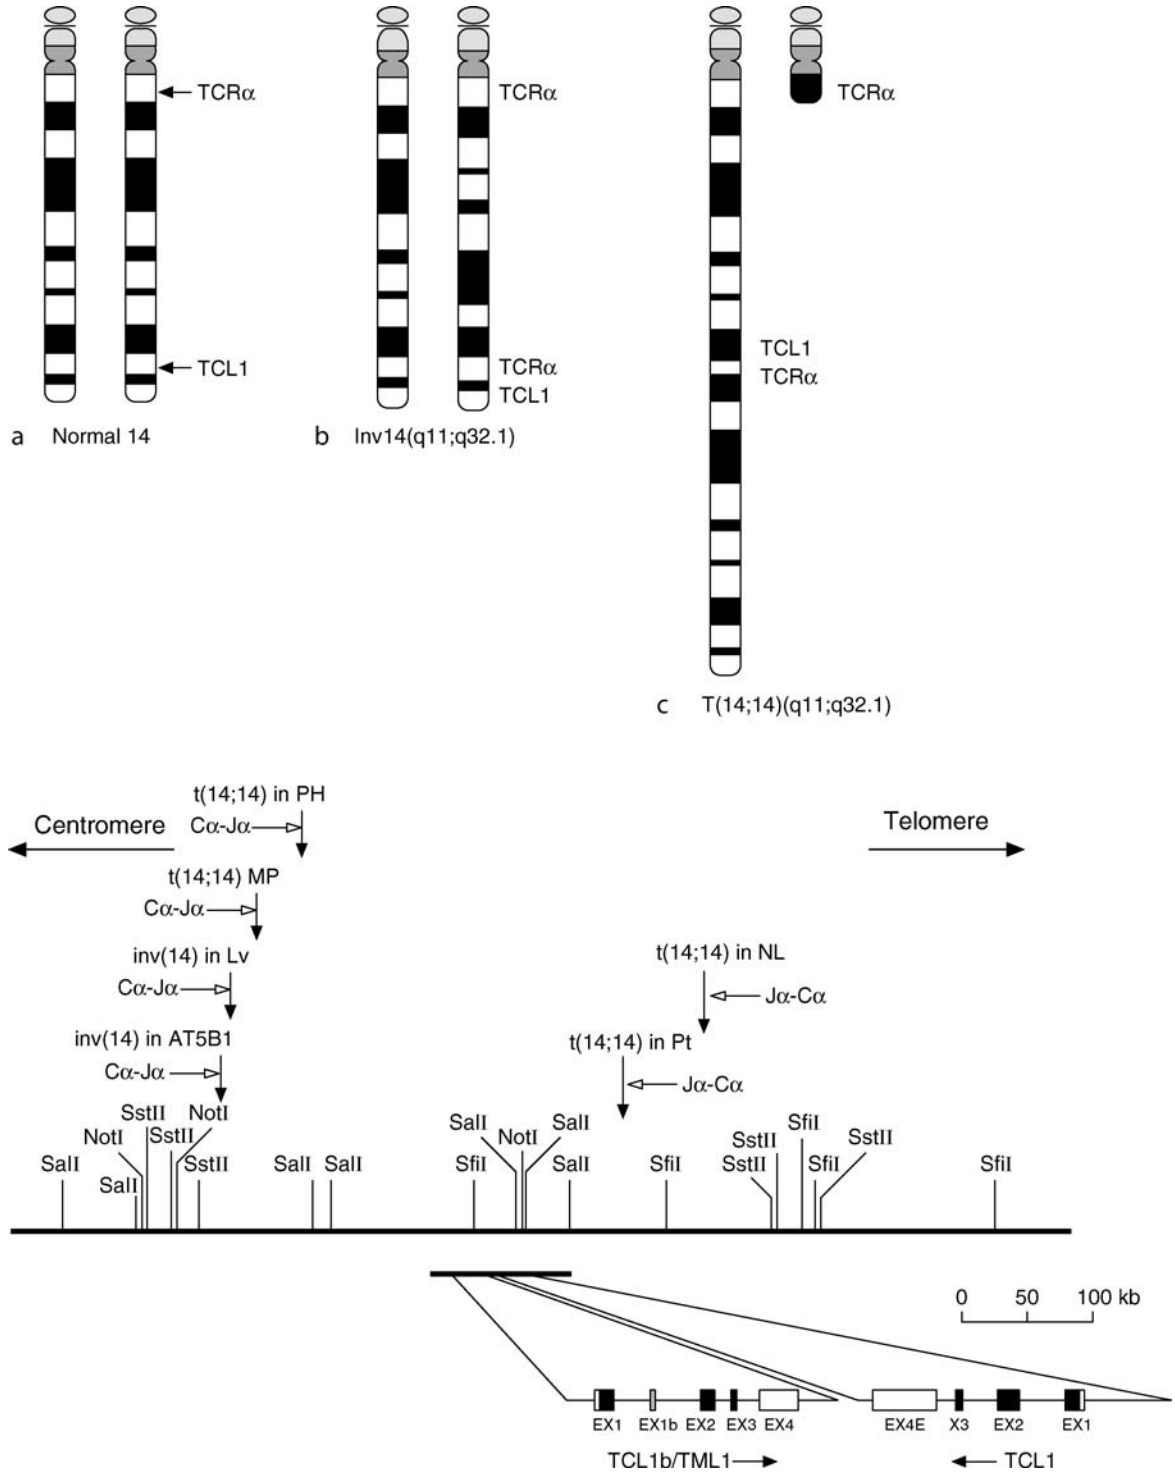
Characteristics

Clinical Characteristics of the T-PLL

T-PLL is a disease that represents 20% of prolymphocytic leukemias. It occurs at an advanced age of 70–80 years, with a slight male predominance. It is, however, quite frequent in patients with the immunodeficiency syndrome ►ataxia telangiectasia (AT) (1–5% of these patients develop it). Clinically it is accompanied by splenomegaly (75%), hepatomegaly (42%), lymphoadenopathy (55%), a high blood count (>200 × 10^9/L), with a very bad survival rate (<8 months). It involves mature T-cells (CD4+ in the 65%; but also CD8+ and CD4+ CD8+); T-cell prolymphocytes usually express CD3, CD5 and CD7. Morphologically the T-prolymphocyte is smaller than its B-counterpart, usually with a single, sometimes irregular, nucleolus. Chromosomal aberrations are quite peculiar and involve either inv 14 (q11;q32); or t(14;14)(q11;q32) and t(X;14)(q28;q11) translocations. Other recurrent changes involve chromosome 8 either as i(8)(q10) or as der(8) t(8;8). Molecular characterization of these breakpoints has been achieved and have brought about the identification of a new class of oncogenes on chromosome 14q32.1 (TCL1) and Xq28 (MTCP1) that are dysregulated (overexpressed) in this disease.

Cytogenetic and Molecular Characteristic of the TCL1 Locus

Intracellular overexpression of the TCL1 gene, is usually the result of a ►chromosome translocation or inversion juxtaposing the human region of chromosome14q32.1 (TCL1) to the region 14q11 of the alpha/delta locus of the T-cell receptor gene (TCR) (Fig. 1, *top*), as a result of a mistake in ►V(D)J recombination. Less frequently the translocation involves the TCL1 gene and the β locus of the TCR, thus giving origin to a t(7;14)(q35;q32.1) translocation. The TCL1 gene was first identified inside an 80 kb area comprised between the group of cloned inversions and translocations. This area has been recently fully characterized and completely sequenced (Fig. 1, *bottom*): other than TCL1, it comprises three other genes: TCL1b (also named TML1), that is highly homologous to TCL1 and lies just 15 kb on the centromeric side of TCL1; TNG1 and TNG2 (also named TCL6), with no homology of TCL1. All of these genes are overexpressed in T-PLL, probably as a consequence of the juxtaposition of the TCR regulatory elements. The chromosomal aberrations described above are present in ~85% of T-PLL, while in the remaining 10 ± 15% it is observed another chromosome translocation between region Xq21 (MTCP1 gene) and region 14q11 (TCR α/δ). The TCL1 and MTCP1 genes share more than 41%



TCL1. Figure 1

of identity and 61% of homology. As mentioned above T-PLLs are rare in the normal population but quite frequent in the patients affected by the autosomic immunodeficiency ataxia-telangiectasia (AT), a syndrome that results from the disruption of the ATM gene (►ATM protein). The disruption of both the alleles of the ATM gene is also present in those cancer cells derived from patients with T-PLL but without AT, thus showing

that alterations in these two genes, i.e. disruption of the ATM loci and overexpression of TCL1 or MTCP1, are necessary for the development of the T-PLL.

Animal Models

Evidence for the oncogenic role of the TCL1 gene is also supported by animal models. Transgenic mice that carried either the TCL1 gene, under the transcriptional control of the $p56_{lck}$ promoter, or the MTCP1 gene under the control of the CD2 regulatory gene, develop a form of chronic leukemia resembling morphologically and phenotypically to the T-PLL. These results indicate that transcriptional activation of the TCL1 and MTCP1 oncogene can cause malignant transformation of T lymphocytes. The leukemogenic effect seems to be dependent on the overexpressed copy number of the transgenes. These mice develop mature T-cell leukemias after a long latency period of around 15 months. The leukemia in these transgenics is almost invariably of the CD8+ phenotype.

More recently, TCL1 has also been shown to play a role in the pathogenesis of B-CLL, the most frequent leukemia encountered in the Western world. In fact, overexpression of the TCL1 gene under the control of a VH promoter and B29 in a transgenic mouse line resulted in B-cell tumors of IgM+ CD5+ cells closely resembling those of B-CLL and mature B-cell lymphoma. These animal models are currently used for in vivo clinical trials of new pharmacological compounds developed to combat mature B-cell leukemias.

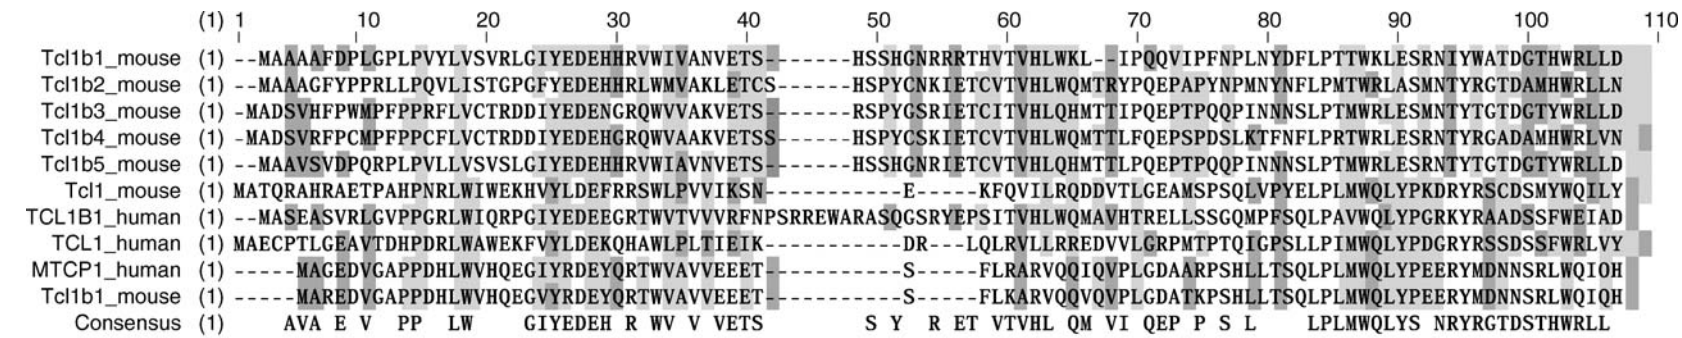
A Tcl1 knockout has been generated and shows impaired early embryonic, and B-cell and T-cell development.

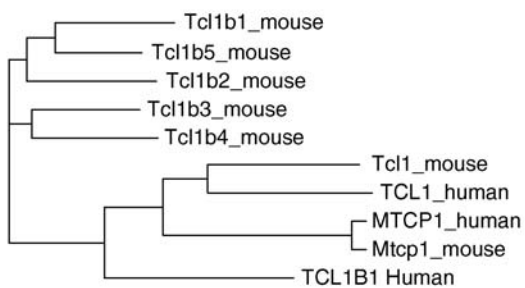
TCL1 Protein

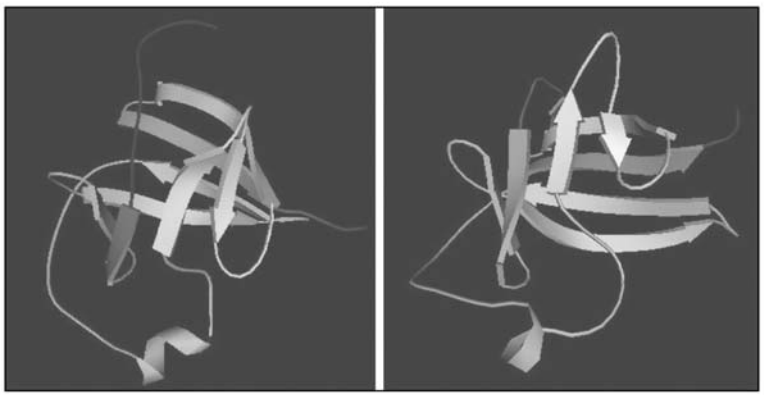
TCL1 codes for a transcript of ~1.3 kb, translated in a protein of 114 aa with a predicted Mr of 14 kD, with homology to no other protein with the exception of the other family members. Ten homologues genes have been identified, seven in the mouse and three in humans (Fig. 2). The 3D structure has been solved by NMR and X-Ray crystallography for both the TCL1 and MTCP1 proteins. These proteins fold in a compact eight-stranded b-barrel structure with a short helix between the fourth and fifth strand, with a unique topology (Fig. 2). The identical residues of the TCL1 and MTCP1 protein are clustered inside the barrel and on the surface at one side of it. Overall the structure resembles those of other proteins involved in the transporting of small molecules (such as lypocalin and calycine): this might lead to the prediction that TCL1 could bind small ligand and function as a transporter. The localization of TCL1 is mainly in the cytoplasm, but a nuclear translocation has also been reported. It is commonly accepted that TCL1 promotes cell proliferation by enhancing the activity of AKT/PKB (►AKT signal Transduction Pathway in Oncogenesis), a serine/threonine kinase having a central role in the signaling pathways that control cell proliferation and survival. Mammalian AKT/PKB is a family consisting of three members, PKBα/AKT1, PKBβ/AKT2 and PKBγ/AKT3, having idiosyncratic roles. TCL1 heterodimerizes with AKT and mediates both AKT transphosphorylation at Ser472/473 residue and AKT transfer to the nucleus. Biochemical approaches have shown that TCL1 binds to the PH domain of AKT enhancing its kinase activity and mediating its translocation to the nucleus. However, there might be other interactors, since both the proteins lack nuclear localization signals. *In vitro* assay demonstrated that this association resulted in a dose-dependent augmentation of AKT activation and suggested that this mechanism might be critical for TCL1-induced neoplasia. Activated AKT increases cell survival/proliferation by phosphorylation of many substrates in distinct signaling pathways. However, *in vitro* analysis concerning TCL1 modulation of AKT targets have shown conflicting results, in fact, some studies have shown that TCL1 overexpression leads to an increased phosphorylation of AKT target substrates FKHR, GSK3-, and BAD, whereas others indicated no effect on the AKT target substrates p70S6 kinase, BAD, IB, and NUR77. However, it is still unclear if these TCL1 functions depend on each other and how they are actually relevant to the promotion of normal/neoplastic cell growth exerted by TCL1.

TCL1 Expression in Normal and Pathological Tissues

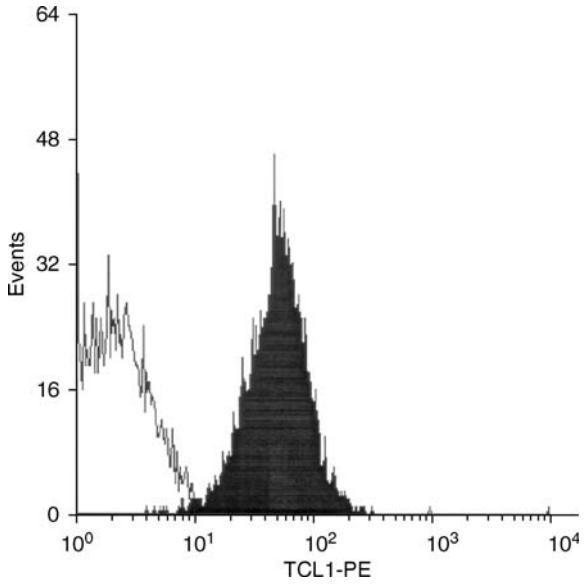
Expression of the TCL1 gene in normal cells is observed mainly in the lymphocytes, but also in ovary and in very early stages of embryogenesis in the mouse. In human T-cells derived from fetal thymus, the gene is confined very early to a CD4-CD8 double negative and no other T-cells seems to express it. FACS analysis of peripheral blood lymphocytes, using a monoclonal antibody, showed that TCL1 is only detectable in malignant T-cells from T-PLL (Fig. 3) while no other T-cell in the blood expresses it. The situation is different in B-cells where TCL1 is absent in the bone marrow in the CD34+ CD19− stem cell rich fraction: weak expression appears in the CD34+ CD19+ subpopulation of pro-B cells, and the expression peaks in the IgM negative pre B-cells with high CD19 and persist in immature IgM+ cells. In the lymph-node TCL1 is expressed by a subset of small lymphocytes of the lymphoid mantles and also by the cells of the germinal centers (centrocytes, centroblasts) of the secondary lymphoid follicles, and by data obtained analyzing a large series of tumors is downregulated in memory and plasma cells. TCL1 was recently found to be highly expressed in the majority of AIDS immunoblastic lymphoma plasmacytoid. The expression of TCL1 was also characterized during preimplantation embryo







TCL1. Figure 2



TCL1. Figure 3

development, namely in the cells from which ES are derived, where it was found to shuttle between blastomere cortical regions and the nucleus by a cell cycle-dependent fashion required for early blastomere proliferation, but not the acquisition of first embryonal differentiation traits. More recently, it has been shown that TCL1 plays a key regulatory role in the maintenance of the proliferation versus differentiation balance embryonic stem (EC) cells. In ES cells, in fact, TCL1 is directly activated by *Oct3/4*, and is among the very few genes that are required for the mitotic self-renewal state, the downregulation of which triggers ES differentiation.

Conclusions

Even if the functional role of the TCL1 and its related genes must be deciphered, this gene plays an important role in the development of the T-PLL, B-CLL, in the B-cell differentiation and in the very early stages of embryo development, and thus its targeting might have therapeutic consequences.

Technical Knockout

Adi Kimchi
Department of Molecular Genetics,
Weizmann Institute of Science, Rehovot, Israel

Definition

Technical knockout (TKO) is a method for function-based gene isolation in mammalian cells.

Characteristics

Technical knockout application has resulted in the isolation of several novel genes involved in apoptosis and in the genetic dissection of certain processes within this important biological process.

In general, TKO is based on two concepts, both directed at overcoming impediments to the use of genetic screens in cultured cells.

- One concept is the use of nucleic acids as "virtual mutagens" for trapping genes based on their function. This was achieved by transfections with anti-sense cDNA libraries to randomly inactivate gene expression, followed by a strong phenotypic selection.
- The other concept was to develop efficient strategies for introduction and recovery of complex cDNA libraries, to allow multiple rounds of phenotypic selection and rapid screens for identification of functionally relevant genes. To this aim, an expression vector that provides an efficient gene transfer system was developed, with the capability of representing a complex library in a single transfection event.

An ►EBV-based, self replicating episomal vector, was chosen to express a directional anti-sense cDNA library. The unidirectional strategy increased the probability of acquiring "recessive mutations" due to loss of expression. The episomal vector had several advantages over vectors that integrate into the genome. It reduced the background of non relevant phenotypic alterations occurring as a result of random integrations into DNA. In addition, the episomes were easily rescued from the transfected cells by a simple DNA extraction procedure with no need for any other genetic manipulations. This yielded a rapid and convenient way to perform multiple rounds of phenotypic selection. It also solved the issue of plasticity of tissue culture cells, since only the individual cDNA fragments that transduced the phenotypic change in subsequent transfections were scored as real positives. The episomal vector accumulated at multiple copies in the stable transfectants, resulting in high expression levels. In addition, the promoter cassette of the vector had been manipulated to confer much stronger expression levels of anti-sense RNAs during the phenotype selection. Since interferon-γ was the trigger that induced apoptosis, an interferon-responsive enhancer element was introduced into the vector to increase expression during the selection by the killing cytokine. In retrospect, the latter manipulation was found to be critical for the success of the functional cloning, since expression of high anti-sense RNA levels during the phenotypic selection was essential to reduce efficiently the protein levels.

Isolation of Genes in Apoptosis

The application of the TKO approach to apoptosis resulted in the discovery and subsequent characterization of five novel genes that function as positive mediators of this biological process. In addition, an anti-sense cDNA fragment to ►cathepsin D was also isolated, suggesting that this well known lysosomal protease is actively recruited to the death process. It was found that the five novel apoptotic genes (named DAP genes for: Death Associated Proteins) encode proteins that display a diverse spectrum of biochemical activities and different intracellular localizations. The list comprises a novel type of calcium/calmodulin-regulated kinase, which carries ankyrin repeats and the death domain, and is localized to the cytoskeleton (DAP-kinase), a nucleotide-binding protein (DAP-3), a small proline-rich, RGD-containing, protein (DAP-1) found in the cytoplasm, and a novel homologue of the eIF4G translation initiation factor (DAP-5). Extensive studies proved that these diverse activities participate in multiple apoptotic scenarios consistent with the initial design of the strategy which was aimed at targeting genes that belong to the basic machinery of apoptosis.

Preliminary results indicate that some of these rescued genes are functionally interconnected; the others may function independently of each other. The DAP genes were highly conserved in evolution. The C. elegans orthologue of DAP-3 shares 35% identity to the human protein and induces apoptosis in mammalian cells, indicating that the protein is also conserved at the functional level.

Clinical Aspects

The advantage of functional approaches to gene cloning is that they select the relevant rate limiting genes controlling a biological process in a unbiased manner. As a consequence, novel targets and unpredicted mechanisms may emerge, as became evident from the study of DAP proteins. For example, the calcium/calmodulin-dependent DAP-kinase, which was found to be localized to the actin microfilaments, may provide a molecular handle to study the collapse of the microfilament system in ►apoptosis and/or may mediate membrane blebbing. Most importantly, DAP-kinase, was found to possess tumor suppressive activities. This has been analyzed initially in mouse model systems where DAP-kinase display strong anti-metastatic effects and later in other in vitro systems that test suppression of oncogenic transformation. In human carcinoma cell lines and B cell lymphomas, DAP-kinase expression was lost at high frequency. Recent clinical studies have revealed that DAP-kinase expression is lost in non-small lung carcinomas, head and neck carcinomas and B cell malignancies. Thus, screening systems for genes that are rate limiting in apoptosis may target tumor suppressor genes. Another breakthrough step relates to the discovery of DAP-5. The structure/function features of this novel translation regulator resemble the proteolytically cleaved eIF4G initiation

factor, which appears in cells upon infection with some RNA viruses and directs cap-independent translation. The rescue of DAP-5 proved the existence of a strong link between apoptosis and the control of protein synthesis, which seems to be critical in certain apoptotic systems, and focused some of the mechanistic studies towards this direction. Another example refers to the isolation of cathepsin D by the TKO method suggesting that lysosomal proteases are recruited during apoptosis, in addition to the well known caspase family of proteases.

Telomerase

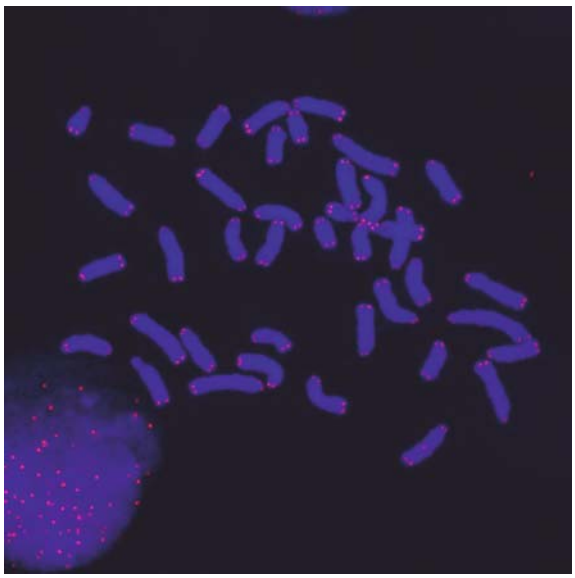
Jerry W. Shay
University of Texas, Southwestern Medical Center, Dallas, TX, USA

Definition

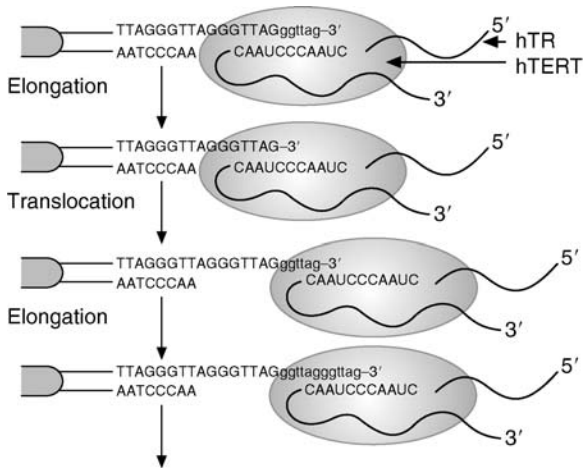
Telomerase (TE-LÓM-ER-ACE) is a ribonucleoprotein enzyme complex (a cellular reverse transcriptase) that maintains chromosome ends and has been referred to as a cellular immortalizing enzyme. Telomerase is composed of both RNA and proteins and uses its internal RNA component (complementary to the telomeric single stranded overhang) as a template in order to synthesize telomeric DNA (TTAGGG)n directly onto the ends of chromosomes using the catalytic hTERT component. Telomerase is present in most fetal tissues, normal adult male germ cells, inflammatory cells, in proliferative cells of renewal tissues and in most tumor cells. After adding six bases, the enzyme is thought to pause while it repositions (translocates) the template RNA for the synthesis of the next six base pair repeat. This extension of the 3′ DNA template end in turn permits additional replication of the 5′ end of the lagging strand, thus compensating for the ►end replication problem.

Characteristics

►Telomeres are the repetitive DNA sequences at the end of all linear chromosomes (Fig. 1). In humans there are 46 chromosomes and thus 92 telomere ends that consist of thousands of repeats of the six nucleotide sequence, TTAGGG. The telomere-telomerase hypothesis of aging and cancer is based on the findings that the cells of most human tumors have telomerase activity, while normal human somatic cells do not. Telomere length is maintained by a balance between processes that lengthen telomeres (telomerase) and processes that shorten telomeres (the end replication problem and oxidative damage). Telomerase is a cellular reverse



Telomerase. Figure 1 Telomeres in human chromosomes. Metaphase human chromosomes that have been both stained with DAPI (blue color which stains DNA/chromosomes) and also in situ hybridized with a PNA (peptide nucleic acid) fluorescently labeled telomere probe (red ends of each chromosome).



Telomerase. Figure 2 Telomeric sequences are synthesized by telomerase, a ribonucleoprotein enzyme (composed of both RNA and protein). Telomerase contains RNA-dependent DNA polymerase activity which uses its RNA component (complementary to the telomeric single stranded overhang) as a template in order to synthesize TTAGGG repeats (elongate) directly onto telomeric ends. After adding six bases, the enzyme is thought to pause while it repositions (translocates) the template RNA for the synthesis of the next six bp repeat. This extension of the 3′ DNA template end in turn permits additional replication of the 5′ end of the lagging strand, thus compensating for the telomere shortening that occur in its absence.

transcriptase that stabilizes telomere length by adding hexameric (TTAGGG) repeats onto the telomeric ends of the chromosomes, thus compensating for the continued erosion of telomeres that occurs in its absence (Fig. 2). The core catalytic subunit of telomerase, ►hTERT, is expressed in embryonic cells and in adult male germline cells, but is undetectable in normal somatic cells except for proliferative cells of renewal tissues (e.g. hematopoietic stem cells, activated lymphocytes, basal cells of the epidermis, proliferative endometrium and intestinal crypt cells). The hTERT gene maps to chromosome band 5p15.33.

In normal somatic cells, progressive telomere shortening is observed, eventually leading to greatly shortened telomeres and to a limited ability to continue to divide. It has been proposed that telomere shortening may be a molecular clock mechanism that counts the number of times a cell has divided, and when telomeres are short, cellular ►senescence (growth arrest) occurs. It has been proposed, but not proven, that shortened telomeres in mitotic (dividing) cells may be responsible for some of the changes we associate with normal aging.

What Are Telomeres and What Do They Do?

Telomeres are repeated DNA sequences that protect the ends of chromosomes from being treated like a broken piece of DNA needing repair. Without telomeres, the ends of the chromosomes would fuse to each other leading to massive genomic instability. Telomeres are also thought to be the "clock" that regulates how many times an individual cell can divide. Telomeric sequences shorten each time the DNA replicates. When at least some of the telomeres reach a critically short length, the cell stops dividing and ages (senesces) which may cause or contribute to some age-related diseases. In cancer, a special cellular reverse transcriptase, telomerase, is reactivated and maintains the length of telomeres, allowing tumor cells to continue to proliferate.

Why Do Telomeres Shorten?

The mechanisms of DNA replication in linear chromosomes is different for each of the two strands (called leading and lagging strands). The lagging strand is made as series of discrete fragments, each requiring a new RNA primer to initiate synthesis. The DNA between the last RNA priming event and the end of the chromosome cannot be replicated because there is no DNA beyond the end to which the next RNA primer can anneal, thus this gap cannot be filled in (this is referred to as the "end replication problem"). Since one strand cannot copy its end, telomere shortening occurs during progressive cell divisions. The shortened telomeres are inherited by daughter cells and the

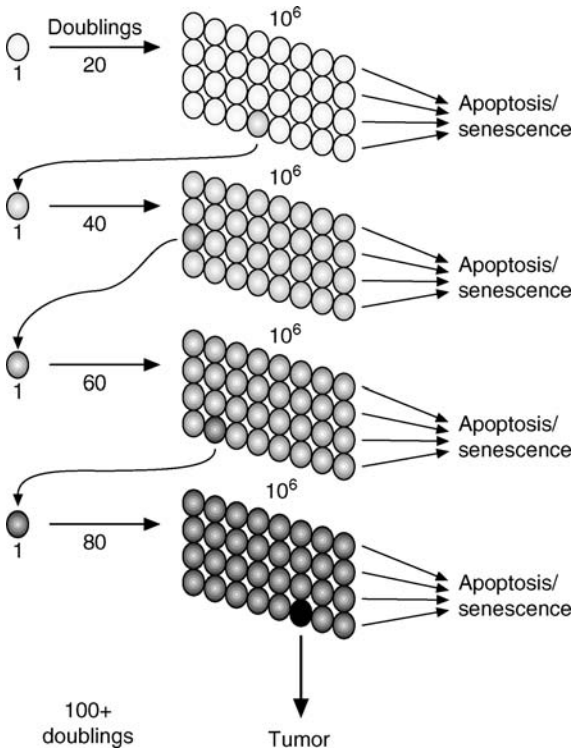
process repeats itself in subsequent divisions. Other factors may lead to telomere loss such as oxidative damage and other end processing events.

What is Cellular Senescence?

In contrast to tumor cells, which can divide forever (are "immortal"), normal human cells have a limited capacity to proliferate (are "mortal"). In general, cells cultured from a fetus divide more times in culture than those from a child, which in turn divide more times than those from an adult. The length of the telomeres decreases both as a function of donor age and with the number of times a cell has divided in culture. There appear to be two mechanisms responsible for the proliferative failure of normal cells. The first, M1 (Mortality stage 1), occurs when there are still at least several thousand base pairs of telomeric sequences left at the end of most of the chromosomes. M1 is induced by a DNA damage signal produced by one or a few of the 92 telomeres that have particularly short telomeres. The M1 mechanism causes growth arrest mediated by the tumor suppressor genes p16, RB1 and p53. If the actions of p53 and p16/pRB are blocked, either by mutation or by binding to viral oncoproteins, then cells can continue to divide and telomeres continue to shorten until the M2 (Mortality stage 2) mechanism is induced. M2 represents the physiological result of critically short telomeres when cells are no longer able to protect the ends of the chromosomes, so that end-degradation and end-to-end fusion occurs and causes genomic instability and cell death. In cultured cells, a focus of immortal cells occasionally arises. In most cases, these cells have reactivated the expression of telomerase, which is able to repair and maintain the telomeres (Fig. 3).

If You Can Stop the Shortening of Telomeres Will This Prevent Cellular Aging?

While there have been many studies indicating that there is a correlation between telomere shortening and proliferative failure of human cells, the evidence that it is causal has only recently been demonstrated. Introduction of the telomerase catalytic protein component into normal human cells without detectable telomerase results in restoration of telomerase activity. Normal human cells stably expressing transfected telomerase demonstrate extension of lifespan, providing more direct evidence that telomere shortening controls cellular aging. The cells with introduced telomerase maintain a normal chromosome complement and continue to grow in a normal manner. Initial concerns that the introduction of telomerase into normal cells may substantially increase the risk of cancer have not proven true. One way to think about this is that special reproductive tissues maintain high levels of telomerase throughout life, and there is no increased incidence of cancers in these special cells compared with other types of cancer. Thus, the major role of telomerase is to maintain telomere stability and keep the cells dividing. These observations provide the first direct evidence for



Telomerase. Figure 3 It has been argued that it may not be necessary to exhaust the replicative potential of normal cells in order to form a massive tumor (e.g. after 50 doublings a single cell could generate a tumor of a size greater than 1,000 kg). However, this theoretical argument assumes that all cells survive, which is highly unlikely to be correct. If the frequency of spontaneous mutations is ~10^{-6}, at least a million cells are needed for a second mutation to occur with reasonable probability. Since these mutations must accumulate in the same cell, a series of clonal expansions must occur as is illustrated in this figure. Since it requires 20 cell doublings to generate approximately one million cells, 20 divisions would accompany each mutation. For example if we assume five mutations are necessary for cancer to arise from a normal cell, more than 100 divisions (doublings) would be required to render a cell malignant. Losses of cells due to apoptosis or inhibition of cell proliferation due to senescence would limit the number of cells in a such a tumor to 10^6–10^8 cells which is less than a 1 g biomass. Thus, with the possible exception of certain stem cells from the bone marrow, skin, and perhaps the intestine, most normal human cells only divide 50–70 times before they growth arrest. Thus cellular senescence could act as a very effective "brake" on the proliferation of cells that had accumulated a few mutations but not all those prerequisite for malignancy.

the hypothesis that telomere length determines the proliferative capacity of human cells.

Can Telomerase be Used as a Product to Extend Cell Lifespan?

The ability to immortalize human cells and retain normal behavior holds promise in several areas of biopharmaceutical research, including drug development, screening and toxicology testing. The development of better cellular models of human disease and production of human products are among the immediate applications of this new advance. This technology has the potential to produce unlimited quantities of normal human cells of virtually any tissue type and may have most immediate translational applications in the area of transplantation medicine. In the future it may be possible to take a person's own cells, manipulate and rejuvenate them without using up their lifespan and then give them back to the patient. In addition, genetic engineering of telomerase-immortalized cells could lead to the development of cell-based therapies for certain genetic disorders such as muscular dystrophy.

Cell and Molecular Regulation

Proteins have been identified that directly interact with telomerase, such as p23/hsp90 (molecular chaperones) and TEP1 (telomerase associated protein 1 with unknown function). In addition, there are likely to be other proteins that help regulate telomerase function that have yet to be identified. The transcriptional regulation of the catalytic subunit of telomerase (hTERT) is clearly complex, but there is evidence that the c-myc gene may be important in some aspects of the transcriptional activation of hTERT. In addition, there is evidence that a gene on chromosome 3 may be involved in the transcriptional repression of hTERT. Since telomerase interacts with the telomeres, there has been a number of proteins identified that directly or indirectly bind to telomeres (TRF1, TRF2, tankyrase, TIN2, hRap1) that are also important in the regulation of telomerase. A single stranded telomere binding protein is called POT1.

There is also regulation of the level of telomerase activity in specific cell types. Telomerase activity is low in the most primitive stem cells of renewal tissues (e.g. crypts of the intestine, bone marrow cells, resting lymphocytes, basal layer of the epidermis), while telomerase activity is increased in the proliferative decendents of these cells. Thus, there are telomerase competent cells that have low activity when quiescent (not dividing) and increased activity when proliferating (dividing). However, these telomerase competent stem cells do not fully maintain telomere length since such cells obtained from older individuals have shorter telomeres than those derived from younger individuals. Thus, in germline (reproductive) cells and tumor cells, telomerase fully maintains telomere length in contrast to stem cells (with regulated telomerase activity) and most somatic cells (with no detectable telomerase activity) in which telomeres progressively shorten with increased age.

Cellular senescence may have evolved, in part, to protect long lived organisms, such as humans, against the early development of cancer. Thus, it has been proposed that upregulation or reexpression of telomerase may be a critical event responsible for continuous tumor cell growth. In contrast to normal cells, tumor cells show no net loss of average telomere length with cell division, suggesting that telomere stability may be required for cells to escape from replicative senescence and proliferate indefinitely. Most, but not necessarily all, malignant tumors may need telomerase to sustain their growth. ►Immortalization of cells may occur through a mutation of a gene in the telomerase repression pathway. Thus, upregulation or reactivation of telomerase activity may be a rate-limiting step required for the continuing proliferation of advanced cancers. There is experimental evidence from hundreds of independent laboratories that telomerase activity is present in ~90% of all human tumors, but not in tissues adjacent to the tumors. Thus, clinical telomerase research is currently focused on the development of methods for the accurate diagnosis of cancer and on novel anti-telomerase cancer therapeutics.

Clinical Relevance

There is mounting evidence that cellular senescence acts as a "cancer brake" as it takes many divisions to accumulate all the changes needed to become a cancer cell. In addition to the accumulation of several mutations in oncogenes and tumor suppressor genes, almost all cancer cells are immortal and, thus, have overcome the normal cellular signals that prevent continued division. Young normal cells can divide many times, but these cells are not cancer cells since they have not accumulated all the other changes needed to make a cell malignant. In most instances a cell becomes senescent before it can become a cancer cell. Therefore, aging and cancer are two ends of the same spectrum. The key issue is to find out how to make our cancer cells mortal and our healthy cells immortal, or at least longer lasting. Inhibition of telomerase in cancer cells may be a viable target for anti-cancer therapeutics, while expression of telomerase in normal cells may have important biopharmaceutical and medical applications. In summary, telomerase is both an important target for cancer and for the treatment of age-related disease.

Could Telomerase be the "Achilles Heel" of Cancer?

We believe that progressive telomere shortening is halted in cancer cells by the presence of the enzyme

telomerase which maintains and stabilizes the telomeres, allowing cells to divide indefinitely. Telomerase activity is detected in almost all human tumors. It is hoped that a therapy can be developed that inhibits telomerase activity and interferes with the growth of many types of cancer. There are several ongoing clinical trials testing these ideas in patients with solid tumors and leukemias.

Will Inhibiting Telomerase Restore the Senescence Program in Cancer Cells and if so Will This Therapy Cure Cancer?

One research strategy is to inhibit the activity of telomerase, forcing immortal cells into a normal pattern of permanent growth arrest (senescence) or death (►apoptosis). Following conventional treatments (surgery, radiotherapy, chemotherapy), anti-telomerase agents would be given to limit the proliferative capacity of the rare surviving tumor cells in the hope that this would prevent cancer recurrence. We believe this treatment would be very selective, in that only cells with an activated telomerase would be affected. As far as we know, that includes only "immortal" tumor cells and germline (reproductive cells) and at lower levels stem cells in renewal tissues.

Will Telomerase Activity be Useful in Cancer Diagnostics?

Telomerase activity is detected in premalignant specimens (in situ lung and breast cancers), while colon and pancreatic cancer have detectable telomerase activity at later (carcinoma) stages. The ability to use almost any clinical specimen and to demonstrate telomerase may allow the detection of cancers at an earlier stage. For example, telomerase activity is detected in lung cells in cancer patients obtained by bronchial alveolar lavage. In addition, fine needle aspirations (breast, liver and prostate cancer), washes (bladder and colon), and sedimented cells from urine (bladder and prostate) provide minimally invasive sources of cells to detect telomerase activity and are likely to have immediate diagnostic utility. Telomerase may also be important in the monitoring of minimal residual disease. In an effort to improve the diagnostic value of telomerase determinations, in situ hybridization methods for the demonstration of telomerase on archival paraffin embedded clinical specimens appears to distinguish cancer from normal cells, correlates well with telomerase activity, and thus may provide added value to telomerase activity assays. In addition, the presence or absence of telomerase may have prognostic value and help risk-stratify patients into those with favorable outcomes (to avoid unnecessary treatments for patients with low or no detectable telomerase) and those with high telomerase activity and with unfavorable outcomes (to help oncologists manage patient treatments more effectively).

Have any Telomerase Therapeutic Agents been Identified and what are the Potential Complications of such Strategies?

Since telomerase is expressed in most advanced cancers, methods for telomerase inhibition using small molecules such as modified oligonucleotides may have utility. There are potential risks in the use of such therapy that must be considered, for example the affects of inhibitors on telomerase-expressing stem cells. However, it is likely that this approach will be less toxic than conventional chemotherapy which affects all proliferating cells, including stem cells. The rate of division of the most primitive stem cells is so much slower than that of most cancer cells that the amount of telomere shortening in the stem cells should be relatively small. Some of the side effects of standard chemotherapy, such as thrombocytopenia, leukopenia, nausea and hair loss due to the death of the cells in rapidly proliferating tissues, may be reduced by the use of telomerase inhibitors, which are predicted to induce cellular senescence or cell death only after a period of growth. This raises what many consider the most important concern with this proposed treatment regimen, the prolonged time potentially required for a telomerase inhibitor to be effective. Since the mode of action of telomerase inhibitors may require telomeric shortening before inhibition of cell growth or induction of apoptosis, there may be a significant delay in efficacy. Thus methods may have to be devised to increase the rate of telomere shortening when telomerase inhibitors are used therapeutically. Telomerase inhibitors will likely be used together with or following conventional therapies, so that once the bulk of the tumor mass is eliminated, anti-telomerase therapy might prevent the large number of cell divisions required for the regrowth of rare resistant cancer cells. They may also be used in early stage cancer to prevent overgrowth of metastatic cells, as well as in high-risk patients with inherited susceptibility to cancer syndromes to prevent the emergence of telomerase-expressing cells (chemoprevention). Finally, there are ongoing telomerase immunotherapy clinical trial. It appears that tumors cells but not normal stem cells express telomerase epitopes on their cell surface. Scientists have identified these epitopes and have produced synthetic peptides and have injected these into patients with advanced cancer. This approach is showing early signs of efficacy and currently Phase III clinical trials for patients with advanced pancreatic cancer are ongoing.

Telomere

Definition

Refers to repeated DNA sequences ((TTAGG)n at the ends of linear chromosomes that protect the ends of the chromosome from degradation. The segment at the end of each linear eukaryotic chromosome arm, consisting of a peculiar structure (including repeated DNA sequences) required to preserve the sticky ends of chromosomes from randomly joining together. They are involved in genome integrity, chromosome stability, nuclear architecture and chromosome pairing during meiosis. The telomeres of humans consist of as many as 2,000 repeats of the 5′ TTAGGG 3′ sequence.

►Genomic Imbalance
►Senescence and Immortalization
►Telomerase

Telomere Length

Definition

Differs between individuals and species and is under complex genetic control. Mean ►telomere length has emerged as a replicative clock within each population of cells and the tissues and organs. In human normal somatic cells, telomere length ranged between 7–15 kb and shortened 50–150 bp in each cell division.

Definition

TMZ is a chemotherapeutic DNA alkylating agent of the imidazotetrazine class.

IUPAC name = 3-methyl-2-oxo-1,3,4,5,8-pentazabicyclo[4.3.0]nona-4,6,8-triene-7-carbo oxamide

CAS number = 85622-93-1

MW = 194.151 g/mol

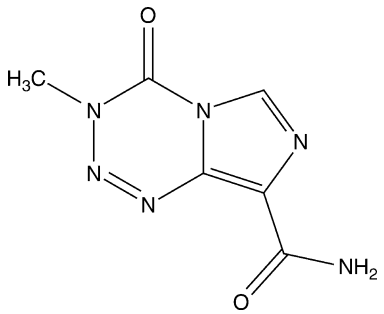
Chemical formula = $C_6H_6N_6O_2$

PubChem Compound information – CID #5394: http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?CMD = search&DB = pccompound&term = 5394

Structure – see Fig. 1.

Characteristics

Temozolomide (TMZ) is a chemotherapeutic alkylating agent, a drug used in the treatment of cancer that causes cancer cell death by transferring an alkyl adduct (a methyl group) to bases in DNA. If left un-repaired, the modified or methylated DNA triggers one of many cell death responses to facilitate the destruction of the tumor. TMZ (Fig. 1) is classified as an imidazotetrazine and was developed in the 1990s. The first of the imidazotetrazines to undergo rigorous evaluation was mitozolomide but this compound proved to be too myelosuppressive, possibly because it was found to cross-link strands of DNA in normal cells. TMZ is an N-methyl derivative of mitozolomide and is a monofunctional methylating agent that does not induce DNA cross-links. TMZ is an oral alkylating agent that was recently approved for therapy of brain tumors such as glioblastoma in combination with radiation and is undergoing clinical trials for other cancers including melanoma and leukemia as well as cancers that have metastasized to the brain. TMZ is 100% bio-available, crosses the blood-brain barrier, and produces mild toxicity, with less than 5% of patients experiencing serious myelosuppression. Partial deletion of chromosome 1p/19q in anaplastic and recurrent oligodendroglioma appears to predict for sensitivity to TMZ as it does for other alkylating agents, although the mechanism is unclear. TMZ has also shown some efficacy in non-glial tumors that have metastasized to the brain.

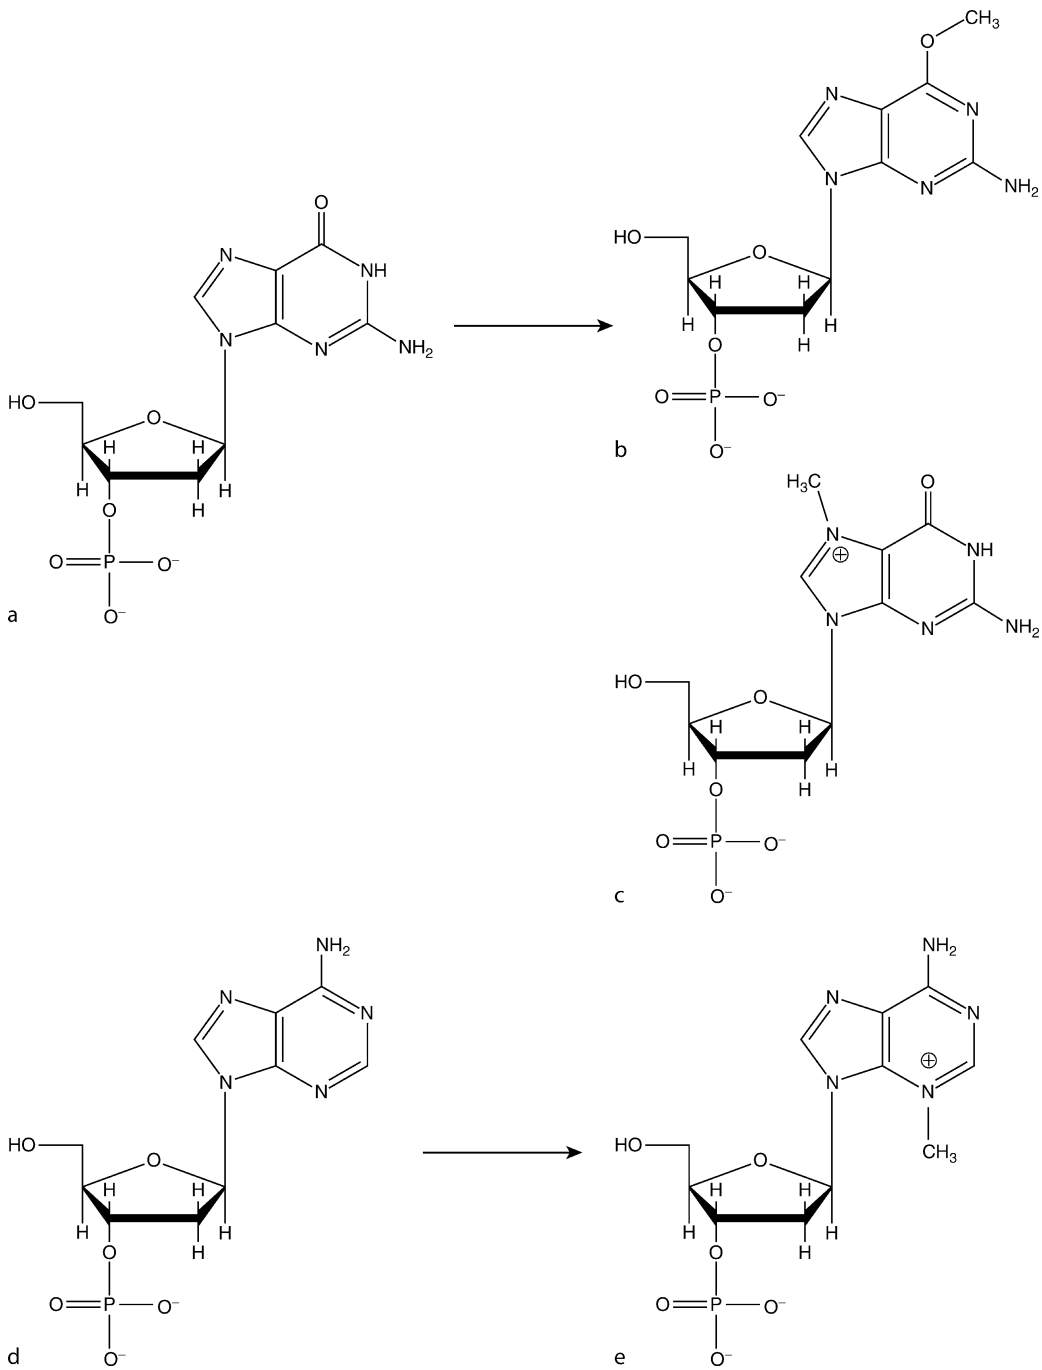


Temozolomide. Figure 1 Diagram of the chemical structure of temozolomide. Only the methyl group (CH_3−) is transferred to DNA. The remainder of the molecule is metabolized in the form of molecular nitrogen (N_2), carbon dioxide (CO_2) and excreted as a molecule of 5-aminoimadozole-4-carboxamide (AIC) in urine.

TMZ is rapidly absorbed after oral administration and undergoes a base-catalyzed addition of water to the C-4 atom and rapid breakdown and decarboxylation to yield MTIC [5-(3-methyl-1-triazeno)imidazole-4-carboxamide] in the peripheral blood. MTIC is the same active metabolite of the alkylating agent dacarbazine (DTIC). DTIC is a pro-drug that requires metabolic activation by enzymes in the liver to generate MTIC. TMZ is also considered a pro-drug although metabolism is spontaneous in that TMZ does not require enzymatic activation to generate MTIC. Once generated, MTIC undergoes acid catalyzed hydrolysis to yield the excreted compound AIC (5-aminoimidazole-4-carboxamide) and the active methyldiazonium ion, which reacts with nucleophilic atoms in DNA: predominantly the N7 and O^6 atom of guanine and the N3 atom of adenine. The major site of methylation is the N7 position of guanine (>70%) followed by the N3 position of adenine (9.2%) and the O^6 atom of guanine (5%). Figure 2 depicts the chemical structure of the naturally occurring bases in DNA (guanine and adenine) and the TMZ-induced alkylated products (O^6-MeG, N7-MeG and N3-MeA).

Temozolomide and MGMT

One of the major cytotoxic DNA lesions or types of DNA damage induced by TMZ treatment is the formation of methyl adducts on the O^6 position of guanine (O^6-MeG; see Fig. 2). However, the cytotoxic guanine lesion O^6-MeG is rapidly repaired by a direct reversal reaction conducted by the DNA repair protein O^6-methylguanine DNA methyltransferase (MGMT or more commonly referred to as AGT). This DNA repair protein is encoded by the O^6-methylguanine DNA methyltransferase gene, *MGMT*, located on chromosome 10 at position 10q26. The MGMT gene encodes a single mRNA (NM_002412) that translates to a single protein of 207 amino acids (NP_002403). MGMT functions to remove O^6-MeG lesions in DNA via a suicide reaction in which the O^6-Me group on guanine is transferred to the cys^{145} residue in MGMT, rendering MGMT inactive. Once alkylated on amino acid residue



Temozolomide. Figure 2 Chemical structures of the guanine and adenine bases in DNA and the temozolomide-induced modification to these bases. The guanine base (a) is modified by temozolomide on the O^6-atom to yield O^6-methylguanine (b) and on the N7-atom to yield N7-methylguanine (c) at a frequency of 5% and >70%, respectively. The adenine base (d) is modified by temozolomide at the N3-position to yield N3-methyladenine (e) at a frequency of 9.2%.

cys^{145}, the MGMT protein is depleted from the cell within a few hours. Depletion of the MGMT protein is facilitated by the ubiquitin-dependent proteosome pathway. The alkylated form of MGMT is targeted for poly-ubiquitylation; a post-translational modification that initiates proteosome-mediated degradation. Interestingly, MGMT activity is observed to be elevated in many tumors (in relation to the surrounding normal

tissue) such as those derived from colon, lung, pancreatic and breast cancer, non-Hodgkin's lymphoma, myeloma and glioma. It is now well established that elevated MGMT expression leads to resistance to clinical alkylating agents due to failure to remove the O^6-MeG lesion.

To improve TMZ efficacy, several strategies have been developed to limit the repair of the O^6-MeG lesion. MGMT activity can be successfully attenuated by the use of free guanine base derivatives, with alkyl groups at the O^6 position, which act as a pseudosubstrate and lead to MGMT depletion. Two of the most promising MGMT specific drugs are O^6-benzylguanine (BG) and O^6-(4-bromothenyl)guanine (Patrin, PaTrin-2, Lomeguatrib). Both of these MGMT-specific small molecule drugs are currently undergoing clinical evaluation to be used in combination with TMZ. In addition, other clinical alkylating agents are found to induce the formation of O^6-MeG adducts to DNA, including the platinum drugs cisplatin and carboplatin as well as the alkylating agent dacarbazine. Combination treatments with TMZ are therefore being evaluated as a novel approach to deplete MGMT protein levels and thereby increase TMZ efficacy. Interestingly, the dosing or scheduling of TMZ administration can also be altered to maximize MGMT depletion. For example, the standard 5-day dosing schedule of TMZ (150–250 mg/m^2/day) leads to complete depletion of MGMT in peripheral blood cells but MGMT levels will recover within 24 h. The observed TMZ-induced depletion of MGMT suggests that variation in the dosing schedules may improve MGMT depletion and clinical response. Compressed scheduling (five doses every 4 h or once every 8 or 12 h) has shown variation in MGMT depletion as well as elevated myelotoxicity. Alternatively, low (75 mg/m^2) extended dosing for 6–7 weeks in cycles of 8 weeks resulted in complete MGMT depletion. Clinical benefit to this or other scheduling paradigms is under intense investigation. The TMZ-mediated induction of the O^6-MeG DNA lesion and the depletion of MGMT has also been used to improve the effectiveness of topoisomerase inhibitors. Topoisomerase inhibitors such as Irinotecan (CPT-11) have been shown to have an enhanced efficacy when delivered in combination with TMZ. The increased level of O^6-MeG in DNA acts as a Topoisomerase I (topo-I) trap and an increase in topo-I/DNA covalent complexes. Recently, pre-treatment with interferon-beta was also shown to down-regulate MGMT expression and to improve the response of xenografts to TMZ in pre-clinical testing.

Conversely, low or undetectable expression of MGMT is generally considered a strong indicator of potential clinical response to TMZ. Loss of MGMT expression in tumors is generally via elevated methylation and hence inactivation of the MGMT promoter. Although MGMT promoter hypermethylation is associated with hypermethylation of many other promoter regions throughout the genome, epigenetic regulation (Epigenetic gene silencing) is not considered a random process in cancer. The development of methylation-specific PCR provides for a highly sensitive and accurate measurement of the methylation status of the MGMT promoter within the tumor tissue. DNA isolated from the tumor can therefore be analyzed for methylation status. Several studies have demonstrated that MGMT methylation status can be used to predict TMZ response. It is possible that MGMT promoter methylation measurements may be used to pre-screen patients for treatment options. However, there are other concerns that define response to TMZ and the cytotoxicity to the O^6-MeG DNA lesion.

Mismatch DNA Repair and Temozolomide Response

The O^6-MeG DNA adduct is not inherently cytotoxic by itself. The adduct is stable and genomic DNA containing O^6-MeG adducts is efficiently replicated during cell division by human replicative DNA polymerases. However, if not repaired by MGMT, either cytosine or thymine may be inserted opposite the O^6-MeG DNA adduct during replication. Insertion of thymine would lead to G to A point mutations in subsequent rounds of cell division and DNA replication, consistent with the elevated level of point mutations in oncogenes and tumor suppressor genes found in tumors with a loss of MGMT expression. The cytotoxicity of the TMZ-induced O^6-MeG adduct stems from the replication-dependent formation of the O^6-MeG:T mispair and the recognition of this mispair by the post-replication mismatch DNA repair pathway (MMR). The MMR pathway is a multi-protein DNA repair and DNA damage signaling pathway that removes errors of DNA replication and functions in meiotic and mitotic recombination as well as in DNA damage signaling and apoptosis following alkylation damage.

Currently, two mechanisms have been proposed for the MMR-dependent cytotoxicity of the TMZ-induced O^6-MeG DNA adduct: a "Futile Cycle of Repair" model and a "Direct DNA Damage Signaling" model. In the "Futile Cycle of Repair" model, the MutSα complex (a heterodimeric complex of the two MMR proteins MSH2 and MSH6) recognizes and binds to the O^6-MeG:T mispair, recruits the MutLα complex (a heterodimeric complex of the two MMR proteins MLH1 and PMS2) to the mispair and initiates repair of the newly synthesized DNA strand. Since this repair process involves removal and resynthesis of the T-containing DNA strand, the O^6-MeG:T mispair is regenerated during each cycle of repair thereby generating the substrate for another cycle. It is proposed that continued rounds of repair may lead to some aborted repair and the formation of double-strand

breaks and cell death. In the "Direct DNA Damage Signaling" model, MutSα binds to the O^6-MeG:T mispair and without repair processing, recruits MutLα and the DNA damage response proteins ATRIP and ATR to initiate the DNA damage checkpoints leading to cell cycle arrest and apoptosis. Critical MMR proteins are therefore required for efficacy of TMZ and hence loss of MMR leads to resistance to TMZ.

By a mechanism similar to that described above for MGMT epigenetic gene silencing, MMR can be compromised by tumor-specific promoter methylation of critical MMR genes. Whereas improved prognosis has been reported in tumors with loss of MGMT expression due to promoter methylation, poor prognosis is observed when MMR capacity is compromised by methylation of the promoter for the essential MMR genes MLH1, MSH2 and MSH6. More recently, loss of expression or inactivating mutations in MSH6 (an essential component of the MutSα complex) have been observed in TMZ resistant glioma tumors and in recurrent tumors following TMZ therapy, implicating an essential role for MHS6 in TMZ response. It is likely that all components of the MutSα complex (MSH2 and MSH6) and the MutLα complex (MLH1 and PMS2) may be essential for TMZ efficacy and response to the TMZ-induced O^6-MeG DNA adduct.

Repair of N7-Methylguanine and N3-Methyladenine DNA Lesions

The N7-methylguanine (N7-MeG) and N3-methyladenine (N3-MeA) DNA lesions (Fig. 2) comprise over 80% of the DNA adducts induced by TMZ. Both of these DNA lesions are repaired by the base excision repair (BER) pathway. BER is the predominant DNA damage repair pathway for the processing of small base lesions derived from alkylation damage. BER is normally defined as DNA repair initiated by a lesion-specific DNA glycosylase and completed by either of two sub-pathways: short-patch BER; a mechanism whereby only one nucleotide is replaced or long-patch BER; a mechanism whereby 2–13 nucleotides are replaced. The majority of repair is currently thought to occur via the short-patch pathway. Repair of N7-MeG and N3-MeA is initiated by the methylpurine DNA glycosylase (Mpg; NM_002434). The paradigm for the short-patch BER pathway initiated by Mpg involves base lesion removal and then AP site hydrolysis by AP endonuclease (Ape1; NM_080649), catalyzing the incision of the damaged strand, leaving a 3′OH and a 5′deoxyribose-phosphate moiety (5′dRP) at the margins. DNA polymerase β (Pol β; NM_002690) hydrolyzes the 5′dRP moiety and fills the single nucleotide gap, preparing the strand for ligation by either DNA Ligase I (LigI; NM_000234) or a complex of DNA Ligase IIIα (LigIIIα; NM_013975) and XRCC1 (NM_006297). Each step throughout BER is coordinated via protein-protein interactions with the XRCC1/DNA Ligase IIIα heterodimer and PARP1 (NM_001618), two important BER scaffold protein complexes. Furthermore, PARP1 has been linked more directly to BER as it interacts both physically and functionally with Pol β and LigIIIα, placing it as a member of the short-patch BER pathway. In addition, PARP1 coordinates with long-patch BER proteins to facilitate the repair of longer stretches of DNA.

BER removes >80% of the DNA lesions induced by TMZ. The advent of TMZ has therefore increased interest in the development of BER specific inhibitors since aborted or blocked BER sensitizes most cancer cells to alkylating agents. Blocking almost any step in the BER pathway will improve TMZ efficacy in cell culture assays, suggesting that BER inhibitors (just as observed with inhibitors of MGMT) may prove useful when administered in combination with TMZ. Few small molecule drugs have been developed that are specific for BER proteins. Lucanthone and CRT0044876 have been reported to inhibit Ape1 and will sensitize cells to TMZ. Methoxyamine is another BER inhibitor; however, this compound does not directly inhibit BER enzymes but instead binds to abasic sites in DNA, making them refractory to further repair and the methoxyamine-bound abasic site is highly cytotoxic. Methoxyamine is currently undergoing clinical trials in concert with TMZ.

The most common BER target for small molecule drugs (inhibitors) is PARP1 although PARP1 is also involved in the repair of double-strand breaks (DSBs) in DNA via a non-homologous end-joining pathway. PARP1 is the founding member of a large family of ADP-ribosyl transferase proteins including six PARPs (poly-ADP-ribose polymerases), eleven MARTs (mono-ADP-ribosyltransferases), seven SIRTs, four PARGs (poly ADP-ribose glycohydrolases) and Pi-MARTs. To date, only PARP isoforms 1, 2 and 3 have been found to respond to DNA damage such as that induced by TMZ. Upon binding to a nick (a single-strand break) or a DSB, PARP is activated to poly-ADP-ribosylate itself and other target proteins and to synthesize poly-ADP-ribose. Inhibiting PARP activation has been shown to significantly improve TMZ-induced tumor cell killing and to improve response to TMZ in pre-clinical xenograft models. Currently, there are at least six PARP inhibitors undergoing clinical trials as anticancer agents, although the specificity of these for PARP1, PARP2, PARP3 or other PARP-family members remains to be determined. Three of these small molecule inhibitors undergoing clinical trials are being evaluated for clinical efficacy in combination with TMZ. These clinical trials (Phase I and II) are for the treatment of solid tumors, metastatic melanoma and glioblastoma multiforme.

Although TMZ is effective in the treatment of glioblastoma and is being evaluated for melanoma and other cancers, efficacy can clearly be improved through combination therapy to inhibit one or more DNA repair pathways. Continued development of MGMT and BER inhibitors is expected to have significant impact on response to TMZ in the near future. Further, analysis of these critical DNA repair pathways in tumors can provide valuable biomarkers to anticipate response.

Temsirolimus

Janet E. Dancey
Division of Cancer Treatment and Diagnosis, National Cancer Institute, Rockville, MD, USA

Synonyms

CCI-779; Torisel™

Definition

Temsirolimus is a small molecule inhibitor of mammalian target of rapamycin (mTOR) kinase. Aberrant intracellular signaling through mTOR is associated with the cancer cell proliferation. Inhibition of this pathway by temsirolimus result in anti-proliferative effects that may result in improved survival in patients with cancer.

Characteristics

Temsirolimus is a soluble 42-[2,2-bis (hydroxymethyl)]-propionic ester of the macrocyclic lactone rapamcyin (also known as sirolimus). Temsirolimus, sirolimus and other members of this class of agents inhibit the proliferation of normal and malignant cells by inhibiting the activity of mTOR, an intracellular serine-threonine kinase within the Phosphoinositide 3-kinase (PI3K)/Akt signal transduction pathway. Temsirolimus, like sirolimus, reacts with the ubiquitous intracellular FK506-binding protein 12 (FKBP12) to inhibit mTOR function.

Mechanism of Action

Activation of the phosphoinositide 3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) pathway plays a pivotal role in essential cellular functions such as survival, proliferation, migration differentiation and carbohydrate metabolism, and is important in the molecular mechanisms of diseases such as diabetes and chronic inflammation, as well as cancer. Normal cells such as lymphocytes, ►endothelial cells and fibroblasts as well as cancer cells are dependent of this signaling pathway. The observed antitumor and immunosuppressive properties of temsirolimus and other agents within this class are due to their ability to disrupt mTOR function.

Both activating mutations and amplification of oncogenes and loss of tumor suppressor genes occur within the pathway in human neoplasms with remarkable frequency. Activation mutations of growth factor receptors and PI3K, as well as amplification and or overexpression of PI3K and Akt have been reported in different tumor histologies. Similarly, the loss of tumor suppressor proteins that regulate the PI3K-Akt-mTOR pathway such as tuberous sclerosis proteins 1 or 2 (TSC1/2), phosphatase and tensin homologue deleted on chromosome 10 (PTEN), and serine/threonine kinase 11 (STK11 also known as LKB1) has been linked to the pathobiology of a number of tumor predisposition syndromes, including ►tuberous sclerosis syndrome (TSC1/2), ►Peutz-Jeghers syndrome (STK11/LKB1), and ►Cowden syndrome (PTEN). In laboratory models, the resultant aberrant activation of the signaling pathway through oncogene stimulation or tumor suppressor gene loss not only leads to a growth advantage during carcinogenesis but also contributes to tumor angiogenesis, metastasis, and resistance to standard cancer therapy. Of interest and relevance to cancer therapeutics development, aberrant pathway activation may also lead to sensitivity to agents that target mTOR.

Temsirolimus does not directly interact with mTOR kinase and does not inhibit all mTOR functions. mTOR functions are dependent on its forming complexes with other proteins. Two mTOR-containing complexes have been well characterized: a rapamycin-sensitive complex (also called mTOR complex 1, mTORC1), which includes mTOR accessory protein Raptor along with mammalian ortholog of LST8 (mLST8) (regulatory-associated protein of mTOR); and a rapamycin-insensitive complex (also called mTOR complex 2, mTORC2), which composed of mTOR and Rictor (rapamycin-insensitive

companion of mTOR). mTORC1, phosphorylates the well-characterized mTOR effectors S6 kinase 1 (S6K1, also known as p70S6K) and eukaryotic initiation factor 4E (eIF4E)-binding protein 1 (4EBP1). TORC2 controls the actin cytoskeleton as well as Akt. However, mTOR when bound to Rictor can phosphorylate Akt at its hydrophobic motif leading to Akt activation. This positive feed back loop may result in increased phosphorylation of Akt in the presence of temsirolimus inhibition of the Raptor-mTOR complex.

Activity in Cancer Models

The antiproliferative effects of temsirolimus and other sirolimus derivatives have been evaluated in numerous in vitro and in vivo tumor models. In sensitive cell lines, these agents inhibit tumor and endothelial cell proliferation in picomolar to nanomolar concentrations and may add to the cytotoxicity of other chemotherapeutic agents and radiation. The antiproliferative effects of temsirolimus may be due, at least in part, to its well-characterized inhibitory effects on the activation of S6K1 and 4EBP1. Inhibition of these proteins alters the translation of subsets of mRNAs, particularly those that may be involved in regulating cell cycle progression. In a relatively limited number of tumor models, this class of agents may induce cancer cell death apoptosis or autophagy. The molecular mechanisms leading to apoptosis in cancer cells have not yet been fully deciphered. In addition, mTOR inhibitors can target tumor growth indirectly by inhibiting endothelial cells and ►pericytes proliferation required for tumor angiogenesis.

Activity in Clinical Trials

Results from cancer clinical trials suggest that temsirolimus is well tolerated and appears to have anti-tumor activity. The most common toxicities seen with the drug are mild to moderate skin reactions, ►stomatitis, reductions in blood counts, particularly platelets, and metabolic abnormalities such hyperlipidemia and hyperglycemia. These adverse effects are reversible with interruption of dosing or, for hyperlipidemia and hyperglycemia, with specific treatment. Rarely, pneumonitis has been reported in patients that have received temsirolimus. To date, there has been no evidence of clinically significant immunosuppression with intermittent schedules.

Effective target inhibition has been shown through pharmacodynamic assays assessing inhibition of either S6K1 or 4E-BP1 phosphorylation in surrogate tissue from patients treated with temsirolimus. More limited data from baseline and on treatment tumor tissue specimens supports that temsirolimus inhibited mTOR and downstream targets. However, optimal dose/schedule for intratumoral target inhibition has not well defined due to limitations in numbers of specimens analyzed.

Results from four phase I studies evaluating increasing doses of temsirolimus on different schedules and with oral and intravenous formulations have been reported. The weekly intravenous schedule is the one that has been most extensively evaluated in phase II and III studies.

Phase II studies of single agent temsirolimus evaluating different doses of 25, 75, and/or 250 mg weekly IV have been undertaken in broad range of tumor histologies. The most promising anti-tumor activity has been seen in ►mantle cell lymphoma and ►endometrial carcinoma with objective tumor response rates of 30–40%. Moderate activity has been reported in breast and ►renal cell carcinoma. Minimal single agent activity has been seen in ►small cell lung carcinoma, ►melanoma and ►glioblastoma multiforme. In general, lower doses appear to be as active as higher doses with better tolerability.

A phase III trial of temsirolimus, temsirolimus with interferon versus interferon in poor prognosis patients with renal cell carcinoma has been reported. Of the 626 patients, overall survival of patients treated with temsirolimus was significantly prolonged compared to those treated with interferon (median 10.9 months versus 7.3 months, Harzard Ratio for death 0.73, $p = 0.0069$). The combination of interferon and temsirolimus did not confer greater benefit than interferon alone, possibly due to compromised dose delivery of the agent(s) due to significant toxicity.

The identification of tumor types that respond to mTOR inhibitors remains a major issue for the development of temsirolimus. mTOR is ubiquitously expressed and therefore the sensitivity or resistance of specific tissues to temsirolimus cannot be predicted solely on the basis of whether the target protein can be detected in the tumor tissue. Activation status of the PI3K/AKT/mTOR signaling pathway seems to be the most promising strategy to identifying tumor types potentially sensitive to temsirolimus. As a significant number of patients have cancers that are insensitive to temsirolimus, combinations of the mTOR inhibitor with hormonal therapy (►hormonal treatment), chemotherapy or other targeted therapies, based on the rationale that simultaneous inhibition of multiple signaling pathways are under evaluation.

Temsirolimus, which inhibits the downstream kinase mTOR, has demonstrated that it may be a useful cancer therapeutic as it may confer clinical benefit to patients with acceptable toxicity. The proof of principle that temsirolimus can improve cancer patient survival has been recently obtained from a large randomized trial in advanced poor prognostic renal cell carcinoma. The major clinical development challenges will be efficiently identifying the optimal dose, schedule and combination regimens for patients with susceptible

malignancies and monitoring and managing toxicities to optimize the therapeutic index.

Tenascin-C

Gertraud Orend
Inserm U682 Institute of Development and Pathophysiology of the Intestine and the Pancreas 3, Avenue Moliere 67200, Strasburg, France

Synonyms

Hexabrachion; Myotendinous antigen; Glial/mesenchymal extracellular matrix protein; GMEM; Cytotactin; J1 220/200; Neuronectin

Definition

Tenascin-C is the founding member of a family of extracellular matrix glycoproteins comprising tenascin-X, -R, and -W in addition to tenascin-C. Its name has been created by Ruth Chiquet-Ehrismann 1986 and represents a combination of the Latin verbs "tenere" (to hold) and "nasci" (to grow, develop, to be born), which provided the roots of the English words "tendon" and "nascent," and reflect the location and developmental expression of the protein observed at that time.

Characteristics

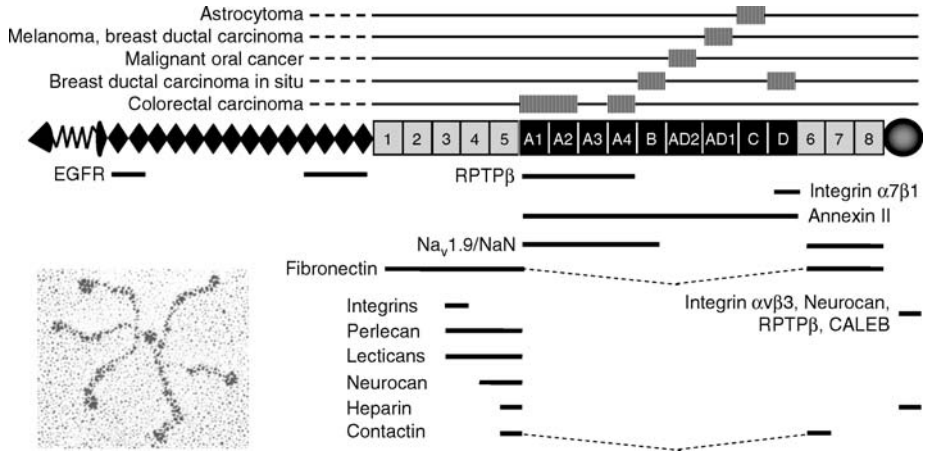
Tenascin-C is part of a ►tumor-specific stroma of most solid cancers, and plays a role in enhancing proliferation, ►angiogenesis, and ►metastasis during tumorigenesis. Moreover, research data support the possibility that tenascin-C contributes to cancer formation via interference with genomic stability, blocking the immunosurveillance and by providing a favorable niche for tumor stem cells (►Cancer stem-like cells, ►stem cells and cancer). Its high expression correlates with bad prognosis for disease-free survival in patients with glioma, lung, and colon cancer.

Molecular Organization

The tenascin-C protein, 2′201 amino acids in length giving rise to a 190–300 kDa monomer, is encoded by 6′603 bp, which are organized into at least 28 exons on chromosome 9q33. Tenascin-C is a modular molecule consisting of an N-terminal region containing a chaperone-like sequence forming coiled coil structures and interchain disulfide bonds that are essential for subunit oligomerization into hexamers. Tenascin-C is comprised of 14.5 epidermal growth factor (EGF)-like repeats, 30–50 amino acids in length, which contain six cysteine residues involved in intrachain disulfide bonds. In tenascin-C, up to 17 ►fibronectin type III domains are present that are ∼90 amino acids in length and that are composed of seven antiparallel β-strands arranged in two sheets. The nature and number of fibronectin type III domains in tenascin-C is generated by alternative splicing that is modulated by the proliferative state of a cell, extracellular pH, and TGFβ1. At least nine different fibronectin type III domains are differentially included or excluded by RNA splicing. This can generate a considerable diversity among different cancers (Fig. 1) and, can cause variable cell responses toward tenascin-C. The C-terminal fibrinogen globular domain resembling the β- and γ-chains of fibrinogen, 210 amino acids in length, forms intrachain disulfide bonds (Fig. 1).

Induction and Processing

Tenascin-C can be induced in a tumor by various pro- and antiinflammatory cytokines and growth factors that are mostly secreted by stromal cells. In addition, hypoxia (►Hypoxia and tumor physiology), ►reactive oxygen species, and mechanical stress, which are also present in tumor tissue, induce tenascin-C expression. In contrast, glucocorticoids suppress tenascin-C expression. Signaling causing activation of transcription factors such as TCF/LEF, NfkB, c-Jun, Ets, SP1, and Prx-1 is involved in tenascin-C gene transcription. Tenascin-C is cleaved by ►matrix metalloproteinases and serine proteases, thus potentially releasing cryptic sites within the fibronectin type III domains of tenascin-C. Cell contact with tenascin-C also induces the expression of matrix metalloproteases, thus presenting a positive feedback loop between induction of matrix metalloproteases by tenascin-C and cleavage of tenascin-C by these enzymes.



Tenascin-C. Figure 1 Domain structure, binding partners and expression of tenascin-C in cancer tissue. The N-terminal oligomerization, EGF-like, fibronectin type III and fibrinogen-like domains are schematically depicted as triangle, rhombomeres, boxes and circles, respectively. The alternatively spliced fibronectin type III domains A1-D are shown in black. An electromicrograph of a tenascin-C hexamer is shown at the left corner. Fibronectin type III domains specifically detected in certain cancers are highlighted above the model. EGFR, epidermal growth factor receptor; CALEB, chicken acidic leucine-rich EGF-like domain containing brain protein; RPTPβ, receptor protein tyrosine phosphatase-β/ζ; Na$_v$1.9/NaN, sodium channel subunit β2. Picture was taken from Orend and Chiquet-Ehrismann (2006) Cancer Lett 244:143–163.

Interaction Partners

Tenascin-C binds to extracellular matrix molecules such as fibronectin, perlecan, aggrecan, versican, and brevican (Fig. 1), thus potentially forming a tumor-specific extracellular matrix network. Cells can interact with tenascin-C via cell surface receptors including integrins (►Integrin signaling in cancer) α2β1, α7β1, α9β1, and αvβ3, syndecan, annexin II, and ►epidermal growth factor receptor (EGFR) among others (Fig. 1).

Cell Rounding and Tumor Cell Proliferation

Tenascin-C has distinct effects on tumor cells, and tumor-associated cells such as carcinoma-associated fibroblasts, tumor-associated macrophages, and endothelial cells within the tumor stroma based on as yet poorly understood cell type-specific responses toward tenascin-C splice variants. Tenascin-C contains adhesive and antiadhesive sequences that coexist in the native molecule. These opposing activities arise as a consequence of tenascin-C binding to extracellular matrix components and to cell surface receptors. One mechanism that induces cell rounding involves tenascin-C inhibition of cell adhesion to fibronectin. This occurs through competitive binding of tenascin-C to fibronectin, thus masking the binding site for integrin α5β1 coreceptor syndecan-4 (►Heparanases). This blocks activation of the small GTPase RhoA and focal adhesion kinase. Activation of oncogenic Wnt (►Wnt signaling), endothelin receptor type A, and ►MAPK signaling induced by tenascin-C and elimination of G0 and G1 cell cycle (►Cell cycle targets for cancer therapy) transition control could contribute to enhanced tumor cell proliferation by tenascin-C.

Metastasis

Tenascin-C is expressed around invasive carcinoma cells that have undergone epithelial-mesenchymal-transition (EMT) (►Epithelial to mesenchymal transition). Tenascin-C supports tumor cell migration and invasion by mechanisms that are little understood. Tenascin-C provides a substratum that supports migration of several cell types including glioma and laryngeal carcinoma cells. A mechanism by which tenascin-C supports colon carcinoma cell invasion involves secretion of tenascin-C by carcinoma-associated fibroblasts, activation of EGFR and, expression of hepatocyte growth factor and activation of its receptor c-Met. This triggered downstream activation and inhibition of the small GTPases Rac and RhoA, respectively in the invading carcinoma cells. In addition to an EMT-associated migration, tenascin-C might also promote other forms of migration in cancer cells.

Angiogenesis

Tenascin-C plays a role during embryonic vascularization and promotes vascular sprouting. It is also expressed during formation of new blood vessels in the adult as, e.g., in granulation tissue of wounds after myocardial infarction, in arthritis, and in neoplastic diseases. In human gliomas, tenascin-C expression correlates with the degree of tumor neovascularization. Tenascin-C may promote angiogenesis by serving as

chemoattractant for endothelial cells, by initiating endothelial cell differentiation, survival, and proliferation, events that involve integrin αvβ3 and vascular endothelial growth factor among not yet identified other molecules.

Phenotype of Tenascin-C Knockout Mice and Cancer

The tenascin-C sequence is highly conserved among species, which suggests that evolutionary forces prevented loss of this gene because of its importance to life. Tenascin-C knockout (►Gene knockout) mice are hyperactive among other neurological defects, which would make them an easy prey. Abnormal behavior in these mice might be due to its role as ligand for neuronal receptors. Despite an otherwise apparently normal phenotype, which is likely due to compensatory mechanisms, tenascin-C knockout mice show difficulties in regeneration upon disturbance of tissue homeostasis such as during healing of wounds in the eye and in the inflamed kidney. Tenascin-C is expressed in stem cell niches (►Adult stem cells) such as those of the bone marrow, brain, and skin. Stem cells are required to maintain and restore tissue homeostasis, in particular upon insults to tissues. This may explain the more severe phenotype in injured tenascin-C knockout mice. The first in vivo evidence for a role of tenascin-C in tumor angiogenesis derives from studies with xenografted melanoma cells into mice lacking tenascin-C expression. In these tenascin-C knockout mice, tumor growth and angiogenesis was strongly reduced in comparison to mice exhibiting tenascin-C expression.

Clinical Aspects

How can we use our knowledge about tenascin-C to combat cancer? Given that expression of tenascin-C correlates with tumorigenesis-enhancing events and with a reduced disease-free survival in patients with some cancers, inhibition of tenascin-C expression at the transcriptional level would be the first choice to block tenascin-C actions in cancer. Unfortunately, this approach is questionable since many factors and conditions that trigger tenascin-C expression are not specific for tenascin-C alone but affect many other genes. Preventing tenascin-C action in a tumor, e.g., by restoration of syndecan-4 function in gliomas offers another approach. However, since tenascin-C has many poorly understood effects at the molecular level on the different cell types within cancer tissue, targeting tenascin-C actions may produce undesirable side effects. The most promising approach today is to target tenascin-C with antitenascin-C-directed antibody fragments that are coupled to cytotoxic reagents in a trojan horse-like strategy, which would trigger destruction of the tumor. Tenascin-C-targeting antibodies are in clinical trials and one needs to await the antitumor response rates in cancer patients.

Tensin2

Definition

Is a focal adhesion protein of the tensin family that acts as an important link among extracellular matrix, actin cytoskeleton, and signal transduction.

►Deleted in Liver Cancer 1

Tensional Homeostasis

Inkyung Kang, Valerie M. Weaver
Department of Surgery, University of California, San Francisco, CA, USA

Definition

A mechano-regulatory network that integrates physical and biochemical cues from the tissue ►microenvironment through mechano—responsive elements such as transmembrane integrins to evoke cytoskeletal re-organization and actomyosin contractility, thereby altering signal transduction and gene expression to modulate cell and tissue phenotype.

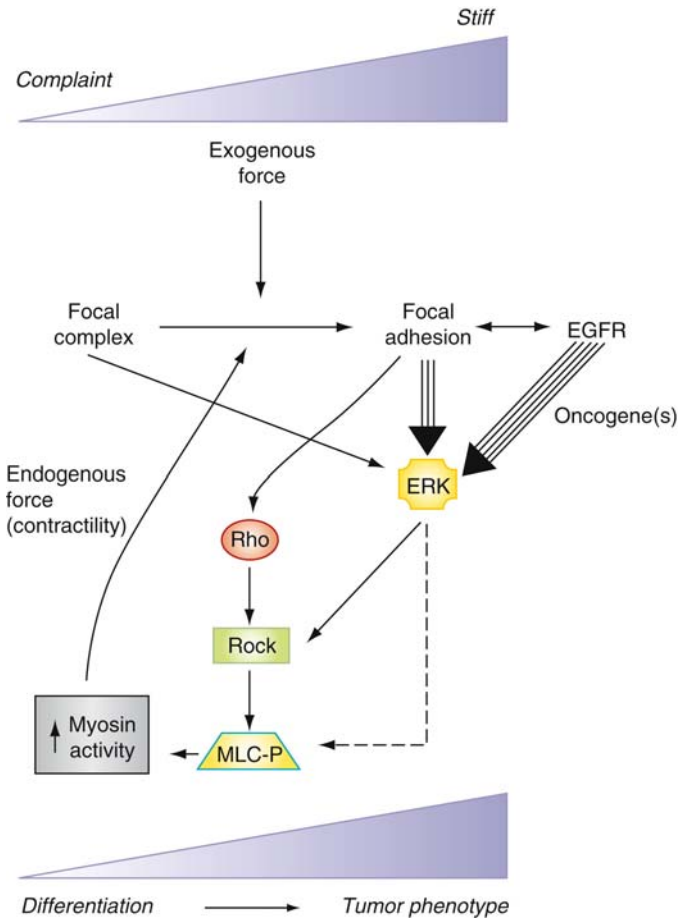
Characteristics

Cells and tissues experience and respond to externally applied mechanical force through mechano-responsive elements that influence signal transduction and result in the generation of reciprocal intracellular force or contractility. The types of ►mechanical stress a cell can experience include compressive or tensile stress which is applied perpendicular to the surface of the cell, and shear stress which is applied parallel to the surface of the cell. For example, osteoblasts and chondrocytes within bone and cartilage are subjected to compressive force induced by walking, lung alveolar cells experience

tensile load resulting from inhalation-induced alveolar sac expansion, and endothelial cells lining the lumens of blood vessels undergo shear force induced by circulating blood flow. Cells integrate external mechanical force on multiple levels. This includes force-dependent changes in the conformation of the plasma membrane lipid bilayers as well as modifications in the orientation and molecular associations of transmembrane proteins. These changes enhance the activity of calcium and potassium ion channels, the extracellular matrix affinity, and cytoskeletal plaque associations of various adhesion molecules including integrins (►Integrin signaling and cancer). Cells also integrate external force cues to generate reciprocal actomyosin-mediated cell contractility and modulate their ►mechanical properties through remodeling of the microtubule, intermediate filament and actin cytoskeletal network. Intracellular mechanical force is transduced to the extracellular microenvironment via functional links between transmembrane receptors that bind to extracellular matrix (ECM) proteins and the intracellular cytoskeletal network and ultimately mediate an equilibrium of extracellular and intracellular forces in the cell. This equilibrium or balance between the extracellular forces and the intracellular forces is called tensional homeostasis. When the extracellular mechanical microenvironment is becomes altered, cells and tissues will coordinately respond by adjusting cell-generated mechanical force or contractility, which in turn elicits changes in cell behavior by modifying the activity and function of signaling pathways and gene expression that determine growth, survival and differentiation. Cells sense and integrate tensional forces by altering the expression and activity of a plethora of putative ►mechanosensors. Nevertheless, integrins are considered key mechanotransducers by virtue of their external associations with the extracellular matrix and their internal links to various adhesion plaque proteins including vinculin, talin and ►focal adhesion kinase (FAK), which in turn mediate interactions with the cytoskeleton and activate various signaling cascades. Extracellular mechanical force can alter the conformation of an integrin from a low ligand-binding affinity state to high ligand-binding affinity state, the conformation of extracellular matrix proteins such as ►fibronectin and collagen I to expose or alter ligand binding sites, and the conformation of vinculin and talin to favor intracellular molecular associations. These mechanically-initiated events promote actin assembly and stabilize adhesion plaque protein assembly and clustering of integrins to convert nascent ►focal complexes into mature ►focal adhesions. Force-dependent integrin activation and focal adhesion maturation increase the magnitude and duration of adhesion signaling including ERK ►MAP kinase and RhoA GTPase (►Rho family proteins). Elevated and sustained activity of ERK and RhoA GTPase drive actomyosin-mediated intracellular contractility by altering the function of Rho kinase (ROCK) and phosphorylated myosin light chain. The elevated intracellular tension in turn promotes focal adhesion maturation, creating a feedback loop of biochemical signaling pathways resulting in an elevated intracellular force generated by actomyosin cytoskeleton and inside out remodeling of extracellular matrix proteins (see Fig. 1).

When the balance between the external and intracellular stress is altered, the cell and tissue will adapt to the new mechanical microenvironment challenge, which can result in positive outcomes such as an increase in bone and muscle density due to exercise, or in negative outcomes such as atherosclerosis mediated by chronically elevated shear force applied by perturbed blood flow and cardiac hypertrophy due to hypertension. Mechanical compression can also regulate gene expression to influence tissue development as has been documented during embryogenesis. Changes in matrix stiffness determine the lineage commitment of mesenchymal stem cells, such that the cells express neurogenic markers when grown in mechanical environment closer to the stiffness of brain (0.1–1 kPa), myogenic markers at an intermediate stiffness (8–17 kPa), and osteogenic markers at a higher stiffness (25–40 kPa). This lineage commitment is regulated by nonmuscle myosin II and is accompanied by an increase in the size of focal adhesions and in the expression of focal adhesion components including talin and phosphoFAK. These results suggest that a cell dynamically probes its mechanical microenvironment through active engagement of integrin adhesion receptors and generation of actomyosin contractility, and that an increase in focal adhesion maturation and intracellular contractility drives downstream signaling events which determine lineage differentiation. Thus, tensional homeostasis is emerging as a critical determinant in cell fate during normal morphogenesis as well as pathophysiological processes.

Solid tumors are characteristically stiffer than normal tissue, which allows detecting tumors by palpation. The elevated stiffness is mediated by increased interstitial tissue pressure and changes in the mechanical properties of malignant cells and the surrounding stroma. The tumor stroma is characterized by an increased deposition and reorganization of matrix proteins including collagen, fibronectin and tenascin, and aberrant ECM cross linking induced by lysyl oxidase, transglutaminase, proteoglycans, and glycation, which contribute to the stiffening of the stroma (►Extracellular matrix remodeling). In addition, transforming ►oncogenes such as ►RAS, ErbB/►HER2 neu and c-Myc (►Myc oncogene) can alter the mechano-responsiveness of cells and cooperate with integrin adhesion signaling



Tensional Homeostasis. Figure 1 Key molecular pathways that mediate tensional homeostasis in cells and tissues. Changes in the mechanical environment of cell, such as an increase in ECM stiffness or elevated extracellular tension, promote integrin clustering to drive the maturation of nascent focal contacts into focal adhesions. The assembly of focal adhesions is associated with increased Rho GTPase activity and elevated and sustained ERK signaling. The combination of enhanced Rho and ERK activity increases actomyosin-mediated intracellular contractility by altering the function of Rho kinase (ROCK) and phosphorylated myosin light chain (MLC-P). Elevated cell-generated force promotes focal adhesion assembly and potentiates growth factor dependent ERK activation in a feed forward vicious cycle. Elevated intra cellular force also alters ECM deposition and organization by orienting and further stiffening ECM. Oncogenes which promote RAS-dependent ERK activation and Rho GTPase activity additionally contribute to cell-generated forces by regulating ROCK and MLCK and myosin II activity.

molecules to enhance cell proliferation, survival and invasion. Indeed, oncogenes such as Ras and ErbB/HER activate Rho and ERK that induce actomyosin contractility and elevate cell-generated forces to further promote the assembly and maturation of integrin adhesions and enhance growth factor receptor cross-talk. This raises the intriguing possibility that in addition to promoting cell growth and survival by directly modifying the activity of various signaling molecules, some transforming oncogenes might promote malignancy by altering the cells tensional homeostasis. Consistently, Paszek et al demonstrated that increasing ECM stiffness from 140 Pa (approximating the compliance of the normal murine breast) to 1,000–5,000 Pa (similar to the stiffness of a malignant murine breast) compromised mammary morphogenesis and induced the malignant phenotype of non-malignant mammary epithelial cells in culture, as demonstrated by an increase in cell growth and survival, and the loss of mammary tissue integrity (i.e. disruption of cell-cell junctions and loss of tissue polarity). Stiffening of ECM also significantly increased recruitment and activation of FAK and actin-binding proteins such as vinculin to β1 integrin adhesion, which was accompanied by an increase of larger, mature focal adhesions, contractility, and enhanced growth-factor dependent ERK activation. More intriguingly, malignantly transformed mammary cells with elevated epidermal growth factor receptor (EGFR) signaling that form colonies of disorganized, invasive and continuously growing cancer cells in

response to a compliant normal matrix also exerted higher cell contractility. Strikingly, inhibiting the activity of Rho GTPase or myosin II or ERK was sufficient to reduce the tumor cells contractility and revert the malignant phenotype of these breast cancer cells toward that of a normal breast acini. Likewise, inhibiting Rho or ERK-dependent myosin activity also normalized the phenotype of non-transformed mammary cells interacting with an abnormally stiffened matrix. Together these findings suggest that breast transformation could arise through the combination of oncogenic mutations that promote cell generated contractility and a progressive stiffening of the ECM which compromises the tensional homeostasis to elevate cell contractility and to increase focal adhesion assembly, which enhance abberant cell growth, survival and invasion.

Clinical studies indicate that mammographic density is strongly and reproducibly associated with an increased risk of breast cancer, independent of other risk factors (►Mammographic breast density and cancer risk). For example breast cancer risk rises to 30% when greater than 50% of the mammography qualifies as dense. Although the high cancer risk linked with breast density could be attributed to decreased detection sensitivity and increased epithelial mass, recent data indicate that elevated collagen and proteoglycan content are also risk factors that contribute to the enhanced transformation frequency associated with this condition. Elevated mammographic density frequently precedes ►ductal carcinoma in situ (DCIS), and DCIS often occurs predominantly in the mammographically dense areas of the breast. Because higher collagen density and elevated proteoglycan-mediated cross linking correlate with an increase in ECM stiffness, these findings are consistent with the prediction that mammographic density could promote carcinogenesis by perturbing the cells tensional homeostasis. If true, an increase in matrix stiffening would herald an altered tissue tensional homeostasis and constitute a tractable predictor of future tissue transformation. Accordingly, an improved understanding of the parameters that promote matrix stiffening and alter tissue tensional homeostasis would assist in the development of improved detection, prognosis and treatment strategies for solid cancers.

To summarize, cells and tissues sense and respond to external force through a process called tensional homeostasis that reciprocally alters the external microenvironment through cell-generated force. Tensional homeostasis is emerging as an important determinant of normal tissue development and adult tissue homeostasis and recent studies indicate that an altered tensional homeostasis likely contributes to the pathogenesis of diseases including cancer and atherosclerosis.

TEP1

Definition

TGF-β-Regulated and Epithelial Cell-Enriched Phosphatase; Rarely used synonym for PTEN.

►PTEN

Teratocarcinoma

Definition

Is an embryonic or ►germ-cell tumor.

Teratocarcinoma-derived Growth Factor-1

►Cripto-1

Teratogenic

Definition

Refers to substances that cause developmental malformations during gestation.

►Estrogenic Hormones

Teratoma

Definition

Plural Teratomata. Term derived from Greek meaning "monstrous tumor". Is a germ cell tumor derived from pluripotent cells and made up of elements of different types of tissue from one or more of the three germ cell layers. Is a tumor with tissue or organ components resembling normal derivatives of all three germ layers. Rarely, not all three germ layers are identifiable. The tissues of a teratoma, although normal in themselves, may be quite different from surrounding tissues, and may be highly inappropriate, even grotesque (hence the term "monstrous"). Teratomas have been reported to contain hair, teeth, bone and very rarely more complex organs. Usually, however, a teratoma will contain no organs but rather one or more tissues normally found in organs such as the brain, thyroid, liver, or lung.

N- or C-Terminal Processing

Definition

Proteolytic attack of a protein substrate can have different outcomes depending on the protease at work and the protein under attack:

1. The protein can be completely degraded into small fragments and amino acids;
2. The protein can undergo limited proteolysis, also referred to as processing or maturation;
3. If the protein is a protease inhibitor, it may form a complex and neutralize the protease;
4. The protein might be neither susceptible to proteolysis nor interact with the protease.

When limited proteolysis occurs at either end of a protein it is referred to as N- or C-terminal processing.

►Cystatins

Terminally Differentiated Cells

Definition

Cells most distal to the stem cell, being differentiated to perform a specific function, but having permanently lost the ability to divide.

►Stem Cell Plasticity

Tertiary Cancer Prevention

Definition

Prevention of metastatic spread of tumors. A locution used in parallel with ►primary cancer prevention and ►secondary cancer prevention.

►Adjuvant Therapy

Testicular Cancer

Axel Heidenreich
Division of Oncological Urology, Department of Urology, University of Köln, Köln, Germany

Synonyms

Testicular germ cell tumor; Seminomatous germ cell tumor; Nonseminomatous germ cell tumor

Definition

About 90% of all testicular tumors are malignant germ-cell tumors, and the rest comprise benign tumors deriving from Leydig and Sertoli cells and other interstitial components. Testicular germ-cell tumors originate from totipotent primordial germ cells, which undergo neoplastic transformation as a result of a number of endogenous, exogenous, hormonal and genetic, as well as environmental, events. The neoplastic process results in the development of preinvasive carcinoma in situ (CIS) or TIN representing the common precursor for all testicular germ-cell tumors, except spermatocytic seminoma.

Characteristics

Testicular cancer represents the most common malignant tumor in young men in the age group of 20–40 years. In 1994, ~6,800 new cases of testicular

cancer were diagnosed in the US. There are striking differences in TC incidences around the world, with the highest incidence of 12–14 per 100,000 person-years in Switzerland and Denmark, and the lowest incidence of less than one per 100,000 person-years among African- Americans and the Chinese populations. Cryptorchidism is the best-known risk factor and, according to case–control studies, the relative risk for TC is 2.5–8.8. Familial and genetic factors have been suggested to be involved in the development of TC with a six- to tenfold higher risk in first degree relatives.

Diagnosis

The majority of patients present with a painless scrotal mass and the diagnosis is usually established by physical examination of the tumor-bearing and the contralateral testicle, scrotal ultrasonography and determination of the serum tumor markers alpha-fetoprotein (AFP), human chorionic gonadotropin (hCG) and lactate dehydrogenase (LDH).

Inguinal exploration and scrotal orchiectomy confirms the diagnosis and is the therapy of choice, revealing accurate information with regard to histopathology and pathological-stage classification. Since benign testicular lesions are recognized with increasing frequency, frozen section analysis should be considered. Contralateral testicular biopsy to diagnosis TIN is recommended in high risk patients (testis volume <12 ml, <30 years) with a risk >34. Only in cases of a second metachronously or synchronously occurring TC an organ-sparing approach might be considered to maintain endogenous testosterone synthesis and to preserve fertility.

Meticulous pathological work-up of the orchiectomy specimen should be performed according to the WHO recommendations, to identify all histological subtypes present and vascular invasion. In clinical stage I non-seminomatous germ-cell tumor (NSGCT), a high percentage of embryonal carcinoma associated with the presence of vascular invasion identifies patients at high risk of lymph-node metastases in the retroperitoneum, thereby enabling a risk-adapted approach.

Following radical orchiectomy, further staging includes computed tomography of the abdomen, the chest and the mediastinum, to detect metastatic lymph-node disease or visceral metastases. The primary landing zones of the right testis include the interaortocaval region and the primary landing zones of the left side include the para-aortic and preaortic lymph nodes. Micrometastases are present in up to 20% and in ~30% of clinical stage I seminomas and non-seminomas, respectively, which will not be detected by classical interpretation of abdominal CT scans owing to the inability of morphological differentiation. Therefore, primary landing zones and the transverse diameter of the largest lymph node might be helpful to identify patients at high risk. Magnetic resonance imaging of the abdomen does not provide additional clinically useful information, and is reserved for patients with contraindications to CT. Positron emission tomography scans are not helpful in the detection of retroperitoneal micrometastases.

Tumor markers are clinically useful for diagnosis, clinical staging, prediction of prognosis (see IGCCCG classification, Table 1) and monitoring the response of therapy. The most commonly used markers are AFP, the ß-subunit of hCG and lactic acid dehydrogenase (LDH); in seminomas, PLAP might be of clinical use. Classical seminomas are always AFP-negative. Following the initiation of therapy, elevated tumor markers should decline according to their half-life (ß-hCG: 24–36 h, AFP: 5–7 days). Any plateau phase or any

Testicular Cancer. Table 1 Classification international germ cell cancer collaborative group (IGCCCG)

	Seminoma	NSGCT
Good prognosis	Any primary localization	Testicular or extragonadal retroperitoneal primary
	No non-pulmonary visceral metastases	No non-pulmonary visceral metastases
Tumor markers	AFP < 1.000 ng/ml	
	ß-hCG < 1.000 ng/ml	
	LDH < 1.5 Norm	
Intermediate prognosis	Any primary localization	Testicular or extragonadal
	Non-pulmonary visceral metastases	No non-pulmonary visceral metastases
Tumor markers	AFP 1.000–10.000 ng/ml	
	ß-hCG 1.000–10.000 ng/ml	
	LDH 1.5–10x Norm	
Poor prognosis		Primary mediastinal GCT
		Non-pulmonary visceral metastases
Tumor markers	AFP > 10.000 ng/ml	
	ß-hCG > 10.000 ng/ml	
	LDH > 10x Norm	

delay in decline is predictive for a poor outcome in terms of response to therapy. The prognostic significance of tumor markers at the time of diagnosis becomes evident for advanced disease only, adhering to the International Germ Cell Consensus Classification Group (IGCCCG) classification.

The Lugano classification represents the most widely used clinical staging system for testicular cancer (Table 2), and describes the extent of metastatic involvement of the lymph nodes and visceral organs. In recent years the IGCCCG has introduced a new staging system for advanced TC defining three prognostic risk groups with regard to therapeutic outcome. Patients are classified to be at good risk (probability of cure 95%), intermediate risk (probability of cure 70%) or poor risk (probability of cure 50%). The IGCCCG classification gives high prognostic evidence and enables an individualized risk-adapted approach in patients with advanced TC.

Therapy

Once TIN is diagnosed, therapeutic intervention is recommended, since 70% of patients will develop invasive germ-cell tumor within the next 7 years. Local radiation therapy with 18 Gy is the therapy of choice in patients with a contralateral invasive germ-cell tumor. In patients with unilateral TIN and a contralateral normal testis, inguinal orchiectomy appears to be the preferred management, since local radiation bears the risk of damaging the healthy testicle.

Non-Seminomatous Germ-Cell Tumors (NSGCT)

Clinical stage I NSGCT represents a troublesome entity concerning recommendations for optimal management since about 30% of patients will exhibit microscopic lymph-node disease. Several treatment options such as primary nerve-sparing retroperitoneal lymphadenectomy, primary chemotherapy, and active surveillance have been developed resulting in the same high cure rates of 98%. The European Germ Cell Cancer Consensus Group recommends an individualized, risk adapted approach based on the results of prospective randomized trials considering the presence or absence of the risk factors vascular invasion (VI) and percentage of embryonal carcinoma (ECA). VI has been identified as the most powerful clinical predictor of lymph-node metastasis with 48% of NSGCTs with VI developing metastases, compared to 14–22% of tumors without VI. A combination of VI and ECA might be even more powerful. Nowadays, nerve-sparing RPLND – if performed – is regarded as the standard approach. Up to 10% of patients will suffer from pulmonary relapse within the first 2 years, and will be cured by platinum-based chemotherapy. Even in low-volume lymph-node disease such as pathological stage IIA, the nerve-sparing RPLND can be performed as bilateral radical surgery without compromising the therapeutic outcome. Primary chemotherapy [two cycles of cisplatin, etoposide and bleomycin (PEB)] or surveillance (absence of VI) result in relapse rates of only 7% and 14%, respectively.

Low-Stage (IIA/B) NSGCT

Low-stage testicular disease comprises clinical stages IIA and IIB associated with a cure rate of ~98%. Patients with low volume disease and abnormal tumor marker levels of AFP, ß-hCG, or LDH are treated with 2–3 cycles PEB chemotherapy, patients with negative markers might be offered nerve-sparing RPLND or surveillance Patients with clinical stage IIB TC will undergo primary chemotherapy depending on the serum tumor marker concentrations with three or four cycles of PEB followed by secondary RPLND in about 30% of cases.

Clinical Stages IIC and III

Inductive chemotherapy represents the therapy of choice, with the number of cycles applied depending on the IGCCCG-based prognostic classification. Patients with "good prognosis" face a long-term survival rate of >90%, and are managed by three cycles of PEB.

Testicular Cancer. Table 2 Clinical Lugano – classification of TC

Stage I	Tumor markers normalized or decline according to their half-life after orchiectomy
	No detectable metastases by imaging studies
	Primary TC confined to the testicle
Stage IIA	Retroperitoneal metastases <2 cm
Stage IIB	Retroperitoneal metastases 2–5 cm
Stage IIC	Retroperitoneal metastases >5 cm
Stage IIIA	Supraclavicular or mediastinal metastases
Stage IIIB	Pulmonary metastases
	Minimal: <5 metastases in each lobe <2 cm
	Advanced: >5 metastases in each lobe or 1 lesion >2 cm
Stage IIIC	Extrapulmonary visceral metastases

T

Patients with "intermediate prognosis" face a survival rate of 70–80% and are managed by four cycles of PEB or cisplatin, etoposide and ifosfamide (PEI). Patients with "poor prognosis" have a survival rate of only about 50%; standard therapy consists of four cycles of PEB or PEI. A major advantage of primary high-dose chemotherapy has not been demonstrated, but this approach is currently being tested in prospective randomized trials.

Seminomatous Germ-Cell Tumors

Clinical Stage I Seminoma

Despite negative CT scans, there is a risk of 12–32% of occult retroperitoneal lymph node metastases depending on the absence or presence negative prognostic markers. The cure rate of clinical stage I seminomatous germ cell cancer is close to 100% and can be achieved by the three different therapeutic options active surveillance, radiation therapy and carboplatin monochemotherapy. Adjuvant retroperitoneal radiation therapy to the paraaortic or paracaval region with 20 Gy or adjuvant chemotherapy with one cycle carboplatin AUC 7 are the standard approach for high risk patients (tumor size > 4 cm, rete testis invasion) and result in a relapse-free long-term survival of 97%. Active surveillance represents the most reasonable approach to patients with good prognostic markers associated with a low recurrence rate of about 12%. Treatment of relapses is more intense with systemic chemotherapy of 3–4 cycles PEB in most cases.

Low-Stage (Clinical Stage IIA/B) Seminoma

Radiation therapy with 30 Gy (IIA) and 36 Gy (IIB), including the ipsilateral iliac and inguinal lymph nodes, is one standard therapeutic approach for low-stage seminomas. Relapse-free survival is as high as 92.5% in clinical stage IIA/B; relapse rates are about 5% in stage IIA and about 11% in stage IIB seminomas. Primary chemotherapy with two cycles of PEB is an alternative to radiation in clinical stage IIB seminoma.

Clinical Stage IIC and III

As pointed out for advanced non-seminomatous germ-cell tumors, therapy should be initiated according to the IGCCCG classification. For patients with good prognosis, three cycles of PEB chemotherapy are the treatment of choice, in patients with intermediate prognosis four cycles of PEB chemotherapy are applied.

Residual Tumor Resection (RTR) Following Chemotherapy for Advanced Testicular Cancer.

RTR represents an integral part of the multimodality treatment of advanced testicular germ cell tumors. The rationale for RTR is to completely resect mature teratoma and vital cancer which will be found in 30–40% and 20% of the patients, respectively. Currently, all residual lesions independent on size should be resected in NSGCT since even small lesions <1 cm in diameter will harbor mature teratoma and vital cancer. The extent of surgery depends on individual risk factors for relapse and quality of life issues. If the histology of the resected retroperitoneal masses is necrosis only, further resection of residual lesions in other organs might be omitted since there is concordance of histology in about 90% of the patients. RTR is a complex surgery associated with the necessity to resect adjacent organs or vascular structures in about 25% of the patients and should, therefore, be performed in experienced tertiary cancer care centers only. According to a recent analysis of prognostic markers patients harbouring a residual mass with >10% vital cancer cells or those with uncomplete resection might benefit from consolidation chemotherapy with two cycles. Postchemotherapy or post-radiotherapy RPLND in seminomas has only to be performed in lesions with a positive PET scan performed about 6 weeks after chemotherapy or radiation therapy in patients with residual lesions >3 cm.

Salvage Chemotherapy, High-Dose Chemotherapy

In seminomas relapsing after first-line radiation therapy a cure rate of >90% can be achieved by cisplatin-based chemotherapy according to the IGCCCG algorithm with regard to advanced seminomas. About 50% of relapsing seminomas following conventional chemotherapy can be salvaged with another combination chemotherapy consisting of PEI– etopside, ifosfamide and platinol (VIP) or – vinblastine, ifosfamide and platinol (VeIP). Currently, a 10% benefit of high-dose chemotherapy with regard to survival has been demonstrated; therefore, it seems advisable that all relapsing patients should be treated in a tertiary referral center.

NSGCT relapsing following conventional chemotherapy, salvage rates are as low as 15–40% using standard salvage protocols such as PEI–VIP or –VeIP. In some institutions the addition of paclitaxel to ifosfamide and cisplatin has been favored due to a high response rate >50%. Conventional-dose cisplatin-based salvage chemotherapy can achieve long-term remission in 15–40% of patients. Early consideration of high-dose chemotherapy seems advisable: trials suggest a benefit for the use of high-dose chemotherapy and autologous bone marrow transfer, with 46% and 50% of the patients being alive and disease-free after a median follow-up of 31 months and 30 months, respectively. Options for third-line chemotherapy are combinations such as paclitaxel and gemcitabine, gemcitabine and oxaliplatin or paclitaxel, gemcitabine and cisplatin, within clinical trials.

Genetics

With regard to predisposing genetic events, the locus Xq27 predisposes for bilateral TC and bilateral cryptorchidism. Other studies have reported the loci 1p36,

4p14–13, 5q21–21, 14q13–q24.3 and 18q21.1–21.3 to be highly associated with TC. Recently, it has been demonstrated that somatic mutations of exons 10, 11 and 17 of KIT occur significantly more often in patients with bilateral TC as compared to patients with unilateral disease. The results indicate that KIT might be involved in the development of familial and a minority of sporadic germ cell tumors and that KIT mutations primarily take place during embryogenesis such that primordial germ cells with KIT mutations are distributed to both testes.

Currently, all molecular markers such as p53, Ki-67, bcl-2, cathepsin D and E-cadherin have not been proven to be clinically useful prognosticators; only reverse transcriptase-polymerase chain reaction for AFP, hCG and germ cell alkaline phosphate (GCAP) mRNA for the detection of circulating tumor cells appears to be an interesting approach, with 60% of clinical stage I testicular cancer patients exhibiting positive signals that turn into negative signals following adjuvant chemotherapy.

Future Directions in TC

Based on the excellent therapeutic outcome, there appear to be only a few developments possible that will have further impact on the survival of testicular cancer patients. However, there might be many options to improve quality of life either due to reduction of acute toxicity or due to the development of treatment regimes associated with a significantly reduced long-term toxicity. It has been that the risk of cardiovascular disease is significantly increased after standard chemotherapy with 3–4 cycles PEB and/or salvage treatment (RR = 2.59). The increased risk is not due to an increase in classical cardiac risk factors but directly dependent on first line therapy. For the future, attempts to minimize treatment should be undertaken especially in patients with good prognosis in whom this type of long-term toxicity might be a greater risk to long-term survival than testicular cancer itself.

Elucidation of those mechanisms involved in the development of intrinsic and extrinsic chemorefractoriness in testicular cancer will be a major issue in the future, to apply effective chemotherapeutic protocols and to save even more lives. There are some promising approaches using modern molecular techniques such as gene expression profiling to explore the role of mismatch repair genes, multidrug resistance genes and potentially unknown genes.

Despite the high cure rates, it will be necessary for testicular cancer to be treated by clinicians and institutions with sufficient experience in diagnosis and management of germ-cell tumors. Specific problems such as extended tumor masses, relapsing tumors or poor prognosis at initial diagnosis must be referred to tertiary centers having the ability of an interdisciplinary approach.

Testosterone

Definition

Testosterone is a steroid hormone from the androgen group. In mammals, testosterone is primarily secreted in

the testes of males and the ovaries of females, although small amounts are also secreted by the adrenal glands. It is the principal male sex hormone.

►Sex Hormone Dependent Cancers
►Hormonal Carcinogenesis

2,3,7,8-Tetrachlorodibenzo-*p*-dioxin

►Dioxin

Tetracopeptide Repeat TPR Domains

Definition
A structural motif that mediates protein: protein interactions. Each TPR motif consists of repeats of a 34-amino acid sequence. It is present in a wide range of proteins; in particular many of the co-chaperones involved in the heat shock protein 70 and 90 folding systems.

►Molecular Chaperones

Tetraploidization

Definition
Process whereby the entire genome is duplicated.

Tetraspanin

►Metastasis Suppressor KAI1/CD82

TF

Definition
Tissue factor.

►Proteinase-Activated Receptors

TFF

►Trefoil Factors

TFIIH

Definition
Is a protein complex that plays a key role in both transcription and DNA repair.

TG2

Definition
An enzyme (EC 2.3.2.13) of the transglutaminase family. Like other ►transglutaminases, it crosslinks proteins between an N of a lysine residue and a glutamine residue in two protein chains, creating a bond (isopeptide) that is highly resistant to proteolysis.

►Transglutaminase-2

TGc

►Transglutaminase-2

TGF

Definition
Transforming Growth Factor.

►Transforming Growth Factor Beta

TGFα

Definition

Transforming growth factor alpha.

►ADAM17

TGF-β

Definition

►Transforming growth factor β; Is a multifunctional dimeric 25 kDa polypeptide growth factor, whose main functions are growth inhibition, immunosuppression and regulation of extracellular matrix formation and turnover. There are three different mammalian gene products. Activation renders the biologically latent TGF-β into its active form, which can bind to the cell surface receptors and initiate signaling. The TGFβ superfamily contains at least forty cytokines currently divided into two classes: the bone morphogenetic proteins (BMP) and the TGFβ/activin. These cytokines regulate cell fate (proliferation, differentiation and apoptosis) and extracellular matrix deposition.

►Smad Proteins in TGFβ Signaling

TGF-β Activation

Definition

An event that renders the biologically latent ►TGF-β into its active form, which can bind to the cell surface receptors and initiate signaling.

TGF-β-Regulated and Epithelial Cell-Enriched Phosphatase

Definition

►TEP1; Alternative, rarely used name for ►PTEN.

TGF-β Superfamily

Definition

Is a group of structurally related multifunctional peptides that control proliferation, morphogenesis, differentiation, migration and a variety of other functions in many cell types. Members of this family include the transforming growth factor βs (►TGF-β), ►bone morphogenetic proteins (BMPs), growth differentiation factors (GDFs), activins/inhibins, mullerian inhibitory substance (MIS), glial cell derived neurotrophic factors (GDNFs) and macrophage inhibitory cytokine-1 (►MIC-1).

Th1

Definition

CD4+ helper T cells providing cytokines related to cell-mediated immune reactions.

►Allergy

Th2

Definition

CD4+ helper T cells providing cytokines related to humoral immune reactions.

►Allergy

Th1 Immune Response

Definition

Two types of effector CD4 + T helper cell responses can be induced by a professional antigen presenting cell (APC), designated Th1 and Th2, each designed to eliminate different types of pathogens. The Th1 response is characterized by the production of interferon-gamma, which induces B-cells to make opsonizing

(coating) antibodies, and leads to cell mediated anti-tumor immunity.

►DNA Vaccination

Th2 Immune Response

Definition

Is characterized by the release of ►interleukin 4, which results in the activation of B-cells to make neutralizing (killing) antibodies, leading to humoral immunity.

►DNA Vaccination

Thalidomide and its Analogues

Synonyms

Thalidomide = (ph)thal(ic acid) + (im)id(e) + (i)mide, $C_{13}H_{10}N_2O_4$; Immunomodulatory drugs (IMiDs) = CC-4047, Lenalidomide (CC-5013 or Revlimid)

Definition

First synthesized in 1954 in Germany from the glutamic acid derivative α-phthaloylisoglutamine, thalidomide was used as a sedative and treatment for morning sickness in the 1950s until its teratogenic effects became apparent. Phocomelia is the most well known toxicity of thalidomide, making it absolutely contra-indicated in pregnancy. The IMiDs are immunomodulatory derivatives of thalidomide, rationally designed to be more potent at inhibiting ►cytokine production. The chemical structures of thalidomide and two IMiDs are shown in Fig. 1.

Characteristics

Thalidomide is commonly used in the treatment of moderate to severe erythema nodosum leprosum and less frequently in the treatment of a wide range of non-malignant clinical conditions refractory to standard therapies, such as rheumatoid arthritis, the inflammatory and wasting effects of chronic tuberculosis, Behcet's disease, Crohn's disease, aphthous ulcers, and cachexia associated with HIV infection.

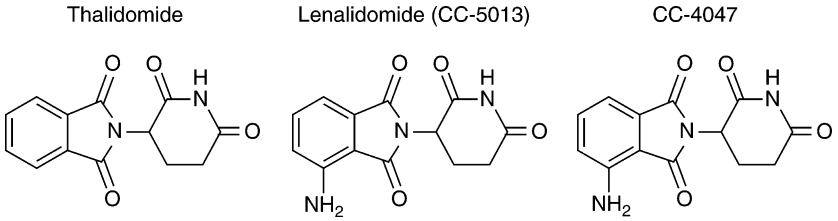
The growth and survival of myeloma cells is critically dependent on the interaction with the bone marrow microenvironment. Thalidomide (Thal) and immunomodulatory drugs (IMiDs) act via mechanisms to disrupt this interaction and inhibit myeloma cell growth and survival. For abbreviations, see main text.

Mechanisms of Action

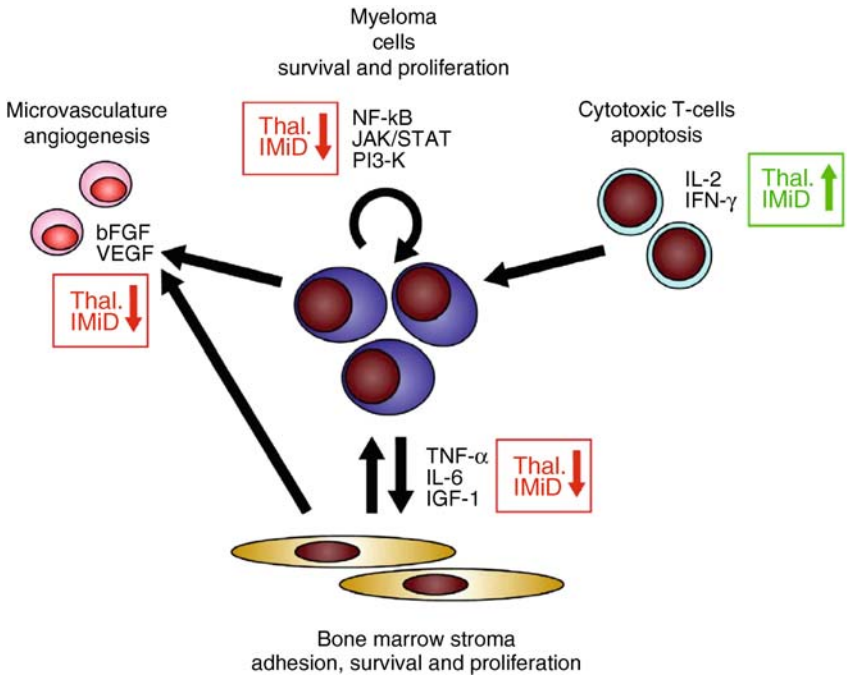
Thalidomide influences the production of and cellular effects of inflammatory cytokines, particularly those involved in ►angiogenesis. It has also been shown to activate cytotoxic T-lymphocytes, a process involving the release of interleukin-2 (IL-2) and ►interferon (IFN)-γ. Thalidomide enhances IL-4 and IL-5 production and down-regulates IL-12 production, effecting a shift in cytokine profile which is generally considered favorable in the treatment of cancer. Thalidomide may also have direct effects on the growth and survival of malignant cells, e.g. it inhibits the activity of ►cyclooxygenase-2 via inhibition of ►nuclear factor κ-B (NF-κB) activity. IMiDs demonstrate a similar range of biological activities to thalidomide, with significantly greater potency in certain activities. For example, CC-4047 exhibits a 20,000-fold higher potency than thalidomide at inhibiting ►tumor necrosis factor (TNF)-α production. Several mechanisms of action are shown in Fig. 2, which lead to alterations in the interplay between ►multiple myeloma (MM) cells and the bone marrow environment.

Multiple Myeloma

Early studies using thalidomide in patients with relapsed multiple myeloma described responses in around half of the patients treated, although typically with a duration of less than 12 months. Initial attempts to achieve high target doses (up to 800 mg/day) resulted in frequent dose limiting toxicity. The reported side effects were dependent on dose and patient age. Somnolence and constipation were common, although manageable in most cases. Peripheral neuropathy occurred in up to a third of patients, particularly with long term treatment, and it was disabling and irreversible in some cases. Particular concerns were raised concerning patients with multiple myeloma who may develop neuropathies for other reasons, thus increasing the severity of the symptom, e.g. concomitant drugs, amyloid deposition or paraproteinaemia. There was also a significant rate of venous thromboembolism (VTE) complicating treatment with thalidomide.



Thalidomide and its Analogues. Figure 1 Mechanism of action of thalidomide and IMiDs in multiple myeloma.



Thalidomide and its Analogues. Figure 2 Chemical structures of thalidomide, lenalidomide and actimid (CC-4047).

More recent clinical studies have suggested that high doses of thalidomide cause unnecessary toxicity since its efficacy in treating multiple myeloma is equivalent at lower doses (100–400 mg/day). A number of groups have investigated the combination (TD) of thalidomide and dexamethasone in patients with relapsed multiple myeloma. Collectively, the results suggest that the TD combination is superior to thalidomide monotherapy for treating relapsed disease and, although there is no published data to directly confirm this advantage, TD combination treatment is widely used in this context. Although an overall survival benefit has not yet been demonstrated, the response rate may be further improved with the addition of cytotoxic agents (Table 1), albeit at the cost of increased toxicity. TD is effective in ~30% of patients resistant to thalidomide when it is used as a single agent.

Based on its activity in relapsed patients, TD has also been tested in patients newly diagnosed with multiple myeloma. The response rate is superior to that obtained using standard infusional chemotherapy with Vincristine, ►Adriamycin and Dexamethasone (VAD) and offers the benefits of an oral regime versus one requiring the insertion of a central venous catheter. These advantages have led to TD being widely adopted as standard first line therapy in younger patients prior to autologous stem cell transplant (ASCT), although whether the improved response rates will translate into an overall survival advantage is not yet known. In patients not suitable for ASCT, two recent studies have demonstrated that the addition of thalidomide to standard chemotherapy (Melphalan and Prednisolone) results in improvements in both response rate and survival (Table 1).

Thalidomide and its Analogues. Table 1 Summary of the activity of thalidomide in the treatment of multiple myeloma

Disease status	Regimen	
Relapsed disease	Thalidomide: Monotherapy	Response rate 25–48% Complete response rare
	Thalidomide + Dexamethasone (TD)	Response rate 41–55% Synergistic in-vitro and in-vivo Effective in relapse post ASCT
	Thalidomide + Steroids + Chemotherapy	Response rate 36–79% Many combinations tested Increased toxicity with intensive regimens
	Thalidomide + Novel agents	Ongoing phase I/II trials Bortezomib, IMiDs, investigational drugs
Newly diagnosed disease (Pre autologous stem cell transplant (ASCT)	Thalidomide + Dexamethasone	Response rate 65–75% CR in 7–15% Survival benefit over standard induction chemotherapy plus ASCT unproven
	Thalidomide + Dexamethasone + Chemotherapy	Response rate up to 90% Many regimens, increased toxicity over TD Survival benefit over standard induction chemotherapy/TD plus ASCT unproven
Newly diagnosed disease (Not candidates for ASCT)	Melphalan + Prednisolone + Thalidomide (MPT)	Response rate 75–80% CR in up to 15% Response rate and event free survival superior to MP but increased non-hematological toxicity
Maintenance post ASCT	Thalidomide + Bisphosphonates	Event free survival and overall survival superior to no maintenance in single study Survival advantage most marked if <90% response to prior treatment Unproven benefit following thalidomide containing induction regimen

Only peer-reviewed published data regarding the efficacy of thalidomide in the treatment of multiple myeloma at various stages of the disease are presented.

Thalidomide has also been investigated in patients with multiple myeloma as maintenance treatment following ASCT. In a single randomized study of patients treated with VAD chemotherapy followed by ASCT, the event free survival was significantly prolonged in patients receiving maintenance compared to those that did not, with a non-significant trend observed towards improved overall survival.

Two IMiDs are currently used in the treatment of multiple myeloma. A phase I study of CC-4047 demonstrated an encouraging response rate of 67% using the drug as a single agent, but the sample size was small. More data are available on the use of lenalidomide. Two phase I studies have demonstrated a maximum tolerated dose of 25–30 mg/day. Subsequent phase II trials have defined the optimal daily dosing schedule and described significant responses in 30–40% of patients, including those previously treated with thalidomide. In 2006, the Food & Drug Administration in the United States of America approved the use of lenalidomide as treatment for relapsed multiple myeloma.

Preclinical data suggesting synergy with steroids has also led to investigation of the efficacy of treatment with a combination of lenalidomide and dexamethasone (Len/Dex). Two large randomized multicenter phase III studies comparing Len/Dex to Dexamethasone in relapsed or refractory disease have produced strikingly similar results. Interim analyses of both studies have demonstrated significantly improved response rates and median time to progression following combination therapy versus dexamethasone alone; both trials were therefore prematurely closed to recruitment. Since activity has also been demonstrated in ►chronic lymphocytic leukemia and ►non-Hodgkin lymphoma, ►clinical trials of lenalidomide treatment in patients with these disorders are ongoing.

►Myelodysplastic Syndromes (MDS)

There has been considerable international interest in the use of lenalidomide in the treatment of MDS. A phase I-II study in 43 patients defined the optimal dose as 10 mg/day and demonstrated responses in almost half

of the patients studied, including a striking response in over 80% of patients with the 5q-syndrome. A subsequent multicenter phase II study of 148 patients, all of whom exhibited the 5q deletion, confirmed the results of the earlier trial. In this trial, 76% of patients responded to lenalidomide treatment, 67% achieved durable transfusion independence (median duration not reached at 2 years) and almost half of all patients attained cytogenetic remission. A second phase II study investigated the use of lenalidomide in 215 patients with low risk MDS without 5q deletions, of whom 44% responded to treatment and 26% became transfusion independent, although the duration of response was less that that reported in the study in patients with 5q deletions. The results of these studies led the Food & Drug Administration in the United States of America to approve the use of lenalidomide as a treatment for anemia in patients with MDS exhibiting a 5q deletion. The optimal duration of treatment is not currently known.

Solid Malignancies

When compared to the use of thalidomide in the treatment of multiple myeloma, the role of thalidomide in the treatment of solid malignancies is less clear, particularly in view of the somnolence, constipation, VTE, peripheral neuropathy and fatigue associated with treatment. Whereas therapeutic doses of 50–400 mg/day orally (2–8 mg/kg/day) are currently used for dermatologic and inflammatory diseases, oncological investigators have generally used 100–800 mg/day either as single agent therapy or in combination with cytotoxic chemotherapy (e.g. carboplatin (►Platinum drugs), docetaxel (►Taxotere) or irinotecan (►Topoisomerase enzymes as drug targets)) or cytokines such as ►interferon-α. Thalidomide at a dose of 400 mg/m^2/day can be safely administered to children with solid tumors in combination with carboplatin.

Thalidomide (100–600 mg/day) has been studied in patients with a variety of solid tumors. In phase II studies, responses have been observed in patients with glioma, metastatic melanoma, pancreatic cancer, Kaposi's sarcoma, malignant melanoma and prostate cancer. Results for patients with renal-cell carcinoma were considered particularly promising, leading to a randomized phase II study in 60 patients with this condition. Patients received either thalidomide or medroxyprogesterone as monotherapy. There was no difference in overall survival between the two groups, leading the investigators to conclude that the risk/benefit ratio did not favor the use of thalidomide as monotherapy in patients with ►renal carcinoma. Similarly, phase II studies of the combination of thalidomide and interferon-α have shown minimal efficacy and unacceptable toxicity in patients with metastatic renal cell carcinoma.

Early data would suggest that the palliative response to thalidomide is separate from the objective radiological response and that it may occur earlier. The most promising palliative results have been reported in Kaposi's sarcoma, malignant melanoma and prostate cancer, especially when thalidomide is combined with chemotherapy. In a study of 40 heavily pre-treated patients with ovarian cancer, thalidomide appeared to be comparable in symptom response and quality of life to single agent intravenous chemotherapy.

Of particular note in the palliative treatment of solid malignancies is the potential for thalidomide to treat ►cancer cachexia. The postulated mechanism of action is compatible with the probable role of TNF, INF-γ, and IL-6 in the aetiology of this debilitating symptom. Randomized, placebo-controlled trials of thalidomide in weight-losing patients with advanced solid malignancies, such as pancreatic cancer, have demonstrated weight gain and improvements in physical functioning.

Future Directions

When one compares IMiDs to thalidomide treatment, in addition to their increased potency in inhibiting the production of cytokines such as TNF-α, one of the most attractive features of the IMiDs is the lack of neurotoxicity caused by drug treatment. Although their safety in long-term administration (i.e. many years) remains to be demonstrated at the phase IV (post-licensing) level of clinical trial development, the toxicity profile of lenalidomide appears compatible with the concept of maintenance treatment for diseases in which its anti-inflammatory properties, anti-angiogenic activity, apoptotic producing activity or inhibition of ►T-cell response would benefit from chronic exposure to the drug. In particular, the ability of IMiDs to inhibit T-regulatory cells (as well as being co-stimulatory) may represent an ideal property for enhancing immunotherapeutic and cancer vaccine approaches to the treatment or prevention of cancer.

Although a large randomized study which was terminated prematurely did not shown any significant impact of lenalidomide treatment on overall survival in patients with stage IV malignant melanoma, several anecdotal responses have been observed in this disease. Patients with malignant melanoma in whom objective responses were demonstrated in a phase II study of lenalidomide treatment, who had also been exposed to melanoma vaccines previously, have led to the suggestion that increased responses may be associated with a reduction in T-cell regulatory activity and co-stimulatory abilities. This highlights the possibility that this class of drugs may work even better in combination with other modalities and may be synergistic with cancer vaccines.

A major target for drug development to inhibit the growth and spread of cancer is angiogenesis. Several ►small molecule drugs which inhibit multiple tyrosine kinase pathways and angiogenesis are currently in

clinical trials. IMiDs inhibit angiogenesis but it is not currently known if they also inhibit ►receptor tyrosine kinase pathways. Indeed, the other immunomodulatory and cytokine modulating properties of IMiDs may in fact be more synergistic in the inhibition of angiogenesis than the inhibition of multiple tyrosine kinases. Since such drugs are likely to be taken for many years by patients with cancer in order to maintain response, lack of toxicity and convenience of oral dosing are important factors.

Therapeutic Active Targeting

Definition

Systemic delivery of a therapeutic agent to a tumor by linking tumor specific ligands to the therapeutic agent, which facilitates accumulation of the therapeutic agent inside the tumor.

►Nanotechnology

Therapeutic Cloning

Definition

Reprogramming the nucleus of an adult cell through transfer into the cytoplasm of an enucleated oocyte. This is sometimes referred to as "cell-nuclear replacement" or "somatic cell nuclear transfer."

Therapeutic Efficacy

Definition

Beneficial health effect from a treatment.

►Chemoprotectants

Therapeutic Passive Targeting

Definition

Systemic delivery of a therapeutic agent to a tumor which exploits leaky vascular endothelium characteristic of tumors. The therapeutic agent leaks out of circulation through fenestrations in tumor vessels allowing accumulation of the agent in the tumor.

►Nanotechnology

Therapeutic Vaccine Therapy

Definition

Is a form of active ►immunotherapy that treats established diseases by eliciting a systemic, antigen-specific, cellular and humoral immune response. For active immunization against cancer, tumor-associated antigens (TAAs) are presented in an immunogenic formulation to induce a sufficiently powerful acquired immune response. Either the TAAs themselves, or an appropriate mimic such as an anti-idiotypic or mimotopic antibody or peptide, can be used as the immunogenic trigger.

Therapeutic Viruses

►Oncolytic Virus

Thiazolidin

Bingliang Fang
Department of Thoracic and Cardiovascular Surgery, The University of Texas M. D. Anderson Cancer Center, Houston, TX, USA

Synonyms

Thiazolidinone

Characteristics

Thiazolidins are a group of synthetic compounds that can selectively induce ►G2/M arrest (►Cell cycle targets for cancer therapy) and ►apoptosis in cancer cells. They were identified as potential anticancer agents by screening a chemical library for compounds that can kill ►paclitaxel-sensitive and paclitaxel-resistant cancer but not normal cells. The representatives are 5-[(4-methylphenyl)methylene]-2-(phenylamino)-4(5H)-thiazolone and 5-(2,4-dihydroxybenzylidene)-2-(phenylimino)-1,3-thiazolidin. Chemically, the compounds contain three ring structures, a middle oxothiazolidine ring connected with two benzyl rings, one on each side. Several of those compounds can effectively inhibit the growth of human lung, colon, breast, ovary and prostate cancer cell lines. Treating cancer cells with thiazolidin compounds can induce cell cycle arrest in the G2/M phase and apoptosis, activating ►caspase-3, -8, -9, and causing the release of cytochrome *c* from mitochondria. Nevertheless, they had no obvious toxic effects on normal human fibroblasts and mesenchymal stem cells at the 50% inhibitory concentration for susceptible cancer cell lines. The inhibitory effect on cancer cells is independent of the status of p53 and ►P-glycoprotein. They are effective against cancer cells with p53 mutations or cancer cells overexpressing P-glycoprotein. Although the molecular targets and mechanisms of thiazolidin-induced cell cycle arrest and apoptosis are not yet clear, the activation of ►c-Jun-N-terminal kinase (►JNK) (►MAP kinase) by thiazolidin compounds is known to be required for thiazolidin-induced apoptosis in cancer cells. Thiazolidin-induced apoptosis was abrogated when JNK activation was blocked. Moreover, thiazolidins can suppress the expression of ►hypoxia-induced factor 1α (►HIF1α) (►Hypoxia and tumor physiology) and vascular endothelial growth factor in cancer cells. In vivo administration of thiazolidin can suppress the growth of human xenograft tumor in nude mice, indicating that those compounds might be used as anticancer agents.

Thioredoxin

Definition

A protein with oxidoreductase activity, having a typical "Trx-fold" and a -CPGC- active site sequence involving a redox active dithiol/disulfide motif. Thioredoxins exist as several isoforms and are found in nearly all cells. Cytosolic Trx1 and mitochondrial Trx2 are the main thioredoxins in human cells.

►Thioredoxin System

Thioredoxin is Identical to ADF Adult T cell Leukemia Derived Factor

►Thioredoxin System

Thioredoxin Reductase

Definition

A flavoprotein with oxidoreductase activity, reducing the disulfide in the active site of thioredoxin to a dithiol. Thioredoxin reductases exist as several isoforms in human cells, with cytosolic TrxR1 and mitochondrial TrxR2 being the two major forms.

►Thioredoxin System

Thioredoxin System

Elias S. J Arnér, Arne Holmgren
Department of Medical Biochemistry and Biophysics, Karolinska Institutet, Stockholm, Sweden

Synonyms

Protein disulfide reductase; Thioredoxin is identical to ADF adult T cell leukemia derived factor; Trx80 is truncated thioredoxin comprising the 80 or 84 N-terminal amino acids of human cytosolic Trx

Definition

►Thioredoxin (►Trx) is a small ►dithiol-disulfide oxidoreductase existing in all living cells. The thioredoxin system is comprised of Trx, NADPH, and ►thioredoxin reductase (►TrxR) and functions as the cells' major NADPH-dependent protein disulfide reductase. Trx have numerous functions in cell growth such as the electron donor for ribonucleotide reductase, which is essential for DNA synthesis and repair. ►Reduced Trx is alo central in antioxidant defense, regulation of transcription factors such as ►p53, or ►apoptosis inhibiton of ASKI. TrxR is an essential ►flavoprotein with a catalytic ►selenocysteine residue, which is a target for many chemotherapeutic drugs. Both Trx and TrxR are upregulated in most but not all forms of ►cancer.

Characteristics

Trx contains a conserved active site (-Cys-Gly-Pro-Cys), which is present as a disulfide in ►oxidized Trx (Trx-S_2). This disulfide is reduced to a dithiol Trx-(SH_2). Trx-(SH_2) is the cells' major protein disulfide reductase, which is responsible for keeping proteins reduced and maintaining a reducing intracellular environment and controls the cells' redox potential together with GSH and glutaredoxins. As a disulfide-reducing protein, Trx has many targets including ribonucleotide reductase, which makes the deoxyribonucleotide building blocks for DNA, both for DNA replication and repair. In cancer cells ribonucleotide reductase is often strongly upregulated and a target for chemotherapy by, for example, hydroxyurea. Both Trx and TrxR are expressed in mammalian cells as dedicated isoforms for either predominantly cytosolic (Trx-1 and TrxR1) or mitochondrial (Trx-2 and TrxR2) localization. One important function of thioredoxin is to participate in antioxidant response. This is because Trx is the electron donor for the family of thioredoxin peroxidases, which act to remove hydroperoxidases by cysteine residues, which are oxidized to disulfides. Thioredoxin will also reduce and activate proteins, which have been oxidatively inactivated. Thioredoxin is a reducing agent for methionine sulfoxide reductase, which restores Met-SO residues to Met. One function of thioredoxin which is general, is to act as an activator or reducing agent for many transcription factors, which upon DNA-binding in the nucleus require reduced sulfhydryl groups. Examples of such factors are p53, NFκB (►Nuclear factor κB), and ►AP-1. In cells ►oxidative stress often leads to movement of cytosolic Trx1 to the nucleus, where its activity is linked to redox control of transcription factors.

Oxidative stress or activation of many cells leads to secretion of Trx1 by a leaderless pathway, which generates Trx levels of around 25 ng/ml in plasma. In cancer but also in ►inflammation the level of Trx1 in

Thioredoxin System. Table 1 Reactions of importance for cancer involving the thioredoxin system. The thioredoxin system is involved in a number of critical reactions having importance for the progression of cancer. This table shows a list of some of the reactions in which the thioredoxin system is involved. For further discussion or reference to publications describing these reactions, please see the cited review articles

Event	Reaction	Role of the thioredoxin system
Development of ►cancer	Protection from selenium	It is possible that the Trx system is important for the chemopreventive effects of selenium
	Critical role of p53	The transcriptional activity of p53 is regulated by Trx
	Critical role of apoptosis	Several events of apoptosis, including triggering by oxidative stress and signaling through ASK-1, are regulated by Trx
Progression of cancer	Production of DNA precursors	Trx supports ribonucleotide reductase
	Resistance to oxidative stress	The Trx system is an essential part of the cellular antioxidant defense
	Support of growth of leukemia	Extracellular Trx support growth of certain types of leukemic cells
	Histone acetylation	Regulation of histone acetylation by TXNIP links this event to the Trx system
	Telomerase integrity	TrxR1 antisense adversely affects telomerase maintenance
Treatment of cancer	Therapy with anticancer ►alkylating agents	TrxR is a cellular target for many compounds including ►cisplatin, other ►platinum drugs, ►curcumin, and several ►xenobiotics
	Therapy with selenite	Selenite may be cytotoxic toward cancer cells through the action of TrxR

plasma may increase and serve as a diagnostic tool. Extracellular thioredoxin acts as a cocytokine for immune cell growth and was also discovered as adult T-cell leukemia derived factor (ADF) secreted from malignant T-cells resulting from HTLV-I transformation. Plasma also contains a truncated form of Trx called Trx 80, which acts a mitogenic growth factor for monocytes and can induce a Th1 response in the presence of lymphocytes. The levels of Trx80 in cancer have not been investigated.

►TrxR is a ►selenoenzyme, which contains a carboxy terminally located selenocysteine (Sec) containing active site (-Gly-Cys-Sec-Gly) present in all the three isoenzymes of TrxR in a 16-residue elongation to a glutathione reductase-like scaffold structure. Both cytosolic and mitochondrial TrxR are expressed as a large number of isoforms derived from alternative ►pre-mRNA splicing. TrxR has a number of activities, apart from its function to reduce oxidized Trx, such as reducing selenite, dehydroascorbic acid, and members of the thioredoxin fold family such as protein disulfide isomerase (PDI).

Many clinically used anticancer drugs are targeting TrxR and the highly reactive selenol in the active site of the enzyme. Chemotherapeutic drugs targeting TrxR include cisplatin, nitrosoureas, antitumor quinones, melphalan, chlorambucil, and gold compounds.

The special interest in the thioredoxin system in relation to cancer is the potential role of TrxR in the chemopreventive effects of ►selenium compounds in cancer. TrxR is a selenoenzyme, which is dependent on selenium for activity as well as having a role in antioxidant defense and control of p53 and other functions such as the role of thioredoxin in prevention of apoptosis via binding to ►ASK-1, Trx, and TrxR; also has a potential role in the mechanism of selenium in prevention of cancer. However, today the role of TrxR as a target of selenium is not yet proven.

Finally, the protein called TXNIP (also TBP2 or VDUP-1) is critically regulated by binding to Trx in the reduced form and is a key component in the action of, i.e., histidine diacetylase inhibitors on inhibiting cell growth of tumor cells. A general result seems to be that tumor cells are under oxidative stress and the thioredoxin system is thereby upregulated. Normal cells upon treatment with drugs which induce oxidative stress, such as doxorubicin or SAHA, are able to upregulate Trx and TrxR to meet the increased oxidative stress, whereas tumor cells are more sensitive and killed.

The accumulated knowledge from many studies implies that the thioredoxin system is involved in many events of cancer development, treatment, or progression. Some of the critical events in which the thioredoxin system are involved are summarized in Table 1.

Three-Dimensional Tissue Cultures

Kevin O. Hicks
Auckland Cancer Society Research Centre, The University of Auckland, Auckland, New Zealand

Definition

Three dimensional (3D) tissue cultures are in vitro methods for growing cells in a system that more accurately reproduces the structure, function and ►microenvironment of the tissue of origin.

Characteristics

There is wide recognition that most cells require the complex structure and function of the 3D tissue microenvironment to provide the many signals and interactions for appropriate proliferation, growth, ►apoptosis, ►differentiation and ►invasion necessary to form relevant models of the corresponding in vivo structures. 3D cultures have arisen to overcome the inadequacies of simple (2D) cultures in reliably

representing tissue and organ function in vitro and as a model of intermediate complexity between the cell and the tissue or organ. In cancer research this is reflected in different cell responses to therapeutic agents and other experimental manipulations when cells are in 3D culture rather than (2D) ►monolayer culture which has usually been used for cell propagation and therapeutic testing. For example, promising drugs selected using 2D culture models often fail in 3D cultures, tumor ►xenografts and in human patients. Tumors are a complex tissue consisting of cancer, stromal, immune and endothelial cells, together with ►extracellular matrix which provides support and signaling molecules and binds diffusible growth factors. This unique mechanical and chemical microenvironment has important consequences in cellular function, producing major changes in gene expression and regulation of intracellular signaling as 3D cancer tissue grows. Consequently 3D tumor cultures are used experimentally to better understand tumor biology and provide more realistic testing conditions for therapeutic agents. Below, several of the 3D culture techniques used in cancer research are discussed by increasing complexity, although this scheme is arbitrary since there is often much overlap between categories.

Multicellular Spheroids

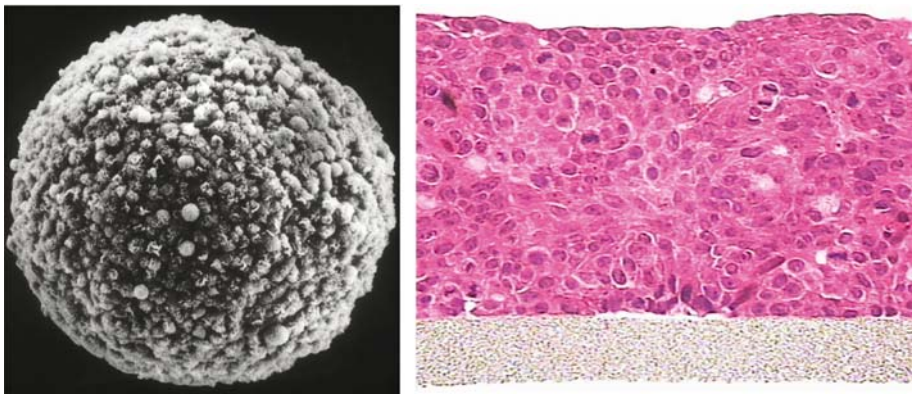
►Multicellular spheroids (MS, spheroids, multicellular tumor spheroids, MTS) are spherical aggregates of cancer cells that model of the extravascular compartment of solid tumors (Fig. 1A). Developed in the early 1970s, they are particularly representative of avascular tumor nodules, micrometastases and densely packed intercapillary regions in large tumors. Spheroids are the most extensively used 3D tissue culture method for cancer cells.

Culture

They are generally grown in mammalian tissue culture medium at 37°C, either as liquid overlay cultures or in suspensions, where attachment to the apparatus is prevent by culturing over agar or in stirred spinner flasks respectively. Spinner cultures allow large scale and economic growth of spheroids with well defined structure and physiology.

Diffusion Limited Growth, ECM and Differentiation

Spheroids generally grow in a Gompertzian fashion, developing many features of the solid tumor microenvironment such as ►hypoxia, ►HIF-1 expression and ►necrosis in the central region when larger than 400–500 μm in diameter. This diffusion limited growth is related to limited penetration of oxygen, nutrients and growth factors, together with depletion of energy reserves in the central region. These gradients, which form over surprising small distances (10–20 cells diameters), limit the thickness of the viable rim of cells to 100–220 μm in most spheroids. Although they will often grow to a diameter of 500–1,000 μm they may be used at any stage for experimentation. During growth the cells secrete extracellular matrix (ECM) components and form cell-cell and cell-ECM interactions necessary for the maintenance of a multicellular structure at cell volume fractions of 45–65%, similar to tumors. One advantage of even simple human 3D cultures such as spheroids is that the ECM, although not completely representative of the in vivo situation, is produced by syngeneic cells rather than by the host cells as may occur in tumor xenografts. Because of the more realistic 3D structure cells in spheroids are more likely to express differentiation markers such as keratins and form cell junctions such as desmosomes and ►tight junctions and often undergo terminal differentiation with formation of pseudoglandular and acinar structures and therefore represent a close



Three-Dimensional Tissue Cultures. Figure 1 Histological structure of spheroids and MCL. *Left*: Scanning electron micrograph of a human cervical squamous cell carcinoma multicellular spheroid ~300 μm in diameter. Haematoxylin and eosin stained HT29 human colon cancer MCL ~150 μm thick.

approximation to the tissue architecture seen in vivo. This contrasts with the homogeneous morphology of reproducing stem cells seen in monolayer culture.

Dissociation, Histology and Other Study Methods

Investigation of the relative effect of the 3D microenvironment is often performed by exposing spheroids to experimental treatments after which they are dissociated into single cell suspensions by exposure to trypsin, and the cellular responses compared to those seen in cells treated after dissociation or grown in monolayer culture. For example, when irradiated under physiological oxygen tensions spheroids demonstrate resistance due to poor killing of the central hypoxic cells, usually demonstrated using the ►clonogenic survival assay (CSA) where dissociated cells are plated in culture dishes and stained colonies are counted ~1–2 weeks later. The so-called radiobiologically hypoxic fraction can be calculated by comparing the sensitivity of cells from spheroids exposed under physiological oxygen concentrations to those exposed under hyperoxic (95%) and anoxic conditions. In some cell lines additional resistance (compared to cell suspensions from monolayer culture) is due to a cell contact effect that lasts at least one cell cycle after dissociation.

Cell Proliferation

A fundamental similarity between spheroids and tumors is that gradients of cell proliferation occur, from rapidly dividing surface cells in the outer 3–5 cell layers (~75 μm) to non-dividing central cells. These proliferation gradients match the gradients of oxygen and nutrients and may be visualized by bromodeoxyuridine assay of histological sections or decreased expression of the proliferation marker ►Ki-67 and increased expression of ►CDK inhibitors such as the quiescence marker ►p27. Consequently, spheroids have a large population of quiescent cells and this explains, in part, the observations of increased resistance to some drugs. Spheroid studies have shown that cells in the central region may exit the cell cycle but remain viable for several days, even under hypoxia, and start reproducing again if conditions change. The lifespan of hypoxic cells was 3–5 days in human spheroids which is similar to (but less variable than) that seen in corresponding xenografts.

pH and Metabolite Gradients

Gradients of metabolites have been demonstrated using quantitative bioluminescence, with increased lactate and lower pH in the central region, due to the marked tumor cell ability to utilize anaerobic glycolysis for energy production and to survive in low pH microenvironments. This is consistent with ATP and glucose concentration gradients not being as steep as O_2 gradient indicating that energy production is partially maintained in central regions. The simple spherical geometry simplifies experimental investigation. This is because the microenvironmental gradients that determine structure and physiology, although present in tumors, are not as highly correlated with distance from the blood vessel as they are with distance from the surface in spheroids.

Cancer Biology

Since function in spheroids may be related in such a direct way to structure they have been extensively used to investigate the biological causes and effects of these microenvironmental gradients. The biology of cell populations from different depth in spheroids may be investigated by histological techniques using fluorescent antibodies and in vivo confocal microscopy and therapeutic response studied using sequential dissociation, centrifugal elutriation, and, especially, fluorescence activated cell sorting (►FACS) where cells are selected by ►flow cytometry based on the differential uptake of fluorescent molecules. Microenvironmental regulation of cell-cell interactions and invasion has been investigated with demonstration of important roles for ►cell adhesion molecules, such as the integrins and cadherins.

Drug Effects and Multicellular Resistance

The variations in tumor cell biology and microenvironment also leads to variability in sensitivity to many drugs in both tumors and 3D cultures. Multicellular resistance in spheroids was found to be partly due to cytokinetics as demonstrated by the difference in sensitivity of freshly dissociated cells to exponential phase monolayer cultured cells. Another key determinant of drug resistance in 3D cultures is survival signals from the microenvironment mediated by adhesion and other molecules. In addition the ►multidrug resistance pump, ►P-glycoprotein, has been demonstrated to be expressed in the centre of large spheroids and gene expression analysis has implicated suppression of DNA mismatch repair in multicellular resistance to alkylating agents.

Drug Transport

With the investigation of drug effects in spheroids it became apparent that poor drug penetration could also cause drug resistance in multicellular structures. Penetration has been studied by microscopy or autoradiography of spheroids after exposure to fluorescent or radiolabeled drugs. This demonstrated poor penetration especially for drugs bound in cells to high concentrations such as anthracyclines and drugs rapidly metabolized such as tirapazamine while others such as 5-fluoruracil and vincristine penetrated well. The reduced cytotoxic response of ►doxorubicin has been correlated with its poor penetration using FACS.

Without this information the interpretation of similar doxorubicin gradients seen in vivo is equivocal. Spheroids have also been extensively used to confirm penetration and binding of nitroimidazole radiosensitizers and hypoxia markers. That tumor penetration is poorest for macromolecules has been convincingly demonstrated in many spheroid studies of antibodies and immunotoxins.

Individualized Therapy

Spheroids, in common with other in vitro methods, have so far found limited use in predicting patient response, mainly because of the difficulties in primary culture of human tumor cells in a timely manner.

Multicellular Layers (MCL, Multilayered Cell Cultures, MCC)

►Multicellular layers (MCL) are flat aggregates of tumor cells grown in culture medium by seeding cancer cells onto a porous support membrane in the commercial culture inserts used for growing cell monolayers. When submerged in culture medium for 3–7 days (depending of the number of cells seeded) they grow to 50–300 μm thick. Histologically they resemble their corresponding multicellular spheroids and tumor xenografts and have similar ECM and matrix components (laminin, collagen types I, IV). They have regions of hypoxia and central necrosis due to oxygen diffusion limitations and differentiated subpopulations of cells. MCL may be studied by similar methods to spheroids and many features in common with spheroids have been demonstrated including radiobiological resistance due to central hypoxia, necrosis and gradients of cell proliferation.

A particular advantage of MCL is the planar geometry allowing drug transport studies by separating two compartments of a diffusion apparatus, introducing drug into one (donor) compartment and measuring its appearance in the other (receiver) compartment, using compound specific analytical techniques such as high performance liquid chromatography (HPLC) and mass spectrometry (LCMS). This allows separation of parent drug from any metabolites or breakdown products which is not usually possibly with observation of fluorescence or radiolabel in histological sections. Consequently drug transport parameters (diffusion coefficients and rates of drug metabolism) may be quantified. Slow penetration has been demonstrated for several DNA binding compounds and limited penetration for tirapazamine, due to rapid drug metabolism, when incubated under anoxic conditions. A pharmacokinetic/pharmacodynamic model combining MCL transport parameters with cellular cytotoxicity is predictive of activity of tirapazamine analogs in tumor xenografts, confirming that the efficiency of penetration is a key determinant of antitumor effect in these hypoxia targeted drugs. The chemical properties which determine transport have been extensively studied demonstrating that low molecular weight, high lipophilicity and low hydrogen bonding capacity are important.

Some cell lines that do not grow well as spheroids will grow as MCL and mixed cultures are easy to establish. MCL formed from mixed cultures of cells able to activate prodrugs with cells than cannot do so have been used to demonstrate the ►bystander effect due to local diffusion of active metabolites.

Multilayered Post-Confluent Cultures (MPCC)

Post confluent cultures in V-bottomed welled plates have been developed in an effort to create a representative of solid tumor multicellular structure that is also simple enough for ►high throughput screening in new drug development. Confluence is reached in 3–5 days after which plateau phase growth and a multilayered structure develops in which there is a range of cell proliferation rates and more heterogeneous and differentiated cell population. These cultures may be used with standard growth inhibition assays using a plate reader in a semi-automated fashion. Multilayers were more resistant to the drugs than monolayers, similar to the situation with spheroids and solid tumors. This model is less amenable to studies of drug transport, but the system is easily controlled to show differences between the drugs effects under altered culture conditions such as hypoxia or in drug combination studies.

Co-Cultures of Tumor and Normal Cells
