Classically, mucins are known to play a central role in the protection and lubrication of luminal epithelial surfaces. Several lines of evidence also suggest that mucins might serve as cell-surface receptors and sensors, transducing signals in response to external stimuli leading to coordinated cellular responses that include proliferation, differentiation, apoptosis, and secretion of specialized cellular products. The basic structure of a mucin molecule includes a protein backbone, termed "apomucin," decorated with a large number of ►*O*-linked oligosaccharides and a few ►*N*-glycan chains. Additional posttranslational modifications, including sialylation and sulfation, have also been commonly reported in mature mucin glycoproteins. Structural features common to all known mucins are: (i) A large extracellular region composed of a variable number of tandem repeats (►VNTRs) rich in serine, threonine (which constitute the potential *O*-glycosylation sites), and proline (so-called STP-rich regions) residues. In humans, several distinct genes (*MUC1–MUC20*) coding for mucin core polypeptides, containing 5–500 tandem repeats, have been thoroughly characterized. Some mucins, like MUC5B and MUC7 exhibit a constant number of repeats, whereas in the majority of mucins the amino acid length of their repeated domains is subjected to genetic polymorphism. (ii) The high content of *O*-linked oligosaccharide side chains attached to a serine and threonine-rich peptide core. ►*O*-glycosylation with complex oligosaccharides plays a crucial role in determining mucin structure and function. Indeed, the sugar moieties constitute up to 80% of the mucin's total mass, confer an elongated and rigid structure to the molecule, and contribute to the rheological properties of mucus secretions. Under normal physiological conditions, mucins exhibit a well-defined tissue-, time-, and developmental state-specific expression pattern. Deregulated mucin expression has been regarded as one of the most prominent characteristics of many types of cancers.

Considering the cellular expression pattern, mucins can be grouped into two main classes:

1. Membrane-bound mucins (MUC1, MUC3A, MUC3B, MUC4, MUC12, MUC13, MUC15, MUC16, MUC17, and MUC20) comprising three distinct regions: a large extracellular domain, a hydrophobic transmembrane region, and a short cytoplasmic tail that associates with cytoskeletal elements and participate in signal transduction. The extracellular region of membrane-bound mucins can be released from the cell surface through proteolytic processing. In addition, many secreted forms result from alternative mRNA splicing that eliminates the transmembrane domain. Among the cell-surface expressed mucins, MUC1 and MUC4 are the best characterized with respect to signal transduction.
2. Secreted mucins, which lack a transmembrane domain and are thus secreted into the extracellular space. Two subfamilies of secreted mucins can be distinguished, the "gel-forming" mucins (MUC2, MUC5AC, MUC5B, MUC6, and MUC19), and the "nongel-forming" mucins (MUC7, MUC8, and MUC9). Some genes encoding gel-forming mucins (MUC2, MUC5AC, MUC5B, and MUC6) share some degree of sequence similarity and appear to be clustered

on chromosome 11p15. A distinct feature of secreted gel-forming mucins is their ability to form a network of multimeric complexes as a result of intra- and intermolecular associations through cysteine-rich domains.

In epithelial cancers, many of the markers for premalignant and malignant cells have been found on the carbohydrate and peptide moieties of mucins, and these structures greatly contribute to the phenotype and biology of cancer cells. Upregulation, downregulation, and de novo expression of apomucins have been reported in cancer cells. Alterations differentiating cancer mucins from normal mucins include both, mucin protein expression and distinct patterns of *O*-glycosylation. These abnormalities are frequently associated with altered adhesion and invasion and could modulate the immune recognition of cancer. To date, it is not clear whether deregulation of mucin expression is a cause or a consequence of the transforming phenotype. An increasing number of reports point to mucins as key players in the development and onset of malignancy. The ectopic and/or overexpression of membrane-bound mucins in tumor cells have been generally associated with an augmented malignant potential and a poorer prognosis for the patient. In contrast, the expression of secreted mucins in certain types of tumors appears to correlate with a better prognosis. Muc2 ►knock out mice have been shown to be significantly more prone to the development of gastrointestinal tumors compared to their wild-type counterparts, suggesting a tumor suppressive effect for this mucin.

Several mucins appear to contribute to the malignant phenotype of tumor cells. Hence, membrane-bound MUC1 probably represents the best characterized mucin, and a number of studies converge to suggest a direct involvement of MUC1 in the cellular processes underlying the molecular pathogenesis of various neoplastic diseases. Overexpression of this mucin has been shown to induce cellular transformation and to inhibit stress-induced apoptosis. MUC1 is known to transduce signals through the MAP kinase and β-catenin pathways. Signals are transmitted to the nucleus through association of the MUC1 cytoplasmic tail (MUC1-CT) with signal transduction molecules, including ►β-catenin, p120 ►catenin, ►Ras, ►p53, and the ►estrogen receptor α (ER-α). The intermolecular association of MUC1 and β-catenin is increased upon phosphorylation of MUC1-CT by activated EGF receptor and c-Src. The increased MUC1-CT/β-catenin interaction is likely to reduce the pool of cytoplasmic free β-catenin, thereby weakening intercellular adherence. MUC1-CT has also been proposed to localize to mitochondrial membranes under conditions of genotoxic stress, where it attenuates the apoptotic pathway and confers resistance to apoptosis-inducing drugs. Another important aspect of MUC1 biology is its role in tumor immune evasion. Thus, cells overexpressing MUC1 adhere deficiently to natural killer cells and cytotoxic T-cells, and are therefore resistant to killing by these cells. The impact of MUC1 overexpression in cancer biology correlates with clinical observations; a high level of MUC1 expression and secretion has been shown to be associated with poor prognosis and high metastatic potential.

Mucins are the main carriers of altered oligosaccharide patterns in cancer cells. They are normally highly glycosylated, and thus, the antigenic peptide core is physically inaccessible to the immune system, particularly to antibodies. However, the deregulation of key enzymes (►glycosyltransferases) of the *O*-glycosylation pathway leads to the generation of new glycan antigens at the mucin surface. The resulting aberrant glycosylation patterns include short mono-, di- and trisaccharide chains, and result in both the exposure of cryptic peptide-core epitopes, and in the expression of cancer-associated *O*-linked carbohydrate chains (i.e., TF, Tn, and sialyl-Tn antigens) discontinuously distributed along the peptide backbone. Therefore, these neopeptide and neocarbohydrate epitopes become accessible for recognition by components of the immune system. The expression of distinct oligosaccharide structures, alone with the differential glycosylation of mucin core proteins, endows tumor cells with an enormous range of potential ligands for interacting with a number of cell surface receptors.

Immunohistochemical studies have identified several ►tumor-associated antigens (TAAs) on mucins. Antibodies against TAAs on mucins are widely used in the clinic as diagnostic tools (e.g., serum assays) for different types of cancers. Increased concentration of mucin-type glycoproteins in serum has been correlated with enhanced tumor burden and poor prognosis. Several assays detecting TAAs in serum samples are directed against the circulating MUC1 antigen (e.g., CA15-3, CASA, MCA, CA549, and BCM), which are used in the postoperative monitoring of breast and ovarian carcinoma patients. Another tumor marker of clinical significance is DU-PAN2, which is exposed by MUC1 and is being used for the diagnosis of pancreatic adenocarcinoma. The cancer antigen 125 (CA125), the most widely used biomarker for ovarian cancer, was identified in 2001 as mucin MUC16. MUC16/CA125 represents the only FDA-approved ovarian cancer relapse marker. Several other serum tumor assays which are mainly applied for gastrointestinal cancer diagnosis, involve mucin-associated carbohydrate antigens, like CA72-4 (sialyl-Tn) and CA19-9 and CA50 (sialyl-Lewis^a). It was established that sera from normal individuals as well as from tumor patients contain circulating antibodies directed towards the MUC1 protein core. High anti-MUC1 antibodies levels have

been associated with a significantly better survival of patients with breast, lung, or pancreatic cancer. Therefore, the determination of MUC1-specific antibodies in sera could be of clinical value.

Cancer-associated mucins show antigenic differences from normal mucins. They are highly immunogenic, and as such, represent potential targets for immunotherapy. Particularly, MUC1 is the most intensively investigated mucin protein with regard to cancer immunotherapy, and this mucin is the target of several anticancer vaccine clinical trials. Underglycosylated MUC1, the tumor-associated mucin ►glycoform, leads to enhanced accessibility of the peptide core by many MUC1-specific antibodies and to increased humoral and cellular immune responses, as shown for breast, colon, pancreatic, and ovarian cancer patients. Studies on vaccination using synthetic peptides (and glycopeptides) derived from MUC1 show promising activities including induction of the proliferation of T-cells and cytotoxic T-cell responses.

Mucoepidermoid Cancer

Frederic J. Kaye
National Cancer Institute, NIH and National Naval Medical Center, Bethesda, MD, USA

Synonyms

Malignant salivary gland cancer; Low grade/well differentiated MEC; High grade/undifferentiated MEC

Definition

Muco ►epidermoid carcinoma (MEC) is the most common malignant salivary gland tumor that can arise from both major and minor salivary gland tissues.

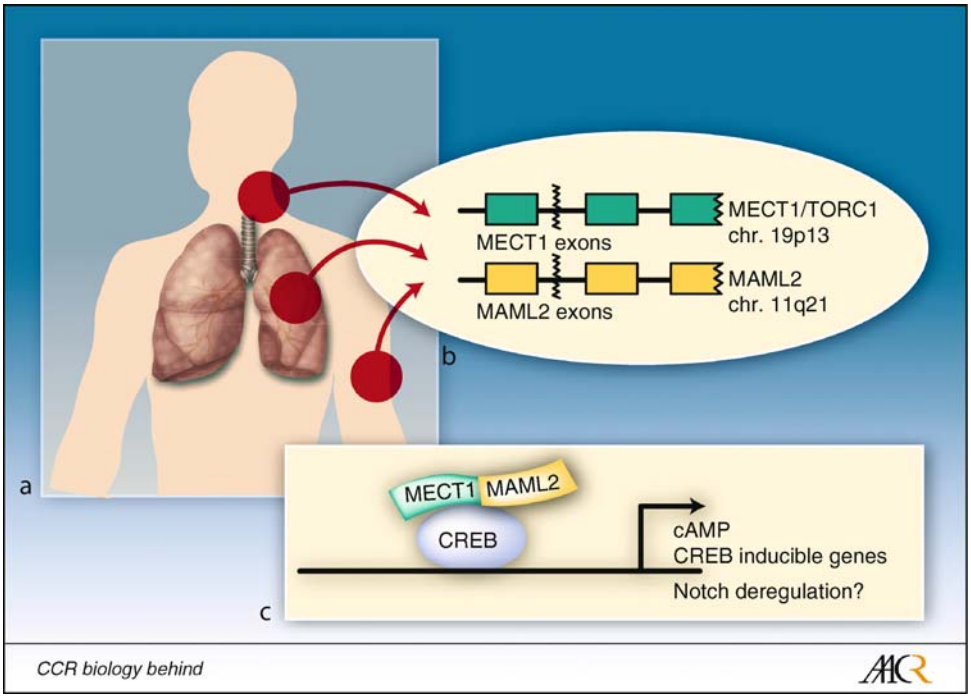
Characteristics

Historical Data

Volkmann is credited with first describing this clinical entity in 1895. Stewart (1945) first used the term "mucoepidermoid" and Foote and Frazell (1953) defined the histological features and malignant nature of this disease.

Histological Features

Mucoepidermoid carcinoma is a unique epithelial tumor that arises from salivary gland tissues and is characterized by varying proportions of three different cell types represented by epidermoid cells, ►mucin producing cells, and "intermediate cells." These tumors are predominantly detected within major salivary glands (such as the parotid and submandibular glands), as well as from minor salivary glands that are scattered throughout the oral cavity and upper aerodigestive tract. In addition, tumors with mucoepidermoid-like histological features are occasionally seen as primary lesions within the bronchopulmonary tree, the skin, as well as other organ sites. Importantly, there is cytogenetic and molecular genetic data that unifies the biology of these mucoepidermoid-like tumors irrespective of the primary tissue of origin (Fig. 1). To address the wide range of morphological differentiation and the corresponding differing degree of clinical aggressiveness, histological grading schemas have been proposed which score tumors as high grade/undifferentiated, as intermediate grade, or as low grade/well-differentiated. These systems employ either qualitative or quantitative parameters



Mucoepidermoid Cancer. Figure 1(a) MEC-like tumors arising from major or minor salivary glands of the head and neck, from the bronchopulmonary tree, or from a cutaneous clear cell hidradenoma which have been reported to express the identical Mect1-Maml2 product. (b) The t(11;19) chromosomal breakpoint maps within intron 1 of both the Mect1/Torc1 and Maml2 genes in all cases tested and results in exon1 swapping between the genes. (c) Preliminary model depicting the ability of Mect1-Maml2 to activate a group of cAMP/CREB inducible genes which are hypothesized to participate in tumorigenesis. (Figure is reproduced from Ref. [1]).

based on the relative amounts of epidermoid and mucin-type cells and the degree of cellular differentiation and cyst formation detected.

Epidemiology

Although mucoepidermoid cancer is the most common malignant salivary gland tumor, it is, nonetheless a rarely diagnosed entity that can be estimated at approximately 1,000–2,000 new cases/year in the United States. In the majority of cases, no known environmental or inherited factors can be elicited. Prior radiation exposure, however, is a known susceptibility factor and an exceptionally strong radiation dose risk has been noted for this disease. In addition, mucoepidermoid cancer frequently presents as a second malignancy in children.

Etiology

Although several oncogenes had been previously implicated in a subset of these tumors, a major advance in understanding the biology of mucoepidermoid cancer was the detection of a reciprocal t(11;19) ►chromosomal translocation in several cases of salivary gland or pulmonary mucoepidermoid cancer. This led to the eventual mapping and identification of the chromosomal breakpoints which revealed the fusion of two new genes called Mect1 (also known as Torc1 and CRTC1) on chromosome 19p13 and Maml2 gene on chromosome 11q21. This oncogenic event fused 42 amino acids from exon 1 of the Mect1 gene with 981 amino acids from exons 2–5 of the Maml2 gene. Further evidence proving that this genetic event was pathogenic for cancer development was (i) the demonstration that Mect1-Maml2 could neoplastically transform rat epithelial cells and (ii) that blocking Mect1-Maml2 protein expression resulted in the selective killing of mucoepidermoid cancer cells but had no effect on non-mucoepidermoid salivary cells. The subsequent application of ►fluorescent in situ hybridization (►FISH) techniques on tumor biopsy sections or the application of ►RT-PCR techniques on RNA extracted from frozen or paraffin embedded material has demonstrated that 70–90% of well-differentiated mucoepidermoid salivary tumors are Mect1-Maml2 fusion positive while 0% of undifferentiated cancer were fusion-positive. This is the first evidence that high grade/undifferentiated mucoepidermoid cancer did not arise from well-differentiated tumors and, therefore, is biologically distinct should be classified as a separate disease entity. Although the biology underlying Mect1-Maml2 induced tumorigenicity is still unknown, a working model has been developed based on recent data showing that Mect1 is an essential co-activator of the ►CREB/cAMP

signaling pathway while the Maml2 gene is a human homologue of the drosophila Mastermind gene which regulates ►notch signaling pathways.

Staging Parameters

►Salivary gland tumors largely use the same TNM (tumor size-nodal status-metastasis status) system from the America Joint Committee on Cancer that is applied for other head and neck cancers. One important exception, however, is the T staging for tumors located within the head using both size criteria (T1-T3) as well as evidence for infiltration into local tissues and bone (T4a; T4b). In addition, as mentioned above, histological grading is an important parameter for assessing patient prognosis and treatment planning.

Treatment

Surgical resection with clear surgical margins is the primary treatment of choice for all subtypes of malignant ►salivary gland cancer, including mucoepidermoid cancer. In addition, cervical neck dissection is undertaken for cases where there is clinical, radiological, or pathological evidence demonstrating or suggesting cervical node involvement. Due to the small number of cases, the variability in tumor differentiation, the unpredictability of selected clinical cases, and the lack of randomized trials for this disease, the role of adjuvant treatments (►Adjuvant therapy) such as radiation and chemotherapy with cytotoxic or biological agents is unknown. Many clinicians include adjuvant radiotherapy for cases with positive or close tumor margins after resection, for large or locally infiltrating tumors (stages T3-T4), and for tumors that are scored as high grade or undifferentiated. The benefit of adjuvant chemotherapy is unknown. Similarly, the optimal management of recurrent disease is undefined and these cases are best managed in referral centers with access to surgical expertise and clinical trials.

Multicellular Layers

Definition

MCL, multilayered cell cultures, MCC; are planar aggregates of tumor cells grown on porous support membranes in culture medium which are a model for the extravascular compartment of solid tumors considered to more accurately reflect the tumor microenvironment than monolayer cultures. They have a very similar structure to multicellular spheroids often with regions of ►hypoxia and central necrosis due to diffusion limitations of oxygen, glucose and other nutrients. Their well-defined planar structure makes them very useful for drug transport studies. Some cell lines that do not grow as spheroids will grow as multilayers. They are more expensive than spheroids with lower throughput and are used mainly for drug transport and binding and drug effect studies.

►Hypoxia and tumor microenvironment
►Three-Dimensional Tissue Cultures

Multicellular Spheroids

Definition

MS, Spheroids, Multicellular tumor spheroids, MTS, MCTS; Spherical aggregates of cells grown in culture medium in liquid overlay of stirred suspensions. They are an in vitro model of avascular tumor nodules or micrometastases or the extravascular space of solid tumors and generally grow to a diameter of 100–220 μm similar to the maximum intercapillary region. They develop many features related to diffusion limitations of oxygen, glucose and other nutrients, including hypoxia and central necrosis and three dimensional interactions typical of tumors. They are simple and cost effective with a well defined spherical geometry and provide consistent results with many cell lines available. Not all cell lines grow as spheroids and they lack of cellular stroma and hence their extracellular matrix is not entirely typical of tumors. Spheroids do not incorporate tissue elements such as functional capillaries and do not evaluate therapeutic index in therapeutic studies. They have been used to study the effect of 3D structure, cell-cell and cell-extracellular matrix (ECM) interactions on tumor cell biology, gene expression, invasion, response to therapy, drug penetration, tumor markers, nutrient gradients, and tumor cell metabolism.

►Hypoxia and tumor microenvironment
►Three-Dimensional Tissue Cultures

Multidrug Resistance

Definition

MDR; Describes the phenomenon that cancer cells are simultaneously resistant against several structurally unrelated drugs, i.e., that these drugs are not effective in killing the cells. Several mechanisms have been recognized that cause multidrug resistance, including the presence of membrane transporters that affect accumulation of anticancer drugs in the cancer cells.

►ABC-Transporters
►Membrane Transporters
►P-Glycoprotein
►Fluoxetine

Multidrug Resistance Proteins

Definition

MRP; Are plasma membrane transporters and belong to subfamily C of ATP-binding cassette transporters. In terms of amino acid sequence similarity and substrate specificity, they are very distinct from ►P-glycoprotein, which is member 1 of subfamily B. Substrates of multidrug resistance proteins are organic anions or anionic conjugates of hydrophobic substances with glutathione, glucuronate, sulfate, or phosphate. Multidrug resistance proteins are efflux pumps localized in many cells and tissues including gastrointestinal and renal epithelia, hepatocytes, and blood–tissue barriers. They are essential for absorption, elimination, and detoxification of endogenous and ►xenobiotics. Because multidrug resistance proteins also function as anticancer drug efflux pumps, they are involved in conferring multidrug resistance to cells.

Synonyms

Multiple endocrine adenopathy type 1; MEN1; Wermer syndrome; WMEN1

Definition

►Multiple endocrine neoplasia type 1 (MEN1) is characterized by the combined occurrence of tumors of the parathyroids, pancreas, and pituitary, and is inherited as an autosomal dominant trait.

Characteristics

Multiple Endocrine Neoplasia type 1 is characterized by the combined occurrence of tumors (Table 1) of the ►parathyroid glands, ►pancreatic islet cells and ►anterior pituitary gland. Some patients may also develop adrenal cortical tumors, carcinoid tumors, facial angiofibromas, collagenomas and lipomas. MEN1 is inherited as an autosomal dominant disorder with a high degree of ►penetrance, such that >95% of patients develop clinical manifestations of the disorder by the fifth decade. The earliest age at which manifestations of MEN1 may occur has been reported to be 5 years. Parathyroid tumors, which lead to hypercalcemia (Table 1), are the most common feature of MEN1 and occur in about 95% of patients. Pancreatic islet cell tumors, which consist of gastrinomas, insulinomas, pancreatic polypeptidomas (PPomas), glucagonomas and vasoactive intestinal polypeptidomas (VIPomas) occur in about 40% of patients; and anterior pituitary tumors, which consist of prolactinomas, somatotrophinomas, corticotrophinomas or non-functioning adenomas,

Multiple Endocrine Neoplasia Type 1. Table 1 Multiple endocrine neoplasia type 1 (MEN1), its characteristic tumors and associated biochemical abnormalities

Tumors	Biochemical features
Parathyroids	Hypercalcemia and ↑ PTH
Pancreatic islets	
Gastrinoma	↑ Gastrin and ↑ basal gastric acid output
Insulinoma	Hypoglycemia and ↑ insulin
Glucagonoma	Glucose intolerance and ↑ glucagon
VIPoma	↑ VIP and WDHA
PPoma	↑ PP
Pituitary (anterior)	
Prolactinoma	Hyperprolactinemia
GH-secreting	↑ GH
ACTH-secreting	Hypercortisolemia nad ↑ ATCH
Non-functioning	Nil or α subunit
Associated tumors	
Adrenal cortical	Hypercortisolemia or primary hyperaldosteronism
Carcinoid	↑ 5-HIAA
Lipoma	Nil
Facial	
Angiofibromas	Nil
Collagenomas	Nil

Autosomal dominant inheritance of MEN1 has been established. Key: ↑, increased; PTH, parathyroid hormone; VIP, vasoactive intestinal peptide; WDHA, watery diarrhea, hypokalemia and achlorhydria; PP, pancreatic polypeptide; GH, growth hormone; ACTH, adrenocortcotrophin; 5-HIAA, 5-hydroxyindoleacetic acid.

occur in about 30% of patients. The clinical manifestations of MEN1 are generally related to their products of secretion and less frequently to their primary sites or metastasis. In the absence of treatment, MEN1 tumors result in an earlier mortality in patients.

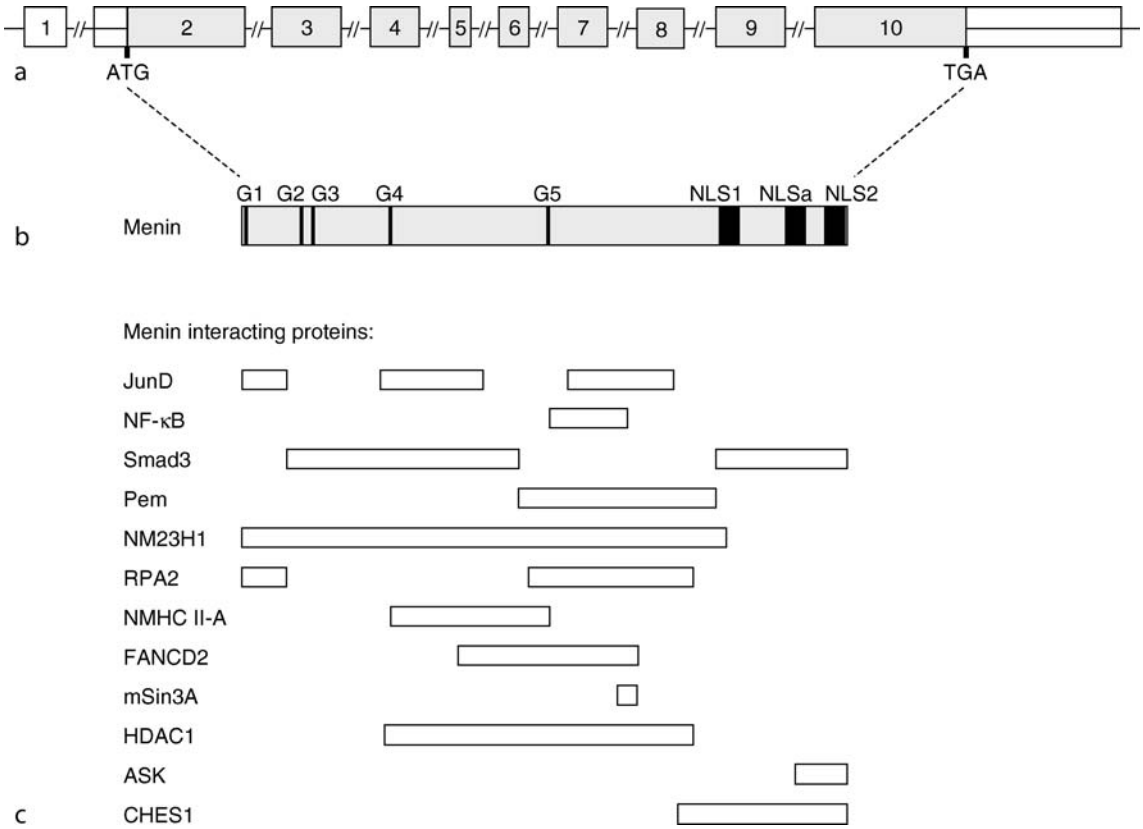
Genetics

The *MEN1* gene, which is a ►tumor-suppressor gene located on chromosome 11q13 was identified in 1997. It consists of ten ►exons (Fig. 1) that span ~>9 kb of genomic DNA and encodes a 610-amino acid protein referred to as menin. Mutations of the *MEN1* gene have been identified and the total number of mutations identified between 1997 and 2007 is 1,336. These 1,336 mutations comprise of 1,133 germline and 203 somatic mutations. The 1,133 independent *MEN1* germline mutations consist of 459 different germline mutations and the 203 somatic mutations, consist of 167 different mutations. Sixty-one of the germline mutations are also found to occur as somatic mutations, thus yielding 565 different *MEN1* mutations.

The 1,133 germline mutations are scattered throughout the entire 1,830 bp ►coding region and splice sites of the *MEN1* gene, and consist of 23% ►nonsense mutations, 9% splice site mutations, 41% ►frameshift deletions or insertions, 6% in-frame deletions or insertions, 20% ►missense mutations, and 1% whole or partial gene deletions. Several mutations recur in apparently unrelated kindreds, thereby indicating potential mutational hot spots. Mutations at four sites account for 12.3% of all mutations. These consist of a deletion at ►codons 83–84, a deletion at codons 210–211 and an insertion at ►codon 516, and a ►nonsense mutation Arg460Stop. The three deletional or insertional ►frameshift mutations occur in repetitive DNA sequences and this is consistent with a replication-slippage model of mutagenesis. Between 5% and 10% of MEN1 patients do not harbor mutations in the coding region or adjacent splice sites. Such MEN1 patients may harbor mutations in the ►promoter or ►untranslated regions, or ►introns, or they may represent phenocopies.

MEN1 Mutations in Hereditary Endocrine Disorders

The role of the *MEN1* gene in the etiology of other inherited endocrine disorders, in which either parathyroid or pituitary tumors occur as an isolated endocrinopathy, has been investigated by mutational analysis. *MEN1* mutations have been reported in 42 families with isolated hyperparathyroidism (FIHP) and 38% of these are missense mutations that are less likely to result in an inactivated protein. This contrasts significantly



Multiple Endocrine Neoplasia Type 1. Figure 1 Schematic representation of the genomic organization of the *MEN1* gene, its encoded protein (menin) and regions that interact with other proteins. (a) The human *MEN1* gene consists of ten exons that span more than 9 kb of genomic DNA and encodes a 610-amino acid protein. The start (ATG) and stop (TGA) codons in exons 2 and 10, respectively, are indicated. (b) Menin has three nuclear localization signals (NLSs) at codons 479–497 (NLS1), 546–572 (NLSa) and 588–608 (NLS2), indicated by closed boxes, and five putative guanosine triphosphatase (GTPase) sites (G1-G5) indicated by closed bars. (c) Menin regions that have been implicated in the binding to different interacting proteins (Table 2) are indicated by open boxes, below. The regions of menin that interact with GFAP, vimentin, Smad 1/5, Runx2, MLL-histone methyltransferase complex and estrogen receptor-alpha remain to be determined.

($p < 0.01$) with the situation in MEN1 patients in whom 20% are missense mutations. These observations are consistent with a more likely association between missense mutations and the milder FIHP variant, but it is important to note that the mutations associated with FIHP are also scattered throughout the coding region and not clustered, a situation that is similar to that found for germline *MEN1* mutations. Furthermore, the occurrence of protein-truncating mutations in FIHP patients and particularly deletions, such as the 4 bp, involving codons 83–84 which are identical to those observed in MEN1 patients, makes it difficult to establish an unequivocal phenotype/genotype correlation. However, the sole occurrence of parathyroid tumors is remarkable in FIHP families that harbor similar *MEN1* mutations as MEN1 families, and the mechanisms that determine the altered phenotypic expressions of these mutations remain to be elucidated. In addition, nonsense mutations (Tyr312Stop and Arg460Stop) have been detected in MEN1 families with the Burin or prolactinoma variant which is characterized by a high occurrence of prolactinomas and a low occurrence of gastrinomas. Furthermore, a splice site mutation (c.446–3C > G) has been detected in an MEN1 kindred from Tasmania, in whom there is an absence of somatotrophinomas. However, some other families with isolated acromegaly do not have abnormalities of the *MEN1* gene, even though segregation analysis and tumor deletion mapping have indicated that the gene is likely to be located on chromosome 11q13. Interestingly, mutations of the aryl hydrocarbon receptor interacting protein (*AIP*) gene, which is also located on chromosome 11q13 and 2.7 Mb telomeric to the

MEN1 gene, have been identified in some families with isolated acromegaly.

MEN1 Mutations in Sporadic Non-MEN1 Endocrine Tumors

Parathyroid, pancreatic islet cell, and anterior pituitary tumors may occur either as part of MEN1 or more commonly as sporadic, nonfamilial tumors. Tumors from patients with MEN1 have been observed to harbor the germline mutation together with a somatic loss of heterozygosity (LOH) involving chromosome 11q13 or point mutations, as expected from Knudson's model and the proposed role of the *MEN1* gene as a tumor suppressor. However, LOH involving chromosome 11q13, which is the location of *MEN1*, has also been observed in 5–50% of sporadic endocrine tumors, thus implicating the *MEN1* gene in the etiology of these tumors. Somatic *MEN1* mutations have been detected in ~20% of sporadic parathyroid tumors, ~40% of gastrinomas, ~15% of insulinomas, ~60% of VIPomas, ~15% of non-functioning pancreatic tumors, ~60% of glucagonomas, <5% of adrenal cortical tumors, ~35% of bronchial carcinoid tumors, <5% of anterior pituitary adenomas, ~10% of angiofibromas, and ~30% of lipomas. The 203 somatic mutations are scattered throughout the 1,830 bp coding region, and 18% are nonsense mutations, 40% are frameshift deletions or insertions, 6% are in-frame deletions or insertions, 7% are splice site mutations, and 29% are missense mutations. The tumors harboring a somatic *MEN1* mutation had chromosome 11q13 LOH as the other genetic abnormality, or "hit," consistent with Knudson's hypothesis. These findings indicate that inactivation of the *MEN1* gene has a role in the etiology of some sporadic endocrine tumors.

Function of the MEN1 Protein (Menin)

Menin, which is ubiquitously expresses, has three nuclear localization signals (NLSs) in its C-terminal segment. Subcellular localization studies have shown that menin is predominantly a nuclear protein in non-dividing cells, but in dividing cells it is found mainly in the cytoplasm. Studies of protein–protein interactions have revealed that menin interacts with several proteins involved in transcriptional regulation, genome stability, cell division and proliferation (Fig. 1, Table 2).

Mouse Models for MEN1

Mouse models for MEN1 have been generated through homologous recombination (i.e. knockout) of the mouse *Men1* gene. In all of these adult heterozygous *Men1* +/− mice, develop parathyroid tumors, pancreatic islet cell tumors, anterior pituitary tumors, and adrenal cortical tumors. Some *Men1* +/− mice have also developed tumors of the thyroid, testis, ovary, and mammary glands. Homozygous *Men1*−/− mice have been reported to die in utero at embryonic days 11.5–13.5. The *Men1*−/− mice are often developmentally delayed and smaller, develop craniofacial abnormalities that involve the BPM-2 signaling pathway, suffer from extensive hemorrhage and edema, and have abnormalities of the neural tube, heart, and liver. These results from the *Men1*−/− mice reveal an important role for the *MEN1* gene in the embryonic development of multiple organs.

Clinical Application

MEN1 is an uncommon disorder, but because of its autosomal dominant inheritance, the finding of MEN1 in a patient has important implications for other family members; first-degree relatives have about a 50% risk of development of the disease. Occasionally, MEN1 may arise sporadically (i.e. without a family history), although it may be difficult to make the distinction between sporadic and familial forms. In some cases, a family history may be absent because the parent with MEN1 is not available and may have already died before any manifestations developed, and other cases

may be due to de novo mutations, which will be transmitted in an autosomal dominant manner in future generations.

Screening for MEN1 in patients involves the detection of tumors and ascertainment of the germline genetic state, that is, normal or mutant gene carrier. Detection of tumors entails clinical, biochemical, and radiologic investigations for MEN1-associated tumors in patients. The characterization of the *MEN1* gene has facilitated identification of individuals who have mutations and hence a high risk of acquiring the disease.

Molecular genetic analysis for MEN1 either by detecting mutations or by performing segregation studies using linked markers is useful in identifying individuals who are mutant carriers and thus have a high risk of tumor development. The advantages of DNA analysis are that it requires a single blood sample and does not in theory need to be repeated because the analysis is independent of the age of the individual and provides an objective result. Such mutational analysis may be undertaken in children within the first decade because tumors have developed in some children by the age of 5 years, and appropriate intervention in the form of biochemical testing, or treatment, or both has been considered. An integrated program of both mutational analysis, to identify mutant gene carriers, and biochemical screening, to detect the development of tumors, has been shown to be of advantage and is used by many centers. Thus, a DNA test identifying an individual as a mutant gene carrier is likely to lead not to immediate medical or surgical treatment but to earlier and more frequent biochemical and radiologic screening, whereas a DNA result indicating that an individual is not at risk will lead to a decision for no further clinical investigations. Thus, the identification of *MEN1* mutations is of help in the clinical management of patients and their families with this disorder.

Synonyms

MEN 2; MEN II; MEA II; Sipple syndrome

Definition

MEN 2 is a syndrome of inherited susceptibility to tumors of endocrine cell types including the thyroid "C" cells, the adrenal medulla and the parathyroid glands. In some disease subtypes, developmental abnormalities may also be present. MEN 2 is caused by inherited mutations of the gene that encodes the RET receptor tyrosine kinase which lead to its unregulated activation. Subtypes of MEN 2 are: MEN 2A, MEN 2B, FMTC (familial medullary thyroid carcinoma).

Characteristics

The principal tumor in MEN 2 is medullary thyroid carcinoma (MTC), arising from the "C" cells of the thyroid (thyroid carcinogenesis), the normal function of which is to produce the hormone calcitonin. MEN 2 is an early onset tumor syndrome and MTC may first be detected in early childhood (in the MEN 2B subtype as early as the first weeks of life) but the age of appearance of symptoms varies. While nearly 100% of individuals who inherit the susceptibility mutation will have thyroid involvement, only about 70% will have clinically significant disease by the age of 70.

Tumors of the adrenal medulla (pheochromocytoma), and the parathyroid are less frequent, affecting roughly 50% and 10–30% of individuals, respectively. Pheochromocytomas are usually (but not always) benign, and cause their effects through overproduction of adrenaline and related substances, leading to high blood pressure. The parathyroid glands may be affected by diffuse enlargement (hyperplasia) or by benign tumors (adenoma). These are commonly silent but may have

clinical effects through overproduction of parathyroid hormone, leading to elevated blood calcium levels. In addition, some individuals with MEN 2 have associated developmental abnormalities that are characteristic of the clinical subtype (Table 1). Rarely, MEN 2 may also be associated with another rare presentation, Hirschsprung disease, a developmental abnormality in which nerve cells in the wall of the lower intestine are absent, resulting in impaired function of the gut.

Cellular and Molecular Disease Aspects

All forms of MEN 2 are caused by mutations that inappropriately activate the RET receptor tyrosine kinase. RET is a cell surface protein expressed primarily in cells that originate in the neural ectoderm and in genitourinary tissues. A number of distinct developmental functions have been identified to date including roles in development of the kidney, the autonomic nerves (►Autonomic Nervous System) in the gut, and endocrine tissues in the thyroid, parathyroid and adrenal glands, as well as in maturation of spermatogonia and maintenance of dopaminergic neurons. At various developmental times, and in different cell types, RET may promote cell proliferation, survival or migration. In normal cells, RET receives specific signals at the cell surface and conducts this information, along multiple signaling pathways, into the cell where it leads to changes in gene expression and thus cellular behavior. The signals are provided by binding of members of each of a family of cell surface receptors and a family of ligands, permitting tight control on the ability of RET to signal.

MEN 2 is caused primarily by single amino acid changes (point mutations) in RET that alter the properties of the protein and cause it to be constantly active without any ligand. The majority of mutations that activate RET affect one of a small number of amino acid hot spots and there is a general correlation between the specific mutation identified and the disease subtype (Fig. 1). The molecular effects of specific RET mutations vary and the differences in the relative enhancement of RET activity, coupled to differences in sensitivities of each tissue type to increased activity may in part explain the variation between MEN 2 subtypes. For example, the mutations that cause the strongest increase in RET signals are also associated with more aggressive disease and wider range of disease features. In rare cases, a group of RET mutations in codons 609, 611, 618 and 620 with relatively lower signaling ability (JANUS mutations) may be associated with both MEN 2A and with Hirschsprung disease.

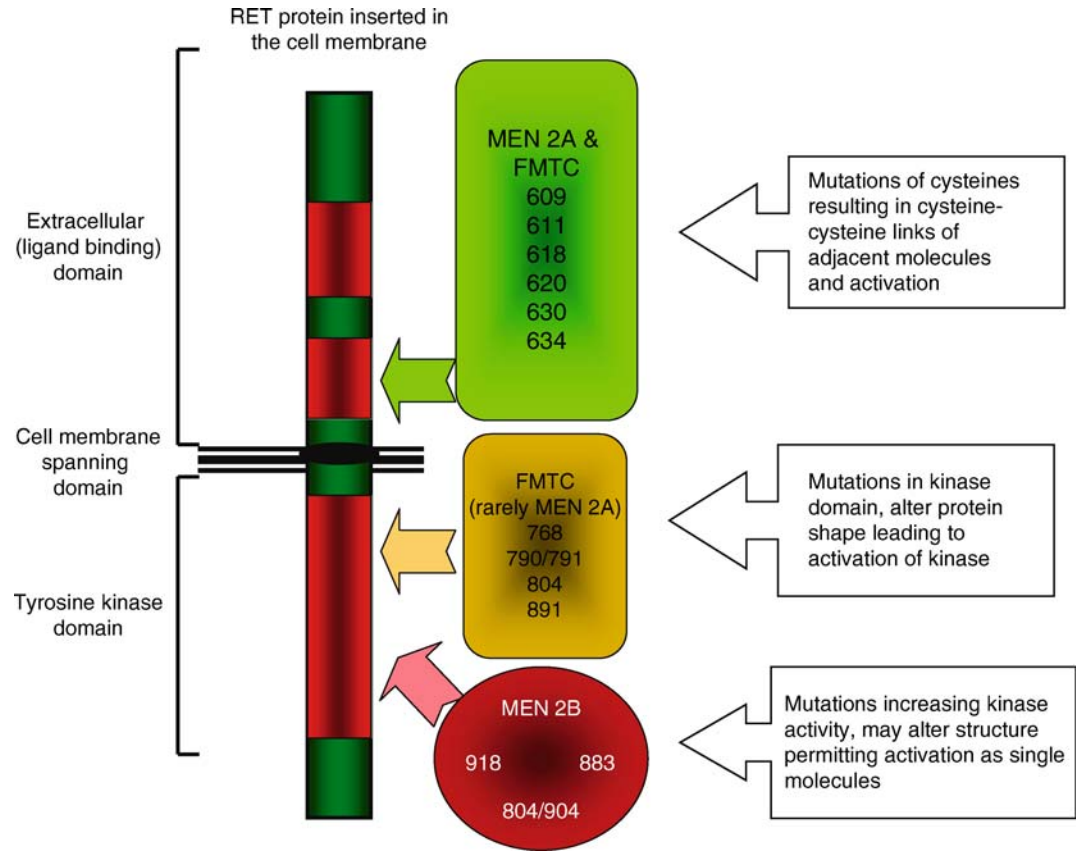
Clinical Aspects

MEN 2 is rare, with an estimated 20–25 new cases detected per year in the UK (population 55 million). However, it is important because early recognition and surgery is effective in preventing both deaths and unpleasant symptoms.

The tumors that are characteristic of MEN 2 can also occur, and more commonly, in a non-inherited form (sporadic tumors). A very young age at diagnosis, a family history of the disease, or pathology findings of multiple tumors or hyperplasias may suggest that a new patient has an inherited form of the disease (i.e. MEN 2). DNA testing for RET mutations is the accepted first investigation in suspected cases and confirms familial disease. In families with a history of MEN 2, mutation testing should be performed in early childhood to allow presymptomatic disease management. In general, prophylactic thyroidectomy is a straightforward and acceptable operation that is recommended in childhood to those who have an MEN 2 mutation. Adrenalectomy carries higher morbidity and is only recommended when there is evidence of developing adrenal disease.

Multiple Endocrine Neoplasia Type 2. Table 1 Clinical subtypes of MEN 2 and tissues

	MEN 2A	MEN 2B	FMTC
Thyroid C cells	Tumors	Tumors	Tumors
Adrenal medulla	Tumors	Tumors	Not involved
Parathyroid	Hyperplasia or tumor	Not involved	Not involved
Other	–	Skeletal abnormalities; overgrowth of nerve tissue in lips and conjunctiva leads to abnormal facial appearance, characteristic overgrowth with impaired function	–
Comments	Most common form (~85%)	Least common (~5%); earlier onset; impaired reproductive success; high proportion of isolated cases which represent “new” families	Intermediate frequency (~10%); later onset; generally less aggressive



Multiple Endocrine Neoplasia Type 2. Figure 1 MEN 2 associated mutations in the RET protein.

Although only a minority of tumors are part of the inherited syndrome, the identification of previously unrecognized RET mutations in supposedly "sporadic" cases of MTC and pheochromocytoma have led to recommendations for direct RET mutation testing for all individuals with these tumors. The presence of a mutation confirms heritable disease and has implications for further tumors in that individual or in family members. Absence of a mutation is strong evidence against inherited disease as more than 99% of cases have detectable RET mutations. If a mutation is found, other family members can be offered testing and those who test positive can be offered prophylactic surgery.

Multiple Hamartoma Syndrome

►Cowden Syndrome

Multiple Myeloma

Definition

A malignancy of circulating plasma cells.

►Minimal Residual Disease

Multiple Osteochondromas

Definition

MO; Autosomal dominant disorder characterized by the occurrence of multiple osteochondromas causing disproportionate short stature and bowing of the forearm. MO is genetically heterogeneous and is caused by mutations in the ►EXT-genes.

►Chondrosarcoma

Multiplex Profiling Technologies

Definition

Parallel measurement of numerous entities of given biomolecules (e.g. protein or DNA microarrays)

►Oncopeptidomics

Multipolar Spindles

Definition

Mitotic spindles having more than two poles. This causes chromosomes to segregate asymmetrically, and often chaotically, leaving daughter cells with abnormal numbers of chromosomes.

►Aneuploidy
►Genomic Imbalance

Multipotent

Definition

Able to give rise to more than one differentiated cell type.

Multipotent Stem Cells

Definition

Can only produce cells of a closely related family of cells (e.g., mesenchymal stem cells, hematopoietic stem cells).

►Adult Stem Cells

Multistep Development

George Klein
Microbiology, Tumor and Cell Biology, Karolinska Institute, Stockholm, Sweden

Definition

Multistep development is the stepwise development of malignant tumors by successive changes in multiple characteristics (Fig. 1).

Characteristics

Tumor development can be regarded as a Darwinian process, based on variation and selection. In the neoplastic microevolution, "survival of the fittest" means the successive emergence of increasingly emancipated subclones that are less and less restrained by the multifactorial growth controls of the organism.

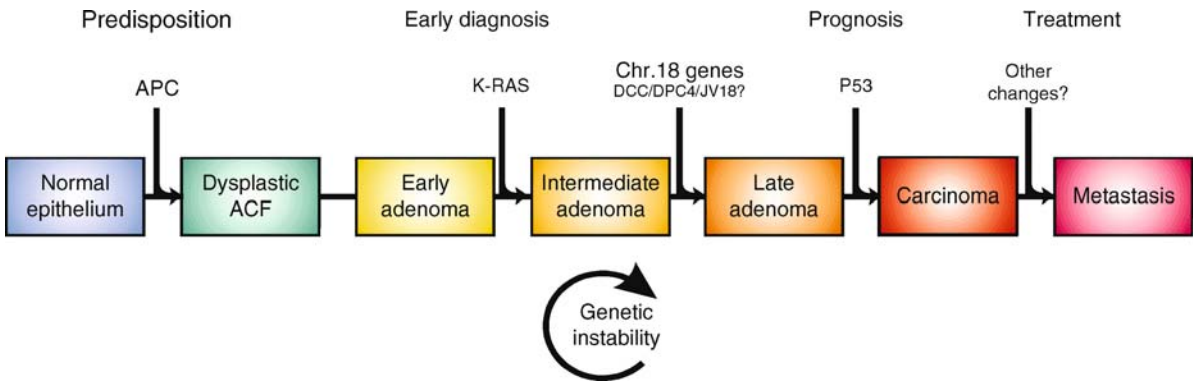
History

Epidemiological studies have shown that the incidence of cancer increases exponentially with age. The analysis of age incidence curves indicated that between three and seven mutations are required for full development of cancer. This is consistent with the modern molecular analysis. Carcinomas and sarcomas appear to require a larger number of changes than leukemias. In addition to changes in the DNA sequence that can be referred to as mutations, epigenetic changes, affecting gene expression, without any change in the DNA sequence, provide valid alternatives that may have the same or similar phenotypic consequences. MicroRNAs can also participate in the modification of gene expression.

Participating Genes

The major known categories are:

- Oncogenes that drive the cell towards an S-phase when activated



Multistep Development. Figure 1 Multistep pathway from normal cell to metastatic colon carcinoma. The rate-limiting step is postulated to be the loss of the APC gene on chromosome 5. Individuals with familial adenomatous polyposis (FAP) inherit the first mutation (APC gene) and only need to acquire a second mutation. Other individuals need to acquire both mutations in the same cell lineage. Additional genetic damage is accumulated, including loss of genes on 17p, exemplified p53 and 18q as well as other changes. These can occur in any order and result in progressively abnormal cells, eventually capable of metastasis (figure provided by Bert Vogelstein).

- Suppressor genes that can arrest the growth of illegitimately driven cells and contribute to tumor development when inactivated or deleted
- Genes that raise the apoptotic threshold when activated or genes required for the apoptotic process that contribute by their loss
- DNA repair genes whose dysfunction may create genetic instability

Genes that provide the ability for an interminable sequence of cell divisions (immortalization). Genes that influence invasion and metastasis.

Less well known genes may contribute to angiogenesis, hormone insensitivity and escape from immune rejection.

Minimum Requirements for Tumor Development

Genetic analysis of tumor development in many different tissues has created a scenario where transformation of a normal cell into a cancer cell requires the activation of at least one oncogene (e.g. myc, ras), the loss of one or several suppressor genes (e.g. ►RB, ►p53, ►p16, ►APC), activation of a gene that raises the apoptotic threshold (►Bcl-2) or, alternatively, the loss of genes required for apoptosis (e.g ►ARF or p53, ►Bax). It is a general rule, with few if any exceptions, that both the Rb and the p53 pathway is inactivated. They can be inactivated at different points, however. For instance, the p53 pathway can be crippled by p53 mutation, ARF deletion or MdM2 ►amplification. The Rb pathway can be inactivated by Rb mutation, p16 inactivation, usually by methylation (an epigenetic change), or the amplification of CDK4 or 6.

Highly immunogenic, DNA virus-associated tumors may escape rejection in immunodefective hosts. Cellular escapes may be due to the down regulation of rejection inducing tumor antigens or of presenting MHC class I proteins.

Successive steps in tumor development have now been defined as specific changes in DNA sequences or epigenetic changes affecting gene expression. The inactivation of tumor suppressor genes by either mutation or genetic loss, or by the dense hypermethylation of a CpG island at the 5′ end of the gene, an epigenetic change, may be responsible.

Distinct molecular events have been linked to progression related phenotypic changes in carcinomas of the colon and rectum, prostate, lung, breast, skin, in gliomas and tumors of the hemopoietic system. The loss of tumor antagonizing (growth arresting and/or apoptosis promoting) genes appears to be more frequent than the activation of proliferation-driving genes but this may be due, at least in part, to their easier detectability, e.g. by loss of heterozygosis (LOH). Microarray techniques that show gains or losses at the DNA level, changes in expression at the RNA level or specific methylation of the DNA in regulatory regions, provide different "signatures" that have diagnostic and prognostic significance and may give guidelines for therapy.

Colorectal tumors (►Colon cancer) progress through a series of well defined phenotypic changes, from hyperplasia, through different stages of adenomas, to malignant cancers. Two familial forms, hereditary non polyposis colon cancer (►HNPCC) and familial

adenomatous polyposis (FAP (►APC gene in familial adenomatous polyposis)) are initiated by germline mutations in mismatch repair genes in the former and the APC gene in the latter condition. The multifunctional APC protein is involved in cellular adhesion, signal transduction and apoptosis. The development of the hereditary forms of colorectal cancer is associated with the inactivation of the second allele and a series of sequential changes during somatic development. The latter are also found in the sporadic form. They include activation of Ki-ras, or N-ras (more: ►RAS), inactivation of both copies of p53 and loss of a gene on chromosome 18 that is identical with or closely linked to ►DCC. Later stages of progression are associated with extensive aneuploidy, particularly in the FAP, but less in the HNPCC based tumors. The changes do not occur in the same order in different tumors, confirming the notion of alternative pathways.

About 15–20% of ►breast cancers have a family history. About 5% can be attributed to dominant susceptibility genes. Two of them ►BRCA1 and ►BRCA2 are responsible for 40–50% and 30–40% of inherited breast cancers. The subsequent development and the biology of sporadic breast cancers is very diverse, indicating the existence of different progressional pathways. A gamut of growth factors and receptors (e.g. EGFR, ►HER-2/neu), signaling molecules (Ras, Src) and other intracellular growth regulators (e.g. Myc, Cyclin D) can be activated. Tumor suppressor genes (e.g. p53, RB) and adhesion molecules (e.g. cadherin) may be set out of function. Many as yet unidentified genes may be involved in addition, as indicated by the numerous LOHs. Amplification of HER-2/neu is a bad prognostic sign. However, the protein product of the amplified gene can be used as therapeutic target.

►Prostatic carcinoma provides a similarly diverse panorama. In addition to mutations of Ras, p53, ►RB1, CDKN2 and other known oncogenes and suppressor genes, cadherin down-regulation and LOHs affecting chromosomes 5, 6, 8, 10 and 16 have been detected. No single gene or chromosome region is affected in all prostatic carcinomas. Progression from hormone dependence to independence is often associated with the amplification of the androgen receptor gene on the X chromosome.

Lung cancer in heavy smokers (►Tobacco carcinogenesis) is often a multifocal disease. Deletions affecting the short arm of chromosome 3 are found already at the hyperplastic or dysplastic precursor stage. Subsequent progression may feature 5q deletions, K-ras mutations, p16 inactivation, ►FHIT, p53 or RB1 mutations. The deletions and rearrangements on chromosome 3 may become more extensive, affecting several genes within a cluster. During late stages of small cell lung cancer (SCLC) progression, amplification of the myc-family genes (c-, N-, or L-myc) is a bad prognostic sign.

►Astrocytomas show an increasing number of changes with ascending grade. The least aggressive forms show loss of wild type p53 and a number of LOHs. ►Glioblastoma, the most malignant form, has a large number of genetic abnormalities. They include losses from chromosomes 6, 10, 13 and Y, gains on chromosomes 7 and 19, and structural abnormalities of chromosomes 1 and 9. Frequent double minutes indicate gene amplification. Homozygous deletions on 9p, affecting the CDKN2A, CDKN2B (p15/16) and p14 ARF loci, are found in 40–50%. The inactivation of p15/16 deranges RB dependent cell-cycle control, whereas the deletion of the alternatively spliced p14 product of the same gene cripples the p53 dependent apoptotic pathway. Understandably, homozygous deletions of the p15-16-14 cluster is found in tumors that show no abnormalities of CDK4, RB1, MDM2 or p53 and vice versa. This illustrates the existence both of alternative pathways of progression, or more specifically alternative modes of inactivating the cell-cycle regulating and apoptosis controlling genetic systems. This can be further exemplified by the fact that 90% of the glioblastomas have either no wild type p16/p15 or wild type pRB1 or overexpress CDK4. In 75% of the glioblastomas, the apoptotic pathway is either inactivated by the lack of wild type p53, the inactivation of p14 ARF or over-expression of MDM2. Tumors with amplified MDM2 have two wild type p53 alleles. These examples illustrate how genetic aberrations may target different members in the same cellular control pathway and create similar phenotypes. Additional changes in glioblastomas include EGFR amplification and over-expression (35%) and allelic loss from chromosome 10 (90%), probably acting through the inactivation of PTEN/MMAC1 (>40%), a putative tumor suppressor that encodes a dual specificity phosphatase.

It is noteworthy that phenotypically different (angiogenic, non-invasive, and nongangiogenic, invasive) subclones could be selected from the same clonal glioblastoma that showed the same multiple DNA changes but expressed different genes on RNA arrays. This is another example to show that epigenetic differences may have a decisive impact on the phenotype of tumor cells with similar or identical DNA changes.

The hereditary form of ►renal carcinoma is often initiated by a mutation in the VHL gene at 3p26. The ►VHL gene is also frequently mutated in sporadic clear cell RCC. A cluster of genes at 3p21.3 are frequently deleted during tumor progression, both in the hereditary and the sporadic form. When an intact human

chromosome 3 is introduced into mouse tumor cells and the monochromosomal hybrids are grown in immunodefective mice, a corresponding region, designated as CER1 (commonly eliminated region 1) is regularly eliminated, indicating the presence of one or several tumor antagonizing genes. In contrast, a gene cluster at the telomeric end of the long arm (3q) is frequently retained and may be amplified.. Hereditary papillary renal cell carcinoma (HPRC) shows no association with chromosome 3 losses or VHL mutations.

In skin cancer (►Basal cell carcinoma), allelic losses in basal cell carcinomas are almost entirely confined to the Gorlin locus at 9q (►Gorlin syndrome). Squamous cell carcinomas show allelic losses in 25–30%, affecting chromosomes 3, 9, 13 and 17.

►Pancreas carcinoma shows a distinct profile. K-ras is activated in 90% of the tumors by point mutations in codon 12. Among the suppressor genes, p16, p53 and DPC4 are frequently inactivated, RB1 less frequently. DPC4 is biallelically inactivated in almost 50% of all pancreatic cancers, but only rarely affected in other tumors.

In endometrial cancer, microsatellite instability, K-ras, PTEN and p53 mutations are most common. p53 overexpression is correlated with poor prognosis.

In carcinoma of the uterine cervix (►Cervical cancer), the HPV (►Human papillomaviruses) encoded transforming proteins E6 and E7 play an important early role (early HPV proteins). This is at least partly due to their inactivating effect on p53 and RB1, respectively. This promotes genetic instability, counteracts apoptosis and abolishes part of the cell-cycle regulatory controls. In addition, amplification of myc and HER-2/neu, as well as loss of genes from chromosomes 1, 3, 5 and 11 may play important roles. 3p losses are particularly interesting, since the same regions are deleted in renal, lung and nasopharyngeal carcinomas.

In ►bladder cancer, chromosome losses are frequent. Monosomy of chromosome 9 is the most common abnormality. In addition, deletions are common on 9p, 17p and 13q. p53 and RB mutations are correlated with poor prognosis. Multiple primary tumors may be generated by the spread and further progression of a single progenitor clone.

Hepatocellular carcinoma (►Liver cancer, molecular biology) is initiated by the DNA virus hepatitis B virus (HBV). Sequential changes include p53 losses. The virally encoded transactivator HBV-X is believed to induce the overexpression of several oncogenes.

Hemopoietic tumors (►Hematological malignancies) are often initiated by chromosomal translocations, leading to gene fusions (in CML and a wide variety of childhood leukemias), juxtaposition of an oncogene to an Ig locus (B-cell lymphomas) or to a TCR locus (T-ALL). Sequential events affect mainly the apoptosis regulating systems, with up-regulation of bcl-2 or inactivation of p53, p19 ARF or BAX. In T-ALL, p16 may remain unaffected, whereas ARF is disrupted or deleted. In the absence of ARF, p53 usually remains in wild type configuration. A similar alternative inactivation has been found between p16 and RB, as in other tumors.

Clinical Relevance

For diagnosis, oncogene activation by chromosomal translocation, with or without gene fusion, is diagnostic for certain leukemias, lymphomas and sarcomas. For prognosis, the identity of the activated oncogene may be decisive for the biological behavior of the tumor. Oncogene amplification, a well defined step in the progression of carcinomas and gliomas, may be a bad prognostic sign; it is being used clinically to determine prognosis in ►neuroblastoma and is a parameter for therapy design.

Microarray techniques that can assess the DNA, RNA, methylation and protein profiles in tumors generate characteristic signatures that permit the division of diagnostic categories into subgroups, differing in prognosis and therapeutic sensitivity. They also provide targets for therapeutic approaches.

►Micrometastasis detection by antibodies and/or by molecular techniques, and the identification of residual, translocation carrying leukemia or sarcoma cells by polymerase chain reaction (PCR) are useful for the diagnosis of residual disease and for predicting the probability of recurrence. These parameters may also provide surrogate endpoints for the evaluation of new therapies.

Therapeutic choices are decisively influenced by the molecular findings. This can be exemplified by the identification of the genes involved in the translocations found in ALL and APML. Current therapeutic experimentation aims at the inhibition of pathologically activated signal transduction chains with small peptides, antibodies or DNA constructs. Faulty protein-protein interactions provide other important targets. It is not necessary to correct all genetic aberrations in tumors that have evolved by multiple steps. Inhibition of a dominating driving mechanism or, alternatively, induction of apoptosis may be sufficient.

Mutagen Sensitivity

Xifeng Wu
Department of Epidemiology, The University of Texas MD Anderson Cancer Center, Houston, TX, USA

Definition

Mutagen sensitivity is a phenotypic measurement that indirectly reflects an individual's ►DNA repair capacity (DRC). The typical test for mutagen sensitivity is measuring the number of ►chromatid breaks in short-term cultures of peripheral blood lymphocytes (PBLs) after exposure to ►bleomycin or other types of mutagens. The unit of measurement is the mean breaks per cell (b/c): the higher the number of b/c, the higher the mutagen sensitivity ►phenotype. High mutagen sensitivity has been consistently shown to be a ►genetic susceptibility factor for a variety of cancers.

Characteristics

Overview of Human DNA Repair System

All living organisms are equipped with DNA repair systems that deal with a wide variety of DNA lesions. In mammalians, the DNA repair system can be classified into four major pathways based on the specific DNA lesions that each pathway repairs: ►nucleotide excision repair (NER), ►base excision repair (BER), ►double strand break (DSB) repair, and mismatch repair (MMR). The NER mainly removes bulky DNA adducts, which are typically generated after exposure to environmental genotoxic agents such as ultraviolet (UV) light and benzo(*a*)pyrene (a tobacco carcinogen). The BER mainly copes with damaged DNA bases arising from endogenous oxidative and hydrolytic decay of DNA. The DSB repair pathway fixes double-strand breaks caused by a plethora of pathologic stimuli, including ionizing radiation, chemotherapeutic drugs, and free radicals. The MMR pathway eliminates base-base mismatches and insertion-deletion loops occurring as a consequence of DNA polymerase slippage during

DNA replication. Deficient DNA repair system has been convincingly associated with increased cancer risks in laboratory and epidemiologic studies.

Inter-Individual Variations in DNA Repair Capacity Within General Population

It has long been recognized that there is a wide spectrum of DRC within the general population. The majority of people have normal levels of DRC. At the extreme low end are individuals with rare genomic instability syndromes who exhibit severely compromised DNA repair system due to mutations in critical DNA repair genes. Two classic examples of such DNA repair deficiency syndromes are ►Xeroderma pigmentosum (XP) and Ataxia-telangiectasia (A-T). XP patients have mutations in XP genes, which are critical components of NER. Therefore, XP patients are extremely sensitive to UV-light due to defects in NER, which is the pathway responsible for repairing UV light-induced ►DNA damage. XP patients show abnormal pigmentation and freckling in sun-exposed skin, and they usually develop skin cancer at very young age. A-T patients, on the other hand, have mutations in ATM gene. One of the major functions of ►ATM protein is in DSB repair. Therefore, A-T patients exhibit hypersensitivity to ionizing radiation due to their inability to repair radiation-induced DSB and they have increased risk of developing cancer, such as lymphoma, leukemia, and breast cancer.

In addition to these rare individuals with genetic syndromes who are at the extreme low end of DRC, there are some individuals who are at the less extreme end with suboptimal DRC. Under normal physiological conditions, the suboptimal capability of DNA repair in these individuals may not be manifested, i.e., these individuals possess latent DNA repair deficiency and latent genetic instability. However, if exposed to high level of carcinogen, these individuals may reveal higher level of DNA damage and hence greater risk of developing cancer than general population who are similarly exposed but possess normal DRC. It would be of great public health and clinical importance to be able to identifying individuals with suboptimal DRC, who may belong to high-risk groups for cancer if they are exposed to high levels of environmental carcinogens, and may therefore be candidates for intensive monitoring and cancer prevention. Mutagen sensitivity is such a quantitative assay that indirectly measures DRC and the degree of genetic instability.

Development of Mutagen Sensitivity Assay

The mutagen sensitivity assay was developed about two decades ago by Hsu et al The theoretical basis for mutagen sensitivity assay is that latent genetic instability could be unmasked by mutagen challenge. Hsu et al hypothesized that in response to mutagen exposure, higher levels of genetic damage would accumulate in people with suboptimal DRC than in normal individuals. Therefore, the level of chromatid breaks induced by a mutagen challenge would reflect an individual's ability to repair DNA damage. The basic procedures of mutagen sensitivity assay include: culture PBLs or other somatic cells in vitro, add specific mutagen to cell culture and incubate for a few hours to a few days, block cells in metaphase, fix cells to slides, stain slides with Giemsa to visualize metaphase chromosomes, and count the number of chromatid breaks in 50 metaphases per slide under a microscope. The mean number of breaks/cell (b/c) is the quantitative measurement of mutagen sensitivity. Because genetic susceptibility factor should be present in all normal somatic cells, PBL is the most convenient material and have been the predominant choice of cell source for the assay. The reading of chromatid breaks under a microscope requires a certain level of technical expertise; however, the assay is reproducible within and between different experienced observers and different laboratories. The original mutagen sensitivity assay was developed using bleomycin as the mutagen challenge. The assay has since been expanded to employ other etiologically relevant mutagens to assess genetic susceptibility to different cancers, such as ►benzo[*a*]pyrene diol epoxide (BPDE), a metabolic product of benzo[*a*]pyrene (a tobacco mutagen), for smoking-related cancers; ►4-NQO, a UV-mimetic mutagen, and ►UV radiation, for skin cancer; and γ-radiation for breast cancer. By using different mutagens to induce different types of DNA damage, specific information can also be acquired about host susceptibility with regard to a specific DNA repair pathway. For example, BPDE forms bulky DNA adducts that are repaired by the NER pathway. By using BPDE as a mutagen challenge, relative DNA repair efficiency by NER pathway can be measured. On the other hand, γ-radiation is capable of inducing single- and double-stranded breaks and initiating BER and particularly DSB repair pathways. Furthermore, if using BPDE and γ-radiation in parallel, one can examine the activity of several DNA repair pathways and increase the power of predicting cancer risk compared to using only one variable.

Heritability of Mutagen Sensitivity

The mutagen sensitivity assay measures the cumulative effect of DNA damage and repair, which is a complex phenotype affected by many factors, including genetic, environmental, or pathologic factors. To use such a phenotype as a predictor of cancer risk in ►cancer epidemiology studies, one has to determine the degree

to which mutagen sensitivity phenotype is genetically inherited. A high genetic heritability would give more confidence that this phenotype is more likely to be the cause of the disease rather than the result of the disease. Several lines of evidences have strongly supported high genetic heritability of mutagen sensitivity phenotype. A few ►case control association studies showed that mutagen sensitivity remained a risk factor for cancer independent of demographic and environmental factors, suggesting genetic contributions. Several family studies found that the first-degree relatives of mutagen sensitive individuals were also mutagen sensitive. In one study of measuring radiation sensitivity in PBLs from families of breast cancer patients, 62% of the first-degree relatives of radiation sensitive patients exhibit sensitive phenotype; in contrast, only 7% of the first-degree relatives of patients with normal sensitivity exhibit sensitive phenotype. This observation strongly suggests high genetic inheritability of mutagen sensitivity phenotype. However, the most powerful method for assessing the genetic heritability of complex traits is the classical twin study design. The twin model, comparing similarities between monozygotic (MZ) twins (who are genetically identical) and dizygotic (DZ) twins (who share half their genes), can partition inter-individual variability into components reflecting genetic and environmental factors. The simplest and most straightforward estimation of genetic contribution in twin study is to compare the intra-class correlation among MZ twins and DZ twins. If mutagen sensitivity has high genetic heritability, it is expected that the intra-class correlation of mutagen sensitivity data within MZ pairs are significantly higher than within DZ pairs, because MZ pairs are genetically identical and DZ pairs only share half of their genes. Otherwise, if environmental factors play a dominant role in determining mutagen sensitivity, the intra-class correlation should be similar within MZ pairs and within DZ pairs. Indeed, three independent twin studies have shown that mutagen sensitivity have high genetic heritability. Furthermore, by applying sophisticated genetic modeling, the percentages of genetic contribution and environmental contribution have also been estimated. The genetic heritability of mutagen sensitivity ranges from 45 to 65%, depending on mutagen types. In addition, the contribution of non-shared environment is also substantial, accounting for 30–40% of the variations, whereas the contribution of shared environment was relatively small (generally <25%). It is apparent that while heritability varies to different mutagens, it plays the most prominent role in determining mutagen sensitivity for any mutagen evaluated. The non-shared and shared environments also contribute to mutagen sensitivity but to a lesser degree. It is understandable that different mutagens exhibit varying degrees of genetic heritability, since different mutagens elicit different DNA repair pathways that involve distinct gene sets.

High Mutagen Sensitivity is a Genetic Susceptibility Factor for Cancer Development

Almost a hundred epidemiologic studies have been published evaluating the association between mutagen sensitivity and cancer risk and there has been at least one positive study showing high mutagen sensitivity confers high risks for most of the major cancers, including cancers of lung, breast, prostate, bladder, colorectum, brain, skin, head and neck, and soft tissue. Most of these studies were ►retrospective studies with modest sample sizes. The largest retrospective case-control study evaluated almost 1,000 lung cancer patients and 1,000 healthy controls. The risk estimates conferred by higher mutagen sensitivity are in the range of 1.5- to 2.5-fold depending on what mutagen is used. In addition, high mutagen sensitivity has also been shown to confer increased risk of developing ►preneoplastic lesions, progression from preneoplastic lesions to cancer, and developing recurrence and/or secondary primary tumors. Moreover, high mutagen sensitivity can greatly increase the efficiency of predicting cancer risk when combined with epidemiologic risk factors, such as tobacco smoking and alcohol consumption in the case of head and neck cancer, and smoking and occupational exposure in the case of bladder cancer. High mutagen sensitivity can also increase prediction power of cancer development in the presence of other somatic genetic events. A recent ►prospective study measured baseline bleomycin sensitivity in PBLs from patients with Barrett's esophagus (BE), a precursor of esophageal adenocarcinoma (EAC), and found that higher bleomycin sensitivity was associated with a greater risk of developing ►aneuploidy and EAC, particularly in BE tissues with loss of heterogeneity of ►TP53 locus. It is promising that mutagen sensitivity measurement may find clinical application in identifying high-risk groups of cancer development in the context of a comprehensive risk-assessment model incorporating demographic, environmental, and other genetic predictors.

Mutagen sensitivity has emerged as one of the best-established phenotypic susceptibility markers for cancer risk over the past two decades. The epidemiologic evidence supporting its association with cancer risk is strong and consistent. The classical twin study has demonstrated its high heritability. The question of which genes is responsible for the mutagen sensitivity trait for each specific mutagen is currently under study. The identification of such genes will not only improve our understanding of the mechanism of mutagen sensitivity phenotype, but also provide novel candidate genetic markers for cancer risk assessment and cancer prevention.

Mutagenic

Definition

Mutagenic agents such as ionizing radiation or chemicals are able to induce genetic alterations, thereby, contributing to/inducing malignant transformation of cells and cancer development.

►Mutagen

Mutated in Multiple Advanced Cancers 1

Definition

MMAC1; sysnonym for ►PTEN

Mutation

Definition

Is a permanent, heritable change in the genetic information of a cell or organism that can be acquired or hereditary. It may involve an altered base sequence in DNA or a deletion or rearrangement of chromosomes. Mutations in genes are often associated with a different phenotype.

►Mutagen

Mutation Rate

David J. Araten
Assistant Professor of Hematology, NYU School of Medicine, NYU Cancer Institute, and the New York VA Medical Center, New York, NY, USA

Definition

The mutation rate is defined as the probability of a cell acquiring a mutation in a gene. This probability, abbreviated by the symbol "μ," depends on specific parameters, such as the cell type and the gene, the effect of the mutation (e.g. gain of function versus inactivation) and the nature of the event (e.g. point mutation versus translocation). Factors that influence μ include the fidelity of DNA polymerases, activity of repair pathways, and exposure to mutagens. μ can be expressed as the probability of a mutation occurring in a gene per cell division, as the probability of a mutation in a nucleotide pair per cell division, or as mutations per unit of time. A related parameter, the mutant frequency (f), represents the proportion of cells in a population harboring a mutation in a gene at any one point in time, whereas μ represents the rate of increase in f over time. Because μ is typically a low number, it can be measured only in a large number of cells, for which any measurement represents a population average.

Characteristics

One can consider the *somatic* mutation rate, but it is instructive to consider how this parallels the *germline* mutation rate. By determining the incidence of individuals born with mutations that are not inherited from either parent, the probability of a new mutation in a parental germ cell (or in the zygote) can be estimated. Germline mutation rates vary markedly, and can be as high as 10^{-4} per generation for the ►Neurofibromatosis 1 gene NF1, or orders of magnitude lower for other genes. Apart from genetic diseases, the germline mutation rate will influence the generation of genetic diversity within a population, a potentially advantageous phenomenon. In contrast, somatic mutations do not appear to have a physiologic role, apart from the generation of diversity in antigen receptors.

In a culture of microorganisms, there is no distinction between the germline and somatic mutation rates, and it was in bacteria that Luria and Delbruck provided the first measurement of μ, based on the rare spontaneous acquisition of resistance to the phage T1 (a consequence of *TonB* mutations). They set up multiple replicate liquid cultures, starting from a small number of phage-sensitive cells. After expansion to N cells per tube, the cultures were plated on a petri dish containing the phage, such that only phage resistant cells could form

colonies. They made the critical observation that the variance in the number of phage resistant colonies on the plates was very high, and they concluded that mutations occurring early in culture resulted in many resistant colonies, whereas later mutations produced fewer colonies. Some tubes gave rise to plates with no colonies, presumably because no mutations had occurred. They calculated the proportion of such tubes (P_o) and from the Poisson distribution, they derived a formula for the mutation rate, $\mu = -\text{Ln}\ (P_o)/N$, which they estimated to be 4.6×10^{-9} mutations per cell division (Table 1). They also derived an alternative formula for μ, $r = \mu N \ln(NC\mu)$, where r is the mean number of resistant colonies per tube and C is the number of replicate tubes. (This formula can not be directly solved, but μ can be estimated easily by computer using iterations).

An implication of this landmark work is that if μ is constant and there is no selection in favor or against mutants, over time, the frequency (*f*) of phage resistant mutants will increase linearly as a function of cell divisions (*d*), with a slope of μ (i.e. $\Delta f = \mu\ \Delta d$). This linear relationship was demonstrated experimentally by Novick and Szilard in 1950 using a method called a chemostat, which keeps bacteria growing in a bulk culture at a constant rate over many cell divisions. In 1954 Ryan and Wainwright used the chemostat to calculate μ, starting with a histidine-requiring (auxotrophic) strain. Over time, they sampled the bulk culture, measuring the frequency of cells that spontaneously regained the ability to grow on plates lacking histidine, due to a second (reversion) mutation. (For example, if the initial strain had a single base pair insertion in a gene required for histidine biosynthesis, a single base pair deletion in the same vicinity could restore the reading frame). They plotted *f* as a function of *d* and calculated μ from the slope of the curve, with an estimate of 8.5×10^{-9} mutations per cell division (Fig. 1).

Other genes in microorganisms were subsequently used as sentinels for spontaneous mutations. Inactivating mutations in the *LacI* repressor gene result in induction of β-galactosidase, producing blue bacterial colonies in the presence of X-gal. It is estimated that for *LacI*, $\mu = 4.5 \times 10^{-7}$ mutations per cell division. Similarly, in *S. cerevesiae*, inactivation of the *CAN1* gene (encoding arginine permease) confers resistance to canavanine, and it is estimated that $\mu = 3.5 \times 10^{-7}$ mutations per cell division in this gene. These values are notably higher than in the previous studies, probably because a broader spectrum of mutations can produce the phenotype. (As an illustration, consider that a broad spectrum of mutations can inactivate ►p53, whereas only one missense mutation can result in constitutive *Jak2* activation.) In 1991 Drake used this and other data to demonstrate that in microorganisms, μ seems to be inversely related to the size of the genome.

As in microorganisms, any potential human sentinel gene must not be essential for growth or survival, but, when mutated, must produce a readily detectable phenotype in a cell, which must be identified amongst a vastly larger population of normal cells. A further limitation in humans, though, is the diploid nature of the genome: a loss of function mutation is likely to be complemented by the remaining normal allele on the homologous chromosome, whereas the probability of both copies being mutated in the cell is so low as to preclude detection. Although a single *gain of function* mutation might produce a detectable phenotype in a dominant manner, as in the case of *Jak2*, these mutations are probably much rarer than inactivating mutations and thus may also elude detection.

One solution is to study inactivation mutations in a gene on the X-chromosome. Due to hemizygosity in males and X-inactivation in females, a *single* inactivating mutation can cause a loss of function in X-linked genes. Germline mutations in the *hprt* gene

Mutation Rate. Table 1 From Luria, Delbruck (1943) Genetics 28:49

× = # resistant colonies per culture	# Cultures with × resistant colonies	Po (proportion of cultures with zero mutants)	*N* = number of bacteria per culture	ln (Po)	μ = −ln(Po)/*N*

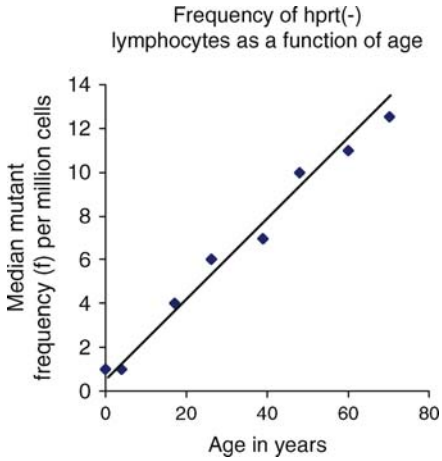
Mutation Rate. Figure 1 Mutant frequency as a function of cell divisions. Ryan and Wainwright grew histidine requiring bacteris in a single bulk culture using the chemostat technique, and the culture was periodically sampled to determine the frequency of reversion mutants that could grow on plates in the absence of histidine. The mutation rate is calculated as the slope of the linear regression curve, in this case 8.5×10^{-9} per cell division. Unlike fluctuation analysis, this method requires one bulk culture, rather than multiple cultures.



Mutation Rate. Figure 2 Median population f values for HPRT as a function of age. Green estimated that the slope of this curve is 1.95×10^{-7} mutations per year, and given estimates of the rate of cell divisions of circulating lymphocytes, estimated the mutation rate to be 8.4×10^{-7} mutations per cell division.

(Xq26–q27.2) result in Lesch-Nyhan syndrome and disrupt the purine salvage pathway, conferring resistance to 6-thioguanine (6-TG). Pioneering work by groups in Vermont and Australia demonstrated rare 6-TG-resistant mutants among the circulating lymphocytes of normal individuals, which harbor acquired mutations in *hprt* that are similar to those inherited by patients with Lesch-Nyhan syndrome. *f* can be calculated by limiting dilution cloning and dividing the cloning efficiency in the presence of 6-TG by the cloning efficiency in the absence of 6-TG. Using *hprt* as a sentinel, a wealth of information has been generated on the frequency and spectrum of spontaneous somatic mutations.

Since *hprt* mutations are growth-neutral, it is reasonable to expect that the mutant frequency in humans would increase with age, by a process reminiscent of the earlier experiments with the chemostat. By studying the mean *f* values for large populations, this has been shown to be the case (Fig. 2). The slope of the regression curve, 1.95×10^{-7}, represents the rate of new spontaneous inactivating mutations per year in *hprt*. Resting human lymphocytes are thought divide once every 4.3 years, so the mutation rate in the general population would be $\approx 8.4 \times 10^{-7}$ mutations per cell division. Fluctuation analysis has also been used to measure μ in *hprt*, with a somewhat lower estimate. Another approach applied to malignant cell lines has been to use HAT media to deplete *hprt* mutants, followed by growth of cells in bulk culture, and measuring *f* periodically by limiting dilution cloning. μ can then be calculated using a curve similar to Fig. 1.

Another X-linked gene, *PIG-A* (Xp22.1), has been used as a sentinel for spontaneous mutations. A broad spectrum of mutations in *PIG-A* can inactivate the function of the gene, resulting a loss of all glycosylphosphatidylinositol (GPI)-linked membrane proteins. This phenotype can be detected by flow cytometry, which can screen large number of cells for rare mutants and can also eliminate pre-existing mutants from a population. In bulk culture experiments similar to that of Ryan and Wainwright, μ in B-cell lines from normal individuals ranged from 3 to 29×10^{-7} mutations per cell division. In patients with the conditions ataxia-telangiectasia and ►Fanconi anemia, μ was shown to be elevated, as expected, given the predisposition to cancer and chromosomal abnormalities in these disorders. The factors that contribute to the variance in μ values in normal individuals has not been established, but may be due to differences in the activity of various repair pathways, involving not only ►ATM and the Fanconi anemia proteins, but also mdm and p53, base excision repair, nucleotide excision repair, and mismatch repair pathways, mechanisms for the inactivation of mutagens (such as endogenous anti-oxidants and glutathione S-transferase enzymes), and the fidelity of DNA polymerases.

Once a mutation has occurred in a given gene in one allele, the remaining allele can be inactivated by a second independent mutation (which will be determined by μ), or it can be lost by events that result in a loss heterozygosity (LOH), such as mitotic recombination,

gene conversion, and mitotic non-disjunction. Based on studies of heterozygotes for germline mutations in the *aprt* and Rb genes, and compound heterozygotes for HLA-A alleles, the rate of LOH events seems to be at least as high as μ itself – and in some situations considerably higher. Though the factors that influence LOH probably differ from those influencing μ, there may be an interaction between LOH events and μ. For example, in an individual with a heterozygous germline mutation in MLH1 (which is essential for mismatch repair and stability of microsatellite repeats), μ may be initially normal but then increase in the subset of cells that have undergone an LOH event that causes the normal allele to be lost. Conversely, CIN genes – which maintain chromosomal stability – could be inactivated by somatic mutations, the likelihood of which is determined by μ. The consequent increase in LOH events could then unmask the effects of previous mutations in genes – like MLH1 – that influence μ.

In 1991 L.A. Loeb proposed that an increase in μ is *indispensable* for malignant transformation. To paraphrase this reasoning, if f in the normal population is 10^{-5}, and the number of mutations required for transformation (n) = 5, then the probability of these five mutations all being present in the same cell would be $(10^{-5})^5 = 10^{-25}$. However, the number of cells in the body is only $\sim 10^{13}$, so cancer should be an exceedingly rare event. Since cancer instead is common, hypermutability must occur at some point in the generation of a malignancy. (Hypermutability could well explain the emergence of chemotherapy-resistance in clinical oncology.) To extend this reasoning, considering that the frequency of mutations in any gene would equal μd, where d represents the number of cell divisions since embryogenesis, we can estimate the probability (P) of n mutations being present in the same cell as = $(\mu d)^n$, where μ is the geometric mean mutation rate among different genes. This formula predicts that the higher the value for n, the greater the elevation in μ that would be required for malignant transformation.

The formula $P = (\mu d)^n$ also predicts that there would be a greater than linear increase in cancer risk with age (since d must increase with age) – very much in accordance with epidemiologic data. This formula also predicts that among individuals with different μ values, the probability of cancer will increase more than linearly as a function of μ. For example if $n = 5$, then an individual with an increase in μ that is twice normal will have a 32-fold increase in cancer risk. Since Knudsen originally proposed the ►two-hit hypothesis to explain the inheritance of retinoblastoma, common estimates of the value of n have increased. Hahn and Weinberg recently estimated n to be at least five, and preliminary data from the cancer genome project suggest that n may be as high as 15. Therefore, small variations in the mutation rate may be pivotal in determining an individuals' cancer risk. While this seems to be the case in special situations (e.g. Fanconi Anemia, ►Ataxia telangiectasia, inherited abnormalities in the mismatch repair and nucleotide excision pathways) the role of μ in cancer risk in the general population awaits epidemiologic confirmation.

Summary

The mutation rate is likely to be a critical parameter in carcinogenesis. μ may increase during the process of malignant transformation, a process where a related parameter, the rate of LOH events, may play a critical role as well. There are estimates of μ in humans (about 8×10^{-7} in *hprt* and $3–29 \times 10^{-7}$ in *PIG-A*), though most of the data on somatic mutagenesis in humans relates to f rather than μ. In contrast to bacteria and yeast, measuring f or μ is challenging in mammalian cells. Technical advances in the measurement of these parameters would facilitate investigations on genomic instability as a risk factor for malignancies.

Mutator Phenotype

Lawrence A. Loeb
University of Washington, Seattle, WA, USA

Definition

Mutator phenotype refers to the increase in mutation rate of cancer cells. The Mutator Phenotype Hypothesis was formulated to account for the disparity between the infrequency of spontaneous mutations in normal cells and the large numbers of mutations observed in human tumors. The hypothesis states that an increase in mutation rate is an early event in tumorigenesis. Some of the random mutations produced throughout

the genome are located in genes that normally function to guarantee the accurate transfer of genetic information with each cell division. The expression of this "mutator phenotype" leads to a cascade of mutations throughout the genome including mutations in other genes required for the maintenance of genetic stability. Among the many mutations produced are ones that promote growth, invasion and metastasis, the hallmarks of cancer.

Characteristics

Mutations and Cancer

The ability of cancer cells to continually mutate may be central to how tumors evolve. In the case of solid tumors, there is approximately a 20-year interval from the exposure of an individual to a carcinogen until the clinical detection of a tumor. During this interval, cancer cells acquire properties that allow them to flourish in a changing environment. By the time a tumor is detectable, the cancer cells are able to divide where normal cells do not, to invade adjacent cellular architectures, to metastasize and eventually to kill the host. In addition, tumors have the capacity to rapidly develop resistance to a variety of chemotherapeutic agents. Each of these phenotypes can be mimicked by mutations in normal cells.

Chromosomal Alterations in Human Cancers

Mutations can be defined as a change in the nucleotide sequence in DNA. Mutations in cancer cells cover a wide spectrum from chromosomal alterations that encompasses millions of nucleotides to point mutations that involve only a few nucleotide substitutions in single genes. Multiple somatic chromosomal alterations are diagnostically associated with cancer cells and involve translocations, deletions, amplifications and aneuploidy (a change in the number of chromosomes in individual cells). Unique chromosomal changes occur at high frequencies in certain tumors and are of diagnostic significance. However, there is a striking heterogeneity of chromosomal alterations in cancer cells within individual tumors. In general, there is a positive correlation between the number of chromosomal changes within a tumor and the malignant potential of that tumor. As molecular techniques are becoming more sensitive, more and more chromosomal abnormalities are being reported in different tumors. In some tumors there is evidence for a sequential order in chromosomal mutations during ►tumor progressions. Measurements of the number of copies of segments of the genome in tumor cells (DNA copy number) and the loss of pieces of DNA (►loss of heterozygosity) have established that many tumors harbor as many as 40 chromosomal alterations. It should be emphasized that these methodologies only score a very small fraction of the genome and as a result may greatly underestimate the number of small chromosomal rearrangements within the genome.

Point Mutations in Human Cancer

Only recently has evidence accumulated indicating that cancer cells not only contain multiple chromosomal alterations, but also contain thousands of smaller changes in nucleotide sequence. These studies have provided strong support of the mutator phenotype hypothesis involving a reduction in the fidelity of DNA replication and/or a decrease in the efficiency ►repair of DNA. An early clue to the large numbers of mutations in cancer cells was the observations that the resistance of cancer cell lines to divergent chemotherapies was mediated by gene ►amplification. The first direct evidence in support of a mutator phenotype in cancer was provided by the demonstration that cells from patients with ►HNPCC (hereditary non-polyposis colon cancer) exhibit ►microsatellite instability in association with mutations in DNA repair genes. Microsatellites are short repetitive sequences of nucleotides in DNA that are subjected to slippage during copying by DNA polymerases. In normal individuals, mutations in microsatellites are corrected by the DNA ►mismatch repair system. In HNPCC tumors, the deficits in mismatch repair result in expansions and contractions in the length of repetitive nucleotide sequences. Based on the enormous number of microsatellites in the human genome, it has been calculated that each tumor could harbor more than 100,000 mutations in these sequences alone. Repetitive sequences located within genes are also mutated at high frequencies in these tumors. Changes in the lengths of repetitive sequences have also been reported in a variety of tumors that are not known to be associated with mutations or deficiencies in mismatch repair, but may be associated with mutations in other genetic stability genes. Thus, repetitive sequences in DNA may be a "hot-spot" for mutagenesis and serve as a sentinel for the detection of a mutator phenotype in cancer.

Rarity of Spontaneous Mutations in Normal Cells

In normal cells, DNA replication and chromosomal segregation are accurate processes. Measurements of mutagenesis of cells grown in culture yield values of $\sim 2.0 \times 10–7$ mutations/haploid gene/cell division. Taking into account this very low frequency of mutations, it seems improbable that the spontaneous mutation rate is sufficient to generate the large numbers of genetic alterations that are observed in cancer cells. If one assumes that ►stem cells, which give rise to a cancer, have a similarly low rate of mutagenesis, then it can be calculated that the average stem cell would accumulate only one or two mutations during tumorigenesis. A few stem cells could accumulate as many as 12 mutations and thus account for the inactivation of ►tumor suppressor genes in ►retinoblastomas and other tumors. However, the

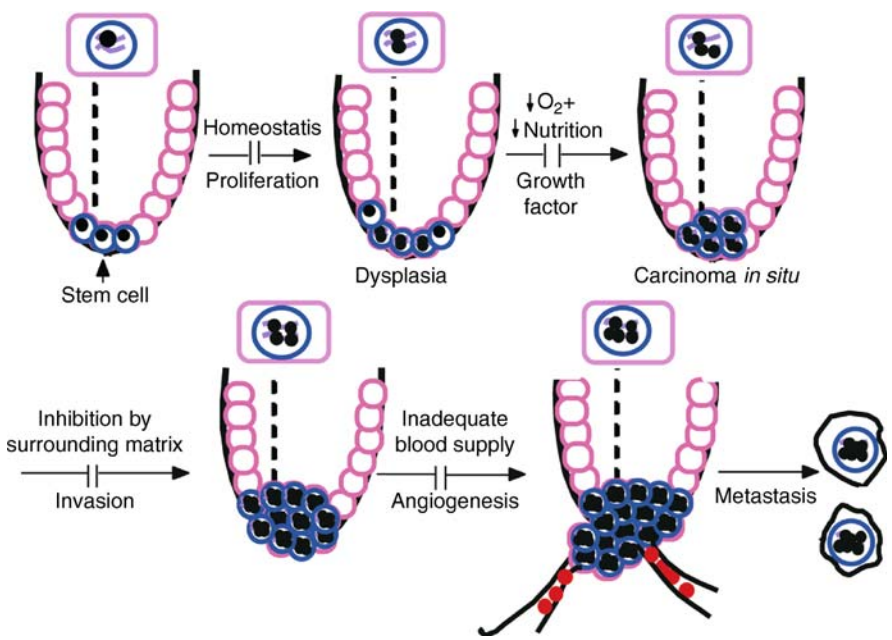
normal spontaneous mutation rate is inadequate to account for thousands of mutations observed in most tumors.

Historical Perspective

The hypothesis that cancer cells exhibit a mutator phenotype was proposed more than 25 years ago and was set forth on the postulate that there is an decrease in the accuracy of DNA synthesis during tumorigenesis. These random mutations could arise by mutations in DNA polymerases that render them error-prone during DNA synthesis or by mutations in DNA repair enzymes making them less efficient in correcting DNA damage or mistakes in incorporation by DNA polymerases. The production of more errors and/or their lack of repair could result in an increase in point mutations and, indirectly, in chromosomal aberrations in cancer cells. Further mutations in these genes would result in cascading numbers of mutations as tumor cells multiplied. Independently, Nowell postulated that cancer cells accumulate multiple mutations by successive rounds of clonal selection. Analysis was based on chromosomal changes in the evolution of human tumors. Leukemias with minimal chromosome changes were considered to be early in clonal evolution, while highly ►aneuploid solid tumors were considered to have undergone multiple rounds of clonal selection. Increases in both mutation rate and clonal selection could contribute to an increase in number of mutations in tumors. Studies in bacteria suggest that these mechanisms may reinforce one another. Sequential rounds of selection for different mutants yielded populations of bacteria that invariably contained mutations in genes that normally function to maintain genetic stability. The conclusion is that selection for mutant clones simultaneously enriches for mutations in genes that can produce the mutant clones. With successive rounds of selection there is increasing enrichment for cells that express a mutator phenotype.

Tumor Evolution

The ability of cancer cells to express a mutator phenotype provides a mechanism for tumor cells to circumvent the host's mechanisms that determine when cells divide and their position within tissues. As tumors expand, they encounter a sequence of restrictive blockages that curtail further expansion. As indicated in Fig. 1 impediments to expansion include the architecture of surrounding tissues, reduced nutrition, decreased oxygen, need for growth factors and inadequate blood supply. Each of these impediments can be overcome by the selective clonal expansion of cancer cells with mutations in genes that impart the required phenotypes. Some of these mutations could be selected from a population of cells harboring multiple mutations. Others could result from new mutations induced by additional mutations that



Mutator Phenotype. Figure 1 Accumulation of mutations during tumor proliferation. As each cancer enlarges it encounters barriers to further proliferation. Rare mutants within the tumor have the properties to escape these barriers and to permit clonal expansion. These mutants also contain mutations in DNA stability genes. Thus with repetitive selection for mutant cancer cells exhibiting specific properties there is simultaneous selection for mutators. This repetitive selection could be an important driving force in the establishment of a mutator phenotypein cancer.

render genetic stability genes error-prone. Thus, with each round of selection there would be a "piggy-backing" of mutations in genes that increase the overall mutation frequency in cancer cells. In order for a mutator phenotype to account for the many mutations in a cancer cells, it would have to be present early during the course of tumor progression. The continued expression of a mutator phenotype might not be compatible with the enhanced growth of cancer and thus may not be exhibited by cancer cells by the time a tumor is clinically apparent. Nevertheless, the footprints of its presence, multiple mutations, would persist in all cell descendents throughout the course of tumorigenesis (►multistep development).

Implications of a Mutator Phenotype

The multiplicity of mutations in cancer cells resulting from a mutator phenotype has implications with respect to pathogenesis, diagnosis, treatment and prevention of human cancer. The presence of large number of mutations in cancer cells implies that the malignant process is irreversible. Once a mutation occurs in a gene it is highly unlikely that a second mutation would occur at the same position to change the mutation back to the wildtype sequence. Also unlikely is the possibility that a second mutation would occur at a different loci and suppress the effects of the first mutation, particularly if the first mutation occurs at a tumor suppressor gene and inactivates that gene. Thus the concept of a mutator phenotype is not compatible with the hypotheses that cancer cells have the potential to differentiate into normal cells. The reports that certain tumors spontaneously regress does not necessarily indicate that these tumor cells have been transformed into normal cells. It is more likely to reflect the selective killing of tumor cells by normal host mechanisms that reject foreign cells.

The heterogeneity of mutations within a tumor provides a population of cancer cells harboring mutants that are resistant to a many chemotherapeutic agents. In addition, the mutator phenotype exhibited by many cancer cells allows them to continuously generate new mutant clones that are resistant to and proliferate in the presence of chemotherapy, immunotherapy and even radiation therapy. While such a scenario allows cancer cells to thwart many therapeutic protocols, it might offer new approaches to cancer therapy. It might be feasible to develop drugs that target the genetic instability of tumor cells. For example, nucleotide analogs can be designed that are preferentially incorporated into DNA by mutant error-prone DNA polymerases.

The large number of mutations in microsatellite sequences in cancer cells may facilitate the early detection of certain human malignancies. Rare tumor cells circulate, can be detected in the blood and could account for the hematological spread of tumor cells to distant sites. In addition, cancer cells in tumors frequently undergo cell death (apoptosis) and shed their DNA into the blood. Thus, methods can be developed for the detection of altered microsatellite sequences in DNA and cells in blood for the early detection of human malignancy and for calibrating the potential of tumors for metastatic dissemination.

If a mutator phenotype is rate-limiting for tumor progression, it is important to identify the agents and genes involved in its expression. Sources for a mutator phenotype such as mutant DNA polymerases, which are error-prone, or mutations in DNA repair enzymes are not easily corrected. Other sources might be more easily attenuated. Recent evidence indicates that cells contain a number of error-prone DNA polymerases that are induced by DNA damage, and it might be feasible to develop drugs to selectively inhibit these enzymes. More immediately open to experimental analysis is increased DNA damage by normal cellular metabolites, such as oxygen free radicals. These radicals can be scavenged by the administration of specific drugs and vitamins.

If a mutator phenotype constitutes a rate-limiting step for the development of a cancer it might be possible to prevent cancers by delay. Even a twofold reduction in the rate of accumulation of mutations in cancer cells might have profound effects on the age at which patients succumb to certain adult cancers. Consider primary hepatoma resulting from hepatitis virus B infection that occurs in early infancy and persists chronically (►Hepatitis Virus Associated Hepatocellulor Carcinoma). The persistence of chronic hepatitis in individuals increases the risk of subsequent hepatoma by more than 200-fold. It usually takes 40 additional years for the tumor to be clinically manifested. A reduction in the rate of mutation accumulation by only twofold could delay the clinical appearance of the tumor from age 50 to 90. It has been postulated that the persistence of hepatitis results in an inflammatory reaction with generation of oxygen free radicals. Thus, drugs that scavenge ►reactive oxygen species (ROS) might have a role in the prevention of primary hepatoma. It should be emphasized that prevention by delay does not affect the rate of initiation of the malignant process, but rather is directed at slowing down the rate of its progression. This approach may offer new direction to reducing the number of cancer-associated deaths.

►Microsatellite Instability

MUTYH-Associated Colorectal Polyposis

Jeremy P. Cheadle
Institute of Medical Genetics, Cardiff University, Heath Park, Cardiff, UK

Definition

MUTYH-associated polyposis; MAP: An autosomal recessive disorder caused by germline mutations in the base excision repair gene *MUTYH* and characterized by multiple colorectal adenomas and carcinomas.

Characteristics

Inherited Predisposition to Colorectal Cancer

Inherited factors are thought to play a major role in up to one third of colorectal cancers (CRCs), but only a minority of these can be accounted for by established CRC predisposition genes. Familial adenomatous polyposis (FAP) (MIM 175100) is an autosomal dominant disorder characterized by the development of hundreds or thousands of colorectal adenomas (CRAs), some of which progress to cancer. FAP is caused by inherited mutations in the adenomatous polyposis coli (*APC*) gene that acts as a gatekeeper regulating proliferation of colonic cells. A milder form of this disorder termed attenuated FAP (AFAP) is associated with smaller numbers of adenomas and is caused by germline mutations in the extreme 5′ or 3′ ends of *APC* or in the alternatively spliced region of exon 9. Hereditary nonpolyposis CRC (HNPCC; MIM 114500) is an autosomal dominant disorder characterized by early-onset CRC (in the absence of florid polyposis) and other extracolonic cancers and is caused by inherited deficiencies in the mismatch repair pathway.

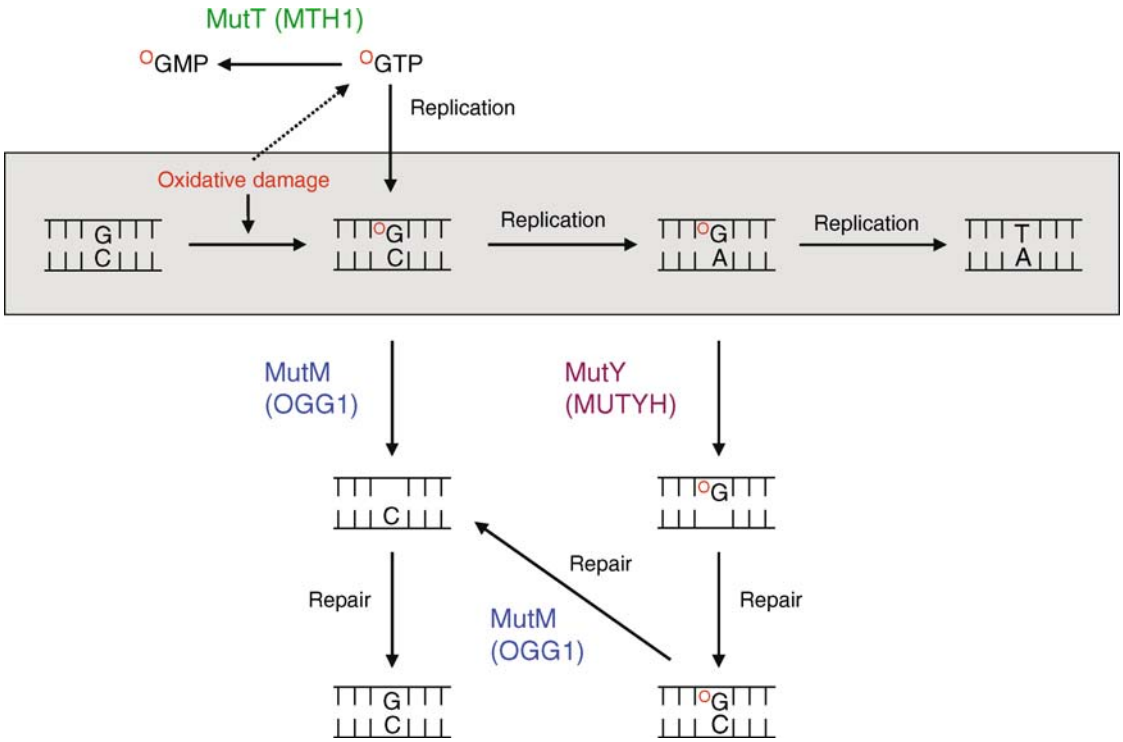
Identification of an Unusual (G:C→T:A) Mutator Phenotype in Family N

In 2002, Al-Tassan et al. [1] studied a British family (Family N) with three affected siblings with multiple CRAs and carcinoma. Sequencing of the entire *APC* gene open reading frame (ORF) in germline DNA samples from two of the affected siblings, together with haplotype and expression analyses, excluded an inherited *APC* gene defect. To provide a clue as to the underlying genetic defect, the investigators examined colorectal tumors from Family N. Sequencing of the *APC* ORF in each of the eleven tumors revealed eighteen somatic mutations, 15 of which were G:C→T:A transversions. This class of mutations accounts for only ~10% of reported somatic *APC* mutations which normally lead to inactivation of *APC* in colorectal tumors. Comparison of the findings in Family N with a database of somatic *APC* mutations from sporadic and FAP-associated colorectal tumors, confirmed that the excess of G:C→T:A transversions in Family N ("the mutator phenotype") was highly significant.

Reactive oxygen species generated during aerobic metabolism represent a potent source of DNA damage. 8-oxo-7,8-dihydro2′deoxyguanosine (8-oxoG) is the most stable product of oxidative DNA damage and readily mispairs with adenines, leading to G:C→T:A mutations in repair-deficient bacteria and yeast. In *Escherichia coli*, three enzymes help protect cells against the mutagenic effects of guanine oxidation. The base excision repair (BER) DNA glycosylase MutM removes the oxidized base from 8-oxoG:C base pairs in duplex DNA, the BER DNA glycosylase MutY excises adenines misincorporated opposite unrepaired 8-oxoG during replication, and the 8-oxo-dGTPase MutT prevents the incorporation of 8-oxo-dGMP into nascent DNA (Fig. 1). Homologues of *mutM*, *mutY* and *mutT* have been identified in human cells and termed *OGG1*, *MUTYH* (*MYH*) and *MTH1*, respectively.

Inherited Mutations in *MUTYH* Predispose to Colorectal Tumors

To determine whether an inherited defect in the 8-oxoG repair pathway was responsible for the pattern of



***MUTYH*-Associated Colorectal Polyposis. Figure 1** The 8-oxoG repair system in *E.coli*. MutT (human orthologue MTH1), an 8-oxo-dGTPase, prevents the incorporation of 8-oxo-dGMP into nascent DNA, MutM (human orthologue OGG1) DNA glycosylase removes the oxidized base from 8-oxoG:C base pairs in duplex DNA, and MutY (human orthologue *MUTYH*) DNA glycosylase excises A residues misincorporated opposite unrepaired 8-oxoG during replication. 8-oxoG readily mispairs with A residues, leading to G:C→T:A mutations in MutM and MutY-deficient bacteria (gray box). 8-oxoG is denoted by °G.

somatic G:C→T:A mutations in Family N, Al-Tassan et al. [1] sequenced the ORFs of *OGG1*, *MUTYH* and *MTH1* in a blood DNA sample from an affected sibling. Two non-conservative amino acid variants were identified in *MUTYH* (Y165C and G382D), but no likely pathogenic changes were identified in *OGG1* or *MTH1*. All three affected siblings from Family N were found to be compound heterozygotes for Y165C and G382D, suggesting transmission as an autosomal recessive trait.

In a follow up study, the investigators identified seven further unrelated patients with multiple CRAs (six with CRC) and biallelic germline *MUTYH* mutations, including four cases homozygous for truncating mutations. Again, colorectal tumors from the affected individuals displayed a highly significant excess of somatic G:C→T:A mutations in *APC*, as compared to sporadic or FAP-associated colorectal tumors. These findings supported the role of biallelic inherited mutations in *MUTYH* in causing an AFAP-like syndrome characterized by multiple CRA and CRC. This disorder has been termed *MUTYH*-associated polyposis (MAP).

The Pathway of MAP Tumorigenesis

Consistent with the G:C→T:A mutator phenotype observed in *APC*, a proportion of MAP adenomas show a specific, activating missense mutation of *K-ras* (G12C) that also results from a G:C→T:A transversion. Established genetic pathways of CRC development include those associated with microsatellite instability (MSI) and chromosomal instability (CIN). MSI is not a feature of MAP tumors. The role of CIN in MAP-associated tumors is unclear; some investigators have reported that MAP tumors appear to be near diploid whereas others have shown that up to 80% of MAP polyps are aneuploid.

The Phenotype of MAP

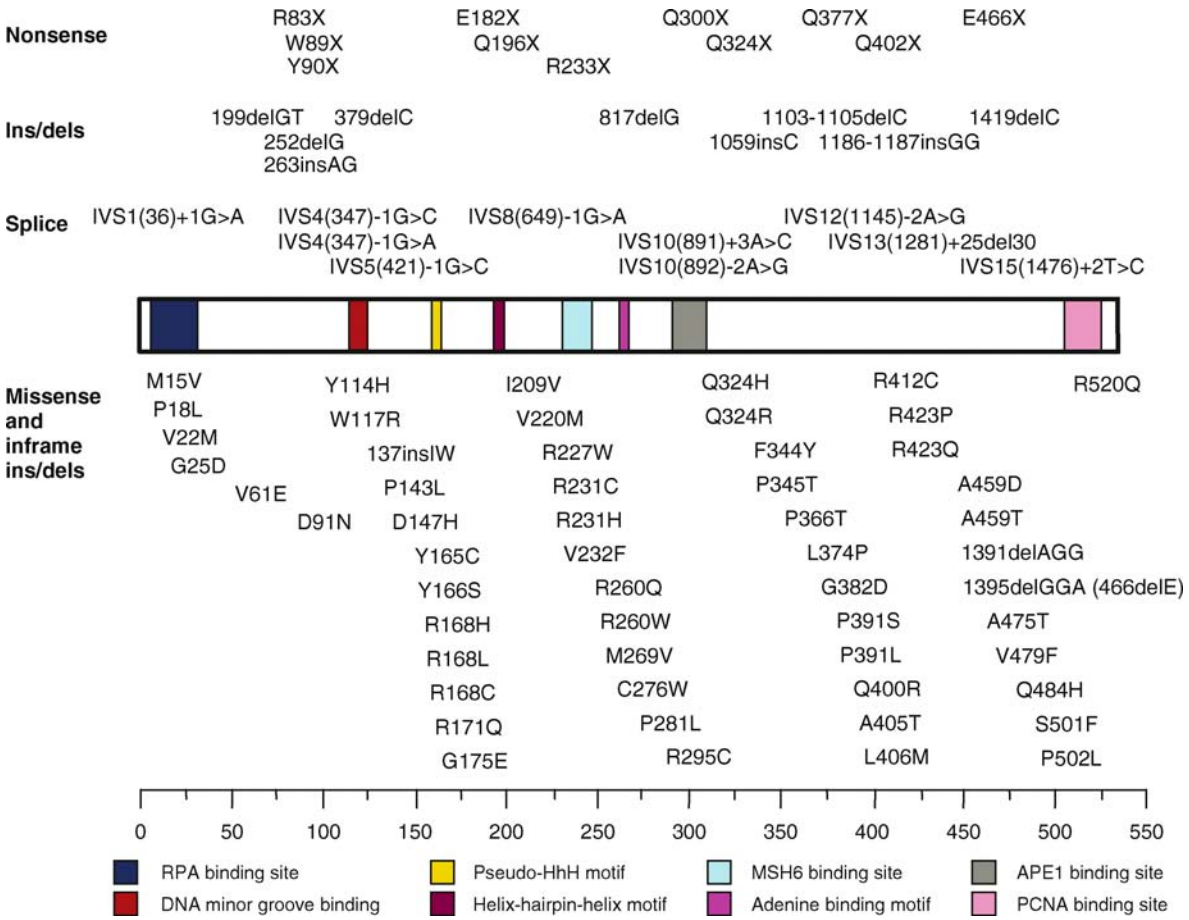
Mutation analysis of *MUTYH* has now been undertaken in several series of patients with FAP-like and AFAP-like phenotypes and in whom no inherited *APC* mutation could be identified. Biallelic *MUTYH* mutations have been identified in a quarter of such cases and, in general, segregation has been consistent with transmission of MAP as an autosomal recessive trait with high/complete penetrance. The colorectal

phenotype of MAP closely resembles AFAP (10–100 adenomas), or FAP (100–1,000 adenomas), but not severe FAP (>1,000 adenomas). In addition, some cases appear to develop fewer than ten macroscopic adenomas by middle age and to have developed CRC in the absence of obvious polyposis. As expected for a recessive trait, many cases appear to be sporadic and hence present symptomatically.

A possible explanation for the predominantly colorectal phenotype in MAP is the high level of oxidative damage that occurs in the large bowel. An alternative or additional factor was proposed after examination of the target sequence surrounding the somatic G:C→T:A mutations in MAP tumors – the two bases immediately 3′ to the mutated G are almost always AA and this preponderance of G:C→T:A mutations at GAA sequences is highly significant. *APC*, the key gatekeeper in colorectal tumorigenesis, has a total of 216 GAA sites in which G:C→T:A mutations could lead to termination codons. By comparison, gatekeeper genes for other tissues have significantly fewer target sites and therefore *APC* may be a particularly vulnerable target for mutagenesis in MAP.

MUTYH Mutation Spectrum

As of November 2006, 30 mutations that are predicted to truncate the protein product have been reported in *MUTYH*, comprising eleven nonsense, nine small insertion/deletions and ten splice site variants (Fig. 2). In addition, 52 missense variants and 3 small inframe insertion/deletions have been reported that are distributed throughout the gene. Although there is



***MUTYH*-Associated Colorectal Polyposis. Figure 2** Spectrum and distribution of truncating mutations and missense/inframe insertion/deletion variants identified in *MUTYH* (as of November 2006). Approximate positions of putative functional domains are indicated in relation to the *MUTYH* coding region (The N-terminal domain of *MUTYH* contains the catalytic region and shares several motifs with other BER glycosylases, including the helix-hairpin-helix (HhH), pseudo HhH and the iron–sulfur cluster loop motif and the C-terminal domain plays a role in 8-oxoG recognition. *MUTYH* has also been shown to interact with AP endonuclease, PCNA, RPA and the MMR heterodimer MSH2/MSH6 via MSH6).

some reporting bias, the missense variants Y165C and G382D together account for ~73% of all *MUTYH* mutations reported to-date, and have been identified commonly in the British, Italian, American, Portuguese and Dutch populations. In addition, specific mutations in *MUTYH* have been identified in different populations and diagnostic screening strategies will have to be optimized accordingly. Apart from Y165C and G382D, most missense variants are rare; however, their collective frequency and the lack of functional data for the vast majority pose major difficulties for molecular diagnostics since many will be benign polymorphisms.

Genetic Testing and Clinical Management of MAP

Genetic testing of *MUTYH* in patients with phenotypic features suggestive of MAP is essential in planning for the surveillance needs in the extended family. MAP must be distinguished from FAP/AFAP as it is the siblings, rather than offspring of MAP cases who are most likely to require further investigation. Genetic testing can be used to identify those siblings of MAP cases who are at risk and also to clarify the genetic status of spouses of those with biallelic mutations so that their offspring can be counseled accurately. Since polyp number may be very low or even zero in cases with CRC and biallelic *MUTYH* mutations, some researchers have suggested wider testing for *MUTYH* among incident CRC cases.

We recommend annual or biennial colonoscopic surveillance for individuals with biallelic *MUTYH* mutations, commencing by 20 years of age. Although duodenal adenomas have been reported in some MAP patients, the case for upper gastrointestinal tract surveillance is unclear and there is currently no evidence for screening of other organs. Surgical options for colorectal disease need to be tailored to the individual patient, since tumor burden can apparently vary from a count of one to many hundred.

MYB

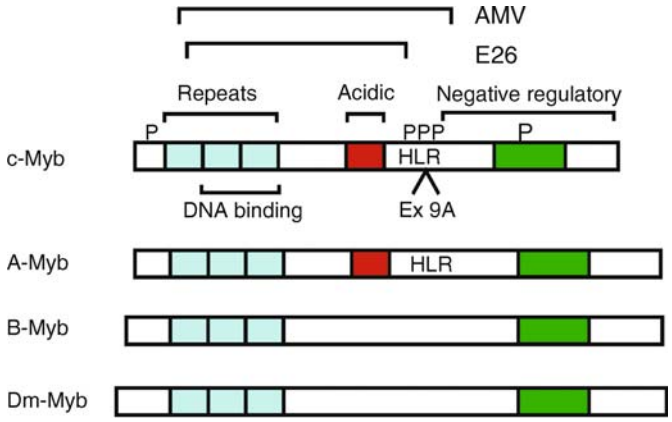
Joseph Lipsick
Stanford University, Stanford, CA, USA

Definition

MYB is a family of genes related to the C-MYB proto-oncogene. The name of this gene comes from myeloblastosis, the type of leukemia caused by the V-MYB viral oncogene in chickens. All vertebrates contain three related MYB genes, C-MYB (MYB), A-MYB (MYBL1), and B-MYB (MYBL2). The fruit fly and sea urchin have only one closely related MYB gene, whereas the nematode *C. elegans* appears to have lost the MYB gene during evolution. Other more distantly related MYB-like genes are present in animals, plants, and fungi (Fig. 1).

Characteristics

The MYB gene family was first discovered because the avian myeloblastosis virus, a ►retrovirus that causes acute myelogenous leukemia in chickens, contains V-MYB. Like most other retroviral ►oncogenes, V-MYB represents an altered form of a normal cellular ►proto-oncogene, namely C-MYB. A second leukemia virus in chickens, the E26 erythroleukemia virus, contains both V-MYB and another oncogene of cellular origin, V-ETS (►ETS transcription factors). Furthermore, retroviruses without oncogenes can cause leukemias and lymphomas in chickens and in mice by insertion of the virus into the C-MYB proto-oncogene. Consistent with the role of V-MYB and



MYB. Figure 1 Animal Myb Proteins. The brackets next to AMV and E26 indicate the portion of C-MYB encoded by the V-MYB oncogenes of these retroviruses. The shaded boxes indicate the most highly conserved domains. HLR indicates a heptad leucine repeat. Ex 9A indicates the position of an alternatively spliced exon in C-MYB. P indicates a known phosphorylation site. Dm-Myb indicates Drosophila MYB.

altered forms of C-MYB in causing cancers of blood cells (leukemia and lymphoma), mice that lack a functional C-MYB gene die as embryos because they fail to produce blood cells. The normal C-MYB gene is turned on (expressed) in immature blood cells and then turns off as these blood cells mature (differentiate). C-MYB is also expressed in immature cells in other tissues including skin, gut and lung, but these tissues appear to develop normally in mouse embryos that lack a functional C-MYB gene. Recent studies have shown that C-MYB is required for the maintenance of normal of gut epithelium in the mouse.

Like C-MYB, the expression of A-MYB is limited to particular tissues and cell types including testes, brain, mammary gland, and germinal center B lymphocytes. Mice that lack a functional A-MYB gene survive to adulthood. However, the males do not produce functional sperm. The females are fertile but their mammary glands do not proliferate in response to pregnancy. Mice that express too much A-MYB develop an abnormal proliferation of germinal center B lymphocytes.

The B-MYB gene appears to be expressed in all dividing cells in vertebrates. Mice that lack a functional B-MYB gene die very early in embryogenesis, with a severe defect in cell proliferation. The single MYB gene of sea urchins and fruit flies most closely resembles the B-MYB gene of vertebrates. This observation suggests that the more specialized A-MYB and C-MYB genes arose more recently by gene duplication and divergence during the evolution of vertebrates.

All the proteins encoded by these MYB genes contain a very similar domain near the amino terminus that binds directly to a specific DNA sequence (AACNG). This DNA-binding domain itself is composed of three tandem repeats of a ~50 amino acid protein sequence. Sequences similar to these Myb protein repeats are also present in a number of proteins that regulate the structure of chromatin and chromosomes including SWI3, ADA2, and the major telomere (►Telomerase) binding proteins of animals, plants and fungi.

All the Myb proteins of animals also contain a conserved domain near the carboxyl terminus that appears to act as a regulatory switch to control protein function. The A-Myb and C-Myb proteins contain an additional central domain that includes an acidic region and a heptad leucine repeat. This central domain causes other genes to be activated when these Myb proteins bind to them. A similar central domain is not present in B-Myb or the Myb proteins of invertebrates, although these proteins have nevertheless been reported to activate or repress the expression of various genes.

Cellular and Molecular Regulation

The regulation of B-MYB gene expression is fairly well understood. B-MYB is off when cells are not engaged in the division cycle and is turned on just before actively dividing cells begin to synthesize new DNA (S phase). The expression of the B-MYB gene is directly regulated by a critical cellular pathway that includes the p16/Ink4a tumor suppressor gene product, the ►cyclin D oncogene product, the p107/p130 relatives of the RB (►RB1) tumor suppressor gene and the ►E2F transcription factor. This pathway keeps the B-MYB gene off until late in the G1 phase of the cell cycle. B-MYB is then turned on at the same time as many genes that encode proteins essential for DNA replication. The regulation of the C-MYB gene appears to be similar to that of B-MYB, but its expression is limited to particular cell types. In contrast,

the expression of A-MYB does not appear to be similarly regulated during the cell cycle.

The amino and carboxyl termini of C-Myb protein are critical for its normal regulation. Both the V-Myb protein of the avian myeloblastosis virus (AMV) and the V-Myb-Ets fusion protein of the avian E26 leukemia virus (E26) have truncations of both termini of C-Myb. Experiments with recombinant retroviruses have shown that these truncations are important for activating the oncogenic potential of the C-Myb protein. In addition, retroviral insertions into C-MYB that cause leukemias and lymphomas in mice and birds also result in the production of truncated versions of the C-Myb protein. Although both C-Myb and V-Myb can regulate the expression of a number of other genes, in most cases the role of these "target" genes in oncogenesis remains unclear. One exception is the abnormal indirect activation of a growth factor gene by V-Myb that clearly promotes the growth of leukemic cells.

The C-Myb protein can be phosphorylated by a number of protein kinases including casein kinase II, glycogen synthase kinase III and MAP kinase. An indirect regulation of the C-Myb protein via the pim-1 protein kinase has also been proposed, as has a direct regulation of the Myb DNA-binding domain by prolyl isomerases. The B-Myb protein can be phosphorylated by the cyclin A-CDK2 protein kinase during S phase. However, the physiologic relevance of these suggested modes of regulation remain unclear, pending appropriate genetic analyses.

Recent studies have shown that Drosophila Myb protein, the ortholog of vertebrate B-Myb, is present in a large multiprotein complex that includes homologues of Rb, a repressor E2F, DP, a histone deacetylase, and a number of other nuclear proteins. Previous studies in C elegans showed that the genes encoding many of these Myb-associated proteins (synMuvB genes) inhibit signaling by activated tyrosine kinase receptors via the RAS pathway.

Interestingly, the loss of Drosophila Myb has been shown to result in alterations in chromosome condensation, spindle assembly, and ploidy. Because vertebrate B-Myb can complement Drosophila Myb null mutants in some cell types, it seems likely that B-Myb may play a similar role in regulating mitosis, a hypothesis supported by the recent characterization of a zebrafish mutant of B-Myb. The role of other Myb-associated proteins in these processes remains to be investigated.

Clinical Aspects

Until recently, the MYB genes had not been identified as targets of frequent and consistent chromosomal translocations, gene amplifications or point mutations in human cancers. However, recent studies have identified consistent chromosomal translocations and gene duplications of C-MYB in human T cell acute lymphocytic leukemias. Other reports suggest that C-MYB may be amplified in as many as 10% of all pancreatic carcinomas. Even in the absence of obvious genetic aberrations, the levels of expression of the MYB genes have been shown to correlate with clinical prognosis for a number of different types of cancer. In particular, B-MYB is one of a small number of genes, the increased expression of which has been reported to be sufficient to predict the clinical behavior of human breast cancer. As the tools for the analysis of altered gene expression and copy number in human cancers become more refined and widely available, our knowledge of the involvement of the MYB genes in a variety of human cancers is certain to become clearer.

N-myc Downstream-Regulated Gene

Sonia Mohinta, Kounosuke Watabe
Department of Medical Microbiology, Immunology and Cell Biology, Southern Illinois University, School of Medicine, Springfield, IL, USA

Synonyms

N-myc downstream-regulated gene, *NDRG1*; *RTP*, *cap43*, *rit42*, *TDD5* (mouse), *Ndr1* (mouse), *Bdm1* (rat)

Definition

NDRG1 stands for N-myc downstream-regulated gene/differentiation-related gene, which was originally identified as being strongly upregulated on induction of differentiation in colon carcinoma cell lines. *NDRG1* encodes a 3.0 kb mRNA that translates to a 43-kDa cytoplasmic protein with an isoelectric point of 5.7. *NDRG1* is expressed almost ubiquitously in most of the organs, and the level of expression is particularly high in prostate, ovary, intestine, and kidney. Amino acid sequence of the NDRG1 protein reveals three serine phosphorylation sites, five calmodulin kinase 2 phosphorylation sites, five myristoylation sites, three protein kinase C phosphorylation sites, one tyrosine phosphorylation site, one thioesterase site, and one phosphopantotheine attachment site. It has been shown that protein kinase A and calmodulin kinase 2 are also involved in the phosphorylation of this protein in vitro. It has also been shown that phosphorylation of NDRG1 is negatively correlated to the cell density thereby suggesting a possible role in cell proliferation.

Characteristics

NDRG1 is a ►metastasis suppressor gene and has been shown to suppress metastasis in colon, prostate, and breast cancer. In the case of prostate cancer, the reduced NDRG1 expression correlated significantly with the ►Gleason grade as well as the ethnic origin of the cancer patients. In both prostate and breast cancers a significant level of differential expression of NDRG1 between patients with organ-confined disease and those with lymph node or bone metastasis were observed. Similar results were also observed in pancreatic adenocarcinoma thus suggesting the reduced expression of NDRG1 to be a strong predicator of lymph node and bone metastasis. In clinical specimens of prostate and breast cancer, it has been shown that phosphatase and tensin homolog deleted on chromosome 10 (►*PTEN*) gene expression in normal and poorly differentiated tumor cells has a positive correlation with NDRG1 expression. Apart from PTEN, ►p53 and N-myc have also been demonstrated to regulate the NDRG1 expression. Treatment of tumor cells with inhibitors of DNA methylation and histone deacetylation induced the expression of *NDRG1* gene indicating that histone deacetylation and ►CpG island hypermethylation as possible mechanism of suppression of NDRG1 in tumor cells. In a recent study, it has been shown that NDRG1 downregulates the expression of activating transcription factor 3 (*ATF3*) gene that is capable of promoting tumor metastasis. NDRG1 also plays a role in cell adhesion as it upregulates the expression of cell adhesion molecule, ►E-cadherin, suggesting one of the mechanisms via which NDRG1 blocks metastasis of tumor cells. In relation to angiogenesis, overexpression of NDRG1 suppressed the expression of two angiogenic factors, ►vascular endothelial growth factor-1 (VEGF-1) and interleukin-8 (IL-8). NDRG1 is also regulated by the ►hypoxia-inducible factor 1 (HIF-1) transcription factor that is activated in hypoxia thus indicating the role of *NDRG1* as a stress responsive gene. From all the above investigations it is evident that *NDRG1* has a critical role in tumor progression and a higher expression level is an indicator of less aggressive phenotype thus acting as a reliable prognostic marker in several forms of cancer.

Myc Oncogene

Ami Albihn and Marie Henriksson
Department of Microbiology, Tumor and Cell Biology (MTC), Karolinska Institutet, Stockholm, Sweden

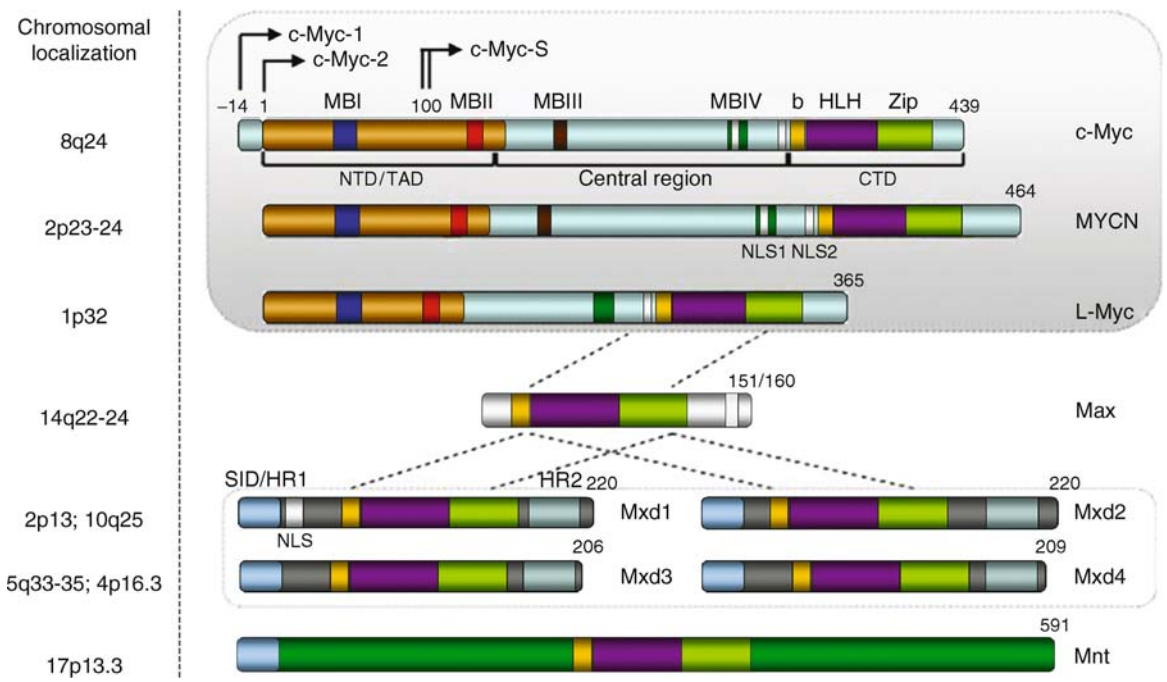
Definition

The *myc* gene was originally identified in the avian ►*myelocytomatosis* retrovirus as the ►oncogene responsible for inducing myeloid leukemia in birds. The cellular homologue, c-*MYC*, was discovered as a promoter insertion in chicken and the human gene was later identified in the ►B-cell tumor Burkitt lymphoma. The related *MYCN* and *MYCL* genes were found ►amplified in ►neuroblastoma and in small cell ►lung cancer, respectively. The *myc* genes are highly conserved through evolution and are found in all animals examined with the exception of the nematode *caenorhabditis elegans* that seems to lack a *myc* ortholog. In vertebrates, c-*myc* and *MYCN* are essential during development. Two additional *myc* genes: S-*myc* and B-*myc* are expressed exclusively in rodents and are not as well characterized. The gene product Myc is a multifunctional protein with the ability to regulate the cell cycle, cell growth and metabolism, differentiation, ►apoptosis, ►angiogenesis, and transformation.

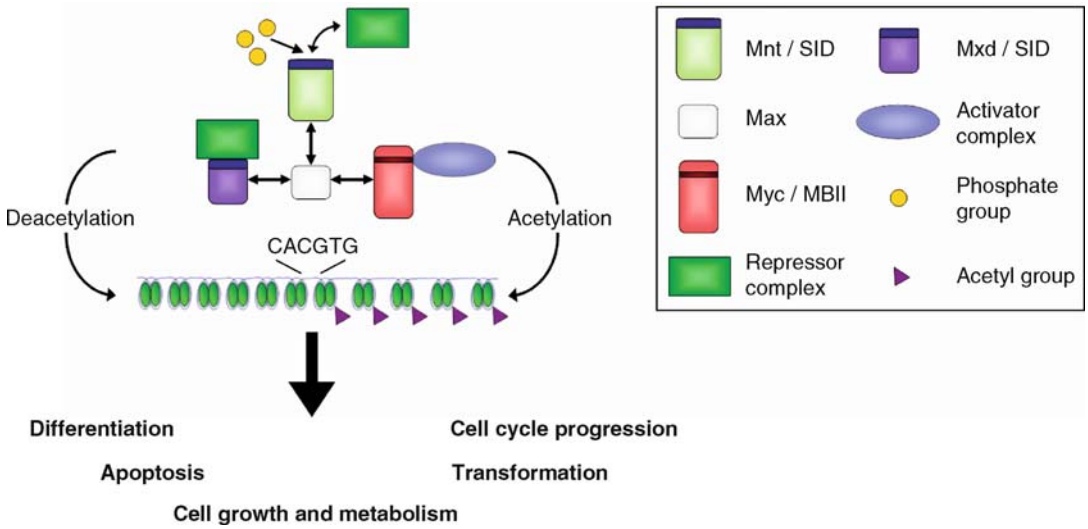
Characteristics

The *MYC* proto-oncogene encodes a nuclear ►transcription factor of the basic region-helix-loop-helix-leucine zipper (bHLH-Zip) family, belonging to the Myc►/Max/►Mad(Mxd) network (Fig. 1). The expression of *MYC* is regulated by external signals such as growth factors and extracellular matrix contacts, and through internal cell cycle control. Myc has an important role in driving proliferation and is expressed during all stages of the cell cycle during division. When quiescent cells are stimulated to re-enter the cell cycle, Myc levels increase dramatically and then return to steady-state levels once cells start to cycle. In contrast, Myc is normally downregulated during differentiation while ectopic *myc* expression inhibits this process.

Myc forms a complex with Max, and these heterodimers bind specifically to 5′-CACGTG-3′ or non-canonical ►E-box sequences and regulate transcription through recruitment of ►histone acetyltransferases (HATs) and ►chromatin remodeling proteins (Fig. 2). These proteins will acetylate Myc target gene promoters and open up the chromatin to permit access



Myc Oncogene. Figure 1 Schematic presentation of the Myc network proteins, including chromosomal localization of the human genes encoding these proteins. In the c-Myc protein, the transcriptional initiation sites for the three different isoforms are indicated. MB, Myc Homology Box; NTD, N-terminal domain; TAD, transcriptional activation domain; CTD, C-terminal domain; b, basic region; HLH, helix-loop-helix; Zip, leucine zipper; NLS, nuclear localization signal; SID, Sin3-interacting domain; HR, homology region.



Myc Oncogene. Figure 2 Transcriptional regulation by Myc network proteins upon binding to the 5′-CACGTG-3′ E-box sequence. During quiescence or differentiation, Mxd/Max represses transcription by recruiting the repressor complex containing histone deacetylases to promote a closed chromatin conformation. In proliferating cells, Myc/Max promote transcription through activator complexes containing histone acetyltransferases and co-factors resulting in an open and accessible chromatin configuration. Mnt is expressed at all stages of the cell cycle and confers transcriptional repression in a similar manner as the Mxd proteins. Indicated below are some of the biological effects of these transcription factors. SID, Sin3-interacting domain; MBII, Myc Homology Box II.

for transcription factors and co-activators. Complexes containing the HATs GCN5 or TIP60 are recruited to the N-terminal of the Myc protein via the adaptor TRansformation/tRranscription domain-Associated Protein (TRRAP). Increasing evidence suggest that Myc regulates general acetylation of the genome and not only of specific targets. Another important role of Myc is the transcriptional activation of ribosomal DNA (rDNA), promoted through interaction with Max in nucleoli.

In addition, Myc possesses the capacity to repress transcription through interaction with transcriptional activators such as ►Miz-1. Miz-1 promotes transcription when bound to initiator elements (Inr) in promoters of target genes. By forming a ternary complex with Max and Miz-1 at the Inr, Myc quenches gene activation.

To date, several thousand Myc targets have been identified, some of which are activated and some which are repressed. ►*cyclin D*2, ►*cyclin-dependent kinase* 4 *(CDK4), carbamoyltransferase-dihydroorotase* (*cad*), *ornithine decarboxylase (ODC*), and ►*telomerase* reverse transcriptase *(hTERT)* are examples of target genes activated by c-Myc, and genes repressed by Myc include those encoding the CDK inhibitors $p15^{INK4b}$ and ►$p21^{CIP1}$, and the transcriptional repressor *Mxd4*.

Myc Structure and Function

The Myc protein can be divided into three major parts: the C-terminal domain harboring the basic region and the HLH-Zip motifs, the central region, and the N-terminal domain that is also referred to as the transcriptional activation domain (TAD) (Fig. 1). Myc forms a complex with Max through the HLH-Zip motif and the basic regions of the Myc/Max heterodimer confer DNA binding to the E-box. Most of the functions of Myc have been ascribed to four highly ►conserved regions within the protein called Myc homology boxes (MB). MBI and MBII within the TAD are the best characterized ones while MBIII and MBIV in the central region were more recently identified. Collectively, the Myc boxes are important for proliferation, oncogene cooperation to induce transformation, Myc-induced apoptosis, and blockage of differentiation.

Post-Translational Modifications and Regulation of Myc Turnover

Myc is a highly unstable protein with a short half life (15–30 min). The protein is degraded by the ►ubiquitin/proteasome system where ubiquitin tagged molecules are recognized and degraded by the proteasome. To date, three ubiquitin ligases that regulate Myc protein turnover and/or activity have been identified. Ubiquitination by the F-box proteins Skp2 and Fbw7 targets the protein for degradation. In addition, Skp2-mediated ubiquitination seems to be required for Myc-induced transriptional activation. Similarly, the HectH9 ligase facilitates Myc target gene activation but forms a ubiquitin chain that does not induce protein degradation. Post-translational modifications, such as phosphorylation

M

and de-phosphorylation of highly conserved residues within the TAD of the protein, dictate whether Myc will be ►ubiquitinated for degradation or stabilized. These events are in large monitored by the ►Ras pathway, controlling both stabilization and de-stabilization of the Myc protein. Acetylation of Myc will also influence its stability by affecting its subcellular localization and turnover.

Other Members of the Max-Interacting Network

The small phosphoprotein Max is in the center of the network (Fig. 1), and a prerequisite for transcriptional activity of the other network proteins. Myc as well as the transcriptional repressors ►Mad(Mxd) and ►Mnt needs to dimerize with Max in order to bind E-box DNA (Fig. 2). Max is ubiquitously expressed at levels that remain constant throughout the cell cycle. Transcriptional repression by Mxd and Mnt is mediated through association with the adaptor protein Sin3 that in turn recruits ►histone deacetylase complexes (HDACs) to target genes (Fig. 2). Removal of acetyl groups results in a closed chromatin conformation, inaccessible for the transcription machinery. The expression pattern of Mxd proteins is mainly the opposite to that of Myc, being upregulated during differentiation and barely detectable in proliferating cells. The exception is Mxd3 that is expressed primarily during S-phase of the cell cycle. Of the four Mxd proteins identified Mxd1 and Mxd2 are the best characterized (Fig. 1). Mnt is ubiquitously expressed throughout the cell cycle and has been suggested to be a modulator of Myc function. This notion is supported by the finding that *mnt* deficient mouse fibroblasts show a disrupted cell cycle control and can be transformed by the oncoprotein Ras alone, traits resembling Myc over-expressing cells. The network also includes the larger transcriptional repressor ►Mga as well as ►Mlx that heterodimerizes with Mxd1 and Mxd4.

Effects of Myc Activation

The cellular response to activated Myc will mainly depend on the immediate cellular environment and include cell cycle progression, blockage of differentiation, apoptosis, cell growth and division as well as transformation.

Myc is required to drive cellular proliferation, a function that is carried out primarily during the ►G1/S transition of the cell cycle by directly upregulating cyclin D2 and CDK4. When in complex, these proteins will both initiate phosphorylation of the ►retinoblastoma protein (pRb) to enable release of ►E2F transcription factors and sequester the CDK2 inhibitor $p27^{KIP1}$ to release the cyclin E-CDK2 complex for continued pRb phosphorylation. In addition, Myc regulates expression of CDK inhibitors, either by repressing the expression $p15^{INK4b}$ and $p21^{CIP1}$ through inhibition of Miz-1-mediated transcription, or by promoting ubiquitin-mediated degradation of $p27^{KIP1}$. The fact that Myc also induces expression of E2Fs reveals that Myc is acting at several different levels to promote proliferation.

Another important function of Myc is potentiation of apoptosis in response to different cellular stress signals such as activation of the Fas death receptor and growth factor deprivation. The ability of Myc to enhance the apoptotic effects of many mechanistically distinct inducers indicates that Myc acts in a common control and/or execution pathway of apoptosis. It has been suggested that proliferation of cells is essentially tied to apoptosis as a built-in safety mechanism to defend against inappropriate proliferation. Thus sensitization to apoptosis is a normal function of Myc and the suicide signal can be rescued by specific survival factors such as insulin-like growth factor (IGF) or ►platelet-derived growth factor (PDGF). According to this model, the availability of apoptosis inhibitors determines whether cells divide or die.

In vitro experiments in rat cell lines have shown that cyclin A and ODC are potential mediators of Myc-induced apoptosis. Blockage of ODC inhibited apoptosis in Myc-overexpressing cells and forced expression of cyclin A was sufficient to induce apoptosis under low serum conditions. Ectopic expression of cyclin A could also restore drug-induced apoptosis in *c-myc* null cells. In addition to the Fas receptor and its ligand, induction of apoptosis by Myc has also been correlated to proteins in the ►Bcl-2 family, normally active at or in proximity to mitochondria. The anti-apoptotic proteins Bcl-2 and Bcl-X_L are repressed by Myc while expression and/or activity of pro-apoptotic members such as Bim or Bax is induced. In particular, the pro-apoptotic Bax molecule appears to be essential for triggering c-Myc-induced apoptosis by permeabilizing the mitochondrial membrane to release additional pro-apoptotic factors such as cytochrome c that will initiate the apoptosis cascade.

The tumor suppressor protein ►p53 acts as a sensor for intrinsic cellular damage signals by inducing cell cycle arrest to enable DNA-repair or, if this fails, to induce apoptosis. Myc has been reported to potentiate apoptosis both through p53-dependent and -independent mechanisms.

Consequences of Myc Deregulation

Myc activation triggers apoptosis in normal cells. However, if the apoptotic pathway is affected by mutations there will be an imbalance between proliferation and cell death with predominance for the former. This results in uncontrolled cell proliferation and, as the pool of proliferating cells has an increased risk of secondary mutations contributing to tumor development, thereby facilitates Myc driven tumor

development. Oncogenic activation of *MYC* is induced by events such as point mutations, gene ►amplification, translocation, overexpression, enhanced translation, or increased protein stability. This in turn results in immortalization, induction of genomic destabilization, and angiogenesis.

Deregulation of the *myc* gene alone is not sufficient for induction of cellular transformation of mouse cells *in vitro*, but requires co-operation with other oncogenes, such as *ras* or *bcl-2*. This is also manifested in human malignancies since many tumors with deregulated c-*MYC* overexpress *BCL-2* or harbor *RAS* mutations.

Tumors Associated with Myc

MYC is activated in a number of different tumors such as small cell lung cancer, breast ►carcinoma, osteosarcoma, glioblastoma, cervix carcinoma, myeloid myeloma, ►acute lymphoblastic leukemia, Burkitt lymphoma, and neuroblastoma. ►Chromosomal translocation is the most common aberration in ►hematological malignancies. In Burkitt lymphoma, the c-*MYC* gene is translocated to one of the immunoglobulin loci, resulting in constitutively high Myc levels. In contrast, the most common *MYC* aberration in solid tumors is gene amplification. In childhood neuroblastoma, amplification of the *MYCN* oncogene, occurring in 40–50% of high-risk neuroblastoma cases, is one of the key predictors of poor outcome.

Targeting Myc as an Approach to Treat ►Cancer

The high frequency of tumors with deregulated *MYC* expression is the main reason why Myc is an attractive target for cancer therapy. Thus, a Myc-targeting drug has the potential to provide an efficient treatment of a broad range of human cancers. However, since the protein is expressed in all proliferating cells it will be important to consider the potential damage inflicted on the gastrointestinal tract, the reproductive system, and the hematopoietic system if such a drug is administered systemically.

It has been shown that Myc-induced tumorigenesis can be reversible in conditional *myc*-driven transgenic models. In most of the cases, inactivation of *myc* resulted in induction of proliferation arrest or differentiation and/or apoptosis depending on the type of cancer as well as on the tumor-specific genetic events. However, tumor cells can also develop compensatory mechanisms to evade the dependence on Myc. In addition, some tumors may contain ►cancer stem cells that remain ►dormant when *myc* is inactivated but recover their tumorigenic properties upon *myc* reactivation. In other cases, even brief inactivation of Myc is sufficient for induction of sustained tumor regression.

Given the fact that *MYC* is one of the most frequently deregulated oncogenes in human cancer, much would be gained from specifically targeting Myc or the Myc pathway in tumor cells. For this purpose, one strategy would be to identify molecules that can reactivate the intrinsic response to Myc overexpression by reversing the acquired resistance to Myc-driven apoptosis. It is also possible to design or identify drugs directly targeting the Myc protein, stimulating its degradation or preventing its interaction with Max. With these approaches, the efficacy of conventional ►chemotherapy would be enhanced and enable the use of lower drug doses to reduce adverse effects.

Conclusion

Myc is a key regulator of cell cycle, cell growth and metabolism, differentiation, apoptosis, angiogenesis, and transformation. In spite of the efforts and progress that has been made in understanding Myc function much remains to be resolved. Unraveling the complexity of the Myc protein and its many roles may provide insights for design and development of novel therapies for treatment of human cancer.

MYCL

Definition

Is a protein of 364 amino acids that dimerizes wih ►MAX to bind DNA in a sequence specific manner. It belongs to the family of basic region helix-loop-helix proteins, most of which are transcription factors. The gene maps to position 1p34. In a subset of small cell lung cancers, an increase in gene copy number (by ►amplification) has been reported.

►Amplification
►Helix-Loop-Helix (HLH) domain
►LMYC
►L-myc

MYCN

Definition

The MYCN gene encodes a nuclear protein of 464 aa, 49 kD Differential phosphorylation of the protein will result in two major components with the relative molecular mass of 62 and 64 kD. MYCN is a member of the basic helix-loop-helix family of transcription factors that binds DNA as a dimer with MAX to activate transcription. The gene maps to 2p24; an increase in gene copy number (by amplification) in is seen in neuroblastoma (here associated with poor prognosis) and occasionally in small cell lung carcinoma and retinoblastoma; amplified MYCN is expressed at an elevated level.

►Amplification
►Neuroblastoma
►NMYC
►N-myc

Mycobacterium

Definition

Acid-fast bacteria with a rather prolonged doubling time under laboratory conditions. Mycobacteria share a characteristic thick and biochemically complex cell-wall. Include pathogens which cause serious disease in humans such as leprosy and tuberculosis. An attenuated vaccine strain termed BCG is available for prevention of tuberculosis and for ►immunotherapy of ►bladder cancer.

►Bacillus Calmette-Guérin

Mycobacterium bovis BCG

►Bacillus Calmette-Guérin

Mycoplasma

Definition

Are a very large group of bacteria. There are more than 70 types. They are very simple one-celled organisms without an outer membrane. They penetrate and infect individual cells. *Mycoplasma hominis* is among the dozen types of mycoplasma that occur in humans. *Mycoplasma arginini* has high occurrence in cats and a wide distribution in nature.

►Arginine-Depleting Enzyme Arginine Deiminase (ADI)

MyD88

Definition

Is a protein component of the signaling pathways mediated by toll-like receptors. In response to microbial ligands MyD88 reacts with the toll receptors and also the interleukin-1 receptor to initiate a signaling cascade that results in activation of the transcription factor NFκB.

►Kupffer Cells

Myeloablative Megatherapy

Bernhard Kremens
Department of Pediatric Hematology, Oncology and Respiratory Medicine, University Hospitals of Essen, Essen, Germany

Synonyms

Autologous bone marrow transplantation; Autologous (hematopoietic) stem cell transplantation; High-dose (myeloablative) chemotherapy

Definition

The term "Myeloablative megatherapy" describes a strategy of anticancer chemotherapy, in which the dose of drugs is increased to the extent that myelosuppression as a side effect will not recover by itself. To restore the patient's hematopoiesis, his own blood stem cells are harvested and frozen before the high-dose chemotherapy and thawed and reinfused thereafter.

The alternative to autologous stem cell transplantation is allogenic stem cell transplantation; this means that a healthy donor provides the cells to restore the patient's hematopoiesis.

Characteristics

Therapeutic Concept

Anticancer drugs are not dosed according to maximal damage to the cancer cell, but to keep their toxicity within limits tolerable for the patient. The amount which can safely be given is usually less than that which would exhaust the drug's potential against cancer cells. This undertreatment – from the view point of the malignant cell – favors the emergence of resistant cells against a specific drug.

Two major strategies have been developed to overcome such drug resistance: combination of drugs and dose escalation.

Dose escalation means, if a certain drug is active against a specific type of cancer cell, more of it will – within a certain range – kill more tumor cells. If this dose range cannot be exploited because lethal bone marrow suppression would follow, autologous stem cell transplantation can circumvent this danger. With a myeloablative megatherapy regimen, more effective cancer therapy can be delivered for once (in cases even twice) because the hematopoiesis is restored afterwards by the patient's own blood stem cells.

Thus "myeloablative megatherapy" names the treatment, and "autologous stem cell transplantation" denotes the rescue from potentially lethal myelosuppression.

Timing of Megatherapy within a Treatment Strategy

At the time of diagnosis, the cumulative mass of cancer in the patient's body is highest. Each treatment course reduces the malignant mass, at best to a minimum which cannot be detected any more by imaging, histology or cytology, or by biologic markers. This state of disease is called "complete remission." At this state, the undetectable minimal residual disease (MRD) consists of the few cells which have escaped all drugs given so far; the danger that they develop resistance is high. This is the moment to escalate the dose of those drugs to which the disease has been sensitive so far.

That is why myeloablative megatherapy must always be part of a complete therapeutic protocol and should not be used as an isolated treatment.

Which Drugs Can be Used for Megatherapy?

Drugs must qualify in two ways to be useful for myeloablative megatherapy:

1. The tumor cells must be sensitive to conventional doses of the drug. Once resistance to a drug has emerged, even a higher dose of this drug will not cure the cancer.
2. The major side effect of the drug must be myelosuppression, since only this side effect is rescued by the stem cell transplantation. Negative influences upon other organs, e.g. liver, renal function or brain, are not alleviated; they can only be put up with to an extent from which the organs will recover by themselves.

Myeloablative Megatherapy. Table 1 Drugs frequently used in megatherapy regimens

Drug	Diseases
Total body irradiation (TBI)	Acute leukemia
	Neuroblastoma
	Myeloma
Cyclophosphamide	Leukemias, lymphomas
	Breast cancer
Etoposide	Acute lymphoblastic leukemia
	Many solid tumors breast cancer
Carboplatin	Solid tumors
	Breast cancer
Busulfan	Leukemias, lymphoma
Treosulfan	Ewing tumor
Cytosin-Arabinoside	Acute leukemia
	Lymphomas
Melphalan	Multiple myeloma
	Childhood solid tumors
BCNU	Lymphomas, brain tumors

Table 1 lists those drugs which are most frequently used for megatherapy.

Treatments with dose escalation carry additional risks for the patient and are expensive. Such concepts must therefore be evaluated in clinical studies in order to prove their benefit for the patient and for the society which provides the resources. In some diseases, e.g., breast cancer, the initial enthusiasm in view of a megatherapy concept did not stand large clinical trials which tested its benefit for the patients.

More is not necessarily better.

Myelocytomatosis

Definition

Is a cancer type in birds, induced by a viral oncogene that was later defined as *v-myc* (*my*elo*c*ytomatosis).

►*Myc* Oncogene

Myelodysplasia

Definition

Abnormal bone marrow cells that may lead to myeloid leukemia.

►Myelodysplastic Syndromes.

Myelodysplastic Syndromes

Ulrich Germing
Klinik für Hämatologie, Onkologie und Klinische Immunologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

MDS; Preleukemia; Dysmyelopoietic syndrome

Definition

Myelodysplastic syndromes (MDS) are a group of stem cell disorders, mainly of the elderly, characterized by defects in maturation of bone marrow cells, resulting in cytopenia in peripheral blood, possibly associated with increased medullary and peripheral blasts and an increased risk of evolution to ►acute myeloid leukemia.

Characteristics

Epidemiology: MDS are diseases mainly of the elderly. The median age at the time of diagnosis is about 70 years. Less than 10% of the patients are younger than 50 years. MDS patients in Asia are 10 years younger in median. The male-female ratio shows a slight preponderance of males. The incidence of MDS is about 4–5/100,000/year and more than 30/100,000/years in patients older than 70 years (►Cancer epidemiology). This means that MDS are one of the most frequent bone marrow disorders and at least as frequent as CLL, Myeloma and acute Leukemias. There is no evidence of an age-adjusted increase of incidence, whereas the number of newly diagnosed MDS patients rises with the graying of the population.

Causative Factors: The vast majority of the patients develop MDS without known reasons. About 10% of the patients develop a treatment-related MDS after being treated with chemotherapy, radiation or radioiodine therapy. Topoisomerase II inhibitors as well as azathioprine can also cause MDS. A very small proportion of the patients bear inherited disorders that may promote MDS such as ►Fanconi anemia and paroxysmal nocturnal hemoglobinuria (PNH), as well as the presence of a family history of hematopoietic cancers. Environmental and occupational noxes may also play a role in the development of MDS. Smoking, exposure to agriculture chemicals, benzene and other solvents (►Benzene and Leukemia) significantly increase the risk of MDS. Polymorphisms and mutations of detoxifying enzymes such as ►glutathione s-transferases may also possibly play a role in the risk of MDS development.

Clinical Presentation: Almost all MDS patients present with a hemoglobin level of less than 10 g/dL. Bicytopenia is found less frequently, and about 30% of the patients are pancytopenic. The resulting clinical features are signs of anemia, infections and, less frequently, bleeding (►Neutropenia).

Diagnosis and Classification: MDS is always a diagnosis of exclusion; there is no pathognomonic finding. Morphologic assessment of blood and bone marrow cytology is the backbone of diagnostic measures. The presence of dysplastic signs in the peripheral blood in case of unexplained cytopenias leads to bone marrow examination by cytologic as well as histologic means. Major morphologic signs in blood and marrow are dysplastic features in at least one cell lineage as well as the presence of blasts in up to 19% of the nucleated cells. Typical signs of dysplasia of the erythropoiesis are megaloblastoid changes, nuclear abnormalities such as bridging, karyorrhexis, basophilic stippling, ring sideroblasts and impaired maturation. Dysplastic features of the granulopoiesis are the presence of Pseudo-Pelger cells, hypogranulation of promyelocytes and myelocytes, an elevated blast count and peroxidase insufficiency. Micromegakaryocytes, mononuclear megakaryocytes and megakaryocytes with multiple nuclear fragments are typical features of dysmegakaryopoiesis. None of these criteria alone is sufficient for diagnosis, but the combination of different dysplastic features allows confirmation of the diagnosis of MDS. Almost all MDS patients show dyserythropoiesis in more than 10% of all erythroid cells. The terms "dysmegakaryopoiesis" and "dysgranulopoiesis" are used if more than 10% of the cell lines are dysplastic.

It is necessary to assess the amount of dysplasia within a marrow because the number of affected cell lines play a major role in the classification of MDS and provide valuable prognostic information. The present classification of MDS has been proposed by the WHO. Table 1 presents the different WHO types. As long as the blast count is not elevated in blood and marrow, the number of dysplastic cell lines is the only relevant parameter for diagnosis. Patients with exclusive dyserythropoiesis are called refractory anemia (RA) or RA with ringsideroblasts if they harbor more than 15% ring sideroblasts in marrow. As soon as an additional cell line is dysplastic, the patient is diagnosed refractory cytopenia with multilineage dysplasia (RCMD) or RCMD with ringsideroblasts. If one of the above mentioned MDS types present with a deletion of 5q, they are classified as a different subtype called 5q– syndrome. Patients presenting with elevated blasts are called refractory anemia with excess of blasts (RAEB). Medullary blasts counts of less than 10% and peripheral blast counts of less than 5% defines the diagnosis of RAEB I. If the blast count is higher than 5% in blood or 9% in marrow, the disease is called RAEB II (►Leukemia Diagnostics).

Cytogenetic Findings: About 50% of all MDS patients show chromosomal aberrations in bone marrow cells at the time of diagnosis. There is a great variability of numerical and structural cytogenetic findings in MDS. Although there are some typical findings, there is no aberration that is restricted to MDS. The most frequent aberrations are del(5q) (~30% of abnormal cases), complex abnormalities (~25%), –7/7q– (~15%), trisomy 8 (~15%), 20q– (~5%) and – Y (~5). Some of the aberrations are associated with a distinct type of MDS and have prognostic implications. In general, patients with a normal karyotype, del(5q), del(20q) or – Y have a relatively good prognosis and patients with an aberration of chromosome 7 as well as those with a complex karyotype (more than 2 chromosomal aberrations) have a poor prognosis. In case of an unclear diagnosis, i.e. mild cytopenia, mild dysplasia, no blasts in marrow and blood, the karyotype has a diagnostic impact when a chromosomal aberration can be found. Chromosomal aberrations also play a role with regards to treatment, as some drugs show higher response rates in the presence of distinct cytogenetic findings (►Chromosomal translocations).

Prognosis: The natural course of the disease is extremely heterogeneous. Twenty percentage of the patients die within 6 months whereas another 20% of the patients survive 6 years and longer. The most important adverse prognostic parameters are elevated medullary blasts in blood and marrow, adverse cytogenetic findings, low cell counts and elevated LDH values in the blood. Several prognostic scoring systems have been established. The most important of them is the International Prognostic Scoring System (IPSS), which relies on medullary blast count, type of cytogenetic aberration and number of cytopenias in the blood (Table 2). This Scoring System serves as a tool for assessing the expected natural course of the disease. Low risk patients have a median survival time of about 6 years, intermediate I risk patients of about 3 years, Intermediate II risk patients of about 2 years and high risk patients of about 1 year. There are also differences regarding the risk of AML evolution. Low risk patients bear a minimal risk of AML whereas high risk patients face a cumulative risk of AML of about 80%.

Treatment Options

Supportive Care: The standard of care includes supportive care measures including red cell transfusions in case of low hemoglobin levels, and transfusion of platelets in case of bleeding or severe thrombocytopenia. Due to frequent red cell transfusions patients develop iron overload, resulting in severe end organ damage like heart failure including arrhythmias, liver cirrhosis, disorders of the endocrine organs and bronze diabetes. Patients who show ferritin levels of over 1,000 ng/mL should receive iron chelation, preferably with the oral iron chelator Desferasirox. Low risk MDS patients who received a total of 50–100 red cell transfusions are at risk of becoming iron overloaded and therefore are candidates for iron chelation therapy. Other treatment approaches are not approved by the

Myelodysplastic Syndromes. Table 1 WHO-classification of myelodysplastic syndromes

MDS subtype	Medullary blast count	Peripheral blast count	Additional criteria
RA with unilineage dysplasia	<5%	<1%	
RA with multilineage dysplasia (RCMD)	<5%	≤1%	
RARS with unilineage dysplasia	<5%	<1%	>15% ringsideroblasts
RARS with multilineage dysplasia (RSCMD)	<5%	≤1%	>15% ringsideroblasts
RA with excess blasts I (RAEB I)	5–9%	<5%	
RA with excess blasts II (RAEB II)	10–19%	<20%	Auer rods possible
5q–Syndrome	<5%	<5%	Isolated del(5q)

Myelodysplastic Syndromes. Table 2 IPSS (International Prognostic Scoring System)

	Scoring value				
	0	0.5	1	1.5	2
Blasts (%)	<5	5–10	–	11–20	21–30
Karyotype	Good	Intermediate	Poor	–	–
Blood cytopenias[a]	0/1	2/3	–	–	–

Low risk	0				
Intermediate I risk	0.5–1				
Intermediate II risk	1.5–2				
High risk	2.5 or more				

Good: normal, –Y, del(5q), del(20q). *Poor*: complex (≥3 abnormalities) or abnormal chromosome 7. *Intermediate*: all other abnormalitiesz
[a]Hemoglobin level below 100 g/L, absolute neutrophil count below 1.8 × 10^9/L, thrombocytes below 100 × 10^9/L.

EMEA. Therapeutic interventions should be discussed with the patient very carefully as we do not know yet if treatment will result in a prolongation of survival, with the exception of the epigenetic drugs and ATG. Patients who present with low EPO levels should receive an ►erythropoietin subcutaneously in order to avoid red cell transfusions. The lower the erythropoietin level in the blood, the better the response with regard to the hemoglobin level. In case of non-responders, G-CSF can be added.

Immunosuppressive Agents (►*Immunotherapy*): As inhibitory cytokines in the marrow may also play a role in the development of cytopenia, immunoinhibitory therapy can be used to restore the hematopoiesis. Antithymocyte globulin (ATG) and cyclosporine A (CSA) can produce long lasting remissions by normalizing the peripheral cell counts. This treatment is appropriate for patients with RA and RCMD, possibly in particular for those with a hypocellular marrow.

Immunomodulatory Agents: Lenalidomide, a derivative of Thalidomide (►Antiangiogenesis) (►Thalidomide and its Analogues), is an immunomodulatory compound that shows astonishing erythroid responses in patients with del(5q) anomalies. Within large studies, its efficacy and an acceptable side effect profile could be shown impressively. About 2/3 of anemic patients with del(5q) achieve long lasting normalization of the cell counts and, in addition, the majority of the patients achieve cytogenetic responses as well. The median increase of the hemoglobin level is about 4–5 g/dL and the time to response averages about 1 month. The drug is approved by the FDA in the United States. There is no evidence of teratogenic effects or neuropathy. The main side effects are transitional drops of neutrophils and platelets.

Epigenetic Agents (►*Epigenetic Therapy*): Besides genetic aberration, epigenetic changes may also play a role in the pathophysiology of MDS. Gene silencing by variable states of DNA ►methylation and histone modification (►Histone Modification in Cancer biology) (►Histone Deacetylation) can lead to chromatin remodeling. Genes involved in the cell cycle, (►Cell-cycle targets for Cancer Therapy) differentiation and ►apoptosis may be inactivated via methylation status. DNA methyltransferases inhibitors like 5-azacytidine (Vidaza, s.c.) and 5-aza-2deoxyctidine (Dacogen, i.v.) (►5-aza-2′ deoxycytidine and Cancer) have been shown to prolong survival in high risk MDS patients. In up to 50% of the patients a remission or at least an improvement of cell counts can be achieved. Both drugs are approved by the FDA. A combination of these drugs with histone deacetylase inhibitors may be even more powerful. Histone deacetylating agents like ►Valproic acid are effective in a subset of low – risk MDS patients, either alone or in combination with methylating agents in high risk patients.

New investigational agents like ►Arsenic, Farnesyl transferase inhibitors, (►Farnesyl Transferases) are used in clinical trials.

Intensive Chemotherapy and Allogeneic Hematopoietic Stem Cell Transplantation: (►*Chemotherapy of Cancer*) High risk MDS patients can be administered induction chemotherapy based on cytarabine and an antracycline, followed by consolidation therapy. About 60% achieve a complete remission, but the vast majority relapse within a year. Long term remissions can be seen in about 15–20% of the patients. Only those high risk MDS patients that show a normal karyotype benefit from induction chemotherapy. Patients with a high risk karyotype, especially those with a complex karyotype, should not be treated with an induction as long as they are not going to receive allogeneic stem cell transplantation. Allogeneic hematopoietic stem cell transplantation is a potentially curative treatment approach for younger patients with MDS. The long-term success of this therapy

is primarily influenced by disease, as well as patient related factors such as medullary blast count at the time of transplantation, karyotype, age and comorbidities. Allogeneic hematopoietic stem cell transplantation should be taken into consideration for high risk patients and intermediate II risk patients according to the IPSS. Low and intermediate I risk patients may be candidates for allogeneic hematopoietic stem cell transplantation in case of disease progression. It is still unclear if there is a major difference in the outcome between those patients who receive a "standard" myeloablative conditioning and those who only receive non-myeloablative conditioning. The latter one may be useful for elderly patients with MDS.

Definition

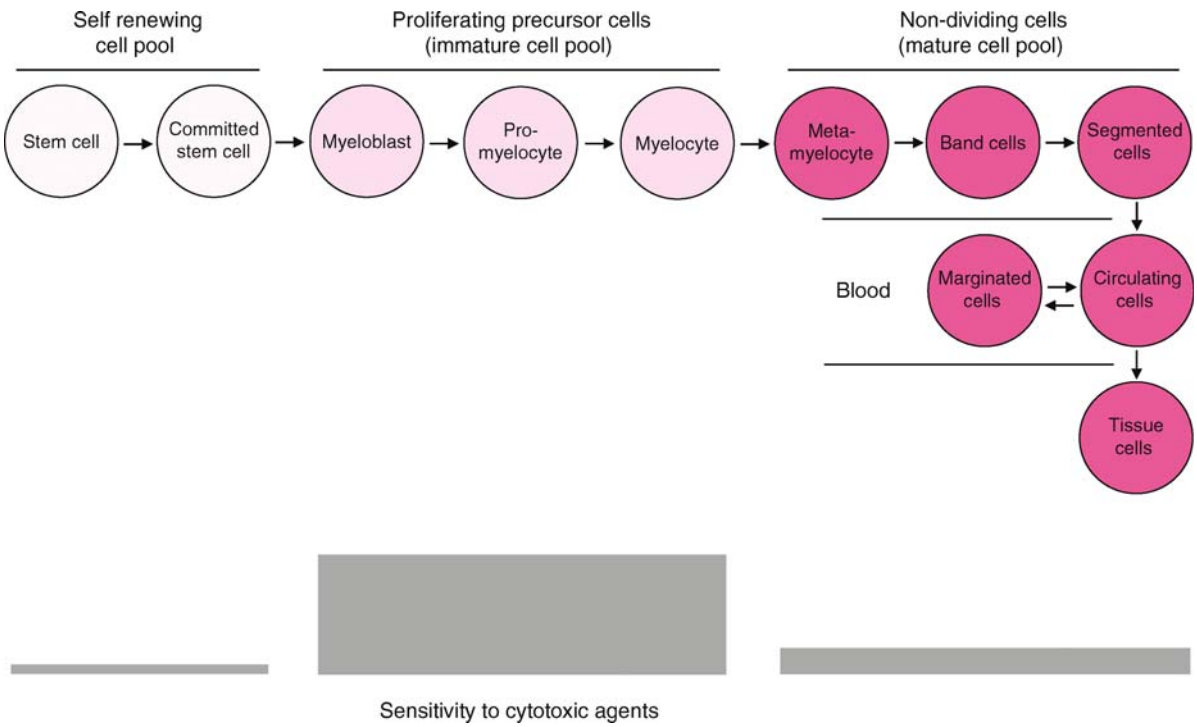
Myelosuppression (acute suppression of the bone marrow) is the most common adverse side effect of cytotoxic anti►cancer therapy. It describes the decrease in the production of blood cells in the bone marrow. The bone marrow produces three types of blood cells: red blood cells (erythrocytes) and white blood cells (leukocytes) (which include lymphocytes, monocytes, granulocytes) and platelets (thrombocytes). Since these cell types serve distinct and important functions, myelosuppression can be associated with moderate to severe life-threatening complications, such as anemia, increased risk of infection, and bleeding.

Characteristics

The bone marrow contains ►stem cells able to reproduce and differentiate into red blood cells, white blood cells, and platelets, depending on the body's need for replacing these cell pools. Because the proliferating precursor cells produced by stem cells are almost always in mitosis and reproduce rapidly, they are highly susceptible to cytotoxic damage. The stem cells themselves are usually not affected by a single administration of cytotoxic agents, but they may resume cell division to become vulnerable to subsequent treatments. Nonproliferating cells like metamyelocytes, band cells, segmented cells, and the pool of circulating mature cells in the blood (Fig. 1) are believed to be rather resistant. The decrease in blood cell counts does not occur immediately after cytotoxic therapy, however, treatment may temporarily prevent the formation of new blood cells by bone marrow stem cells and the progenitor cell pool composed of proliferating precursor cells.

Myelosuppression is the most common toxicity associated with the administration of systemic ►chemotherapy or therapeutic ►x-rays that reach the bone marrow, and infections remain a common cause of death in these patients. The cell types which are most strongly affected during treatment and the drop of which causes most of the clinical complications are platelets and ►neutrophils (neutrophil granulocytes).

The normal range for platelet counts is between 150,000 and 450,000 per milliliter of blood.



Myelosuppression. Figure 1 Neutrophil development from its birth in the bone marrow to circulation in the blood and migration in peripheral compartments.

Thrombocytopenia (low platelet count) may cause bleeding due to the inability to form blood clots at the site of injury. Drugs containing acetylsalicylic acid (aspirin) or other ►nonsteroidal antiinflammatory drugs (NSAIDS) can increase the risk of thrombocytopenia under cytotoxic therapy.

Neutrophils are the most numerous type of leukocytes normally ranging between 2,500 and 6,000 cells per milliliter, which is about 60–70% of total leukocytes. Neutropenia (low neutrophil count) itself is not associated with symptoms and does not affect quality of life. However, it can confer a substantial risk of life-threatening infections accompanied by increased morbidity and mortality, and the magnitude of this risk is closely correlated with the extent and duration of neutrophil loss. Moreover, neutropenia often prevents patients from receiving their chemotherapy at the prescribed times and dose. Neutrophils migrate to the site of infection to fight bacterial and fungal infections, thereby initiating the body's first line defense. They are constantly renewed by the pool of stem cells and immature neutrophils in the bone marrow, and their short life-span makes this cell population so sensitive to cytotoxic treatment. The lowest count that blood cell levels fall to is called the nadir. It is at this point in time when patients with a neutrophil count below 500 are at high risk of infection. Upon a bolus administration of chemotherapy, neutrophils reach the nadir within 7–14 days and suppression may continue for several days until day 21–28 before recovering to normal levels. Most combination chemotherapy regimens have therefore been designed to accommodate the kinetics of bone marrow recovery and are given in 21–28-day cycles. Although high levels of the soluble ►tumor necrosis factor ligand-receptor (p75-R-TNF) seem to be associated with an increased risk of chemotherapy-induced myelosuppression and thus may assist in risk assessment, a reliable marker for the prediction of neutropenia and its symptoms does not exist. Therefore, risk assessment relies on empirical data based on the type of anticancer agent used and its dose which can roughly predict how far the cell count drops and for how long the nadir may last. Due to their reduced responsiveness, neutropenic patients may not show the typical signs of infection, such as redness, pus and swelling, and the most reliable and often only sign of neutropenia is fever above 38°C. Febrile neutropenia is the most serious stage of this complication, and fever always indicates the presence of an infection which requires immediate antibiotic treatment.

Hematopoietic Growth Factor Support

For patients suffering from a malignant tumor, the aim of cytotoxic anticancer therapy is to destroy the malignant cells to reduce disease symptoms, prolong survival or increase the chance of cure. Usually, combinations of several anticancer agents are used in a treatment regimen. The agents are given at a defined dose and a specific time schedule. These parameters have been derived from a large number of preclinical and clinical data to produce the highest efficacy for a given cancer type. In case neutropenia occurs, the dose of the cytotoxic agents needs to be reduced or the treatment must be delayed or even discontinued. A way to avoid the symptoms of neutropenia and also thrombocytopenia is prophylactic support with hematopoietic growth factors (HGFs) as biological agents that help in maintaining hematopoiesis by regulating the proliferation, differentiation, and maturation of the hematopoietic stem cell pool. Interleukin-11 has been used to increase platelet numbers in thrombocytopenic patients, but side effects are frequent and include fluid retention, tachycardia, and dispnoe. ►Myeloid HGFs such as granulocyte-macrophage colony stimulating factor (GM-CSF) and granulocyte colony stimulating factor (G-CSF) have been extensively investigated and found useful in the management of neutropenia related to cytotoxic therapy and its clinical symptoms. These growth factors, which are generally well tolerated, can speed the recovery of neutrophil counts to enable continuation of standard therapy regimens or maintain a higher level of cellular resistance and viability to allow the use of high-dose therapy, which can be given less frequently with often better efficacy. G-CSF primarily stimulates an increase in circulating neutrophils. GM-CSF has a wider effect by promoting the expansion of granulocytes and macrophages, but obviously for the sake of more troublesome side effects like fever, myalgia, malaise, and rash.

In recombinant form these colony stimulating factors (CSF) have been available for the prevention or duration of neutropenia upon cytotoxic chemotherapy for over 15 years. Prophylactic CSF treatment thereby not only reduces the risk of neutropenia, but also helps to ensure that patients receive their planned doses of anticancer agents on schedule. On the other hand, there are indications where the use of CSFs has no clinical benefit regarding morbidity and mortality from infectious complications, frequency of antibiotic use or rate of hospitalization. Thus, CSF application should be limited to indications with proven benefits or evidence of cost-effectiveness. Patients, who most likely profit from prophylactic CSF support and for whom international guidelines have been generated, have an expected incidence of life-threatening febrile neutropenia of more than 40%. Secondary prophylaxis is recommended in cases of previous febrile neutropenia during earlier cycles of chemotherapy or when the symptoms from neutropenia require dose reduction or delay, which may thwart curative treatment intents.

Specific guidelines for the evidence-based use of CSF have also been elaborated for elderly patients, who are at greater risk of myelosuppression. Even when the chemotherapy regimen is relatively mild and myelotoxicity is limited, elderly patients tend to be more vulnerable than younger patients. As a consequence of the higher risk of neutropenia, chemotherapy delays and dose reductions are significantly more frequent in this patient population, for which factors such as treatment intent (cure vs. palliation), type, and dose of drug combinations have to be taken into more serious consideration.

Regulation of Neutrophil Cell Death

As a major part of modern biomedical research, intensive efforts in the field of molecular oncology and hematology have focused on ►apoptosis regulation in cancer and hematopoietic cells as a determinant of chemotherapy outcome and myelotoxicity. DNA damage is clearly a crucial event, which in most normal cell types results in the activation of a ►p53 tumor suppressor gene-regulated pro►apoptotic pathway. On the other hand, as cytotoxicity induced by anticancer agents not always correlates with the expression and activation status of p53, other roads to death are believed to exist in parallel. Recent research has indeed identified multiple stress-activated intracellular molecules, including Jun kinase, mitogen-activated protein kinase (MAPK), ►nuclear factor (NF)-κB and ►ceramide, which are implicated in the proapoptotic decision too. In addition, there is evidence for a role of ►phosphatidylinositol-3-OH kinase (PI3K) and protein kinase B/Akt (PKB/Akt). More downstream of this survival pathway, ►survivin, a member of the ►inhibitor of apoptosis protein (IAP) family was recently reported as a further mechanism of antiapoptosis in hematopoietic stem cells, immature neutrophils, and in certain cancer cell types. Of clinical importance is that treatment with cytotoxic anticancer agents, which reduces survivin specifically in immature neutrophils, a mechanism which likely contributes to myelosuppression in patients. The molecular basis of this adverse effect seems to be a neutrophil-typical PKB/Akt-independent reduction of PI3K activity, which is not observed in cancer cells. This may provide the rationale for the reduction of survivin levels by targeting a pathway distal to PKB/Akt as a strategy to attenuate myelosuppression without jeopardizing potential therapeutic success. As expected from their clinical activity, HGFs can also enhance the resistance of neutrophils to apoptosis induction, and antiapoptotic proteins can be activated by G-CSF.

Conclusion

Myelosuppression, in particular neutropenia, is a serious complication of cytotoxic anticancer therapy, which can make patients vulnerable to potentially life-threatening infections. This often results in dose reduction and delay of planned treatment regimens with the consequence of therapy failure and reduced survival. Neutropenia can in principle be reduced by the use of G-CSF during the first and subsequent cycles of cytotoxic therapy. However, since not all patients benefit from this effect, the use of CSF should be limited to indications recently determined by international guidelines. It is expected that the lack of appropriate risk models for severe myelosuppression motivates further efforts in this direction as they may help facilitating cost-effective strategies to reduce life-threatening neutropenia. Extensive investigation of apoptosis regulation in malignant and normal cell types including hematopoietic cells has significantly improved our understanding of the molecular basis of this clinical complication. This knowledge must be employed for the design of treatment regimens which offer reduced myelotoxicity, and may assist in the design of clinically relevant models valid for neutropenia risk assessment.

Myopodin

Yan Ping Yu, Jian-Hua Luo
Department of Pathology, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms
Homologue of synaptopodin

Definition
►Myopodin, a ►zyxin binding protein, possesses capabilities to regulate cell growth and motility. The myopodin gene, deleted in many advanced ►prostate cancers, is considered a tumor suppressor.

M

Characteristics

Myopodin is a homologue of ►synaptopodin. Its sequence shares six stretches of degenerative homology with synaptopodin, an actin binding protein in glomerular podocytes and dendritic spine in nervous system. The myopodin gene is mapped to chromosome 4q25. Its mRNA sequence of 4,208 bases is translated into a protein of 80 kDa in prostate and skeletal muscle, and 95 kDa in heart muscle.

Myopodin is abundantly expressed in skeletal muscle, but also expressed in organs such as prostate, heart, bladder, kidney, liver, spleen, small and large intestines. However, it is not detected in lung, placenta, brain, leukocytes, testes, colon, ovary, thymus, stomach, thyroid, spinal cord, lymph, trachea, adrenal gland, and bone marrow.

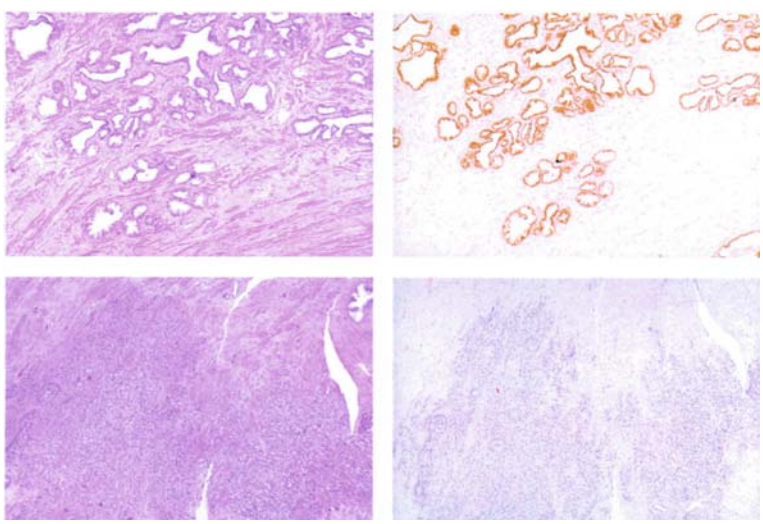
Myopodin Gene Expressed in Prostate but Deleted or Down Regulated in Prostate Cancer

In prostate, myopodin is primarily expressed in prostate epithelium with the strongest expression in the acinar cell layer (Fig. 1).

Myopodin was first recognized as a gene deleted in an advanced prostate cancer case by the analysis of genome wide differentiation subtractive chain (►differential subtraction chain) reaction. In chromosome 4q25, a 54-kb minimal common deletion region that contains the sequence encoding myopodin was identified in >50% of prostate cancers in a study. Frequent complete or partial deletions of the myopodin gene most often occur among invasive prostate cancer cases and result in decreased myopodin mRNA levels (Fig. 1). Hemizygous deletion and down-regulation of myopodin expression also occur in some aggressive prostate cancer cell lines (PC3, DU145 and LNCaP). These prostate cancer cell lines were utilized to carry out studies to investigate the function of myopodin. To study the effects of deletion or down regulation of myopodin in prostate cancer, over-expression of mypodin was achieved by transfecting myopodin gene into PC3 and LNCaP cell lines. The cancer cells with over-expression of myopodin showed decreased cell growth in proliferation and colony formation analyses. *In vitro* matrigel transmigration analysis suggested that myopodin suppressed prostate cancer cell invasion. These studies support a role of myopodin as a tumor suppressor in prostate cancer. When a truncated myopodin gene was introduced into prostate cancer cells, the cells with C-terminus deletion mutant were found to lose all suppression activities of cell growth and invasion, suggesting the critical role of this domain in regulation of cell growth and migration. In a rodent model, over-expression of mypodin in PC3 and DU145 cells suppressed the growth and metastasis of their xenografted tumors in SCID mice, and decreased xenografted tumor induced mortality.

Myopodin Expression and Relapses of Prostate Cancer

A large-scale analysis of myopodin expression in prostate cancer samples was conducted to examine the relationship between myopodin expression and several pathological and clinical outcomes. Immunostaining using anti-myopodin antibodies was performed on formalin-fixed paraffin-embedded tissue samples to



Myopodin. Figure 1 Expression of myopodin in prostate tissues. Upper left panel – H&E staining of normal prostate; upper right panel – *In situ* hybridization of myopodin mRNA of adjacent section of left panel; lower left panel – H&E staining of prostate cancer; lower right panel – *In situ* hybridization of myopodin mRNA of adjacent section of left panel.

evaluate the level of myopodin expression in prostatic tissue. Lower myopodin expression was found to associate with samples having positive surgical margins. Complete inactivation of myopodin expression correlated with a greater than 86% rate of clinical relapse. However, there was no correlation between myopodin expression and Gleason grading. As a result, myopodin is an important predictor of prostate cancer metastasis, independent of Gleason score, preoperative prostate-specific antigen level, and pathological stages.

Mechanism of Myopodin Mediated Tumor Suppression

Myopodin is localized in the cytosol of prostate cancer cells. How does myopodin regulate cell growth? Through protein binding screening in a yeast two hybrid system, a target protein, zyxin, a two compartmental protein was found in direct interaction with the C-terminus of myopodin. Zyxin is a major regulatory protein for cytoskeleton reorganization and forming plague adhesion where the cell contacts the extracellular matrix. It regulates actin filament assembly to the plasma membrane at the focal contact. Interaction of myopodin with zyxin results in slower random migration, and lower rate of matrigel penetration by cancer cells.

Zyxin was first identified as a protein involving in focal adhesion. It was later found that zyxin plays a pivotal role in regulating actin assembly through interacting with its partners such as α-actinin and VASP. Zyxin is essential for cell motility since interference of zyxin function halts cell migration and alters cell spreading. Similarly, blocking the interaction of zyxin with h-warts generates an aberrant mitosis in Hela cells. Since zyxin plays such a crucial role in cytoskeleton reorganization related activities, the interaction of myopodin with zyxin may hold the key for understanding the invasion inhibition mechanism of myopodin in prostate cancer.

Myopodin Expressed in Muscles

Myopodin is found in the Z-disc of skeletal muscle and is colocalized with α-actinin. Its function in the skeletal muscle can be purely a structural protein for bundling actin protein and anchoring of thin filaments to the Z-disc. However, much of myopodin function is still not known, since it is found to translocate to the nucleus in stress myocytes. Cytosolic myopodin is considered a differentiation marker of muscle fiber. The role of nuclear redistribution of myopodin in the stress muscle remains unclear. But, the existence of nuclear myopodin has prompted the speculation of an involvement in stress related signaling pathways.

Myxoid Liposarcoma

Pierre Åman
LLCR, Department of pathology, Institute of Biomedicine, Sahlgrenska Academy, Goteborg University, Gothenburg, Sweden

Synonyms

MLS/RCLS

Definition

Myxoid liposarcoma (MLS) is a malignant soft tissue tumor composed of mesenchymal tumor cells and a variable number of lipoblasts. Round cell liposarcoma (RCLS) is a morphologically distinct and more

aggressive variant of MLS. In many cases the two forms are mixed within the same tumor.

Characteristics

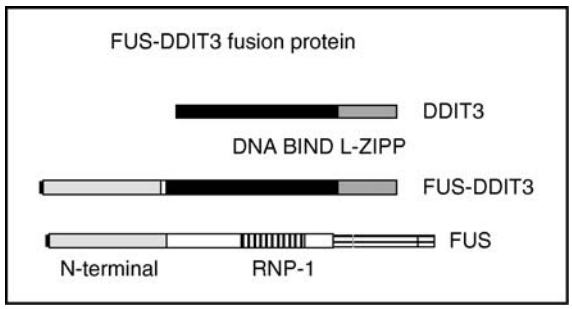
MLS/RCLS is one of the most common types of liposarcoma and accounts for more than a third of all the cases. MLS/RCLS is uncommon in children and young adults. The incidence increases with age and peaks at the middle ages. In ~70% of the cases, the tumors are found in the large muscles of the thigh but they may occur in deep seated locations in any part of the body. MLS/RCLS most often presents as a large painless mass. The tumor is multinodular and the tissue surface is pale and myxoid. The RCLS variant is more cell rich and contains less of the myxoid components.

MLS tissue is composed of round- to oval-shaped mesenchymal cells and a variable number of lipoblasts in a myxoid matrix. The tumor tissue contains a rich capillary network with a typical branched morphology.

A subset of the tumors shows progression to hypercellular round cell morphology (RCLS), associated with a more aggressive disease. Hypercellular areas with an undifferentiated round cell morphology are ranging from 5 to 80% in the mixed variant to more than 80% in the pure round cell type.

Genetics

MLS/RCLS tumor cells carry with few exceptions a t(12;16)►chromosome translocation or, more rarely, a t(12;22). In the majority of cases, these are the only chromosome aberrations found at diagnosis. Normal tissues of the patients show no chromosomal aberrations and there are no indications of heredity. The translocations result in fusions of FUS (a.k.a. TLS) on chromosome 16 or EWSR1 on chromosome 22 with DDIT3 (a.k.a. CHOP) on chromosome 12. The resulting ►fusion oncogenes typically consist of exons 1–5 or 1–7 of FUS, or exons 1–7 of EWSR1 juxtaposed to exon 2 of DDIT3. Other, rare fusion variants are also reported. In some cases, alternative splicing gives rise to two isoforms of the fusion transcripts and proteins within the same tumor. All fusions result in the formation of fusion proteins containing the N-terminal parts of FUS linked to the entire DDIT3 protein (Fig. 1). The localization of the chromosomal breakpoints within DDIT3, FUS, and EWSR1 varies and results in several variant fusion transcripts and fusion proteins but the variant breakpoints have not been shown to associate with prognosis or tumor subtype. The FUS–DDIT3 and EWSR1–DDIT3 belongs to a family of fusion ►oncogenes in which all members have one of the three closely related genes FUS, EWSR1, or TAF15 as 5′ fusion partners and one of many different transcription factor encoding genes as 3′ partners (Fig. 2). Each of the fusion oncogenes are, with exception for FUS–ERG, found in only one tumor entity.



Myxoid Liposarcoma. Figure 1 The *FUS–DDIT3* encoded fusion protein consists of N-terminal parts of the FUS protein juxtaposed to the entire DDIT3 protein. In the junction, 26 amino acids from normally nontranslated parts of *DDIT3* are added to the fusion protein. L-ZIP, leucine zipper dimer forming domain; RNP, RNA-binding domain.

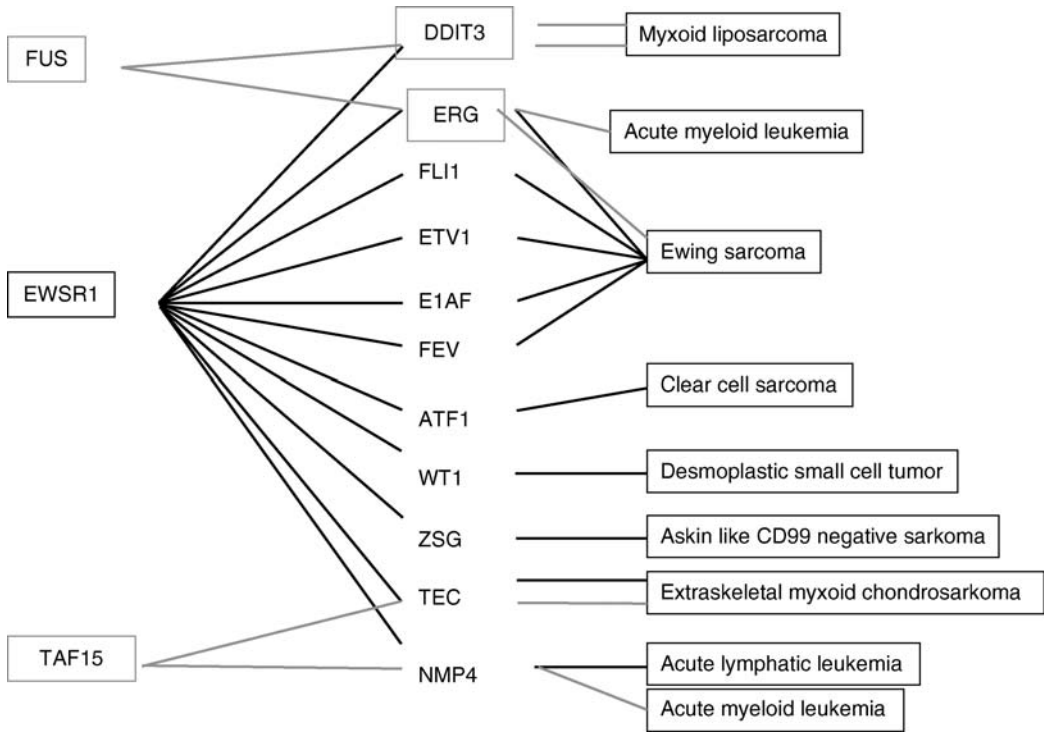
Etiology

The mechanism causing the chromosome translocations in MLS/RCLS is not well understood. No specific sequence motifs are reported in or around the breakpoint regions and the translocations are probably the result of random events.

The FUS–DDIT3 fusion gene has been shown to cause liposarcomas in transgenic mice and in mice inoculated with mesenchymal stemcells carrying FUS–DDIT3. FUS–DDIT3 also transforms NIH3T3 fibroblasts. Based on these observations, it is concluded that FUS–DDIT3 is a causing factor in development of MLS/RCLS.

FUS–DDIT3 and the normal DDIT3 can induce an MLS/RCLS phenotype when expressed in human low differentiated sarcoma cells. This shows that the tumor morphology in MLS/RCLS depends on the DDIT3 part of the fusion. The "instructive" effect of FUS–DDIT3 may explain why this lipoblast containing tumor occurs most often in muscle and rarely in adipose tissue. Similar results have been reported for EWSR1–FLI1 in ►Ewing sarcoma, indicating that at least two members of this family of fusion oncogenes have an instructive effect on cell and tissue morphology.

DDIT3 encodes a DNA-binding transcription factor of basic leucine zipper type (C/EBP family) that binds to DNA as a dimer. DDIT3 can not form homodimers, but other C/EBP family members are considered major dimer partners to DDIT3. The dimer forming function is maintained in the FUS–DDIT3 fusion protein. DDIT3 and FUS–DDIT3 may therefore interfere with C/EBP family transcription factors and their binding to transcription regulatory C/EBP sites. The DDIT3 protein has been implicated in adipocyte differentiation as a dimer partner with C/EBPα and C/EBPβ. C/EBPα is a critical factor for the development of adipose tissue and blocks proliferation as preadipocytes enter terminal



Myxoid Liposarcoma. Figure 2 The *FUS*, *EWSR1*, *TAF15* group of fusion oncogenes (only some of the members are shown). All fusion oncogenes of this group contain the 5′ parts of *FUS*, *EWSR1*, or *TAF15* juxtaposed to the 5′ or central parts of transcription factor genes. With exception for *FUS–ERG*, which is found in myeloid leukemia and in Ewing sarcoma, the fusion oncogenes are specific for one tumor entity.

differentiation. FUS–DDIT3 has been shown to interfere with this function by complex formation with C/EBPα.

The FUS–DDIT3 and EWSR1–DDIT3 encoded chimerical proteins are believed to function as abnormal transcription factors that probably act as heterodimers with other C/EBP family proteins. Several affected target genes such as IL6 and IL8 have been identified. Consistent with a role in transcriptional regulation, the fusion proteins have been found to localize predominantly to the nuclei and in a minority of the cells to multiple nuclear structures that also contain transcription and splicing associated factors.

FUS, EWSR1, and TAF15 encode RNA-binding proteins with extensive similarities. Their proteins are found within protein complexes that participate in transcription, splicing, and mRNA transport. Some reports suggest functions in translational control and in stress response. FUS-deficient mice exhibit increased radiation sensitivity, deficient DNA repair, and male sterility. These observations suggest that the FUS protein participates in DNA repair and homologous recombination.

The natural function of the N-terminal parts of FUS, EWSR1, and TAF15 that are present in the chimerical oncoproteins is not known. However, when expressed as fusion proteins with DNA-binding transcription factors, they have been shown to act as transactivating domains. They are also critical for the transforming activity of the fusion oncogenes.

Immunohistochemistry analysis of growth and cell cycle controlling factors in MLS/RCLS, revealed a strong expression of cyclin D1, cyclin E1, CDK4, and CDK6 in the majority of the tumor cells. The tumor suppressor protein P16 (a.k.a. CDKN2a or INK4a) is also strongly expressed in most tumor cells.

Diagnostics

The diagnosis of MLS/RCLS is based on microscopic examination of tissue specimens. MLS/RCLS tissue is characterized by presence of lipoblasts, myxoid matrix, and the typical plexiform capillary network. The FUS–DDIT3 or EWSR1–DDIT3 fusion oncogenes can be detected by RT-PCR and tests for the fusion genes may be helpful when the morphology is unclear.

Treatment

Surgery remains the main treatment of MLS/RCLS. MLS/RCLS tumors are sensitive to radiation therapy. Surgery is therefore often combined with pre- or postoperative radiotherapy. In cases where surgery is out of option, radiation and chemotherapy are employed.

Prognosis

The main prognostic factor is the histological grade with an RCLS component of more than 5% as an unfavorable predictor. Local recurrence is common in MLS but the pure MLS variant rarely metastasize. The risk of metastasis increases with the presence of RCLS components and common sites are retroperitoneum, subcutaneous soft tissue, bone, and lungs. Overexpression of TP53 (p53) is associated with a poor prognosis.

Definition

Nanoparticle (NP)-based tumor diagnostics – methods of detection of tumor cells and/or quantitative analysis of tumor biomarkers using NP.

Nanoparticle-based anti-tumor treatment – methods of anti-cancer therapy which use NP as anti-tumor agents or as delivery systems for anti-tumor drugs.

Characteristics

Types of Nanoparticles

Nanoparticles (NP) are objects that are different in shape with sizes varying from 1 to 1,000 nm. NP can be classified into two major types: particles that contain organic molecules as a major building material (organic NP) and those that use inorganic elements, usually metals as core (inorganic NP).

Among the organic NP, liposomes, dendrimers and carbon NP are commonly used for tumor diagnostics and treatment.

- Liposomes are self-assembled organic nanoparticles with closed colloid structures composed of lipid layers;
- Dendrimers are globular macromolecules in which all bonds emerge radially from a central focal point with regular branching pattern and repeated units;
- Carbon NP are carbon cylinders composed of benzene rings (nanotubes), used for gene therapy and tumor imaging.

Inorganic NP share the same basic structure with a central core that defines the fluorescent, optical, magnetic, or electronic properties of the particle and a protective, usually organic, coating on the surface that protect NP from chemical degradation. Additionally, the outer layer of NP can be conjugated with different biomolecules such as peptides, proteins, oligonucleotides. Most commonly used inorganic NPs are:

- Supramagnetic NP – contain a metal core (iron oxide, cobalt or nickel) which is magnetically active and are used as contrast enhancement agents to improve the sensitivity of magnetic resonance (MR) imaging of the tumor; as well as for targeted tumor imaging and/or drug delivery;
- Nanoshells – contain dielectric core (usually silica) coated with thin metal (usually gold) shell; used for tumor imaging and therapeutics;
- Colloidal gold NP – contain gold as a core and used mostly for tumor imaging;
- Quantum dots – usually contain cadmium selenide (or other chemical elements of II and IV groups) in the core, and zinc sulfide shell surrounded by coating of coordinating ligand and amphiphilic polymer and are used for fluorescent imaging of tumors and for profiling tumor biomarkers;
- Raman probes – typically contain a metal core of silver or gold for optical enhancement, a reporter molecule for spectroscopic detection and silica shell for biomolecules conjugation; used for tumor biomolecular profiling;
- Near infrared (NIR) NP – fluorescent NP emitting on near infra red diapason of spectrum, used for tumor cells in vivo imaging (sentinel lymph nodes mapping).

Nanoparticles in Tumor Diagnostics

Tumor Detection

Supramagnetic NPs are commonly used as contrast agents for magnetic resonance (MR) imaging. They have greater magnetic susceptibility than conventional MR contrast (►gadolinium). Because of their small size (5–10 nm), these NP demonstrate better distribution in tissues including bone marrow and lymph nodes and are more efficient in the detection of regional and peripheral metastases for tumor staging, than other contrast agents. Supramagnetic NP can be conjugated to tumor-recognizing ligands and used for selective tumor imaging. For example, iron oxide NP conjugated to antibodies recognizing receptor tyrosine kinases (HER2/neu) and luteinizing hormone-releasing hormone (►LHRH) are used for specific breast cancer detection; conjugated with an antibody specific for $\beta_v\beta_3$ (endothelial surface antigen) these NP can be used for imaging the tumor vascular system. Quantum dots (QDs) can be used for noninvasive fluorescent *in vivo*

tumor imaging. Conjugated with an antibody targeted for ►prostate-specific membrane antigen (PSMA), QDs can specifically bind human ►prostate cancer cell implanted into animals. Because of the exceptional brightness and the stable emission fluorescence from QDs tumor cells can easily be visualized by mercury lamp excitation. Because of multicolor nature of QDs several colored particles can be conjugated with specific ligands and used for imaging multiple tumor structures, for example the angiovascular system, tumor tissue and lymphatic vessels at the same time. NIR particles emit in 800–1,000 nm range which is far from tissue autofluorescence range (400–600 nm) and thus are recognizable under NIR light even in the tissues with high autofluorescence. These NP are used for the intra-operative detection of sentinel lymph nodes in breast cancer and melanoma. Because of the composition of heavy metals and potential cytotoxicity, the widespread use of QDs and NIR NP for in vivo tumor imaging may be limited.

Profiling of Tumor Biomarkers

QDs are commonly used for quantitative analysis of biomarkers in tumor cells. QDs have unique optical properties such a multicolor nature due to tunable fluorescent emissions e.g. by changing the size of NP from small to large fluorescent emission and thus visible color can be manipulated. QDs demonstrate exceptional photostability, larger Stoke's shift (distance [in nm] from excitation to emission peaks) and the ability for simultaneous visualization (only single excitation source can be used for various QDs). Multicolor QDs can be directly conjugated with antibodies to form a QD-antibody complex which can be targeted to several surface and intracellular (including nuclear) proteins of the cancer cell. A mixture of QD-antibody conjugates are incubated with preliminary processed diagnostic samples such as formaldehyde fixed paraffin embedded cancer surgical biopsies (FFPE), diagnostic fine needle aspirates (FNA), frozen tumor sections and formaldehyde fixed *in vitro* cultured tumor cells. After staining samples can be analyzed on waive-resolving spectrometry, where individual fluorescent QD emission peaks representing targeted antigens can be simultaneously visualized. The fluorescent intensity of these QD peaks represents the level of expression of labeled biomarkers. Such an approach can be used to simultaneously detect and quantify five different breast cancer biomarkers. Similarly, the expression of cellular biomolecules can be assessed using Raman probes with surface enhanced Raman scattering (SERS). These NP have a metal (usually gold) core surrounding by a coating that contains reporter molecules and is linked to a targeting antibody with a unique spectroscopic signature which represents information about the reporter molecule's vibrational quantum state. While the golden core emits fluorescence, reporters create individual spectral curves at a range from 400 to 1,600 nm. Thus biomarkers labeled with Raman probe NP can be recognized on microscopy and detected by spectroscopy. This approach needs to be further optimized, since the large size of the particle (~100 nm) can limit access to the intracellular and nuclear cancer antigens.

FISH

Multicolor QDs can be conjugated to different specific oligonucleotide probes targeted for RNA or DNA of tumor cells and used for multiplex fluorescent in situ hybridization (►FISH) of cancer cells and tissues to detect the level of matrix RNA or gene activity of the biomarker of interest.

Nanoparticles in Anti-tumor Therapy

Liposomal Based Drug Delivery

Liposomes, micelles, and polymersomes are nanoscale lipid-based vehicles. This class of delivery vehicles is used for delivery of ►anthracyclines, ►taxanes, ►vinca alkaloids, and other chemotherapy agents. Major drawbacks include nonspecific uptake and toxicity, which can be improved by additional coating of these particles with PEG and conjugation with a targeted antibody (Ab). Dendrimers can be used to deliver fluorouracil, methotrexate, doxorubicin.

Nanoparticle-albumin bound ►paclitaxel (Abraxane)–NP has a core containing paclitaxel surrounded by albumin, which significantly improves tumor penetration. This nano-drug has a more potent anti-tumor effect than conventional paclitaxel. Additionally, the albumin covering protects paclitaxel from interaction normal tissues which results in a significant decrease in chemotherapy-associated side effects such as hypersensitivity reactions and neutropenia.

Gene Delivery

NP-based DNA and RNA delivery systems offer several potential advantages for gene delivery to various tumors. A DNA plasmid can be encapsulated into a lipid containing NP and thus be protected from *in vivo* degradation. In addition, such NP can be conjugated with tumor-targeted antibodies and used for the delivery of genes with anti-tumor activity. Short interfering RNA (►siRNA) can be linked to NP for the *in vivo* delivery of siRNA. When encapsulated into NP siRNA are protected from degradation in aggressive *in vivo* environment. When conjugated with siRNA targeted for tumors ►oncogene siRNA-NP complexes demonstrated the ability to decrease tumor growth by inhibiting expression of the targeted oncogenes.

►Nanotechnology

Nanotechnology

Stephen R. Grobmyer, Nobutaka Iwakuma
Department of Surgery, Division of Surgical Oncology, University of Florida, Gainesville, FL, USA

Definition

Is the rapidly progressing interdisciplinary field that is focused on the engineering and development of man-made structures between 1 and 100 nm. One ►nanometer equals 1×10^{-9} m. Cancer nanotechnology is focused specifically on the application of nanotechnology to the diagnosis and treatment of cancer.

Characteristics

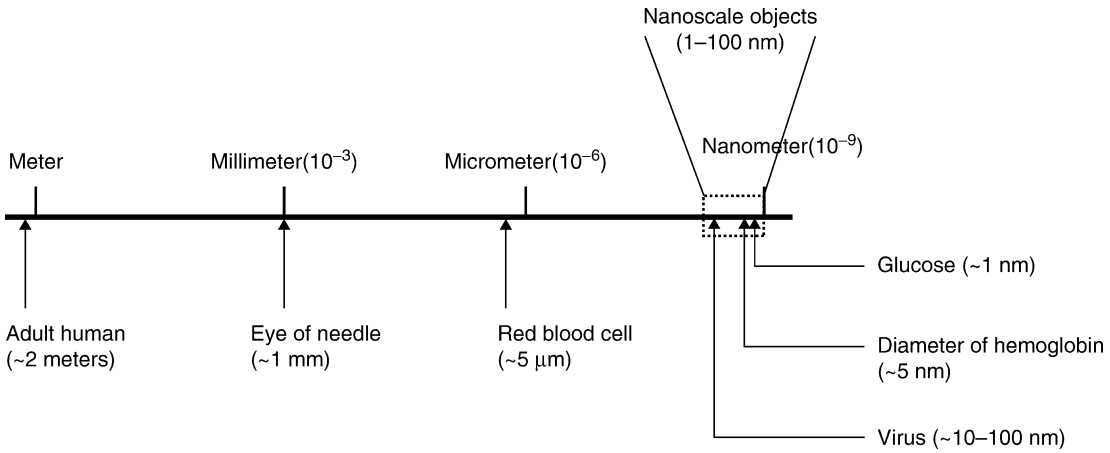
Nanotechnology involves the engineering of *man-made* structures ranging between 1 and 100 nm (Fig. 1). Nanotechnology is an interdisciplinary field that includes chemical engineering, physics, chemistry, biomedical engineering, material and particle science. Cancer nanotechnology specifically also incorporates the expertise of cancer biologists and oncologists. The goal of cancer nanotechnology is to utilize nanotechnology to improve early diagnosis and treatment of cancer. Nanotechnology has the potential to capitalize on advances in cancer biology, genomics, and proteomics and convert advances into clinical benefit for patients.

Nanoscale materials and particles have unique and useful optical, structural, and electronic properties that are not associated with either individual molecules or larger materials. Nanoscale materials and particles can be engineered to specifically function at the subcellular level. The ability to specifically engineer and functionalize particles and materials on the nanoscale represents a tremendous opportunity to design particles with no toxicity to normal cells and maximal toxicity to cancer cells. Nanoscale materials and constructs may be designed to allow ultra-sensitive detection of cancer in the laboratory.

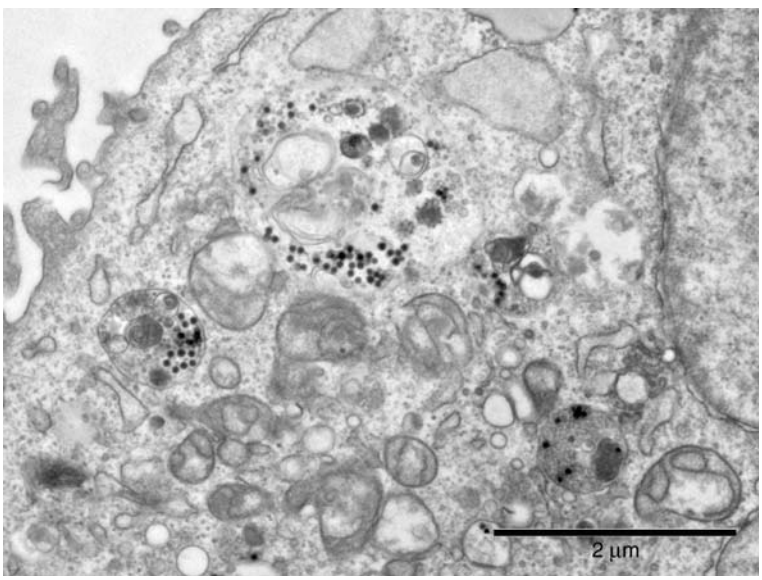
Nanoparticles

►Nanoparticles are particles designed on the nanoscale. In cancer nanotechnology, nanoparticles are used as contrast agents for imaging and as therapeutic agents. Unique properties of specific nanoparticles and the ability to specifically engineer the chemical and physical properties of nanoparticles as well as the ability to attach one or more cancer cell specific ligands to the surface of nanoparticle represent a tremendous opportunity to develop novel strategies for cancer detection and treatment. New nanoparticles with novel properties are continually under development. Some particles that are under current investigation and development include the following.

1. ►Quantum Dots are composed of an inorganic elemental core (e.g. cadmium or mercury) with a surrounding metal shell. Quantum dots absorb white light and then redirect light at a different wavelength. The emission spectra may be altered by varying the size and composition of the quantum dot. Quantum dots have been primarily studied for experimental imaging applications and ►in vitro cancer diagnostics. The use of quantum dots ►in vivo may be limited by toxicity of elemental core.
2. ►Nanoshells are composed of a silica core surrounded by a thin metal shell, usually gold. Nanoshells are optically tunable. Nanoshells have been studied for experimental imaging, tumor ablation, and drug delivery. Figure 2 demonstrates nanoshells (50 nm) delivered inside human breast cancer cells.
3. Gold Nanoparticles are biocompatible nanoparticles composed of colloidal gold. They have been utilized for experimental imaging, tumor ablation, drug delivery, and as a radiation sensitizer.
4. Silica Nanoparticles are biocompatible nanoparticles that have been used for experimental imaging and drug delivery.
5. ►Liposomes are biocompatible phospholipid based vehicles. Drug molecules can be entrapped into liposomes or inside their lipid bilayer. Liposomes



Nanotechnology. Figure 1 The nanoscale perspective demonstrating the relative sizes of conventional objects and nanoscale objects.



Nanotechnology. Figure 2 Transmision electron microscopy demonstrating intracellular accumulation of nanoshells in human breast cancer cells in culture (MCF-7). In this figure, nanoshells (50 nm) appear as black dots.

are biocompatible and have been used for drug delivery and imaging.

6. ►Dendrimers are highly branched polymeric molecules that are synthesized from monomers in a reproducible fashion. Dendrimers with highly charged surfaces allow conjugation of targeting molecules. Dendrimers have potential applications in drug delivery and imaging.
7. ►Supraparamagnetic nanoparticles are composed of iron oxide. There are used as a contrast agent for magnetic resonance imaging (MRI). These particles are attractive as MRI contrast agents because they have greater magnetic susceptibility than traditional MRI contrast agents. Iron oxide crystals have also been used for magnetic field drug targeting. In magnetic field targeting, externally applied magnets are used to preferentially direct iron oxide crystals to know sites of cancer.

Two different strategies have been utilized to deliver nanoparticles to tumors in living organisms, passive targeting (►Therapeutic passive targeting) and active targeting (►Therapeutic active targeting). Passive targeting takes advantage of fenestrations present in tumor blood vessels. Circulating nanoscale particles travel through the fenestrations allowing nanoparticles

to accumulate in tumors. Active targeting involves linking nanoparticles to tumor specific ligands such as antibodies or peptides allowing nanoparticles to accumulate preferentially on or inside tumor cells.

The introduction of man-made nanoscale particles into living organisms may be associated with toxicity to cells or organs. An understanding of toxicity related issues will be required before new nanoscale platforms can be adopted for clinical use. Research into understanding toxicity related issues with nanoscale particles is an important area of active research and development.

Nanoscale Cancer Imaging Contrast Agents

Nanoscale contrast agents are have been and are currently under development. The goal of this work is to allow cell specific imaging and functional imaging as well as to allow improved resolution of imaging with ultra-sensitive contrast agents. Nanoscale contrast agents for conventional imaging modalities including Magnetic Resonance Imaging and Computed Tomography as well as for newer imaging modalities such as Photoacoustic Tomography, which uses sound waves induced by pulsed laser light to generate images, have been and are under development. Quantum dots have been used for experimental lymphatic mapping and sentinel lymph node biopsy.

Biologically targeted contrast agents have allowed imaging of specific cell types such as tumor vascular endothelial cells as well to monitor cellular processes such as ►apoptosis. Nanoscale particles have also been developed which allow simultaneous imaging with multiple modalities. The development of ultra-sensitive contrast agents has allowed the development of high resolution in vivo imaging on the molecular level.

Nanoscale Cancer Therapeutics

Nanoparticles have been and are currently under development as cancer therapeutics. Nanoparticles may be biologically targeted to cancer specific ligands for tumor targeting. Targeted nanoparticles have also been developed as simultaneous carriers of antitumor agents. Inherent properties of specific nanoparticles also make them attractive as cancer therapeutics. For example, tumor specific nanoshells may be engineered to generate heat in response to near infrared light. This is referred to as ►photothermal ablation. Gold nanoparticles delivered to cancer cells have been demonstrated to serve as a radiation sensitizer in the experimental setting.

Laboratory Nanoscale Cancer Diagnostics

Nanoscale engineering and material development is allowing the development of new in vitro cancer diagnostic tests. The application of nanotechnology to laboratory cancer diagnostic tests seeks to lower the limits of the detection of cancer related molecules and to allow the simultaneous detection of multiple molecules. Examples of highly sensitive nanoscale diagnostics include:

1. Nanowires are made of conductive material that can be engineered to bind specific molecules. Binding of small amounts of molecules to the wires alters flow of current in the wires that can be detected as a change in electrical current.
2. Nanocantilevers are flexible nanoscale beams that can be engineered to bind small amounts of specific molecules. Binding of small amounts of molecules to cantilevers induces bending of cantilevers which can be detected by highly sensitive laser imaging systems.
3. Surface Enhanced ►Raman Scattering (SERS) Nanoparticles are nanoparticles with high scattering efficiency that can be detected by Raman instrumentation. These particles can be used in assays for high sensitivity cancer detection.

Biologically tagged nanoparticles such as quantum dots and gold nanoparticles have also been demonstrated to have application for in vitro cancer diagnostics. Nanoparticles offer improved stability, tunability, and sensitivity compared to conventional in vitro diagnostic approaches which, for instance, utilize antibodies.

Current Applications of Nanotechnology in Clinical Medicine

Several nanoscale drug formulations are in clinical use. This includes liposomal encapsulation of drugs to increase efficacy and to reduce toxicity (e.g. liposomal encapsulated Doxorubicin (►Adriamycin). Other drugs (e.g. ►Paclitaxel) linked to nanoscale proteins have demonstrated increased efficacy and reduced toxicity and are currently in clinical use.

With regard to imaging, MRI contrast agents have made the largest impact on current clinical cancer practice. Many further applications as discussed above are under development that likely will revolutionize cancer diagnosis and treatment.

Nasopharyngeal Carcinoma

Pier Paolo Claudio, David A. Denning
Department of Surgery, Marshall University, Huntington, WV, USA

Synonyms

Lymphoepithelioma; Rigaud and Schmincke types of lymphoepithelioma; Transitional carcinoma

Definition

Nasopharyngeal carcinoma (NPC) is an epithelial cancer that has a worldwide distribution. It is also known as lymphoepithelioma, but this term is misleading and should not be used because this tumor derives entirely from epithelial origin. The benign lymphoid component is secondarily associated. It is endemic in southeast China, particularly in the Cantonese population of the Guangzhou area (up to 80 cases per 100,000 people per year). An intermediate incidence is found in other parts of Southern Asia, North Africa and among Eskimos in Alaska and Greenland (8–12 cases per 100,000 people per year). The incidence of NPC is extremely low in the rest of the world.

The World Health Organization (WHO) has proposed a classification of NPC based on the degree of differentiation:

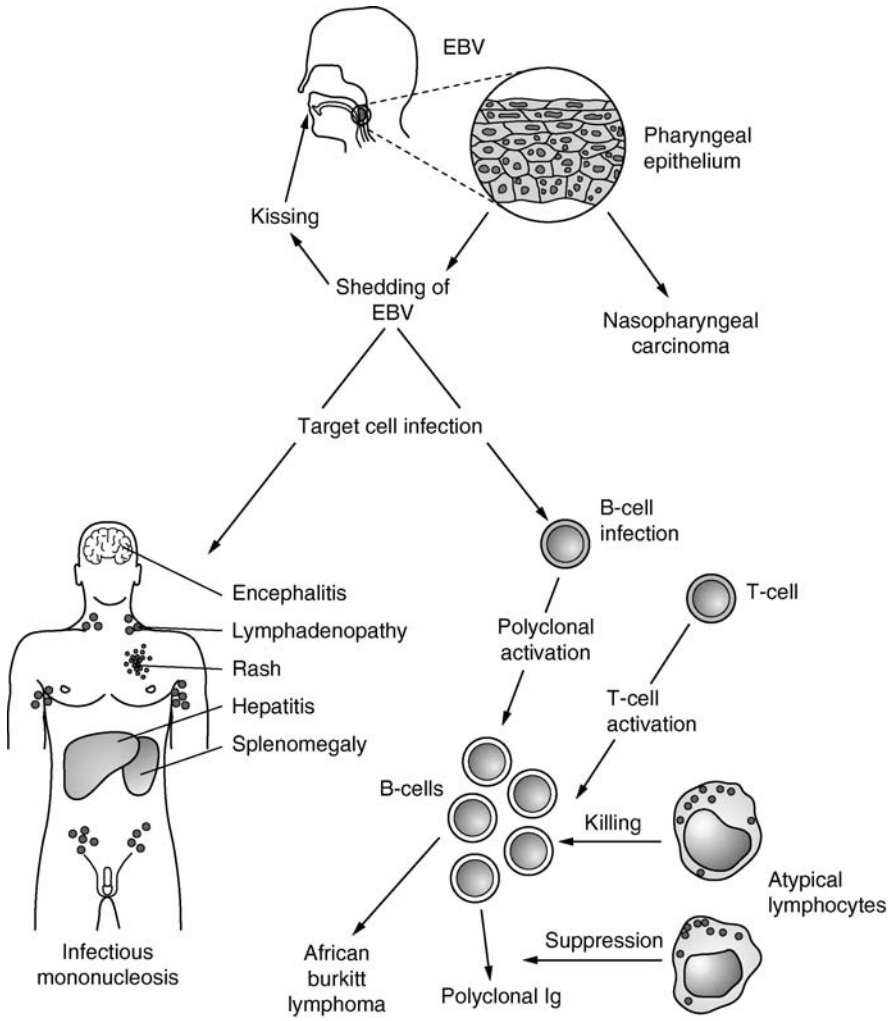
- WHO type 1: keratinizing squamous cell carcinoma (SCC)
- WHO type 2: nonkeratinizing epidermoid carcinoma
- WHO type 3: nonkeratinizing undifferentiated carcinoma (UNCT)

Characteristics

NPC is a variant of squamous cell carcinoma that has been serologically linked to the presence of ►Epstein-Barr virus (EBV) since 1966. EBV is a member of the human herpesvirus family and is the etiologic agent of infectious mononucleosis (Fig. 1). EBV consistently associates with the less differentiated types of NPC such as the nonkeratinizing and undifferentiated types of nasopharyngeal squamous carcinomas (WHO types 2 and 3). The ►human papillomavirus (HPV), a double stranded DNA member of the papovavirus family, causes proliferative lesions of squamous epithelium such as common warts, flat warts, plantar warts, anogenital warts (condyloma acuminatum) and laryngeal papillomatosis, and has been found in some keratinizing squamous carcinomas (WHO type 1).

Genetic and geographic factors play an important role in the genesis of NPC. Although the incidence of NPC among Chinese people decreases after immigration to low incidence areas such as the United States, the risk profile of the Chinese immigrants remains higher than that of the indigenous population. HLA-A2, HLA-Aw19, HLA-B17, HLA-Bw46 and HLA-Bw58 ►major histocompatibility loci have all been associated with an increased risk of developing NPC, whereas the HLA-A11 locus is associated with a decreased risk of NPC in the Chinese population. Conversely, the haplotype HLA-A2 has been correlated with a lower incidence of NPC in whites living in the United States, especially if homozygous. This suggests that different environmental insults may combine with specific genetic predispositions making the pathogenesis of NPC geographically distinct.

Additionally, deletions of the short arm of chromosome 3 as well as of 9p21-22 have been associated with NPC, which suggests that inactivation or deletion of a putative ►tumor suppressor gene located in these loci may be implicated in the pathogenesis of this disease. One of the candidates for this genetic implication is the ►p16 gene, which encodes for an inhibitor of the cyclin-dependant kinase that directly regulates the retinoblastoma tumor suppressor gene (►Retinoblastoma, cancer genetics) (RB). Homozygous deletions of the p16 gene that maps to chromosome 9p21 have been reported in 35% of the cases of primary UCNT (WHO type 3). Additionally, several reports showed that mutations of the "guardian of the genome," p53, which occur frequently in SCC, are present in only 10% of patients affected with NPC. Recently, point mutations in the retinoblastoma-related gene ►RB2/p130 have been described in 30% of NPC patients. RB2/p130 is a novel tumor suppressor gene that maps to chromosome 16q.12.2, an area that is frequently altered in several human neoplasias including breast, ovarian, hepatic, prostatic and endometrial carcinomas. Interestingly, ►amplification of the ►Bcl-2 oncoprotein, which inhibits ►apoptosis (programmed cell death), has been found mostly in NPC WHO types 2 and 3 and less frequently in the differentiated type 1.



Nasopharyngeal Carcinoma. Figure 1 Role of the Epstein-Barr virus (EBV) in infectious mononucleosis, nasopharyngeal carcinoma, and Burkitt lymphoma. EBV first invades and replicates within the salivary glands and the pharyngeal epithelium, and is shed into the saliva and respiratory secretions. In some people, the virus can transform the pharyngeal epithelium, leading to nasopharyngeal carcinoma. In people that are not immune from childhood exposure, EBV causes infectious mononucleosis. EBV infects B lymphocytes which undergo polyclonal activation. These B cells stimulate the production of atypical lymphocytes which kill virally infected B cells and suppress the production of immunoglobulins. Some infected B cells are transformed into malignant lymphocytes of Burkitt lymphoma.

Keratinizing NPC accounts for approximately 25% of all NPC and is more frequent after the age of 40 years. The nonkeratinizing nasopharyngeal carcinoma is the least common, representing only 12% of all NPC. The undifferentiated carcinoma is the most common, representing almost 60% of all NPC, and being the most frequent in younger age.

NPC has been linked by epidemiological and experimental evidence to certain environmental factors such as dietary and life style habits. In fact, a series of studies have suggested that continuous exposure to salted fish and other preserved food containing volatile nitrosamines, which are well-known carcinogens, constitutes a significant cause of NPC in the Chinese population. Tobacco use and alcohol consumption have been linked to an increased incidence of WHO type 1 NPC in white North Americans in proportion to the intake amount.

Because of their location, most NPC remain asymptomatic for a prolonged period and present at an advanced stage. Palpable cervical node metastases are most often (75–90%) the first sign of the disease, even if there are no specific local complaints from the patients. This is due to the growth pattern of this neoplasia, which is not a large space occupying mass,

but instead is an infiltrating and organ-substituting tumor. This growth pattern results in a variety of neurological symptoms such as hearing loss, tinnitus, ►ansomia, epistaxis, a feeling of an obstruction, ►dysphagia, ►odynophagia, ►dysphonia, ►hoarseness and ►diplopia.

Because NPC remain asymptomatic for a long time, an early diagnosis is difficult. Molecular biology and cytogenetic techniques have improved the detection of EBV. Southern blot analysis distinguishes between latent and infectious EBV involvement, whereas in situ hybridization allows the localization of single virally infected NPC cells. PCR of the Zebra EBV gene on fine-needle biopsies in patients with neck nodal involvement and unknown primary lesions may help in the identification of the nasopharyngeal origin of the disease. Serological analysis of different EBV ►antigens, such as screening for anti-EBNA IgG (►IGs), anti-EA IgG and IgA, anti-VCA IgG and IgA and anti-Zebra IgG, may be used to identify early cases of NPC as well as relapses. Increased anti-VCA, anti-EA IgA and IgG are used as markers to monitor the disease, the response to therapy and may suggest recurrence, but are neither highly predictive nor accurate. In fact, many long-term disease-free patients show persistently high levels of these markers.

Diagnosis

Diagnosis and staging of NPC is reserved to imaging techniques such as ►CT scanning and ►magnetic resonance imaging (MRI), which are essential for accurate evaluation of tumor extension and spreading and for guiding radiation treatment planning and evaluation of possible recurrences. Other tests and procedure commonly used to diagnose this disease are:

Physical exam of the throat: An exam used by the doctor to feel for swollen lymph nodes of the neck. It is completed by inspecting down the throat with a small, long-handled mirror to check for lesions.

Neurological exam: A series of tests to check the patient's nerve function. The exam checks a person's coordination, and how well the muscles, senses, and reflexes work.

Nasoscopy: It consists in the inspection inside the nose with a nasoscope. A nasoscope is a thin, tube-like instrument with a light and a lens for viewing and a tool for removing tissue samples (biopsy).

Head and Chest X-Ray, and PET Scan (positron emission tomography scan).

Biopsy: Removal of tissue sample that will be viewed under a microscope by a pathologist to verify the presence of cancer.

Treatment

Treatment of local NPC is based essentially on external ►radiation therapy, because of its radiosensitivity and because of its anatomic location. In fact, surgical resection of the tumor adjacent to the skull base with tumor-free margins is often impossible. Surgery, when feasible, is usually reserved for nodes that fail to regress after radiation therapy or for nodes that reappear following clinical complete response. The overall control rate of localized lesions with radiotherapy is generally about 70–90%. Although most tumors are treated with external-beam radiation therapy exclusively, in some tumors radiation therapy may be enhanced with intracavitary or interstitial implants or by the use of stereotactic radiosurgery when clinical expertise is available, and the anatomy allows for it. At 5 years, local relapse ranging between 15 and 54% has been reported. Tumor control rate of more advanced lesions is instead dramatically decreased. Future improvement of NPC treatment may result from advances in radiation therapy techniques such as three-dimensional conformal therapy, proton-beam therapy or intracavitary ►brachytherapy, which allows the delivery of higher radiation doses to the tumor. Combined radiation therapy and ►chemotherapy have been suggested to improve both local control and metastatic spreading of the disease. Novel approaches and future directions may include testing the appropriateness of adjunctive ►gene therapy oriented to either improve local control, by reducing the tumor volume prior to radiation therapy, and/or to decrease the probability of distant metastasis.

National Institute for Health and Clinical Excellence

Maxwell Summerhayes
Associate Head of Medical Affairs; Roche Products Limited, Welwyn Garden City, UK

Synonyms

NICE

Definition

►NICE is part of the of the United Kingdom's National Health Service (►NHS) which provides medical care, free at the point of delivery, to the entire population. Its overarching purpose is to provide national guidance on the promotion of good health and the treatment of ill health.

Characteristics

The Overall Purpose of NICE

According to its website NICE is "the independent organization responsible for providing national guidance on the promotion of good health and the prevention and treatment of ill health." It does this by commissioning and publishing guidance documents. These fall into one of five categories and are the responsibility of three "virtual" centers as follows:-

1. Centre for Public Health Excellence
   - Public health intervention
   - Public health programs
2. Centre for Health Technology Evaluation
   - Technology Appraisals
   - Interventional procedures
3. Centre for Clinical Practice
   - Clinical Guidelines

Although in its guidance NICE may make recommendations for future research it does not conduct or fund such research. As such its purpose is best described as ►health technology appraisal (HTA).

HTA is a rapidly expanding field NICE and is still unusual (but not unique – the Canadian Coordinating Office for Health Technology Assessment [CCOHTA] predates it by a decade) in the breadth of its remit and in its efforts to assess cost-effectiveness alongside clinical-effectiveness in many of its appraisals.

Why Was NICE Established?

It may seem evident that the provision of guidance to improve healthcare was sufficient reason for its establishment. In fact there are particular characteristics of the NHS and the way that technology has advanced that provided a strong impetus for the foundation of NICE in 1999.

Although the NHS is a national service it is delivered at local level and local managers have long struggled to balance the resources made available to them by national government with local demand. In many cases they have achieved this by restricting the availability of certain technologies and services in their areas resulting in regional inequality of access to particular treatments. These inequalities became more obvious in the early 1990's when an NHS reorganization devolved much budgetary responsibility to local NHS Trusts (►Primary Care Trusts (PCTs)) who sometimes made different decisions about whether or not treatments should be paid for, with the consequence that patients living in different PCT areas and being treated in adjacent beds in the local cancer centre sometimes had different access to certain treatments.

The problem of "►postcode prescribing" was acknowledged even by government ministers responsible for the NHS and became a source of great dissatisfaction amongst clinicians and patients whose stories regularly appeared in the media. The problem was nowhere more apparent than in oncology where the 1990's represented a period of rapid therapeutic advance as taxanes, camptothecins and monoclonal antibodies replaced or were used in conjunction with older and much cheaper drugs for the first time.

Dissatisfaction with inequalities of access to treatment was such that the government announced a number of initiatives to promote a consistent approach to NHS provision. These included the establishment of the National Institute for Clinical Excellence (the inclusion of Health in the organization's name was a later addition) in 1999. They also included, in the same year, the appointment of Professor Mike Richards was appointed as the UK's first National Cancer Director with responsibility for working with national policy makers, ►Cancer Networks and service providers to implement the first National Cancer Plan which aimed to improve the quality of all aspects of cancer services in the UK and reduce inequalities of care.

Professor Richards realized that equity and quality care required uniform access to innovative treatments and pressed for those new cancer treatments that were the subject of reported postcode prescribing to be appraised by NICE. Guidance notes on the use of taxanes in the treatment of ovarian and breast cancer were amongst the first ►Health Technology Appraisals (HTAs) completed by NICE – the third and sixth, respectively. Since then cancer drugs have formed the largest single subject group for HTAs, and are the subject of 24 of 97 completed and Appraisals currently listed on the NICE intranet site (this list excludes those now deemed obsolete).

What Sort of Guidance Does NICE Produce?

HTAs give guidance to the NHS on whether specific health technologies should be available to the NHS based on whether there is sufficient evidence that they are both clinically and cost-effective. The HTA program is not restricted to drugs, but the majority of HTAs have concerned drugs.

As well as HTAs NICE has also produced two Clinical Guidelines (CGs), about 20 pieces of interventional procedures guidance (IPG) pertinent to oncology and 10 Cancer Service Guidelines (CSGs). CGs set out to provide more comprehensive guidance on the appropriate treatment and care of people with specific diseases within the NHS, IGs provides guidance on whether interventional procedures used for diagnosis or treatment are safe enough and work well enough for routine application and CSGs, which were inherited from other bodies – there are no new ones in preparation- deal with the organization of cancer services within the NHS in England and Wales.

Why Has NICE Been Controversial?

However, it is NICE's HTA program that has attracted most attention and caused most controversy. There are several characteristics of HTA's which make them controversial:

- *HTAs are directive in their recommendations*. They always state explicitly whether or not the technology under review should be available under the NHS either as an option or as the treatment of choice. Other types of guidance weigh the evidence and give an opinion on the value of interventions but seldom direct that something must or must not be employed.
- *HTAs usually cover well-tried treatments*. Unlike most of the interventions considered in IPGs and many of the topics covered by CGs, drugs reviewed in HTAs have already been the subject of a review of their safety and efficacy for licensing purposes leading to the criticism that NICE review is duplicating work already done and thus unnecessarily delaying patient access.
- *Cost-effectiveness is an explicit part of HTAs*. Assessment of cost-effectiveness is not part of the preparation of IPGs and although CGs may make reference to the cost and cost-effectiveness of treatments they do not include a rigorous cost-effectiveness analysis of all recommendations made. However, all HTAs include such an analysis. Therefore, it is almost inevitable that the HTA process sometimes leads NICE to recommend that the NHS denies patient access to treatments which both NICE and NHS clinicians agree are highly efficacious, but which NICE deem to be not good value for money. The preferred currency for appraisal of cost-effectiveness is the cost per ►quality adjusted life year (QALY). NICE states that at a cost per QALY gained of below £20,000 cost-effectiveness is unlikely to be a barrier to positive guidance from NICE, whereas above £30,000 per QALY very compelling arguments will need to be made with regard to the certainty of the benefits associated with a new treatment and the needs of the patient population who are expected to receive it.
- Provision of treatments recommended in HTAs is mandatory, but recommendations do not trigger any increase in the funding of health services at local level. Consequently, health service managers are often unhappy about HTAs that make new treatments available and complain that they will result in cutbacks in healthcare provision in other areas.

The other controversial element of the NICE HTA process has been its lack of timeliness with appraisals carried out under the original "Multiple Technology Appraisal" (MTA) following a fixed timetable which runs over a period of one year from the invitation to the product manufacturer and other interested groups to submit evidence to the publication of final guidance (or longer if an appeal is launched against the final guidance). The delay from a product being granted a Marketing Authorization to NHS guidance being made available can also be extended – sometimes indefinitely – if an intervention is not selected promptly by the UK Department of Health as being one which satisfies its criteria for NICE review i.e. interventions:

- Which may have an impact on a clinical priority area for the NHS?
- Which may have a major impact on NHS budgets?
- Where guidance is likely to alter current practice?

One of the reported consequences of delay is "►NICE blight" where NHS organizations decide at local level not to make use of new technologies because NICE guidance has not yet been published. Despite advice to the NHS that in the absence of NICE guidance local decisions should be made about the suitability of new interventions for NHS use, there is a suspicion, fuelled by the rapid increase in NHS uptake once NICE endorsement has been received, that NICE blight is a real phenomenon.

In an attempt to reduce delays NICE has, in addition to reviewing the way appraisal topics are selected, introduced a streamlined Single Technology Appraisal (STA) process, for novel stand-alone interventions. Provided the resulting guidance is not appealed, STA process can be completed in 6 months from the point where submission of evidence is invited. If the STA process is started during the period when regulatory approval is being sought, NHS guidance can be issued within weeks of Marketing Authorization, as was the case in the recent appraisal of adjuvant trastuzumab for early breast cancer.

The main difference between the STA and MTA processes is in the role of the academic Evidence Review Group (ERG) which is involved in both processes. In the MTA process, the ERG produce their own detailed analysis of the cost- and clinical-effectiveness of the intervention. This is a time consuming step which is omitted from the STA process where the ERG role is restricted to providing a critical review of the submission received from the manufacturer.

How Does NICE Reach Its Decisions?

All evidence submitted to NICE is reviewed by an Appraisal Committee, which formulates draft guidance to the NHS in the form of an ►Appraisal Consultation Document (►ACD) which is then distributed to stakeholders for comment. These comments are then considered at a second Appraisal Committee meeting when the ACD can be either ratified as it is or with minor modifications, or subjected to major revision and circulated, once again, for stakeholder comments. Once the Appraisal Committee has agreed final guidance, in the form of a "Final Appraisal Document" (►FAD), this is issued to the NHS unless an appeal is launched against it by one of the consultees on the guidance. Appeals are allowed only on three specific grounds:

- That NICE has failed to act fairly and in accordance with its appraisal procedure.
- That NICE has prepared guidance which is perverse in the light of the evidence submitted.
- That NICE has exceeded its powers.

What Impact Has NICE Had in Oncology?

There is no definitive answer to this question. However, a recent review suggests that NICE HTA's of oncology products have had an impact, though not necessarily that expected. From a positive perspective most new oncology drugs have been recommended by NICE for use within their licensed indications with such endorsement resulting in increased usage within the NHS. On the other hand, NICE guidance has not abolished local inequality of access with large local differences in the utilization of drugs remaining many months after the publication of NICE guidance.

Additionally, it is widely accepted that it has led to the phenomenon of NICE blight described above. This has the potential to slow down the introduction of any new anticancer drug, but is likely to have a disproportionate impact on patients with less common cancers. This is because few products have regulatory approval for these tumors and NICE, generally, restricts itself to guidance on products used within their licensed indications.

Consequently, if PCTs are reluctant to pay for new drugs that have not been endorsed by NICE, patients with rarer malignancies are, inevitably, disadvantaged when it comes to accessing new drug treatments.

Natural Killer Cell Activation

Garnet Suck
Health Sciences Authority, Centre for Transfusion Medicine, Singapore

Synonyms

NK cell induction; NK cell stimulation; Induction or stimulation of NK activity; Induction or stimulation of a NK cell response

Definition

Induction of ►NK cells by double-stranded RNA, soluble factors (►cytokines, antibodies, e.g.) or ligands

expressed by pathogen infected or malignant cells, to exert or enhance NK mediated immune effector functions, which include cytotoxicity, cytokine release and mobilization of the adaptive immune system.

Characteristics

Cytokine Activation of NK cells

Cytokines are important regulators of the immune system and as such have crucial functions in regulating NK activity. Several cytokines produced by immune cells, mainly by macrophages, dendritic cells and activated T cells, enhance NK cell cytotoxicity or stimulate NK cells to secrete cytokines. Important functions for the cytokines ►interleukin (IL)-2 and IL-15, which both significantly increase the killing potential of NK cells, are well established. NK stimulatory functions have been described for IL-21, a cytokine with significant sequence homology to IL-2 and IL-15. IL-21 is released by activated $CD4^+$ T-helper cells and stimulates NK cytotoxicity and cytokine release interferon (IFN)-γ e.g.). Furthermore, synergies among cytokines play important roles. For example, costimulation with IL-18 and IL-12 triggers NK cells to release high amounts of IFN-γ, whereas stimulation of NK cells with IL-15 and IL-12 induces pronounced secretion of tumor necrosis factor (TNF)-α, granulocyte-macrophage CSF (GM-CSF), macrophage inflammatory protein-(MIP)-1α), and MIP-1β. Notably, engagement of the activation receptor NKp46 in the presence of IL-12 triggers NK cells to release IFN-γ, TNF-α, and GM-CSF. Such enhancing effects of cytokines on NK effector functions are exploited in NK mediated cancer cellular therapies against malignancies.

NK cells are generally characterized by the expression of the ►adhesion marker CD56 (neural cell adhesion molecule, NCAM) and the lack of CD3 (T cell marker). However, they do not represent a uniform population of cells, but constitute different subsets with divergent functions. Most studied are $CD56^{dim}CD16^+$ and $CD56^{bright}CD16^{dim/-}$ subsets, distinguished by different expression levels of CD56 and the low affinity Fc receptor CD16 (Fc-γRIII). $CD56^{dim}CD16^+$ NK cells constitute more than 95% of peripheral blood NK cells. They are cytotoxic effectors, which express the cytolytic granule content perforin, an array of activating and inhibitory receptors and are hypothesized to be terminally differentiated NK cells. Furthermore, this subset comprises NK cells that are poor cytokine secretors, however release a unique cytokine profile, including IFN-γ, TNF-α, and IL-6, upon engagement of the immunoglobulin (Ig)-like CD160 activation receptor with its ligand ►human lymphocyte antigen (HLA)-C. NK cells of the $CD56^{bright}CD16^{dim/-}$ subset, on the other hand, constitute less than 5% of peripheral blood NK cells and reside primarily in secondary lymphoid tissues, in particular lymph nodes and tonsils, where they form the predominant NK population. The $CD56^{bright}CD16^{dim/-}$ subset embraces cytokine producers, which are generally incapable of mediating cytolysis due to the lack of perforin expression and a diminished receptor repertoire. However, activation with IL-2 for 3–7 days induces perforin expression and upregulation of receptors in these NK cells and converts them into cytolytic cells.

The study of different NK subsets for their effectiveness in tumor eradication is of particular clinical relevance. Recently, a role for a NK subset, with a $CD56^+$ $CD16^+$ phenotype, that could not be clearly delineated into $CD56^{bright}CD16^{dim/-}$ and $CD56^{dim}$-$CD16^+$ subpopulations has been implicated in survival of cancer patients, after fully HLA matched ►hematopoietic stem cell transplants and NK reconstitution. Crucial functions in autologous tumor eradication (►acute myeloid leukemia, (AML) patients) have been demonstrated for another NK subset, which is defined by the expression of the CD8 antigen. CD8 is expressed by NK cells as the CD8α/α homodimer (NK phenotype $CD3^-CD56^+CD8^+$), different from T cells, which express the CD8α/β heterodimer. The CD8α/α positive NK subset is highly cytotoxic and CD8 expression seems to remain stable after IL-2 activation and long-term culture, which argues strongly for an important role of CD8 in NK cell cytotoxicity. In fact, superior cytotoxicity for eample against K562 and autologous AML blasts has been demonstrated for NK cells of the $CD56^+CD8^+$ subtype compared to the $CD8^-$ subset. Signaling through CD8α/α triggers upregulation of the activation marker CD69 and seems to protect NK cells from "cytotoxicity induced cell death" (CICD). Consequently, $CD56^+CD8^+$ NK cells could be more powerful killers by transmitting multiple "lethal hits." Further insight into cytotoxic mechanisms of highly cytotoxic NK subsets in conjunction with cytokine activation, is a prerequisite for potential translation to effective cancer treatment.

Activation of Natural NK Cytotoxicity by Tumor Cells

In recent years significant progress has been made in elucidating the complex scenario of events involved in NK mediated target cell killing. Apart from characterization of the signaling pathways that constitute NK activation, assigning distinct functions to the numerous inhibitory and activating NK receptors remains a challenging task. A milestone was the conception of the "missing self-hypothesis" soon after the discovery of NK cells. According to this model, lack of ►MHC class I (self) molecule expression renders cells susceptible to NK lysis, since NK inhibitory killer cell immunoglobulin-like receptors (KIR) do not encounter their ligands. For example, tumor cells frequently downregulate MHC class I as a camouflage mechanism

to escape the adaptive T cell response, which in turn renders them sensitive to NK killing. An autologous NK attack, on the other hand, is prevented on account of MHC class I expression by healthy cells. Although this elegant model for NK cytotoxicity seems to define mechanisms for tumor specific cytolysis as well as self-tolerance, major roles for NK activating receptors, including ►NKG2D, and the natural killer cell receptors (NCRs) NKp30, NKp44, NKp46 e.g. are increasingly apparent. However, tumor ligands for several activation receptors remain to be identified, a prerequisite for further insights into NK cytolytic mechanisms.

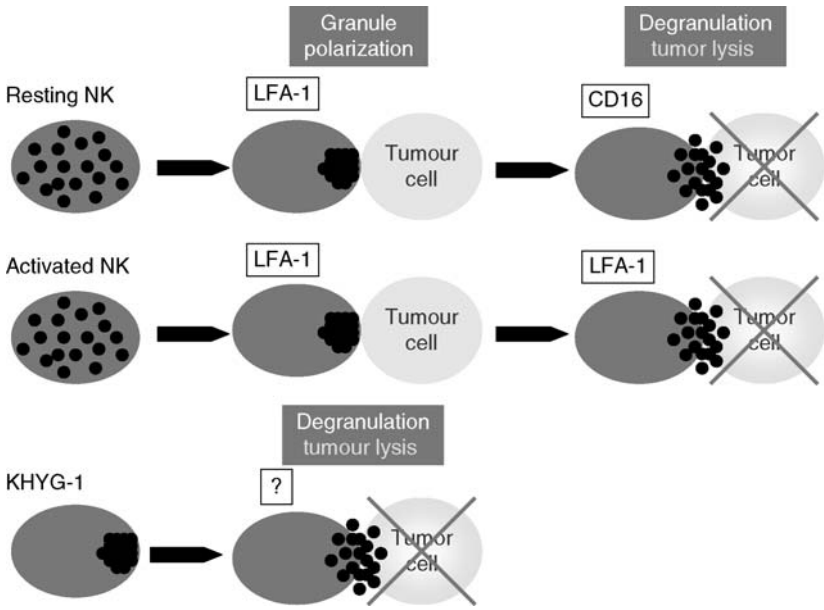
Activation of NK cells upon sensitive target cell contact triggers formation of the ►cytolytic synapse and initiates signaling pathways that include ►tyrosine kinase activation pathways, which are ►immunoreceptor tyrosine-based activation motif (ITAM)-dependent or ITAM-independent (e.g. NKG2D-DAP10), a scenario that eventually results in granule polarization and target cell lysis. The most downstream kinase known so far is the ►mitogen-activated protein kinase-extracellular signal-regulated kinase (►ERK), which is transiently induced by sensitive target cell contact. A specific signaling pathway for ERK activation has been identified, which involves ►phosphatidylinositol 3-kinase (PI3K), the small GTP-binding protein Rac1, the p21-activated kinase (PAK) 1 and the mitogen-activated protein kinase kinase (MEK) 1. Furthermore, Src and ►Syk family kinases induce ►lipid raft polarization toward the target cell. These signaling scaffolds recruit activation receptors, which aggregate and form complexes with signaling molecules, for example linker for activation of T cells (LAT), lipid kinase and PI3K. Activation of NK cytotoxicity is furthermore dependent on the activation of phospholipase C (PLC)-γ2, ►protein kinase C (PKC), the rise of intracellular calcium levels by depletion of intracellular calcium stores and the subsequent influx of calcium through membrane pores.

In contrast, inhibitory receptor engagement with cognate ligands on resistant target cells involves ►immunoreceptor tyrosine-based inhibition motif (ITIM)-dependent pathways, blockage of raft redistribution, inhibition of activation signaling pathways and recruitment of tyrosine phosphatases Src homology 2 (SH2) domain tyrosine phosphatase (SHP)-1 or SHP-2 or the lipid phosphatase SH2-containing inositol 5′-phosphatase 1 (SHIP)-1 to the contact side. It is conceivable that future advances in our understanding of NK cytotoxic mechanisms and in particular, identification of tumor ligands that engage NK activation receptors, will enable more specific targeting of different tumor types with NK cells.

Refined models are imperative to unravel specific NK receptor functions, since target cells generally express ligands for several NK receptors. Recently, insect cells (Drosophila Schneider cells (SC2) that are otherwise resistant to human NK lysis have been introduced as valuable models, since transfection of SC2 cells with cognate NK receptor ligands allows the analysis of downstream mechanisms triggered by distinct receptor-ligand interactions. In ►resting NK cells, the two major steps, granule polarization and degranulation are triggered by different receptors, for example by the ►integrin leukocyte functional antigen (LFA)-1 (polarization) and CD16 (degranulation), respectively. In contrast, in IL-2 stimulated NK cells LFA-1 alone seems sufficient to activate the entire cytolytic process. Interestingly, in the highly cytolytic IL-2 dependent NK cell line KHYG-1 granules are constitutively polarized, but target cell contact is still required to induce degranulation. KHYG-1, which was established from a patient with NK leukemia, appears to be primed for action. This is notably different from other NK cell lines (IL-2 dependent or independent) yet perhaps is also found in a subset of primary NK cells, from which KHYG-1 might have originated. KHYG-1 does not express CD16 and is an intriguing model system to identify the roles for other activation receptors in NK tumor cell killing (Fig. 1) In fact, a potential cooperative function for NKG2D and NKp44 in the induction of degranulation, based on this model, has been discussed. Future mechanistic analyses promise to elucidate additional receptor functions and signaling molecules in the granule exocytosis signaling pathways.

Activated NK Cells in Cancer Therapy

NK cell cytolytic action is immediate with the potential to target a wide range of malignancies, features that renders these innate immune cells promising candidates for ►adoptive immunotherapy (AIT) against cancer. Hematological malignancies are the most promising targets for NK cell therapy, since obstacles due to inefficient trafficking do not apply. However, treatment of solid tumors by administration of NK cells directly to the tumor site could also increase therapeutic effectiveness. Although autologous lymphokine-activated killer (LAK) cells have been employed in AIT for more than 20 years, as well as cytokine infusions to activate endogenous NK cells the overall clinical success rate was low. Obstacles included toxic side effects caused by high-dose systemic cytokine treatments, like IL-2. Moreover, the cytotoxic potential of endogenous NK cells against tumors may be insufficient. Several novel approaches aim to employ activated NK cells with enhanced cytotoxicity, which are the focus of this paragraph, to overcome limitations of traditional NK therapies. For example clinical application of stimulated, Hsp70-specific autologous NK cells to target Hsp70 expressing tumors holds promise. Safety and a potential therapeutic effect for the procedure were demonstrated in a Phase I ►clinical



Natural Killer Cell Activation. Figure 1 Simplified schematic representation of resting NK cells, IL-2 activated NK cells, and KHYG-1 encountering a sensitive tumor target cell. Cytotoxic granules are illustrated as black dots. LFA-1 (granule polarization) and CD16 (degranulation) are examples for receptors that are known to be involved. Primed KHYG-1 with constitutively polarized cytotoxic granules is shown. Target cell contact is required in NK cells for granule polarization and degranulation, however only for degranulation in KHYG-1 (receptor involvement unknown (?)).

trial reported from Germany, which involved patients with metastatic ►colorectal cancer and a patient with non-small cell ►lung cancer.

Another strategy exploits the highly cytotoxic, IL-2 activated NK cell line NK-92, which has been established from a patient with ►non-Hodgkin lymphoma. NK-92 can be easily expanded in culture and is an efficient anti tumor agent for example against hematological malignancies, including AML, T-cell ►acute lymphocytic leukemia (ALL), B-lineage-ALL, and ►chronic myeloid leukemia (CML). Clinical Phase I trials in USA and Germany demonstrated safety for the application of irradiated NK-92 and a Phase I trial in patients with refractory hematological malignancies is in progress in Canada. Clinical application of other highly cytotoxic NK cell lines, like KHYG-1, in the future, or genetically altered NK-92 variants to efficiently target specific tumors could further enhance this kind of AIT. However, feasibility and success of clinical applications of NK cell lines requires further evaluation.

Recently, a novel activation mode for resting NK cells, using the tumor cell line CTV-1 has been discovered. Interestingly, resting NK cells downregulate CD16 and upregulate the C-type lectin activation receptor CD69 upon CTV-1 priming. CD69 is in fact the predominant trigger signal for such primed tumor activated NK cells (T-aNKs) and its unknown ligand, CD69L, has been implicated as a tumor marker. T-aNK cells are capable to effectively and specifically lyse a broad range of tumor targets and seem to overcome NK resistances. These features render T-aNK cells potential novel candidates for AIT (AML e.g.).

Cellular therapies are emerging in clinical medicine and NK cells are potentially powerful tools against cancer. However, a better mechanistic understanding of specific receptor functions and signaling pathways involved in enhanced NK cytotoxicity and different activation modes are essential to significantly enhance AIT approaches in the future.

Acknowledgments

Natural Products

Young-Won Chin, A. Douglas Kinghorn
College of Pharmacy, The Ohio State University, OH, USA

Synonyms

Compounds from organisms; Secondary metabolites

Definition

"Natural products" are generally recognized as small-molecular-weight organic compounds with no known role in the primary metabolism of their terrestrial or marine prokaryotic or eukaryotic organism of origin. Natural products currently used as either cancer chemotherapeutic drugs or anticancer drug candidates are produced by higher plants, terrestrial microbes, and marine organisms.

Characteristics

Since natural products are "secondary metabolites" of organisms, such compounds of a specified structural class are biosynthesized only by certain organisms, and tend to have a limited taxonomic distribution in nature. It is generally agreed that secondary metabolites are produced by mainly sessile (immobile) organisms for ecological reasons as survival tools, and, for example, may help repel predators and locally competitive organisms, or serve as pollination attractants. These natural products are biosynthesized in the correct chiral form to elicit biological effects in mammalian systems. Natural products are produced through the interaction of a variety of proteins in living organisms, and consequently have conformational and configurational attributes that may lead them to modulate enzymes or receptors with considerable binding selectivity and high affinity.

When compared with "libraries" or collections of synthetic compounds, produced by synthesis or by "combinatorial chemistry," natural products may be observed as having more bridgehead atoms, rotatable bonds, ring fusion, and stereogenic centers, among other features in their molecules. The elemental components of natural products are reported to contain lower numbers of halogen, nitrogen, or sulfur atoms than synthetic compounds, while incorporating more oxygen-containing functional groups. Overall, natural products as perceived as having inherently more "drug-likeness" than synthetic molecules.

Natural Products Drug Discovery

There are many examples of structurally defined secondary metabolites from organisms serving as drugs in orthodox medicine either in their naturally occurring form or when subjected to synthetic modification. Of some 210 small-molecules listed in the 13th Edition of the World Health Organization Model List of Essential Medicines, there were included 44 structurally unmodified natural products, 25 semi-synthetic derivatives of natural products, and over 70 synthetic drugs based on the ►pharmacophore of a natural product or synthetic mimics of natural products. The term "pharmacophore" refers to the molecular region of a drug or other bioactive molecule that acts at the site of a receptor, and thereby confers the biological activity observed. In terms of anticancer drugs, 66% of those currently approved worldwide between 1940 and 2006 were either natural products or drugs based on a prototype natural product molecule.

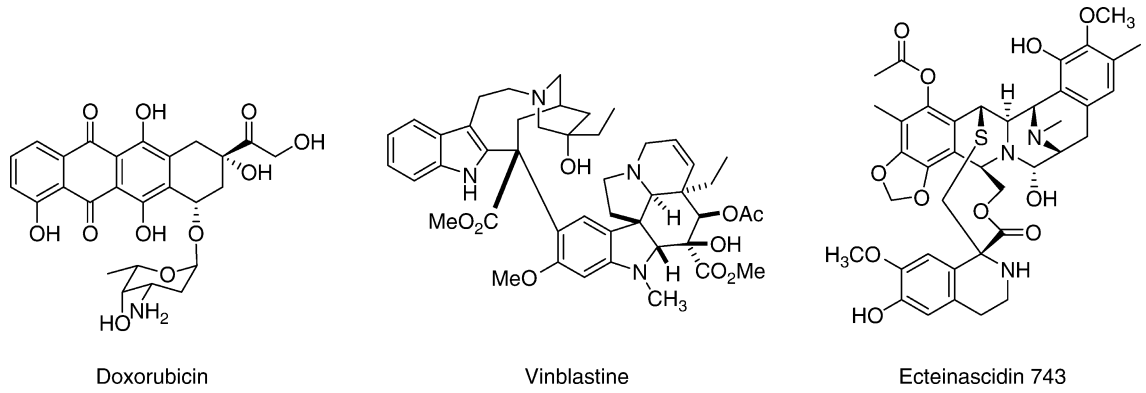
There is an active interest in the discovery of new natural product drugs in countries all over the world. A fundamental tenet of such work is that the wider the range of "biodiversity" afforded by studying as broad a taxonomic range of organisms as possible, the greater the structural diversity represented by the resultant bioactive molecules to be discovered. Major taxonomic groups of organisms include an estimated 1.5 million fungi, 300,000–500,000 flowering plants, and 200,000 invertebrate animals and algal species of marine origin. Only a small proportion of these natural resources has been analyzed for their possible medicinal uses. There is great potential for the future evaluation of marine actinomycetes and cyanobacteria (blue-green algae), as well as endophytic fungi and other microorganisms occurring on terrestrial plants. Many new chemical entities of natural origin are under preclinical development and clinical trial as anticancer drug candidates, and these have been discovered from terrestrial microorganisms, marine organisms, and plants, largely as a result of advances made in screening techniques using contemporary biological molecular targets.

Natural products drug discovery is dependent on access to diverse genetic natural resources, mainly from developing countries. According to the United Nations Convention on Biological Diversity, passed in Rio de Janeiro in 1992, genetic materials such as organisms are owned by their country of origin. Therefore, it is necessary to formulate formal benefit-sharing agreements between agencies in source countries holding genetic resources of interest and institutions in countries seeking to investigate these materials. Such "collection agreements" must be in force before the collection of any organisms commences, and they provide for an equitable distribution of any future income that may accrue from licensing agreements and patent royalties.

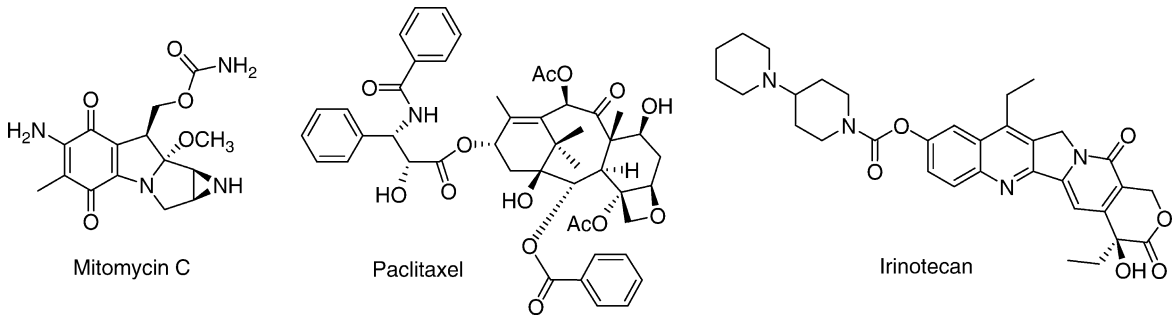
Natural Product Anticancer Drugs

In the discovery and development of cancer chemotherapeutic agents, natural products have served as drugs, drug precursors, and drug templates. Well-established representative examples have been isolated from both microorganisms and higher plants, such as actinomycin-D and vinblastine, respectively. Other examples of natural anticancer drugs used in unmodified forms are the ►anthracycline, ►doxorubicin, and the ►taxane, ►paclitaxel, obtained from a terrestrial microbe and a plant, respectively (Fig. 1). Currently, no anticancer drugs of marine origin are yet approved, but several such compounds are under development, with ►ecteinascidin-743 (ET-743) from a tunicate in late clinical trials as an anti-sarcoma agent. Several natural products have played the role of "lead" compounds, to afford currently used antineoplastic agents (Fig. 1). For example, the plant constituents ►camptothecin and podophyllotoxin, have both afforded two drugs each, namely, ►irinotecan and topotecan, and ►etoposide and teniposide, respectively.

Natural product anticancer agents have efficacy by virtue of interacting with a variety of targets in the cancer cell (Fig. 2). For example, they intercalate, cleave, or alkylate DNA and RNA (►actinomycin D, ►bleomycin, ►mitomycin C, ►ecteinascidin 743); interact with the protein tubulin (►vinblastine, ►vincristine, ►paclitaxel, ►docetaxel); and inhibit the enzymes topoisomerase I (►irinotecan, ►topotecan) and ►topoisomerase II (►etoposide, teniposide, ►daunorubicin, ►doxorubicin). Natural product-derived compounds under development are of interest by having high affinity and selectivity toward new molecular targets, such as the inhibition of ►protein kinase C (►staurosporine), ►heat shock protein 90



Natural Products. Figure 1 Examples of natural product anticancer agents from a microbe, a plant, and a marine organism.



Natural Products. Figure 2 Natural product anticancer agent with diverse mechanisms of action.

(17-allylamino-geldanamycin), and 20S proteasome (salinosporamide A). Combretastatin A4 phosphate is plant-derived stilbenoid that both inhibits tubulin assembly and can cause a selective shut down of the blood flow to tumor tissue. A number of analogues based structurally on the epothilone macrocyclic lactones, from a terrestrial sliding bacterium, are under development as potential cancer chemotherapeutic agents, and these have a similar mechanism to paclitaxel, in stabilizing microtubules and preventing their disassembly.

Nek2

Andrew M. Fry
University of Leicester, Leicester, UK

Definition

NIMA - related kinase 2; Nek2 is a cell cycle regulated, intracellular protein kinase that contributes to passage of cells through mitosis. It's upregulation in a number of cancer types has raised the possibility that its expression level is important to normal cell division and that it might make a novel ►cell cycle target for cancer therapy.

Characteristics

Nek2 is a ubiquitously expressed, serine/threonine protein kinase. It localizes to the centrosome and functions in cell cycle control contributing to the correct assembly of the bipolar mitotic spindle upon which chromosomes are segregated. As such, Nek2 belongs to a small group of important protein kinases, including ►Cdk1, Plk1 and ►Aurora A, that are centrosomal and regulate structural aspects of mitosis. Elevated levels of Nek2 have been detected in a number of human cancer types and cancer-derived cell lines raising the possibility that deregulated Nek2 may contribute to aspects of the disease such as ►aneuploidy and ►chromosomal instability.

By sequence, Nek2 shares similarity with the NIMA protein of the filamentous fungus *Aspergillus nidulans*.

NIMA is an essential protein for mitotic entry in *Aspergillus*, although homologues are not required for mitotic entry in budding or fission yeast. Proteins from higher eukaryotes that share homology with NIMA are called Neks, for *N*IMA-*r*elated *k*inase*s*. The human genome encodes eleven different Neks, named Nek1 to Nek11, and while studies on Neks from lower eukaryotes generally support a function in cell cycle regulation, the individual roles and relevance to cancer of the different human Neks remain to be determined.

Nek2 is subject to alternative splicing with the predominant splice variant in adult cells, Nek2A, being 445 amino acids in length (~48 kDa). Nek2B lacks the extreme C-terminus and has only 389 amino acids (~44 kDa), while Nek2C is identical to Nek2A except lacking 8 amino acids in the C-terminal region. The catalytic kinase domain is located at the N-terminal end of the protein with a number of important regulatory motifs, including dimerization and destruction signals, present in the C-terminus. The extreme C-terminal dipeptide of Nek2A, a methionine-arginine pair, is an unusual destruction motif, allowing direct interaction with the E3 ►ubiquitin ligase, the anaphase-promoting complex. The C-terminus of Nek2A also contains a binding site for the catalytic subunit of protein phosphatase 1 (PP1), which acts as a physiological inhibitor of Nek2. Interestingly, in frogs, Nek2B, which is more stable than Nek2A and does not bind PP1, is the only variant expressed during early embryogenesis implying a developmental stage-specific role for this splice variant.

The localization of Nek2 at the centrosome, the primary site of microtubule nucleation in animal cells, is consistent with a role in bipolar spindle formation. ►Centrosomes are organelles that form the poles of the microtubule-based mitotic spindle and therefore play a critical role in ensuring even chromosome segregation. During interphase of the cell cycle, the centrosome undergoes a duplication event in preparation for mitosis. However, prior to mitosis, the centrosomes are maintained in close proximity to each other due to the presence of a physical tether that links the duplicated centrosomes. It has been proposed that Nek2 facilitates the separation of the duplicated centrosomes to the opposite ends of the spindle at the ►G2/M transition by triggering the dissolution of this tether. It does this by phosphorylating centrosomal linker proteins, such as the large coiled-coil domain proteins C-Nap1 and rootletin, displacing them from the centrosome. However, Nek2 is also localized in the cytoplasm and nucleus, and possibly at the kinetochores and has been reported to phosphorylate chromatin-associated, e.g. HMGA2 and ►spindle assembly checkpoint, e.g. HEC1, proteins. Phosphorylation of HMGA2 promotes chromatin condensation, at least in mouse meiotic spermatocytes. Hence, it is plausible that Nek2 contributes to multiple aspects of mitotic and meiotic cell division.

How increased amounts of Nek2 interfere with ►mitosis is an open question. In cultured cell models, Nek2 overexpression leads to premature centrosome separation during interphase of the cell cycle, as well as to centrosome fragmentation. These consequences might be detrimental for cells that subsequently enter mitosis and attempt to establish a bipolar spindle. Indeed, Nek2 overexpression can cause mitotic failure with accumulation of multinucleated cells that have failed to divide properly. Moreover, as tumour cells frequently possess multiple centrosomes, elevated Nek2 activity may encourage the extra centrosomes to separate forming multipolar spindles, rather than allowing them to cluster and assemble a bipolar spindle. Expression of kinase-inactive mutants also cause mitotic defects, however, such mutations have not been detected in tumours. The underlying basis for the abnormal expression of Nek2 in tumours and cancer-derived cell lines is also unclear. The Nek2 gene locus, 1q32, undergoes ►amplification in ►breast cancer and ►gastric cancer which may explain some overexpression, but the Nek2 gene is also subject to transcriptional repression in normal cells which may be lost in tumours.

Further research is required to determine how abnormal Nek2 expression contributes to the cancer phenotype and whether targeting Nek2 with small molecule inhibitors will be useful in treatment of particular cancers.

Nemosis

Antti Vaheri
Haartman Institute, University of Helsinki, Helsinki, Finland

Definition

Nemosis (from Nemesis, Goddess in Greek mythology who brought justified revenge or compensation) is a newly discovered type of ►fibroblast activation which

is thought to operate in ►inflammation and cancer. Experimentally, nemosis is induced when normal fibroblasts are not allowed to adhere and spread on a solid substratum but are instead forming spheroids and making cell–cell contacts. This may be achieved by placing fibroblasts e.g., on top of agarose-coated culture wells or growing them in hanging drops.

Characteristics

Nemosis is characterized by a massive induction of ►cyclooxygenase-2 (COX-2 producing prostanoids), growth factors and especially ►hepatocyte growth factor/scatter factor (HGF/SF), proteolytic enzymes (►plasminogen activation, ►matrix metalloproteinases MMP-1, MMP-10, and MT1-MMP), and proinflammatory chemokines (e.g., MIP-1α, RANTES, and IL-8) promoting leukocyte migration. In cell culture conditions the fibroblast ►spheroids terminate in programmed ►necrosis with typical ultrastructural changes in electron microscopy but no induction of ►apoptosis-related markers. Under the same conditions malignant cells grow to enlarging spheroids, used as a model of primary avascular tumors without any early signs of necrosis.

The massive amounts of ►HGF/►SF produced by the fibroblast spheroids (>200-fold in monolayer cultures of fibroblasts) promote human carcinoma cell spreading and invasion to collagen provided a functional, properly processed c-Met receptor is present on the tumor cells which was then rapidly phosphorylated. Interestingly, not only function-blocking antibodies to HGF/SF inhibited the tumor cell invasion but also ►nonsteroidal anti-inflammatory drugs (COX-2 inhibitors) which have been shown to be protective against a variety of cancers in vivo. Nemosis is initiated by fibronectin–integrin interaction which leads to over 100-fold induction of 30 genes and 10–100-fold upregulation of over 300 genes.

Possible Significance of Nemosis

While activation of fibroblasts in spheroids thus far only represents primarily an in vitro model, it is of interest that fibroblasts activated to myofibroblasts form direct cell–cell contacts in wound healing and that such myofibroblasts are found in association with cancer cells (cancer-associated fibroblasts, CAFs). CAFs are considered a prerequisite for effective tumor progression. Similarly, in chronic ►inflammation, which is often associated with tumor ►progression, sustained fibroblast activation seems to play a crucial role. The results on nemosis present a novel role for ►fibronectin as the mediator of fibroblast clustering and as the initiator of a massive induction of inflammatory genes and growth factors suggesting that this kind of fibroblast activation may be involved in pathological conditions and specifically in chronic inflammation and cancer.

Neoadjuvant

Definition

Treatment given before the main treatment, e.g. radiotherapy before surgery.

►Ionizing Radiation Therapy
►Neoadjuvant Therapy
►Adjuvant Therapy

Neoadjuvant Chemotherapy

►Neoadjuvant Therapy
►Induction Chemotherapy

Neoadjuvant Therapy

Charles L. Vogel
Aptium Oncology - Lynn Cancer Institute West, Boca Raton, FLA, USA

Synonyms

Primary chemotherapy; Primary systemic therapy; Preoperative chemotherapy; systemic therapy; Protoadjuvant therapy

Definition

Neoadjuvant therapy is an auxiliary therapy (e.g. androgen ►ablation in ►prostate cancer) administered prior to another therapy (e.g. surgery or radiation). It is given prior to surgery in an attempt to decrease the size of the tumor. It is performed in an attempt to make

the tumor easier to remove and to increase the chances that removal of the tumor is curative.

Characteristics

In most solid tumors, surgery remains the initial primary modality of treatment. With the increasing effectiveness of systemic therapies (►chemotherapy and ►hormonal therapy) in advanced disease stages and also in the post-operative "adjuvant" setting, studies were instituted in many solid tumor types using systemic therapies prior to surgery. Advantages of this approach may include:

- Downstaging of the tumor allowing for less extensive surgery to be performed
- Ability to quantitatively measure in vivo sensitivity to the systemic agent that would not be possible in the post operative "adjuvant" model
- The ability to measure pre- and post-systemic therapy biologicmarkers (e.g. by fine needle aspirates or core biopsies) providing valuable insights into the mechanisms behind systemic therapeutic effects
- Earlier initiation of systemic therapy to eradicate systemic metastases.

If neoadjuvant chemotherapy could clearly be shown to produce an overall survival benefit compared with postoperative systemic therapy, it could produce a major paradigm shift in multidisciplinary cancer care. Thus, if systemic therapy, used primarily, increased cure rates and/or produced convincing and consistent increases in overall survival compared with post-operative use, then local therapeutic modalities such as surgery and/or radiation therapy would become "adjuvants" to primary systemic therapy.

Primary (neoadjuvant) systemic therapy is being studied in a number of tumor types, and its use in breast cancer serves as an example. Neoadjuvant chemotherapy has been used effectively in women with locally advanced ►breast cancer, frequently converting cases where mastectomy was the only realistic option to a situation where breast conservation surgery could be accomplished. In one study series, women with tumors greater than 5 cm in size were able to undergo breast conservation surgery instead of mastectomy 62% of the time. However, most published series indicate a breast preservation rate of about 30% for such large tumors. Despite the ability to induce significant antitumor responses in 75–80% of patients, in general three quarters of women continue to have viable tumor within the breast. In addition, most series have not yielded a survival advantage compared with the use of the conventional therapeutic sequence of surgery, chemotherapy and then possibly radiation therapy. If (and when) more effective systemic therapies emerge, more widespread use of primary systemic therapy is likely to become a reality.

Neoangiogenesis

Definition

This is the formation of new capillaries and blood vessels by growth and differentiation from existing ones. It occurs mainly during embryonic development, but also at wound sites, and is an important feature of tumor growth.

►Angiogenesis

Neobladder

Definition

Construction of new bladder after ►cystectomy using patient's own intestine to ensure voiding from the urethra.

►Urothelial Carcinoma, Clinical Oncology

Neocarcinostatin

Definition

Member of a group of naturally occurring ►enediyne antibiotics, including esperamicin, neocarcinostatin, kedarcidin and dynemicin constituting a unique class of reactive compounds that can undergo aromatization to produce biradicals.

Neocentromere

Definition

A functional ►centromere, which lacks alpha-satellite sequences usually present in a human centromere.

►Adipose Tumors

Neohormone

Definition
Is a new term used to describe hormones that have evolved recently to address specifically mammalian traits, such as viviparity (live birth), lactation, a scrotal testis, or post-reproductive survival.

►Relaxin

Neoplasia

Definition
Is an abnormal cell growth in a tissue or organ results in the formation of a neoplasm. Synonym for cancer or tumor. Neoplasms can be benign or malignant lesions.

Neoplasms with Perivascular Epithelioid Cell Differentiation

Definition
PEComas; A family of tumors composed of perivascular epithelioid cells, including angiomyolipoma, clear cell "sugar" tumor of the lung, lymphangioleiomyomatosis, clear cell myomelanocytic tumor of the falciform ligament/ligamentum teres and clear cell tumors of the pancreas, rectum, abdominal serosa, uterus, vulva, thigh and heart. The cells express melanocytic markers.

►Uncertain or Unknown Histogenesis Tumors

Neoplastic Cell Transformation

Definition
The process by which carcinogenic chemicals, oncogenic viruses, or radiations change the genotype and phenotype of the cell, such that the cells are able to form progressively growing tumors.

►Chemically Induced Cell Transformation

Neoplastic Development

Definition
Term used as equivalent to formation of cancerous tissue or any kind of tumor formation in which unchecked cell proliferation of the tissue affected is involved.

Neoplastic Meningitis

►Leptomeningeal Dissemination

Neovascularization

Definition
The generic name for the process of new vessel formation, which encompasses ►angiogenesis (from pre-existing vessels) and ►vasculogenesis (from endothelial precursor cells). Vasculature in cancer is newly formed to support tumor cells to grow.

►Antiangiogenesis
►Drug Delivery Systems for Cancer Treatment
►Neoangiogenesis

Nephroblastoma

Hitoshi Ikeda
Department of Pediatric Surgery, Dokkyo Medical University Koshigaya Hospital, Koshigaya, Saitama, Japan

Synonym
Wilms tumor

Definition
Nephroblastoma is the most common form of renal cancer in children, representing 95% of total renal cancers. Others include clear cell sarcoma of the kidney, rhabdoid tumor of the kidney, congenital mesoblastic nephroma, and renal cell carcinoma. Nephroblastoma is synonymously called Wilms tumor after Dr. Max Wilms'

detailed description in 1899. Due to its morphological resemblance, nephroblastoma is believed to arise from metanephrogenic blastema that comprises primitive renal tissue in the early stage of embryonic development. Nephroblastoma represents ~6% of total malignant tumors among children younger than 15 years of age. The annual incidence is 8 per million children younger than 15 years of age and is slightly higher in black populations, while it is lower in children of Asian origin. Nephroblastoma occurs most commonly among children younger than 5 years of age, and 75% of the tumors are diagnosed in infants younger than 3 years of age. Both kidneys are affected in 7% of patients and familial cases are seen in less than 2% of patients. Although the majority of tumors occur in children with no other abnormalities, 10% of patients with nephroblastoma have malformation syndrome or congenital anomalies such as ►aniridia, ►hemihypertrophy, undescended testis, and ►hypospadias.

Characteristics

Genetics

Although the causes of most sporadic nephroblastomas still remain unknown, genetic abnormalities are thought to be responsible for the development of certain nephroblastomas (Table 1). The association of nephroblastoma, aniridia, genitourinary malformation, and mental retardation is called WAGR syndrome. The syndrome is associated with germline deletions at a certain region of the short arm of chromosome 11 (11p13), where the first nephroblastoma gene, *WT1*, and the *PAX6* gene that causes aniridia are located. *WT1* is a ►tumor suppressor gene and its coding WT1 protein functions as a transcriptional factor to regulate the expression of other genes involved in cell proliferation, differentiation, and cell death. *WT1* plays a role in normal genitourinary development and is important for the differentiation of renal blastema. Germline point mutations of the gene were shown in patients with ►Denys-Drash syndrome that is characterized by pseudohermaphroditism, degenerative renal disease, and nephroblastoma.

There is an association between nephroblastoma and congenital overgrowth syndromes such as ►Beckwith-Wiedemann syndrome and ►Perlman syndrome. Beckwith-Wiedemann syndrome predisposes to several embryonal neoplasms including nephroblastoma, hepatoblastoma, rhabdomyosarcoma, and adrenal cortical tumor. In Beckwith-Wiedemann syndrome, chromosomal abnormalities are frequently observed at a region of the short arm of chromosome 11 (11p15.5), where the presence of the second nephroblastoma gene, *WT2*, is assumed. One of the most probable candidates of *WT2* is the insulin-like growth factor II gene, *IGF2*, which encodes an embryonal growth factor. Because overexpression of the *IGF2* gene is sometimes observed in nephroblastomas, upregulation of the *IGF2* gene is likely to cause overgrowth in patients and tumor development. In humans, the maternal allele of the *IGF2* gene is imprinted and only the paternal allele is expressed, and loss of ►imprinting and paternal disomy is thought to be a mechanism of *IGF2* overexpression. However, whether Beckwith-Wiedemann syndrome and nephroblastoma result from alterations (mutations or deregulations) of the same gene or whether a single or more genes are involved in their pathogenesis are unknown. In association with the familial occurrence of nephroblastomas, there is some evidence showing that responsible genes are located on the long arm of chromosomes 17 (17q) and 19 (19q).

Clinical Aspects

Children with a predisposition to develop nephroblastoma should be screened until the age when nephroblastomas are unlikely to develop. Usually, nephroblastomas are solitary, spherical masses sharply demarcated from the adjacent renal tissue. Tumor extension into the renal vein is sometimes seen and it may extend up to the vena cava or the right atrium. Histopathologically, there are three different cell types: blastemal, stromal, and epithelial cells. Anaplasia is defined as the presence of cells with markedly enlarged hyperchromatic nuclei exhibiting multiple mitotic figures, which may be found focally or diffusely in

N

Nephroblastoma. Table 1 Congenital anomalies (abnormalities) and responsible genes for nephroblastoma

	Hemihypertrophy			
	Perlman syndrome			
	Perilobar nephrogenic rests			

the tumor. It is present in ~10% of tumors and is more frequent in children older than 5 years of age. Anaplasia is thought to represent a resistance to chemotherapy. When it is present, patients generally have a poor prognosis and tumors are histologically termed "unfavorable." On the other hand, nephroblastomas with no anaplasia are histologically "favorable" and patients have a good prognosis.

Nephrogenic rests, abnormally persistent embryonal kidney precursor cells arranged in clusters, are frequently seen in normally-appearing renal tissues in patients with nephroblastoma. They may be found even in children without neoplastic renal disease. The presence of multiple nephrogenic rests is designated as nephroblastomatosis. Nephrogenic rests are composed of small clusters of blastemal cells, tubules, or stromal cells, and are classified into intralobar and perilobar ones according to their location within the kidney. Intralobar nephrogenic rests are associated with WAGR and Denys-Drash syndrome, while perilobar nephrogenic rests are found in the kidneys of patients with hemihypertrophy and Beckwith-Wiedemann syndrome. Although the majority of nephrogenic rests regress spontaneously, it is considered that most nephroblastomas arise from these nephrogenic rests. However, a study regarding ethnic differences in nephroblastoma development suggested that patients in Asian children seem to be unrelated to nephrogenic rests.

Common manifestations of nephroblastoma include an abdominal mass, abdominal pain, macroscopic or microscopic hematuria, fever, and anorexia. Severe acute abdominal pain is sometimes caused by spontaneous or traumatic rupture of the tumor. Abdominal ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) are useful in evaluating the tumor extent and detecting metastases. The most common sites of metastases are the lungs, abdominal lymph nodes, and liver. Small lesions in the contralateral kidney, if present, can be demonstrated by the above examinations.

Staging of the tumor extent is essential to predict each patient's prognosis and to determine his or her treatment. The staging systems of the two major study groups, the National Wilms Tumor Study Group (NWTS) in North America and the International Society of Pediatric Oncology (SIOP) in Europe, are essentially the same and are based on the anatomical extent and surgical respectability of the tumor. The difference is that the former classifies tumors after surgery while the latter classifies those after preoperative chemotherapy and surgery. Stage I is defined as a tumor confined to the kidney and is completely resected. When a tumor extends beyond the kidney but is completely resected, it is classified into Stage II. When there are gross or microscopic residual tumors after surgical resection of the tumor, it is classified into Stage III. Stage IV is defined as a tumor with distant metastases, and Stage V as bilateral nephroblastomas. Tumor stage, along with histology, is an extremely important prognostic factor.

Treatment

Overall survival of total nephroblastoma patients is more than 90% according to recent clinical and epidemiological investigations. This has been achieved by clinical trials which were mainly performed by NWTS and SIOP. Currently, the main objectives of the trials performed in the group studies are focused on achieving higher cure rates, reducing the acute toxicities of treatment, and decreasing the incidence of late adverse effects. Generally, patients are treated according to their risk groups, and the modalities include surgery, radiotherapy, and chemotherapy.

While ►SIOP has been advocating preoperative chemotherapy, surgery is usually the initial treatment for most patients in NWTS. The procedure is radical nephrectomy and lymph node sampling through a transabdominal incision. In NWTS, preoperative therapy is recommended in patients with unresectable tumors, bilateral tumors, or such tumors as those extending deeply into the inferior vena cava. It makes tumor removal easier by reducing tumor burden and decreasing the incidence of surgical complications. Regarding the surgical management of bilateral nephroblastomas, nephrectomy of the more involved side and wedge resection or partial nephrectomy in the contralateral kidney have been performed. However, because renal insufficiency develops in many of these patients, bilateral renal salvage procedures are currently recommended. Initial biopsy of bilateral tumors followed by chemotherapy and delayed resection of the tumors are effective in controlling tumors without deteriorating renal function and adversely affecting survival. The renal salvage procedure in unilateral nephroblastoma has been a matter of controversy. It is sometimes recommended in tumors limited to a small portion of the kidney to preserve the function of the involved kidney. At the same time, however, the procedure may increase the risks for incomplete tumor resection and following local recurrence.

►Actinomycin D was the first agent demonstrated to be effective in the treatment of nephroblastoma. Multiagent chemotherapy including actinomycin D and other agents such as vincristine, adriamycin, and cyclophosphamide is given to patients according to the risk classification based on stage and histology. A two-drug regimen with actinomycin D and ►vincristine is effective against nephroblastomas of early stages (Stages I, II), while a three-drug regimen with actinomycin D, vincristine, and adriamycin is given to patients with tumors of advanced stages (Stages III, IV). In patients with tumors of unfavorable histology, more intensified chemotherapy is usually necessary.

Radiotherapy is another useful modality in the treatment of patients with advanced nephroblastoma due to the high radiosensitivity of the tumor. It is also indicated in patients with tumors of unfavorable histology that are resistant to chemotherapy. Lung or liver metastases can be controlled by irradiation, although some adverse effects such as ►radiation pneumonitis might be caused. In patients with bilateral nephroblastomas, radiotherapy is usually reserved for tumors unresponsive to chemotherapy or residual tumors after surgical resection, since it may cause damage to the remaining renal function.

Recurrences, most of which occur during the first 2 years after diagnosis, are experienced in a definite number of patients with nephroblastoma, particularly in patients with unfavorable histology. The most common sites of recurrences are the lungs, intraabdominal primary site, and the liver. Modern multidisciplinary treatment with salvage regimens has improved the survival of patients with recurrent nephroblastoma of favorable histology. The outcome in those with unfavorable histology is still poor.

Survivors of nephroblastoma are at high risk for second malignant tumors due to cytotoxic chemotherapy and irradiation as well as patients' inherited predisposition to malignant tumors. Renal function should be monitored because many of these survivors are still young and the risk of renal dysfunction continues into adult life for more than several decades.

[2]Arthur and Sonia Labatts Brain Tumor Center, Hospital for Sick Children's Research Institute, University of Toronto, ON, Canada
[3]Department of Pathology, UHN, University of Toronto, ON, Canada

Synonyms

Brain tumors; Gliomas

Definition

Primary CNS tumors are those that arise from transformation of one of the cellular elements that collectively give rise to the brain and spinal cord, plus their coverings, the meninges brain tumors, cancer, ►GBM.

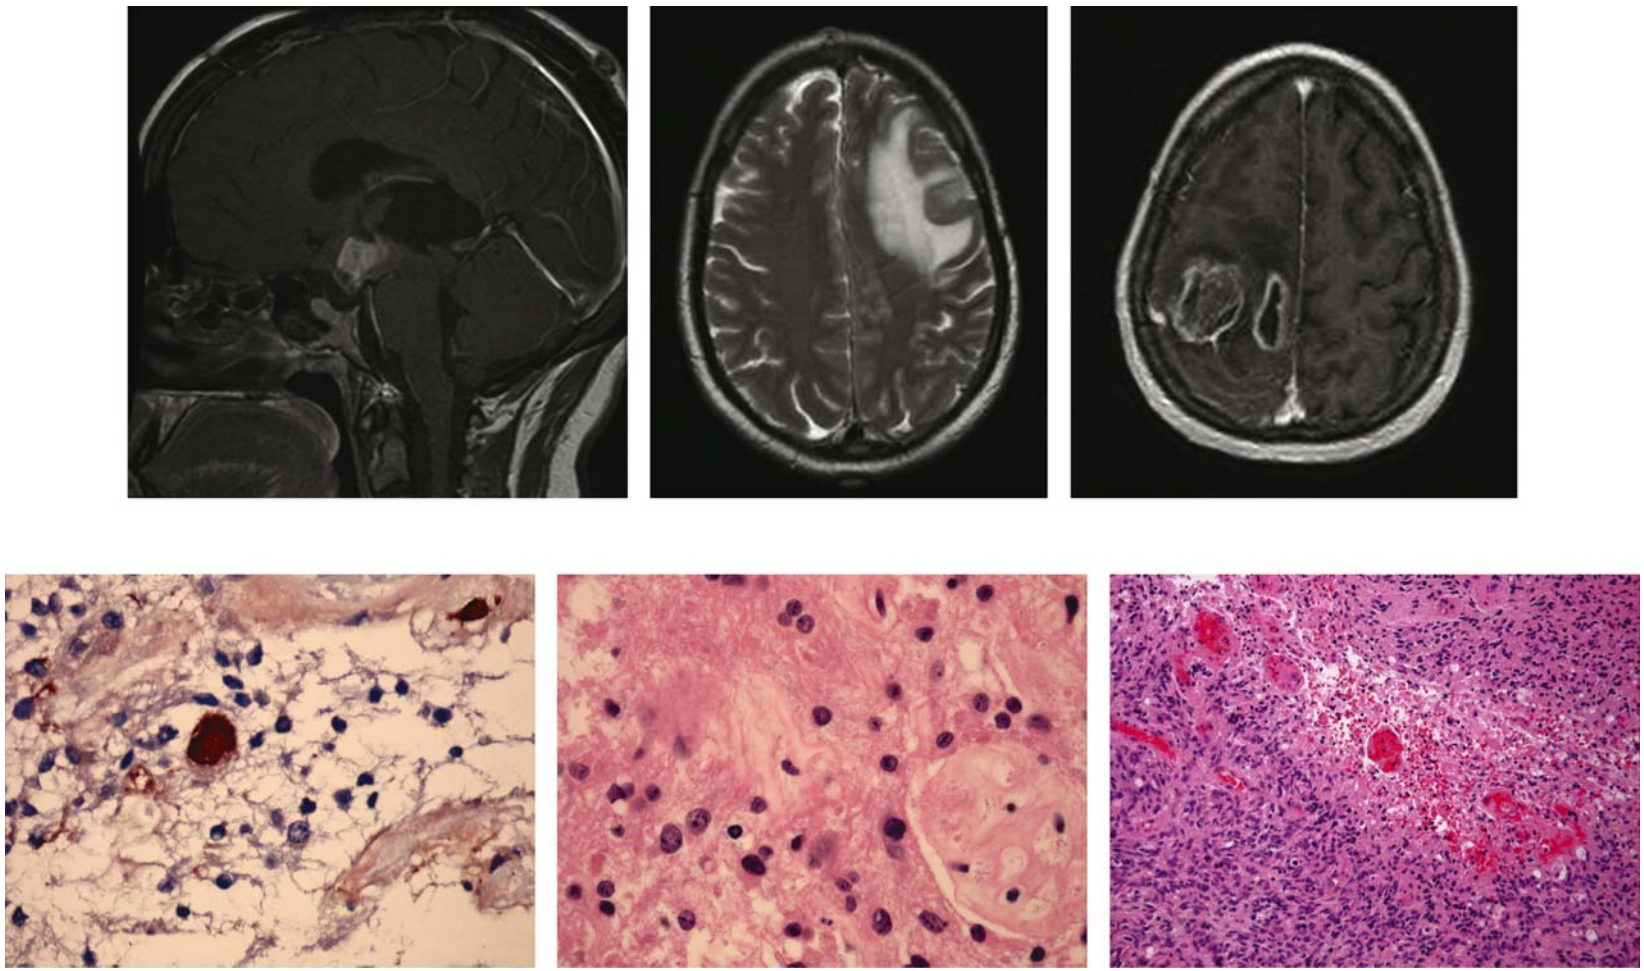
Characteristics

Epidemiology

Primary CNS tumors constitute a relatively small percentage of the total cancer burden in the human population, with an approximate incidence of 13/100,000 population and accounting for ~4% of all cancer related deaths. The incidence of CNS tumors is highest in the fourth to sixth decade of life, although as a percentage of total cancer burden, it is greater in children. Pediatric nervous system tumors however differ significantly in their clinical presentation, location, treatment, prognosis and molecular pathogenesis from those in adults. Our discussions here are limited to adult primary CNS tumors.

Classification

Primary CNS tumors can arise from any of the cellular constituents or their progenitors that collectively form the brain and spinal cord. Clues about the tumor subtype can be obtained from the age of the patient, location (supra- vs. infratentorial; intraxial vs. extraaxial), specialized regions (sella, pineal region, intraventricular), MRI signal characteristics, mode of presentation etc. However, a differential diagnosis usually exists, often requiring surgery for obtaining tissue and definitive classification. The current classification adopted by the WHO (World Health Organization) is based on immunohistopathological characterization of putative cells of origin. However, the recent postulate of the existence of different brain tumor stem cells giving rise to different tumor subtypes, based on differential molecular expression, may require revisiting this classification schema in the future. Tumors arising from neuroepithelial origin are common, with those arising from glial cells, especially the astrocytomas, being the most common primary CNS tumors in adults. Grade1 astrocytomas are present usually in children, associated with glioma pre-disposition syndromes such as Neurofibromatosis1,2 (NF1,2) ►Neurofibromatosis and rarely progress to higher grades. Grade2 or low-grade ►astrocytoma (LGA) is usually found in young adults and usually progresses to higher grades over a variable interval of time. Grade3 or anaplastic astrocytoma (AA) and Grade4 or ►glioblastoma multiforme (GBM) GBM, Glioblastoma Multiforme collectively termed as malignant astrocytomas, are unfortunately the most common and lethal of all primary CNS tumors in adults (Fig. 1). The next common glioma subtype is ►oligodendroglioma (low and malignant grade), followed by ►ependymomas (low and malignant grade) and choroids plexus papillomas. In addition to the glial derived tumors, tumors originating from neurona or neural-glial cells, such as ganglioglioma, ►medulloblastoma,



Neuro-Oncology: Primary CNS Tumors. Figure 1 (*Top*): MRI scans demonstrating various grades of astrocytomas: *Left*: Grade 1: MRI + gadolinium contrast scan of an Optic Nerve Glioma, a pilocytic astrocytoma associated with Neurofibromatosis1 patients which usually remains indolent and does not progress; *Middle*- Grade2: MRI T2 weighted scan of a non-enhancing low-grade astrocytoma (LGA) in a young adult, which usually progresses to higher grade malignant astrocytomas; *Right:* Grade4: MRI + gadolinium contrast scan of a ring enhancing GBM. (*Bottom*): Corresponding H&E sections of various grades of astrocytomas: *Left:* Pilocytic astyrocytoma with Rosenthal fibers; *Middle:* Grade2 LGA with increased cellularity and slight nuclear pleomorphism; *Right:* GBM with regional necrosis surrounded by pseudopalisading tumor cells and increased vascularity.

esthesioneuroblastoma or pineal region tumors also exist, but are rare.

After glioma, ►meningioma (benign, atypical and malignant) arising from the arachnoid cap cell is the most common. These extraaxial tumors are followed by tumors of the anterior pituitary gland (pituitary adenomas) and those arising from cranial nerves, especially the vestibular schwannomas. Hence in summary, there exists a large differential of primary CNS tumors, extending from benign tumors that are potentially amenable to surgical cure to frankly malignant and locally invasive tumors, typified by GBMs that will be the focus of the rest of this essay.

Clinical and Radiological Presentation

Patients with CNS tumors present with essentially a constellation of symptoms which can be broadly classified into those that reflect: (i) Increased intracranial pressure (headaches); (ii) Gradual global deficit in cognition and memory; (iii) Gradual and progressive focal deficit, such as those involving motor power, variety of sensory functions, speech etc.; (iv) Acute neurological dysfunction such as in a seizure or a stroke. The clinical presentation will depend on the location of the tumor and peri-tumoral edema and associated normal neurological function of that region. After excluding a secondary source of a CNS tumor, the incidence of which is increasing, CT or MRI imaging is helpful, but not always pathognomic in giving a definitive diagnosis of tumor subtype. Current imaging modalities include administration of contrast, visualization of which is dependent on breakdown of the blood-brain-barrier, however, this often fails to distinguish between CNS tumor subtypes and grade. The development of biological imaging modalities such as MR Spectroscopy, which is dependent on the metabolic state of the tumor and in the future imaging based on the tumor genetic profile, will be of tremendous benefit. Until these imaging modalities are developed and demonstrated to be robust, current requirement of surgery to obtain tissue for pathological and molecular classification will still be required.

Etiology

The majority of adult primary brain tumors occur sporadically, in an increasing age-dependent manner. Environmental links remain speculative, with radiation being the most tightly linked, usually resulting in tumors of the meninges and/or cranial nerves. A variety of chemicals, viruses and more recently electromagnetic waves from powerlines and cell phones have been implicated; however, confirmatory studies are lacking. Certain patient demographics have also been linked to certain tumor subtypes. The incidence of gliomas is slightly higher in males, while meningiomas (especially those in the spine) are far more common in females, suggestive of hormonal influences. Primary CNS lymphomas are associated with chronic immunosupression (transplant or HIV patients), though the recent increase in these tumors is mainly in the immunocompetent patient, for reasons that remain unclear.

A few CNS tumor pre-disposing germline tumor suppressor gene syndromes do exist, but account for <5% of cases. childhood cancer. Amongst these are the ►Phakomatosis Syndromes, with NF1 being the most common, associated with Grade1 astrocytomas involving but not exclusive to the optic nerve pathway. Next is NF2, associated with multiple cranial nerve schwannomas, but also meningiomas and gliomas (astrocytomas and ependymomas) of the brain and spinal cord. ►Tuberous Sclerosis (TSc) is associated with CNS developmental anomalies (tubers) and hence seizures, plus usually an indolent subtype of astrocytoma termed subependymal giant cell astrocytomas (SEGA). The next is ►von Hippel Lindau disease with multi-system vascular tumors including retinal and CNS ►hemangioblastoma and hemangiopericytomas. Among non-Phakomatosis is the ►Li-Fraumeni Syndrome, where young adult onset low- and high-grade astrocytomas occur as part of the multi-tumor types in these patients. In addition to ocular tumors, ►Retinoblastoma Syndrome patients can have other CNS tumors involving the pineal and olfactory bulb. Last are several syndromes that are rarely associated with tumors in specific regions such as the pituitary gland (►Multiple Endocrine Neoplasia: MEN) or cerebellum (Medulloblastomas associated with ►Turcot Syndrome and ►Gorlin Syndrome).

In addition to the genetically defined cohorts of predisposition syndromes cursorily discussed above, familial clustering of primary brain tumors have been noted, with likely a yet-to-be-identified multi-genetic basis. However, of importance, these syndromes share many of the molecular pathogenetic pathways found in the larger cohort of sporadic CNS tumors, thereby facilitating and focusing research which may be applicable to all patients and not just the minority of those linked with a pre-disposition syndrome.

Molecular Pathogenesis

The multi-genetic aberrations that lead to primary brain tumors are being slowly deciphered, as reviewed in the WHO primer. The pathological subtype of glioma that arise (astrocytoma vs. oligodendroglioma etc.) are a function of the specific molecular alterations and the developmental stage of the glial or glial precursor cell they occur in. Furthermore, some of these molecular alterations act as initiation factors, while others are involved in progression. Experimental proof for the above thesis for example comes from our transgenic glioma models. Mutant EGFRvIII, usually associated with adult malignant astrocytomas, by itself does not

lead to gliomas; however, it enhances tumors in transgenic glioma prone mice. Of interest, embryonic expression of EGFRvIII in these glioma pre-disposed mice leads to oligodendrogliomas, with adult expression in these mice leading to the predicted malignant astrocytoma, demonstrating the importance of the developmental stage of the transformed cell. The hypothesis of the brain tumor cancer stem cell has made us further aware of the importance of the interplay of neuro-glial development and oncogenesis. This hypothesis, extrapolated from the longstanding leukemia literature and still awaiting conclusive verification in solid tumor systems such as gliomas, has implications beyond pathological subtype. Targeting cancer stem cells may play a role in therapeutic sensitivity and/or resistance.

The Cancer Genome initiative, with a part focused on GBMs, has already added to the complexity of the required understanding of the molecular pathogenesis of astrocytomas. Clinical-pathological-molecular studies to date pointto at least two molecular pathogenic pathways to pathologically indistinguishable GBMs. A smaller and slightly younger age group of "Secondary GBMs," progressed from a documented LGA and harbored ►p53 mutations. In contrast, a larger number of older adults presented with a "Primary GBM," which did not harbor p53 mutations, but had alterations in ►EGFR (►amplification and mutation) and mutations plus loss of the tumor suppressor gene PTRN. However, this paradigm has recently been complemented by the high throughput detailed analysis of the Cancer Genome Project, suggesting not one but two relevant molecular pathways of "Secondary GBMs." Efforts such as this will likely lead to several molecular pathogenic pathways, which need to be tested for their oncogenic and therapeutic relevance.

The last overview point about molecular pathogenesis of gliomas is the influence of the tumor microenvironment on the molecular profile through genetic or ►epigenetic mechanisms. As the name "Multiforme" implies in GBMs, these are pathologically heterogennous tumors. Regional variations in the tumor ►microenvironment, notably ►hypoxia, may lead to profound alterations in the regional molecular profile, which is reflected in the heterogenous pathology. Molecular profiling of isolated regional glioma cells attests to this hypothesis of regional molecular heterogeneity. Treatment failure in gliomas is due to mainly local recurrence around the treated region. Hence, understanding the regional molecular heterogeneity will facilitate our ability to target different regions of gliomas more effectively.

Current Management

The majority of gliomas, except for the lower-grade ependymomas and choroid plexus papillomas, for the most part are not curable, with definitive optimal management pending. Some gliomas, such as Grade1 pilocytic gliomas in NF1 patients, are best served by observation. The treatment of LGA in adults is another area of controversy, due to their long and unpredictable time course of progression. GBMs, representing the largest and most lethal cohort of gliomas, are where most of the clinical trials to date have been undertaken, though with very little positive progress. What we have learned is that whenever possible with reasonable morbidity, aggressive surgery should be attempted, followed by external beam radiation of 5,500–6,000 rads. Despite a variety of chemotherapy trials, the median survival curves were not further altered and remained at a dismal 9–12 months for several decades. However, recently this median survival has been extended to 14–16 months with the use of the orally well-tolerated chemotherapeutic agent, Temodar, Temozolomide given concomitantly with radiation therapy. This regime, although far from a cure, is now the backdrop against which all novel therapies will be judged.

Future Directions

Molecular Therapy: Molecular Based Diagnostics-Prognosis-Targeted Therapy

In glioma management, the implications of molecular diagnostics in augmenting classification, predicting prognosis and in several instances tailoring therapy, have already commenced. In classification, several similar or difficult diagnostic entities which were subject to inter-pathological evaluation variability, are now clarified by genetic characterization such as ►FISH or ►PCR based diagnostics. Such examples are the diagnostic difficulties with oligodendrogliomas and mixed oligo-astrocytomas, which are now complemented with evaluation of molecular signatures associated with these tumors. Amongst the two most important independent prognosticators within a grade of astrocytoma such as GBMs, are the patient's age and neurological function at presentation. The availability of certain molecular profiles of the tumor (such as the presence or absence of mutant EGFR, methylation and thereby silencing of DNA repair pathways) are also in many cases independent significant prognostic variables. In the realm of therapeutics, molecular diagnostics has definitely altered the current management of oligodendrogliomas, based on the seminal observation of the role of 1p and to a lesser extent19q loss in dictating a more indolent biology and inherent chemosensitivity. Although the exact genetic basis of this favorable outcome is not yet known, stratification of several other glioma subtypes based on this molecular signature is under study. Less definitive but evolving are therapeutic decisions based on the knowledge of the status of DNA repair mechanisms, such as methylation of MGMT and influence on chemo- and radiation sensitivity.

The importance of this and other potential repair pathways was demonstrated by the initial molecular-translational report accompanying the favorable results of concomitant Temodar and radiation in GBMs. This observation needs further verification before it becomes part of our standard of practice and influences definitely therapeutic choices. Another example where molecular diagnostics may influence glioma therapeutics is the initial observation that small molecule EGFR inhibitors were effective in the small subset of GBMs which harbored amplified and mutant EGFRs, but not loss of PTEN expression, a receptor independent negative regulator of the PI3Kinase pathway. Simplistically, this deduction is logical and would suggest that in the larger set of GBMs, with both EGFR alterations and PTEN loss, multi-targeted therapy directed at EGFR or its downstream signaling pathway mediated by activated p21Ras plus inhibitors targeting the hyperactive ►PI3-Kinase pathway (i.e. ►mTOR inhibitors) may be required. This specific postulate is undergoing verification in larger trials, but does attest to the likely scenario that multi-modal biological therapies will be required to make perhaps small but significant alterations in the prognosis of patients with malignant gliomas.

Adjuvant Therapy: Novel Biologicals and Therapeutic Delivery

The invasive nature of gliomas likely will render focal therapies such as surgery or radiation limited in providing sustained cure. Systemic therapeutic modalities or delivery modalities that are capable of widespread delivery, hold promise though they remain unproven to date. Non-specific systemic chemotherapy was of limited use until Temodar, mainly due to toxicity and resistance of the tumor cells. Biologically targeted systemic therapies, targeting aberrant relevant signaling biological pathways in gliomas such as EGFR, Epidermal Growth Factor Receptor PDGFR, Platelet Derived Growth Factor Receptor VEGF/VEGFR, Vascular Endothelial Growth Factor/Receptor p21Ras and PI3-Kinase, are under current examination. However efficacy if demonstrated will likely be in the context of recurrence after failure from conventional therapy and in combinatorial use with other biological therapies. The immune system has long been a desirable target in gliomas. However, lack of specific glioma antigens, maintenance of an intact blood-brain barrier in the infiltrating and recurrent tumor edge, are only some of the reasons why immune modulation either passively with immune stimulants and vaccinations or passively with expansion and re-infusion of tumor cell lymphocytes, have not shown any clinical efficacy to date.

Delivery of biologicals specifically to the invading tumor cells is another challenge that has been and is currently being pursued. Notable amongst these was the replication incompetent Herpes simplex virus type 1 mediated TK (thymidine kinase) gene transfer trial, which failed mainly due to limitation in spreading beyond the injection sites to the infiltrating glioma cells. In recognition of this limitation, replication competent viruses are being brought to clinical trials in GBMs, however, with cautious optimism. ►Immunotoxin therapy, based on differential expression of antigens in glioma cells such as Transferrin or IL13receptors, conjugated to modified diphtheria or pseudomonas toxins are another promising strategy. Macromolecule strategies such as immunotoxins are theoretically limited due to their inability to penetrate and kill the invading glioma cells in regions where the blood-brain barrier is still intact. To overcome this hurdle, novel delivery modalities such as ►Convection Enhanced Delivery (CED), dependent on bulk flow induced by slow infusion rather than diffusion, holds promise, but again requires careful clinical verification.

Biological Imaging

Among the many differences in the management of primary CNS tumors from neoplasms in many other organs is the eloquence of the brain and its limitation to be sampled repeatedly. In addition, as mentioned, considerable tumor heterogeneity at a pathological and molecular level exists and evolves with a changing tumor microenvironment, especially in malignant gliomas. To overcome this limitation biological imaging beyond current conventional anatomic CT/MRI imaging will be required. MR Spectroscopy, MR based evaluation of tumor cellularity and angiogenesis, and PET scanning for determination of tumor metabolism are already under clinical evaluation, with some promise. Gene-expression and protein activation dependent imaging is under current development and experimental evaluation. These biological imaging modalities will hopefully be invaluable in the diagnosis of subtype and grade of the primary brain tumor and how the biology alters with tumor growth, thereby providing rational targeted therapies without risks of repeated biopsy.

Conclusions

Primary CNS tumors, especially malignant gliomas, have been synonymous with a terminal human cancer. Although this remains factual in many instances, there is much activity toward the understanding of the molecular biology of these tumors. The Cancer Genome initiative involving gliomas is but one important example of this heightened interest. Molecular diagnostics, imaging and therapy have started to make small positive alterations in the management and prognosis of CNS tumor patients and holds much future promise. Instead of being relegated as a lost cause, CNS tumors are being actively studied by the scientific community and are of high interest to biopharmaceutical companies towards development of novel therapeutic strategies.

Neuroblastoma

Manfred Schwab
DKFZ, Heidelberg, Germany

Definition

Neuroblastomas are childhood embryonal tumors of migrating neuroectodermal cells, derived from the neural crest and destined for the adrenal medulla and sympathetic nervous system.

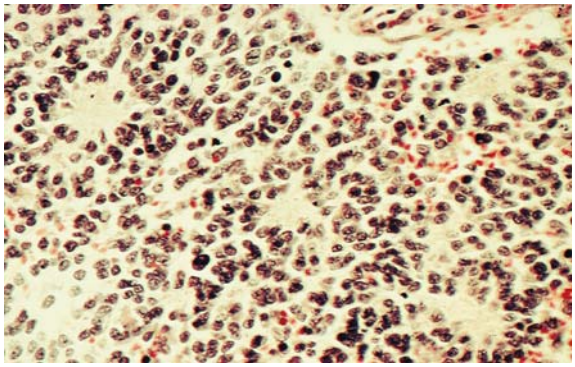
The term neuroblastoma is commonly used for all types of neuroblastic tumors. The International Neuroblastoma Pathology Committee distinguishes between four types of neuroblastic tumors:

- Neuroblastoma (Schwannian stroma-poor)
- ►Ganglioneuroblastoma, intermixed (Schwannian stroma-rich)
- ►Ganglioneuroma (Schwannian stroma-dominant)
- Ganglioneuroblastoma, nodular (composite, Schwannian stroma-rich/stroma-dominant, and stroma-poor

Characteristics

Neuroblastic tumors are the most common solid extracranial malignant tumors during the first 2 years of life. In the United States of America there are seven new cases per million population per year are detected in black children and 9.6 per million in white children. More than 90% of cases occur in the first decade of life. Neuroblastoma has been detected in the fetus in utero by prenatal ultrasound examination. There is no sex predilection.

The primary sites include the adrenals (40% of neuroblastic tumors), followed by the abdominal (25%), thoracic (15%), cervical (5%), and pelvic



Neuroblastoma. Figure 1 Schwannian stroma-poor. A tumor composed of neuroblastic cells forming groups or nests.

sympathetic ganglia (5%). These structures are derivatives of migrating neuroectodermal cells originating from the neural crest. It has been suggested that in ganglioneuroblastoma (Schwannian stroma-rich) the diploid Schwann cells are reactive, in contrast to triploid ganglion cells. All ganglioneuromas (Schwannian stroma-dominant), the fully mature form of neuroblastic tumors, were once neuroblastomas (Schwannian stroma-poor) (Fig. 1).

Neuroblastic tumors have favorable prognosis in infants less than 1 year of age. Adrenal neuroblastic tumors have a worse prognosis than extraadrenal tumors, particularly thoracic tumors. Children with stage 1 and 2 neuroblastic tumors survive longer than those with stage 3 and 4 tumors. Spontaneous regression is most apparent in patients with stage 4S tumors, i.e., infants with a local stage 1 neuroblastoma or unknown primary with involvement of the liver, skin, and/or bone marrow with <10% tumor cells. However, even within stage 4S is a subset of tumors with poor prognosis, which is characterized by unfavorable histology or amplified ►*MYCN*. Regression also occurs in a subset of patients with other stages of neuroblastoma, but predominantly in infants. It is not clear whether spontaneous maturation or an immunological phenomenon is related to regression.

Prognostic evaluation is based on an age-linked histopathologic classification distinguishing two prognostic groups; the favorable and the unfavorable histology group (►Shimada system).

Tumors in the favorable histology group include:

- Age up to 1.5 years: neuroblastoma poorly differentiated subtype with low (<2% or <100/5,000 cells) or intermediate (2–4% or 100–200/5,000 cells) mitosis-►karyorrhexis index (►MKI)
- Age between 1.5 and 5 years: neuroblastoma, differentiating subtype with low ►MKI
- Ganglioneuroblastoma, intermixed, usually seen in older children

- Ganglioneuroma, maturing and mature subtypes, usually seen in older children

Tumors in the unfavorable group include:

- Any age: neuroblastoma, undifferentiated subtype
- Age between 1.5 and 5 years: neuroblastoma, poorly differentiated subtype
- Any age: neuroblastoma with high (>4% or >299/5,000 cells) MKI
- Age between 1.5 and 5 years: neuroblastoma with intermediate MKI
- Age 5 years or older: all neuroblastoma subtypes
- Ganglioneuroblastoma, nodular

The etiology of neuroblastoma is unknown, it appears unlikely that environmental exposure plays a major role. However, cases of neuroblastoma have been described that were associated with the fetal hydantoin, phenobarbitol or alcohol syndromes, suggesting that prenatal exposure to these substances may increase the risk of neuroblastoma. Other studies have been suggesting a weak association between neuroblastoma and paternal occupational exposure to electromagnetic fields, or maternal use of hair coloring products, but none of these associations has been confirmed. Moreover, no prenatal or postnatal exposure to drugs, chemicals, or radiation has been strongly or consistently associated with an increased incidence of neuroblastoma.

Although most neuroblastomas appear to be sporadic, a number of reports have been describing familial neuroblastoma, as well as bilateral or multifocal disease, that are consistent with hereditary predisposition.

Constitutional chromosomal abnormalities have been described in lymphocytes of patients with neuroblastoma, even though there is no apparent pattern. An interstitial ►deletion and a reciprocal ►translocation t(1;17), both affecting 1p36, were observed in patients with neuroblastoma. However, it is unclear if these 1p36 rearrangements were contributing to a neuroblastoma predisposition. Somatic genetic changes associated with neuroblastoma progression include ►amplification of ►MYCN and ►allelic loss at 1p, 11q, 14q, and gain of 17q. ►Amplification is a highly informative ►biomarker for clinical management of neuroblastoma. Different signaling pathways are under clinical investigation in clinical studies.

Neurocytoma

Dirk Rades
Department of Radiation Oncology, University Hospital Schleswig-Holstein, Campus Luebeck, Germany

Synonyms

Central neurocytoma; Typical neurocytoma; Well-differentiated neurocytoma; Atypical neurocytoma

Definition

The term "neurocytoma" was established by Hassoun et al. in 1982 in order to distinguish these lesions, which occur mainly in adults, from ►neuroblastoma, which occurs mainly in children. Neurocytomas are rare tumors of the central nervous system, mostly located in the ventricular system, which are usually considered benign. However, in 1989, a more aggressive variant of this tumor called "atypical central neurocytoma" was reported.

Characteristics

Central neurocytomas account for 0.25% to 0.5% of all central nervous system tumors. Less than 600 cases have been reported in the literature. Because neurocytomas are very rare, no prospective studies are available. The ratio of male to female is approximately 1.25:1. In the majority of patients, the age at diagnosis is between 20 and 35 years. Most lesions are located in the ventricular system. Spinal tumors are extremely rare.

Neurocytomas can be divided in two major subgroups, typical (well-differentiated) neurocytomas and atypical neurocytomas. About 75% of the neurocytomas are typical lesions, which represent a less aggressive variant considered benign. Typical neurocytomas are characterized by a ►MIB-1 labeling index ≤3% and absence of atypical histologic features such as focal ►necrosis, increased mitotic activity, and vascular

proliferation. Intracerebral hemorrhage and transformation to a more aggressive malignant lesion (atypical neurocytoma) are considered serious complications. Atypical neurocytomas are characterized by a MIB-1 labeling index >3% and presence of atypical histologic features. Children with a neurocytoma appear to have a marginally better prognosis than adults.

Diagnosis

The diagnosis of a neurocytoma is based on histopathological findings and imaging.

Macroscopically, a neurocytoma appears as a gray, partly calcified mass. On light microscopy, the lesion is composed of small round cells with intercellular fibrillar zones and rosette-like structures. The nucleus is round or oval with a finely specked chromatin and an occasionally prominent nucleolus. Clear cells are common and result in a honeycomb appearance. Mitoses and necrosis are extremely rare. High mitotic activity and necrosis must be considered as indicators for a more aggressive behavior (atypical neurocytoma). Calcifications and well developed vascularization are common.

On electron microscopy, tumor cells have regular round nuclei with finely dispersed chromatin and sometimes a neat small nucleolus. The cytoplasm contains parallel ergastoplasmic channels, a prominent Golgi apparatus, and lysosome-like inclusions. Numerous thin and intermingled cell processes were found which contain mitochondria and microtubules.

Neurocytomas may show immunoreactivity for a variety of neuronal marker proteins such as neuron-specific enolase (NSE), synaptophysin, synapsin, neurofilament protein, neuron-associated class III beta-tubulin, microtubule-associated proteins MAP2 and tau, neuron-specific antigene L1, S-100 protein, or Leu-7. An occasional staining for glial fibrillary acidic protein (GFAP) demonstrates a potential for astrocytic differentiation. However, most of these markers are non-specific. The most reliable one is synaptophysin.

On computed tomography, a neurocytoma appears as a well circumscribed round or poly-lobed hypodense mass which may show homogeneous enhancement with contrast medium. The lesion may contain cystic areas or calcifications. Magnetic resonance imaging shows an isointense or slightly hyperintense signal in comparison to the cortex both on T1-weighed and on T2-weighed images. Administration of ►Gadolinium-DTPA usually leads to a slight homogeneous enhancement. The enhancement may be inhomogeneous if cysts or calcifications are present.

Therapy

Gross tumor resection (GTR) is associated with significantly better survival and local control than subtotal tumor resection (STR). Therefore, GTR should be performed whenever safely possible. After STR, the treatment outcome may be improved with post-operative radiotherapy. However, the role of radiotherapy and the recommended total dose vary between the different neurocytoma types (typical, atypical, neurocytoma in children). Both conventional ►radiotherapy and ►stereotactic radiosurgery may improve the outcome after STR. However, there is only little data available regarding the role of stereotactic radiosurgery in the treatment of neurocytomas.

Typical lesions were associated with better outcomes than atypical lesions. In a retrospective series of 351 patients with a typical neurocytoma, the 10-year survival rates were 100% after GTR alone ($N = 137$), 100% after GTR followed by conventional radiotherapy ($N = 29$), 90% after STR alone ($N = 90$), and 97% after STR followed by conventional radiotherapy ($N = 97$). The 10-year local control rates were 76%, 100%, 43%, and 82%, respectively. The outcome was not significantly improved by radiotherapy following GTR in terms of survival ($P = 1.0$) and local control ($P = 0.08$). After STR, radiotherapy resulted in significantly better survival ($P = 0.03$) and local control ($P<0.001$). Thus, if only STR can be performed, post-operative radiotherapy can be recommended. A radiation dose of 50 Gray (Gy) given in 2-Gy-fractions appears sufficient.

Atypical neurocytomas are more aggressive than typical lesions. In a retrospective series of 87 patients, the 5-year survival rates were 91% after GTR alone ($N = 15$), 93% after GTR plus conventional radiotherapy ($N = 14$), 46% after STR alone $N = 19$), and 69% after STR plus conventional radiotherapy ($N = 39$). The 5-year local control rates were 59%, 63%, 5%, and 65%, respectively. After GTR, the outcome was not significantly improved with post-operative radiotherapy in terms of survival ($P = 0.87$) and local control ($P = 0.30$). After STR, radiotherapy resulted in both better survival ($P = 0.05$) and better local control $P<0.001$). Thus, post-operative radiotherapy and can be recommended after STR. In contrast to patients with typical lesions, those with atypical lesions appeared to benefit from higher radiation doses. A dose of >54 Gy was associated with better local control ($P = 0.05$) than a dose of ≤54 Gy. Thus, the radiation dose after STR of atypical neurocytomas should be 56–60 Gy given in 2-Gy-fractions.

Of a retrospective series of 438 patients, 73 patients (17%) were children (age ≤18 years). The median age was 16 years (range 1–18 years). Sixty-two children had typical and 11 children atypical lesions. The prognosis for children appears quite good. In that series, the 5-year survival rates were 100% after GTR alone ($N = 25$), 100% after GTR plus conventional radiotherapy ($N = 12$), 82% after STR alone ($N = 19$), and 100% after STR plus conventional radiotherapy ($N = 17$). The 5-year local control rates were 89%, 100%, 52%, and 94%, respectively. After GTR, the

outcome was not significantly improved by radiotherapy in terms of survival (P = 1.0) and local control (P = 0.30). After STR, radiotherapy significantly improved local control (P = 0.002), but not survival (P = 0.16). The difference in survival of 18% appears reasonably large. The fact that significance was not achieved may be explained by the small sample size. A dose of 50 Gy given in 2-Gy-fractions appears sufficient to achieve long-term local control for both typical and atypical neurocytomas in children. However, caution should be used in the interpretation of these data because of the few children in the radiotherapy groups.

Although local control can be improved by post-operative radiotherapy, one should be more reserved recommending radiotherapy for children. ►Psychomotor retardation was reported in one child treated with STR followed by 40 Gy. The rate of children with psychomotor retardation may be underestimated, because neuropsychologic testing was not always performed. Until now, ►secondary tumors of the brain have not been reported after radiotherapy of a neurocytoma. However, according to the literature, the development of a radiation induced malignancy is an important issue in children. Thus, in children with a neurocytoma, it appears reasonable to administer post-operative radiotherapy only in limited situations such as incompletely resected neurocytomas, especially atypical lesions, and recurrent tumors.

Neuroectodermal Tumor

►Carcinoid Tumors

Neuroendocrine Carcinoma

Ignacio Duran, Lillian L. Siu
Department of Medical Oncology and Hematology, Robert and Maggie Bras and Family New Drug Development Program, Princess Margaret Hospital, Toronto, ONT, Canada

Synonyms

APUDOMAS; Carcinoid tumors; Islet cell tumors; Neuroendocrine tumors of the pancreas; Malignant endocrine tumors

Definition

Neuroendocrine carcinomas are tumors derived from the ►diffuse neuroendocrine system.

Characteristics

Neuroendocrine carcinomas will include a heterogeneous group of tumors that can arise wherever the diffuse neuroendocrine system is found throughout the body.

Classification

It is widely accepted to divide these malignancies in two major groups: ►carcinoids tumors and ►neuroendocrine tumors of the pancreas. There are other, rare malignancies that also are classified as neuroendocrine carcinomas, including ►pheochromocytomas, ►medullary thyroid carcinoma, ►merkel cell tumors.

Other subclassifications will consider these tumors according to: site of origin (lung, gastrointestinal tract, etc.), capability or producing certain hormones (functioning and nonfunctioning tumors), degree of cellular differentiation as an indicator of biological aggressiveness (well, moderate, or poorly differentiated tumors), and type of presentation (sporadic tumors or within hereditary cancer syndromes).

Epidemiology

Neuroendocrine carcinomas are rather rare with estimated incidences of 1–2 cases per 100,000 for ►carcinoid tumors and 4 cases per million for neuroendocrine tumors of the pancreas.

The incidence increases with age, with the highest observed in the fifth decade and upwards, except for carcinoid of the appendix that occurs mostly in patients below 30 years of age. The ratio of gender distribution is about one to one for males to females.

Natural History

Neuroendocrine carcinomas usually present with indolent behavior. However, once they have spread to distant organs, the cure rates are low and the 5-year survival rate is around 30–40%.

The diagnosis of neuroendocrine carcinomas is challenging, as they can be asymptomatic for long periods of time. Even if there are symptoms, they usually are vague and nonspecific, thus resulting in difficulties and delays in the diagnostic process.

These tumors may present as a sporadic disease or within an inherited syndrome such as the ►multiple endocrine neoplasia type 1, ►multiple endocrine neoplasia type 2, ►neurofibromatosis type 1 or ►Von Hippel–Lindau disease.

Carcinoids

This term was first introduced by Oberndorfer in 1907 to describe a type of tumor in the gut that was similar to carcinomas (therefore "carcinoid") but with "slower growth and less malignant behavior."

Carcinoid tumors have been traditionally classified into foregut carcinoids (arising from lung, thymus, esophagus, stomach, duodenum, pancreas); midgut carcinoids (arising from jejunum, ileum, appendix, ascending colon); and hindgut carcinoids (arising from transverse and distal colon, rectum). The midgut carcinoids are the most frequent representing ~40–60% of all, while 25 and 15% correspond to foregut and hindgut tumors respectively.

Carcinoid tumors have cells that contain neurosecretory granules capable of synthesizing, storing, and releasing a number of substances such as serotonin, histamine, tachykinins, bradykinins, and ►prostaglandins. Some patients may present with a specific clinical syndrome related to the release of the above-mentioned substances to the systemic circulation, called the ►carcinoid syndrome.

Neuroendocrine Tumors of the Pancreas (Islet Cell Tumors)

The pancreas is a small organ of the digestive system that lies behind the stomach inside a loop formed by part of the small intestine. Its functions include: (i) Collaborating with the digestion of food through production of digestive juices and (ii) Producing hormones (such as insulin) that regulate food storage and use.

The region of the pancreatic gland that produces digestive juices is the exocrine pancreas while the one producing hormones, comprised by the so-called islet cells, is the endocrine pancreas. The neuroendocrine tumors of the pancreas derive from the islet cells and are generally denominated ►islet cell tumors.

When islet cells become cancerous, they may or may not overproduce hormones. These entities are considered as functioning and nonfunctioning endocrine tumors, respectively.

Functioning endocrine tumors constitute ~60% of all islet cell tumors, and are subclassified according to the predominant hormone produced as follows: ►gastrinoma, ►insulinoma, ►VIPoma, ►glucagonoma, and ►somatostatinoma.

Diagnosis of Neuroendocrine Carcinomas

The diagnosis of neuroendocrine carcinomas comprises three different aspects: pathological, biochemical, and imaging diagnosis.

Pathological Diagnosis

Generally, tumor tissues are obtained through a biopsy procedure whereby a small piece of tumor is removed from the body with a needle using sterile techniques. Sometimes, the diagnosis of neuroendocrine carcinomas is made incidentally, when the tissue specimens were removed for other purposes.

The first step in the diagnosis of these tumors is an accurate analysis of their appearance when examined under the microscope by a pathologist (histopathological analysis). Through specific staining techniques (►Immunohistochemistry), typical neuroendocrine markers such as ►chromogranin A, neuron specific enolase, and synaptophysin should be evaluated in the tumor tissue specimens.

Biochemical Diagnosis

Determination of certain substances in the blood of patients being worked-up for a neuroendocrine tumor is a critical component of the diagnostic process.

Chromogranin A. Serum analysis of chromogranin A seems to be the most promising biochemical test with high specificity and sensitivity values. This serum marker correlates with tumor burden and is useful in both functioning and nonfunctioning tumors.

►*5-Hydroxyindoleacetic Acid (5-HIAA)*. Measurement of 24-h urine levels of ►5-HIAA is also accepted as an important diagnostic tool. It is very helpful in midgut carcinoids while it is rarely useful in other neuroendocrine carcinoma varieties that do not secrete serotonin frequently.

Other Markers. Depending on the specific hormone(s) secreted by functioning neuroendocrine tumors, such as gastrin in gastrinoma or insulin in insulinoma, monitoring of these hormone(s) may be considered.

Other useful serum markers proposed are: plasma pancreatic polypeptide, α-HCG, chromogranin B, and secretogranin II. Their use in clinical practice is limited at present.

Imaging Diagnosis

Conventional imaging tests, such as computerized tomography, ultrasound, and magnetic resonance, are useful in the initial work-up of these tumors to demonstrate the size and extent of the primary tumor, especially for those with pancreatic neuroendocrine tumors. These imaging tests can also evaluate for any distant metastases such as liver, chest, or pelvic involvement.

►Somatostatin receptor scintigraphy (SRS) (also known as OctreoScan) is an important imaging

investigation in patients with suspected neuroendocrine carcinomas. ►SRS utilizes a radiolabeled form of the ►somatostatin analogue octreotide (^{111}Indium-Penetreotide), based on the fact that a majority of neuroendocrine carcinomas contain a high concentration of somatostatin receptors. The uptake of radiolabeled octreotide will help, not only in the staging, but also in predicting the clinical response to somatostatin analogues.

Meta-iodobenzyl-guanidine (MIBG) is a radiopharmaceutical agent that concentrates in cells of selected neuroendocrine tumors, though not as often as octreotide. I-131-labeled MIBG scintigraphy is sometimes used in addition to SRS to complete the diagnosis of neuroendocrine tumors.

►Positron emission tomography using ^{11}C-labeled 5-HTP (hydroxytryptophan) has been tested with encouraging results and has proven to be very effective in localizing small tumors.

Echocardiogram. Patients with carcinoid tumors are at risk for developing right-sided valvular heart disease. Hence, baseline and annual echocardiograms should be considered especially in those with abnormal 24-h urine ►5-HIAA levels. Patients with carcinoid heart disease should be followed by a cardiologist.

Treatment of Neuroendocrine Carcinomas

Treatment of neuroendocrine tumors requires a multidisciplinary approach. Surgeons, interventional radiologists, medical and radiation oncologists should coordinate efforts to achieve better therapeutic results.

Surgery

Surgery is the only curative treatment in patients with localized neuroendocrine tumors. Resection of local or locoregional disease can cure some patients.

Neuroendocrine tumors most frequently spread to the liver, but they can also spread to other organs such as lungs, pelvis, bones, etc. In patients with metastatic disease that has spread beyond their primary site and/or nearby lymph nodes, more aggressive treatment strategies have recently emerged, including cytoreductive procedures (partial resection of tumor), radiofrequency ablation (RFA), laser treatment, or ►embolization of liver metastases.

In selected cases, metastatic disease in the liver from neuroendocrine carcinomas can be surgically removed, along with the primary tumor, to provide long-term symptomatic relief and improve survival. Generally, this approach should be taken in patients who are medically fit and have a limited number of liver metastases, and by an experienced surgeon.

Liver transplant may be considered in young patients with no evidence of disease outside of the liver, even though the long-term outcomes of this therapy remain unclear.

Radiofrequency Ablation

RFA is a procedure whereby a special needle electrode is placed in the tumor under the guidance of computerized tomography or ultrasound, and then a radiofrequency current is transmitted through the electrode to heat the tumor tissue near the needle tip to destroy it. This technique is sometimes used in cases of liver metastases arising from neuroendocrine tumors that cannot be surgically removed. It is less invasive than surgical resection but its benefit in this disease has not been well established.

Liver Embolization

Embolization. Embolization (or temporary occlusion) of selective arteries alone (Bland embolization) or combined with intra-arterial chemotherapy (►Chemoembolization) is a procedure indicated to reduce clinical symptoms from liver tumor deposits that are not suitable for resection.

This technique is based on the principle that tumors in the liver derive most of their blood supply from the hepatic artery, while healthy liver tissue receives most of their blood supply from a different blood vessel, the portal vein.

Success rates are measured either by a decrease in hormonal secretion or by radiographic regression and vary from 30 to 70%. However, the duration of the response can be brief, ranging from 4 to 51 months in the different published series with unclear survival benefit.

Chemoembolization. Chemoembolization refers to the embolization of hepatic artery in combination with chemotherapy using agents such as dacarbazine, ►adriamycin, ►5-Fu, etc. Its role and relevance in the management of patients with neuroendocrine carcinomas remain undefined as the data are limited and it is a highly toxic procedure.

Irradiation Therapy

External Beam Radiotherapy. External radiation therapy is not very effective in neuroendocrine carcinomas, and it is only recommended as a ►palliative measure to improve symptoms in some specific cases such as bone, skin, or brain metastases.

Targeted Radiotherapy. Some studies have utilized different radiolabeled compounds as Indium-DTPA-Phe-Octreotide or 90Y-DOTA-Lanreotide, based on the principle that these substances will bind to the somatostatin receptors in the tumor and thus will deliver a high amount of radioactivity locally. Some preliminary results seem encouraging, mostly in tumors with very high uptakes in the SRS.

Systemic Treatment

The medical management of neuroendocrine carcinomas includes somatostatin analogues, alpha ►interferon and cytotoxic drugs.

Somatostatin Analogues. Based on the observation that ►somatostatin inhibits the release of different hormones, some derivatives of this substance (somatostatin analogues) have been developed for the symptomatic treatment of neuroendocrine carcinomas. ►Octreotide (Sandostatin®) is the most extensively used drug in the clinical setting. It is used either as a short acting drug or as a long acting formulation. It produces subjective symptomatic improvement in more than 70% of the patients. It is normally well tolerated with minor side effects such as gastrointestinal symptoms, gallbladder stones, hyperglycemia, and hypocalcaemia. In addition to symptom control, these compounds have shown biochemical responses (decrease in the production of hormones) in 30–70% of patients. Its cytostatic effect (delay on tumor growth) and impact on survival are still controversial. The role of somatostatin analogues in suppressing 5-HIAA levels to protect against heart damage is also unclear.

Interferons. ►Interferon (IFNs) comprises a group of proteins produced and released by white blood cells as part of the immune response to a viral infection or other immune triggers. There are different types of IFNs such as alpha, beta, and gamma. IFN-α has been demonstrated to inhibit proliferation of malignant cells, increase the activity of the immune system, and control hormonal secretion. IFN-α has been used for the treatment of carcinoid tumors either alone or in combination with somatostatin analogues.

Chemotherapy. Standard cytotoxic treatments have shown limited efficacy in the treatment of advanced neuroendocrine carcinomas, and their use for disease palliation remains suboptimal. Regimens using the drugs streptozocin and dacarbazine have been tested with only modest activity and may also be associated with significant toxicity. Other agents such as ►docetaxel, ►paclitaxel, and ►gemcitabine have demonstrated poor efficacy in neuroendocrine carcinomas.

New Agents

The limited efficacy of conventional treatments for metastatic neuroendocrine carcinomas and the emerging knowledge on the molecular biology of these tumors have facilitated the development of new targeted therapies.

Promising results have been reported with ►antiangiogenic agents such as ►bevacizumab (Avastin®), ►sunitinib (Sutent®); and ►mTOR inhibitors such as ►temsirolimus and ►everolimus. Randomized clinical trials with these promising agents are underway, to confirm their efficacy in neuroendocrine carcinomas. Other compounds are in development pending definitive results.

Confirmatory studies about the efficacy and tolerability of these drugs are needed and the future may be sought by combining targeted therapies with each other or with the more classical cytotoxic chemotherapy agents, or alternatively with different approaches such as gene transfers or immunotherapy.

Neuroendocrine Tumors

Annette Schmitt-Graeff
Institute of Pathology, University Hospital Freiburg, Freiburg, Germany

Definition

Neuroendocrine tumors (NETs) are neoplasms with a broad range of morphologic patterns, grade of differentiation and biological behavior that share common features of neuroendocrine (NE) programming. NETs contain various amounts of molecules involved in the regulated release of neuropeptides, neurotransmitters and ►hormones, and may be associated with hypersecretory syndromes or be non-functioning.

Most NETs originate from the disseminated/diffuse NE system (DES) and are of endodermal (Foregut, midgut and hindgut) derivation. The gastroenteropancreatic (GEP) DES comprises numerous NE cell types producing different hormones and biogenic amines. NETs occur in a variety of topographic locations, with a predilection of the gut, the pancreas and the lung. Other primary organs include the skin, salivary glands, prostate and various sites in the urinary, genital and biliary tracts. A second group of NETs develops in NE glands such as adenohypophysis, parathyroid, adrenal medulla or paraganglia. Examples include catecholamine-releasing ►pheochromocytoma or endocrinologically silent paragangliomas.

Here, only NETs related to the DES are considered.

Characteristics

Diagnostic Criteria for Entering the NET Category

General marker molecules of NE differentiation which reside in different cellular compartments are currently used for the diagnosis of NETs. The cytoplasm of NE cells contains neuron-specific enolase (NSE) and protein gene product 9.5. Members of the chromogranin family, cytochrome b561, ►somatostatin and various hormones are localized in large dense-core vesicles (LDCVs). Synaptophysin is one of the most abundant proteins of synaptic vesicle-like microvesicles (SLMVs) and conserved even in poorly differentiated NETs. The SLMV membranes contain abundant trafficking proteins including SNAREs and Rabs. SNAREs of the ►synaptobrevin/VAMP family are highly expressed in normal and neoplastic NE cells. Together with the SNAREs syntaxin I and SNAP-25 on the plasma membrane they are implicated in the fusion events of regulated exocytosis. The neural cell adhesion molecule NCAM (CD56) is another membrane molecule widely used in the diagnosis of NETs but also expressed in non-NE tumors.

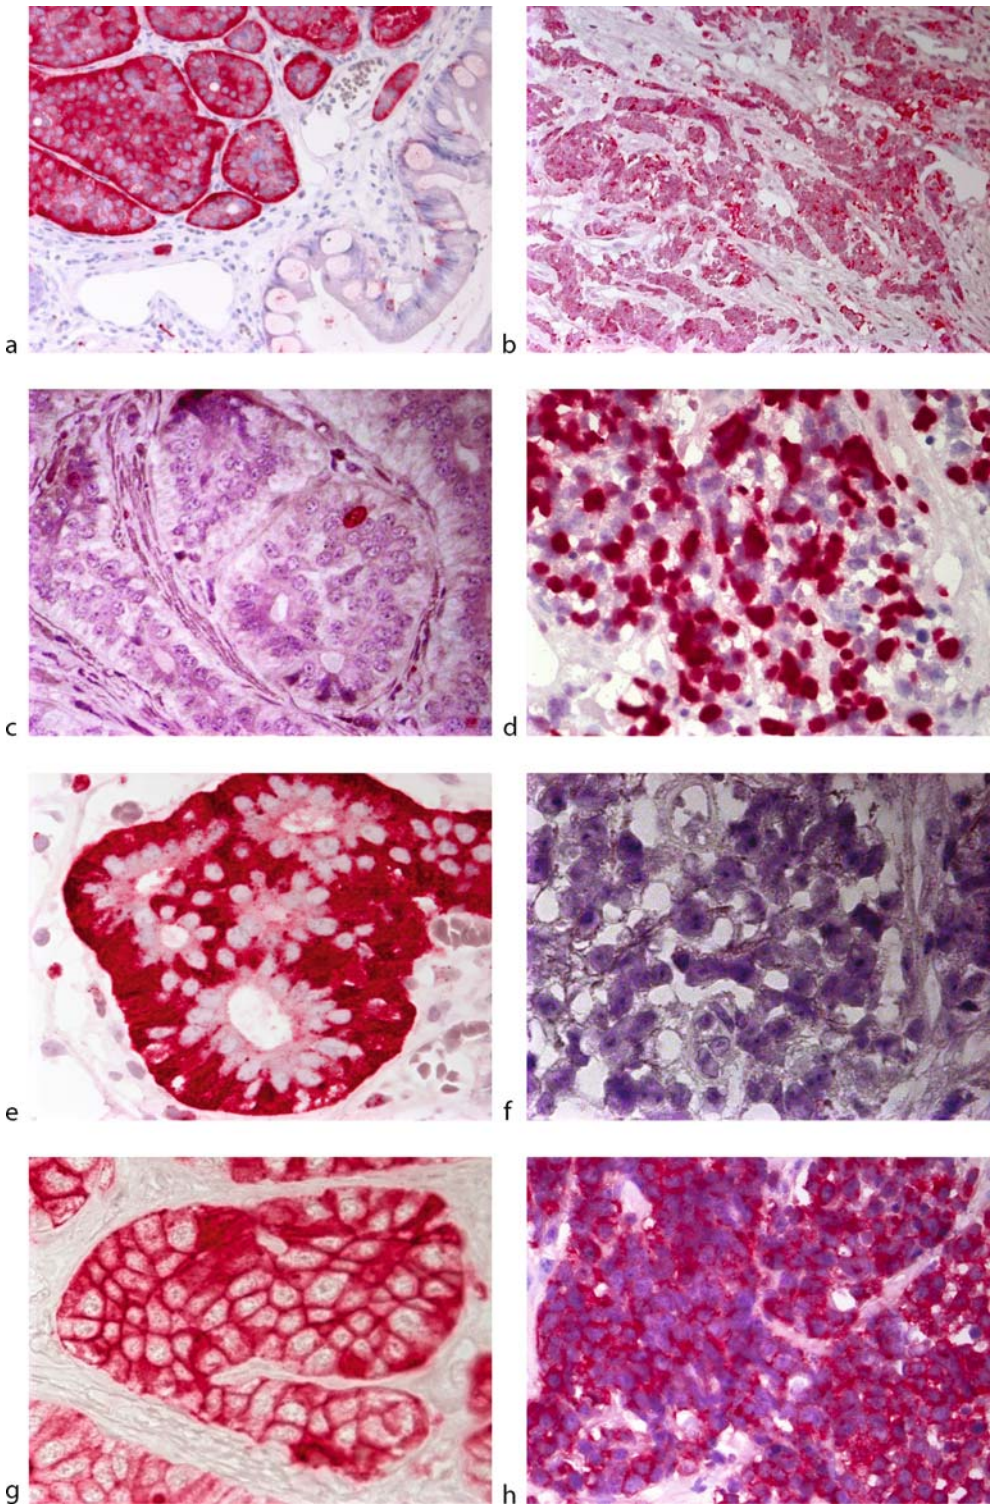
Expression of somatostatin receptors, which belong to the superfamily of G protein-coupled receptors, is found in the majority of NETs. The effective binding of somatostatin-analogues (►octreotide, lantreotide) is of therapeutic relevance. ►Serotonin and its metabolites are considered to cause the carcinoid syndrome. Traditional histochemical techniques based on silver reduction and electron microscopy, showing LDCVs and SLMVs, have now given way to immunolabeling techniques. Immunohistochemically, the positivity for synaptophysin, synaptobrevin1,2/VAMP1,2 and ►chromogranin A is generally the best way to provide evidence of NE differentiation. The synaptophysin, synaptobrevin/VAMP or SNAP-25 immunostains are the most reliable since they are positive even in poorly differentiated NETs, which may be practically devoid of LDCV constituents (Fig. 1). In mixed exocrine-neuroendocrine tumors, the neuroendocrine population should represent >30%. Tumors with exocrine and endocrine features present in identical cells are designated as amphicrine. A minority of NE cells, which may have prognostic implications, may be identified in tumors that do not belong to the NET category.

Prognostic Classification Concepts of NETs

Among various classification systems using different terminologies, the new World Health Organization (WHO) classification reflects the present state of knowledge. The WHO classification applies the term "endocrine" instead of "neuroendocrine" and defines major categories:

- Well-differentiated endocrine tumor, functioning vs. non-functioning;
- Well-differentiated endocrine carcinoma, functioning vs. non-functioning;
- Poorly-differentiated endocrine carcinoma;
- Mixed endocrine-exocrine tumor.

The term well-differentiated endocrine tumor/carcinoma now largely replaces ►carcinoid tumor (CT) or islet cell tumor. Functioning tumors may still be designated according to the hormonal syndromes, such as ►insulinoma or ►gastrinoma. Organoid growth patterns, forming islands, uniform nests, ribbons of tumor cells, are characteristic features of well-differentiated NETs. High-grade cellular atypia, high mitotic index/proliferative activity, focal necroses and an aggressive course are indicative of poorly-differentiated (large cell-form and small cell-form) NETs of category 3. The greatest difficulty concerns the distinction between lesions of benign or uncertain behavior included in category 1 and low-grade endocrine carcinoma (category 2). Features associated with malignancy are local extension, angioinvasion, cellular atypia, increased



Neuroendocrine Tumors. Figure 1 Expression patterns of synaptophysin (a, b), Ki-67 (c, d) chromogranin (e, f) and SNAP-25 (g, h) in well-differentiated (a, c, e, g) and poorly differentiated (b, d, f, h) neuroendocrine tumors (NET) of the small intestine. Synaptophysin and SNAP 25 are detected in both tumor categories while assessment of the Ki-67 index reveals a low (<2%) versus a high (>50%) proliferation. Chromogranin A is absent in the majority of tumor cells in poorly differentiated NET which shows a prevalent cytoplasmic rather than membranous pattern of SNAP 25 (labeled streptavidin–biotin immunostaining).

mitotic index/proliferative activity, ►Ki-67 labeling index and the presence of ►metastases. Tumor size and tissue-appropriate or -inappropriate hormonal products in conjunction with the primary tumor site have to be taken into consideration, since different degrees of aggressiveness may occur within each tumor category. In general, well-differentiated NETs measuring 1 cm or less rarely metastasize, while lesions >2 cm frequently metastasize, but are usually rather indolent with a median survival of ≥2 years. A mitotic count of >2 per 10 high power field (HPF) or a Ki-67 index >2–5% are correlated with a malignant behavior. The majority of poorly-differentiated endocrine carcinomas are metastatic at the time of diagnosis and have a poor prognosis with a medial survival <1 year. A correct clinicopathological evaluation may predict the clinical behavior and is essential for the management of patients.

In addition, a new consensus includes proposals for the TNM ►staging and ►grading of GEP NETs thus providing criteria for a better prognostic assessment and standardization in the management of patients.

Genetics

The understanding of the genetic background of induction and progression of NETs obtained by cytogenetic, CGH and refined molecular analyzes is rapidly increasing but still incomplete. The typical mutations of GEP adenocarcinomas are not identified in NETs. Genomic changes are highly variable according to localization, differentiation, functional activity, size and disease stage of individual tumor types. Losses of ►tumor suppressor gene function by loss of heterozygosity (►LOH) or mutations are probably more important than amplifications of oncogenes. Most NETs are sporadic neoplasms, but subsets occur as a part of heriditary cancer syndromes including ►multiple endocrine neoplasia type 1 (MEN-1), ►von Hippel-Lindau disease (VHL) or ►neurofibromatosis type 1 (NF1). Allelic deletions and mutations at 11q13 have also been documented in about 40% of sporadic GEP NETs and in up to 70% of atypical pulmonary carcinoids indicating that the MEN-1 gene, the tumor suppressor protein menin and perhaps other genes at 11q13 may play a role in their tumorigenesis. Somatic VHL mutations are extremely rare in sporadic NETs. In pancreatic NETs, losses at chromosome 1 and 11q and gains of 9q are early events. Losses at 18q are frequently found in pancreatic gastrimomas and mid-/hindgut NETs. DNA sequence copy number changes include losses of various chromosomal regions at 3pq, 6pq, 10pq, 11pq, Xq and the Y chromosome and gains at 5q, 7pq, 9q, 12q, 17pq, 20q and Xp in different tumors. Furthermore, promoter hypermethylation is a common event in GEP-NET. In the lung, small cell carcinoma (SCLC) often show ►p53 mutations, ►amplification of ►MYC, ►methylation of ►caspase-8 and inactivation of the ►retinoblastoma (RB) gene.

NETs of the Pancreas

Pancreatic NETs which have traditionally been referred to as islet cell tumors are accompanied by hormonal activity in about 50–60%. Distinct clinical syndromes are related to the inappropriate secretion of insulin (hyperinsulinemic hypoglycemia), glucagon (glucagonoma syndrome), gastrin (►Zollinger-Ellison syndrome, ZES), somatostatin (hypersomatostatinemia), vasoactive intestinal peptide (watery diarrhea syndrome), growth hormone releasing hormone (acromegaly), adrenocorticotropic hormone (►Cushing syndrome), serotonin (carcinoid syndrome) and others. The terms used to designate various subtypes reflects the specific hypersecretory syndromes (insulinoma, gastrinoma). Nonfunctioning NETs may contain certain hormones but are silent (nonsyndromic).

Pancratic NETs with a diameter of ≤1 cm, a <2% Ki-67 index and absence of angioinvasion are generally benign. When the size is >2 cm and the Ki-67 index <2%, NETs may have a benign or low-grade malignant behavior. Tumors with a size of >4 cm and a Ki-67 index between 2 and 20% fit in the low-grade malignant category. Moreover, even small tumors with evidence of angioinvasion or metastases are considered as malignant. Neoplasms of the first three categories are well differentiated. They are composed of uniform cells with no, mild or moderate atypia and show a trabecular or a solid-medullar (insular) growth pattern. Small-sized insulinomas (1–2 cm in diameter) with a benign behavior account for the majority of functioning NETs. Most other functioning and non-functioning tumors are of uncertain behavior or are low-grade malignant carcinomas. When the diameter is >2 cm, metastasis are often present at initial diagnosis, especially in gastrinomas. Pancreatic NETs measuring <0.5 cm are classified as microadenomas and may be multiple in MEN1.

High-grade malignant NETs are poorly differentiated. This category encompasses tumors with a high Ki-67 index of >20%. Small to intermediate or large-sized cells grow in solid aggregates, often with central necrosis. True mixed endocrine-exocrine (amphicrine) neoplasms, with at least one-third endocrine cells, are rare. Their prognosis depends on the exocrine component.

NETs of the Stomach and the Oesophagus

NETs of the esophagus are rare neoplasms of the middle and lower thirds. They either belong to the categories of well-differentiated carcinoid tumors (CT) or of poorly-differentiated small to intermediate-sized carcinomas with a poor prognosis and frequent systemic dissemination. A combination of small cell with ►squamous cell carcinoma or adenocarcinoma may occur. Poorly-differentiated NETs of the esophagus have been associated with smoking and ►Barrett esophagus.

Most well-differentiated gastric endocrine tumors are histamine-producing VMAT-1 positive ECL cell tumors and are composed of trabecular, adenoid or solid nests of endocrine cells. The classification depends on the underlying gastric pathology. Hypergastrinemia is involved in the pathogenesis of ECL cell tumors type 1 and 2. They often arise as multiple lesions on a background of endocrine-cell hyperplasia in chronic atrophic gastritis (type 1) or with MEN-1 or the ZES syndrome (type 2), and are benign or low-grade malignant. Sporadic (type 3) tumors develop in the absence of hypergastrinemia and are solitary. The prognosis of type 1 NETs is excellent. About one third of type 2 and 3 NETs present with a diameter is >2 cm, infiltration of the submucosa or angioinvasion and are likely to have metastasized at the time of diagnosis. Type 4 NETs of the stomach are poorly-differentiated carcinomas showing tightly packed small- to intermediate-sized cells with frequent mitoses. They are high-grade malignant carcinomas with a poor outcome.

NETs of the Small Intestine, Colon and Rectum

The majority of intestinal NETs are well-differentiated slow-growing neoplasms (carcinoids), which may metastasize to mesenteric lymph nodes and liver. Poorly-differentiated carcinomas are rare. Intestinal NETs arising in the different parts of the intestine are heterogeneous with regard to clinical symptoms and prognosis. They may be associated with production of ectopic hormones including serotonin, pancreatic polypeptide, glucagon, gastrin, somatostatin, cholecystokinin, ►calcitonin or bombesin. Secretion of may lead to the carcinoid syndrome results from the secretion of vasoactive amines especially serotonin by NETs that are metastatic to the liver NETs arising in the duodenum have a lower metastasizing rate than those of the jejunum and ileum. About 40% of duodenal NETs produce gastrin and may be associated with MEN1 and/or ZES. Lymph node metastases which are larger than the primary tumor may occur even in small gastrinomas. Most non-functioning tumors express serotonin and have a more favorable prognosis than gastrinomas and somatostatin-producing tumors. The latter tumors tend to involve the papilla, and typically include psammoma bodies and frequently develop in neurofibromatosis type I. Gangliocytic paragangliomas, composed of epithelial and neuromatous elements, may arise in the duodenal wall and are generally benign.

Serotonin- producing EC cells are the predominant component of most NETs arising in the jejunum, ileum, appendix and proximal colon (midgut), while enteroglucagon-producing cells are often present in NETs of the distal colon and rectum (hindgut). Most intestinal NETs are well differentiated, are located in the ileum, measure frequently >2 cm and have already lymph node or liver metastases at diagnosis. A carcinoid syndrome may develop if liver metastases are present. About 40% of ileal NETs are multiple. NETs of the appendix are usually benign and rarely metastasize. The majority resemble its counterparts in the ileum but their prognosis is more favorable. Appendical NETs are composed of serotonin- and substance P-producing EC cells arranged in solid nests. The so-called goblet-cell carcinoids of the appendix contain clusters of ►mucin-producing cells with an endocrine component and are now considered as mixed endocrine/exocrine neoplasms. They may involve lymph nodes and liver or spread to peritoneal surfaces.

NETs of the colon and rectum which are related to EC-cells are similar to NETs of the jejunum. Tumors of the hind-gut type are mainly derived from GLI/PYY positive L-cells. Well-differentiated NETs occur more frequently in the rectum than in the colon where they may be detected as small mucosal nodules. Poorly-differentiated NETs or composite adenocarcinoma-small cell carcinoma (category 4) arise more frequently in the colon and may present with an extensive local and metastatic tumor growth. High-grade NETs of the rectum are rare. Small well-differentiated rectal NETs which express glucacon or pancreatic polypeptide are generally confined to the submocosa.

The histologic appearance of well differentiated NETs of small intestine, colon and rectum is characterized by solid nests, trabeculae or tubules with peripheral palisading or a ribbon-like pattern. Tumor cell nests tend to be surrounded by a dense highly vascularized fibrous stroma. Poorly-differentiated carcinomas (category 3) may resemble its small cell counterparts in other organs and show clusters of anaplastic cells with high mitotic activity, necrosis and lymphatic and vascular invasion, indicating an aggressive behavior with a poor outcome.

NETs of the Lung

The actual WHO classification recognizes four main categories of bronchopulmonary NETs which share certain morphological and immunophenotypic patterns but are distinct with regard to prognosis. They may be derived from disseminated neuroendocrine cells of the airways (carcinoids) or from pluripotent bronchial precursor cells (small and large cell neuroendocrine carcinomas).

Carcinoid Tumors

Carcinoid tumors (CT) comprise two types of NETs which are not related to smoking. CTs form well circumscribed peripherally or centrally localized masses which may cause bronchial obstruction. The architecture is characterized by nests, cords, strands, microacinar or papillary structures in a fibrovascular stroma. CTs are separated into low grade typical carcinoids (TC) and intermediate grade atypical carcinoids (AC). In TCs mitoses are rare (<2 per 2 mm^2 or 10 HPF) and necroses

are absent, while ACs present 2–10 mitoses per 2 mm^2 (10 HPF) and/or focal necroses. Cellular atypia or prominent nucleoli do not reliably discriminate between TC and AC. Both categories are composed of polygonal, ovoid or spindle cells with a finely dispersed chromatin, small nucleoli and an eosinophilic cytoplasm. Immunohistochemical staining (IHS) reveals coexpression of cytokeratins (CK) (in about 80%) with chromogranin A, synaptophysin and CD56.

TCs often present with a diameter of <3 cm and have a favorable prognosis with a cure obtained by surgical resection in most cases (90–98% 5-year survival). However, since lymph node metastases may develop in a minority of patients in keeping with a low-grade malignancy. The prognosis of ACs depends on stage and criteria such as tumor size (>3.5 cm) or vascular invasion. Five-year survival rates of about 60% after radical surgery. A carcinoid syndrome is only observed in widespread metastatic disease. Most CT are sporadic. Rare cases rarely occur in the setting of MEN1 syndrome.

Small Cell Lung Carcinoma

Small cell lung carcinoma (SCLC) constitutes about 20% of ►lung cancer. This high-grade NET is strongly associated with smoking. Small-sized tumor cells with scanty cytoplasm contain ovoid to spindle shaped nuclei with dispersed chromatin and often show nuclear molding. Pseudoreosettes may be present. Mitoses (at least >11, average 70–80 per 2 mm^2 or 10 HPF), necroses and crushing artifacts are frequent. IHS generally shows reactivity for synaptophysin, CD56 and thyroid transcription factor (TTF-1) in about 90%. SCLCs with a subpopulation of at least 10% larger cells are classified as combined small and large cell carcinoma. Other combined types contain subpopulations of squamous or adenocarcinoma. Patients with SCLC may present endocrine symptoms (►Cushing syndrome inappropriate anti-diuretic hormone production, ►Eaton-Lambert syndrome). ►SCLC is a highly aggressive disease with early and rapid dissemination to lymph node and extrathoracic organ such as bone, liver or brain. Multiagent chemotherapy may obtain a favorable response.

Large Cell Neuroendocrine Carcinoma

In the actual WHO classification, large cell ►neuroendocrine carcinoma (LCNEC) are listed as a subtype of showing a large cell morphology. LCNEC cells show a high mitotic activity (at least >11, average 70–20 per 2 mm^2 or 10 HPF) but are of larger size, contain more abundant cytoplasm and prominent nucleoli than SCLC. Neuroendocrine differentiation may only be detected by IHS (synaptophysin, CD56) in carcinomas with a large cell morphology. About 3% of all lung cancers correspond to LCNEC which develop predominantly in smokers.

Thymic NETs

The classification system of pulmonary NETs is widely applied to thymic neoplasms ranging from TCs and ACs to poorly-differentiated small cell or large cell carcinomas. With regard to the tendency to local invasion and metastasis in about 50% of CTs, all NETs are actually designated as carcinomas. About 25% of thymic CTs are MEN-1 associated and more aggressive than sporadic tumors.

Medullary Thyroid Carcinoma (MTC)

This tumor of parafollicular C-cell differentiation may be sporadic or in about 25% hereditary (MEN 2A or B, familial ►Medullary thyroid carcinoma). Hereditary tumors are often multicentric and bilateral and develop on a background of C-cell hyperplasia. Tumor cells express calcitonin in addition to neuroendocrine marker proteins, TTF1and are stained by ►CEA-antibodies.

The histology may be classic, with sheets of polygonal tumor cells, or display various patterns (follicular, anaplastic, small cell). Amyloid deposits are present in about 80%. Lymph node metastases in the neck and the upper mediastinum may be found at initial presentation. Gain of function germline mutations in the ►*RET* proto-oncogene are found in MEN-2A and -2B or in familial MTC. A variety of chromosomal losses and somatic point mutations in the RET gene (RET M918T) occur in sporadic cases.

NET (Merkel Cell Carcinoma) of the Skin

This cutaneous type of NET is an aggressive neoplasm composed of small basophilic cells that are arranged in nests within the dermis. The tumor cells contain NE markers in addition to ►cytokeratin 20 (CK20). About 60% of small cell carcinomas of the salivary gland express CK20, indicating a close relationship to ►Merkel cell carcinoma.

Synonyms

NF1; von Recklinghausen disease; peripheral neurofibromatosis

Definition

Neurofibromatosis 1 (NF1) is an autosomal dominant disorder that affects about 1 in ~3,500 persons worldwide. Half of the cases are caused by a new mutation. NF1 is a highly variable disease, the most prominent hallmarks being visible on skin: ►cafe-au-lait macules, and cutaneous ►neurofibroma. NF1 is the most common cancer predisposition syndrome.

Characteristics

Diagnostic Criteria and Clinical Aspects

The diagnosis of NF1 is based on the presence of two or more of the following findings:

Six or more cafe-au-lait macules with diameter more than 5 mm in prepubertal patients and more than 15 mm in postpubertal patients; two or more neurofibromas of any type, or one ►plexiform neurofibroma; axillary or inguinal freckling; ►optic glioma; two or more ►Lisch nodules of the iris; a distinctive osseous lesion such as sphenoid dysplasia or ►pseudarthrosis; first-degree relative with NF1 according to the preceding criteria. Based on these criteria, the penetrance of the NF1 mutation is virtually 100% by the age of 10 years. Indeed, NF1 can in most cases be diagnosed by the age of six years on routine clinical examination.

Cafe-au-lait macules are sharply demarcated spots that are slightly darker than the apparently normal skin of the patient. Cafe-au-lait macules are the most common first sign of neurofibromatosis. It is of interest to note that cafe-au-lait macules never undergo malignant transformation to ►melanoma. The appearance of the spots is followed by freckles in the flexural areas and Lisch nodules of the iris by the age of six. ►Lisch nodules are asymptomatic and non-precancerous hamartomas of the iris, the diagnosis of which requires slit lamp examination.

Cutaneous neurofibromas are benign tumors which arise from the cells of the connective tissue sheath of cutaneous nerve tributaries. Cutaneous neurofibromas usually appear in or after puberty. The number and size of these tumors varies between adult individuals with NF1: there may be only a limited number of tumors with a diameter of few millimeters, while the tumor burden in some individuals may reach thousands, some of which with a diameter of centimeters. Cutaneous neurofibromas may project out of the skin surface, or reside within the skin. It is worth to note that cutaneous neurofibromas do not undergo malignant transformation and that cutaneous neurofibromas are usually painless. Neurofibromas may also grow within the nerve forming knot-like thickenings in deeper nerves. These intraneural tumors may be painful. Subcutaneous tumors are single nodules situated underneath the skin. Neurofibromas may also grow along peripheral nerve trunks and extend to smaller nerve braches and surrounding tissue. These tumors are called plexiform neurofibromas. Plexiform neurofibromas infiltrate surrounding tissues and are poorly demarcated. About one third of NF1 patients have plexiform neurofibromas which may eventually form large and disfiguring tumor

masses in the craniofacial region, trunk, and extremities. Plexiform, subcutaneous and intraneural neurofibromas are associated with an increased risk of transformation to ►malignant peripheral nerve sheath tumor (MPNST). NF1 patients have an estimated lifetime risk of about 10% to develop an MPNST. Patients with a plexiform neurofibroma have a higher risk since MPNSTs often arise from preexisting plexiform neurofibromas. It has been estimated that approximately 2–5% of plexiform neurofibromas undergo malignant change. About half of all MPNSTs are NF1-associated. MPNSTs in NF1 patients usually occur in young age, between 20 and 40 years, in contrast to about 60 years in patients without NF1. The MPNST is an aggressive tumor with 5-year life expectancy of 20–40%, or the median survival of 17 months. Prognosis of MPNST in NF1 patients has been reported to be less favorable than in patients without NF1.

In the central nervous system, the most common NF1-related tumors are optic tract gliomas which histologically are pilocytic astrocytomas. MRI scan reveals optic gliomas in ~15% of NF1 patients. Most of these tumors however remain indolent. Gliomas in other central nervous system locations, such as cerebellum and brain stem, occur in less than 5% of patients. The majority of the central nervous system tumors are diagnosed in childhood. NF1 shortens the life expectancy by approximately 15 years, mainly due to malignancies of the central and peripheral nervous system. In addition to nervous system tumors, NF1 patients are also predisposed to ►phaeochromocytoma, ►carcinoid tumor, or ►gastrointestinal stromal tumors.

The spectrum of NF1 related manifestations include skeletal dysplasias such as pseudarthrosis of tibia, macrocephaly, short stature and sphenoid wing dysplasia. Learning disabilities are present in more than half of the NF1 patients and mild cognitive impairment also in adulthood is common. Vascular stenosis caused by the proliferation of the intimal cells most commonly manifests itself as high blood pressure, or strokes.

Genetics

NF1 results from mutations in the *NF1* gene located in chromosome 17, band q11.2. The gene is complex and large, spanning more than 350 kb of genomic DNA and divided into 61 exons. The mRNA of the *NF1* gene is 11–13 kb and it is ubiquitously expressed in tissues. All affected individuals are heterozygous for an *NF1* mutation and the mutation can be found in all cells of the individual with NF1. NF1 is inherited in autosomal dominant manner which implicates that a person with NF1 has a 50% risk of transferring the disease to the next generation. About 50% of the NF1 cases are caused by a new, sporadic germline mutation in the *NF1* gene. Approximately 80% of new *NF1* mutations are paternal in origin. About 300 mutations and several different mutation types have been reported in the *NF1* gene. The mutation types include point mutations that may affect the splicing of the *NF1* gene or create premature stop codon; small deletions or large deletions, e.g. microdeletions that cover the entire *NF1*, and additionally affect the flanking regions of the *NF1* gene; insertions and mutations in introns. Majority of the mutations cause truncation of the neurofibromin protein. Mutations have been identified throughout the gene, and with few exceptions, genotype-phenotype correlations have not been established. However, microdeletion results in a phenotype with dysmorphic facial features, heavier tumor burden, lower IQ and increased risk of ►MPNST. In opposite to most other *NF1* mutations, microdeletions are maternal in origin.

Neurofibromin

The *NF1* gene product is called ►neurofibromin with an estimated molecular mass of 280 kDa. Neurofibromin has a central domain (the Nf1-GAP-related domain or Nf1-GRD) that shares extensive sequence homology with other ►GTPase activating proteins (GAPs) that regulate ►Ras. The GAP domain accelerates the switch of active Ras-GTP to inactive Ras-GDP in various cell types. Neurofibromin is considered as a ►tumor suppressor protein since selected malignant tumors display inactivation of both *NF1* alleles, either by ►loss of heterozygosity (LOH), or by a new somatic mutation in the originally intact *NF1* allele.

Gene Mutations in NF1 Related Tumors

In NF1, all cells harbor a mutation in one *NF1* allele. This, however, is not sufficient to result in the development of a neurofibroma. According to the two-hit hypothesis, neurofibroma develops when a somatic mutation in Schwann cell lineage disrupts the remaining functional copy of the *NF1* allele leading to biallelic inactivation of the gene. One mechanism that leads to inactivation of both *NF1* alleles is ►LOH, i.e. loss of the wild type allele at a heterozygous locus. The mechanisms leading to LOH are mitotic recombination, chromosomal microdeletion, and chromosome loss with reduplication. LOH only occurs in the chromosome that does not carry the germline mutated allele. Biallelic inactivation of *NF1* has been demonstrated in neurofibromas, plexiform neurofibromas, MPNSTs, pheochromocytomas, astrocytomas and juvenile myelomonocytic ►leukemia in NF1 patients. However, since biallelic inactivation of the *NF1* occurs in benign neurofibromas, mutations in *NF1* gene alone are not sufficient for the progression from a plexiform neurofibroma to an MPNST. Additional mutations in other regulatory genes have been described in MPNSTs. These additional mutations include loss-of-function mutations of the

►p53 tumor suppressor; deletions of the region of chromosome 22 encoding ►merlin; and mutations of genes that regulate cell cycle progression. Approximately half of MPNSTs in NF1 patients contain mutation of the ►CDKN2A (also known as *INK4A* or INK4A/ARF) gene, which encodes two distinct tumor suppressors, ►p16INK4A and ►p14ARF, while this deletion is not found in benign neurofibromas. Decreased or altered expression has been reported for p16INK4A, a protein that arrests cells in the G1 phase of the cell cycle by inhibiting cyclin-dependent kinases 4 (CDK4) and 6 (CDK6). Decreased levels of p27kip1, a ►cyclin-dependent kinase inhibitor that controls G1/S progression, and ►p19ARF, a polypeptide that binds to ►Mdm2 and prevents it from degrading ►p53 have also been reported. Mutations in the ►Retinoblastoma (Rb) gene ►RBA a tumor suppressor that impedes cell cycle progression and becomes inactivated when phosphorylated by CDK4/6 kinases may also contribute to peripheral nerve sheath tumorigenesis in some cases. These findings show that tumorigenesis in NF1 is a complex multistep process involving a variety of different types of genetic defects at multiple genes.

NF1 Gene Mutations in Cancer

NF1 gene mutations and alterations in neurofibromin expression have been found in malignant tissues unrelated to NF1, which further supports its status as a tumor suppressor. Specifically, NF1 gene mutations have been found in colon ►adenocarcinoma, ►myelodysplastic syndrome, ►anaplastic astrocytoma, ►neuroblastoma, juvenile ►myelomonocytic leukemia, ►small cell lung carcinoma, ►urinary bladder carcinoma, ►uveal melanoma, and in cell lines cultured from ►malignant melanoma of patients who do not have NF1. Futhermore, the amount of neurofibromin has been reported to be altered in certain proliferative diseases, such as urinary bladder carcinoma, ►basal cell carcinoma, ►pheochromocytoma, ►meningioma and psoriasis. Additionally, changes in NF1 mRNA isoforms expression ratio have been reported in ►ovarian cancer, ►small cell lung carcinoma and ►colon cancer.

Neurofibromatosis 2

James F. Gusella
Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA, USA

Synonyms

NF2; Bilateral acoustic neurofibromatosis; Central neurofibromatosis

Definition

Neurofibromatosis 2 (NF2) is an ►autosomal dominant disorder characterized by the bilateral development of ►vestibular schwannoma, along with the occurrence multiple other benign intracranial, spinal cord and peripheral nerve tumors. Cataracts are nontumorous manifestations of NF2.

Characteristics

Diagnostic Criteria and Clinical Aspects

The diagnostic criteria for NF2 are the observance of bilateral eight-nerve masses (vestibular schwannomas) with appropriate imaging techniques (e.g., ►CT or ►MRI), or the existence of a first-degree relative with NF2 and either a unilateral vestibular schwannoma or two of the following: meningioma, neurofibroma, glioma, schwannoma or juvenile posterior subcapsular lenticular opacity.

Vestibular schwannomas, formerly termed acoustic neuromas, are a universal feature of NF2. They are slow growing, benign tumors that form in the internal auditory canal where the eighth nerve and facial nerve are close together. Initial symptoms of NF2 usually begin subtly but progress as the slow-growing tumor expands, causing tinnitus, hearing loss, and balance problems. Schwannomas sometimes occur on other cranial nerves, more often on sensory than motor nerves, and on peripheral nerves, with skin tumors that can be particularly painful. The schwannomas of NF2 rarely, if ever, become malignant. About half of all NF2 patients also develop intracranial, and occasionally spinal ►meningioma, although neither shows a preferred location of occurrence. Spinal schwannomas arise in about two-thirds of NF2 patients and can be extremely debilitating. ►Astrocytoma and ►ependymoma, occur in a small minority (5–10%) of patients. Decreased visual acuity due to cataracts, which may occur even before tumors are evident, affects at least one-third of NF2 patients.

The mean onset age for NF2 is ~21 years but the disorder has been seen as early as age 2 and as late as age 70. The first manifestations of disease are usually related to vestibular schwannomas causing hearing loss,

tinnitus, or loss of balance but may include facial weakness, visual impairment, and painful skin schwannomas. The progression of NF2 shows extreme variability as it depends on tumor number, location and growth rate. The mean survival from diagnosis is currently 15 years, leading to an average age of death of 36 years for NF2 patients, although this life expectancy is likely to increase with advances in diagnostic and surgical techniques.

Genetics

NF2 affects in 25-40,000 individuals due to germline mutation in a gene on chromosome 22q that encodes a protein named ►merlin (schwannomin). About half of cases are new mutations and half show a family history. The disorder is inherited in an autosomal dominant pattern, but has a recessive mechanism of action at the level of individual tumor cells, making the NF2 gene a classic tumor suppressor locus. NF2 involves an inherited inactivating mutation that only leads to tumor formation when a somatic mutation inactivates the remaining copy of the NF2 gene in an appropriate target cell, leading to absence of functional merlin. Almost all NF2 mutations, both germline and somatic, involve evident inactivation of the gene due to deletion, chromosomal loss or rearrangement, or truncating mutations. ►Missense mutations or small in-frame deletions have been described, which presumably impact critical functional domains of merlin. Somatic mutations that inactivate both NF2 copies in target cells also account for essentially all cases of sporadic unilateral vestibular schwannoma and more than half of all sporadic meningiomas in the general non-NF2 population.

The NF2 gene spans 110 kb with 16 constitutive exons and one alternatively spliced exon. It encodes two major merlin isoforms that differ only at the extreme carboxy terminus. Isoform 1, encoded by exons 1–15 and 17, comprises 595 amino acids. Alternative splicing of exon 16 eliminates the final 16 amino acids and replaces them with 11 novel residues to produce merlin isoform 2. Germline NF2 mutations have been found in all exons except exons 16 and 17, suggesting that both major isoforms may have tumor suppressor activity. Nonsense mutations due to C to T transitions in CGA codons are particularly frequent. There is some degree of correlation between mutation type and disease severity as missense mutations in exons 7, 11, and 15 as well as large deletions are generally associated with mild disease manifestations. By contrast, nonsense mutations throughout the gene, and especially in exon 6, cause more severe disease. Somatic mutations also occur throughout the gene except in exons 16 and 17, and deletions are more frequent than in germline. Complete loss of chromosome 22 leading to readily detectable loss of heterozygosity in the tumors is an especially frequent mechanism of somatic alteration.

Merlin Protein

Merlin was named for its similarity with three known proteins, moesin, ezrin and radixin (merlin = moesin, ezrin, radixin-like protein). These closest relatives of merlin are known collectively as ►ERM proteins, and all four are members of the protein 4.1 family, which also includes erythrocyte protein 4.1, talin, certain unconventional myosins, several protein tyrosine phosphatases and several anonymous proteins. The protein 4.1 family is defined by the presence of a conserved ►FERM domain, spanning ~270 amino acids, that is believed to mediate interactions with integral membrane proteins. In merlin and the ERMs, this domain is located in the NH2-terminal half of the protein, and is followed by a long alpha helical segment and a charged COOH-terminal domain. Protein 4.1, the prototype for this family, helps to maintain membrane stability and cell shape in the erythrocyte where it connects the spectrin-actin cytoskeletal lattice with the integral membrane proteins, glycophorin, and the anion channel. The ERMs, closer relatives to merlin, also bind integral membranes proteins, such as ►CD44, via the FERM domain and to actin via a COOH-terminal binding site. The ERM proteins all show intramolecular interaction whereby the COOH-terminal region binds to a more NH2-terminal segment, effectively blocking the binding site for actin and certain other interactors. This "closed" conformation can be altered to an "open conformation" by specific phosphorylation or phosphoinositides, permitting binding to the actin cytoskeleton. Each of the ERMs is ~78% identical to the others and they may have overlapping functions.

Merlin is ~63% identical to the ERM proteins across the FERM domain and the immediate downstream region but is much more divergent across the long alpha helical domain, which has a notable interruption by a cluster of proline residues. Merlin is the only one of these four proteins that displays alternate COOH-termini, creating two major isoforms. Merlin ►isoform 1 undergoes the same "closed conformation/open conformation" regulation as the ERMs due to intramolecular interaction, although no conserved actin binding site is present near its COOH-terminus. By contrast, merlin isoform 2 does not exhibit "head to tail" intramolecular binding and remains constitutively in the "open conformation."

The precise normal function of merlin remains to be defined, although it is likely to involve linking cytoskeletal and membrane elements like protein 4.1 and the ERMs. Indeed, in cultured cells, where merlin is expressed as a protein with an apparent size of ~66 kDa in SDS-polyacrylamide gel electrophoresis, the protein

is found in areas of membrane remodeling, particularly membrane ruffles, where it co-localizes with actin. However, merlin is not associated with cytoplasmic actin stress fibers. To date, a number of proteins capable of interacting with merlin have been described, including among others F-actin, β2 spectrin, CD44, ►hepatocyte growth factor-regulated tyrosine kinase substrate, β1 integrin and ERM proteins. Perhaps the most intriguing interactor to date is NHERF, which also binds to ERMs in the "open conformation." NHERF is a 358 amino acid protein with two ►PDZ domains upstream from a C-terminal region that binds to the unmasked N-terminal half of merlin and the ERMs. It was originally described as an adaptor protein required for protein kinase A regulation of the kidney sodium-hydrogen exchanger (NHE3). NHERF binds to NHE3 via the second of the PDZ domains and to several other membrane proteins, such as the β2 adrenergic receptor, the purinergic P2Y1 receptor and the ►cystic fibrosis transmembrane conductance regulator, via the first PDZ domain. potentially tying these proteins, and merlin/ERMs to sodium-hydrogen exchange or to protein kinase A regulation.

That growth control in Schwann cells and meningeal cells is disrupted by the loss of merlin function, implies that lack of merlin subtly alters some aspect of intracellular signaling, resulting in a slow proliferation. Despite having an overall structure similar to the ERMs, merlin is the only one of these four proteins demonstrated to have a specific tumor suppressor function, suggesting that it affects one or more signaling pathways different from the ERMs. Although the tumors of NF2 are benign, merlin mutations can also be involved in progression of non-NF2 tumors, most notably malignant meningiomas, suggesting that loss of the protein can have different effects in different circumstances. For example, in the mouse, merlin deficiency is associated with the development of highly malignant tumors such as osteosarcomas and rhabdomyosarcomas. The NH2-terminal half of merlin has been implicated in growth control in Drosophila, where inactivation of the NF2 homolog leads to cellular overproliferation. Thus, it seems likely that merlin deficiency can affect different aspects of the web of signal transduction that connects the cell membrane, actin-cytoskeleton and the nucleus. Indeed, any signaling pathway in which NHERF can act as a cofactor and any of the growing list of proteins with which NHERF physically interacts are already candidates for disruption in the absence of merlin. The delineation of merlin's full complement of interactions and their effects in the target cells, Schwann cells and arachnoidal cells of the meninges, will probably be required to understand merlin's tumor suppressor activity in NF2.

Neurofibromin

Definition

Is a tumor suppressor protein encoded by the ►NF1 gene on human chromosome 17. Neurofibromin serving as a GTPase Activating Protein (GAP) that inactivates Ras in certain glia cells. People with mutations in the NF1 gene develop ►neurofibromatosis I (NF1), a neurological disorder that affects 1 in 3,500 people world-wide. NF1 patients develop benign tumors along their peripheral and optic nerves, as well as ►café-au-lait spots on the skin.

►RAS Activation

Neurologically Eloquent

Definition

Literally means the expression of neurologic function. The phrase is applied to those regions of the central nervous system that mediate vital unduplicated neurological actions, the destruction of which would result in a functional disability to the patient.

►Oligodendroglioma

Neuromedin

Yataro Daigo
Institute of Medical Science, The University of Tokyo, Tokyo, Japan

Definition

A family of peptides that comprises the neuromedins A, B and C (bombesin-like), K (neurokinin B) and L (neurokinin A), N (neurotensin-like), S, and U.

Characteristics

This family of peptides termed "neuromedins" that were initially isolated from porcine spinal cord on account of their ability to contract smooth-muscle. This family of peptides currently includes the neuromedins A (NMA), B (NMB), C (NMC), K (NMK), L (NML), N (NMN), S (NMS), and U (NMU), however their structural and functional characteristics vary greatly. These neuromedins are found in many tissues including the central nervous system as well as in the gastrointestinal tract, and have been implicated in a wide variety of physiological functions as neuropeptides. Neuropeptides function peripherally as paracrine and autocrine factors to regulate diverse physiological processes and act as neurotransmitters or neuromodulators in the nervous system. In general, the receptors which mediate signaling by binding neuropeptides are members of the superfamily of G protein-coupled receptors (GPCRs). Some of the neuromedins expressed in several types of human tumors including neuroendocrine tumors. NMK and NML abundantly express in human carcinoid tumors. NMN have growth-stimulatory effects on human pancreatic cancer cells. The ►autocrine and ►paracrine involvement of NMB or NMU as well as some of their receptors have biological significance in human cancers.

NMB in Human Cancer

The bombesin-like peptides, NMB and ►gastrin-releasing peptide (GRP), are among the first neuropeptides to be implicated as autocrine growth factors in ►lung cancer cells. Two receptors for bombesin-like peptide in mammals, NMBR and GRPR, can interact with both NMB and GRP to relay extracellular signals to cells, as measured by intracellular Ca2+ mobilization in response to applied NMB or GRP. GRPR and NMBR can also be detected in various human lung carcinoma cells. GRP and NMB have mitogenic activity as autocrine growth factors in small cell lung carcinoma (►SCLC). NMB stimulates arachidonic acid release, c-fos gene expression, and the growth of ►glioma cells.

NMU in Human Cancer

NMU is abundantly expressed in the majority of ►acute myeloid leukemia (AML), ►ovarian cancer, ►bladder cancer, and ►lung cancer. NMU expression is related to MYB and the NMU/NMU1R axis constitutes a growth-promoting autocrine loop in myeloid leukemia cells. NMU is regulated by the ►metastasis suppressor Rho GDP Dissociation Inhibitor 2 (RhoGDI2). NMU overexpression in bladder cancer cells significantly enhanced their lung metastatic ability and cancer cachexia in mice. NMU and hetero-dimerization of two GPCRs (GHSR1b and NTSR1) are likely to play an essential role in creating an autocrine growth-promoting pathway in lung cancers by modulating transcription of down stream target genes. NMU is epigenetically silenced in esophageal squamous cell carcinoma (►ESCC) and head and neck squamous cell carcinoma (►HNSCC).

Clinical Relevance

Interruption of autocrine and paracrine neuropeptide signaling with specific antagonists are considered to be new therapeutic approaches to the treatment of human cancers. Therapeutically, the ability of antagonists, radiolabeled analogs, or neutralizing antibodies acting against neuromedin peptides and/or their receptors so as to reduce the growth of some cultured cancer cells have been demonstrated *in vitro* and in animal models.

Akira Nakagawara
Chiba Cancer Center Research Institute, Chiba, Japan

Synonyms
NGF family; Neurotrophic factors

Definition
In normal neurons, neurotrophins and their receptors regulate growth, differentiation and cell survival during neural development and maintaining the adult nervous tissues. Neurotrophins are composed of ►nerve growth factor (NGF), ►brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3) and neurotrophin-4/5 (NT-4/5). In cancers, neurotrophins and their receptors

are often aberrantly expressed or rearranged, and modulate biological characteristics of cancer cells or are involved in carcinogenesis.

Characteristics

Neurotrophin signaling through activation of the ►TRK family of tyrosine kinase receptors as well as $p75^{NTR}$ is important in regulating growth, differentiation and survival of neurons in both central and peripheral nervous systems. In cancers, however, aberrant expression of neurotrophins and TRK family receptors is often associated with abnormal growth, invasion and metastasis of cancer cells, resulting in acquisition of resistance to chemotherapy and radiation therapy. In addition, in certain types of cancer, the *TRK* gene is rearranged to be oncogenic.

Gene targeting: ►TRK-A signaling supports the survival of sympathetic neurons and sensory neurons responsive to temperature and pain, TRK-B signaling supports the survival of sensory neurons responsive to tactile stimuli, and TRK-C signaling supports the survival of sensory neurons responsive to limb movement and position.

Neurotrophin signaling in cells: The binding of ligands triggers activation of TRK receptor(s) by phosphorylating the tyrosine residues at the intracellular tyrosine kinase domain. Like other receptor tyrosine kinases, the main signaling pathways are mediated by Ras/MEK/ERK1,2 as well as ►PI3K/AKT, and induce cellular differentiation and survival. The depletion or inactivation of TRK often induces cell death. The $p75^{NTR}$ receptor enhances TRK signaling by heterodimering with TRK. However, $p75^{NTR}$ itself has an intracellular death domain and often sends death signals mediated by ceramide or inhibiting ►NFκB pathway. The developmentally regulated neuronal programmed cell death is caused by depletion of neurotrophins when the cells are dependent on the particular ligand(s) for survival.

TRK oncogenes in cancers: The proto-oncogene *TRK* was originally identified as an oncogene from colon cancer. The gene was fused with the tropomyosin gene at the *TRK-A* extracellular juxtamembrane region, and the chimeric receptor was constitutively activated. The similarly oncogenic TRKs have been reported in ►papillary thyroid carcinoma and ►acute myeloid leukemia. Mutation of the *TRK* genes is rare in human cancers. Rearrangement of the *TRK* gene is rarely observed in cancers with neuronal origin.

Aberrant expression of neurotrophins and their receptors in cancers: In more than several cancers, abnormal expression of neurotrophins and TRK receptors have been reported. In general, neurotrophins are supplied from the target cells to neurons by retrograde transport. In tumor tissue, however, the neurotrophin-mediated cross-talk between stromal cells and tumor cells or in tumor cells themselves may be regulated abnormally in autocrine and/or paracrine manner, resulting in aggressive growth, enhanced invasion and metastasis.

Clinical Relevance

►Neuroblastoma is originated from sympathetic precursor cells derived from neural crest. Both TRK-A and $p75^{NTR}$ are highly expressed in favorable neuroblastoma occurred in patients under one year of age, that might lead to spontaneous regression of tumor cells under relative deficiency of the stromal NGF, while they are strongly down-regulated in aggressive tumors in patients over one year of age. TRK-A alone or $p75^{NTR}$ alone may cause apoptosis in neuroblastoma cell, but their cooperative function may prevent the cell death and induce cellular differentiation and survival. The TRK-A signal also inhibits ►angiogenesis in the tumor. In neuroblastoma with ►*MYCN* amplification, the autocrine/paracrine loop of BDNF or NT-4/5 and TRK-B is functional and enhances invasion and metastasis. The reagents to inhibit BDNF/TRK-B pathway could be potential therapeutic tools against high-risk neuroblastoma. The downstream signaling molecule ShcC is expressed at high levels in advanced neuroblastoma and is significantly correlated with poor prognosis. Interestingly, in ►medulloblastoma and ►Wilms tumor, high expression of TRK-C is associated with favorable prognosis.

In ►papillary thyroid carcinoma, there are somatic rearrangements of the *TRK-A* gene, producing ►chimeric oncogenes with constitutive tyrosine kinase activity. The *TRK* oncogene with replacement of ligand-binding domain by heterologous sequences including tropomyosin or *TFG* gene is found in about 25% of thyroid papillary carcinoma.

In ►prostate cancer, expression of TRK-A and TRK-B is associated with invasive capacity and aggressiveness of the tumor. The TRK inhibitors suppress tumor growth *in vivo*. Human ►lung cancer also expresses both TRK-A and TRK-B, but not TRK-C. There is no expression of $p75^{NTR}$ receptor protein in the cancer tissue. In human astrocytoma and ►glioblastoma, expression of TRK-A and TRK-B may contribute to progression towards malignancy.

In ►pancreas cancer, TRK-A and TRK-C are expressed in duct, islet and cancer cells, while TRK-B is expressed only in alpha-cells in islet. The neurotrophins are also expressed in both normal and cancer cells in a different manner. The expression and distribution of neurotrophins and their receptors may play a role in regulating neural invasion of the pancreatic cancer cells.

Both NGF and TRK-A are abundantly expressed in epithelial cells of epithelial ►ovarian cancer, and enhance the cell growth in an autocrine manner.

TRK-C mRNA is widely expressed in human soft tissue tumors. The expression of *TRK-C* may be involved

in the progression of early stages of melanoma. The ►*ETV6-TRK-C* fusion gene, whose tyrosine kinase is constitutively activated, is found in infantile fibrosarcoma, acute myeloid leukemia and secretary ►breast cancer.

Neurotrophins and their receptors are down-regulated in human ►gastric cancer.

Neutropenia

Gary H. Lyman
Department of Medicine, University of Rochester, Rochester, NY, USA
James P. Wilmot Cancer Center, University of Rochester Medical Center, Rochester, NY, USA

Synonyms

Leukopenia; Granulocytopenia; Agranulocytosis

Definition

Is an inherited or acquired condition manifested by low numbers of circulating white blood cells known as neutrophils. The absolute neutrophil count (ANC) may be estimated directly or as the product of the total white blood cell count and the fraction of polymorphonuclear cells and band forms in the blood count differential and is generally expressed as the number of cells per mm^3. The Common Toxicity Criteria established by the US National Cancer Institute grades neutropenia as: Grade 0: ≥2,000/mm^3; Grade 1: ≥1,500–<2,000/mm^3; Grade 2: ≥1,000–<1,500/mm^3; Grade 3: ≥500–<1,000/mm^3; Grade 4: <500/mm^3. However, the term neutropenia clinically is generally reserved for ANC <1,500/mm^3 (grades 2 or greater).

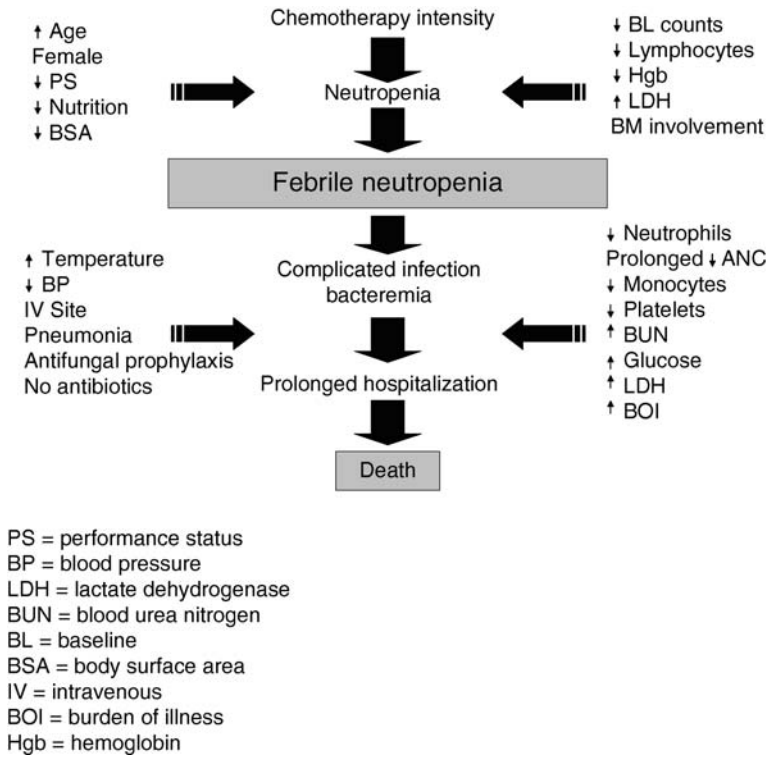
Characteristics

Hematopoiesis

Normal hematopoiesis is characterized by the controlled proliferation and maturation of multiple cell lines critical to the development of the healthy individual. The maturation and functional integrity of these cell lines are controlled by an array of hematopoietic cytokines which regulate the rate and direction of maturation to the myeloid cell line from a multipotential stem cell through cells committed to the granulocyte and monocyte lineage and then eventual maturation into functional end cells including ►monocytes, ►basophils, ►eosinophils, and ►neutrophils. ►Cytokines involved in the early maturation of the myeloid cell line include ►interleukin 3 (IL-3) and granulocyte-macrophage (GM-) ►colony-stimulating factor (CSF) while granulocyte (G-) CSF facilitates the terminal morphologic and functional maturation of the neutrophil. In healthy adults, this process occurs almost entirely in the bone marrow and extends over a period of 10–14 days, following which mature neutrophils migrate into the circulation where they persist, on average, for 5–10 h. In the setting of active infection, circulating neutrophils move quickly into infected tissues to fight infection by ingesting and destroying infectious organisms. Neutrophils clearly represent the principle white blood cell lineage responding to bacterial infection.

Neutrophil Disorders

Neutropenia may be either inherited (congenital, cyclic) or acquired from disease or exposure to certain toxic agents. Severe Congenital Neutropenia (►Kostman syndrome) is rare but often associated with severe recurrent infections. A specific syndrome of cycle neutropenia is characterized by regular oscillations in the numbers of cells of the various myeloid cell lines. Acquired neutropenia may result from either decreased production or increased destruction of neutrophils. Common causes of the later include various infections and primary immune disorders and hypersplenism. Antibodies to the ►G-CSF receptor may result in ►Felty syndrome. Decreased production of neutrophils may result from bone marrow disorders including conditions such as certain nutritional deficiencies, alcoholism, aplastic anemia and ►myelodysplasia and ►acquired immunodeficiency syndrome (AIDS) as well as in association with neoplasms including the leukemias and any malignancy infiltrating the bone marrow inhibiting normal myelopoiesis. Drug-induced neutropenia is most often idiosyncratic and may result from a wide variety of agents including the thionamide antithyroid agents, several ►nonsteroidal anti-inflammatory drugs, several antibiotics including chloramphenicol and the sulfonamides, the quinine antimalarials and a range of cardiovascular, diuretic,



Neutropenia. Figure 1 Clinical management of neutropenia. Lyman GH, Kuderer NM, Djulbegovic B (2002) Prophylactic granulocyte colony-stimulating factor in patients receiving dose intensive cancer chemotherapy: a meta-analysis. Am J Med 112:406–411.

psychotropic and anticonvulsant agents among many others. The most common cause of neutropenia in the cancer population is the direct result of the ►myelosuppression associated with cytotoxic chemotherapy and radiation therapy. Myelosuppression and ensuing neutropenia as well as anemia and thrombocytopenia represent the leading cause of dose-limiting toxicity associated with systemic cancer chemotherapy. The risk of myelosuppression and neutropenia correlate directly with the dose intensity of cancer chemotherapy and are most profound in association with marrow ablative regimens in preparation for hematopoietic stem cell transplantation. Fever in the setting of neutropenia (febrile neutropenia) represents a potentially serious infection requiring immediate evaluation, cultures and broad-spectrum antibiotics until recovery. As a result, episodes of febrile neutropenia are associated with considerable morbidity, mortality as well as cost and often compromising effective cancer treatment. The risk of febrile neutropenia correlates directly with both the severity and duration of myelosuppression and neutropenia. Febrile neutropenia often occurs early in the course of cancer chemotherapy and is associated with a number of demographic and clinical factors (Fig. 1). Of importance, hematopoietic reserves in the bone marrow diminish with age such that older individuals are more prone to neutropenia. In particular, older patients experience a greater risk of neutropenia and febrile neutropenia in the setting of myelosuppressive chemotherapy (Table 1).

Neutropenia. Table 1 Febrile neutropenia

Fever is defined as:
• A single oral temperature of ≥38.3°C (101.0°F)
• A temperature of ≥38.0°C (100.4°F) for a least 1 h
Neutropenia is defined as:
• An absolute neutrophil count of <500 cells/mm^3 (grade 4)
• An absolute neutrophil count of <1,000 cells/mm^3 (grade 3 or 4), with a predicted decrease to <500 cells/mm^3

Neutrophil Growth Factors

Neutrophil growth factors are a specific class of cytokines termed the CSF. The term CSF has been applied to certain glycoproteins that are capable of promoting and supporting the formation of *in vitro*

Neutropenia. Table 2 Pharmacokinetics of the colony-stimulating factors

CSF	Generic name	Brand name	Vector	$t_{1/2}$ life (h)	Clearance (mL/min/kg)
G-CSF	Filgrastim	Neupogen	E. coli	SC 2.5–5.8 IV 1.3–5.1	SC 19–56 IV 4–21
	Lenograstim	Neutrogin	CHO		
GM-CSF	Sargramostim	Leukine	Yeast	SC 1.6–5.8 IV 1.1–2.4	SC 249–312 IV 9.9–178
	Molgramostim	Leucomax	E. coli		
	Regramostim		CHO		
Pegylated G-CSF	Pegfilgrastim	Neulasta	E. coli	15–80	

CSF, colony-stimulating factor, CHO, chinese hamster ovary cells; SC, subcutaneous; IV, intravenous.

colonies of hematopoietic elements when present in bone marrow cell cultures. Endogenous CSF is produced by various sources including monocytes, macrophages, endothelial cells, fibroblasts and bone marrow stromal cells. The ►G-CSF receptor is expressed primarily on mature neutrophils and their precursors while the GM-CSF receptor is expressed on monocytes, eosinophils, myeloid progenitors and T-lymphocytes as well as neutrophils. Following binding and dimerization of the receptor, the biologic action of the cytokine is orchestrated by a number of signaling pathways, the most important of which is the ►JAK/►STAT pathway, followed by transcriptional activation in the nucleus. Defects in the receptor or its down stream signaling elements are incriminated in the pathogenesis of severe congenital neutropenia or Kostman syndrome. Endogenous G-CSF is normally present in very low concentrations but is necessary to sustain neutrophil production and is highly stimulated by inflammatory cytokines and bacterial cell wall products. Endogenous G-CSF levels rise in neutropenic states and most dramatically with febrile neutropenia. G-CSF acts on late myeloid progenitors leading to increase cell division and shortens the transit time through the bone marrow to the peripheral blood and tissues. It also increases differentiation and functional maturation of neutrophils including chemotaxis, phagocytosis, and antibody dependent cellular toxicity. GM-CSF stimulates ►macrophages and monocytes as well as granulocytes and stimulates the functional activity of neutrophils but appears to have little role in steady state white blood cell production. Following identification and cloning of the genes associated with both G-CSF and GM-CSF, recombinant forms of these cytokines were produced and are commercially available. The pharmacology and ►pharmacokinetics of the recombinant CSFs have been studied in both healthy individuals as well as those with chronic or episodic neutropenia due to chemotherapy (Table 2). Most CSFs are eliminated by renal clearance and metabolized by receptor binding and internalization. ►Pegylation of recombinant G-CSF virtually eliminates glomerular filtration, significantly prolonging systemic circulation and action, most notably in the setting of neutropenia. When administered to healthy volunteers, the CSFs result in a prompt increase in circulating neutrophils. Clinical trials have convincingly demonstrated that these agents are effective in reducing the risk of neutropenia and its complications in both congenital and acquired neutropenia, most notably in the prevention of infection in patients receiving myelosuppressive chemotherapy.

Neutrophil

Definition

A white blood cell that is an abundant and important ►phagocyte.

Neutrophil Elastase

Zhifu Sun, Ping Yang
Department of Health Sciences Research, Mayo Clinic College of Medicine, Rochester, MN, USA

Synonyms

Neutrophil Elastase 2 (*ELA2* as the official gene symbol); Leukocyte elastase; Serine elastase; Polymorphonuclear leukocyte elastase; Granulocyte elastase

Definition

NE; is a single-chain glycoprotein with 218 amino acid residues and belongs to a member of the chymotrypsin superfamily of ►serine protease, which includes chymotrypsin, trypsin, and elastase. With three residues in the active site, His^{41}-Asp^{88}-Ser^{173} comprises a "charge-relay" system to carry out hydrolysis. All serine proteases have their own internal inhibitors to prevent any overdose effects of cell lysis. A natural inhibitor of NE is α_1-antitrypsin (α_1AT). The major physiological function of NE is host-defense, i.e., to degrade foreign microorganisms or organic molecules that were phagocytosed by neutrophils. NE also degrades a variety of substrates including elastin, the most important of all, and other ►extracellular matrix proteins (►collagen, ►proteoglycan, ►fibronectin, and ►cadherins), ►platelet receptors, ►complement receptors, thrombomodulin, lung surfactant, and certain growth factors (►granulocyte-colony stimulating factor (G-CSF), stromal cell-derived factor-1, and their respective receptors, G-CSFR and CXCR4). NE mostly releases and acts locally but can be detected in serum.

Characteristics

The most commonly used assay method is enzyme-linked immunosorbent assay (ELISA), which measures the level of NE and α_1AT complex. The reported normal range is 56–136 ng/ml but fluctuates greatly under ►inflammation, ►Behcet disease, interstitial lung disease, and pulmonary fibrosis.

NE Gene and Its Variations

The gene for NE is officially named by HGNC (HUGO Gene Nomenclature Committee) as Neutrophil Elastase 2 with the gene symbol *ELA2* to differentiate from similar enzymes elastase1 and elastase 3 (*ELA1* and *ELA3A* or *B*) produced in the pancreas. The gene is located on chromosome 19p13.3 with five exons and four introns. During the past few years, up to 30 different mutations have been identified on the gene and these mutations are linked to two rare inherited diseases, cyclic neutropenia and congenital neutropenia. There are over 47 ►SNPs deposited in the NCBI SNP database within the 5 kb region of the gene, with one validated from the HapMap project, but their functional significance is largely unknown.

In the 5′ flanking region of ELA2, there are six tandem repeats of a 53-bp nucleotide sequence, which contains a potential binding site for a basic helix-loop-helix protein located at −1032 to −716. The structure has the enhancer function of *ELA2* activity. Two SNPs and one tandem repeat variation in the promoter region and their significance with lung cancer have been reported in the literature: T or G SNP at −903 bp, A or G at −741 bp from the transcription initiation site, and an extra 52-bp repetitive sequence between the fourth and fifth repetitive motifs.

NE and Cancer Development

The role of NE in cancer development is mostly inferred from cell line and animal models. In ultraviolet B or chemically (Benzopyrene) induced skin tumors, elastase-deficient mice develop significantly less tumors than normal mice, and administration of elastase inhibitors to normal mice generates the similar reduction of induced tumors. Inhibition of NE can significantly suppress the proliferation, motility, and chemotaxis of a ►pancreatic cancer cell line and completely stall the tumor growth or metastasis of human lung and ►colon cancer cell lines.

The polymorphisms at the promoter region of *ELA2* likely affect the gene expression activity and have been implicated in lung cancer risk from epidemiologic studies in humans. Individuals with −903TT or −741GG or certain haplotype (T-G) at the two loci have a significantly increased risk (two- to four-fold) of developing lung cancer than those with −903TG, −741AA/AG alleles or a haplotype of T-A; the elevated risk seems related to increased functional activity of the gene.

Long-term follow-up of patients with severe congenital neutropenia caused by mutations in one or several genes including *ELA2* reveals that ~1 in 10 patients develops ►myelodysplastic syndrome or acute ►leukemia; Proteinase 3 and neutrophil elastase are overexpressed in many myeloid ►leukemia. These suggest that NE dysfunction may lead to tumor development.

NE and Cancer Progression and Prognosis

Elevated NE has been detected in many different types of cancer, and the level of NE is associated with cancer stage, grade, and survival. Higher levels of NE are observed more often in later stage, larger or more invasive tumors than in earlier stage, and smaller or less invasive tumors. The patients with a high level of NE within tumors have shorter survival than those with lower levels of NE. Higher levels of NE in tumors are also associated with rapid relapse or recurrence of ►breast cancer and a higher grade of ►brain tumors.

Prognostic significance of NE in hematological tumors seems different from that in solid tumors. For example, low expression of CD7 in combination with high expression of NE or proteinase 3 in ►chronic myelogenous leukemia (CML) correlates with longer patient survival. This may be related to the fact that instead of working as an enzyme to degrade surrounding tissues, NE may be a tumor specific antigen to induce cytotoxic T lymphocyte immune response to kill tumor cells.

NE as Cancer Therapeutic Target

The association between elevated NE levels and tumor progression and metastasis has prompted researchers to explore the possibility of targeting NE as a treatment (Therapeutic target). A NE specific inhibitor such as ONO-5046_Na has shown a strong tumor inhibitory effect. In laboratory studies, when the inhibitor is administered into the tumor-bearing animals, it can completely suppress the tumor growth and appearance of metastatic foci for some solid tumors (breast and ►gastric carcinoma). Additionally, NE levels may be a marker in predicting a treatment response of breast cancer to an anti-HER2 antibody like Trastuzumab: a higher NE level was correlated with a better response. Using NE in ►CML as a specific antigen to stimulate CD8 induced immune response or developing an anti-NE vaccine to treat the tumor has also been proposed and is under investigation.

Possible Mechanisms of NE in Cancer Development and Progression

In spite of observed roles of NE in tumor development, progression, and metastasis, the mechanisms are unclear. Several potential mechanisms have been postulated based on laboratory experimental data. Multiple mechanisms more likely act together to give rise to the observed clinical presentations, acting and interacting differently among different cell types.

Carcinogen Exposure Enhancer

Individuals with varying degrees of lung tissue damage from NE as seen in ►emphysema may have longer exposures due to air trapping, thereby increasing absorption and enhancing the action of ►carcinogens present in ►tobacco smoke. This may be part of the reason emphysema patients have a much higher risk for developing ►lung cancer.

Apoptosis Inhibitor

NE may be directly involved in ►carcinogenesis through the ►tumor necrosis factor receptor (TNFR) signaling pathway. NE is capable of removing an active fragment of the TNFR-2 from the cell surface, and the removal of the TNFR-2 lowers the affinity of ►TNF for TNFR-1. The shed TNF receptors consume extra circulating TNF. All these cause significantly reduced response to TNF signaling and continued cell growth. TNFα signaling is a very complicated cell process, and TNF plays an important role in the pathway as a mediator of ►apoptosis, ►inflammation, and immunity. In its initial step, TNF, produced primarily by activated ►macrophages, binds to the outer domain of TNF-R1 located on the surface of the cell membrane. The binding triggers a series of intracellular events that ultimately result in the activation of ►caspase-8, leading to an ►apoptosis cascade and two other major transcription factors, ►nuclear factor κβ and ►c-Jun. c-Jun overexpression, an indicator of oncogenesis, was observed in lung cancer and its surrounding atypical areas. c-Jun overexpression was associated with increased breast cancer cell motility and invasiveness, and tumor formation in nude mice. All these may lead to uncontrolled tumor cell growth.

Invasion and Metastasis Promoter

NE released by inflammatory cells or produced by tumor cells breaks down the structural proteins of the extracellular matrix surrounding the tumor and makes it easier to invade and migrate. NE can activate matrix metalloproteinases such as ►MMP2 through membrane-type 1 matrix metalloproteinase (MT1-MMP) and ►MMP3. The MMPs are a group of Zn-dependent enzymes that have been extensively documented for their roles in tumor invasion and metastasis, particularly MMP2 and MMP9. Furthermore, NE released from activated leukocytes can injure endothelial cells and cause microcirculatory disturbance. These changes may in turn result in the expression of ►adhesion molecules and the formation of microthrombi in the capillaries, the conditions that promote cancer ►metastasis.

Cancer Promoting Gene Derepressor

Protease may remove the repression of a variety of genes via proteolytic cleavage of protein repressors and promote carcinogenesis. In prokaryotic and eukaryotic cells, the SOS system (►DNA repair system) plays a key role in fixing DNA damage caused by carcinogens and preventing cell transformation. However, the existence of proteases may induce an error-prone SOS system by hydrolyzing the protein repressor and render cells prone to transform.

NE Suppresses Granulopoiesis of Hematopoietic Cells

Patients with hematological disorders, such as severe chronic neutropenia and myelogenous leukemia, may have mutations in *ELA2* or alterations in the expression, localization, or activity of the proteins. These changes may lead to the deregulation of stem cell proliferation and differentiation in bone marrow through the ►G-CSF. NE generally has a counteractive effect (negative feedback) on the G-CSF and suppresses normal granulopoiesis. NE production, combined with

a relative independence from the G-CSF for proliferation, allows ►CML clonal dominance and accounts for the early loss of Philadelphia negative granulocytes during the course of leukemia.

In summary, excess neutrophil elastase may facilitate cancer development, but may also serve as a marker in predicting a treatment response. NE inhibitor may deter cancer progression and prolong patient survival therefore would deserve further evaluation for cancer prevention at multiple levels.

Neutrophil Granulocytes

Definition

Phagocytic cells of the innate immune system with a characteristic segmented, multilobed nucleus. Active in the early phases of ►inflammation and equipped with multiple antimicrobial effector mechanisms.

►Bacillus Calmette-Guérin

Neutrophil Polymorphonuclear Granulocytes

Definition

PMNs; Synonym ►neutrophils; Are the most abundant type of white blood cells in humans important for initiation of the inflammatory process and in the protective immune response against infection.

►BORIS

Neutrophils

Definition

White blood cells, contain tiny sacs of enzymes that help the cell to kill and digest microorganisms which it has engulfed by ►phagocytosis. The neutrophil has a lifespan of about 3 days. Decrease of neutrophils is referred o as ►neutropenia.

Nevi

Definition

Plural of ►Nevus.

►Melanocytic Tumors

Nevocellular Nevus

►Melanocytic Tumors

Nevoid Basal Cell Carcinoma Syndrome

Definition

Synonym ►Naevoid Basal Cell Carcinoma Syndrome.

Nevus

Definition

Plural: nevi. UK: naevus; naevi); Usually brief for: ►melanocytic nevus, a benign neoplasm of pigment-producing cells (melanocytes) in the skin. Originally, a

nevus has been defined as a circumscribed developmental lesion of skin or mucous membrane involving excess or deficiency of any one of the normal structures. This broader definition explains the use of the term in some nonmelanocytic lesions (i.e. epidermal nevus, or sebaceous nevus, which are not melanocytic lesions). Clonal proliferation of melanocytes in the skin. The precise location of the nevus cells determines a histological classification into dermal, junctional or compound nevi. The majority of nevi are acquired. Nevi are more common in sun-exposed areas of the body. The distribution and number of nevi are strongly determined by heredity, interacting with sun-exposure. Numbers and size typically increase during puberty.

►Basal Cell Carcinoma
►Melanoma
►Melanocytic Tumors

Nevus of Ota

Definition

►Oculodermal Melanocytosis.

Newcastle Disease Virus

Definition

NDV; A poultry pathogen of the Paramyxoviridae family with a negative strand RNA genome, an helical nucleocapsid, and enveloped particles used in ►oncolytic virotherapy.

NICE

Definition

Abbreviation for the ►National Institute for Health and Clinical Excellence. The organization that describes itself as "the independent organization responsible for providing national guidance on the promotion of good health and the prevention and treatment of ill health" in England and Wales.

NICE Blight

Definition

Refusal of local managers within the United Kingdom's National Health Service to allow the use of a new treatment because it has not yet been the subject of a review by the ►National Institute for Health and Clinical Excellence.

Nickel Carcinogenesis

Joseph R. Landolph
Departments of Molecular Microbiology and Immunology, and Pathology; USC/Norris Comprehensive Cancer Center, Keck School of Medicine; Department of Molecular Pharmacology and Pharmaceutical Sciences, School of Pharmacy, Health Sciences Campus, University of Southern California, Los Angeles, CA, USA

Synonyms

Nickel-induced cell transformation; Nickel tumorigenesis

Definition

Is the process of the formation of respiratory tumors (carcinomas) induced by inhalation of specific insoluble nickel compounds, and the series of sequential steps that occur when animals or humans are exposed to specific nickel compounds that leads to tumor development. After all these steps are accomplished, the physiological mechanisms regulating control of growth in the normal cells are degraded. Hence, the normal cells are degraded and converted into tumor cells. The tumor cells then grow autonomously in an unregulated fashion and evade the host immune system, leading to development of visible tumors.

Characteristics

Nickel, the Chemical Element, and its Ionic Species and Chemical Compounds

Nickel and iron form alloys that are found in many meteors. Nickel is also found in deposits in central regions of the Earth. Nickel is commonly found in nature. In nature, nickel is found in combination with ►arsenic, antimony, and sulfur. An example of a nickel compound found in nature is millerite, NiS.

Pentlandite, a sulfidic ore, and garnierite and nickeliferous limonite, which are lateritic ores, are some of the nickel-containing minerals of economic importance. Garnierite is commonly used as a generic name for a series of mixed nickeliferous silicates with a wide range of nickel contents. Nickeliferrous limonite is the term used to describe poorly crystalline nickel-bearing ferric oxide. The main constituent of nickeliferrous limonite is goethite (α-FeO.OH).

Some of the processes used in the refining of sulfidic ores include the carbonyl process and the chloride electrowinning process. The carbonyl process produces high purity nickel metal. In the carbonyl process, carbon monoxide is reacted with impure ►nickel oxide feed at 50°C at atmospheric pressure, or with nickel-copper matte at higher pressures and temperatures, to yield nickel carbonyl [$Ni(CO)_4$]. When nickel carbonyl is heated to 200°C and thereby thermally decomposed,

nickel metal of purity >99.9% can be obtained. Lateritic ores are usually smelted with or without the addition of sulfur to form ferronickel mate. This matte can be further refined by a variety of processes.

Elemental nickel is a solid metal with a silver-white color. It has a high thermal conductivity, a high electrical conductivity, and a high melting point (1452°C). Nickel metal can be drawn, rolled or forged, and polished. It is highly resistant to attack by air or water at ordinary temperatures when compact. Because of this, nickel is often electroplated and used as a protective coating.

The oxidation state of +2 is the most common state for most ordinary nickel chemistry. Higher oxidation states, such as Ni^{+3} and Ni^{+4} can occur in certain oxide systems, but these are rare. Ni^{+2} complexes exist as octahedral complexes, tetrahedral complexes, planar complexes, and trigonal complexes.

In specific biological systems, particularly in bacteria and in plants, nickel is a necessary component of four enzymes: (i) urease, (ii) carbon monoxide dehydrogenase, (iii) hydrogenase, and (iv) methyl-S-coenzyme M reductase. To date, nickel has been shown to be an essential element for certain animals (e.g. rats and goats). However, nickel has not been shown to be an essential element in humans, and no enzymes from mammalian cells have been shown to contain nickel.

Important Commercial Uses of Nickel and Nickel Compounds

Nickel is a very important and useful metal commercially. Nickel is used in large quantities in many important alloys, such as stainless steels. Nickel is also used as a catalyst in the hydrogenation of fats and oils, as a pigment in paints, and in ceramic glazes. In addition, nickel is used in nickel-cadmium batteries, in nickel plating, and in the manufacture of coins.

Exposure of Humans to Nickel Compounds

Humans are commonly exposed through the skin to nickel in the form of coins and jewelry without any harmful effects, except for rare cases of allergies to nickel in jewelry. In the past, exposures of refinery workers, who processed sulfidic nickel ores, to mixtures of insoluble and soluble nickel compounds as dusts and aerosols, in combination with simultaneous exposures to arsenic, in workers who also smoked cigarettes, correlated with an increased incidence of ►lung cancer and nasal cancer in the workers. These incidences of induction of cancer of the respiratory tract were believed to be due to exposure to a combination of mixtures of nickel compounds, sulfuric acid mists, and arsenic in workers who often smoked cigarettes. By contrast, exposures of workers to dusts containing metallic nickel, or to dusts produced during the refining of lateritic ores, have not been associated with increased respiratory cancer risks.

Genotoxicity of Nickel Compounds

Nickel compounds come in the soluble and insoluble forms. Nickel chloride and nickel sulfate hexahydrate are examples of water-soluble compounds of nickel. Soluble nickel compounds are not taken up into mammalian cells to any significant extent, since there is no known biological receptor for soluble nickel ions in mammalian cells. Hence, when humans or animals are exposed to soluble nickel compounds, these soluble nickel compounds are largely excreted unchanged into the urine.

There are many insoluble nickel compounds, such as ►nickel subsulfide (Ni_3S_2), green (high temperature) NiO, black (low temperature) NiO, and crystallline nickel monosulfide (NiS). If these insoluble nickel compounds are present in particle sizes of <10 μm, they are phagocytosed by mammalian cells. ►Phagocytosis involves an invagination of the plasma membrane around the particles, to form a phagocytic vesicle. The phagocytic vesicle then is internalized into the cell with its entrapped particle of insoluble nickel compound. Hence, by the process of phagocytosis, particles containing insoluble nickel compounds can be taken up into mammalian cells. The phagocytosed insoluble nickel compounds then enter the lysosomal network, as shown by fluorescent microscopy studies. The resultant intracellular nickel compounds then dissolve into soluble nickel ions and counterions. The nickel ions then migrate through the cell in an attempt to establish chemical equilibrium. Eventually, some Ni^{+2} ion may travel into the nucleus.

Following phagocytosis of insoluble nickel compounds by mammalian cells, the resultant intracellular Ni^{+2} ions cause cytotoxicity to the mammalian cells. In cell culture studies, the Ni^{+2} ions also induce ►chromosomal aberrations, in the forms of gaps, breaks, fragments, dicentrics, and satellite associations. In addition, Ni^{+2} ions have been shown to induce ►gene amplification in mammalian cells. This has been demonstrated for ►amplification of the ect-2 gene, a guanosine triphosphate (GTP)-guanosine diphosphate (GDP) exchange factor for the rho A protein (►rho family proteins). Hence, insoluble nickel compounds of particle size <10 μm can be phagocytosed by mammalian cells, liberate Ni^{+2} ions inside the cells, and as a result of this are ►genotoxic to mammalian cells. This genotoxicity is manifested in the form of chromosomal aberrations and gene ►amplification in the cells. Whether these effects occur in vivo remains to be confirmed. To date, there have been no mutation studies conducted in lung epithelial cells of animals inhaling insoluble nickel compounds.

There is also some evidence that nickel compounds can generate ►reactive oxygen species (ROS) in mammalian cells. In mammalian cells, ►superoxide radicals arise from normal cellular oxidative metabolism.

Following the dismutation of two superoxide radicals by superoxide dismutase, ►hydrogen peroxide is formed, particularly in the mitochondria. There is some evidence that intracellular Ni^{+2} ions can catalyze pseudo-Fenton reactions, in which Ni^{+2} ions can catalyze the reaction of superoxide radical and hydrogen peroxide to generate hydroxyl radicals and hydroxyl ions. The resultant hydroxyl radicals are able to cause formation of 8-hydroxy-deoxyguanosine, and therefore mutations, in DNA. However, this latter pathway has not been demonstrated conclusively with rigorous experimentation.

Nickel-Induced Cell Transformation

As noted above, nickel compounds can be phagocytosed into mammalian cells, leading to the accumulation of intranuclear Ni^{+2} ions. These intranuclear Ni^{+2} ions can induce chromosomal aberrations, which are genotoxic events. If these aberrations lead to loss of regions of chromosomes bearing ►tumor suppressor genes, or disrupt areas of chromosomes bearing tumor suppressor genes, this can lead to loss of tumor suppressor genes from cells, contributing to morphological, anchorage-independent, and neoplastic cell transformation.

Specific insoluble nickel compounds, such as green NiO and crystalline NiS, can also cause gene amplification, in particular, amplification of the ect-2 proto-►oncogene in cultured C3H/10T1/2 Cl 8 mouse embryo fibroblastic cells. This is also a genotoxic event. This leads to over-expression of the ect-2 proto-oncogene at the mRNA and protein levels. This event also contributes to nickel compound-induced morphological, anchorage-independent, and neoplastic cell transformation.

In addition, Ni^{+2} ions also bind strongly to histidine, imidazole, and cysteine, with association constants of approximately 100,000. Ni^{+2} ions can also bind strongly to histidine, imidazole, and cysteine groups of proteins, particularly to histones. When intracellular Ni^{+2} ions bind to histones inside the nucleus of mammalian cells, this causes condensation of chromatin. The resultant condensation of chromatin has been shown to lead to ►methylation of the promoters of genes, leading to their transcriptional repression. When this happens to actively transcribed tumor suppressor genes, they will become transcriptionally quiescent. This is an ►epigenetic event, or a non-genotoxic event. Transcriptional silencing of tumor suppressor genes by Ni^{+2} ions therefore could also be part of the mechanism leading to carcinogenesis by nickel compounds. Therefore, induction of cell transformation by specific, insoluble, carcinogenic nickel compounds occurs by a combination of genotoxic events (chromosomal aberrations and gene amplifications) and non-genotoxic/epigenetic events (►DNA methylation and transcriptional silencing of tumor suppressor genes).

Nickel Carcinogenesis

Some water insoluble compounds of nickel are respiratory carcinogens in rats. These include nickel subsulfide and green nickel oxide (NiO), when administered by inhalation. Mice and hamsters do not appear to be susceptible to the carcinogenic effects of nickel compounds. Interestingly, administration of soluble nickel compounds, such as nickel sulfate, to rats by inhalation does not induce lung tumors in these animals, even at the maximum tolerated dose. In humans, exposure of workers in nickel refineries in the past, to aerosols generated during the refining of sulfidic ores of nickel-containing mixtures of insoluble and soluble nickel compounds, was associated with increased incidences of nasal and lung cancer. In many cases, these workers were simultaneously exposed to arsenic and mists of sulfuric acid, as well as to cigarette smoke.

Mechanisms of Nickel Carcinogenesis

Mechanisms of nickel carcinogenesis appear to be due to a combination of genotoxic effects and non-genotoxic effects. The genotoxic effects include the ability of intracellular Ni^{+2} ions to induce ►amplification of ►proto-oncogenes, such as the ect-2 gene, and to cause chromosomal aberrations, which are both genotoxic events. There is also some thinking that nickel compounds can act as redox catalysts to cause pseudo-Fenton reactions, generating hydrogen peroxide and hydroxyl radicals. This could lead to generation of 8-hydroxy-deoxyguanosine in the DNA of mammalian cells, and hence to mutations in specific genes, such as proto-oncogenes and tumor suppressor genes. The evidence for this latter mutational pathway is less clear. In addition, intracellular nickel ions can also bind to histones, leading to chromosomal condensation. This can then lead to methylation of the promoters of various actively transcribed tumor suppressor genes, silencing their transcription. It is currently thought that a combination of genotoxic and epigenetic events leads to nickel carcinogenesis. These genotoxic events include induction of mutations in proto-oncogenes, activating them to oncogenes, through oxygen radical-induced mutations, or chromosomal aberrations in regions containing proto-oncogenes, activating them to oncogenes, or amplification of proto-oncogenes. Additional types of genotoxic events include mutational inactivation of tumor suppressor genes, possibly through nickel-generated oxygen radicals, or loss of chromosomes bearing tumor suppressor genes. An example of an epigenetic event induced by intracellular ions would be nickel-induced chromosomal condensation, leading to methylation and hence transcriptional silencing of tumor suppressor genes. All these intracellular nickel ion-induced events together, both genotoxic and epigenetic, activate proto-oncogenes and inactivate

specific tumor suppressor genes, leading to global deregulation of gene expression, the emergence of the first tumor cell, and hence, carcinogenesis.

Nickel-induced Cell Transformation

►Nickel Carcinogenesis

Nickel Oxide

Definition

A nickel compound containing one atom of nickel and one atom of oxygen. During nickel refining, the nickel in nickel-containing ores is usually converted to nickel subsulfide, then roasted to convert it to nickel oxide. There are two prominent types of nickel oxides – green (high temperature) NiO, which is formed at calcining temperatures above 1,100°C, and black (low temperature) NiO, which is formed at calcining temperatures below 1,100°C.

►Nickel Carcinogenesis

Nickel Subsulfide (Ni_3S_2)

Definition

A nickel-containing compound consisting of nickel and sulfur, that is an insoluble nickel compound. This compound is one that nickel in sulfidic nickel-containing ores is usually converted to during the process of nickel refining. This nickel compound is phagocytosed by mammalian cells and can cause cytotoxicity, chromosomal aberrations, and morphological transformation of mammalian cells and lung tumors when lower animals inhale it.

Nicotine

Definition

A compound present in tobacco and tobacco smoke which is responsible for the addictive properties of these products.

►Tobacco Carcinogenesis
►Nicotine Addiction

Nicotine Addiction

Joseph DiFranza
Department of Family Medicine and Community Health, University of Massachusetts Medical Center, Worcester, MA, USA

Synonyms

Nicotine dependence; Tobacco addiction; Tobacco dependence

Definition

Some authors define nicotine addiction as a loss of autonomy over the use of tobacco resulting from craving

N

or other drug withdrawal symptoms that make it difficult or unpleasant to discontinue use. Others define addiction in terms of various combinations of symptoms that include nicotine withdrawal symptoms, loss of control over use, and continued use despite impairment to the person's health or social functioning.

Characteristics

People use tobacco to obtain nicotine. However, when tobacco is smoked or chewed, chemical and radioactive carcinogens are absorbed along with the nicotine. It is estimated that tobacco is responsible for about one third of all cancer deaths in the US, (►tobacco carcinogenesis and ►tobacco related cancers). The vast majority of tobacco users have made multiple attempts to discontinue tobacco use, but over 90% of quit attempts end in failure.

The Nicotine Withdrawal Syndrome

The ►nicotine withdrawal syndrome presents a formidable obstacle to maintaining abstinence. Symptoms include strong craving, urges or a need to use tobacco, restlessness, anxiety, bad mood, irritability, difficulty concentrating, and disturbed sleep. The nicotine withdrawal syndrome is the patient's experience of neurophysiologic events. The nicotine from a single cigarette occupies 88% of the nicotinic receptors in the human brain, and in rats, a single dose of nicotine triggers a number of enduring modifications in brain physiology. Some youths report nicotine withdrawal symptoms after smoking their first cigarette. Most smokers have experienced nicotine withdrawal before they have progressed to daily smoking. Indeed, nicotine withdrawal appears to be the primary factor leading to daily smoking. The time elapsed between the last cigarette and the onset of withdrawal symptoms is termed the ►drug latency to withdrawal. When symptoms of nicotine withdrawal first develop, the latency to withdrawal may be measured in days or weeks. In other words, a single cigarette can completely relieve withdrawal symptoms and postpone their reappearance for long stretches of time.

Drug Tolerance

With repeated use, ►drug tolerance to nicotine develops and the latency to withdrawal ►progressively shortens as cigarettes become less effective at staving off withdrawal. Over time, smokers who could initially manage their withdrawal by smoking one cigarette per week, find they must smoke several days per week, and then every day. Unless a constraint is placed on the frequency of smoking, most will progress to smoking every hour. As nicotine has a half-life of about 2 h, this maintains the presence of nicotine in the brain throughout the day. In some smokers, the latency to withdrawal can be as short as 30 min and withdrawal begins even while nicotine is present in high concentrations in the brain. Behaviors such as smoking immediately upon awakening, smoking when sick in bed, and giving up other activities in order to smoke, are manifestations of severe tolerance and the correspondingly short latency to withdrawal.

Early Onset of Addiction

All of the symptoms of nicotine addiction that are not manifestations of tolerance are present in individuals who smoke only one cigarette per week or less. Many adolescent smokers report symptoms of nicotine addiction after smoking only a few cigarettes. Failed attempts at smoking cessation are very common among smokers who have never smoked as much as one cigarette per day. If tolerance did not develop, nicotine addicted smokers might forever be content with smoking one cigarette per week, and tobacco use would be a negligible contributor to cancer mortality.

NIH-3T3 Cells

Definition

Murine fibroblast permanent in vitro cultured cell line, often used in experimental analyses, like ►NIH3T3 transformation assay, or in experimental drug tests.

NIH3T3 Transformation Assay

Definition

This assay, which is essentially based on the focus-forming assay developed by Howard Temin for titrating particles of transforming ►retroviruses in chicken embryonic fibroblasts, makes use of the contact inhibition response of the murine embryonic fibroblast cell line NIH3T3. Originally, this assay was developed to discover novel oncogenes by transfecting NIH3T3 cells (host) with sheared genomic tumor cell DNA (donor DNA). Host cell clones, which had acquired a active oncogene from the donor DNA, loose the characteristic contact inhibition response, continue to proliferate in the environment of a confluent monolayer and will eventually give rise to a clonal colony of transformed cells (focus). In later years, cDNA libraries were employed using classical transfection techniques or retroviral vectors. The focus can then be isolated and the acquired oncogene from the donor DNA can then be identified using various molecular biological techniques. Several ►oncogenes, e.g. ►*RAS*, were identified using this assay.

Nijmegen Breakage Syndrome

Martin Digweed
Institute of Human Genetics,
Charité – Universitätsmedizin Berlin,
Berlin, Germany

Synonyms

Ataxia-telangiectasia variant 1 and variant 2; Berlin breakage syndrome; Semanová II syndrome

Definition

A genetic disease characterized by an extreme sensitivity towards ionizing radiation and a high risk for the development of lymphatic tumors.

Characteristics

Nijmegen breakage syndrome (NBS) is a rare genetic disease; inheritance follows an autosomal recessive modus with complete penetrance. Although birth weight and size of homozygotes are normal, microcephaly and growth retardation soon become apparent and are major symptoms of the disorder. Progressive mental retardation is typical, however, IQ is usually within the normal range during early childhood. A sloping forehead and receding mandible give NBS patients a characteristic facial appearance which becomes more pronounced with age. NBS patients are immunodeficient in both cellular and humoral immune systems leading to frequent infections particularly of the respiratory tract. Approximately 40% of NBS patients develop cancer before the age of 21. B- and ►T-cell lymphomas are the most common malignancies seen, although ►rhabdomyosarcoma, hemoblastoma, and ►neuroblastoma have all also been observed.

NBS is caused by biallelic mutations in the *NBN* gene which codes for ►nibrin, a protein involved in the repair of DNA damage. The majority of patients are homozygous for a 5 bp deletion in the *NBN* gene, a ►founder mutation. However, ten further mutations, all of which also lead to a truncated protein, have also been described.

The involvement of nibrin, in the repair of DNA damage, is demonstrated by the chromosomal instability observed in patient cells. The cytogenetic aberrations seen are chromatid breaks and recombination figures, frequently involving chromosomes 7 and 14 where immunoglobulin and T-cell receptor genes are located. The frequency of chromosome breaks is greatly increased in patient cells after irradiation, or treatment with radiomimetic drugs. Indeed, their radiosensitivity makes treatment of malignancy in these patients problematical.

Cellular and Molecular Regulation

The DNA lesion caused by ionizing radiation, to which NBS patients and their cells are most sensitive, is the double-strand break (DSB). Unrepaired DSBs increase the mutation rate in NBS cells and thus contribute towards accelerated tumorigenesis.

Three distinct repair systems are available for the repair of DSBs in eukaryotic cells: nonhomologous end joining (NHEJ), single-strand annealing (SSA), and homologous recombination (HR). NHEJ/SSA systems are active particularly before DNA replication while repair after or during DNA replication can exploit the potentially error-free process of homologous recombination.

Nibrin is a component of the RAD50/MRE11/nibrin complex which is probably involved in all three repair pathways. DSB repair by the RAD50/MRE11/nibrin complex after ionizing radiation can be visualized microscopically in cells by immunostaining with antibodies to MRE11, RAD50, or nibrin. Discrete nuclear foci, the sites of DSB repair, can be seen in normal cells but are completely lacking in cells from NBS patients: nibrin is apparently responsible for the recruitment of the complex to the sites of DSB repair. Electron microscopy and other techniques suggest that the trimeric complex forms a bridge at the site of a DSB to hold the DNA ends together, clearly a requisite for repair by any of the three mechanisms mentioned above. Furthermore, the MRE11 component of the complex has exonuclease activities which may be required for general preparation of DNA ends before repair by one of the specialized processes.

Mutations in *MRE11* and *RAD50* lead to genetic diseases with a similar cellular and clinical phenotype to NBS as do mutations in the gene ►*ATM*, responsible for ►Ataxia telangiectasia. ATM is a central player in the response to DNA damage and it seems that a major function of the RAD50/MRE11/nibrin complex is to recruit ATM to the sites of DNA-DSBs where it is activated by monomerization and autophosphorylation. Activated ATM then leads to arrest at cell cycle checkpoints to prevent entry into S-phase or mitosis with damaged DNA. Indeed both AT and NBS patient cells fail to stop semiconservative DNA synthesis or prevent entry into S-phase in response to a mutagenic challenge. Thus in addition to its repair functions, nibrin is also clearly important for the correct functioning of cell cycle checkpoints.

Clinical Relevance

Reduced cell proliferation and increased apoptosis due to the accumulation of DNA damage explain the growth retardation and microcephaly of NBS patients. Similarly, their immunodeficiency stems from the involvement of nibrin in the processing of DSBs which are formed as a natural intermediate during immunoglobulin gene-rearrangement and class switching. In terms of somatic mutation rate, the NBS cell, which due to the loss of nibrin function is unable to effectively repair DNA-DSBs by any pathway, and to arrest the cell cycle appropriately, is particularly endangered. Null mutation of *NBN* in mice is embryonically lethal and survival of NBS patients is attributable to the fact that the known *NBN* mutations are hypomorphic and partially active nibrin fragments are found in patient cells. The occurrence of cancer in NBS patients is probably modulated by the amount of these nibrin fragments.

Cancer incidence amongst NBS heterozygotes is increased and the impact of NBN mutations within the general population is therefore of some concern. In several studies, sequence variations in NBN have been found in patients with various malignancies suggesting that in some populations, *NBN* mutations may be responsible for a significant proportion of cancers.

Nilotinib

Ellen Weisberg
Department of Medical Oncology, Dana Farber Cancer Institute, Boston, MA, USA

Synonyms

Tasigna™; AMN107; 4-Methyl-N-[3-(4-methyl-1H-imidazol-1-yl)-5-(trifluoromethyl)phenyl]-3-[[4-(3-pyridinyl)-2-pyrimidinyl]amino]benzamide

Definition

Nilotinib (Novartis Pharma AG) is a novel and selective inhibitor of the ►BCR-ABL tyrosine kinase, which was developed to override resistance to the BCR-ABL inhibitor, ►imatinib (Glivec®, Gleevec™, STI571; Novartis Pharma AG).

Characteristics

Implications of Nilotinib in Treatment of Imatinib-Resistant CML

►Chronic myelogenous leukemia (CML) comprises approximately 15% of adult leukemias. The *BCR-ABL* ►oncogene, which is the end product of a reciprocal ►t(9;22) chromosomal translocation, encodes a protein that has constitutively activated ABL tyrosine kinase activity, and which is the underlying cause of CML. CML patients express a 210 kDa BCR-ABL protein,

and ►Philadelphia chromosome positive (Ph±) ►acute lymphoblastic leukemia (ALL) patients express a smaller 190 kDa BCR-ABL protein.

The essential role that BCR-ABL plays in causing CML prompted the design and development of the small molecule kinase inhibitor (►small molecule drugs), imatinib, which is an effective frontline therapy for CML. In addition to ABL kinases, imatinib also inhibits the PDGFR and c-KIT kinases. Imatinib induces ►complete hematologic remissions in the majority of newly diagnosed patients in the ►chronic phase of the disease, and complete ►cytogenetic responses in a high percentage of patients. However, patients in the ►accelerated phase or ►blast phase/►blast crisis advanced of CML, as well as Ph + ALL patients, have substantially poorer response rates and shorter remissions in response to treatment with imatinib as a single agent.

Resistance to imatinib often results from the development of point mutations in BCR-ABL that impedes binding of imatinib to its target, although resistance has also been attributed to amplification of the *BCR-ABL* gene with overexpression of the BCR-ABL protein. In some patients, BCR-ABL mutations may exist as a rare event prior to imatinib therapy and result in expansion of that clone due to the selective pressure of imatinib. However, imatinib-resistant BCR-ABL point mutations can also be acquired, or arise during imatinib treatment, or may be transient in some cases. The majority of the more than 50 BCR-ABL point mutations that have been described are found in the kinase domain of BCR-ABL, however those conferring the most resistance are found at or near residues that are in direct contact with imatinib. For example, an isoleucine substitution at residue 315 in the BCR-ABL kinase domain (T315I mutation) is highly resistant to imatinib. This residue has been found to be critical for the interaction of imatinib with ABL, and is located at the so-called ►gatekeeper position at the periphery of the nucleotide binding site of the protein. This mutation sterically hinders imatinib binding to ABL, which leads to imatinib resistance.

Development and Preclinical Studies with Nilotinib

Researchers at Novartis Pharmaceuticals carried out rational design of novel kinase inhibitors displaying efficacy against imatinib-resistant BCR-ABL point mutants, leading to the discovery of the ►phenylaminopyrimidine-based ATP-competitive inhibitor, nilotinib. Nilotinib was designed to fit into the ATP-binding site of BCR-ABL with a higher affinity than imatinib. In addition to displaying a higher potency than imatinib against BCR-ABL, nilotinib also has the ability to inhibit many forms of BCR-ABL that are resistant to imatinib due to the presence of kinase domain point mutations. An exception is the T315I mutation, which in addition to being highly resistant to imatinib, is also resistant to nilotinib, as well as ►dasatinib (Sprycell™; BMS-354825; Bristol Myers Squibb), another second generation inhibitor of BCR-ABL. Dasatinib has been granted US Food and Drug Administration (FDA) approval for the treatment of adults in all phases of CML with resistance or intolerance to imatinib therapy, as well as for treatment of adults with Ph + ALL with resistance or intolerance to prior imatinib therapy.

Crystallographic analysis of nilotinib in complex with ABL, shows that the drug binds, like imatinib, to the inactive conformation of ABL, and suggests that the better overall topographical fit to ABL and subtle differences in the nature of binding to ABL are responsible for the higher potency of nilotinib (versus imatinib) (►drug design).

Nilotinib is ~20- to 30-fold potent than imatinib in inducing programmed cell death of BCR-ABL positive cells. Nilotinib was also shown to prolong the survival of mice harboring BCR-ABL positive leukemia, as well as mice harboring imatinib-resistant disease. There is growing interest in testing the notion that administration of multiple ABL kinase inhibitors simultaneously or sequentially can prolong the onset of emergence of imatinib-resistant BCR-ABL point mutants. Indeed, additive to ►synergistic toxicity against BCR-ABL positive cells that are either sensitive or resistant to imatinib has been observed when combining nilotinib and imatinib compared to treatment with a single inhibitor. Preliminary reports suggest that the different mechanisms by which nilotinib and imatinib are taken up by cells may contribute to the ability of these agents to synergize with one another.

Nilotinib Resistance

To assist in the selection of patients who are most likely to benefit from nilotinib, as well as to assess those combinations of ABL inhibitors that are likely to be the most effective, researchers have appreciated the importance in being able to establish the resistance profiles of imatinib, nilotinib, dasatinib and other BCR-ABL inhibitors that are expected to be used alone as therapeutics, or in combination with other BCR-ABL inhibitors. As is the case with imatinib, mutations in the kinase domain of BCR-ABL are likely to be associated with resistance to second generation inhibitors such as nilotinib. *In vitro* random mutagenesis assays have been designed and developed to predict such mutations, and some overlap has been observed between the pattern of mutations arising that confer nilotinib or dasatinib resistance to the pattern of mutations arising that confer imatinib resistance. The T315I mutant is one common mutation recovered in these assays that confers resistance to imatinib, nilotinib, and dasatinib. These *in vitro* findings are consistent with clinical findings in imatinib-treated CML and ALL patients. In addition to

random mutagenesis of BCR-ABL *in vitro* serving as a tool to help predict mechanisms of ►drug resistance, highly sensitive, ►PCR-based screening assays and denaturing high performance liquid chromatography (D-HPLC)-based assays have also greatly facilitated the identification of BCR-ABL point mutations in drug-resistant patients. These strategies could be used to establish the best course of treatment for patients resistant to imatinib or second generation BCR-ABL inhibitors like nilotinib and dasatinib.

Clinical Assessment of Nilotinib

Early phase clinical findings indicate that nilotinib may have significant clinical utility in treating patients who have developed resistance to imatinib treatment due to the emergence of point mutations. The clinical trial data also support the notion that nilotinib could potentially be used as a single agent in patients who are at risk for disease progression. The promise of nilotinib in the treatment of imatinib-refractory CML is due to its strong binding affinity to ABL, its efficacy against imatinib-resistant BCR-ABL point mutants, and its effectiveness and tolerability in clinical trials.

Significant clinical responses have been obtained in phase I and phase II trials in CML patients with advanced (accelerated or blast crisis) disease and CML patients in the early, chronic phase of the disease.

Future Prospects

While second generation BCR-ABL inhibitors, such as nilotinib and dasatinib, are predicted to substantially slow down the progression of BCR-ABL-positive disease in imatinib-resistant patients, the development of ►drug resistance is a general challenge in treating cancer patients. Even with the current push toward design of more "global" pan-BCR-ABL inhibitors, which have the ability to override resistance to highly imatinib-resistant BCR-ABL point mutants like T315I, there will still be the potential for the emergence of new drug-resistant BCR-ABL point mutations in positions that interfere with drug-target binding or that influence the expression and/or activity of the BCR-ABL protein. This warrants the continuation of identification and development of novel inhibitors of BCR-ABL, as well as the combined therapeutic use of more than one BCR-ABL inhibitor, especially those that bind at non-overlapping sites, or inhibitors of different signaling pathways.

Nitric Oxide

Gautam Chaudhuri
Department of Molecular and Medical Pharmacology and Department of Obstetrics and Gynecology, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Definition

NO; is a combination of two of the most common gasses in the atmosphere; nitrogen and oxygen, and is produced in mammals by various cell types where it has a physiological role and also plays a role in some pathophysiological states.

Characteristics

NO was previously considered to only be an atmospheric pollutant until it was first demonstrated in 1987 that mammalian cells generate NO and that it accounted for the bio-activity of a substance produced by the endothelial cells initially named as endothelium-derived relaxing factor (EDRF). Once produced by the endothelial cells, this substance diffuses rapidly to the surrounding vascular smooth muscle and causes relaxation and, hence, the initial name. This discovery that NO is produced in mammals led to an explosion in NO research to identify its role in both normal and diseased states in mammals. NO produced by endothelial cells plays a physiologic role in maintaining blood pressure and blood flow to various organs. NO is also produced by numerous other cell types, including the central nervous system where it serves as a neurotransmitter. In the peripheral nervous system, NO serves as a neurotransmitter in a network of nerves termed the nonadrenergic and noncholinergic nerves and mediates some forms of neurogenic vasodilation regulating various gastro-intestinal, respiratory, and genito-urinary functions. NO modulates platelet aggregation, cardiac contractility, and is also produced in large quantities during host defense as it is generated by ►macrophages following their activation and

probably has a role in non-specific immunity. It is a mediator in various pathophysiologic states, such as inflammation, septic shock, and in the hyperdynamic state of cirrhosis. More recently, its role as an intracellular messenger, in modulation of cellular respiration, and in tumor biology affecting, both, growth and death of cancer cells has received increased attention.

Chemistry and Biological Synthesis of NO

NO is a colorless gas that is moderately soluble in water (up to 2 mmol/l) but is highly soluble in organic solvents. It has a biological half-life of 3–30 s. In view of its lipophilic nature it can diffuse through cell membranes very easily and because of its short half-life, acts locally at the site of production. NO is biosynthesized in mammalian systems via the enzymatic oxidation of a terminal guanidinium nitrogen on the amino acid l-arginine. *N*-Hydroxy-l-arginine is formed as an intermediate in the conversion of l-arginine to NO. The other product of this reaction is the amino acid, citrulline (Fig. 1).

NO biosynthesis from arginine is carried out by a class of enzymes known collectively as ►nitric oxide synthases (NOS). NOS can be immediately classified into two distinct classes: an inducible class (►iNOS), and that which is constitutively present in cells, the constitutive class (►cNOS). Within each class, subclasses exist. For example, ►cNOSs have been isolated and characterized from endothelial cells and brain and are sometimes referred to as ►eNOS (also known as type III) and nNOS (also known as type I), respectively. Inducible NOS has been found in a variety of cells, although most of the enzymological work has been performed on ►iNOS (also known as type II) from macrophages. The eNOS and nNOS are regulated by calcium ions via the calcium binding protein calmodulin and produce low concentrations of NO, usually in the nanomolar range, and are responsible for physiological functions such as smooth muscle relaxation. iNOS is translationally regulated and does not require calcium for activity. iNOS induction leads to production of high concentrations of NO, usually in the micromolar range, and is usually produced during pathophysiological states.

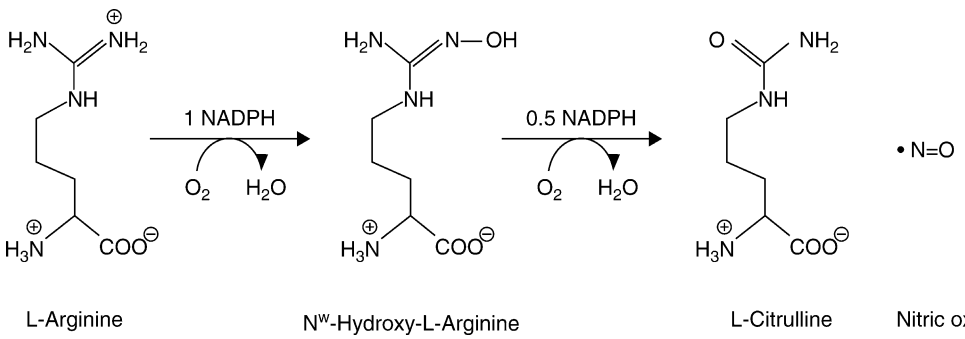
Biochemical Basis of NO Action

NO has an unpaired electron and is, therefore, a free radical. It can be either oxidized or reduced to form the nitrosonium cation (NO^+) or nitroxyl (HNO), respectively. NO and derived species can react with numerous substances, including metals and thiols. As such, it can cause cysteine modification to form *s*-nitrosothiols and many proteins can be modified by nitrosation after their synthesis (post-translational modification), which can affect various cellular functions.

NO can also react with the superoxide anion O_2^- to form peroxynitrite ($ONOO^-$), which, although less stable and short lived than NO, is much more cytotoxic and can cause DNA damage. Another method of NO signaling involves the activation of cytosolic soluble guanylate cyclase where NO acts as a ligand for the enzymes heme group and, following binding, alters the coordination state of the heme iron leading to an increase in the rate of ►cGMP formation. In general, low concentrations of NO, as produced in physiologic states, act by activation of ►guanylate cyclase (GC), whereas, higher concentrations of NO act through a GC-independent manner.

Cancer and NO

The precise mechanism by which cancer develops is not exactly known. It is characterized by uncontrolled cell division with the ability to spread, either by direct growth into adjacent tissue through invasion or by implantation into distant sites by ►metastasis. The unregulated growth that characterizes cancer can be caused by damage to DNA. This can result in mutations to genes that encode for proteins controlling cell division.



Nitric Oxide. Figure 1 Nitric oxide biosynthesis from L-arginine is carried out by a class of enzymes known collectively as the nitric oxide synthases (NOS). The terminal guanidinium nitrogen on the amino acid L-arginine is initially N-hydroxylated by NOS to give as a biosynthetic intermediate, N-hydroxy-L-arginine, which then undergoes further oxidation to NO and citrulline, which is formed in stochiometric amounts.

Role of NO in Initiating Cancer

NO can cause mutation of genes and, therefore, long term exposure of cells to high concentrations of NO following induction of iNOS as a result of chronic inflammation could play an active role in carcinogenesis. This can occur by various mechanisms, including DNA damage or by inactivating a tumor suppressor oncoprotein ►p53. There is a strong association between iNOS activity and p53 mutation in many forms of ►lung cancer, in human ►colon cancer, and also some cases of carcinoma of the head and neck. However, a cause and effect is yet to be established, although peak iNOS activity has been reported in colonic adenomas before transition to carcinoma, thereby, supporting a carcinogenic role. Increased NOS activity has also been suggested for some forms of ►breast cancer.

Role of NO in Cancer Cell Proliferation and Tumor Growth

Nitric oxide has both tumor promoting properties and it can also cause ►cytostasis and ►apoptosis of cancer cells and this is usually concentration dependent. Low concentrations of NO are usually tumor promoting, whereas, high concentrations are usually tumoricidal. Low concentrations of NO increase the translation of cyclin D_1 and ornithine decarboxylase proteins, and lead to the proliferation of some breast cancer cell lines. However, this effect is cGMP-independent indicating that low concentrations of NO can act by both a cGMP-dependent and independent manner. This effect is mediated by ►ras, a protein which is attached to the cell membrane following its posttranslational modification. NO activates ras, which acts as a molecular switch that links the activation of cell surface receptors with signaling cascades by activating ►MAP kinase, certain key proteins downstream by attaching a phosphate group, which ultimately leads to translation of some key proteins involved in cell proliferation. Low concentration of NO may also cause cancer cell proliferation by a cGMP-mediated mechanism.

Various other factors modulated by NO, in addition to tumor cell proliferation, like cell survival, migration invasiveness, function of immune cells infiltrating tumors, as well as blood supply to the tumor, can affect tumor growth. Increase in blood supply to the tumor is due to the development of new blood vessels from preexisting vessels, a process known as ►angiogenesis. NO stimulates proliferation and migration of endothelial cells in vitro. ►Vascular endothelial growth factor (VEGF) is the major factor implicated in angiogenesis of many human tumors and NO is its final mediator. Administration of NOS inhibitors has been shown to reduce neovascularization in gastric ulcers induced by acetic acid in rats and human squamous cell carcinoma xenografts in rabbit cornea. The source of NO in tumors could be from the tumor cells themselves or from macrophages infiltrating the tumors. In breast cancer, iNOS expression by macrophages, stromal cells, and tumor cells accounted for most of NOS activity and the greater the iNOS activity, the more the undifferentiated form and the worse the prognosis of the tumor. Although iNOS produces high concentrations of NO and should therefore slow tumor growth, in breast cancer it is associated with a worse prognosis. This paradox has been explained on the basis that, although iNOS is expressed in breast cancer, the activity is at least one to two orders of magnitude lower than the enzyme activity associated with cytotoxicity and apoptosis.

NO and Tumoricidal Activity

NO was first shown to be an essential component of the macrophage antitumor activity against leukemia cells in vitro. Macrophage-produced NO has also been shown to have tumoricidal activity in vivo. When cultured in vitro, peritoneal macrophages obtained from mice previously inoculated with ►bacillus calmette guerin (BCG) release NO, which is cytostatic and/or cytolytic for tumor cells. ►Interferon-γ (IFN-γ) is important for the priming of macrophages and ►tumor necrosis factor-α (TNF-α) or some other cytokine or bacterial lipopolysaccharide, is necessary for full induction of activated macrophage toxicity. NO plays an important role in vivo in mediating both the host resistance to a ►syngeneic ovarian tumor in BCG inoculated mice and host resistance to a ►xenogeneic ovarian tumor graft. Inhibiting NO synthesis obliterates this action of BCG by inhibiting the NO-mediated immune response in both syngeneic and xenogeneic tumor grafts. Similarly, transfection of human tumor cells with iNOS resulted in enhanced iNOS activity, as well as complete inhibition of tumor growth and regional lymph node metastasis in nude (immunocompromised) mice. Moreover, the ablated tumor growth was associated with NO-mediated cytostasis and enhanced apoptosis of the transfected cells, as well as the bystander cells. Various sites of action are involved in the cytostatic and apoptotic actions of high concentrations of NO. These actions are cGMP-independent and involve various signaling cascades with the ►BCL-2 pro-apoptotic proteins ultimately converging to the mitochondria leading to cytochrome *c* release and activation of caspases. The differences in the mechanism of apoptosis of cancer cells, when compounds which release NO are utilized, when compared with cells transfected with NOS, is that when utilizing the NO donor, only the specific action of NO is observed. However, when the effects of NO produced by activated macrophages or cells transfected with NOS are utilized, in addition to NO production, the superoxide radical can be produced leading potentially to peroxynitrite formation, which is cytotoxic and will have a different mechanism of apoptosis when compared with NO.

Furthermore, during biosynthesis of NO from l-arginine, the intermediate compound formed, i.e. *N*-hydroxy-l-arginine, has apoptotic action on human breast cancer cells, which is mediated by an entirely different mechanism than that of NO.

Action of NO on Cellular Respiration

Mitochondria, which are organelles inside the cell, have been considered to be the powerhouse of the living cell, generating energy in the form of the molecule ATP via the reduction of oxygen. They play a role in apoptosis (►apoptosis signaling), or programmed cell death At physiological concentrations, NO, in the nanomolar concentration range that activates soluble GC, can also bind to ►cytochrome *c* oxidase (complex IV) and inhibit it in a manner that is reversible and in competition with oxygen. Cytochrome *c* oxidase is the terminal enzyme of the mitochondrial respiratory chain and is responsible for 90% of cellular oxygen consumption in mammals. NO competes with oxygen at cytochrome *c* oxidase and, therefore, any increase in NO concentration can prevent the enzyme from using any available oxygen, thus, causing a kind of metabolic hypoxia. Such "metabolic hypoxia" may also be responsible, in part, for the well known increase in glucose uptake in tumors.

Clinical Relevance

At present, the potential for treatment of cancer with compounds that release NO are in the experimental stage (►apoptosis-induction for cancer therapy). As endogenous NO increases blood flow to tumors, and also mediates the action of ►VEGF in inducing ►angiogenesis, inhibitors of NOS have been used in animal models with tumor to asses their effects. Inhibitors of NO synthesis reduced blood flow in both animal models of tumors as well as in humans with ►lung cancer, ►prostate cancer and ►cervical cancer. All patients had sustained reduction in tumor vascular blood volume following administration of an inhibitor of NO synthesis. However, the long term effects of inhibiting NOS on tumor and their side-effects on other organs needs to be assessed. Use of NO donors to increase tumor sensitivity to ►radiotherapy is also being tried. Elevated oxygen tension in tumor cells increases their sensitivity to radiation. Tumor sensitivity to radiation is compromised by low oxygen tension, especially at the center of the tumors, which is usually necrotic. It has been suggested that use of hyperbaric oxygen along with NO donors would permit blood vessels to dilate, thereby increasing the blood flow and oxygen tension in the tumor. This in turn would increase its sensitivity to radiation. Targeted delivery of NO by combining ►nonsteroidal anti-inflammatory drugs (NSAID) to an NO donor (NO)-NSAIDs, which were initially conceived for rheumatologic and cardiovascular applications, are now under intense study for their anticancer properties, especially as a safe and effective chemopreventive agent against ►colon cancer. Similarly, targeted delivery of NO by combining an NO donor with tamoxifen may be potentially useful for the treatment of some cases of breast cancer. Intraluminal installation of ►BCG has been utilized for treatment of some forms of ►bladder cancer, and this is likely due to increased activation and production of NO by immune cells. Further studies need to be carried out to assess whether intraperitoneal installation of BCG may be effective for treating minimal residual disease following cytoreductive surgery for ovarian cancer.

NKG2D; natural killer group 2D; KLRK1; killer cell lectin-like receptor subfamily K member 1; CD314

Definition

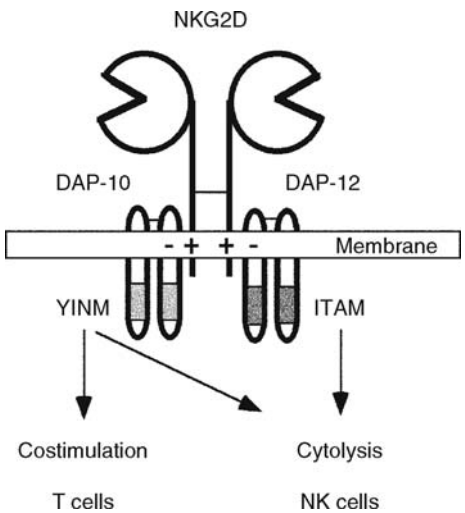
The NKG2D receptor complex mediates the elimination of distressed host cells via the activation of innate immune effector cells such as ►natural killer cells.

Characteristics

The NKG2D Receptor

NKG2D is a homodimeric, type II integral membrane protein, which belongs to a sub-family of C type lectin-like receptors. The NKG2D receptor is constitutively expressed on natural killer (NK) cells, most TCRγδ T cells, and a large fraction of NK T cells where it serves as a primary activation receptor. The *NKG2D* gene is located in the NK gene complex on mouse chromosome 6 or human chromosome 12. This locus harbors a significant number of C-type lectin like receptors that are preferentially expressed in NK cells.

NKG2D is a multi-subunit receptor complex, whereby the NKG2D homodimer mediates ligand binding. Specialized adaptor molecules, which are associated non-covalently, transduce signals into the cell (Fig. 1). Mouse NKG2D is linked to the adaptors ►DAP-10 and ►DAP-12, while human NKG2D exclusively uses DAP-10. DAP-12 contains a single immunoreceptor tyrosine-based activation motif (►ITAM). ITAM's are defined by the consensus sequence YxxL/I x_6 YxxL/I (whereby x denotes any amino acid). Upon receptor engagement, the tyrosines in the ITAM are phosphorylated by ►src family tyrosine kinases, which generate docking sites for Syk family kinases. The recruitment of Syk family kinases is needed to induce calcium flux and the activation of extracellular signal-regulated kinase (►ERK). Both events are required for the exocytosis of cytotoxic granules, which mediates target cell lysis. DAP-10 lacks an ITAM but instead contains a YINM sequence, which closely resembles a motif present in co-stimulatory molecules such as CD28. Nevertheless, also the NKG2D/DAP-10 complex is able to mediate granule release in human NK cells. In addition to cell-mediated cytotoxicity, NKG2D cross-linking results in the production of cytokines such as interferon-γ (IFN-γ).



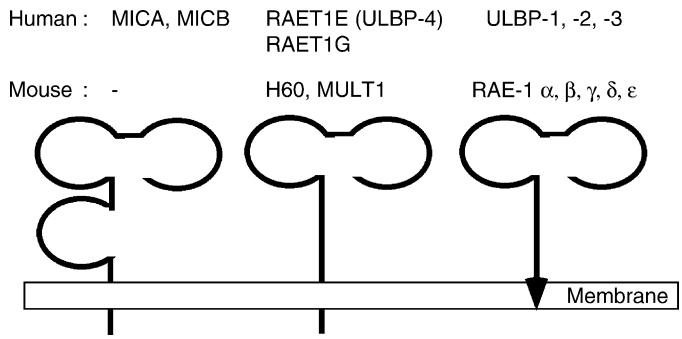
NKG2D Receptor. Figure 1 Schematic representation of the NKG2D receptor complex. The NKG2D receptor homodimer is non-covalently associated with the signaling adapters DAP-10 and/or DAP-12 (only in the mouse). DAP-12 signals via a single ITAM and mediates primary activation function in mouse NK cells. DAP-10 signaling is mediated via the YINM motif. In T cells, NKG2D/DAP-10 is costimulatory while in NK cells it mediates primary activation function.

Besides NK cells, NKG2D is constitutively expressed on human $CD8^+$ T cells and, upon activation, on mouse $CD8^+$ T cells. Since T cells lack DAP-12, NKG2D signaling is mediated exclusively via DAP-10. Signaling via the NKG2D/DAP-10 complex serves a co-stimulatory role in the T cell receptor (TCR) mediated induction of a T cell response. There are, however, instances where NKG2D can act as a primary activation receptor also in T cells. The prolonged exposure of ►T cells to ►interleukin (IL)-15 confers NKG2D-mediated cytolytic function to CD8 T cells independent of the specificity of their TCR. Thus the consequences of NKG2D receptor engagement are influenced by additional signaling inputs.

NKG2D Ligands

The NKG2D receptor recognizes a significant number of distinct ligands that are all distantly related to major histocompatibility complex (MHC) class I molecules (Fig. 2). In the human these ligands include the two ►MIC (MHC class I-chain-related) ►MICA, MIC proteins, and five ►RAET1 (►retinoic acid early transcripts)/ULBP (UL-16 binding proteins) family proteins. Murine NKG2D ligands correspond to the latter protein family and comprise MULT-1 (Murine UL-16-binding protein like transcript 1), ►H60 and the five ►Rae-1 (retinoic acid early 1 α to ε) molecules. The *RAET1*/*ULBP* genes are clustered in the telomeric region of human chromosome 6; a corresponding region with NKG2D ligands is found on mouse chromosome 10. The *MICA* and *MICB* genes localize to the human HLA locus on chromosome 6. They are not present in the mouse genome.

NKG2D ligand expression is not detected on differentiated cells in healthy adult humans or mice. Some expression occurs on immature precursor cells in the thymus and the bone marrow. In mature cells, surface expression of NKG2D ligands is induced upon various types of cellular stress. For example, heat shock induces MICA expression on colon epithelial cells. Retinoic acid, an agent used to differentiate cells, rapidly induces Rae-1 expression in embryocarcinoma



NKG2D Receptor. Figure 2 Schematic representation of NKG2D ligands. All NKG2D ligands are distantly related to MHC class I-molecules and contain MHC class I-like α1 and α2 domains, which mediate the interaction with NKG2D. MICA/B also have an α3 domain. None of these ligands is associated with β2m. Several murine and human NKG2D ligands have transmembrane and cytoplasmic domains. Others (ULBP1–3 and Rae-1s) are inserted into the membrane via glycosylphosphatidylinositol (GPI) anchors.

cells. NKG2D ligand expression is also detected in the context of bacterial and viral infection, which is based in part on signaling via ►Toll-like receptors (TLR). The importance of the NKG2D pathway to protect against infection is highlighted by viral mechanisms, which prevent the cell surface expression of NKG2D ligands on infected cells.

Normal cells express NKG2D ligands transiently due to various types of stress. In contrast, established tumor cell lines of various tissue origins constitutively over-express NKG2D ligands. This is linked to the process of malignant transformation, with a role for certain oncogenes (such as BCR-ABL or adenovirus E1A) or ►tumor suppressor genes (such as JunB). The ►DNA damage response plays an important role for the induction of NKG2D ligands in primary, untransfromed cells. DNA damage induced by ionizing radiation or alkylating agents results in double strand breaks and/or stalled DNA replication, which induces the ►ATM and ATR protein kinases. These mediate cell cycle arrest and DNA repair. ►Apoptosis via ►p53 is induced when the genomic damage is too extensive. p53 is not required for the induction of NKG2D ligand expression. Thus, cells sense genotoxic stress and rely this information to the cell surface in order to alert the immune system of a potential threat.

NKG2D and Cancer Immunosurveillance

The over-expression of NKG2D ligand on tumor cell lines confers the rejection of tumor cell grafts *in vivo*. Depending on the tumor cell line used, rejection is mediated by NK cells or the combined action of NK cells and $CD8^+$ T cells. The recognition of NKG2D ligand-expressing tumor cells can induce T cell memory, which is capable of controlling a subsequent challenge with corresponding NKG2D ligand-negative tumor cells.

Many primary human tumors express substantial levels of NKG2D ligand, whereas more advanced tumors and metastases express lower levels, if any, ligand. This is consistent with a role of NKG2D in tumor immunoediting: The immune system is thought to eliminate tumor cells that it recognizes as "transformed". Transformed cells, which progressively lack these specific tumor antigens, are spared. These give rise to tumors that can spread without eliciting an anti tumor immune response.

Consistent with this model, blocking of NKG2D receptor exacerbates the development of chemically induced skin tumors. Cell lines derived from primary tumors express high levels of NKG2D ligand and fail to grow in wild type mice. In contrast, when NKG2D function is left intact, growing tumors express lower levels of NKG2D ligand and grow upon transfer into wild type mice. The protective role of NKG2D during cutaneous carcinogenesis is mediated at least in part by resident TCRγδ cells, while NK cells reject transplanted tumors. Despite the role of NKG2D to protect against grafted or chemically induced tumors, there is currently no evidence that NKG2D protects from spontaneously arising tumors.

Tumor Escape

NKG2D ligands are induced at some point during the development of most types of cancers. Nevertheless, many NKG2D-ligand positive tumors progress, suggesting that NKG2D function is impaired at some stage during cancer progression. Indeed, tumor-derived ►matrix metalloproteinases can cleave MICs from the surface human tumors. The binding of soluble MIC results in NKG2D down-regulation and a reduction of NKG2D function. Similarly, prolonged engagement of NKG2D with cell-bound NKG2D ligands greatly impairs NKG2D function. Finally, tumor-derived immunosuppressive cytokines such as TGF-β (►transforming growth factor β) also reduce NKG2D cell surface expression and function.

NM23 Metastasis Suppressor Gene

Patricia S. Steeg, Jong Heun Lee, Christine Horak
Women's Cancers Section, Laboratory of Molecular Pharmacology, Center for Cancer Research, National Cancer Institute, Bethesda, MD, USA

Synonyms

Nme nonmetastatic in the human; Awd (abnormal wing discs) in Drosophila; Nucleoside diphosphate kinases; NDPKs; Ndks; NDP kinases

Definition

Nm23 is a ►metastasis suppressor gene. Metastasis suppressors are typically identified by their reduced expression in primary tumors or tumor cell lines of high metastatic potential as compared to equally tumorigenic but less metastatic cell lines. Validation of a gene as a metastasis suppressor involves its experimental introduction into a metastatic tumor cell line, resulting in expression at physiologic levels. Upon in vivo injection, MSGs significantly reduced metastasis with no significant effect on primary tumor size. Where studied, most of the MSGs impacted the late steps in the metastatic process, extravasation from the circulatory system (Kai-1), or colonization at the metastatic site (►Kiss1, Mkk4, ►Nm23-H1), consistent with their lack of effect on primary tumor size. Because of their novel mechanisms of action and impact on metastatic colonization, the MSGs may represent important therapeutic targets in cancer.

Characteristics

The ►metastatic process, in which cells spread from a primary tumor to distant sites of the body, is a significant contributor to cancer patient morbidity and mortality. Defining the key molecular pathways that contribute to metastasis will fuel the development of therapeutic approaches.

The concept of metastasis suppressive pathways arose from studies in which nonmetastatic and metastatic cells were fused, resulting in tumorigenic but nonmetastatic hybrids. Introduction of chromosomes into metastatic cells reduced metastatic capacity but not tumorigenicity. The list of validated metastasis suppressor genes (MSGs) is growing. Several, including ►E-cadherin, ►maspin, and the ►TIMPs, have predictable mechanisms of action in adherence, proteolysis and invasion. Others including ►*nm23*, ►*kiss1*, ►*KAI1*, and *Brms1*, have unknown mechanisms of action and may identify new pathways important to metastasis.

NM23-H1 and Family Members

The *nm23* gene was discovered using differential colony hybridization between low and high tumor metastatic potential K-1735 murine ►melanoma cell lines. Nm23 mRNA and protein levels were quantitatively higher in two cell lines of low metastatic potential than five related, more highly metastatic cell lines. A correlation of reduced *nm23* expression and high tumor metastatic potential was observed in many, but not all other model systems examined, consistent with the complexity and heterogeneity of the metastatic process. Since its discovery, eight human homologs of Nm23-H1 have been identified. These conserved (DR+HS larger). 16–20 kDa proteins localize to all subcellular compartments and are expressed by many cell types.

Several lines of investigation indicate a role for Nm23 in normal development and differentiation. Reduced expression or mutation of Drosophila awd resulted in defective differentiation of the presumptive epithelial cells in the imaginal discs postmetamorphosis, resulting in lethality. Introduction of *nm23* into rat PC12 ►phaeochromocytoma cells induced the extension of neurite processes. Similarly, *nm23* introduction into human MDA-MB-435 breast carcinoma cells induced morphological and biochemical aspects of mammary ductal differentiation. The function of Nm23 in "normal" physiology may be in the acquisition or stabilization of the differentiated phenotype.

A number of experiments have been reported in which *nm23* homologs were introduced into metastatic cancer cells. A significant reduction in experimental or spontaneous metastatic potential was consistently observed, with no effect on tumorigenicity, confirming *nm23* as a suppressor gene. Nm23 re-expression reduced metastatic propensity of multiple cancer histologies exerting suppressive effects on lymph node, lung, and liver metastases.

In vitro assays of Nm23 transfectants have pointed, consistently, to reduced ►motility, ►invasion and ►metastatic colonization. The latter may be clinically

relevant, as colonization of metastatic cells in a distant organ has not been completed in many cancer patients at the time of diagnosis and therapy, and would therefore remain open for therapeutic intervention. ►Motility in ►Boyden chamber assays was significantly reduced in the *nm23* transfectants to a wide variety of ►chemoattractants, including serum and growth factors, suggesting that Nm23 blunts signal transduction responses downstream of specific receptors. Whenever tested, the proliferative capacity of the control- and *nm23*-transfectants in tissue culture was comparable.

The *in vivo* impact of Nm23 on the metastatic process was recently bolstered by the characterization of mice lacking the Nm23-M1 gene, the murine homolog of Nm23-H1. Nm23-M1$^{-/-}$ mice developed normally, but were smaller in size than wild-type littermates and exhibited a mammary defect. The incidence of lung metastases was significantly higher for the Nm23-M1 knockout mice as compared to Nm23-M1$^{+/+}$ mice, when the mice were genetically induced to develop ►hepatocellular carcinoma (HCC) by simian virus 40 large T antigen expression, despite similar primary tumor sizes.

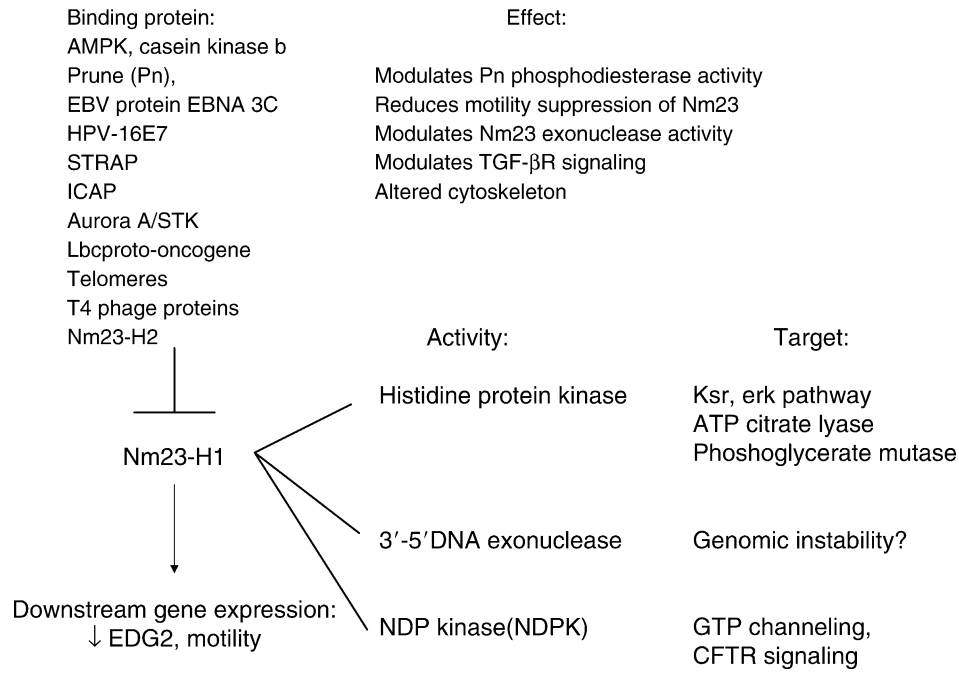
Mechanism of Metastasis Suppression

Nm23 proteins are abundant and exist as monomers and homo- and hetero-oligomers. The proteins are found in all cell compartments and are generally regarded as "sticky," resulting in a number of nonspecific interactions. Tremendous advances have been made in identifying biochemical pathways involving Nm23. Pinpointing those activities involved in the biology of differentiation and/or tumor metastasis is a major ongoing effort. The emerging picture of Nm23 action is tripartite, including Nm23 biochemical activities, Nm23 binding proteins, and gene expression changes downstream of Nm23 (Fig. 1).

Biochemical Activities

The first described activity for Nm23 was that of a NDP kinase, which transfers a terminal phosphate from a nucleoside tri- to a diphosphate via a high energy Nm23-phosphohistidine intermediate. The reaction is reversible. In model systems, NDP kinase activity failed to correlate with metastasis suppression, casting doubt on its participation in biology. However, interest in this activity was recently heightened with the report of a complex between AMP-activated protein kinaseal (AMPk), Nm23-H1, and fatty acid synthetase (ACC) in lung epithelial cells, resulting in the "channeling" of ATP. The CFTR story is separate from the ACC story.

The same Nm23 phosphohistidine has been demonstrated to transfer a phosphate to protein substrates constituting a histidine kinase activity. Demonstrated substrates include the Kinase suppressor of ras (Ksr) and ATP citrate lyase. Ksr is a scaffold protein for the



NM23 Metastasis Suppressor Gene. Figure 1 The mechanism of metastasis suppression by Nm23 likely involves three sets of molecular pathways. Nm23 functions as both a histidine kinase and a nucleoside diphosphate kinase. The function of Nm23 may be limited by sequestration upon binding to an assortment of proteins. Finally, alterations in gene expression downstream of Nm23 may influence the motility phenotype.

Erk ►Map kinase pathway, assembling component proteins near the cell membrane. Altered Nm23-H1 levels were shown to affect the stoichiometry of client protein binding to Ksr and Erk activation. Using in vitro motility as a readout, the histidine kinase activity of Nm23-H1 correlated with its inhibition of tumor cell motility among a panel of wild-type and substitution mutants, supporting a role for this activity in metastasis. Nm23-H1 was also reported to complex with GAPDH, and the complex to phosphorylate phosphoglycerate mutase with resultant effects on glycolytic flux.

Other activities described for Nm23 include a DNA exonuclease activity in vitro. Exonucleases play roles in DNA repair and ultimately genomic stability which may be important in cancer aggressiveness.

Binding Proteins

Nm23 has been reported to bind many proteins, of which a partial list is shown on Fig. 1. Protein-protein complexes involving Nm23-H1 serve at least two purposes: in some cases, protein complexes serve to remove free Nm23-H1, thus enhancing the aggressiveness of tumor cells. In other cases, the association of Nm23-H1 and another protein changes the function of either partner. The ►Prune (Pn) protein is a representative example of the latter case. Pn, a cAMP phosphodiesterase, can bind Nm23-H1 and overcome its inhibition of motility. Binding is mediated by Nm23 phosphorylation at serines 122 and 125 via casein kinase I CKI mediates this intraction.

The same serine 122 of Nm23-H1 is involved in another protein complex with AMPK. AMPK bound and phosphorylated Nm23-H1 on serine 122, resulting in "substrate channeling," formation of ATP by the NDPK activity of Nm23 which is shielded from the surrounding medium and preferentially activates AMPK activity.

Nm23-H1 also binds serine-threonine kinase receptor-associated protein (STRAP), a ►TGF-β receptor binding protein. As a result of this interaction, TGF-β signaling is reduced, with enhanced association between the TGF-β receptor and Smad7, and a prevention of Smad3 nuclear translocation.

Finally, Nm23-H1 was reported to bind the ►Epstein-Barr virus nuclear antigen 1 (EBNA1) protein, which is involved in the maintenance of viral episomes in infected cells. The complex abrogated the motility suppressive capacity of Nm23-H1 in lymphoblastoid cell lines. These and related HPV-16E7 data suggest that viral proteins may induce a more aggressive disease via Nm23-H1 binding.

Downstream Gene Expression Alterations

Given the effects of Nm23-H1 on tumor cell motility, invasion, and colonization, it is likely that multiple signaling pathways are involved. We recently reported a microarray gene expression analysis of MDA-MB-435 tumor cells expressing wild type Nm23-H1 or substitution mutants that could not suppress motility. The analysis identified eight cell surface or secreted proteins whose expression was down-regulated by wild-type Nm23-H1, of which only EDG2, the LPA receptor, was able to restore motility to Nm23-H1 suppressed tumor cells. EDG2 was upregulated in liver tumors from Nm23-M1$^{-/-}$ mice, demonstrating the generality of this effect.

Viral proteins can also serve to down-regulate Nm23-H1 expression. The human papillomavirus-16E7 down-regulated Nm23-H1 in vitro, resulting in increased invasion.

Translational Development

Nm23 mRNA and protein levels were reported in many human cancer types and inversely correlated with indicators of metastatic propensity, such as patient disease-free and overall survival, the presence of lymph node metastases, tumor grade, etc. These studies indicate that reduced Nm23 expression is relevant to human cancer progression. Generally, they do not indicate that Nm23 is a independent prognostic factor on multi-variate analysis. This is consistent with the presence and activity of many binding proteins, where Nm23 can be present but taken out of the active pool by protein-protein sequestration.

Based on the observations that (i) many aggressive human tumors exhibit relatively low levels of Nm23 expression and (ii) introduction of Nm23 significantly decreased tumor metastatic potential, it can be hypothesized that elevation of Nm23 expression in overt occult metastases may be of therapeutic benefit to the patient. High dose medroxyprogesterone acetate (MPA) was identified to elevate Nm23-H1 expression in two metastatic cell lines, MDA-MB-435 and -231, via an unconventional interaction with the glucocorticoid receptor. In preclinical experiments MPA reduced the outgrowth of breast cancer micrometastases in the lung. A Phase II trial of MPA for hormone receptor negative, aggressive breast cancer is being conducted at Indiana University.

NNK

Definition
4-(Methylnitrosamino)-1-(3-Pyridyl)-1-Butanone; A tobacco-specific carcinogen which induces lung tumors in laboratory animals. A powerful lung carcinogen that is formed specifically from nitrosation of nicotine during tobacco curing and smoking. It belongs to the nitrosamine class and is believed to be involved in lung cancer induction by smoking.

►Tobacco Carcinogenesis
►Sulforaphane

Nodal Involvement

Definition
►Lymph Node Metastasis

NOD-SCID

Definition
Non-obese diabetic severe combined immune deficient mice. Breed of immune incompetent mice that lacks both humoral (B-cell antibody production) and cell-mediated adaptive (T-cell) immunity.

Non-adaptive Immunity

Definition
Immunity from various exogenous molecules and microorganisms afforded by physical barriers, leukocytes and soluble molecules. A locution used in antithesis with ►adaptive immunity and implying the absence of antigen-specific receptors, clonal diversity and immune memory.

►Innate Immunity
►Natural Immunity
►Non-specific Immunity
►Immunoprevention

Non-essential Amino Acid

Definition
Is an amino acid that can be synthesized *de novo* by the organism (usually referring to humans), and therefore does not need to be supplied in the diet.

►Arginine-Depleting Enzyme Arginine Deiminase

Non-genotoxic Carcinogen

Definition
A carcinogen that is unable to cause a change to the structure of the genome.

►Toxicological Carcinogenesis

Non-Hodgkin Lymphoma

Definition

A wide group of hematological malignant diseases with differing histology, clinical course, treatment, and prognosis, distinct from ►Hodgkin lymphoma. A type of cancer involving lymphocytes. In lymphoma these malignant cells are predominately in lymph node tissues.

►Anaplastic Large Cell Lymphoma
►Malignant Lymphoma, Hallmarks and Concepts

Non-homologous End Joining

Definition

NHEJ is the joining of broken DNA directly at its ends, mediated by DNA-dependent protein kinase. It is the ligation of double-stranded DNA ends with no need for sequence homology between the ends joined. Several proteins are known to be involved in this process, which is considered the major double-strand break (DSB)-repair pathway in mammalian cells. ►Nijmegen breakage syndrome

►Double-Strand Break Repair
►Homologous Recombination Repair

Non-Insulin Dependent Diabetes

Definition

►Diabetes Type 2.

Non-invasive Breast Cancer

►Ductal Carcinoma In Situ

Non-ionizing Radiation

Definition

Any type of electromagnetic radiation that does not carry enough energy to ionize living material – that is, to remove completely an electron from an atom or molecule.

►UV Radiation

Non-Lamellar Phase

Definition

Refers to secondary lipid structures other than the lipid bilayer and includes hexagonal, cubic, rhombohedral phases, etc.

►Membrane-Lipid Therapy

Non-myeloablative

Definition

Refers to ►stem cell transplant; synonym mini-transplant, transplant-lite, or reduced intensity transplant. Is a stem cell transplant from a donor (►allogeneic) that uses a less aggressive combination of chemotherapy and/or radiation to prepare the patient for the transplant. In the "conventional" allogeneic transplant the goals of the preparative chemotherapy/radiation are to kill as many cancer cells as possible and to suppress the immune system of the patient to allow the donor cells to grow. The non-myeloablative transplant aims just to suppress the patient's immune system sufficiently to allow engraftment of the donor cells.

►Chronic Lymphocytic Leukemia

Non-receptor Tyrosine Kinases

Definition

Are intracellular ►tyrosine kinases present in the cytoplasm, nucleus or attached to the inner leaflet of

the plasma membrane. Multiple families of these kinases exist, with Src being the prototypical member for which ►Src homology domains (SH2, SH3 and SH1) are named.

Non-Rhabdomyosarcoma Soft Tissue Sarcomas

Andrea Ferrari[1], Michela Casanova[1], Paola Collini[2]
[1]Pediatric Oncology Unit, Fondazione IRCCS Istituto Nazionale Tumori, Milano, Italy
[2]Anatomic Pathology Department, Fondazione IRCCS Istituto Nazionale Tumori, Milano, Italy

Definition

NRSTS; Soft tissue sarcomas (STSs) are a heterogeneous group of mesenchymal extraskeletal malignant tumors, classified on the basis of their differentiation according to the adult tissue they resemble.

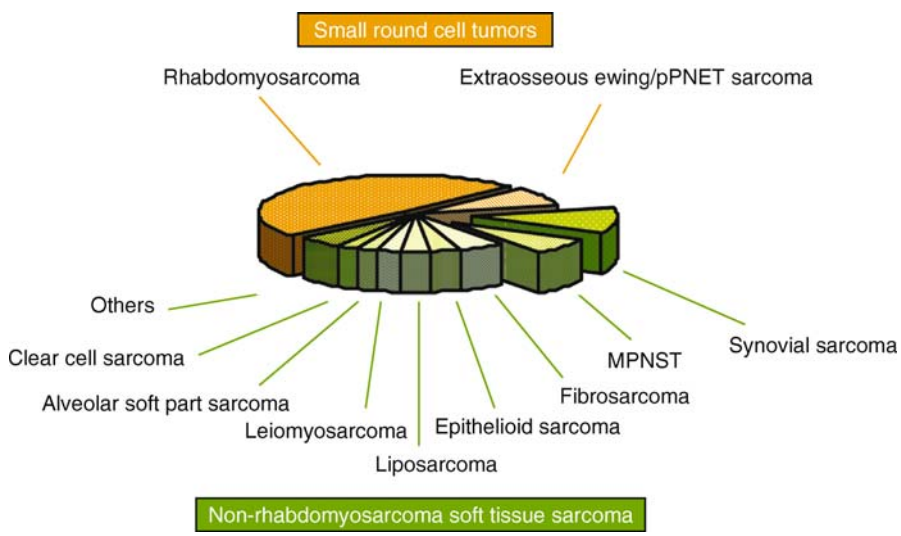
While benign neoplasms of soft tissues (i.e., ►lipoma, ►fibroma, ►leiomyoma, ►hemangioma) are relatively frequent and outnumber by 100 times malignant cases (incidence of about 300 new cases per 100,000), malignant tumors are rare, with an incidence of around 2–3/100,000/year, accounting for less than 1% of all malignant tumors and 2% of all cancer-related deaths. However, in pediatric age STSs represent about 8% of all malignancies, though their absolute number is lower than in adult age.

Characteristics

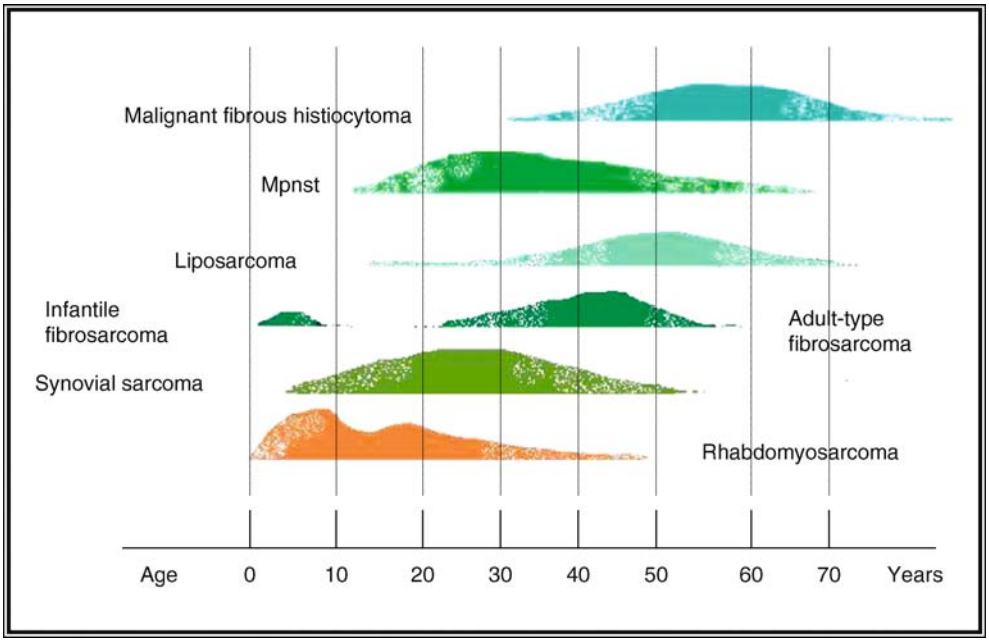
In childhood and adolescence, about half of STSs are represented by ►rhabdomyosarcomas (RMSs), one of the most typical ►childhood cancer, characterized by a peak incidence between 3 and 5 years (and a second, smaller peak in adolescence). The remainder 50% of pediatric STSs are the so-called "non-rhabdomyosarcoma" soft tissue sarcomas (NRSTSs).

Different entities with a different biology and clinical behavior are included in the heterogeneous group of pediatric NRSTSs: some histotypes are more common in adults and very rare in children (i.e., ►liposarcoma), others are peculiar of young children (i.e., infantile fibrosarcoma), while others are typical of adolescents [i.e., ►synovial sarcoma, ►malignant peripheral nerve sheath tumors (MPNST)] (Figs. 1 and 2).

STSs are malignant tumors by definition, with an aggressive and destructive local behavior together with high propensity to local relapse and potential tendency to distant metastases. Though, they can show a different grade of malignancy along histotype and grading. The tumor aggressiveness and the propensity to give metastases (and thus, at the end, the outcome of patients) are usually correlated with the grade of malignancy, and different histotypes with the same grade of malignancy often display the same clinical behavior. Low-grade tumors are often locally aggressive, but unlikely to metastasize (about 2–10% of risk). High-grade tumors are more aggressive and have a strong propensity to metastasize, particularly to the lung, in 20–100% of cases. However, the clinical course



Non-Rhabdomyosarcoma Soft Tissue Sarcomas. Figure 1 Percentage of different histotypes of soft tissue sarcomas in pediatric age.



Non-Rhabdomyosarcoma Soft Tissue Sarcomas. Figure 2 Incidence of soft tissue sarcomas in the different age groups.

can widely vary, not only according to the grading but also along the histotype. NRSTS can grow rapidly and present at diagnosis with metastatic spread, but can also have an indolent growth rate (they are sometimes diagnosed after removing a small swelling that has existed for several years and relapses can occur many years after the first diagnosis).

As for most pediatric malignancies, the pathogenesis of NRSTS is still unknown and there are no well-established risk factors. Ionizing radiations, chemical carcinogens and oncogenic viruses have been variously associated to the development of some type of sarcomas, but the aetiological relation is yet unclear. The clinical evidence of a genetic predisposition is rare: ►Li–Fraumeni syndrome for STSs and bone sarcomas, ►neurofibromatosis type 1 (particularly associated with ►MPNST), ►Costello syndrome, and other genetic diseases may be rarely associated with pediatric STSs.

Clinical Diagnosis and Staging

NRSTSs can virtually develop anywhere in the soft part of the body, generally as a progressively expanding mass. The most common clinical presentation is that of a mass in the soft tissues of the lower extremities; less frequent sites are the trunk or the head and neck region. A painless mass is the most usual presentation, but pain, functional impairment, and other specific symptoms correlated to the anatomic location can be present.

Ultrasonogram is often the first instrumental assessment utilized in case of suspected STS. More careful imaging studies, such as computed tomography (CT) scan or magnetic resonance imaging (MRI), are however required for the determination of the size and invasiveness of the tumor. MRI, in particular, is currently considered superior to CT scan in defining soft tissue extension, and should be required in all cases of STS.

After the clinico-radiologic accurate description of the local extent of the tumor, pathological assessment is necessary to define the histological diagnosis and grading when appropriate. This assessment should be performed before any surgery or other therapy, since the surgical and therapeutical approach varies in dependence of histotype and grading. The initial biopsy is aimed not only to define the diagnosis, but should also provide enough material to allow cytogenetic and molecular studies. A central pathological review is also required for patients that could be included in multicentric trials. In case of large and deep soft tissue mass, biopsy should be always the initial surgical procedure, in order to avoid inadequate surgery (i.e., tumorectomy). Open biopsy (incisional biopsy) or core needle biopsy (tru-cut, guided by ultrasound or CT scan) should be preferred to fine needle aspirates (FNAC). In fact, a cytological approach could establish the presence of malignancy, but exceptionally identifies the histotype and grade and provides enough tissue required for additional studies. In any case, the surgical procedure should be carefully planned by experienced surgeons, taking into account the definitive surgery that must include the scar and the biopsy tract.

Diagnostic procedures are completed by staging investigation, aimed to detect regional and distant

metastases: chest CT scan, technetium bone scan, and abdominal ultrasound are required to identify lung, bone, and abdominal metastases, respectively.

All these examinations are fundamental to stratify patients in stage-groups and then define a risk-adapted treatment strategy. NRSTS patients are usually staged according to the clinical TNM classification (based on local invasiveness and tumor size, T1 and T2, A or B, i.e., less or more than 5 cm; absence or presence of nodal and distant involvement, N0 and N1, M0 and M1, respectively) and the Intergroup Rhabdomyosarcoma Study (IRS) postsurgical grouping system (based on the quality of surgical resection: group I – completely excised tumors with negative microscopic margins; group II – grossly resected tumors with microscopic residual disease and/or regional lymph nodal spread; group III – gross residual disease after incomplete resection or biopsy; and group IV – metastases at onset).

Pathology and Biology

The definition of histotype and grading is of paramount importance not only for prognostic implications but also in the planning of therapy. The most updated classification of STSs is the WHO classification of 2002, which is based on pathology and genetics of the tumors and gives a stratification of histotypes along their degree of malignancy. Sarcomas are defined as malignant tumors with a locally destructive behavior, tendency to local relapse and a percentage of distant metastases above 2%. They are subgrouped on the basis of their differentiation in adipocytic tumors, fibroblastic/myofibroblastic tumors, so-called fibrohistiocytic tumors, smooth muscle tumors, pericytic/perivascular tumors, skeletal muscle tumors, vascular tumors, and tumors of uncertain differentiation. Today in the major part of cases the diagnosis of histotype requires the application of immunocytochemistry and cytogenetics/molecular techniques. The definition of histotype has prognostic and predictive implications.

Once the histotype is defined, the grade of malignancy is estimated. The grade of malignancy usually indicates how aggressive a tumor is and its natural history; however, some histotypes (i.e., synovial sarcoma, alveolar sarcoma, angiosarcoma) should be considered high-grade regardless of their morphological parameters, whereas in some cases (i.e., clear cell sarcoma, extraskeletal myxoid chondrosarcoma) the biological course seems impossible to predict from any histology. Tumor grade is usually established from a combined assessment of histological features: degree of cellularity, cellular pleomorphism or anaplasia, mitotic activity, degree of necrosis. Over the years, different grading systems have been developed, in particular the Pediatric Oncology Group (POG) system for pediatric sarcomas and the French system (FFCLCC – French Federation Nationale des Centres de Lutte Contre le Cancer), a three-tiered system tested on adult series (but used in Europe also for pediatric ►NRSTSs). Another task of pathologist is to assess the quality of margins on the surgical specimen, always in strict collaboration with the operating surgeon.

In particular, an aspect emerging in recent years, with the application of preoperatory therapies, is the evaluation of treated tumors, to assess the effect of therapies on the tumor mass. In these cases, the diameters of the tumor mass should be registered, along with the percentage of viable tumor, its mitotic index and the presence of differentiation induced by therapy, and the percentage and description of post-treatment changes (i.e., ►necrosis, hemorrhage, fibro-histiocytic reaction with hemosiderin, sclerosis, hyalinosis, calcification, myxoid changes).

Treatment and Outcome

The first concept is that the treatment of pediatric patients with STS is complex and demands a multidisciplinary approach: the rarity and the heterogeneity of these tumors suggest that children and adolescents with STS should be referred to selected institutions with adequate experience in treating patients with STS, and with multidisciplinary skills in enrolling patients in clinical trials. It is a fact that in the past 30 years the cure rate for pediatric STSs has significantly improved, and currently approximately 70% of cases are cured. As for other pediatric malignancies, the improvement in therapeutic results is largely due to the development of treatment approaches that have been: (i) *multidisciplinary* (including surgery, radiotherapy, and chemotherapy), (ii) *risk-adapted* (different prognostic factors have been used to stratify treatment intensity in the different subsets of patients), (iii) *cooperative multi-institutional* (within trials able to enroll a large number of patients). However, it is true that pediatric ►STS researches addressed their main attentions on ►RMS studies: the published studies on pediatric NRSTS are far less numerous than RMS and it is noteworthy that the largest two reported series of pediatric NRSTS are single-institution experiences (published by two highly qualified centers, the St Jude Children's Research Hospital and the Istituto Nazionale Tumori of Milan). Also the term "non-rhabdomyosarcoma" ►STS reflects the fact that most of the experience gained on the treatment of pediatric NRSTS has been based on principles deriving from the management of RMS, which is a clearly distinct entity. But times have changed, and both the North-American Children's Oncology Group (COG) and the newly created European pediatric Soft Tissue Sarcoma Study Group (EpSSG) are currently carrying out clinical trials specifically tailored to NRSTS (also drawing insight from the numerous reports on adult sarcomas).

Another important issue to consider in establishing the treatment strategy for NRSTS concerns the heterogeneity of these tumors, that are a very mixed group of different histotypes, with very different clinical history: i.e., MPNST occur most frequently at axial sites, are often associated with neurofibromatosis type 1 and are characterized by high local aggressiveness and poor prognosis; epithelioid sarcomas present typical features such as peculiar superficial distal location (i.e., hand, fingers), indolent growth, and tendency for lymph node involvement; infantile fibrosarcomas may have initial rapid growth, but also indolent evolution, can give metastases, but also spontaneous regressions have been described, and the overall prognosis is good; ►desmoplastic small round cell tumors (DSRCT) usually present as a large abdominal mass already widely disseminated at the time of diagnosis, with extensive spread to regional lymph nodes, peritoneal seeding, and distant metastases, and the outcome is extremely poor outcome despite intensive multimodality treatment approaches.

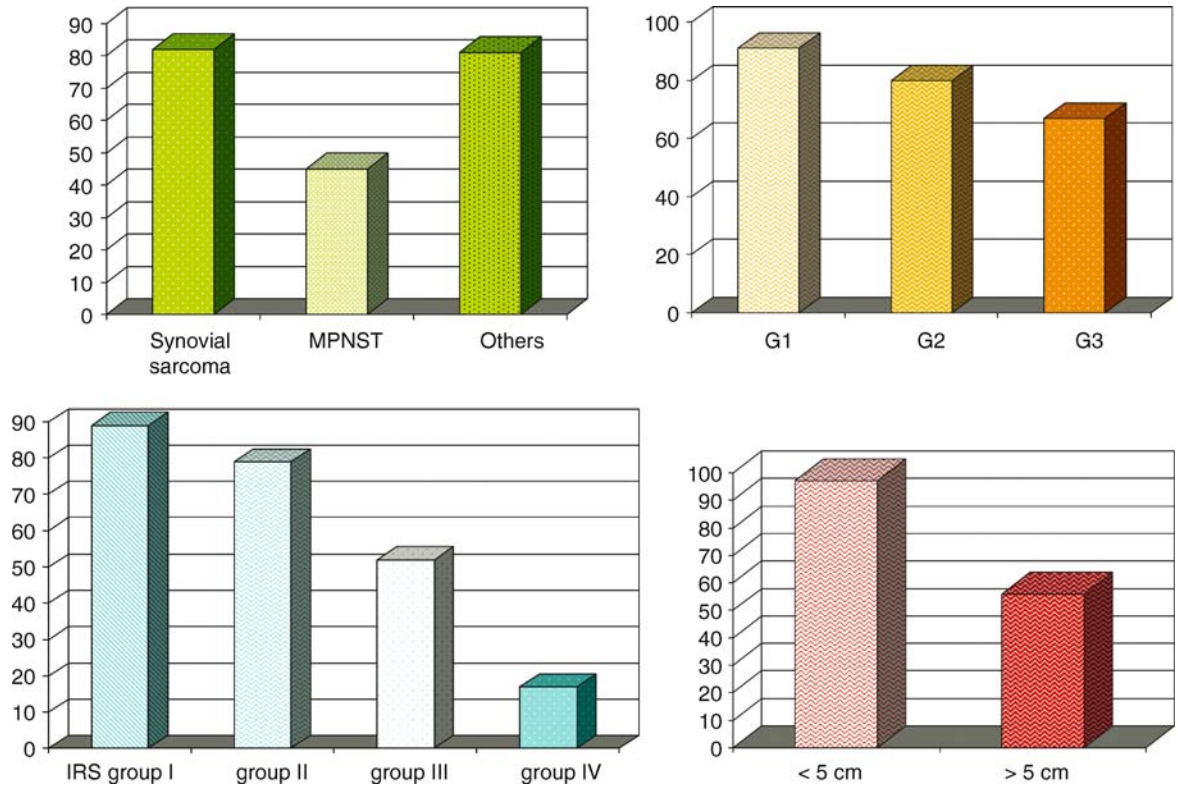
Despite this heterogeneity, NRSTS have to be analyzed as a group because the rarity of each histotype makes it impossible to perform clinical trials on single tumor types. However, it is important for investigators to identify and select diagnostic subgroups that are as specific (and homogeneous) as possible. The definition of "adult-type" NRSTS focuses on a subgroup of NRSTS histotypes that are typical of adulthood, definitely malignant, with morphological features resembling differentiated/mature tissues, thus ruling out infantile fibrosarcoma, for instance, intermediate malignancy tumors and small round cell tumors (i.e., RMS, extraosseous ►Ewing sarcoma and ►DSRCT), which are biologically and clinically different entities that are sometimes studied together with adult-type NRSTS, giving rise to misleading results. Therefore, the definition of "adult-type" NRSTS includes adult-type fibrosarcoma, MPNST, epithelioid sarcoma, leiomyosarcoma, clear cell sarcoma of soft part, liposarcoma, alveolar soft part sarcoma, undifferentiated polymorphous sarcomas, malignant solitary fibrous tumor/hemangiopericytoma, angiosarcoma, dermatofibrosarcoma.

In the direction of selecting specific subgroups of NRSTS histotypes it is also the decision to analyze *synovial sarcoma* separately, not only because it is the most common NRSTS in childhood and adolescents, but also because its chemosensitivity would probably stand midway between that of the most typical adult STS (less than 40% of patients respond to chemotherapy) and that of pediatric small round cell tumors, such as RMS (up to 80% respond to chemotherapy).

In order to plan a risk-adapted treatment strategy, basically, it is of fundamental importance to identify the prognostic variables capable of influencing the outcome. Various findings have suggested that the quality of initial surgery (namely the IRS group), the initial tumor size, and the grade of the tumor are the most important prognostic factors Fig. 3.

Surgery. Surgery is unquestionably the keystone of treatment of NRSTS. The aim of surgery is that of obtaining adequate surgical margins with limited or no long-term sequelae. The quality of the surgical operation is crucial and the chances of adjuvant therapies being able to compensate for inadequate surgery are still debatable. For this reason, patients should be referred to specialist centers for local treatment, preferably before undergoing biopsy. A critical issue concerns the definition of "adequate margins," that means the quality and the quantity of healthy tissues surrounding the tumor (the quality of the resection is defined by its worst margin). A surgical resection could be defined as complete when histological margins were microscopically free, including the so-called *compartment resections* (when the tumor is removed en bloc with the entire muscular or anatomical compartment of origin, where tumor was entirely anatomically confined) and the *wide excisions* (en bloc excisions through normal tissue, beyond the reactive zone but within the muscular compartment, removing the tumor with its pseudocapsule; the tumor is covered at every point by healthy tissue, i.e., muscle, subcutaneous tissue, thick fascia, or intermuscular septum). *Marginal resection*, or microscopically incomplete resection, is any resection coming just outside the pseudocapsule, with suspected microscopic residual disease (the tumor surface emerges macroscopically at the resection surface), while *intralesional resection* means that macroscopic tumor residue is left in situ. A crucial question remains, besides, whether and how to give a "metric" definition of a "safety distance" between tumor and resection margins: "adequate" margins could be considered those >1 cm of healthy tissue around the tumor, in all directions, when the tissue is a muscle or adipose tissue, while when the tissue is periostium, vessel sheath, epineurium, or muscular fascia (that act as barriers) healthy tissue >1 mm may be considered sufficient.

Radiotherapy. Radiotherapy plays a well-defined role in local control in ►STSs. In particular, in adult STSs irradiation is recommended not only after incomplete resection, but also after wide excision, especially in case of large tumors. Certainly, the indication for radiotherapy has to be stricter in children and young adolescents with NRSTSs than in adults, given the higher risk of severe late effects of radiotherapy (in particular, the risk of retardation or arrest of irradiated bone growth, the risk of functional impairment and that of second postirradiation tumor): the patient's age must always be borne in mind when planning radiotherapy in order to keep its sequelae to a minimum. In patients who received initial wide resection, in fact, the indication for radiotherapy is still debated due to the problem of sequelae, though reported



Non-Rhabdomyosarcoma Soft Tissue Sarcomas. Figure 3 Overall survival of NRSTSs according to histotypes, tumor grade, surgical margins (IRS group), tumor size. (Ferrari et al (2005) J Clin Oncol 23:4021–4030).

series showed a favorable trend for the addition of radiotherapy and therefore seemed to suggest the use of postoperative irradiation in those cases with tumor larger than 5 cm. The indication for postsurgical radiotherapy is clearer, instead, after initial marginal resection (the so-called IRS group II patients): when suspected microscopical residual tumor is left in situ (and when a re-excision is considered unfeasible), radiotherapy should be given, since the risk of local recurrence appears very high. The local treatment strategy is more complicated in patients whose tumors are judged unresectable at diagnosis, and thus receive initial chemotherapy (IRS group III patients). For these patients, delayed surgery is the treatment of choice, but surgery and radiotherapy should be discussed in a multidisciplinary setting and combined in order to define (and customize) the best local treatment for each patient, considering again that radiotherapy should be administered not only considering the need to maximize the chances of local control, but also containing the radiation-related sequelae and preserve function: for instance, irradiation after delayed surgery could be avoided in younger patients, while it might be recommended in the case of large tumors; postoperative radiotherapy may be easier to plan and carries a lower risk of complications, but preoperative irradiation can improve the chances of achieving free margins at the secondary resection, may reduce the risk of intraoperative contamination, and smaller radiotherapy fields and lower doses can often be used.

Chemotherapy. While conservative surgical resection unquestionably remains the mainstay of treatment for NRSTSs, and the effectiveness of radiotherapy is widely appreciated, oncologists are still wondering about systemic chemotherapy and NRSTSs, as adult ►STSs, continue to be considered scarcely chemosensitive (unlike the case of ►RMS, which is a highly chemosensitive tumor). However, it is generally agreed that the outcome is reasonably good in patients with resected, small, noninvasive NRSTSs (survival rate up to 90%), whereas even after initial gross resection, the prognosis for patients with high-grade and large invasive tumors would be unsatisfactory if the treatment were limited to surgery alone (with or with out radiotherapy). The risk of developing distant metastases, particularly to the lung, is higher for high malignant NRSTSs, and the role of different chemotherapy regimens has been variously investigated. Several findings emerging from adult trials have suggested that the combination of full-dose ifosfamide and ►doxorubicin (►adriamycin) was the regimen achieving the highest response rate in STSs.

Of course, chemotherapy has to be recommended in frontline treatment in patients with metastatic and advanced disease at diagnosis, and also in all those

cases where the surgeon is unsure of being able to achieve a complete resection at the first attempt. Neoadjuvant chemotherapy might convert such cases into conservative complete resections, as well as treating any micrometastases promptly, since these patients have a high risk of distant dissemination whatever the local control measures adopted. Overall, the response rate (complete response plus partial response >50%) of NRSTSs to frontline chemotherapy is considered around 40%, though more recent findings would suggest better percentage of response when minor responses were also included (and some cases that had initially been considered unresectable reportedly underwent complete delayed surgery after minor tumor shrinkage induced by chemotherapy).

Even more doubts surround the role of ►adjuvant chemotherapy, though recent evidence seems to suggest that it may have a more significant beneficial impact in selected cases than is generally believed. Despite the relatively good prognosis for patients who received initial resection, a particular group of high-risk patients can be in fact earmarked: the combination of two variables – *high tumor grade* plus *large tumor size* – gives rise to a very high risk of metastases, irrespective of the results of initial surgery, suggesting that systemic chemotherapy should, in principle, be used to improve survival. In patients with these characteristics, in fact, the metastases-free survival is around 30–40%, but it seems clearly better in those patients who received adjuvant chemotherapy, as compared with those who have not been given. Of course, the debate on whether or not to provide adjuvant chemotherapy for STS remains wide open. The role of adjuvant chemotherapy in preventing distant recurrences after initial surgery has long been a point of controversy in the field of clinical studies on adult STS. Most randomized trials performed by North American and European groups showed neither statistically significant benefit for patients given adjuvant chemotherapy, but some of the negative results recorded in those studies need to be reconsider since these trials did not use the combination of drugs currently recognized as the most effective in STS (ifosfamide, in particular, was not included in most of these studies), nor had they selected patients most likely to respond to chemotherapy (tumors of diverse histology, grade, and size were grouped together).

A completely separate discussion should be dedicated to the role of chemotherapy in synovial sarcoma. Over the years, different strategies have been developed for pediatric and adult oncology protocols dealing with synovial sarcoma. High rates of response to chemotherapy were recorded in pediatric series, so synovial sarcoma came to be considered an "RMS-like" tumor and most pediatric patients were consequently included in RMS protocols, receiving adjuvant chemotherapy regardless of the risk factors (i.e., even after the complete excision of very small tumors), whereas adjuvant chemotherapy was generally used only in adult patients as part of trials with a no-therapy control arm and including all soft tissue sarcoma histotypes.

The various reported experiences with this tumor in the field of pediatric oncology reported a 5-year overall survival rate around 80%, i.e, higher than the one usually reported in adult series, and an approximately 60% rate of response to chemotherapy in patients with measurable disease, i.e., higher than the response rate usually reported for other adult STS. Data from adult literature, instead, reported less satisfactory overall results: this finding may have to do with a different incidence of adverse prognostic factors in different age groups (i.e., large tumors were more frequent in older patients), but the different results might also be related, to some degree at least, to the different treatment strategies adopted, and particularly to the different use made of chemotherapy. A formal demonstration of the efficacy of adjuvant chemotherapy in synovial sarcoma is not available, but various data would nonetheless suggest that it does have a part to play. It may be that adjuvant chemotherapy for all synovial sarcoma patients (as pediatric oncologists did) is tantamount to overtreatment: it is probable that a subset of low-risk patients – i.e., completely resected, with tumor smaller than 5 cm – may be identified for which adjuvant chemotherapy can be omitted without jeopardizing the results.

Particular Histotypes

The above discussed considerations are suitable for most of the NRSTS histotypes, and in particular for the so-called "adult-type" NRSTS. However, there are some particular entities that are characterized by peculiar biology and clinical course, and deserve to be considered separately.

Extra-osseous primitive peripheral neuroectodermal tumor (pPNET)/Ewing sarcoma is less frequent than the skeletal ►Ewing sarcoma, but it is likely that there are no biological differences between Ewing sarcomas arising at different sites, so the clinical considerations should be the same: it is a high malignant tumor, with a strong propensity to give metastases, that should be treated with a multimodality strategy including, in all cases, multi-agent chemotherapy.

►DSRCT is a very aggressive neoplasm, usually arising in the abdominal cavity, often characterized by a poor outcome despite the various intensive multimodality treatment approaches attempted over the years (i.e., aggressive surgery, radiotherapy, intensive chemotherapy including high-dose myeloablative chemotherapy (►myeloablative megatherapy) with stem cell rescue).

Soft part ►*rhabdoid tumors* represent the soft tissue counterpart of the intracranial and renal entities: they are very rare and very aggressive disease, for which

improvement in genetic studies are strongly needed to cast light on their common biology in order to think to new treatment approaches.

The heterogeneous assortment of NRSTS includes tumors as ►*epithelioid hemangioendothelioma*, a neoplasm that sometimes arises at soft part, as a single lesion located in the extremities or cervical district, with very little propensity to metastasize or become fatal, but sometimes develop at bone, lung, and liver, often multifocal or metastatic, with indolent course but also a not negligible risk of death, for which treatment with alpha-interferon may have a significant role, probably due to an antiangiogenic effect.

Finally, *infantile fibrosarcoma* is a peculiar tumor of infants (it is the most common soft tissue sarcoma under 1 year of age): its clinical behavior may widely vary (i.e., it can rapidly grow and also give metastatic spread, but some cases of spontaneous regression have been described). However, chemotherapy is fairly effective in this tumor, also utilizing mild alkylating/anthracyclines-free regimens, and, consequently, the overall prognosis is very good.

Future Issues

Despite their heterogeneous nature, NRSTS currently have to be analyzed as a group because of their rarity and the availability of few therapeutic options (i.e., surgery remains the keystone of treatment, and few drugs are effective). However, this situation is changing and the next steps may go in the direction of histology-driven therapies: drugs other than ifosfamide–doxorubicin combination have proved fairly active against particular histotypes (i.e., ►taxanes for ►angiosarcoma, ►gemcitabine for ►leiomyosarcoma, ►ET-743 for ►myxoid liposarcoma). But what physicians are waiting is to really improve the understanding of the biology of these tumors, paving the way toward novel molecular therapeutic approaches. The specific chromosomal translocations occurring in ►STS may become the targets of new molecular agents specifically designed to influence the tumor's biology. Of course, if the near future sees STS studied no longer as a mixed bunch, but focusing separately on each histotype, this will only be feasible (especially for investigators working on pediatric NRSTS) if there is close cooperation between international groups, and between pediatric and medical oncology groups.

Non-small Cell Lung Cancer

Definition

NSCLC; About 80–85% of all cases of ►lung cancer are of the non-small cell type. There are three sub-types of NSCLC. The cells in these sub-types differ in size, shape, and chemical make-up.

Non-syntenic

Definition

Refers to genes or genetic loci that lie on different chromosomes, i.e. are not genetically linked.

Non-Viral Vector for Cancer Therapy

Atsuko Fujihara[1,2], Yasufumi Kaneda[1]
[1]Department of Gene Therapy Science, Osaka University, Graduate School of Medicine, 2-2 Yamadaoka, Suita, Osaka, Japan
[2]Department of Urology, Kyoto Prefectural University of Medicine, Kyoto, Japan

Definition

Non-viral vectors can deliver therapeutic molecules into cells for the treatment of cancer. The molecules used for this purpose are usually anticancer drugs, short interfering RNA (►siRNA), and DNA (Table 1). Non-viral vectors can also be employed for the delivery

of proteins, peptides, and messenger RNA, but such agents are not so frequently used for cancer therapy. Anti-sense oligonucleotides (►Antisense DNA therapy) were previously employed to suppress gene expression, but siRNA has recently taken their place.

Characteristics

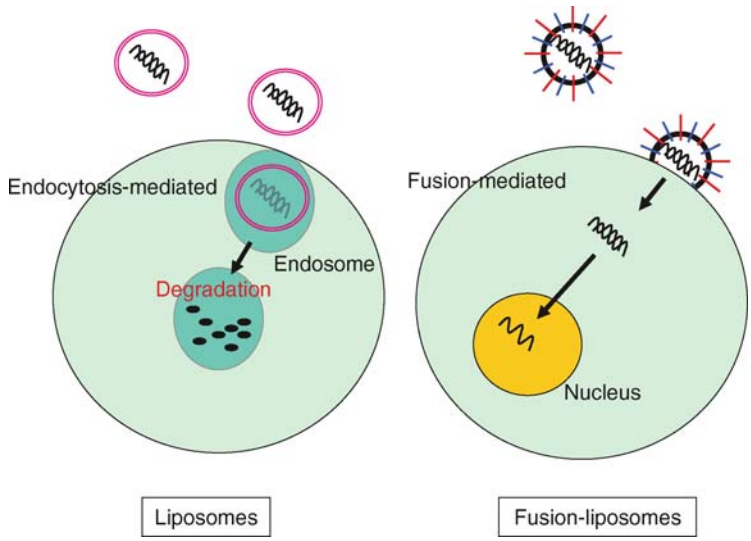
Viral vectors are generally constructed by inserting a therapeutic gene into an engineered viral genome. In contrast, construction of non-viral vectors does not require viral genome engineering and these vectors are synthesized from chemical products or native materials, after which they associate with therapeutic molecules to promote more efficient delivery. Non-viral vectors are generally less efficient at promoting gene delivery and gene expression than viral vectors (►Viral vector-mediated gene transfer), but pose less risk and can also be employed for drug delivery. The most representative non-viral vectors are ►liposomes and ►polymers. Physical methods, such as naked DNA injection, electroporation, and sonoporation, also allow non-viral delivery of molecules, but no carrier or vector is associated with the therapeutic molecules.

Non-Viral Vector for Cancer Therapy. Table 1 Therapeutic molecules for cancer treatment delivered using non-viral vectors

Anticancer drugs	siRNA	DNA
Bleomycin	Rad51	p53
Cisplatin	VEGF	B7–1
Doxorubicin	HIF-1α	IL-12
Methotrexate	β-catenin	HSV-tk

Liposomes

Liposomes are artificial phospholipid bilayer vesicles formed from an aqueous suspension of phospholipid molecules that can be employed for the targeted delivery of macromolecules. Cationic liposomes can bind DNA more tightly and show improved transfection efficiency. However, DNA is taken up into cells by ►endocytosis during lipoplex-mediated transfection. The main problem with endocytosis-mediated delivery is that therapeutic molecules are often subject to degradation within endosomes or lysosomes, as shown in Fig. 1. To solve this problem, several methods have been tried. One method is to employ a neutral lipid (DOPE) that facilitates the endosomal release of DNA. Its discovery has led to the use of a mixture of cationic lipids and DOPE for lipofection. Further analysis of various lipids has revealed that a 1:1 mixture of *N*-[1-(2,3-dimyristyloxy) propyl]-*N*,*N*-dimethyl-*N*-(2-hydroxyethyl) ammonium bromide and cholesterol is capable of destabilizing the endosome membrane more effectively than DOPE. To further protect therapeutic molecules delivered by liposomes, DNA is now conjugated with cationic molecules. For example, protamine sulfate or adenovirus mμ protein is conjugated with DNA, after which the newly formed complexes are incorporated into or mixed with cationic liposomes. Investigations of these methods have shown that cationic liposomes containing the HLA-B7 and β-2 microglobulin genes can induce antitumor immunity in HLA-B7-negative



Non-Viral Vector for Cancer Therapy. Figure 1 Pathways by which therapeutic molecules can be introduced into cells using liposomes or fusion-liposomes. Molecules delivered in liposomes escape into the cytoplasm from the endocytotic pathway, while molecules delivered by fusion-liposomes directly reach the cytoplasm by membrane fusion.

►melanoma patients, and a number of centers have performed clinical trials of a liposomal drug (Allovectin-7) for the treatment of metastatic melanoma. Delivery of the β-interferon gene by cationic liposomes has also been evaluated for the treatment of patients with ►glioblastoma. In addition, several other clinical trials have tested the delivery of various anticancer agents using liposomes.

Tissue targeting (►Targeted drug delivery) is important for the efficient delivery of therapeutic molecules with minimum toxicity.

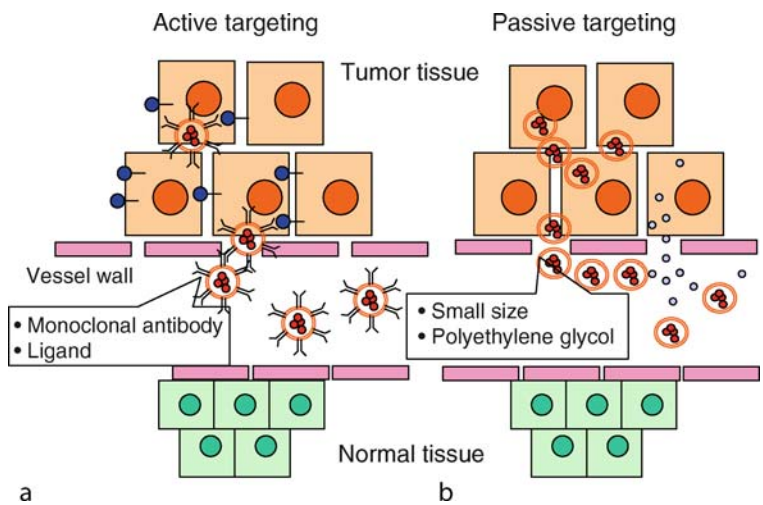
Especially in cancer therapy, tumor-specific delivery is essential for treating metastases. Generally, there are two approaches to tissue targeting, which are known as ►therapeutic active targeting and ►therapeutic passive targeting (Fig. 2). Passive targeting is the method used for most cancer-targeting vectors, because tumor vasculature has an abnormally high permeability due to its incomplete architecture. If a vector remains stable in the circulation and is not trapped by the reticuloendothelial system, it can cross the walls of tumor vessels and accumulate in tumor tissues. To achieve this, the diameter of a vector should be less than 300 nm (preferably less than 150 nm), and the vector should be coated with polyethylene glycol. In addition, the vector should associate effectively with tumor cells. In order to promote the internalization of therapeutic DNA by tumor cells, various cell receptor ligands (such as folate and transferrin) have been used to take advantage of receptor-mediated endocytosis.

Polymers

Polymers are also used as DNA carriers and can be divided into two categories based on their biodegradability. Various cationic non-biodegradable polymers have been widely investigated for enhancing the internalization of therapeutic molecules. The most common linear cationic polymers are poly (ethyleneimine) and poly-L-(lysine). Other polymers include poly (*N*-ethyl-4-vinylpyridinium bromide), poly (dimethylaminoethyl methacrylate), chitosan, and dimethylaminodextran, or branched polymers such as poly (amidoamine) ►dendrimer and branched poly (ethyleneimine). Since DNA is a large and negatively charged molecule, it is difficult to attach it directly to the cell membrane (also negatively charged) and achieve internalization into cells. It is well known that cationic polymers can easily form complexes with negatively charged DNA via electrostatic interactions. Such complex formation condenses the DNA molecule and converts the net electrical charge to positive under appropriate conditions. This condensation and the positive charge of a DNA-cationic polymer complex facilitate attachment to cells and subsequent internalization via the normal endocytosis pathway.

In addition to electrostatic interactions, hydrophilicity and hydrophobicity can be utilized to incorporate therapeutic molecules. Block copolymers with both hydrophilic and hydrophobic characteristics can be assembled to form a micelle structure that incorporates anticancer drugs or DNA. Such ►micelles are small enough (50–100 nm in diameter) to reach tumors by extravasation from their vessels. Targeting molecules can be also bound to particles of the nanometer order in size for tissue targeting.

Biodegradable polymers have been used to achieve controlled release of DNA, thus enhancing and prolonging gene expression. Controlled-release technology increases the concentration of DNA and



Non-Viral Vector for Cancer Therapy. Figure 2 Two different approaches for tumor-specific delivery. (a) Vectors that possess tumor-specific molecules such as monoclonal antibodies and ligands recognize tumor cells by molecular interactions. (b) Vectors with a small size and polyethylene glycol coating passively accumulate in tumor tissues, which are characterized by a high interstitial pressure, enhanced vascular permeability, and the lack of functional lymphatic drainage.

prolongs its persistence at an injection site. By using this method, the biological activity of an antitumor DNA plasmid (NK4) is enhanced.

Virosomes

In order to enhance the efficiency of delivery, trials of viral envelopes or other proteins have been performed. Empty viral envelopes without the viral genome that are used to incorporate drugs and non-viral vectors decorated with viral components are called ►virosomes. The representative virosomal vectors are described below.

Fusion-Liposomes

To avoid degradation prior to reaching the cytoplasm, fusion-mediated delivery systems have been developed (Fig. 1). A fusigenic viral liposome with a fusigenic envelope derived from ►HVJ (►Sendai virus) was constructed first. Primitive ►HVJ-liposomes are made by fusion of liposomes with UV-inactivated HVJ. Reconstituted fusion liposomes can also be created. Use of HVJ-liposomes to deliver anticancer treatment has already been investigated in animal models. A melanoma-associated antigen gene (►Melanoma antigen) or RNA injected into skeletal muscle or the spleen successfully evokes antitumor immunity and prevents the growth of melanoma. A radiation-inducible HSV-TK gene driven by the Egr-1 promoter enhances the efficacy of radiotherapy for ►hepatocellular carcinoma when delivered by HVJ-anionic liposomes. Using an ►EBV replicon plasmid containing the HSV-TK gene, ►suicide gene therapy (►HSV-TK/Ganciclovir mediated toxicity) is more effective against melanoma in tumor-bearing mice. A similar approach to enhance the efficiency of gene transfer uses fusion peptides derived from influenza virus hemagglutinin for receptor-mediated gene delivery. Combining transferrin/poly-L-lysine/DNA complexes with the hemagglutinin peptide increases the efficiency of gene transfer into cultured cancer cells by more than 1,000-fold compared with transfer in the absence of this peptide.

HVJ-Envelope Vector

To simplify the vector system and to increase the efficiency of gene delivery, plasmid DNA has been incorporated into inactivated HVJ particles without liposomes by detergent treatment and centrifugation. The HVJ-envelope (inactivated Sendai virus) vector can deliver DNA, siRNA, proteins, and anticancer drugs to cells both in vitro and in vivo. Rad51 siRNA has been delivered to tumors in mice with approximately 50% efficiency by this HVJ envelope vector. After Rad51 siRNA was delivered to tumors using this envelope vector, sensitivity to ►cisplatin was enhanced more than tenfold compared with use of cisplatin alone. The HVJ envelope vector can also enhanced transfection efficiency after conjugation with a biocompatible polymer or magnetic beads. The vector itself is an effective anticancer agent because it can induce T cell-mediated antitumor immunity through activation of dendritic cells and inhibition of regulatory T cells.

Nonsense Mutation

Definition

A mutation that occurs within a codon and changes it to a stop codon.

Nonspecific Cross Reacting Antigen

Definition

The second member of the ►CEA gene family to be discovered. NCA contains the characteristic IgV domain at the N-terminus but has only two IgC2 like domains. It is linked to the cell membrane via a glycosyl phosphatidyl inositol moiety.

Nonsteroidal Anti-inflammatory Drugs

Satish K. Srivastava, Kota V. Ramana
Dept of Biochemistry and Molecular Biology, University Of Texas Medical Branch, Galveston, TX, USA

Definition

NSAIDs; Are a structurally diverse group of similarly acting compounds that prevent symptoms of pain, fever, and inflammation without steroid chemistry.

Characteristics

NSAIDs are the most commonly prescribed drugs worldwide for the treatment of pain and ►inflammation. They are effective as ►antipyretic and ►analgesic and are also effective in prevention of cardiovascular complications. In recent years, evidence from animal as well as prospective and retrospective clinical studies indicate that NSAIDs may lower the risk of cancer development and more importantly progression of cancer, especially colorectal and breast cancers.

Types of NSAIDs

Depending on their strength, duration of action, and elimination from the body NSAIDs have been classified as

- *Salycylic acids:* Aspirin, Salsalate, and Diflunisal
- *Acetic acids:* Sulindac, Indomethacin, Diclofenac, and Tolmetin
- *Propionic acids:* Ibuprofen, Naproxen, Flurbiprofen, Oxaprozin, Ketoprofen, and Fenoprofen
- *Enolic acids:* Meloxicam and Piroxicam
- *Fenamic acids:* Meclofenamate and Mefenamic acid
- *Pyranocarboxylic acids:* Etodalac
- *Napthylalkanones:* Nabumetone
- *Pyrroles:* Ketorolac
- ►*COX-2 inhibitors*: Celecoxib, Valdecoxib (Bextra), and Rofecoxib (Vioxx). Bextra and Vioxx were withdrawn from market.

Mechanism of Action

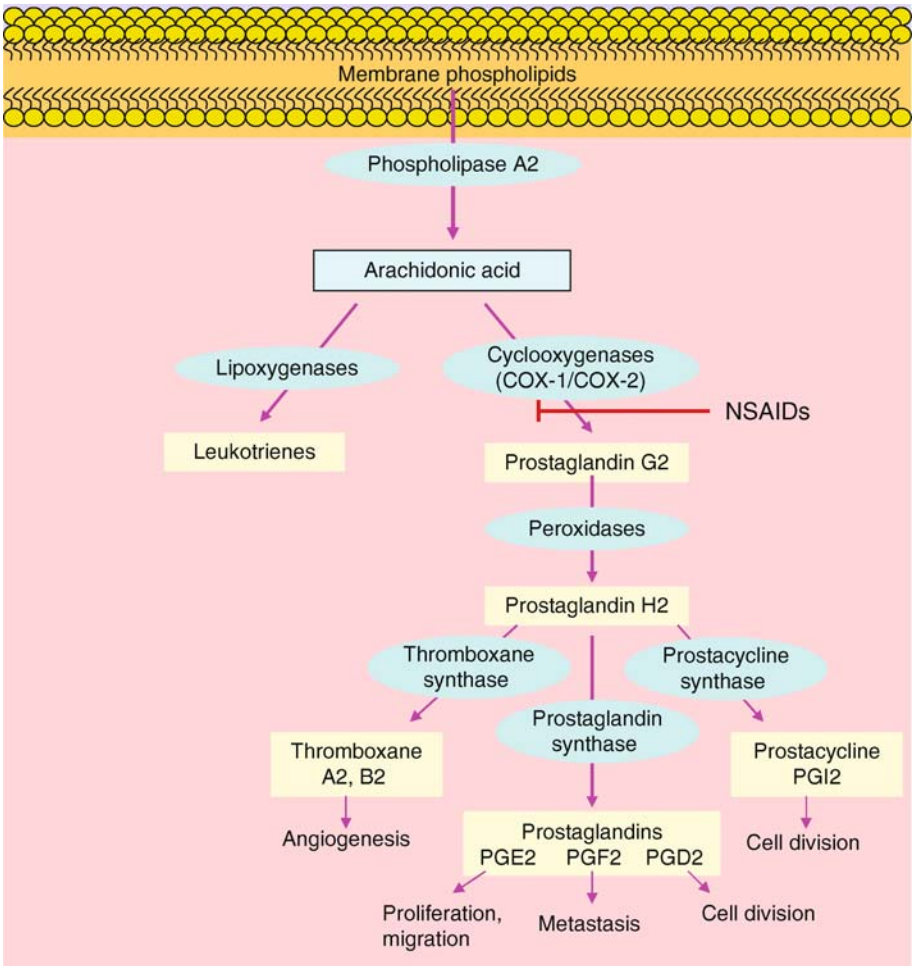
Most NSAIDs act as nonselective inhibitors of the enzyme ►cyclooxygenase – they inhibit both the cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2) isoenzymes. Cyclooxygenases catalyze the formation of ►prostaglandins and ►thromboxane from ►arachidonic acid (Fig. 1). Prostaglandins act as messenger molecules in the process of inflammation and neoplasia. Overexpression of COX-2 stimulates angiogenesis, formation of new blood vessels, in tumors. Angiogenesis is required for the transition of normal cancers to invasive cancer leading to metastasis. COX-2 can stimulate ►angiogenesis by promoting production of ►vascular epithelial growth factor (VEGF), ►matrix metalloproteinases, and prostaglandins. Further, COX-2 increases production of antiapoptotic protein ►Bcl-2 and thus causes resistance to death of cancer cells.

Cancer Chemoprevention

►Inflammation originating from infections, chronic injury, or ►autoimmune diseases can cause immune response, which subsequently forms ►free radicals and ►reactive oxygen species (ROS) through a cascade of reactions. These interact with cellular DNA, proteins, and lipids and cause cellular and genomic damage. In addition, the signals initiated by ROS release ►eicosanoids which trigger cell proliferation, cause resistance to ►apoptosis and facilitate carcinogenesis [2]. Although NSAIDs have been used for many years to treat rheumatic diseases and inflammatory symptoms, in recent years a large number of studies suggest the important chemopreventive properties of NSAIDs against various forms of cancer such as ►colorectal cancer, ►breast cancer, ►bladder cancer, ►prostate cancer, and ►lung cancer.

Colorectal Cancer

Adenomatous polyps are the initial risk for most of the colon cancer tumors. ►Cox-2 overexpression and ►PGE2 production has been observed in various colorectal ►adenomatous polyps and tumors but not in normal. Treatment of patients with familial adenomatous polyps with sulindac for 9 months resulted in a 44% and 35% decrease in the number and size of colonic polyps. Similarly, ►celecoxib resulted in ~30% decrease in the number and size of colonic polyps. In another study, aspirin treatment also significantly reduced the risk of colon polyps. Thus, these and other ongoing clinical studies suggest the significance of NSAIDs in chemoprevention of colorectal cancer.



Nonsteroidal Anti-inflammatory Drugs. Figure 1 COX-2 inhibition by NSAIDs. Cyclooxygenases catalyze arachidonic acid to prostaglandin H2, which is further catalyzed to prostaglandin E2, D2, F2, and I2 and thromboxane A2. The prostaglandins cause cell growth, angiogenesis, and metastasis, leading to cancer development.

Breast Cancer

Increased levels of ►PGE2 production and COX-2 expression along with ►aromatase have been observed in the breast cancer biopsies. Subsequently, in a number of studies NSAIDs such as ►aspirin have been used to prevent breast cancer-related complications. One study has reported a 21% reduction in the incidence of breast cancer in women taking NSAIDs at least twice a week for a period of 5–9 years and a 28% reduction after 10 or more years of use. Further, COX-2 overexpressing transgenic mice developed mammary tumors after several cycles of pregnancy and lactation while wild type animals remained tumor free. In another study, a 35-day course of ibuprofen administered to rats with carcinogen-induced mammary tumors, led to a significant reduction in tumor volume. In animal models, celecoxib was found to be effective in preventing tumors associated with breast cancer. The combination of standard chemotherapy drugs with COX-2 inhibitors has been shown to increase the efficacy of chemoprevention to breast cancer in a number of studies.

Prostate Cancer

Several investigations suggest that chronic ►inflammation leads to ►prostate cancer. Even though overexpression of COX-2 in malignant prostate tissues is not well noticed, the use of NSAIDs such as sulindac and flubiprofen has been shown to decrease risk of prostate cancer in animal models.

Bladder Cancer

The expression of COX-2 has been shown to increase in bladder transient cell carcinoma. Most of the studies performed using NSAIDs in animal models of ►bladder cancer suggest that regular use of NSAIDs

N

could prevent the risk of bladder cancer and is more effective with combinational therapy. COX-2 inhibitors are in ongoing clinical trials in preventing bladder cancer recurrence after transurethral resection.

Lung Cancer

COX-2 overexpression has been observed in the biopsies of ►non-small cell lung cancer. In patients with asbestosis, idiopathic fibrosing alveolitis, and in heavy tobacco users the increased incidence of lung cancer is associated with overexpression of COX-2. Clinical studies have shown that NSAIDs are effective drugs in reducing risk of lung cancer, especially in heavy smokers.

Conclusions

A number of clinical, epidemiological, and animal studies suggest that NSAIDs could be promising anticancer agents. Targeted inhibition of cyclooxygenases alone or in combination with standard chemotherapy could be effective in the treatment of colorectal, bladder, and breast cancers. NSAIDs could also be effective in preventing recurrence of various types of tumors. To discover novel and most potent inhibitors of COX enzymes requires extensive investigations of molecular mechanism(s) by which COX and PGE2 promote angiogenesis and tumorigenesis. An exciting area for future investigations will be to test the nonNSAIDs such as ►aldose reductase inhibitors alone or in combination with standard chemotherapy for the prevention of colon cancer as well as other oncogenic pathways.

Norton-Simon Hypothesis

Tiffany A. Traina, Larry Norton
Breast Cancer Medicine Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY, USA

Definition

The Norton-Simon hypothesis states that the rate of cancer cell death in response to treatment is directly proportional to the tumor growth rate at the time of treatment.

Characteristics

Several experimental models have attempted to describe the fundamentals of tumor cell growth and kinetics. From these systems arose an improved understanding of tumor growth characteristics, a foundation for the key principles of chemotherapy and eventually, recognition of the importance of dose scheduling. Specifically, the Norton-Simon hypothesis of tumor kinetics was an important advance in the history of oncology. The concept of ►dose-density is derived from its principles and ultimately led to improved survival in patients with cancer as a result of optimal dose scheduling.

The Log-kill Model

The Norton-Simon hypothesis builds upon the ►log-kill hypothesis established by Skipper, Schabel and Wilcox. These investigators used a murine leukemia model to describe tumor growth and cell death. A unique feature of this L1210 mouse system is its rapid and exponential growth pattern. The log-kill concept of tumor cell growth suggests that tumor growth is exponential and that growth rate is a constant. In response to treatment with a dose of drug, a constant fraction of cells are killed regardless of the size of the tumor at the start of therapy. Therefore, one dose of drug leads to cytoreduction from 10^6 cells to 10^4 cells in the same way that one dose at 10^4 cells reduces tumor volume to 10^2 cells. Theoretically, enough doses of enough drugs over time could cytoreduce a tumor to <1 cell level, thereby achieving cure. Unfortunately, the observation that cure is rare in the majority of advanced cancers and that even patients with presumably early stage cancer relapse despite treatment suggests that the log-kill model is not entirely representative of clinical reality.

Gompertzian Growth Kinetics

An alternative model of population growth was proposed by Benjamin Gompertz, a nineteenth century British actuary who devised an equation to describe biologic growth curves which occur in nature (e.g. herds of animals). The application of Gompertzian growth to tumor kinetics improved upon our understanding of tumorigenesis. According to the ►Gompertzian growth curve, the rate of cancer growth is not uniform. Cell numbers increase over time, but the relative rate of increase falls exponentially until the tumor reaches a plateau phase of very slow absolute growth.

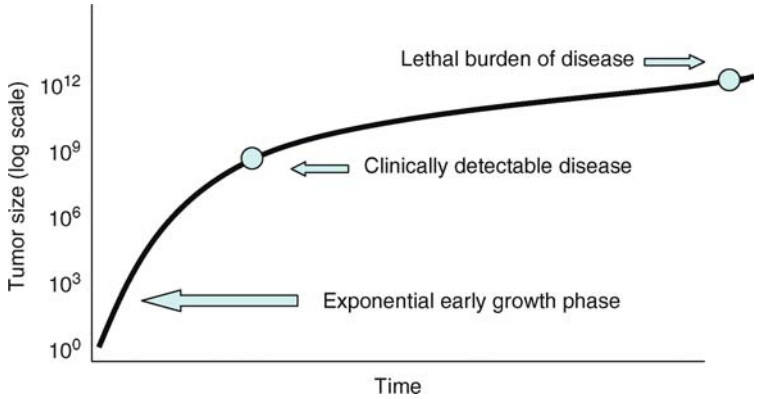
The difference between the log-kill model and Gompertzian growth is most easily visualized using a semilogarithmic plot of the logarithm of cell number versus an arithmetic time scale. In Fig. 1, early exponential growth appears as a straight line, whereas the Gompertzian curve turns continuously downward reaching a plateau that represents a stable population size. Although all tumors seem to observe the characteristic Gompertzian curve, the plateau phase for a particular type of cancer may be theoretically greater than the lethal tumor. Rapidly growing malignancies such as leukemia may appear to grow by nearly exponential growth because the host organism succumbs to the burden of disease well before the plateau phase is attained.

Norton-Simon Hypothesis

Inspired by clinical observation and mathematical modeling, Norton and Simon refined the Skipper-Schabel log-kill model, taking into consideration the kinetic, non-constant nature of population growth described by the Gompertzian equation. The underlying philosophy of the Norton-Simon hypothesis recognizes that a changing process such as cancer growth requires a treatment approach that considers the trajectory of tumor kinetics.

The hallmark of the Norton-Simon hypothesis is that the rate of cytoreduction is proportional to the rate of tumor volume growth. According to this model, log-kill is not constant, but instead it is proportional to the relative growth rate. Therefore, this model predicts that smaller tumors experience greater log-kill in response to treatment because of their rapid growth rate in comparison to larger tumors. Extrapolating further, there is a kinetic advantage to treatment when tumor volume is small such as in the post-operative setting.

The Norton-Simon hypothesis recognized that unless all cancer cells are eradicated, the eventual outcome is similar because of the rapid regrowth anticipated according to the Gompertzian curve. This led Norton and Simon to postulate that delivering treatments at a greater rate ("dose density") could optimize chemotherapy efficacy. Minimizing the regrowth of cancer between



Norton-Simon Hypothesis. Figure 1 A Gompertzian growth curve is shown here, demonstrating the early exponential growth rate at small tumor volumes and a plateau phase as the relative rate of increase diminishes with increasing tumor size.

doses of therapy would increase the cumulative cell kill, thereby achieving greater clinical benefit. The superiority of dose density in chemotherapy scheduling was first supported in a large, randomized ►clinical trial in patients with early stage breast cancer receiving ►adjuvant therapy every 2 weeks rather than the conventional every three week schedule (►Doxorubicin and cyclophosphamide (AC) followed by ►paclitaxel (T)). Since that time, several trials have supported dose dense administration of chemotherapy, leading to the improved survival of patients with cancer.

Notch Signaling

Definition

Activation and regulation of Notch receptors are critical elements for the growth and differentiation of many different cell lineages.

►Notch/Jagged Signaling in Neoplasia

Notch/Jagged Signaling

Marie-Clotilde Alves-Guerra, Renée M. Demarest, Anthony J. Capobianco
The Wistar Institute, Molecular and Cellular Oncogenesis Program, Philadelphia, PA, USA

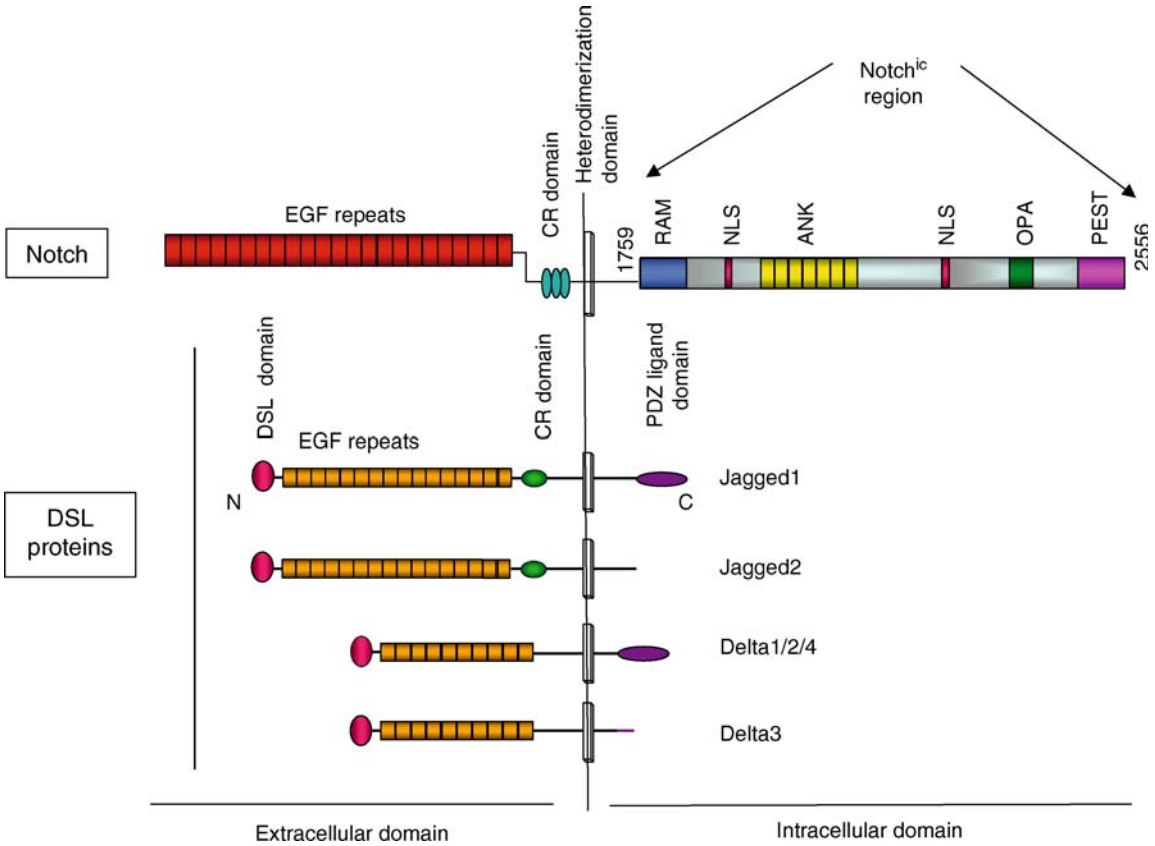
Definition

Notch and Jagged proteins define an evolutionarily conserved signal transduction pathway that is critically important for cell fate decisions in metazoan development. Notch and Jagged are single pass membrane-spanning proteins that share a receptor/ligand relationship, respectively. Jagged is the mammalian orthologue of the *Drosophila Serrate* gene. Collectively, the Notch ligands are referred to as the DSL proteins (Delta/Serrate/Lag). Constitutive activation of the Notch signaling pathway by chromosomal translocation, point mutation or gene amplification plays a role in tumor initiation and/or progression. Aberrant expression of the intracellular portion of Notch proteins ($Notch^{IC}$) is associated with the oncogenic transformation of cells. Notch was linked to cancer through its frequent mutation in T-cell acute lymphoblastic leukemia (T-ALL).

Characteristics

DSL proteins are encoded by the *Serrate* and *Delta* genes. *Drosophila melanogaster* possess only a single *Serrate*, *Delta* and *Notch* gene. However, mammalian genomes possess at least two *Serrate* and four *Delta* genes. Serrate/Jagged and Delta are large (>100 kDa) single pass transmembrane-spanning proteins (Fig. 1). The primary amino acid sequence of the extracellular domain of Serrate/Jagged and Delta reveals a striking similarity to the extracellular domain of Notch proteins. Their extracellular domains are composed of between 1 and 16 tandem copies of an EGF-like repeat. One common feature shared among the ligand proteins is a 45 amino acid sequence rich in cysteine. It is termed the DSL domain and it is located in the N-terminal of the EGF-like repeats. This domain is thought to play a role in ligand-receptor interactions. Unlike Notch proteins, the intracellular sequences of Serrate/Jagged and Delta are short (ca. 100–150 amino acids) and contain no sequence homology to any other proteins in the database. The function of the intracellular sequences of Serrate/Jagged and Delta is not understood. However, the integrity of these sequences are important since deletion of the intracellular domain from either Delta or Serrate/Jagged leads to a phenotype similar to that exhibited by loss of Notch signaling in *Drosophila*. In addition, Serrate/Jagged proteins contain a cysteine-rich domain (CR) located between the EGF-like repeats and the outer face of the plasma-membrane. The presence of this domain is used to classify ligand proteins as either Serrate- or Delta-like.

►Endocytosis plays an important role in Notch activation and inhibition. It was shown that endocytosis of DSL ligands are required for Notch activation in a neighboring cell. It has been determined that Liquid facet, Neuralized and Mindbomb are required for ubiquitination and endocytosis of DSL ligands. However, the mechanism by which endocytosis of DSL ligands activates Notch pathway in the neighboring cell has not been determined. Additionally, it has been shown that ubiquitination and endocytosis of Notch by Numb,



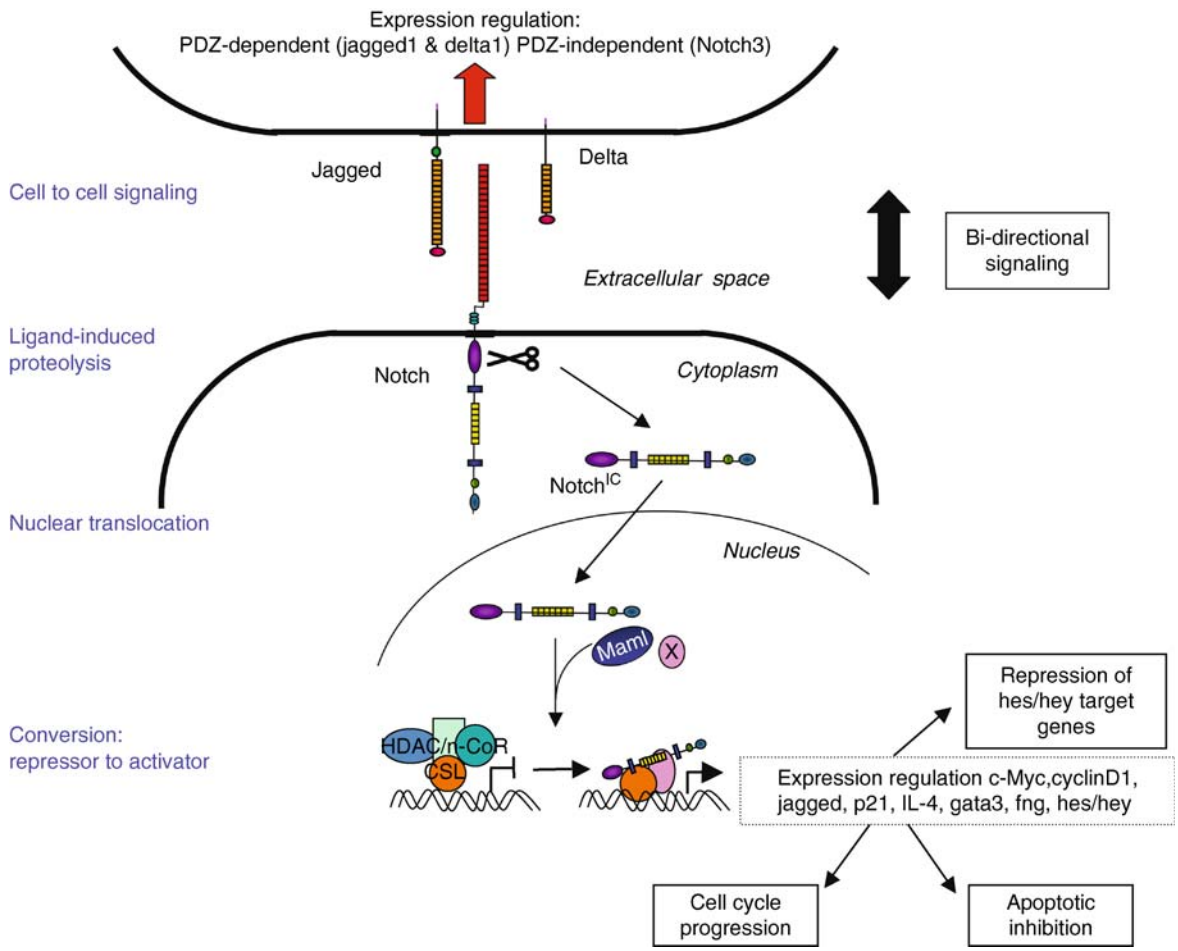
Notch/Jagged Signaling. Figure 1 Structure of Notch and DSL proteins. Notch proteins are transmembrane-spanning receptors for DSL proteins. Notch^{ic} is thought represent an activated Notch molecule. In T-cell Leukemia, the chromosomal translocation t(7;9)(q34;q34.3) fuses the T-cell receptor β locus to the Notch1 locus at the indicated break point (BP). The result of this translocation is the constitutive production of Notch^{IC}-like molecules. RAM, binding domain for CSL transcription factors; ANK, 7-tandem copies of ankyrin repeats; OPA, Glutamine-rich region; PEST, a domain thought to be involved in protein turnover. Putative nuclear localization sequences are indicated by small boxes and flank the ANK domain. Notch ligands are encoded by the Serrate/Jagged and Delta genes. DSL, a 45 amino acid sequence unique to DSL proteins thought to be involved in interactions with Notch. CR, a cysteine-rich domain of unknown function used to classify DSL proteins as either Serrate/Jagged or Delta. The intracellular sequences of the DSL proteins are of variable length and contain no recognizable motifs.

α-adaptin and AIP4/Itch leads to degradation and, therefore, inhibition of Notch.

There are four known mammalian Notch proteins, termed Notch1–4. These proteins are related through a high degree of sequence identity and structural organization. Notch proteins are membrane-spanning receptors with molecular weights of approximately 300 kDa (Fig. 1). The extracellular domain of Notch1 is composed of approximately 1,750 amino acids, which include 36 tandem repeats of a sequence resembling ►Epidermal Growth Factor (EGF) and three repeats of a motif designated as lin-12 repeats. The cytoplasmic domain comprises a sequence of approximately 750 amino acids with no apparent enzymatic activity, but containing seven tandem copies of an ankyrin-like repeat (CDC10/ANK), a region rich in glutamine (OPA), and a region rich in proline, glutamate, serine and threonine (PEST). The CDC10 and OPA repeats are thought to mediate protein-protein interactions, whereas the PEST domain might target the proteins for degradation. The RAM domain is located between the ANK repeats and the interface of the plasma-membrane. This domain is the primary binding site for the transcription factor CSL (CBF1/Supressor of Hairless/Lag1) (Fig. 1).

Notch proteins are synthesized as precursor proteins of approximately 300 kDa. During trafficking through the Golgi network, Notch undergoes a proteolytic processing event that produces the mature receptor. This processing step appears to be carried out by a furin-like protease and the resulting mature Notch receptor is composed of two fragments, the extracellular fragment and an intracellular fragment that remains embedded in the plasma-membrane. One of the major questions in Notch signaling is what is the mechanism of ligand

activation of Notch? One proposed mechanism is that the association of Notch with a DSL ligand on a neighboring cell induces a proteolytic event that releases the intracellular domain of Notch from its membrane tether (Fig. 2). Ligand-induced processing involves at least two distinct cleavage events. The first cleavage event linked to ligand binding is carried out by an ►ADAM-type ►metalloprotease that cleaves Notch in the extracellular domain close to the plasma-membrane. This cleavage is thought to induce a conformational change that allows the intracellular domain of Notch ($Notch^{IC}$) to be released from the plasma membrane following cleavage by a presenilin-dependent γ-secretase-like protease. Currently, it is not understood how ligand engagement of the receptor induces these processing events or if activation of Notch can occur through interactions with ligands present in the same cell. Moreover, there is still debate over the possibility of signaling from membrane-tethered forms of Notch that do not require additional proteolytic processing. Then, $Notch^{IC}$ translocates to the nucleus to form a transcriptional activation complex with the DNA-binding factor CSL and co-activators belonging to the Mastermind-like family of proteins (Maml). Recently, two CSL-$Notch^{IC}$-Mastermind ternary complex structures bound to DNA were determined for *C-elegans* and human orthologous proteins. These studies showed that CSL simultaneously mediates interactions with $Notch^{IC}$, Mastermind and DNA. The structures revealed that the N-terminal helical region of Mastermind forms a tripartite complex with ankyrin repeats 3–7 of $Notch^{IC}$ and the C-terminal domain of CSL. Additionally, the C-terminal helix of Mastermind interacts with the N-terminal domain of CSL. The activation complex exhibits a rapid turn-over rate, in part as a consequence to phosphorylation events triggered by cyclinC-CDK8 and the activity of E3-ligases of the Sel-10 family.



Notch/Jagged Signaling. Figure 2 Model for Notch signaling. Notch signaling is thought to occur following the interaction of DSL proteins and Notch proteins on neighboring cells. This interaction triggers a series of proteolytic processing events (indicated by scissors). Once Notch is cleaved, it is released from its membrane tether and translocates to the nucleus. In the nucleus $Notch^{IC}$ displaces the HDAC/co-Repressor complex and interacts with the transcription factors CSL and Maml and thereby activates gene expression.

The Notch transcriptional activation complex participates in the regulation of gene expression that, in part, serves to govern cellular processes such as differentiation, proliferation and apoptosis. Numerous Notch target genes have been identified, including ►c-myc, ►cyclin D1, Jagged, p21, IL-4 and Fringe. Notch directly upregulates c-myc, a potent oncogene, in T-cells and mammary epithelial cells. Notch has also been found to directly induce the expression of cyclin D1, a positive cell cycle regulator, as well as indirectly suppress the pro-apoptotic protein, ►p53, via downregulation of ►ARF by a yet unidentified mechanism. Additionally, Notch activates two families of basic helix-loop-helix proteins, HES and HEY, which homo- and heterodimerize to actively repress target genes (Fig. 2).

Bi–Directional, Jagged1-Mediated Signaling

The presence of a cysteine-rich region (CR) is used to classify Notch ligands into Delta-like or Serrate-like. Delta1, 2 and 4, not Jagged2 or Delta 3, also contain a putative PDZ-ligand domain (RMEYIV). The significance of the PDZ-ligand domain and the downstream events is not well understood in the context of Notch-DSL signaling. However, it has been shown that overexpression of Jagged1 can induce cellular transformation in RKE cells, which is dependent on its PDZ-ligand domain (PSD-96/DLG/Zo-1).Both the intracellular and extracellular domains are required for Jagged1-mediated transformation. To date, a number of Jagged1 target genes have been identified, including Notch3, Delta1 and Jagged1, itself, although whether they are direct targets has not been determined. Deletion of the PDZ-ligand domain of Jagged1 prevents upregulation of Delta1 and Jagged1, but not Notch3, suggesting that there are at least two signaling pathways downstream of Jagged1.

Fringe proteins provide another level of specificity between the two classes of DSL proteins. Fringe modifies Notch by adding O-fucose glycan to the EGF repeats which results in a decreased affinity for Jagged proteins and a higher affinity for Delta proteins. Therefore, upon expression of Fringe, Delta proteins are able to initiate Notch signaling, while Jagged proteins cannot (Fig. 3). A possible model for bi-directional signaling in the Notch pathway may involve a PDZ mechanism mediated by both Delta and Jagged proteins. In this model, Jagged1 could signal in both directions in the absence of Fringe, whereas the Delta signal would always be bidirectional. In the case of Jagged2, signaling would only be in the Notch direction and this signal could be attenuated by Fringe. In contrast, Delta3 is insensitive to Fringe and would always allow signaling in the Notch direction. This model provides exquisite flexibility for signal specificity and accounts for the multiple distinct DSL proteins.

C-terminal residues		PDZ ligand	Inhibited by fringe
R M E Y I V	Jagged1	+	+
R Y A G K E	Jagged2	–	+
V I A T E V	Delta1/2/4	+	–
I Y A R E A	Delta3	–	–

Notch/Jagged Signaling. Figure 3 Effects of Fringe on Notch signaling. Fringe modifies Notch by adding O-fucose glycan to the EGF repeat region which modulates Notch affinity for its ligands. Upon expression of Fringe, Delta proteins are able to initiate Notch signaling, while Jagged proteins cannot.

The major question is: what is the mechanism by which the Notch activation complex exerts the pleiotropic effects that are observed in distinct cellular contexts?

Over the last several years many proteins have been identified that can physically interact with Notch^{IC}. However, a clear picture has not emerged to describe the mechanism of Notch signaling.

Deltex, an ►E3 ubiquitin ligase, is an exclusively cytoplasmic proline-rich protein localized to endosomal vesicles. It genetically acts as an enhancer of Notch signaling and has been shown to physically associate with Notch through the ankyrin repeat domain. As previously explained, data showed that Deltex ubiquitinates Notch preventing its degradation by sequestering it to endosomal vesicles.

Mastermind like-1 (Maml1) is an integral component of the Notch pathway whose function is poorly understood. Maml1 encodes a nuclear co-activator protein that binds to the ankyrin repeat domain of Notch proteins. It forms a trimeric complex with the intracellular domain of Notch and the DNA binding protein, CSL. It is thought that Mastermind functions, at least in part, by recruiting histone acetyltransferases such as p300.

CSL is the collective term for the mammalian counterparts to Su(H) and Lag1. CSL proteins are transcriptional regulatory proteins that repress transcription under non-induced conditions. Repression by CSL is thought to be mediated by a histone deacetylase (HDAC) complex containing n-CoR/Smrt. Upon ligand activation of Notch it is thought that Notch^{IC} translocates to the nucleus and interacts with Skip to displace the HDAC complex from CSL which leads to the formation of a transcriptional activation complex (Fig. 2).

Additional proteins have been identified that appear to genetically inhibit Notch signaling. These proteins are Dishevelled (Dsh), Numb and Ikaros. Dsh is a protein

with unknown biochemical function that is a component of the Wnt signal transduction system. Dsh has been shown to physically interact with the carboxy-terminal portion of Notch and appears to influence Notch signaling. Numb is a cytoplasmic protein that has homology to phosphotyrosine binding (PTB) domains and may provide a link to protein tyrosine kinase signaling cascades. The molecular basis of these interactions and the mechanism of inhibition of Notch signaling are not known. Additionally, it has been shown that Notch activation of target genes is perturbed by Ikaros, a transcriptional regulator required for development of all lympoid derived cells. This inhibition is the consequence of the ability of Ikaros to bind CSL consensus sequences. Proviral insertion mutagenesis experiments performed in $Notch^{IC}$ transgenic mice using Moloney murine leukemia virus showed an insertion into the Ikaros locus in 40% of tumors generated. These proviral insertions result in truncated Ikaros proteins, and those lacking DNA binding domains may then function as dominant negative inhibitors to full-length Ikaros by forming dimers. These dimers prevent Ikaros-mediated inhibition of Notch transactivation of target genes.

Clinical Relevance

T-Cell Leukemia

The human homologue of Notch1 (TAN1) was cloned from a T-cell acute lymphoblastic leukemia (T-ALL) that harbored the chromosomal translocation, t(7;9)(q34;q34.3). This translocation joins a portion of *NOTCH1/TAN1* to the *T-cell receptor β* locus. This translocation generates aberrant Notch proteins that lack most of the extracellular domain and are not tethered to the plasma membrane. As described above, these forms of Notch are thought to be constitutively active. This translocation can be identified in approximately 10% of all T-ALL cases. Additionally, 50% of human T-ALL exhibit activating Notch1 mutations in the heterodimerization domain and/or the C-terminal PEST region.

Cervical Carcinoma

In situ expression studies comparing normal and neoplastic cervical epithelium, showed an aberrant Notch expression in the development of ►cervical carcinoma. In normal cervical tissue, expression of Notch is limited to the basal layer of the stratified epithelium. However, in dysplastic tissues both Notch and its ligands' expression is increased compared to normal tissues, indicating that inappropriate activation of Notch signaling might play a role in the generation of cervical neoplasia. Approximately 99% of cervical neoplasms are positive for ►Human Papillomavirus (HPV) E6 and E7. HPV infection of cervical epithelial cells frequently leads to cellular transformation. HPV viral proteins, E6 and E7, transform cells, in part by targeting the tumor suppressors p53 and Rb for degradation. It has been demonstrated that E6 and E7 upregulate Notch and presenelin expression, and that growth of CaSki cells (cervical carcinoma cells expressing HPV16) are Notch-dependent. Additionally, the *Notch1* gene is an integration site for HPV16. Paradoxically, data indicate that Notch1 must be downregulated in invasive cervical cancers expressing E6 and E7, suggesting that Notch1 plays a positive role in early cervical carcinogenesis, but suppresses E6 and E7-mediated transformation in later stages of tumorigenesis.

B-Cell Leukemia

►Epstein-Barr Virus (EBV) is the etiologic agent of ►Burkitt lymphoma. The latent viral protein EBNA-2 is a transcriptional activator that functions by binding to host cell CSL proteins and displacing the HDAC repressor complex in an analogous manner to the model for $Notch^{IC}$. Therefore, in transformation of B-cells by EBV infection, EBNA2 may provide a function similar to $Notch^{IC}$ by usurping CSL proteins. Notch can induce the same phenotypic changes as EBNA2 in Burkitt lymphoma cells.

Mammary Carcinoma

Infection of mice with MMTV has been used as an insertional mutagen to identify genes that contribute to the generation of mammary carcinoma. Among the genes affected by such mutations is *Int-3*, a Notch gene family member now termed *Notch4*. The mutations result in aberrant expression of truncated Notch4 proteins comprising only the intracellular portion of the molecule. Additionally, in MMTV-neu/ErbB2 insertional mutagenesis studies, Notch1 insertions were found in 8% of tumors screened. Insertions were found in the genomic region between the transmembrane domain and lin-12 repeats. Furthermore, it has been demonstrated that the expression of constitutively active Notch1, Notch3 or Notch4 is sufficient to induce breast tumors in mouse models. Moreover, it was determined that loss of myc prevents the formation of MMTV-$Notch1^{IC}$ nonregressing mammary tumors. Additionally, it was recently shown that human breast tumor samples expressing high levels of Jagged1 have poor clinical outcome compared to low Jagged1 expressing samples.

Prostate Carcinoma

Jagged1 expression correlates with ►prostate cancer progression, metastasis and recurrence. Additionally, downregulation of Jagged1 expression results in growth inhibition of prostate cell lines, PC3, Du145, LNCaP and C4-2B. Taken together, these data suggest that deregulated Jagged1 expression may contribute to prostate cancer cell growth either by changing the microenvironment and increasing Notch activation in neighboring cells, via its downstream, PDZ-dependent

Notch/Jagged Signaling. Table 1 Evidence of Notch's function as an oncogene and tumor suppressor in human and mouse models

Evidence of the oncogenic potential of Notch	
Human cancers	*Genetic alteration*
Non-small cell lung carcinoma	Increased Notch3 expression via translocation (15;19)(15, 25)
T-ALL	Notch1 activating mutations (25, 72)
Ovarian serous carcinoma	Notch3 gene amplification (49)
Cervical carcinoma	Increased expression of activated Notch1 and Notch2 (75)
Mouse models of cancer	*Genetic alteration*
Brain cancer (choroid plexus)	Constitutively active Notch3 expression (14)
Breast cancer	Constitutively active Notch1, Notch3 or Notch4 expression (24)
T-ALL	Constitutively active Notch1 expression (3, 25)
Evidence of a tumor suppressor role for Notch	
Mouse models of cancer	*Genetic alteration*
Squamous cell carcinoma	dn MAML1 (52)
Basal cell carcinoma	Notch1 knockout (45)

signaling events in the cell in which it is expressed or bi-directionally.

Feline Leukemia Virus (FeLV) Induced T-Cell Leukemia

Infection of cats with replication competent Feline Leukemia Virus (FeLV) yielded T-cell leukemia that harbored recombinant FeLV that had transduced a portion of the feline *Notch2* gene. The transduced gene encodes a Notch2 protein analogous to those expressed in human T-ALL.

Additionally, aberrant expression and/or activation of the various Notch isoforms have also been recently implicated in contributing to non-small lung carcinoma, ovarian serous carcinoma, brain cancer, squamous cell carcinoma and basal cell carcinoma (Table 1).

Cross-Talk Between Signaling Pathways

Notch linked to cancer through its frequent mutation in T-ALL, can integrate with other pathways to accelerate oncogenesis. Like Wingless (Wnt) and ►Sonic Hedgehog (Shh), the Notch signaling pathway is essential in controlling both developmental processes and tumorigenesis. For example, in human and murine medulloblastoma, Notch and Shh synergize to promote tumor proliferation and survival. Also in ►medulloblastoma, Shh dependent tumor growth involves synergy with Notch and Wnt. Notch/Wnt crosstalk has been suggested in Melanoma, activation of Notch1 enhances primary melanoma cell growth and the potential for metastasis through β-catenin upregulation. An important positive oncogenic collaboration was also shown in breast cancer cells between Notch and Wnt.

Notch as a Potential Therapeutic Target

Due to the important role of Notch signaling in cancer development, it has been proposed that targeting the Notch signaling steps including receptor/ligand binding, release of $Notch^{IC}$ and downstream targets could have antitumor effects. One of the approaches used to inhibit Notch signaling is to suppress the γ-secretase-proteolytic step leading to the release of active $Notch^{IC}$. Inhibitors for γ-secretase have been studied for decades for their potential to block the formation of beta-amyloid peptide (Aβ) associated with Alzheimer disease. Aβ peptide is synthesized much in the same way that active $Notch^{IC}$ is generated, via a series of proteolytic cleavages, the final of which is cleavage of the precursor by γ-secretase. It has been demonstrated that γ-secretase inhibitors are capable of preventing Notch receptor activation and are currently being tested for their anti-tumor effects. Encouragingly, various γ-secretase inhibitors have been successfully used in mouse cancer models to inhibit tumorigenesis. Inhibition of tumor growth was demonstrated in xenografts of the ►Kaposi sarcoma cell line, SLK, upon injection of the tumor with a γ-secretase inhibitor, GSI-I. Additionally, intraperitoneal injection of a γ-secretase inhibitor, DBZ, inhibited epithelial cell proliferation in intestinal adenomas from $Apc^{-/-}$ mice and induced goblet cell differentiation. Currently, Merck is recruiting or has completed recruitment of patients for phase I clinical trial to test safety/tolerability and efficacy of a Notch inhibitor, MK0752, in relapsed or refractory T-ALL patients and advanced breast cancers (ClinicalTrials.gov Identifier: NCT00100152 & NCT00106145, respectively).

Nuclear Atypia

Definition

Abnormality of the cell nucleus that may be associated with a precancerous condition.

Nuclear Envelope Breakdown

Definition

NEBD; The nuclear envelope consists of two concentric lipid layers fused to one another that are punctured by nuclear pore complexes, which allow passive and regulated transport of proteins and RNA between the nucleus and cytoplasm. Underlying the inner lipid bilayer is the nuclear lamina, composed predominantly of polymerized intermediate filaments known as nuclear lamins. Nuclear envelope breakdown (NEBD) requires vesicularization of the lipid bilayers, depolymerization of the nuclear lamins to disassemble the nuclear lamina, and the falling apart of nuclear pore complexes. The best understood of these three processes, nuclear lamina disassembly, is caused by a multisite phosphorylation of the nuclear lamins. The number of kinases directly involved in depolymerization of nuclear lamins is unclear, however at least cyclin B1/CDK1 and ►protein kinase C are likely to be involved.

►G_2/M Transition

Nuclear Export Signal

Definition

NES; Amino acid sequence that when present in a protein in appropriate location confers the ability to be recognized by the nuclear export machinery to permit its translocation to the cytoplasm. Several amino acid sequences can act as NES. This domain targets its protein for export from the cell nucleus to the cytoplasm through the nuclear pore complex. The NES is recognized and bound by the transporting molecule family exportins.

►Snail Transcription Factors

Nuclear Factor-κB

Kunal Saigal, Francisco G. Pernas, Carter Van Waes
National Institute on Deafness and Other Communication Disorders and National Cancer Institute, NIH, Bethesda, MD, USA

Definition

Nuclear Factor-kappaB (NF-kappaB, NF-κB) represents a family of transcription factor proteins that regulate expression of multiple genes important in cell survival, host responses to injury and infection, and pathogenesis of various diseases, including cancer. Originally, the transcription factor was discovered as a bacterial lipopolysaccharaide (LPS) induced nuclear transcription factor regulating expression of kappa light chains in B lymphocytes. Currently, it is considered one of the major links between immunity, inflammation, and cancer. Aberrant activation of NF-κB has been linked with a variety of malignancies including head and neck squamous cell carcinoma, ►lung cancer, ►esophageal cancer, ►breast cancer, ►prostate cancer, ►pancreas cancer, ►colon cancer, ►cervical cancer, ►melanoma, and ►hematological malignancies, ►leukemias and lymphomas.

Characteristics

The original link between pathogens, NF-κB activation, and development of cancer was identification of REV-T, a transforming oncogene contained in avian ►retroviruses, which leads to reticuloendothelial lymphomatosis. Like its mammalian homologues (►REL A, REL B, cREL), it shares a C-terminal transactivation domain. In mammalian cells, the NF-κB family includes five known subunits: NF-κB1 (p105/p50), NF-κB2 (p100/p52), REL A (p65), cREL, and RELB (Fig. 1). Each subunit contains a 300 amino acid sequence in its N-terminus known as the REL homology domain. In addition, cREL, REL A, and REL B each contain a transactivation domain in their C-termini. NF-κB1 p105 and NF-κB2 p100 are initially expressed containing contiguous ankyrin repeats. Processing of NF-κB1 and NF-κB2 by the proteasome results in degradation of the ankyrin domains to produce the NF-κB p50 and p52 subunits. The NF-κB and REL subunits form homo- and heterodimers, excluding RELB, which appears to form only heterodimers. The most ubiquitous of these combinations is the p50/REL A heterodimer. In most cells in the resting state, these homo- and heterodimers remain predominantly in the cytoplasm in dormant form, complexed with inhibitor-κBs (IκBα, β, γ), which mask the nuclear localization sequence and DNA binding pocket.

Regulation

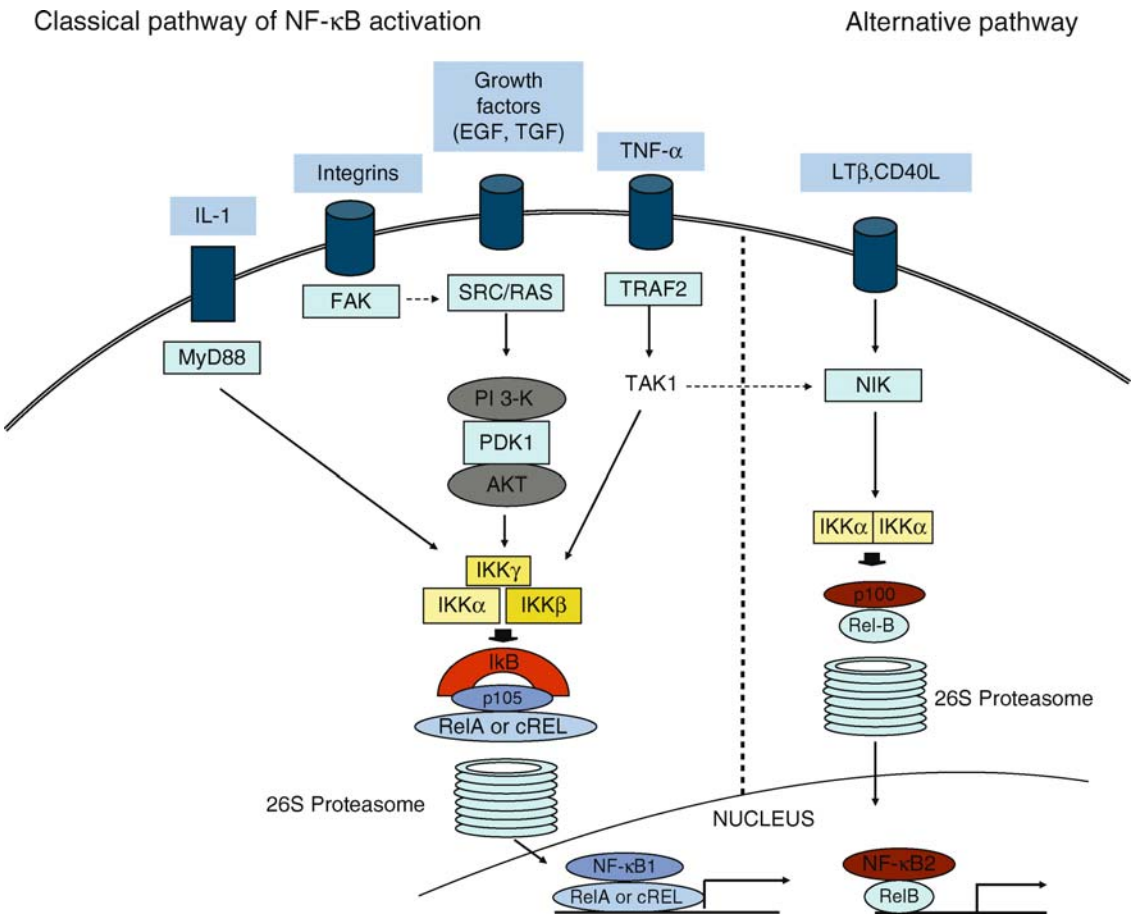
Activation of inhibitor-κB kinases (IKKs) by various cell stimuli leads to phosphorylation and subsequent ubiquitinylation of IκB molecules (Fig. 1). Ankyrin/IκB degradation by the ►proteasome results in exposure of the nuclear localization sequence and DNA binding sites of NF-κB and REL dimers, thus allowing nuclear translocation and DNA binding to 9–10 bp κB binding sequences in DNA of the promoter of target genes. Additional phosphorylations of some of the subunits or cofactors by IKK and other kinases, regulate whether bound NF-κB/REL complexes repress or transactivate target genes.

In a current paradigm, IKK and NF-κB activation is separated into the "classical" (canonical) and "alternative" (noncanonical) pathways (Fig. 1). The classical pathway is typically induced by inflammation, injury, infection, and cytokines such as tumor necrosis factor (TNF), or interleukin-1 (IL-1). It appears to be important for cell survival as well as for innate and adaptive immunity. The alternative pathway, which is activated by other TNF family members, has been implicated in regulation of survival of premature B lymphocytes and development of peripheral lymphoid tissue. In disease states such as cancer, infection, and inflammation, the canonical pathway is often aberrantly activated and NF-κB1/REL A are localized to the nucleus.

Clinical Relevance

Several viral genes which activate the IKK/NF-κB pathway have been identified in ►Epstein–Barr virus, human T cell leukemia virus, ►hepatitis B virus, ►hepatitis C virus, and human papillomaviruses, and have been implicated in their role in pathogenesis of ►Hodgkin disease, leukemias, ►hepatocellular carcinoma, and ►cervical cancer and head and neck ►squamous cell carcinomas. Chronic bacterial-induced ►inflammation by ►*Helicobacter pylori* and colonic flora in inflammatory bowel disease has been implicated in gastric and colon carcinomas.

NF-κB activation by chemical promoters and DNA damage is more widely involved in cancer development and ►progression. Examples of this include nicotine and other carcinogens in tobacco and the betel nut (areca) ►betel Quid, that have been linked to NF-κB activation in pathogenesis of malignancies of the lung as well as head and neck. In addition to such inducible effects, aberrant activation may result from mutation or overexpression of a variety of growth factor receptors (►EGFR, ►ErbB2, etc.), cytokines (►TNF-α, IL-1), cell adhesion molecules (►integrins), and signaling kinases (►RAS, ►BCR-ABL1), which can activate NF-κB via IKK, and promote molecular pathogenesis of epithelial and lymphoid malignancies. In addition to such endogenous stimuli, NF-κB may also be activated by exogenous stimuli, secondary to stress, hypoxia, chemotherapy, and radiation. Inducible activation by these factors



Nuclear Factor-κB. Figure 1 NF-κB activation. In the classical pathway, stimulation by IL-1, integrins, ErbB Family growth factors, and TNF-α leads to activation of an inhibitor-κB kinase (IKK) α, β, γ complex, which in turn leads to phosphorylation, and subsequent ubiquitinylation of IκB molecules. Following proteasome processing, the liberated complex NF-κB1/RELA or NF-κB1/cREL) translocates to the nucleus to promote target genes. In the alternative pathway, stimulation via ligands including CD40L and LTβ leads to activation of the intermediary NF-κB inducing kinase (NIK), an IKKα dimeric complex, and proteasome processing of P100/RELB to p52/RELB. TNF-α may also activate NIK in the alternative pathway. The liberated NF-κB2/RELB complex translocates to the nucleus to promote target genes.

can promote therapeutic resistance to chemotherapeutic agents, immune toxins (i.e., TNF), and radiation therapy.

NF-κB promotes expression of a diversity of genes involved in proliferation, cell survival, invasion, ►inflammation, and ►angiogenesis that have been implicated in cancer. These include genes crucial to cell proliferation and survival such as ►cyclin D (key in progression of cell cycle from G0 to G1 and S phase), and ►BCL-2 and ►IAP gene families (inhibit mitochondria-mediated ►apoptosis). Expression of NF-κB modulated angiogenesis factors such as GRO1, IL-8, and ►VEGF allow tumors to obtain sufficient neovasculaization for tumorigenesis. NF-κB-mediated alterations in expression or interaction of cell adhesion molecules (integrins, CAMs) and ►matrix metalloproteinases (MMPs) with matrix or other cells have been implicated cell migration, invasion, and metastasis.

With all of the above mechanisms by which NF-κB plays a role in cancer progression, inhibiting the transcription factor has become an important candidate for therapeutic investigation. As a result of its central role in inflammation, the first drugs to be used for cancer therapy and prevention and found to inhibit NF-κB were corticosteroids and ►nonsteroidal anti-inflammatory drugs (NSAIDs). Corticosteroids in combination with cytotoxic chemotherapy are now a mainstay of therapy in certain leukemias, lymphomas, and myelomas. NSAIDS, several of which inhibit IKK as well as arachidonic acid synthesis, have been shown to reduce development of inflammatory and heritable colon carcinomas in experimental models and clinical studies. Natural compounds such as ►curcumin, which comes from tumeric (a common Indian spice), have been shown to effectively inhibit NF-κB activation, and have been implicated in the

reduced incidence of colon cancer in India. Standard ►chemotherapy agents, such as ►cisplatin, have been shown to have cytotoxic activity as a result of inhibition of NF-κB activation, in addition to their DNA damaging capability. Recently, agents more specifically targeting the proteasome, IKKs, and other upstream kinases have been investigated. The 26S ►proteasome inhibitor ►bortezomib (VELCADE, Millennium pharmaceuticals) when used alone or in combination with other therapies has been shown to have preclinical and phase I/II clinical activity in ►multiple myeloma, mantle cell lymphomas, ►Waldenstrom macroglobulinemia, ►lung cancer, and head and neck ►squamous cell carcinoma. It is currently approved for treatment of patients with therapy-resistant multiple myeloma. Because of remaining concern regarding the broader effects of proteasome or other NF-κB inhibitors on its physiologic roles in immunity, inflammation, and cellular homeostasis, the role of these agents remains investigational.

Aberrant and inducible activation of NF-κB via multiple signaling pathways has been observed in multiple human malignancies. While the specific role it plays in the progression of each of these diseases is yet to be fully elucidated, its activation in most forms of cancer points to its overall importance in cancer. As more is learned about the molecular regulation of NF-κB and its target oncogenes, novel targeted therapies may allow improvement in current treatment outcomes.

Nuclear Hormone Receptors

Definition

Are ligand-activated transcription factors that regulate gene expression by interacting with specific DNA sequences upstream of their target genes. Upon ligand binding, these cytosolic proteins translocate to the nucleus to bind as dimers to response elements in the promoter regions of target genes and stimulate or suppress gene transcription (e.g. retinoids bind to retinoic acid receptors and retinoid X receptors, which bind as dimers to ►retinoic acid response elements and retinoid X response elements in the promoters of retinoid-responsive genes).

►Carotenoids

Nuclear Imaging

Definition

The use of photon-emitting radionuclides to visualize tumor boundaries.

Nuclear Localization Signal

Definition

NLS; Is an amino acid sequence which acts like a “tag” on the exposed surface of a protein. This sequence is used to confine the protein to the cell nucleus through the nuclear pore complex and to direct a newly synthesized protein into the nucleus via its recognition by cytosolic nuclear transport receptors.

Nuclear Magnetic Resonance

Definition

NMR.

►Magnetic Resonance Imaging

Nuclear Magnetic Resonance Spectroscopy

Definition

A method that uses the nuclear isotopes of atoms to determine the tertiary structure of a molecule, generally in aqueous solution.

►Structural Biology

Nuclear Pore Complex

Definition

NPC; A large multiprotein complex, embedded in the double membrane nuclear envelope, which provides the sole channel for nucleocytoplasmic trafficking of ions, small molecules, proteins, RNAs, and ribonucleoprotein particles in eukaryotic cells through both a passive diffusion and an energy-dependent signal-mediated active transport.

►Major Vault Protein

Nuclear Receptor

Definition

Nuclear receptors are ligand-inducible transcription factors, such as receptors for ⇒ thyroid hormones and ⇒ steroid hormones, retinoids (⇒ ►retinoic acid) and ⇒ ►vitamin D. They typically form homo- or heterodimers that bind to specific DNA binding elements.

►Estrogen Receptor

Nuclear Translocation

Definition

Transport of proteins through nuclear pores (usually by a specific transport system) into the nucleus, enables transcription factor proteins to get access to the nucleus.

Nucleolin

Atsuko Masumi
Department of Safety Research on Blood and Biological Products, National Institute of Infectious Diseases, Musashimurayama-shi, Gakuen 4-7-1, Tokyo, Japan

Definition

Is a ubiquitous, nonhistone nucleolar phosphoprotein of eukaryotic cells and is present in abundance at the sense fibrillar and granular regions of the nucleolus. Nucleolin is also able to localize in the nucleus, in the cytoplasm, and at the cell surface. Nucleolin is an RNA-binding protein and multifunctionally involved in many cellular processes, including ribosome biogenesis, the processing of ribosomal RNA (rRNA), mRNA stability, transcriptional regulation, and cell proliferation, and it is also a downstream target of several signal transduction pathways.

Characteristics

Regulation of Nucleolin Function as a Phosphoprotein

The multiple activities of nucleolin are regulated by covalent modifications, most notably phosphorylation, methylation, proteolysis, and ADP-ribosylation. Nucleolin function is coupled to growth control by its phosphorylation. Active rRNA transcription is positively correlated with highly phosphorylated nucleolin. In growing cells, casein kinase II (CKII) phosphorylates nucleolin. Phosphorylation by CKII enhances nucleolin (~110 kDa molecular size) as a substrates for protease to produce smaller fragments 30 and 72 kDa proteins, which trigger rDNA transcription by RNA polymerase I. Both CKII activity and nucleolin phosphorylation are enhanced after stimulation with mitogens, in regenerating rat liver after partial hepatectomy and in tumor cells. In addition, nucleolin phosphorylation by CKII and rRNA synthesis is dependent on hormones, such as dexamethasone and androgen, and growth factors. Major phosphorylation sites of nucleolin are serine and threonine. Serine phosphorylation is mediated by CKII and related to nucleolar function in the control of rDNA transcription, and threonine phosphorylation is linked to cdc2 kinase during mitosis through condensation of nucleolar chromatin, leading to increased rDNA transcription by RNA polymerase I in the G1 to S phase of cell cycle. Thus, sequential CKII and cdc2 phosphorylation modulates nucleolin function in regulating nucleolar structure and activities between interphase and the mitotic phase during cell growth.

Nucleolin Function of Cell Cycle and Ribosomal Biogenesis

Nucleolin levels are highest in tumors or other rapidly dividing cells. Nucleolin is necessary for cell

proliferation and nucleogenesis and is downregulated during differentiation. In nondividing cells, nucleolin level is low and is preferentially associated with chromatin. In G1 phase, nucleolin decondenses the chromatin by replacing histones. Hormones such as ►androgen and growth factors regulate the expression and phosphorylation of nucleolin by CKII, resulting in increased DNA transcription by RNA polymerase I in the G1 to S phase of cell cycle. Nucleolin binds to the 5′ end of the external transcribed spacer region of preRNA and participates in the preRNA processing along with fibrillarin and small nucleolar RNA. The 48S RNA is rapidly cleaved to yield the mature 18S, 28S, and 5.8S rRNA species during the transcription of rDNA by RNA polymerase I. During ►mitosis, nucleolin is phosphorylated by cdc2 kinase and condensates the chromatin. The nucleolus may be involved in functions other than ribosome biogenesis. The functions of nucleolin are the result of assemblies of nucleolin with other factors to form large complexes which induce or regulate cell growth and cancer cells.

The Role for Nucleolin in Cancer

Role of Nucleolin in B-cell Lymphomas

Nucleolin is a subunit of the ►transcription factor LR1 (switch region binding protein), which activates expression of the c-myc gene and the EBNA-1 (►Epstein-Barr virus nuclear antigen 1) gene, which promote cells to malignancy. LR-1 is a B-cell-specific DNA-binding protein that contains two polypeptides of 106 kDa and 45 kDa. The 106-kDa component of LR-1 is nucleolin. Although nucleolin is ubiquitous, LR1–DNA binding activity is ►B cell specific. LR-1 is present only in activated B cells, not resting B cells. LR-1 regulates the promoter of Epstein-Barr virus, which produces EBNA-1 protein. Nucleolin that is component of LR-1 may contribute to cell-type specific transformation by Epstein-Barr virus.

Nucleolin's Interaction with Cellular Protein, p53, and Rb

Nucleolin is directly involved in two major cellular tumor suppressors, ►Rb and ►p53. The p53 gene is commonly mutated in human cancer cells. The p53 protein has a critical role in cellular responses to DNA damage and other stresses by inhibiting proliferation or inducing G1 arrest, resulting in program cell death. Heat shock induces nucleolin to relocalize from nucleus to nucleoplasm. This nucleolin relocalization is dependent on p53 and cellular stress, including formation of p53–nucelolin complex. Nucleolin relocalization and complex formation are required the p53 C-terminal regulatory domain. Nucleolin–p53 interaction indicates the p53-dependent mechanism in which cell stress mobilizes nucleolin to cause the transient replication inhibition and DNA repair. In addition, ribosomal protein L26 (RPL26), nucleolin, and p53 protein itself bind to the 5′ UTR of p53 mRNA. p53 translation and induction after DNA damage is controlled by these factors. Increased levels of RPL26 enhance DNA-damage-induced p53 translation and its cellular function, such as G1 arrest and ►apoptosis. In contrast, nucleolin suppresses the translation and induction of p53 after DNA damage. Nucleolin has an opposite effect of p53 and RPL26.

High risk ►human papillomaviruses (HPVs) play a central etiologic role in the development of ►cervical cancer, and in this process the deregulated expression of high-risk HPV oncogenes is a critical event. Cervical cancer represents the second most common malignancy in women, with an annual incidence of ~500,000 new cases, and nucleolin is involved in HPV18-induced cervical carcinogenesis. Nucleolin controls the chromatin structure of the HPV18 enhancer in vivo and is directly linked to HPV18-induced cervical cancer formation. Nucleolin binds to the HPV18 enhancer in a sequence-specific manner. Nucleolin is a phosphoprotein whose synthesis positively correlates with cell division rates. When cells are synchronized to the G0, G1, S, and G2 phases of the cell cycle to detect nucleolin DNA binding to HPV18 enhancer, nucleolin binding is detected predominantly in S phase of cell cycle. The E6 and E7 oncoproteins of HPV18+ exert their carcinogenic potential by inactivation of the tumor suppressors pRB and p53. E6 and E7 oncogene transcription are blocked by nucleolin downregulation. Nucleolin expression is altered in HPV18+ precancerous and cancerous tissue from the cervix uteri. Nucleolin distributes mostly diffuse in the nuclei of normal squamous and glandular epithelial cells, however, it is speckled in the nuclei of HPV18+ squamous cell carcinoma.

Rb is a prototypical ►tumor suppressor, frequently inactivated in certain types of human cancer. There are many molecular mechanisms of Rb-mediated tumor suppression to understand the cancer cell proliferation. Nucleolin is associated with Rb in intact cells in the G1 phase of the cell cycle, and the complex formation is mediated by the growth inhibitory domain of Rb. Interaction with Rb inhibits the DNA binding activity of nucleolin for the HPV18 enhancer, resulting in Rb-mediated repression of HPV18 oncogenes. Rb controls the interaction of nucleolin with the HPV18 enhancer and the nucleolin-dependent activation of transcription of E6 and E7, oncoprotein of HPV18. Nucleolin could be a target molecule for the therapy of HPV18+ carcinomas of the cervix uteri.

Nucleolin's Interaction with Other Factors

Nucleolin has been found to interact with several RNA/DNA/protein targets within the nucleus, cytoplasm, and on the cell surface of several cell lines. From these different interactions, a function for nucleolin in different processes was deduced. Nucleolin also binds to Acharan sulfate (AS), isolated from the giant African snail *Achatina fulica*, responsible for inhibitory effect

of tumor growth. AS inhibits tumor growth by binding the nucleolin protein on the surface of cancer cells.

Nucleolin interacts with transcription factors and regulates negatively and positively. The mammalian ►Myb family of oncoproteins is composed of three transcription factors, A-Myb, B-Myb, and c-Myb. c-Myb is expressed mostly in hematopoietic cells and regulates their proliferation and differentiation. Nucleolin binds DNA-binding domain of c-Myb and A-Myb and downregulates Myb-mediated transcriptional activity. Interferon regulatory factor-2 (IRF-2) acts as a positive modulator for interferon-stimulated response element (ISRE)-like sequences such as the promoter H4. The nucleolin acts as a positive modulator of IRF-2-dependent transcriptional activation through an association with IRF-2. IRF-2 plays an important role in cell growth regulation through H4 gene activation and has been shown to be a potential oncogene. IRF-2 is acetylated by histone acetylase PCAF or p300 and acetylation of IRF-2 regulates cell growth by activation of H4 promoter in NIH3T3 cells. Nucleolin associates with an acetylated IRF-2, but its binding activity with nonacetylated IRF-2 is very low. For H4 gene regulation by IRF-2, nucleolin acts as an oncogenic activator via transcriptional activation, suggesting the cooperation of IRF-2 and nucleolin in cell growth regulation. IRF-2 binds H4 promoter with PCAF and nucleolin in growing NIH3T3 cells; however, in growth-arrested cells, nucleolin binding to H4 promoter is much lower compared to growing cells. Nucleolin binds to acetylated IRF-2 and IRF-2/PCAF/nuclelin complexes in turn stimulate the activation of gene transcription, which drives cell growth.

From proteomic analysis, many proteins are identified from the isolated nucleolin-binding complex. Nucleolin binds to the ribonucleoprotein (RNP) complex mainly through the sequence-specific protein–RNA interaction. As nonribosomal protein which binds nucleolin, B23, hnRNP U, DNA helicase (Ku), eukaryotic initiation factor 2(eIF-2), and nuclear factors 90 are identified.

Nucleolin is also induced by ►Myc (c-myc protein product), which is a transcription factor of basic helix-loop-helix zipper (bHLH-Zip) family. c-myc is an immediate early response gene following mitogen stimulation and regulated by tumor suppressor genes, tyrosine kinase receptors, and growth factors and known to be induced in S phase of cell cycle. Myc activates the nucleolin promoter via E-boxes located in intron I, resulting in increase of nucleolin. Nucleolin is implicated in the maturation of ribosomal RNAs with other c-myc-target factors such as a cofactor of RNA polymerase III BN51, indicating of the association of the ribosome biogenesis with Myc.

Nucleolin is a multifunctional protein which located in the nucleolus, nucleus, cytoplasm, and at the cell surface and is abundant in proliferating and cancer cells. Nucleolin is a cell cycle regulated transcriptional activator. There is much information about nucleolin that correlates with normal and cancer cells. Further, function of nucleolin should be clarified in future because of its abundance in the nucleolus.

Nucleolus

Definition

Plural nucleoli; Is a sub-organelle of the cell nucleus. A main function of the nucleolus is the production and assembly of ribosome components (RNA, proteins). Within the nucleus are one or more nucleoli. The nucleolus is roughly spherical, and appears as a mass of densely stained granules and fibers under an electron microscope. It consists of nucleolar organizers. They are specialized regions of some chromosomes with multiple copies of genes for ribosome synthesis, along with a considerable amount of RNA and proteins representing ribosomes in various stages of production. An average, healthy cell can produce up to 10,000 ribosomes per minute.

►G2/M Transition

Nucleophile

Definition

Is a reagent that forms a chemical bond to its reaction partner (the electrophile).

Definition

Nucleoporins are the main components of the nuclear pore complex in eukaryotic cells, and mediate bidirectional nucleocytoplasmic transport, especially of mRNA and proteins. Defects in nucleoporins, e.g., overproduced or involved in ►chromosomal translocation, may affect nucleocytoplasmic transport and cell function, leading to cell transformation and cancer.

Characteristics

The Nucleocytoplasmic Transport

The nucleus is the defining feature of the eukaryotic cell. Unlike their prokaryotic counterparts, eukaryotic cells separate the nuclear synthesis of DNA and RNA from cytoplasmic protein synthesis with a barrier termed the nuclear envelope (NE). The NE is perforated by large proteinaceous assemblies, called nuclear pore complexes (NPCs), which are multiprotein channels that span the double lipid bilayer of the NE and act as the sole gatekeepers controlling the exchange of material between the two locales (Fig. 1a). In yeast, half of the NPC is made up of a core scaffold, which is structurally analogous to vesicle-coating complexes. NPCs are freely permeable to small molecules (such as water and ions), but they restrict the movement of larger molecules (such as proteins and RNAs) across the NE. The selective barrier for transport is formed by large numbers of proteins with disordered regions that line the inner face of the scaffold. To overcome this barrier, macromolecules carry specific signals that allow them to access the nucleocytoplasmic transport machinery of the cell. In this way the cell ensures that only selected macromolecules can travel between the nucleus and cytoplasm. Factors that are important for nuclear transport can be divided into four categories: the proteins of the NPC (nucleoporins), the Ran►GTPase, transport receptors called karyopherins (or importins/exportins) that recognize cargoes for transport, and specialized factors that promote transport of some

Each circle represents a Nup position with green for symmetrical FG Nups, blue for strictly nuclear FG Nups, red for strictly cytoplasmic Nups, gray for non-FG Nups, and purple and purple stripes for different integral membrane proteins associated with the NPC (Rout MP et al. (2000) J Cell Biol 148:635).

protein/RNA complexes. Macromolecular transport in or out of the nucleus generally begins with recognition of the transported cargo by a receptor, followed by docking and movement through the NPC. Karyopherins can generally be thought of as superhelices with an inherent flexibility. The RanGTPase and its regulators control the rate at which cargo is moved in and out of the nuclear pore, as well as the loading and unloading of cargoes.

Nucleoporins

Nucleoporins (Nups) are the individual protein components of the NPC (Fig. 1b). Proteomic analyses of the mammalian NPC have estimated 30–50 Nups, many of which are functionally conserved from yeast to mammals. Nups can be divided into two families: pore membrane proteins (Poms) and FG nucleoporins. Poms are membrane-spanning integral proteins specific to the pore membrane. All of the FG nucleoporins share domains consisting of repeated phenylalanine/glycine (FG), which are separated by spacers that are either highly charged or rich in polar residues. The repetitive motifs are probably distantly related to one another and are predicted to assume a β-sheet conformation. Two classes of FG repeats, GLFG and FXFG subtypes, have been identified. A number of nucleoporins contain one or the other or a combination of these repeats. In addition to the shared repeats, each of the FG nucleoporins has distinct domains that appear to mediate localization and function, such as the coiled-coil domains found in Nup49, Nup84, the leucine zipper found in Nup214, the zinc finger domain found in Nup153, the RNA binding domain included in Nup98 or Nup145. The Nup98 and Nup96 proteins are encoded by a single gene. Much evidence showed that nucleoporins play important roles in docking, translocation and releasing of the cargo. Except for roles in transport, several studies in yeast have demonstrated that nucleoporins are essential for mediating ►epigenetic control of transcription. For example, Nup60 and Nup145 are found to be required for full repression of HMR locus in yeast.

Nucleoporins and Cancer

To date, Nups are reported to be involved in several types of cancers through different mechanisms. Firstly, Nups are shown to be overexpressed in cancer cells. For example, Nup88 was shown to be upregulated in a broad spectrum of tumors. Nup88 was similarly enhanced in severe dysplasias and in situ carcinomas of organs such as colon, stomach, breast, and prostate. Conversely, Nup88 was either sporadic or not detectable in most benign tumors and hyperplasias. In normal adult tissues, Nup88 was occasionally noted in sites such as colonic crypts, bronchial mucosa, and fallopian tubes. However,

whether Nup88 overexpression was simply the result of increased nucleocytoplasmic transport required to meet the increased demand of proteins by transformed cells, or Nup88 might play a role in ►carcinogenesis, remained obscure. Secondary, Nups are involved in ►chromosomal translocations which are predominantly found in ►leukemia (Table 1). The t(7;11)(p15;p15.5) was the first rearrangement discovered in patients with ►acute myeloid leukemia (AML), while the resultant Nup98–HoxA9 was the first fusion protein that was found to involve a nuclear-pore protein. So far the Nup98 has been reported to fuse with at least 20 partner genes in leukemia having 11p15 translocation. An interesting finding is that, about 50% of Nup98 fusion partners are ►homeobox domain (HD)-containing transcription factors. In addition, the non-homeobox fusion partners do not have DNA binding domain, but all bear a putative protein-protein interaction motif, a feature also shared by HD and suggestive of a possible common mechanism. Nup214 has also been reported to be fused to several partners, e.g., DEK, SET in AML and ABL1 in acute lymphoid leukemia (ALL). Interestingly, both Nup98 and Nup214 fusion proteins retain the FXFG repeat region that is characteristic of several nucleoporins. Normally, the FXFG repeats help to regulate the nucleocytoplasmic transport of proteins and RNAs as well as function as docking sites for the karyopherins. One model for the mechanism by which Nup98 and Nup214 fusion proteins promote leukemogenesis is that the FXFG repeats act as protein–protein interaction domains that allow the fusion protein to interact with other transcription factors and act as transcriptional activators.

Changes in nuclear transport machinery can markedly alter cellular function and potentially promote tumorigenesis. For example, nuclear mislocalization of ►nuclear factor κB as a result of IκB degradation and improper acetylation by ►p300, mislocalization by activated AKT, and nuclear localization and activation of the transcriptional activator ►β-catenin, can facilitate tumorigenesis.

Definition

Are, complexes formed by a core particle of eight histone proteins which are surrounded by 147 bp of double-stranded DNA, are the basic elements of the chromatin in eukaryotic cells.

Characteristics

Structure and Function of Nucleosomes

About 99% of human DNA is localized in the nucleus of the cells where it is organized in a multistep manner. In its secondary structure, chromatin is arranged as a chain of nucleosomes. These consist of a central protein component formed by an octamer of the double-represented histone aggregates H2A-H2B and H3-H4. Hundred and forty seven base pairs of double-stranded DNA are twisted around this complex with 14 defined fixing sites and build the disk-like nucleosomes with a molecular weight of ~206 kDa. Thereof nearly half is part of the histones and half of the DNA component. Neighboring nucleosomes are connected by so-called linker DNA, which varies between 10 and 100 bp. A further histone H1 is located at these linking sites outside of the nucleosomes and stabilizes the chromatin chain in its tertiary structure as chromatin fiber.

Beyond the organization and stabilization of the DNA, the arrangement in multinucleosomal order plays an essential role for the regulation of the transcription of genetic information, for the replication and for repair processes. The access of transcription factors to relevant DNA sequences is mainly coordinated by nucleosomal histones which can be modified at their tails by acetyl-, methyl-, phosphor-, ubiquitin-, and ADP-ribose groups. Histone acetylation leads to decondensation of the chromatin, unfixing of intra- and internucleosomal connections, and promotes the transcription process, whereas deacetylation (►Histone deacetylases) and condensation suppress it. Further, genetic and ►epigenetic modifications of the DNA may contribute to the regulation of the interaction between transcription factors and specific promoter regions, too.

The active involvement of DNA in transcription processes requires a flexible and dynamic structure of the nucleosomal organization which is enabled by ATP-dependent chromatin-remodeling factors. These promote the liberation of the DNA from its close connection to the histones by disrupting the contacts, transferring the histone octamer to another DNA molecule, or sliding the core particle along the DNA.

Origin of Circulating Nucleosomes

As small amounts of nucleosomes are also found in blood of healthy adults, ►Apoptosis during physiological cell regeneration is thought to be a major source of nucleosome release. Although most of liberated nucleosomes are engulfed and digested by ►macrophages and neighboring cells, a part of them reaches the blood circulation (►Circulating nucleic acid). In situations of enhanced cell death such as during degenerative, autoimmune, inflammatory, ischemic, traumatic and toxin-mediated diseases, or in malignant tumors, this elimination system seems to be overloaded or impaired resulting in higher levels of circulating nucleosomes in blood. Depending on the type and intensity of the cell damaging stimulus as well as on the type and energy level of the affected cells, various cell death modes can lead to the cellular demise such as apoptosis, oncosis, or mixed forms between these extreme forms. Because most of the DNA is present in blood as small mono- and oligonucleosomal fragments of 200, 400, 600, and 800 bp, apoptosis, which is associated with internucleosomal cleavage of the chromatin by activated endonucleases, is assumed as a major mechanism of nucleosome liberation. In contrary, oncosis produces high molecular weight DNA fragments released into blood after acute damaging events. As a further mechanism, active secretion of nucleosomes by lymphocytes is in discussion.

Metabolism of Circulating Nucleosomes

Generally, cell-free DNA (►Circulating nucleic acids) can circulate in blood as naked DNA, associated with histones in nucleosomes, bound to other plasma proteins, or packed in apoptotic bodies. Although the exact contribution of each form may vary inter- and intraindividually, the main part of the circulating DNA was shown to be organized in multimeric complexes as mono- and oligonucleosomes.

Hemodialysis experiments which produce a considerable release of nucleosomes from lymphocytes have revealed that nucleosomes are removed in vivo from circulation in a biphasic, saturable, and concentration-dependent manner with an initial half-life of 4 min. The degradation and elimination of nucleosomes is thought to be exerted by various systems:

- Intraplasmatic degradation by circulating endonucleases
- Intraplasmatic immunological complexing by anti-nucleosome-antibodies
- Phagocytosis and lysosomal degradation by cells of the reticulo-endothelial system
- Metabolization of nucleosomes in the liver
- Direct renal elimination in form of liposomes

During acute ►inflammation, nucleosomes may bind to acute phase proteins which delay the elimination process.

Relevance of Circulating Nucleosomes

The role played by nucleosomes in the pathogenesis of diseases is only partially known. In systemic lupus erythematodes, the high antigenic potential of circulating nucleosomes in blood or on the surface of antigen-presenting cells leads to the early production of antinucleosome-antibodies. Complexes of nucleosomes and these antibodies were found to aggregate at the glomerular basal membrane in the kidneys and to promote the disease ►progression.

In tumors, circulating nucleosomes are suspected to carry metastatic information as the transfection of DNA to mice resulted in the generation of new tumors. Further reports suggest an important role of nucleosomes for the evasion of tumor cells from immunosurveillance by inhibition of ►natural killer cell-mediated tumor cell lysis. Finally, nucleosomes liberated from tumor cells are reported to stimulate the expression of interleukin-8 in endothelial cells which promotes the local ►angiogenesis in the tumor tissue and supports tumor progression.

Clinical Aspects of Circulating Nucleosomes in Blood

In recent years, several enzyme linked immunosorbent assays (►ELISAs) were developed to quantify circulating nucleosomes in serum, plasma, and other body fluids using mainly monoclonal mouse antibodies directed specifically against the DNA and histone component, respectively. It is noteworthy to point out, that a good correlation between a nucleosome assay and the current "golden standard" for DNA quantification by real time ►PCR was found, suggesting that clinical results obtained by nucleosome or DNA measurements are quite comparable. Although most clinical studies focus on the quantification of DNA amount in plasma and serum, several studies have analyzed the relevance of circulating nucleosomes for diagnostic, staging, and prognostic purposes in cancer diseases as well as in noncancer diseases. As nucleosomes are nonspecific cell death products, they are supposed to appear in circulation in various acute and chronic diseases.

Circulating Nucleosomes in Noncancerous Diseases

Levels of nucleosomes in plasma and serum were found to be elevated in patients with acute infections as compared with healthy individuals and correlated with ►C-reactive protein values. Another study reported elevated nucleosomal levels in sera of septic patients and a strong correlation to the severeness of the disease.

Further, nucleosome levels were elevated in sera of patients after cerebral stroke, particularly in patients with extended volumes of stroke lesions. During the first week after stroke, the levels increased faster and stronger in patients with severe functional deficits than in those with only slight deficits. In addition, nucleosomes showed independent prognostic value for the 1-year recovery after acute stroke.

High nucleosome levels were observed in patients with various autoimmune diseases, too. Because anti-nucleosome-antibodies are found only in patients with systemic lupus erythematodes, it was assumed that nucleosomes may undergo specific qualitative processing, e.g., in antigen-presenting cells to achieve its high antigenicity in this disease.

Similarly, elevated concentrations cell-free DNA were reported in sera of patients with trauma, stroke, burns, graft versus host reaction (graft-versus-host disease) after transplantation, and exhaustive exercise.

Circulating Nucleosomes in Diagnosis and Staging of Cancer Disease

Several studies found higher nucleosome levels in individuals with cancer diseases, particularly in those with advanced stages. A comprehensive study analyzed sera levels of 590 patients with cancer disease including colorectal (►Colon cancer) and various other gastrointestinal cancers (►Gastrointestinal tumors), ►lung cancer, ►breast cancer, ►ovarian cancer and other gynecologic cancers, renal and prostate cancer (►Prostate cancer, clinical oncology), and lymphoma, as well as of the relevant organ-specific benign diseases and of healthy individuals. Nucleosome concentrations in sera of healthy donors were generally fairly low. In contrast, pretherapeutic serum levels in various malignancies were significantly higher. However, various benign diseases, particularly infectious diseases, tended to have elevated serum levels of nucleosomes, too, limiting the diagnostic capacity for cancer disease. While nucleosome levels significantly distinguished between healthy donors and malignant diseases, the difference between benign and malignant diseases did not reach the level of significance in general, but only in subgroup of lung cancer. Among the various cancer types, medians, percentiles, and ranges of nucleosome values were comparable, but lung cancer was associated with significantly higher levels and prostate cancer with lower ones. Regarding tumor ►staging, nucleosome values were found to correlate with tumor stage and the presence of distant metastases only in patients with ►gastrointestinal cancers, in other subtypes there was only a tendency or no correlation at all. In the contrary, in patients with lung cancer and breast cancer, high nucleosome values often were observed already in early stages. No association was found between nucleosome levels and lymph node involvement, cell differentiation (Tumor ►grading), age or gender.

Similar results concerning the diagnostic capacity of nucleosomes or cell-free DNA were obtained

by other studies which, however, mainly analyzed only the difference between cancer patients and healthy donors. Heterogeneous results were obtained concerning the correlation of nucleosomes or cell-free DNA with tumor stage.

Circulating Nucleosomes in Prognosis of Cancer Disease

The prognostic relevance of circulating nucleosomes or cell-free DNA is still in discussion. While some studies reported a prognostic value of nucleosomes or DNA in patients with lung cancer and breast cancer, others could not confirm these findings in the same tumor types. Reasons for the discrepant results may be found in the low number and the heterogeneity of the patients investigated as well as in differences concerning the statistical analysis and the consideration of other relevant prognostic factors. In a large study on 300 patients with advanced ►non-small cell lung cancer, pretherapeutic serum levels of nucleosomes had prognostic impact in the univariate analysis, while it did not show independent prognostic information when other clinical and biochemical markers were included in multivariate analysis.

Circulating Nucleosomes in Therapy Monitoring of Cancer Disease

During systemic cytotoxic therapies such as chemotherapy (►Chemotherapy of cancer, progress and perspectives) and radiotherapy (►Ionizing radiation therapy), the changes in the courses of circulating nucleosomes indicate the response to the therapy. Several studies have shown in various cancer types that strongly decreasing levels were mainly found in patients with remission of tumor disease whereas constantly high or even increasing values were associated with progressive disease. Independent from these general observations, nucleosome levels showed an immediate increase during the first days after start of therapy reaching a maximum after 2–5 days followed by a rapid decrease. These kinetics were observed in various cancers during chemotherapy, radiotherapy and ►immunotherapy. The courses were influenced by the spontaneous, and the therapy-induced release of nucleosomes, and the elimination capacity from circulation of the individuals. Although nucleosomes are not specifically liberated only by tumor cells but may also be the result of the cell death of other cells with high proliferation rates, lung tumor cells have shown to be more susceptible to systemic therapy in vitro than physiological bronchoepithelial cells.

The early nucleosomal course showed significant differences between patients with the favorable and nonfavorable outcome after therapy. A comprehensive study on more than 300 patients with advanced non-small cell lung cancer patients revealed that patients with clinical remission during chemotherapy initially started from lower nucleosome values, had lower maximum values and a more complete elimination of nucleosomes from circulation at the end of the first week of therapy than patients with progressive disease. When nucleosomes were combined with the more specific lung cancer biomarker (►Serum biomarkers) CYFRA 21-1, the nonresponse could be anticipated in about 30% of progressive patients with a specificity of 100% already after the first course of therapy. This information would help to change the therapy earlier than by currently available imaging techniques in 30% of nonresponding patients and may contribute to increase the therapeutic efficacy. Similar results were obtained in smaller studies on colorectal and pancreatic cancer (►Pancreas cancer, clinical oncology) during chemotherapy and radiotherapy.

Altogether, levels of nucleosomes are elevated in sera of cancer patients when compared to healthy controls. However, due to elevations of nucleosome levels in patients with benign diseases relevant for differential diagnosis, they seem not to be suitable for cancer diagnosis. Although nucleosomes showed prognostic relevance in some univariate analyses, their independent value in multivariate models will have to be elucidated further.

Most informative are circulating nucleosomes for the monitoring of anticancer therapy, particularly for the early estimation of therapy efficacy.

Nucleotide Base

Definition

One of four compounds residing between the two strands of DNA which makes up the genetic code by sequence arrangement.

►DNA Damage

Nucleotide Excision Repair

W. Glenn McGregor
University of Louisville, Louisville, KY, USA

Definition

NER; Is a complex biochemical mechanism that recognizes alterations in the chemical structure of DNA due to base modification by physical agents (most notably ►ultraviolet radiation) or endogenous or exogenous chemicals. After recognition of the alteration in the structure of DNA, the damage is removed by excision of the oligonucleotide that contains the damage. The resulting gap is filled in by DNA polymerase using the complementary (undamaged) strand as template and finally ligated. The process is essentially error-free. There are at least 27 polypeptides required to complete the recognition, excision and gap-filling phases.

Characteristics

NER was initially characterized in *E. coli* in the 1960s and was identified by the ability of wild type bacteria to remove ultraviolet light (UV)-induced photoproducts from large molecular weight DNA. The kinetics of this process correlated well with the resumption of DNA replication and led to the idea that removal of such damage was directly related to the recovery of DNA synthesis and improved survival. Since that time, NER processes in mammalian cells have been documented by a great number of cellular and molecular biology studies. The dissection of the pathway in eukaryotic cells has been greatly facilitated by the availability of mutant cell lines, many of which are derived from individuals who are defective in some aspect of NER and are consequently cancer-prone. During the 1990s, all of the central factors involved in NER were cloned, and the basic "cut and refill" reactions have been reconstituted in vitro from purified components. Despite these advances, however, many important aspects of the regulation of NER and its integration with other basic cell biology processes remain to be elucidated. For review, see [1,2].

Cellular Regulation

NER is a versatile and sophisticated pathway for the removal of DNA damage induced by a variety of environmental and endogenous factors. One of the most relevant, and best studied, DNA damaging agents is UV light, which induces dimerization of adjacent pyrimidine bases. The major products of this photochemical reaction (hence the term "photoproducts") are cyclobutane pyrimidine dimers (CPD) and 6–4 pyrimidine-pyrimidones (6–4s). Both lesions induce structural distortions in DNA, and if left unrepaired, can cause errors in replication that can lead to mutations. In addition to photoproducts, a wide variety of bulky chemical adducts are removed by NER, and the common denominator amongst these diverse lesions is distortion of the DNA helix, which in turn interferes with basic nuclear transactions such as transcription and DNA replication. These lesions present such a potential threat to the integrity of the cell that the basic mechanism for removing them has diverged surprisingly little throughout evolution. In all eukaryotic cells that have been studied, two modes of NER have been identified. These are global genomic repair (GGR) and transcription-coupled repair (TCR). These mechanisms are distinguished primarily by the way in which damage is detected. After the damage is detected, the pathway for excision, removal and gap filling is common to both GGR and TCR.

Many of the proteins were identified by cloning the genes responsible for the NER-defective syndrome ►xeroderma pigmentosum (XP). There are seven distinct groups of XP termed XP-A through XP-G, and the general molecular defect associated with each group is outlined in the Table 1.

Global Genome Repair

The global genome is defined as that part of the genome that is not transcribed, which is estimated to be 95% of the human genome. The XPC protein is specifically required for repair of lesions in the global genome, and cells with nonfunctional XPC are completely deficient in such repair. XP-C cells, however, are capable of removing lesions from the transcribed strand of active genes. The exact role of XPC in GGR has been obscure, but recent advances have elucidated its function more fully. XPC is a 125 kDa protein that acts as a heterodimer with one of two homologs of the yeast protein Rad23 (these homologs are termed hHR23A and hHR23B). It is now thought that the XPC-hHR23B (or A) complex acts at the very earliest stages of NER in the global genome in a damage recognition fashion. In ways that are not yet understood, this complex senses and binds to the damaged DNA. In this process, it locally distorts the double helix and then recruits the core repair apparatus. The rate of GGR is strongly dependent on the type of lesion, which presumably reflects the degree of helical distortion and the affinity of the XPC heterodimer. The XPC complex has been shown to have high affinity for DNA that contains a 6–4 photoproduct, and these lesions are repaired very rapidly. Recognition of CPD in the global genome probably requires the XPE protein; the XPE-CPD complex is then recognized by the XPC complex.

Nucleotide Excision Repair. Table 1 Molecular defects in XP complementation groups

Proteina	Defect
XPAb	No lesion recognition
XPBc	Reduced helicase activity that unwinds DNA 3′–5′ of the lesion
XPC	Reduced recognition of lesions in global genome, normal transcription-coupled repair
XPDc	Reduced helicase activity that unwinds DNA 5′–3′ of the lesion
XPE	Reduced recognition of cyclobutane pyrmidine dimers in the global genome
XPF/ERCC1	Mutant endonuclease that cuts 5′ to the lesion
XPGd	Mutant endonuclease that cuts 3′ to the lesion

[a]Cells from complementation groups signified with a hyphen (XP-A); the corresponding proteins are not hyphenated (XPA).
[b]Patients are very severely affected and may have developmental defects.
[c]Proteins also found in transcription factor TFIIH. Patients are likely to have developmental abnormalities.
[d]Defective transcription-coupled repair of oxidative damage suggests a second, non-endonucleolytic function for this protein. These patients may also have developmental defects, possibly due to reduced repair of oxidative damage.

Due to this two-stage mechanism, repair of CPD in the global genome is much slower than that of 6–4s.

Transcription-Coupled Repair

Elongating RNA polymerase II stalls at a wide variety of lesions and must act as a damage sensor, although the mechanism by which it does so remains obscure. In addition to the stalled polymerase, at least two other proteins are required for TCR. These are termed CSA and CSB, and are thought to act in a structural rather than in a catalytic fashion. Depending on the type of lesion, damage in the transcribed strand of an active gene can be repaired either by TCR or GGR. For instance, UV-induced 6–4s in active genes is primarily repaired by GGR because of the very high affinity of the XPC complex for these lesions. UV-induced CPD on the other hand, is repaired by TCR. TCR is highly conserved in both prokaryotes and eukaryotes, presumably because blocked RNA polymerases seriously interfere with cellular metabolism. TCR has also been shown to specifically reduce the frequency of mutations in active genes; mutations in such genes would also be expected to have a deleterious effect on cellular biochemistry and cell-cycle control.

Excision and Gap Filling

After the damage is initially sensed, the XPA protein plays a critical early role in NER. XPA is a DNA binding protein with high affinity for damaged DNA, and nonfunctional XPA leads to a complete loss of NER capacity. The protein was long thought to be the initial sensor of DNA damage, but more recent data implicates the XPC complex in this process. Current thinking is that XPA verifies that the DNA is damaged and acts to position the repair machinery correctly around the lesion. The human single strand binding protein, RPA, acts in concert with XPA and probably helps to maintain the open conformation. Through its extensive network of protein binding sites, XPA recruits the basal transcription factor TFIIH to the lesion. TFIIH is composed of five polypeptides, including the XPB and XPD helicases, which unwind the DNA on both sides of the lesion. Two structure-specific endonucleases, XPF-ERCC1 and XPG cut the DNA on either side of the lesion to release an oligonucleotide 24–32 bases in length that contains the damage. The 3′ terminus acts as a primer, and the gap is filled in by either DNA polymerase d or e, together with cofactors; the relative contribution of each polymerase remains to be determined. The final step in the process is ligation of the 5′ terminus, which is probably carried out by DNA ligase I. Since the gap to be filled is short, and the fidelity of the polymerase complex is very high, NER is considered to be an error-free process.

Clinical Relevance

The central role played by DNA repair in the prevention of cancer was first appreciated in 1968 when Cleaver recognized that patients with the skin cancer-prone disorder xeroderma pigmentosum (XP) had a defect in the repair of UV-induced damage (3). XP patients have a greater than 1,000-fold increase in the incidence of sunlight-associated skin cancer, and if they are exposed to any sunlight they usually succumb to metastatic skin cancer. The cells of XP patients are also defective in the repair of bulky chemical adducts, such as those induced by cigarette smoke and endogenous metabolic processes. Evidence is emerging that XP patients who live longer, because they have compulsively avoided the sun, have an increased risk of internal cancers, particularly if they smoke. Many XP patients also undergo progressive neurological deterioration, and this is thought to be due to the accumulation of damage induced by reactive oxygen species. Repair of such

damage is thought to require some of the NER proteins acting in pathways that are independent of NER. In addition, patients in XP groups that have a molecular defect that affects transcription in addition to NER (groups B and D), are likely to have developmental abnormalities that are presumably related to subtle defects in transcription.

There are two additional syndromes that manifest defects in excision repair but are curiously not cancer-prone. These are ►Cockayne syndrome (CS) and ►trichothiodystrophy (TTD). CS patients exhibit severe mental retardation and varying degrees of photosensitivity. Cells from these patients are defective in TCR because they lack a protein that couples the blocked RNA polymerase to the repair machinery. It has been postulated that the reason these patients do not develop skin cancer is the increased level of apoptosis induced in these cells following UV. The exaggerated apoptotic response may be due to the persistently blocked RNA polymerase II molecules, which cause accumulation of p53. TTD patients exhibit many of the same symptoms and signs of CS patients, but the molecular defect affects the same protein responsible for the XPD phenotype, namely the XPD helicase in TFIIH. The reason that one syndrome is cancer-prone while the other is not is puzzling, but recent studies have shown that mutations in the XPD gene occur in different regions in TTD and XP-D cells. It has been postulated that the mutations in TTD patients differentially affect transcription to a greater degree, and that subtle defects in transcription prevent cellular transformation. It has also been shown that TTD cells are quite proficient in repairing 6–4s while XP-D cells are not. The development of cancer in the latter cells may be related to the greater mutagenic potential of 6–4 photoproducts.

Lack a thymus, they are highly immunocompromised and tolerant for engrafted cells or tissues of other species.

NUP98-HOXA9 Fusion

Malcolm A. S. Moore
Department of Cell Biology, Memorial-SloanKettering Cancer Center, New York, NY, USA

Definition

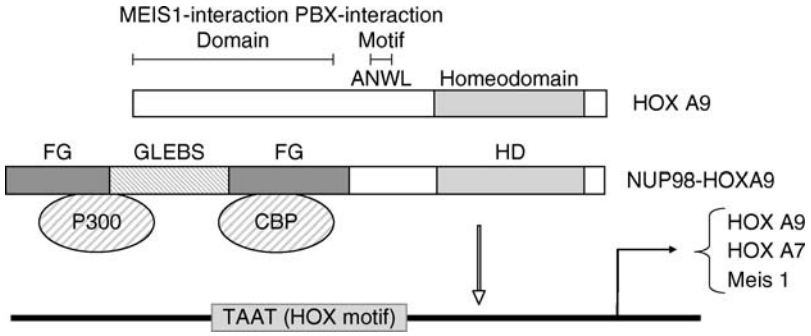
The t(7;11)(p15;p15) chromosome translocation is found in human leukemic bone marrow cells in a subpopulation (1–2%) of patients with acute myeloblastic leukemia (AML), ►myelodysplastic syndrome (MDS) and blastic crisis of ►chronic myeloid leukemia (CML-BC). The translocation involves the association of the C-terminal GLEBS and FG (phenylalanine-leucine) regions of the ►nucleoporin protein NUP98 with the N-terminal region of the ►HOXA9 protein containing the ►PBX heterodimerization domain and the DNA interacting homeodomain (Fig. 1). The clinical course of this subset of leukemias is aggressive, and prognosis is poor.

Characteristics

NUP98 is a component of the ►nuclear pore complex (NPC), an evolutionarily conserved structure made up of multiple copies of ~30 different NPC proteins (nucleoproteins) embedded in the nuclear envelope. The NPC mediates transport of proteins (>40 kDa) and RNA species between the cytoplasm and nucleus and helps organize nuclear architecture. The 98 kDa NUP98 protein is generated by an unusual biogenesis pathway that involves synthesis and autocleavage of precursor proteins yielding NUP98 and NUP96, another stable component of the NPC. The mRNA export factors ►TAP and ►Rae-1 associate in a mutually exclusive manner with different binding sites on NUP98 to form stable ternary compounds. The Rae-1–Nup98 complex functions in both the export of mRNA and import (recycling) of mRNA export factors into the nucleus indicating that this complex is an active player in the gene expression pathway.

The human NUP98 gene, located on chromosome 11p15.5, has been found fused to 21 different genes as a consequence of chromosomal translocations in acute leukemia. The resulting chimeric transcripts encode fusion proteins that juxtapose a common N-terminal region of NUP98 to the C-terminus of the partner gene. The most frequent partner genes are members of the ►Homeobox (HOX) and HOX-related family, particularly HOXA9.

HOXA9 plays an important role in normal hematopoiesis, being expressed in early ►hematopoietic stem cells (HSC) together with Meis1, downregulating with differentiation. Meis1 is a HOX cofactor that alters HOX-DNA binding specificity and affinity, and increases



NUP98-HOXA9 Fusion. Figure 1 Comparison of the structure of HOXA9 and the NUP98-HOXA9 fusion protein. The transcriptional regulatory region of HOXA9 is replaced by the C-terminal FG region of NUP98. Note the retention of the N-terminal DNA binding homeodomain and the PBX-interaction domains of HOXA9 in the chimeric protein

HOX-transcriptional activity. ►Thrombopoietin (Tpo), a key regulator of HSC proliferation, enhanced HOXA9 nuclear import and interaction with Meis1 in HSC in a MAPKinase-dependent fashion. Targeted disruption of HOXA9 in mice leads to reduced numbers of progenitor cells, and a profound defect in HSC. Conversely, enforced expression of HOXA9 promotes enhanced proliferation of HSC with impaired differentiation. These data highlight the importance of precise control of HOXA9 protein levels during hematopoiesis. The ubiquitin ligase ►CUL4A (►Cullin4A) regulates HOXA9 protein levels by ►ubiquitination and subsequent proteosome degradation of the protein. Knockdown of CUL4A by siRNA in myeloid cell lines extended the HOXA9 protein half-life 6–10-fold and enhanced proliferation and blocked differentiation in response to ►granulocyte colony stimulating factor (G-CSF). HOXA9 is one of the most upregulated genes in AML, particularly in the ►CD34+, CD38-leukemic stem cell fraction. HOXA9 behaves as an oncogene in leukemia following mutations that induce its persistent expression or that convert it to a persistent transcriptional activator.

Mouse Models of Leukemogenesis

Expression of NUP98-HOXA9 in murine bone marrow by retroviral gene transfer results in enhanced proliferation *in vitro* resulting in development of an oligo- or poly-clonal ►myeloproliferative disease (MPD) upon transplantation into mice, with neutrophil leukocytosis and extramedullary hematopoiesis, progressing to a mono or bi-clonal AML by 7–8 months. In a transgenic NUP98-HOXA9 model created with a myeloid restricted cathepsin G promoter, ~20% of mice developed MPD and eventually AML by 2 years. Retroviral insertional mutagenesis identified a number of co-factors that interacted with NUP98-HOXA9 in leukemia progression, the most frequent being Meis1. Collaboration of Meis1 with NUP98-HOXA9 reduced the median latency of AML development to 4–5 months. NUP98-HOXA9 has been detected in blastic crisis of ►BCR-ABL positive ►CML indicating that cooperation between NUP98-HOXA9 and the BCR-ABL signaling pathway via receptor tyrosine kinase may be important in progression from chronic disease to ►blastic crisis. Oncogenic interaction is seen between NUP98-HOXA9 and BCR-ABL chimeras in retroviral mediated gene transfer experiments in mice leading to rapid development of AML.

Human Models of NUP98-HOXA9 Leukemogenesis

Retroviral transduction of NUP98-HOXA9 into human HSC and progenitor cells from umbilical cord blood or G-CSF mobilized adult peripheral blood confers a proliferative advantage *in vitro* in long term cytokine stimulated or stromal co-culture assays, and *in vivo* following transplantation in irradiated immunodeficient NOD/SCID mice. The mechanism involves acquisition of serial myeloid progenitor colony recloning capacity and enhanced HSC self-renewal as confirmed by quantitative in vitro limiting dilution assay. Granulocytic and erythroid differentiation is also impaired.

Proposed Mechanism of Leukemic Transformation by the NUP98-NUP98 Fusion

Aberrant Transcriptional Activity

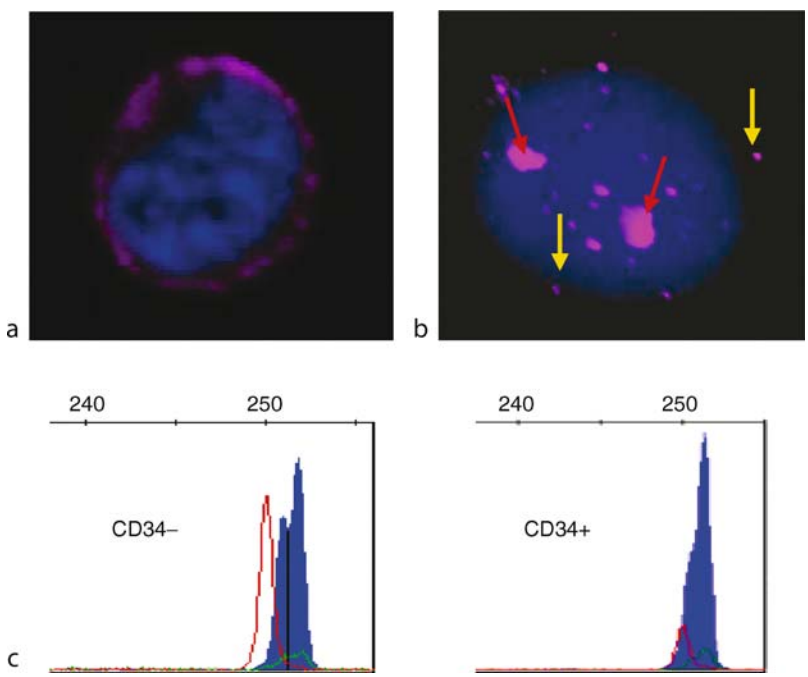
Unlike HOXA9, NUP98-HOXA9 has a strong but aberrant transcriptional activating potential mediated through NUP98FG binding of the transcriptional co-activators ►CBP/p300. Transduction of NUP98-HOXA9 into a human myeloid leukemic cells line significantly altered expression of over a hundred cytoplasmic mRNAs, and in studies with human CD34+ stem and progenitor cells 50–60 genes were upregulated and 4–15 downregulated. The transcriptosome of NUP98-HOXA9 showed little overlap with that of HOXA9. The most striking feature was upregulation of homeobox genes (HOXA5, HOXA6, HOXA7, endogenous HOXA9 HOXB2, HOXC6, HOXB5,

and TALE homeodomain genes *Meis1* and *PBX3*). The "HOX code", minimally defined by expression of the HOXA5-A9 cluster, is reported to be central to leukemogenesis associated with ►mixed lineage leukemia protein (MLL) fusion genes and is probably a significant mechanism in NUP98-HOXA9 transformation. Overexpression of these HOX genes favors self-renewal and blocks differentiation. Downstream pathways involving the HOXA9 component of the fusion protein involve binding to the promoter region of the threonine kinase ►Pim-1 promoter. Pim-1 is a proto-oncogene overexpressed in the transcriptosome of HOXA9 and NUP98-HOXA9 transduced human hematopoietic cells. Pim-1 increases phosphorylation and inactivation of pro-apoptotic ►BAD protein and since unphosphorylated BAD normally binds to and inactivates anti-apoptotic proteins such as ►Bcl-X_L and ►Bcl-2, this would be an anti-apoptotic event. NUP98-HOXA9 upregulation of ►hepatic leukemia factor (HLF) is consistent with upregulation of HLF reported in normal CD34+ and CD133+ and leukemic HSC. HLF is a basic leucine zipper protein defined by a PAR domain that plays a critical role in hematopoietic specific expression of the LMO2 gene. A role for HLF in HSC self-renewal is supported by studies showing that ectopic expression of HLF enhanced HSC engraftment and inhibited apotosis.

The transcription factor CCAAT enhancer binding protein-α (►C/EBPα), a tumor suppressor gene and a crucial regulator of granulopoiesis through inhibition of c-JUN, is down modulated by NUP98-HOXA9. Disruption of C/EBPα, including dominant negative mutations of CEBPα, are found in AML and conditional C/EBPα knockout in mice blocked the differentiation of the common myeloid progenitor with myeloblast accumulation in marrow, absence of neutrophils and enhancement of HSC competitive repopulating capacity and self-renewal. Co-expression of an estrogen-inducible C/EBPα-ER protein together with NUP98-HOXA9 in CD34+ cells showed that re-expression of C/EBPα counteracted the stem cell proliferation and cell expansion associated with C/EBPα downregulation.

Stabilization of HOXA9 Protein Expression

Fusion to NUP98 to HOXA9 results in persistent expression of the homeobox protein due to its reduced sensitivity to CUL4A mediated ubiqitination.



NUP98-HOXA9 Fusion. Figure 2 NUP98 protein localization in normal and NUP98-HOXA9 leukemic cells. (a) NUP98 immunostaining of normal CD34+ cells. Note localization of the protein (purple) in the nuclear membrane and absence of nuclear aggregates. (b) NUP98 immunostaining of a leukemic cell from the bone marrow of a patient with the NUP98-HOXA9 translocation. Note the presence of numerous NUP98+ nuclear aggregates (purple) and impairment in NUP98 association with the NPC. (c) LOH analysis performed by PCR for NUP98 allelic markers on CD34- non-leukemic and CD34+ leukemic cells from the AML patient shown in 2B. Note NUP98 LOH is restricted to the CD34+ leukemic population.

This may be achieved by steric hindrance, dimerization or by the NUP98 FG domains binding CBP/p300 transcriptional co-activators leading to acetylation of the HOX lysine residues required for ubiquitination. The prolongation of the HOXA9 protein half-life in turn leads to persistence of aberrant transcriptional activation.

Depletion of NUP98 from the NPC in Cells Expressing NUP98-HOXA9

NUP98 protein normally moves between the NPC and the nuclear interior where it associates with novel 0.2 μm diameter nuclear bodies termed ►GLFG bodies because the GLFG domain of NUP98 is required for targeting of these structures. Immunostaining for Nup98 and HOXA in normal CD34+ cells transduced with NUP98-HOXA9 also reveals localization of staining in nuclear aggregates with loss of NUP98 from the NPC. In patients with t(7;11)(p15;p15) AML large NUP98+ nuclear aggregates are observed with absence of NUP98 associated with the nuclear membrane (Fig. 2). The chimeric NUP98-HOXA9 may be irreversibly associating with GLFG bodies and may have a dominant negative effect by sequestrating the remaining wild type NUP98 in heterodymeric co-localization bodies. The loss or depletion of NUP98 likely mediates a leukemogenic action by disrupting nuclear export of mRNAs that are critical to a normal balance of HSC proliferation and differentiation. While disruption of NUP98 by NUP98 translocations is a relatively rare event in normal human leukemogenesis there is growing evidence for a wider role for NUP98 disruption in oncogenesis, supported by the observation that there is ►loss of heterozygosity (LOH) at the p11.5 NUP98 locus in nearly a third of human AML (Fig. 2) and this is associated with adverse prognosis.

NUPR1

►p8 Protein

Nur77

Definition

An orphan member of the ►nuclear receptor superfamily that is expressed in various types of cells and mediates diverse biological processes. It regulates gene transcription by binding to the Nur77-binding response element (NBRE) as a monomer. It is rapidly induced by various stimuli, including growth factors and ►phorbol ester- and ►cAMP synthesis-dependent pathways.

►Retinoid Receptor Cross-talk

Nutraceuticals

Blanca Hernandez-Ledesma, Ben O. de Lumen
Dept of Nutritional Sciences and Toxicology, University of California, Berkeley, CA, USA

Synonyms

Functional foods; Designer foods; Medical foods; Pharmafoods; Food for specified health use

Definition

Nutraceutical is a food (or part of food) that provides medical and health benefits, including the prevention and/or treatment of a disease beyond providing nutrition. It has also been defined as a product produced from foods but sold in powders, pills, and other medicinal forms not generally associated with food and demonstrated to have physiological benefits or to provide protection against chronic disease.

Characteristics

The term Nutraceuticals was created by Stephen DeFelice in 1989 by combining the words “nutrition” and “pharmaceuticals.” The name nutrition defines the important difference between nutraceuticals and pharmaceuticals. While the pharmaceuticals do not come

from nature and they are chemically created, nutraceuticals come from food naturally. Food provides calories needed to perform daily functions and maintain normal metabolic processes. Moreover, food contains nutrients and other components that are essential to maintain health and reduce the risk of disease. Some examples of relationships between nutraceuticals and health benefits include the importance of calcium in preventing osteoporosis, folate in the prevention of neural tube defects in infants, and vitamin C in the prevention of the disease scurvy. Mounting evidence from epidemiological studies, animal research, clinical trials, and research in nutritional biochemistry suggests that many nutraceuticals may be beneficial in diabetes, osteoporosis, and other chronic and degenerative diseases such as Parkinson and Alzheimer diseases, coronary heart disease, and cancer.

Nutraceuticals and Cancer

It has been estimated that 30–40% of all tumors can be prevented with a correct lifestyle and diet. It has been demonstrated that ►carcinogenesis is inhibited by factors such as ►retinoids, vitamins E, D, C, polyphenols, fibers, calcium, selenium, and polyunsaturated fatty acids such as ►Omega-3 fatty acids. Other factors, such as lipids, sodium chloride, nitrite, and nitrate tend to favor it.

Numerous epidemiological studies have shown a strong correlation between frequent consumption of fresh fruits and vegetables and a decreased cancer risk. These foods are low in fat, rich in vitamins and minerals, and often contain significant amounts of fiber. The benefits of these are well known, but fruits and vegetables contain a variety of naturally occurring compounds, called phytochemicals that have biological activity in humans. It is the combination of nutrients and phytochemicals working together that benefits health, and helps in reducing the risk of cancer, as well as other important disease including heart disease. Scientists have identified thousands of phytochemicals, although only a small fraction has been studied closely. It has been demonstrated that they may exert physiological effects by different mechanisms of action. They may incite the immune system, contribute to reduce the toxicity of adverse chemical products, influence hormone levels, and control cell growth. They may also involve the activation of antioxidant defenses, signal transduction pathways, cell survival associated gene expression, cell proliferation and differentiation, and preservation of mitochondrial integrity. Furthermore, many of these substances exert antiinflammatory actions through inhibition of oxidative stress-induced transcription factors, cytotoxic ►cytokines, and ►cyclooxygenase-2.

Four main types of phytochemicals are found in fruits and vegetables, terpenoids, phenolics (including polyphenolics), nitrogen-containing alkaloids, and sulfur compounds. The terpenoids include ►carotenoids, many of which are precursors to retinol (►vitamin A). Carotenoids are organic pigments naturally occurring in plants and some other photosynthetic organisms like algae, some types of fungus, and some bacteria. Carotenoids are important factors in human health. Protective effects of carotenoids against serious disorders such as cancer, heart disease, and degenerative eye disease have been recognized, and have stimulated intensive research into the role of carotenoids as antioxidants and as regulators of the immune response system.

Of the phenolic compounds, the ►flavonoids are the most numerous. They are found in a wide variety of fruits and vegetables, tea, and coffee. In addition to their antiallergic, antiinflammatory, and antimicrobial properties, flavonoids have an important role in the prevention of cardiovascular disease and cancer. They are potent antioxidants and also can influence the expression of ►phase I enzymes and ►phase II enzymes. These enzymes metabolize potentially carcinogenic substances to make them more water soluble and hence readily excreted. This ►detoxification process has a potential protective effect against cancer.

►Isoflavones are a class of organic compounds and biochemicals related to the flavonoids. They can be found in many foods but the best known source is the soybean. Due to their similar structure to the hormone ►estrogen, isoflavones act as ►phytoestrogens in mammals with potent hormonal activity. Other beneficial effects on human health such as antioxidant, antiatherogenic, hypolipidemic, antiosteoporotic, and anticarcinogenic effects have been well demonstrated. Several mechanisms have been proposed for the anticarcinogenic activity of isoflavones. These include upregulation of ►apoptosis, inhibition of angiogenesis, inhibition of ►DNA topoisomerases II, and protein ►tyrosine kinase. Their weak estrogenic activity may be involved in its putative activity against some kinds of cancer, such as ►prostate cancer and ►breast cancer. Isoflavones appear to work in conjunction with the ►soy proteins to protect against cancer, as well as against cardiovascular disease and osteoporosis.

Consumer interest in the relationship between diet and health has increased the demand for information about nutraceuticals and functional foods. Found in a mosaic of products emerging from the food and pharmaceutical industries, and the newly merged herbal and dietary supplement market, nutraceuticals are in high demand among consumers looking for specific health benefits. Credible scientific research now makes it fairly evident that diet can help in reducing the risk of chronic diseases and promotes general good health.

Nutrition Assessment

Definition

Thorough evaluation of medical history, dietary history, physical examination, anthropometric measurements, and laboratory data with the intent of developing an individualized nutrition care plan.

►Nutrition Status

Nutrition Screening

Definition

Use of objective and subjective data in a easy to use, cost effective, valid, quick tool to identify the presence or risk of malnutrition.

►Nutrition Status

Nutrition Status

Maureen B. Huhmann
Department of Primary Care, School of Health Related Professions, University of Medicine and Dentistry of New Jersey, The Cancer Institute of New Jersey, New Brunswick, NJ, USA

Definition

The definition of nutrition status varies by discipline. In general it refers to the presence or absence of malnutrition. The term "malnutrition" applies to both underweight and overweight populations. Malnutrition is defined as "any disorder of nutrition status including disorders resulting from deficiency of nutrient intake, impaired nutrient metabolism, or overnutrition."

Although no singe index can accurately indicate poor nutrition status, weight and weight history are the parameters most commonly used. This method has limitations. Weight alone does not indicate the nature and extent of tissue loss in patients with cachexia. It also does not indicate specific metabolic or biochemical nutritional issues.

Characteristics

Weight loss is common in patients with cancer, with 31–100% of oncology patients experiencing weight loss depending upon tumor site, stage, and treatment. As little as 5% weight loss is associated with increased mortality and poor prognosis. Unfortunately the weight loss is multifactorial and commonly requires multiple interventions by a variety of disciplines.

Loss of body weight in patients with solid tumors is attributed to losses of fat, water, and ►lean body mass (LBM). Patients with lung, gastrointestinal (GI), and head and neck tumors experience weight loss >10%, which manifests as a loss of both muscle and fat. Individuals with GI malignancies seem to experience the largest decreases (>50%) in muscle mass and protein content, as well as 30–40% loss in body fat. Despite this, even in severe wasting patients retain some body fat. Visceral mass is also preserved to an extent and skeletal muscle loss is the primary form of lean body mass loss.

►Cancer cachexia syndrome (CCS) manifests as the characteristic wasting seen in some cancer patients. Symptoms associated with CCS include weight loss, anorexia (loss of appetite), fatigue, early satiety, and asthenia. CCS is a complex metabolic state which results from a intricate, and yet to be fully elucidated, interaction of pro-inflammatory cytokines such as tumor necrosis factor, interferon-γ, and interleukins 1 and 6 and tumor byproducts such as proteolysis inducing factor, lipid mobilizing factor, and mitochondria uncoupling proteins 1, 2, and 3. CCS results in depletion of energy and muscle stores unresponsive to aggressive nutrition support (i.e. enteral nutrition or parenteral nutrition). Provision of nutrients in excess of estimated needs does not reverse this weight loss. Treatment of the underlying disease is the only current effective therapy for CCS.

Mechanisms

Nutritional decline is often accepted as part of the cancer course and its treatment. Anti-cancer treatment modality choice (i.e. surgery, ►chemotherapy, radiation therapy) can dictate this decline in nutrition status.

The metabolic stress caused by surgery can lead to a hypercatabolic state. This hypermetabolism contributes to muscle and fat breakdown leading to weight loss

post-operatively. Diet restriction (i.e. liquid diet, nothing per oral) and poor appetite lead to decreased dietary intake further adding to this weight loss. Patients with ►GI malignancies that have lost LBM experience increasing rates of severe complications associated with surgical intervention. Surgically induced anatomical changes to the ►GI tract may present mechanical barriers to food ingestion or digestion. Bowel, esophageal, gastric, hepatic, and pancreatic resections can lead to diarrhea, malabsorption, and ultimately dehydration.

Side effects related to chemotherapy administration vary greatly. Chemotherapy is highly toxic to rapidly dividing cells such as those that line the GI tract. Chemotherapeutic agents may directly impair food intake via stomatoxic reactions such as mucositis, diarrhea, and ►emesis, or indirectly via fatigue, pain, food aversions, and taste changes. Nausea and vomiting are frequently reported as the most distressing side effects associated with chemotherapy. Chemotherapy induced symptoms can occur prior to treatment, during treatment or several weeks later and can last from several hours to days. Aggressive ►supportive care is essential to minimize nutrition related side effects.

Radiation to any portion of the GI tract can cause extreme susceptibility to malnutrition. Radiation to the pelvic and abdominal area causes an acute inflammatory response in bowel tissue. This ►inflammation produces diarrhea, abdominal pain and nausea. Chronic radiation enteritis develops in certain cases necessitating lifelong medication and diet changes. Radiation to the head and neck can also lead to nutrition related side effects, such as mucositis, xerostomia, taste change, and dysphagia. These side effects peak two-thirds of the way through treatment and can become chronic. Radiation therapy in the area of the thyroid can cause permanent thyroid damage leading to changes in metabolism.

Gastrointestinal symptoms induced bay any of the above therapies, such as nausea, vomiting, diarrhea, and constipation; and oral symptoms, such as xerostomia and mucositis may lead to weight loss early in the course of cancer. Fatigue and psychological symptoms such as, depression and anxiety, also influence weight loss.

Assessment of Nutrition Status

►Nutrition screening of all oncology patients facilitates the early recognition of malnutrition. Screening is intended to quickly identify individuals at nutritional risk. ►Nutrition screening tools should be easy to use, cost effective, valid, reliable, and sensitive. Screening tools incorporate objective and subjective data to identify the presence or risk of malnutrition. Objective measures commonly included in nutritional screening tools include height, weight, weight change, primary diagnosis, disease stage and the presence of co-morbidities. Individual objective measures, such as a laboratory value or current weight, alone are not specific enough to indicate nutrition risk so multiple objective measures are combined with subjective measures that may impact nutrition. The American Society for Parenteral and Enteral Nutrition (ASPEN) and the American Dietetic Association (ADA) recommend that all patients receive nutrition screening as a component of their initial evaluation.

Many nutrition screening tools have been developed, with several specifically validated in an oncology population. The ►patient generated subjective global assessment (PG-SGA) and the mini nutritional assessment (MNA) are commonly used in the outpatient oncology setting. Many acute care facilities have designed facility specific screening forms to be completed by the nursing staff upon admission. These acute care forms commonly combine nutrition screening with other disciplines.

The PG-SGA is a modification of an earlier screening tool called the Subjective Global Assessment (SGA) developed by Detsky. Faith Ottery, a surgical oncologist, modified the SGA specifically for the oncology population. The PG-SGA is comprised of two sections; a patient completed section and a section completed by the healthcare professional. Patients provide data regarding weight history, symptoms, dietary intake, and activity level. Healthcare professionals evaluate metabolic demand, disease in relation to nutritional requirements, and perform a physical assessment. The nursing staff, a nurse practitioner, a registered dietitian, or a physician can complete this section. A numeric score is calculated by adding the points obtained in sections one and two. The numeric scores can be used as a triage system to initiate nutrition intervention and guide follow-up. The PG-SGA numeric score, when repeated at subsequent time points, is useful in illustrating small improvements or deteriorations in nutrition status.

The Nestle Mini Nutritional Assessment (MNA) is a commonly used nutritional screening tool in the elderly population. The 18-item MNA, developed by Guigoz with Nestle Nutritional Corporation, is comprised of two main components; screening and assessment. The six-item screening takes approximately three minutes to complete and includes questions related to decline in food intake, weight loss, mobility, stress and body mass index. The healthcare practitioner is directed to complete the assessment section of the MNA if the screening provided a score of 11 or less. The assessment component includes specific medical history and eating habits as well as some anthropometric measurements.

The Malnutrition Screening Tool (MST), although not commonly used in the United States, is a short nutritional screening tool. This three-item tool utilizes data on weight history and appetite to predict nutrition risk The MST, developed by Maree Ferguson, has been validated in both acute care patients and oncology patients receiving radiation therapy.

Nutrition screening should lead to a more in-depth ►nutrition assessment. Nutrition assessment differs from screening in that it is a thorough evaluation which assimilates data obtained from the medical history, dietary history, physical examination, anthropometric measurements, and laboratory data. The nutritional assessment integrates the review of anthropometrics with data on disease and clinical status to evaluate impact on metabolism and nutrient need. Appraisal of disease and treatment related symptoms is also necessary to plan nutrition interventions. This process leads to the identification and diagnosis of nutritional issues. The nutritional assessment is usually completed by a registered dietitian (RD) or nutrition professional, however other members of the healthcare team can complete it as well.

Nutrition Intervention

Nutrition intervention refers to the specific activities required to address and correct the nutrition diagnosis. The nutrition intervention is selected, planned, and implemented with the intent of improving nutrition status. Planning of the nutrition intervention requires the input of all disciplines involved in patient care. Reflection must be taken on the causes of weight loss or weight gain. In taking into consideration these factors the patient should remain at the center of the intervention, with patient preferences of paramount importance.

The goals of the intervention must be documented and reevaluated frequently. The intervention must be individualized to the patient and consideration should be taken for patient comfort and wishes. Although variable between and among patients, common nutritional goals include symptom management, weight maintenance, and preservation of functional status. Attaining these goals may require modified diets, the addition of oral nutritional supplements, or the initiation of enteral or parenteral nutrition. Supportive care measures should be employed as needed These modifications to dietary intake can be costly and flexibility is required on the side of the individual designing the intervention with respect to specific formulas and administration. The services of financial planners and social workers are very beneficial in this situation.

Benefit of Maintenance of Nutrition Status

Health-related ►quality of life (QOL) refers to the physical, psychological and social domains of health that are influenced by an individual's experiences, beliefs, expectations and perceptions. Cancer treatments influence the social, psychological and emotional aspects of patients' lives. The presence of malnutrition can also impact a patient's QOL. Difficulty with eating resulting from the side effects of treatment or disease may cause patients to pass up experiences of social interactions with family and friends. This in turn leads to further depression of appetite. Poorer overall QOL has been observed in patients experiencing symptoms that impact socializing such as odynophagia, weak voice, and unclear speech.

A relationship has been established between weight loss and QOL in oncology patients. Changes in body composition affect symptom control and complication rates. Increased incidence of nutritional symptoms is correlated with decreases in quality of life. To date, there is little information relating changes in specific body compartments to QOL. Preliminary research relating to the use of an anabolic steroid indicate that increases in body cell mass are associated with improved QOL and ►ECOG performance status scores in head and neck and lung cancer patients. However, there has been little quantification of the impact of loss of LBM on QOL.

NWTSG

Definition

National Wilms Tumor Study Group (NWTSG) is an organization that has co-ordinated clinical trials for the treatment of Wilms tumor in North America since the early 1970s. They have data on epidemiological, genetic and clinical features together with treatment outcome on over 6,000 children treated for ►Wilms tumor.

Obesity

Definition

Is a status of excess fat accumulation in the body, to a degree that is much greater than what is considered healthy. It is a major risk factor for type 2 diabetes, cardiovascular disease, and some types of cancers.

►Obesity and Cancer Risk

Obesity and Cancer Risk

Susanna C. Larsson
Division of Nutritional Epidemiology, Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden

Definition

Obesity is a condition in which excess fat has accumulated in the body. The only widely accepted criteria for obesity are based on body mass index (BMI, also called Quetelet index), which is defined as the weight in kilograms divided by the square of the height in meters. According to the World Health Organization (WHO) classification, 'normal weight' is defined as BMI between 18.5 and 25 kg/m^2, 'overweight' is BMI between 25 and 30 kg/m^2, and obesity is defined as a BMI of 30 kg/m^2 or greater.

Characteristics

Trends in Obesity

Over the past few decades, the proportion of people with excess body weight has been increasing in most developed and developing countries along with an adoption of a westernized lifestyle characterized by excessive energy intake and lack of physical activity. There are large between-country and within-country differences in the ►prevalence of obesity. The prevalence of adult obesity is high in North America (particularly in the United States), the Eastern Mediterranean, Central and South America (particularly in Mexico, Paraguay, Argentina, and Chile), Eastern Europe, and some Western European countries (Finland, Spain, Germany, and the United Kingdom). In the United States, the prevalence of obesity doubled over the past two decades, and currently about one-third of the

US adult population is obese and an additional one-third is overweight. Smaller increases in the prevalence of obesity have been observed in many European countries. The MONICA project – a large international study of the monitoring risk factors for cardiovascular disease, led by the WHO – showed a prevalence of obesity above 20% in many parts of Western Europe in the 1990s, and it was has high as 35% in some Eastern European countries. Obesity is still uncommon in China and Japan and most parts of Africa.

Obesity and Cancer Risk

Being overweight or obese is a well-known risk factor for ►type 2 diabetes mellitus and cardiovascular disease, but ►epidemiologic studies are also providing mounting evidence for a link between body weight and cancer risk. In 2002, the International Agency for Research on Cancer (IARC) Working Group on the Evaluation of Cancer Preventive Strategies published an extensive review of the literature on body weight and cancer. The Working Group concluded that, based on data from epidemiologic studies, there is sufficient evidence of a cancer-preventive effect of avoidance of weight gain for cancers of the colon, breast (in postmenopausal women), endometrium, kidney (renal cell), and esophagus (adenocarcinoma). Many studies have been published since the IARC report, and the accumulated evidence indicates that obesity may be a risk factor also for pancreatic, liver, gallbladder, and hematopoietic cancers, and possibly for aggressive prostate cancer. Obesity is not associated with risk of lung cancer, and is probably not a risk factor for ►bladder cancer or noncardia ►gastric cancer. Findings for cancer at other sites are sparse or inconsistent.

Obesity-Related Cancers

There is an extensive body of epidemiologic data showing a relation between obesity and ►colon cancer risk. In general, obesity has been found to be associated with an approximately 30–90% increased risk of colon cancer in men and with a 10–50% increased risk in women. The association between obesity and risk of rectal cancer is less clear, with a generally weak positive association observed in men but no association in women.

The first evidence of an association between excess body weight and increased risk of breast cancer came in 1974 from a Dutch ►cohort study of postmenopausal women. A large number of subsequent studies have found that obesity increases the risk of breast cancer in postmenopausal women by about 30%. Conversely, there is consistent evidence that obesity is associated with a decreased risk of breast cancer in premenopausal women. This reduction in risk may be related to the increased tendency of young obese women to have anovulatory menstrual cycles and reduced circulating concentrations of progesterone and ►estradiol. Several studies have shown a stronger association between BMI and postmenopausal breast cancer risk in women who have never used postmenopausal hormones. This observation is consistent with the hypothesis that the effect of obesity on postmenopausal breast cancer risk may be mediated through increased endogenous estrogen production.

Obesity has been associated consistently with an increased risk of ►endometrial cancer in both pre- and postmenopausal women. The risk increased about linearly with increasing BMI in most studies. In different studies, the risk of endometrial cancer was approximately 2–3 times higher in overweight and obese women than in normal weight women.

An association between excess body weight and risk of kidney (mainly renal cell) cancer has been consistently observed in epidemiologic studies. The majority of studies have reported a linear increase in risk with increasing BMI. The increase in risk generally ranges from 1.5- to 3-fold in overweight and obese individuals.

The ►incidence rates of adenocarcinoma of the esophagus and gastric cardia have been rapidly increasing in developed countries over the last three decades. In contrast, the rates for squamous cell carcinoma of the esophagus and noncardia gastric adenocarcinoma have remained stable or decreased slightly during the same period. Compelling evidence indicates that overweight and obesity increase the risk of adenocarcinoma of the esophagus by about 2–3-fold and of gastric cardia by about 1.5–2-fold. However, excess body weight is not associated with an increased risk of esophageal squamous cell carcinoma or noncardia gastric adenocarcinoma.

Cancers Likely Related to Obesity

Several recent cohort studies have observed a 1.2–2-fold increased risk of pancreatic cancer in obese men and women. While some studies found a dose-response relationship with increasing BMI, other studies showed an increase in pancreatic cancer risk only among obese individuals.

Seven cohort studies in the United States and Europe have observed a 1.5–3.5-fold increased risk of liver cancer in obese individuals, whereas a ►case–control study in Canada reported no association. Obesity may contribute to the risk of liver cancer by promoting the development of non-alcoholic fatty liver disease.

To date, eight cohort studies and three case–control studies have examined the association between obesity and risk of gallbladder cancer, with most studies showing an increased risk in obese men and women. The increase in risk generally ranges from about 1.5–2-fold in obese individuals. Obesity may increase

gallbladder cancer risk indirectly by increasing the risk of gallstones, which, in turn increase the risk of gallbladder cancer.

Several studies published during the last 5 years have found that obesity is associated with an increased risk of hematopoetic cancers, including ►non-Hodgkin lymphoma, ►leukemia, and ►multiple myeloma. Overall, obesity has been associated with an approximately 20–40% excess risk of these cancers.

Other Cancers

Results from a large number of studies of the association between obesity and incidence of overall prostate cancer have been largely null. However, obesity has been related to increased risks of more advanced prostate cancer and prostate cancer mortality, and with higher recurrence rates after radical prostatectomy or radiotherapy treatment. These findings suggest that obesity may influence prostate cancer aggressiveness and progression.

Obesity has been found to be inversely related to risk of lung cancer in several studies, but this association appears to be due to ►confounding by smoking (smoking is the main cause of lung cancer and is inversely associated with body weight). There is no association between obesity and lung cancer in nonsmoking populations.

Studies of the relation between obesity and ►ovarian cancer risk are inconclusive. Although some studies found an increased risk (1.5–2-fold) of ovarian cancer in obese women, several studies observed no association. Results on obesity in relation to cervical cancer risk are limited and inconsistent.

Mechanisms Linking Obesity to Cancer Risk

Several biological mechanisms have been postulated to explain the relation between obesity and cancer risk, including alterations in the metabolism of insulin, ►insulin-like growth factor-I (IGF-I), and sex steroids (►estrogens, androgen, and progesterone). Obesity leads to a state of relative insulin resistance, chronically increased insulin concentrations, and an increase in bioavailable IGF-I. Both insulin and IGF-I act as growth factors that stimulate cell proliferation and inhibit ►apoptosis. Epidemiologic studies have shown that increased circulating concentrations of insulin, C-peptide (a marker of pancreatic insulin secretion), and IGF-I as well as type 2 diabetes mellitus are associated with an increased risk of several cancer types, especially cancers of the colon, endometrium, and pancreas. Sex steroids are involved in the control of cell differentiation, proliferation, and apoptosis, and may also favor the selective growth of preneoplastic and neoplastic cells. There is considerably evidence that the increase in breast and ►endometrial cancer risk with increasing body weight in postmenopausal women is largely the result of the associated increase in circulating concentrations of estrogens, particularly bioavailable estradiol. The relationship between obesity and endometrial cancer in premenopausal women may in part be related to chronic anovulation and decreased progesterone concentrations in young obese women.

Adipocytes (fat cells) secrete a number of fat cell hormones/cytokines or adipokines, such as leptin, ►adiponectin, resistin, tumor-necrosis factor-α, and ►interleukin-6. These ►adipokines have important roles in the regulation of energy balance, lipid metabolism, and insulin resistance as well as in ►inflammation and immune response. It has been proposed that in addition to growth factors and sex hormones, obesity-related alterations in the concentrations of adipokines may be linked with cancer risk.

Definition
Ornithine Decarboxylase.

Odontoblasts

Definition
Primary: Single cell line of highly specialized cells which are located inside the dental pulp, but whose processes reach from the pulp chamber through the dentin tubules to the dentinoenamel junction (primary odontoblasts). Their competence lies in secretion of (physiologic) secondary dentin and reparative dentine due to caries, trauma or tooth preparation.
Secondary: Derive from mesenchymal precursor cells when primary odontoblasts become destroyed. Secondary odontoblasts (or "odontoblast-like" cells) form irregular masses of tertiary dentine. This capability to produce such calcifications plays an important role as a barrier mechanism after a carious, traumatic or iatrogenic insult to the tooth.

Synonyms
Mixed gliomas

Definition
Are tumors located mainly in supratentorial subcortical brain areas showing composite histological features and including cells similar to oligodendrocytes or astrocytes.

Characteristics
Oligoastrocytomas and pure ►oligodendrogliomas constitute a subgroup of ►brain tumors receiving increased attention because of reports of chemosensitivity and of favorable survival rate when compared with ►astrocytomas. This is also reflected in the increasing rate of diagnosis of tumors with an oligodendroglial component raising from about 5% in the past decade to approximately 15% in present years.

The morphological borderlines between astrocytomas, oligoastrocytomas, and oligodendrogliomas are difficult and controversial issues. However the accurate distinction between these tumors has important prognostic and therapeutic implications. Patients with pure oligodendrogliomas are more likely to respond to chemotherapy and have a longer survival than patients with diffuse astrocytomas or oligoastrocytomas of the same grade.

Oligoastrocytomas show a conspicuous mixture of two distinct neoplastic cell types, resembling the tumor cells in oligodendrogliomas and diffuse astrocytomas; the two components may be separated into distinct areas or be diffusely admixed.

A pathological diagnosis based on the assessment of the individual component is difficult, since in most instances the true extent of such component can be hardly determined because of incomplete tumor sampling. Furthermore, precise diagnostic criteria are still lacking, the proposed minimum astroglial component ranging from 1 to approximately 50%. A subclassification of oligoastrocytomas, based on histological features, into oligodendroglioma-predominant, astrocytoma-predominant, or equivalent oligodendroglial and astroglial component has been proposed. However, prognosis and response to therapy were not found to be significantly different for such subtypes.

Oligoastrocytomas are graded, based on the WHO classification, as either low-grade (Grade II WHO classification) or high-grade tumors (anaplastic, grade III WHO classification). The diagnosis of anaplastic oligoastrocytoma requires the presence of histological features of malignancy such as increased cellularity, nuclear atypia, pleomorphism, and increased mitotic activity. Signs of histological malignancy may be present in the oligodendroglial component, the astroglial component, or in both cell types. The histological grading is both of prognostic and therapeutic use.

Glioma genotyping can provide important information complementing the histological analysis. Until now no specific abnormalities associated with oligoastrocytomas have been found. Genetic alterations of these tumors include loss of heterozygosity (LOH) on chromosome 1p and/or 19q, typically found in oligodendrogliomas, but also LOH on chromosome 17p or 10q, frequently found in astrocytomas and associated with the progression to glioblastoma.

►LOH on 1p and/or 19q are present in approximately 50% of oligoastrocytomas, independently of their histological grade; LOH on 17p is seen in 20% and LOH on 10q in 15% and is significantly associated with anaplasia; the observation of 1p loss with intact 19q (or vice versa) is more frequent in oligoastrocytomas than in oligodendrogliomas. Similar to oligodendrogliomas, LOH on 1p and/or 19q has been associated with chemosensitivity and prolonged survival, while LOH on 10q has an unfavorable impact on prognosis.

Therefore, genomic changes may permit the division of tumors into more homogenous groups: oligoastrocytomas with LOH on 1p behave like WHO grade II or III oligodendrogliomas with 1p LOH and they are associated with longer survival; on the other hand, oligoastrocytomas without LOH on 1p behave like grade II or III astrocytomas and have shorter survival.

Despite the clinical relevance of 1p and 19 q losses, the genes targeted on these two chromosomes are unknown. Some very recent progress, however, may help pinpointing the genetics underlying these alterations. Combined loss of on 1p and 19q is mediated by the ►chromosomal traslocation (t(1,19)(q10;p10). The high sequence homology of chromosome 1 and 19 centromeric regions could be the mechanisms favoring translocation, facilitated by tumor-related alterations of normal DNA methylation or histone modification affecting the centromeric region. Chromosome engineering was used to generate mouse models with gain and loss of a region corresponding to human 1p36. By this strategy chromodomain helicase DNA binding domain 5 (Chd5) was identified as a tumor suppressor located on 1p36 that controls proliferation, apoptosis, and senescence via the p19(Arf)/p53 pathway. Future studies will clarify the relevance of Chd5 in the formation of different gliomas, including oligoastrocytomas.

Due to the high variability of morphological criteria used for their classification, oligoastrcytomas incidence rate is highly variable, accounting from 1.8 to 10% of brain tumors. Males are affected slightly more frequently than females.

Oligoastrocytomas typically occur in young adults (mean age at diagnosis, 35–45 years) and epilepsy is the most common initial symptom. Less commonly, patients may present with headaches, progressive paresis, cognitive impairment, signs of increased intracranial pressure, or have no symptoms at all.

Supratentorial subcortical areas are the most frequent locations of oligoastrocytomas. The frontal lobes are most commonly affected. Lesions are usually single, but multiple lesions have been reported. There may be a correlation between the profile of molecular alterations and tumor location. Also, oligoastrocytomas and oligodendrogliomas with LOH on 1p appear preferentially located in the frontal regions.

The issues concerning the diagnosis are similar to those for other low-grade tumors. At neuroimaging oligoastrocytomas do not show features allowing a reliable distinction from oligodendrogliomas. Computed tomography (CT) scans reveal a well-demarcated hypodense subcortical mass. Calcifications may be present, but they are less common than in pure oligodendrogliomas. In about half of low-grade oligoastrocytomas CT scans show contrast enhancement.

Magnetic resonance (MR) shows a hypointense mass in T1 weighted images and a hyperintense mass in T2 weighted images. The abnormal T2 signal represents both vasogenic edema and the infiltrating tumor. Enhancement is associated with anaplasia, but especially in older people, the absence of enhancement does not exclude the diagnosis of anaplasia; when present, enhancement is irregular and nodular.

In most studies patients with oligoastrocytomas are combined with patients with oligodendrogliomas or astrocytomas. However in cohorts of WHO grade II oligoastrocytomas a median survival time of 6.3 years and survival rate of 70% at 5 years and 49% at 10 years have been reported. In WHO grade III oligoastrocytomas the median survival time of 2.8 years and survival rates of 36% at 5 years and 9% at 10 years have been referred. Clinical parameters associated with prolonged survival are young age (<40 years), long duration of symptoms, excellent postoperative neurological status.

Surgery is an important diagnostic and therapeutic modality for patients with oligoastrocytomas. First, it can relieve global symptoms caused by raised intracranial pressure; furthermore, it provides adequate tissue for a pathological diagnosis and grading. The role of gross total surgical excision remains unresolved, although most retrospective studies, in which the extent of surgery is often defined by the surgeon rather than by

postoperative imaging, suggest a survival benefit from aggressive surgical resection.

Postsurgical treatments of oligoastrocytomas are similar to those of oligodendrogliomas and are different in grade II and grade III tumors; nevertheless the optimal therapy at diagnosis and recurrence remains controversial. Generally, in WHO grade II oligoastrocytoma treatment is deferred until there is a clinical or radiological evidence of progression, unless patients have disabling symptoms or signs at presentation. In fact the disease can be indolent for years and neurotoxic effects of radiotherapy must be considered. Indeed, the optimal timing of radiotherapy is not yet established; a conventional treatment with focal radiotherapy up to a total dose of 54 Gy is needed for WHO grade III oligoastrocytomas.

The role of chemotherapy is evolving and some form of chemotherapy may ultimately replace radiotherapy as the initial treatment. PVC chemotherapy (Procarbazine, CCNU, and ►vincristine) is the best studied chemotherapy regimen and can cause measurable tumor regression. However, because of PCV toxicity, temozolomide may be a reasonable alternative.

Most oligoastrocytomas, as well as astrocytomas and oligodendrogliomas, will progress to malignancy. Patients with worsening clinical symptoms and the appearance of contrast enhancement at MRI or hypermetabolism at PET warrant reevaluation. Resection or biopsy is often performed, and further therapy is chosen on the basis of histological features and prior treatment.

Like anaplastic oligodendroglimas, WHO grade III oligoastrocytomas require immediate treatment after diagnosis. A conventional focal radiation dose of 60 Gy is appropriate for WHO III grade tumors. It is unclear how to best incorporate chemotherapy into the treatment strategy. According to many physicians treatment can be initiated with chemotherapy using PCV or temozolomide, followed by radiotherapy; this treatment schedule allows to measure treatment response, when there is a residual tumor. A recently published, large, randomized EORTC trial showed that adjuvant PCV chemotherapy does not prolong overall survival but increases progression free survival. Similarly, a RTOG trial showed that despite significant toxicity, PCV plus radiotherapy is associated with prolonged progression-free survival without changing overall survival.

The deletion of particular genomic regions could have direct consequences for therapeutic intervention. Losses on 1p and 19q correlate with sensitivity for treatment with nitrosureas or temozolomide and with longer survival. However, both in EORTC and RTOG trials, patients with LOH on 1p and 19 q did not achieve a benefit from early chemotherapy and had a longer disease course irrespective of treatment modality, suggesting that this genetic signature is rather a prognostic marker than a predictor of chemotherapy response.

Therefore, at this time it is unclear how to incorporate molecular genetic information into treatment decision for patient with oligoastrocytomas.

Oligodendrocyte

Definition

A cell type found in the central nervous system, the function of which is to wrap neuronal processes with myelin in order to facilitate the transmission of action potentials.

►Oligodendroglioma

0

Oligodendroglioma

Roger E. McLendon
Department of Pathology, Duke University Medical Center, Durham, NC, USA

Definition

Oligodendrogliomas are a diagnostic classification of ►brain tumors formed of cells that cytologically resemble the ►oligodendrocyte and predominately arise in the frontal lobes of adults but may also be found in other regions of the brain and spinal cord and affect all ages.

Characteristics

Clinically, oligodendrogliomas are considered to be aggressive cancer and infiltrative cancer, earning World Health Organization grades of II and III. Recent

therapeutic trials have indicated that the tumor is responsive to certain therapies and that genetic ►biomarkers seem to predict good therapeutic responses to these therapies.

History

Historically, the tumors were first described by Bailey and Bucy (1929) in a classic publication that also described their calcifications, their tendency to occur in the cerebral hemispheres of adults and their slow clinical ►progression. They also noted the presence of astrocytic-like cells in some tumors with transitional cells also present in some tumors.

Epidemiology

Oligodendrogliomas represent ~3–4% of all primary tumors arising in the brain. The incidence is ~0.3 per 100,000 populations. There are no known familial syndromes of which these tumors are a component and there is no known inherited tendency to acquire the tumors. No environmental or occupational hazards are implicated in causation. The majority of these tumors are diagnosed in the fourth and fifth decades though they affect all ages. Infratentorial examples seem to be more common in children than adults. There is a modest male predominance.

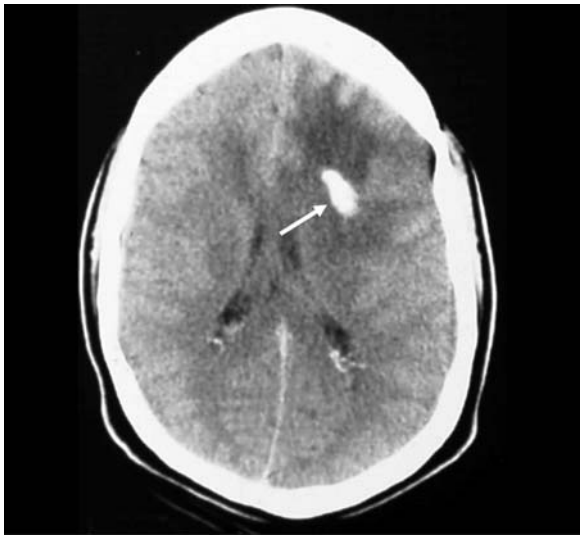
Clinical Presentation

The tumors are commonly associated with ►epilepsy and/or headache. Not uncommonly, a pre-diagnostic period of symptoms related to the tumor of 5 years or more is noted. Examples of adult patients with seizures beginning in childhood are well documented.

Until recently, the post operative survival was relatively uniform despite the variable presentation. Reports indicate a post-diagnostic ►Kaplan Meier survival of 81% at 2 years. Age greater than 65 years has been associated with a significantly shorter survival. Other clinical features associated with poor prognosis include poor post-operative ►Karnofsky performance score, tumoral biopsy rather than gross total removal, and no ►radiation therapy. Of course many clinical decisions are reflected in the choices of biopsy and therapy that may reflect independent features of poor prognosis rather than represent factors themselves. For example, a tumor arising in a ►neurologically eloquent location may preclude gross total excision.

Radiologic Appearance

Radiographic studies reveal that the tumors tend to affect both the cortex and white matter with a proclivity to appear in the frontal lobes (Fig. 1). They are the most common primary intraparenchymal tumor to exhibit calcification which may be seen on plain skull films but



Oligodendroglioma. Figure 1 Noncontrast ►CT scan demonstrates focal (*white arrow*) calcification in a frontal lobe oligodendroglioma.

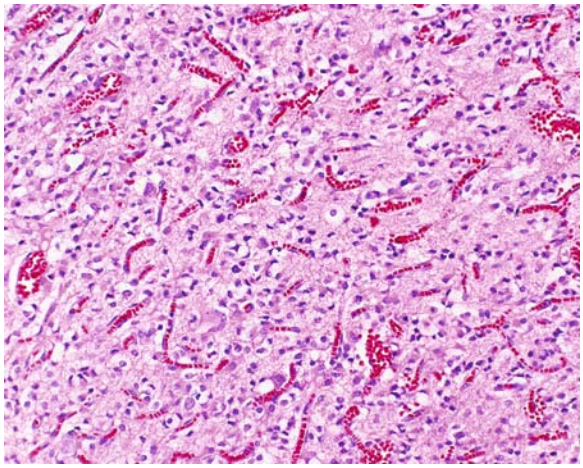
are very commonly encountered on CT scans. While the calcifications may be seen in low grade tumors, they persist after the tumor has progressed to a higher grade. The tumors appear well circumscribed and do not manifest significant edema on CT scanning.

The MR features are variable. Most tumors exhibit regions that are iso- to hypointense on T1-weighted images and hyperintense on T2-weighted images. Microcysts may also be visible on T1- and T2-weighted imaging. Enhancement with gadolinium is rarely significant and typically manifests fine linear or dot-like patterns, if present.

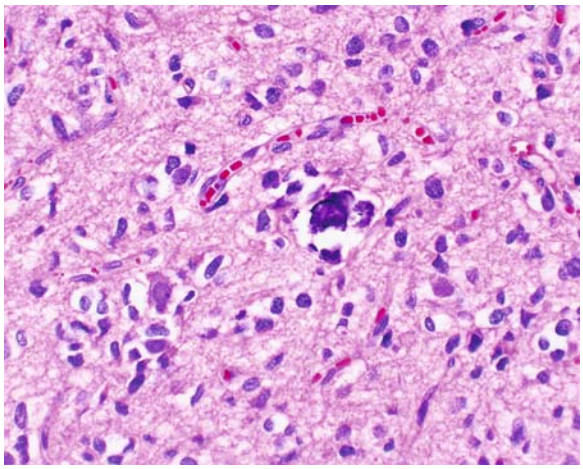
Pathologic Features

Upon gross inspection, oligodendrogliomas often exhibit infiltration into the leptomeninges, resulting in a white, gelatinous, "toothpaste" appearance to the operative surgeon. Other tumors, more deeply situated, may infiltrate the ventricular system or appear to cross the corpus callosum. The gelatinous tumors have a pink appearance in more solid regions with a relatively sharply demarcated border.

Microscopic examination reveals a relatively monotonous cytologic appearance of oval cells of similar size and shape (Figs. 2–4). The tumor cells have a proclivity to accumulate about blood vessels and, in the cortex, about neurons in a process called "satellitosis." The tumor cells exhibit nuclear features that are monotonous with round, regular nuclei that seem to be made from the same mold. The nuclei exhibit filamentous or speckled chromatin that is often associated with a single punctate ►chromocenter, or karyosome. Mitotic activity

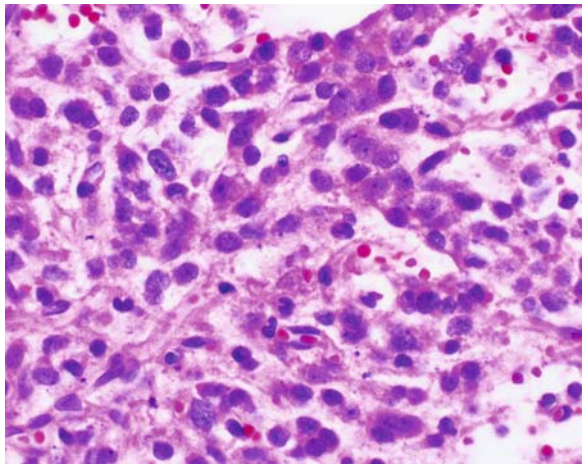


Oligodendroglioma. Figure 2 This microscopic image of an oligodendroglioma shows numerous branching vessels filled with red blood cells.



Oligodendroglioma. Figure 3 This microscopic image of a well differentiated oligodendroglioma shows the round regular blue stained nuclei surrounded by clear zones that are typical of the histologic appearance of the tumor. The clump of blue indicates a small focus of calcium.

is not uncommon, even among low grade tumors. While the cytoplasm of oligodendroglial cells is often clear, resulting in a "fried egg" appearance, the finding itself is artifactual and can be lost with rapid fixation. The vasculature is often described as net-like with small tubular vessels often seen to be branching at various angles (Fig. 2), however, this vascular pattern is not consistently found and may represent the dilated indigenous vasculature of ischemic cortex where it is most commonly found. The calcifications noted by radiology consist of scattered punctate mineral deposits



Oligodendroglioma. Figure 4 This image of an anaplastic oligodendroglioma shows more abundant pink staining cytoplasm in contrast to the image of Fig. 3 and now shows small blue particles indicative of dead nuclei. Cell death and high cell density are indicative of high cell turnover.

along blood vessels and dead cells (Fig. 3). Phenotypically, the tumor cells are glial and show ►immunohistochemical reactivity for Glial Fibrillary Acidic Protein.

Tumor Grading

Spontaneous geographic necrosis is considered an ominous finding indicative of high grade tumor. High grade tumors also frequently demonstrate eosinophilic-cytoplasm maintaining the oval outlines (Fig. 4). Mitotic activity becomes more pronounced and vascular proliferation is manifest. However, in contrast to the ►glioblastoma with its varied histologic appearance, anaplastic oligodendrogliomas maintain a uniform cytologic appearance and often preserve areas of low grade morphology.

Mixed Gliomas

The so-called mixed glioma, or oligo-astrocytoma, is a controversial entity with regards to its definition. Some pathologists insist on two distinctive histologic populations of oligodendroglioma and ►astrocytoma while others indicate tumors with transitional cells exhibiting round regular, "oligodendroglial" nuclei but exhibiting fibrillary eosinophilic "astrocytic" cytoplasm represent these tumors. Therapy often renders once well accepted oligodendrogliomas with clear cytoplasm and round to cuboidal cell outlines into transitional forms on subsequent biopsies.

Genetics

In the early 1990s, researchers using ►loss of heterozygosity analyses found that tumors with oligodendroglial

morphologies commonly exhibited allelic losses of 1p and 19q in up to 85% of these tumors. Subsequent researchers have noted that this change occurs after mitotic division as a result of a t(1,19)(q10,p10) ►chromosomal translocation which results in an apparent centromere to telomere loss of a 1p and a 19q arm. Earlier researchers had noted that tumors with these genetic markers had significantly better responses to chemotherapy and radiation therapy versus gliomas that lacked these markers. However, even so-called mixed gliomas that lost only the distal 1p36 locus had better therapeutic responses compared with those exhibiting intact loci. Oligodendrogliomas of childhood tend not to exhibit the 1p/19q LOH marker and the therapeutic implications of these intact markers in these children are not established. ►*p53* mutations, common in astrocytomas, are not found in oligodendrogliomas.

Mixed gliomas (►oligoastrocytomas) have been studied by 1p/19q analysis but the results are varied due to definitional problems. However, it is clear that this set of tumors holds the highest variation in genetic marker loss than seen in typical oligodendrogliomas. Among these tumors, 1p and 19q loss often do not occur in tandem with only 1p or only 19q exhibiting LOH or only a partial 1p loss is manifested suggesting that the microscopic ambiguity is related in someway to the incomplete genetic picture.

Therapy

Oligodendrogliomas are not cured by current therapeutic regimens. They appear to respond to chemotherapeutic protocols that include external beam radiation and/or ►chemotherapy with ►alkylating agents (such as ►Temozolomide). As noted previously, the response to therapy seems to be related in some unknown way to 1p/19 LOH status.

Oligomerization Domain

Definition

OD; Refer to a region in a protein that mediates the assembly of higher order protein complexes. A major distinction between ODs and other protein-binding modules is that ODs are generally responsible for homotypic interactions or interactions between proteins in the same family.

►p53 Family

Oligonucleotide

Definition

Short sequence of single stand DNA.

►ArrayCGH

Oligosaccharides

Definition

One of the most important posttranslational modifications on proteins. They contain both *N*-glycans and *O*-glycans. There are three kinds of major oligosaccharide molecules, namely, glycoproteins, glycolipids and proteoglycans.

►Fucosylation

Ollier Disease

Definition

Non-hereditary disorder characterized by the occurrence of multiple ►enchondromas preferentially located in the short and long tubular bones of the limbs causing deformity and limb asymmetry, with one side of the body more severely affected. The genetic deficit is unknown so far.

►Chondrosarcoma

OM

Definition
Oligomycin, an inhibitor of oxidative phosphorylation.

►Jasmonates in Cancer Therapy

Omega-3 Fatty Acids

Definition
Omega-3 fatty acids are a family of polyunsaturated fatty acids that have in common a carbon–carbon double bond in the ω-3 position. They are essential to human health but cannot be manufactured by the body. They must be obtained from food being present in fish and certain plant oils. Also known as polyunsaturated fatty acids (PUFAs), omega-3 fatty acids play a crucial role in brain function as well as in normal growth and development.

Omental Immune Aggregates

Edith M. Lord
Department of Microbiology & Immunology, University of Rochester School of Medicine and Dentistry, Rochester, NY, USA

Synonyms
Milky spots; Omentum-associated lymphoid tissue

Definition
Omental immune aggregates are organized clusters of leukocytes (white blood cells), surrounded by an extensive vascular network and partially covered by a layer of ►mesothelial cells. They are found on the ►omentum in a wide variety of mammalian species as well as in frogs and chickens. Similar structures are also found within the mesentery, and interspersed along adipose tissue along the reproductive tract.

Characteristics
Structure and Cellular Composition
These immune aggregates were first described by Recklinghausen in 1863 and in 1874 Ranvier named them "taches laiteuses" or milky spots due to their translucent appearance on the more transparent omentum of rabbits. They have been identified on the omentum from a large number of other mammalian species including man, mouse, rat, guinea pig, sheep, goat, bat, mole, pig, cat, dog as well as frog and chicken. The original studies primarily employed electron microscopic techniques to study tissues from human and rat. More recent studies with mouse tissues utilized immunofluorescence techniques as well as flow cytometric assays to delineate the cell types present. The omentum itself is a thin tissue composed of a double layer of mesothelial cells with blood vessels, a central lymphatic vessel and numerous adipocytes between the layers. The immune aggregates are visible macroscopically on this transparent sheet as opaque spots composed of a variety of immune cells, whose relative amounts appear to vary somewhat among species. In humans and rats macrophages have been reported to be the major cell type present, whereas more recent studies in mice indicated that lymphocytes account for the majority of cells present. In humans the cellular composition of the immune aggregates have been reported to be 48% macrophages, 29% B cells and 11% T cells with small numbers of mast cells. In recent studies with mice, the composition has been found to be 15% macrophages, 45% B cells, 15% T cells, 5% dendritic cells (CD11c+) as well as small numbers of ►NK cells and NKT cells and gamma/delta T cells. It is not clear if these differences are due to the different techniques employed or real differences among species. In humans milky spots have first been observed at 26 weeks gestational age with increasing numbers and size that appear to reach a maximum during the first year of life. Extensive ontogeny studies have not been done in mice or rats.

Structurally, these immune aggregates have a distinct architecture, resembling lymph nodes. There is a central area of T cells surrounding by a B cell area. ►Germinal centers are generally not observed in human or rodent omental immune aggregates. These lymphoid areas are punctuated by small numbers of dispersed ►dendritic cells (found predominately within the T-cell zone) and smaller numbers of NKT cells. Most peripheral are the ►macrophages, which form a diffuse ring around the more central lymphoid areas. The mesothelial cells, which comprise the entire omentum forming an almost continuous lining on both sides of the omentum, have been reported to be discontinuous over the immune aggregates. Basement membrane is also lacking in these areas. In addition to the immune cells, there are also limited numbers of reticular cells, which

electron microscopy studies have shown to have long slender cell processes, which are often connected with neighboring cells. Further structure is provided to the immune aggregates by fine fibers comprised of type I collagen, which form a mesh throughout the aggregates. This mesh is confined to or much denser in the areas of the immune aggregates compared to the rest of the omentum.

Vascularization

A striking feature of the immune aggregates is the extensive and well-formed vasculature network that underlies the immune cells. The omentum is served by a central artery and vein that diverge into a mass of smaller vessels and capillaries at each immune aggregate. These vessels encircle each aggregate forming a dense vascular network that commonly extends beyond the immune cells. Segments of these vessels have been shown to stain positively for the ►peripheral lymph node addressin molecule (PNAd), which would facilitate homing of immune cells from the blood stream. Interestingly, vessels in these areas also stain for the marker CD105, a proliferation-associated antigen also known as endoglin, which is localized primarily to endothelial cells undergoing active ►angiogenesis. Furthermore, vascular sprouting has been observed within the vessels populating the immune aggregates. A percentage of specialized (VCAM+) mesothelial cells located above the immune cells of the MS have been shown to constitutively produce ►vascular endothelial growth factor A(VEGF-A), a potent angiogenic factor involved in new vessel formation. These results are all consistent with the vessels within the immune aggregates being in a pro-angiogenic state. This finding may be indicative of the function (see below) of these cellular aggregates in immune protection within the peritoneal cavity, as the aggregates have been shown to increase in number and in size (in terms of cells/aggregate) in response to the introduction of immune stimuli within the peritoneal cavity. The proangiogenic state of the vessels may be in preparation for the rapid influx of immune cells that can occur in response to inflammatory stimuli.

Function

The function of the ommental immune aggregates and the relationship of the cells present there compared to the cells free in the peritoneal fluid has been an object of considerable study and controversy. It is generally believed that these cells serve as sentinels to provide protection against bacteria that enter the peritoneal cavity due to gut perforation or during operations. It is well-documented that particles within the cavity end up ingested by macrophages found in the milky spots. It is less clear whether the particles are ingested by macrophages within the peritoneal fluid, which then traffic to the milky spots or directly ingested by macrophages within the milky spots. Labeled immune cells injected into the peritoneal cavity have been found to attach to milky spots thus indicating that there is a cellular homing mechanism to these sites. The incomplete coverage of mesothelial cells over milky spots implies that foreign particles might have direct access to omental macrophages. Regardless of the mechanism, the omental immune aggregates appear to play an important role in immune defense of the peritoneal cavity as surgical removal of the omentum results in an impaired anti-bacterial response in the peritoneal cavity.

The milky spots also serve as a site for proliferation and maturation of cells by providing a microenvironment with the appropriate growth factors and vascularization needed for these processes. Several studies have indicated that monocytes from the blood stream can serve as progenitors for macrophages in the milky spots and the peritoneal fluid. The immune aggregates are also the site of large numbers of B1 cells, a unique B cell population with a limited repertoire that can respond in a T independent manner to bacteria. These cells produce large amounts of IgM, which have been termed natural antibodies. In the mouse B1 cells comprise approximately half of the B cells present on the omentum. Recent evidence has demonstrated that B1 cells can home from the blood stream to the peritoneal cavity via the blood vessels in the milky spots on the omentum. They appear to be attracted to these areas by the ►chemokine CXCL13, which is thought to be produced by the mesothelial cells of the omentum. Once established, this population is thought to be self-replenishing within the immune aggregates. Thus, these cell populations play an important role in intercepting infectious agents that enter the peritoneal cavity.

Tumor Cell Adherence and Metastases

Another characteristic of the immune aggregates that is well-documented is the preferential adherence of metastatic tumor cells to these sites. This has been observed in a variety of experimental models in which intraperitoneal injection of tumor cells results in localization to the milky spots as soon as one hour after injection. The omentum is also a primary site of metastatic tumor formation in humans with primary intra-abdominal tumors such as ovarian, gastrointestinal and pancreatic carcinomas. These appear to form from cells that directly seed from the primary tumor spontaneously or are released during surgery, and are perhaps carried by the natural flow of peritoneal fluid. The experimental systems have uniformly indicated that the omentum is the primary site of tumor cell

attachment, although cells subsequently seed to other structures including the mesentery, the peritoneal wall and the diaphragm. The mechanism of this preferential attachment is completely unclear. Early reports based on electron microscopy have indicated that the mesothelial layer overlying the immune cells is incomplete allowing access to the immune cells below. However, very recent studies with confocal microscopy indicate that the tumor cells initially attach to the mesothelial cells. It has been suggested that this attachment is via specific cell adhesion molecules such as integrins, but the mechanism remains unsubstantiated. This is an important question because prevention of attachment might have a substantial effect on slowing or eliminating metastases formation. In addition to the preferential attachment, the immune aggregates appear to be sites particularly well-suited for tumor growth due to the well-formed vasculature present in these locations. Furthermore, the vessels in these areas appear to be in a pro-angiogenic state, presumably to provide the needed oxygen and nourishment when the numbers of immune cells increase during infections. However, this also provides the ideal environment for rapid tumor growth. The immune cells appear to have little if any effect on the growing mass of tumor cells, presumably due to the lack of specifically reactive cells. As the metastases increase in size the structure of the immune aggregates are disrupted. Because the omentum is such a favorable site for metastases, it is often removed during surgery to resect the primary tumor. However, the propensity of cells to attach to the immune aggregates suggests that adoptive immunotherapy might be targeted to these sites of ►metastasis formation.

Omentum

Definition

From Latin, meaning apron; A sheet of tissue composed of a double layer of mesothelial cells encompassing a layer of fat that is well-vascularized and contains aggregates of immune cells. Two are present in the human abdomen. The greater omentum hangs down from the stomach, and extends to the transverse colon. The lesser omentum extends from the liver to the lesser curvature of the stomach and the first part of the duodenum.

Oncofetal Antigen

Thomas D. Southgate, Peter L. Stern
Paterson Institute for Cancer Research, University of Manchester, Manchester, UK

Definition

Oncofetal genes are those that are expressed in developing (fetal) as well as cancer (onco) cells. This expression can reflect shared functions important during development and which are re-activated, during neoplasia. Sometimes the latter can involve functional changes which may be delivered through structural modifications (e.g. amino acid sequence change) or by the levels or context of the expression (altered or different gene promoters of transcription). The term antigen relates to the property of the gene product and/or its added post translational modifications (e.g. ►glycosylation) which can be recognized by the immune system, (e.g. antibodies). Most self molecules are non-immunogenic and not able to induce antibodies in the same organism which are said to be tolerant. Often oncofetal antigens are immunogenic since they are not expressed widely in the adult animals and the immune system is not tolerant and they can elicit self immunity under some circumstances.

Characteristics

Cancers are the mostly the result of the accumulation of successive alterations in gene and cellular function which influence the tumors cells with respect to their replicative potential, self sufficiency in growth signals, evasion of negative growth factors, avoidance of cell death (►apoptosis), acquisition of the ability to spread (►metastasis) and provision of a suitable blood supply (►angiogenesis). The latter properties are all obligatorily shared by embryonic cells and so it is not surprising that during ►carcinogenesis, such embryonic pathways are reactivated to hijack these hall marks of cancer. In doing so the tumor cells express oncofetal antigens which are potential targets for the mature immune system which of course was not present during the time when their expression related to development. Although the overall similarity is striking between cancer and embryonic development, ultimately a cancer is the product of the deranged control of the multiple targets not all of which involve embryonic pathways.

The idea that the human immune system is capable of eliminating cancer was suggested as early as the late 19th century. Paul Ehrlich speculated that an anticancer vaccine or Zauberkugel (magic bullet) in which serum-derived Antikorper (antibodies) would be capable of eliminating cancer cells. We now know that any useful antitumor immunity is likely to involve both the humoral (antibody-mediated) and the cellular mediated arms of the immune response. Oncofetal antigens can be recognized in patients by specific antibodies and T cells. Such natural immunosurveillance may indeed control many nascent tumors but in many advanced cancers multiple tumor immune escape mechanisms including an impaired cellular mediated immunity can lead to progressive disease. Nevertheless the potential for the immune system to be able to recognize oncofetal antigens has driven research seeking to boost such immunity for therapy. Alternatively the ability to recognize the oncofetal antigen in cancer patients compared to normal subjects and been exploited for disease diagnosis and monitoring. Three examples of

oncofetal antigens with some research developments are given.

Alpha-Fetoprotein: Role as an Oncofetal Antigen

►Alpha-fetoprotein (AFP) was first described in the 1960s as a marker for ►hepatocarcinoma. Normally expressed during fetal development, high levels of transcript are present within the hepatocytes and the endodermal cells of the yolk sac with the level of expression being repressed after birth. Measured by immunoassay, elevation of AFP in the serum has been observed concurrent with aberrant growth manifestations such as ►hepatocellular carcinomas and embryonic carcinomas. Although AFP may not be the direct cause of the altered growth, it is conceivable that some shock/stress-induced conformational variant form of this fetal protein may influence the progression of this growth as the 70 kDa glycoprotein is known to bind and transport a number of ligands such as bilirubin, fatty acids, steroids and various drugs. This wide spectrum of interactions has however, made the measurement of AFP, and its ligands, a useful ►biomarker for the differential diagnosis of cancer.

The targeting of the receptor for AFP has therefore been suggested as a potential therapeutic modal for the treatment of cancer. This is based on the observation of the overexpression of AFP receptors on the surface of malignant cells versus the negligible expression on normal cells. Targeting of these receptors would therefore allow the specific delivery of anticancer drug conjugates to cancer cells *in vivo*. With many tumors displaying multi-drug resistance, possibly through the overexpression of membrane receptors/and/or transporters, the cancer cells evade conventional chemotherapeutic approaches. Successful conjugation of AFP to different compounds such as doxorubicin, ►cisplatin or methotrexate has been shown to allow the selective entry into these tumor cells via the AFP receptor mediated endocytic pathway. These tumor cells subsequently have raised drug sensitivity and a greater tumor ablation using these AFP conjugates compared to the unconjugated chemotherapeutic has been demonstrated *in vivo*.

Targeting the immune system against the AFP expressing cells could provide an alternate therapeutic approach. Breaking the natural immune-tolerance towards AFP is possible and DNA-based immunization has been shown to induce ►cytotoxic Tlymphocytes and ►CD4-T-cell mediated growth inhibition of AFP-expressing subcutaneous tumors in mice. Their potential in achieving an effective tumor regression is, however, to date, limited. In another approach patient-derived dendritic cells have been infected with recombinant adenoviruses expressing AFP. Co-culturing of these cells with autologous cytotoxic lymphocytes induced an AFP-specific strong immune response against hepatocarcinoma cells *in vitro* but this is yet to be tested in animal models of cancer. It is likely therefore, that a combination of different treatment modalities such as selective targeting and immunotherapy will need to be utilized for the treatment of AFP positive tumors in patients.

Carcinoembryonic Antigen: Role as an Oncofetal Antigen

►Carcinoembryonic antigen (CEA) was first described nearly 40 years ago as an oncofetal antigen and remains one of the most widely studied human tumor-associated antigens. First characterized in ►gastrointestinal tumors its expression within tumors and levels of circulating CEA is recognized as a valuable adjunct to post-operative surveillance and preoperative prognosis of patients diagnosed with colorectal and other types of carcinoma. The antigen has a molecular weight of between 180–200 kDa and is part of a sub-group of the immunoglobulin super family. It is the structural similarity of CEA with immunoglobulins which mediates a functional role for CEA both as an ►adhesion molecule and as a regulatory protein controlling the movement across the gut of fimbriated bacteria. The regular shedding of CEA thereby influences lymphocyte homing and the translocation of microorganisms.

The anchoring of CEA to the plasma membrane and the overexpression of CEA in a wide range of epithelial cancers has made it a popular target for novel cancer therapies, including cancer vaccines such as those against AFP. In these studies a variety of viral vaccine vectors containing the CEA gene alone or in combination with other molecules that enhance the immune response have been evaluated in clinical trials. These trials are aimed at testing whether generating CEA specific killer T-cells is related to clinical responses and increased survival rates Alternate strategies center around antibody based therapies. One example is ►radioimmunotherapy where antibodies against CEA are labeled with radioisotopes such as yttrium 90 or iodine 131. The antibody when delivered into the circulation binds to the bound CEA on the cell surface of the cancer cells delivering the therapeutic radioisotope to the site of the cancer. Another strategy has been the generation of genetically engineered T-cells where a ►chimeric T cell receptors has been inserted that are composed of a single chain antibody against CEA fused to the activating domain of the T-cell receptor. T-cells naturally recognize processed antigens only when they are presented on ►major histocompatibilty complex (MHC) class I or II molecules This antigen presentation pathway is complex and there are often defects in cancer cells that can result in failure of T-cell recognition, leading to tumor evasion. By engineering T-cells with chimeric receptors, activation occurs on binding to the CEA target on the tumor bypassing the need for MHC presentation. This therapeutic

strategy has proven successful in preclinical animal models and is currently being assessed in Phase I clinical trials.

5T4 Oncofetal Antigen

5T4 oncofetal antigen was discovered in 1988 by looking for molecules that might share functional attributes common to both invasive trophoblast and carcinomas. The name was derived from the monoclonal antibody "5T4" raised against solubilized human syncytiotrophoblast plasma membrane glycoproteins. This antibody was selected by screening for low reactivity with normal tissues but high reactivity with different tumor cell types. Isolation of the human gene established it as a unique member of the leucine rich repeat family which are often associated with molecules that function in protein-protein interactions. The subsequent isolation of the murine gene and mouse specific monoclonal antibodies has allowed the determination of 5T4 expression throughout mouse development. As in humans, there is little expression of the antigen in adult tissues such as the liver, lung, bronchus, heart, testis, ovary, brain, or muscle whilst several specialized epithelia retain low level expression into adulthood; there is expression by all types of trophoblast in the placenta. Embryonic expression of mouse 5T4 antigen is first detected on trophectoderm at implantation and is restricted to extra-embryonic tissues until about day 11. After this the 5T4 expression profile is widely associated with actively cycling, undifferentiated epithelial progenitor cells which may contribute to their migration. In the brain, expression is observed in roof plate, ependymal layers, choroid plexus and subventricular zones of lateral ventricles until about day 14 but this then decreases in the subventricular zone with further restriction to the choroid plexus in adult brain.

5T4 oncofetal molecules function in the process of ►epithelial to mesenchymal transition which facilitates movement of cells in development and metastasis in malignancy. This is consistent with the association of 5T4 tumor expression with poorer clinical outcome in gastric or colorectal or ovarian cancer since this mostly the result of spread (metastasis).

The restricted adult tissue but high frequency and cell surface expression by multiple carcinoma types makes 5T4 antigen an attractive target for both antibody and cell mediated immunotherapies. One approach now in clinical trial takes advantage of the potential of superantigens to activate T-cells by redirecting the specificity to the tumor by using antibodies to 5T4 antigen. A 5T4 specific antibody-superantigen fusion protein interacts with 5T4 positive tumor cells and nearby T cells, activating them to destroy the cancer directly or indirectly through the release of cytokines like gamma interferon. The treatment can safely used and does stimulate the desired immunity in patients and a recent trial has documented very encouraging clinical responses in patients with renal cell carcinoma.

Alternatively the human 5T4 gene has been engineered into a modified version of the vaccinia virus (smallpox vaccine) and this has then been used as a cancer vaccine in patients. This virus is unable to replicate or spread but infected cells produce the 5T4 molecules and this can generate both antibodies and killer T cells which can then target the tumors. Several clinical trials of this vaccine called Trovax® have been performed in patients with colorectal cancer and these showed the treatment to be safe and capable of induced both antibodies and cellular immunity.

Synonyms

Transforming gene

Definition

An oncogene is any gene that has the ability to stimulate cellular growth. Oncogene products can transform eukaryotic cells such that they grow in a way analogous to tumor cells. The definition was originally applied to the transforming genes acquired by RNA tumorviruses

through ►transduction of oncogenes; today the term is used rather broadly.

Characteristics

Oncogenes were originally isolated from ►RNA tumor viruses, where they are responsible for the ability of rapid tumor induction after infection of an animal host. In the viral genome the oncogene was referred to as a viral oncogene or v-onc.

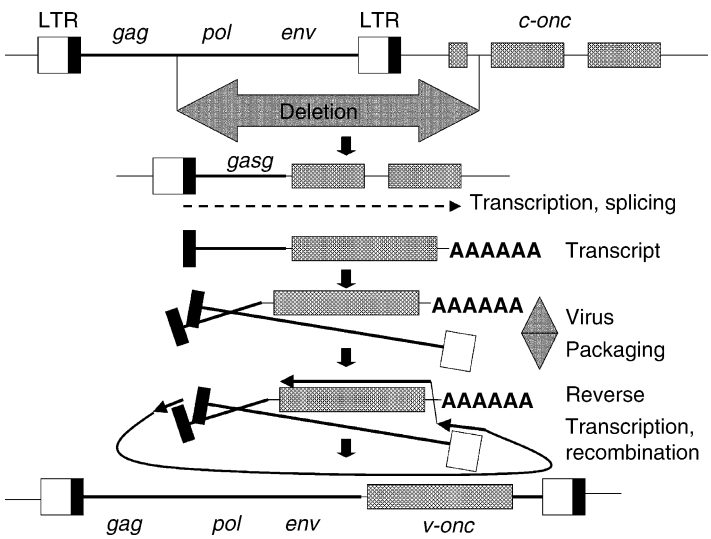
It was soon established that the v-oncs are actually derived from the genome of the host cell. They are captured by the virus after infection of the cell by a process called transduction (Fig. 1; transduction of oncogenes). Transduction appears in a wide range of animal species from chickens to monkeys (Table 1), it has not been observed in humans. The cellular counterparts, from which the v-oncs are derived, are referred to as proto-oncogene, or c-onc. Proto-oncogenes are normal constituents of the cellular genome and are highly conserved among all eukaryotic organisms.

This original rigid definition has softened in subsequent years. Broadly speaking, the term oncogene now includes any gene that has a growth stimulatory effect on cells, with the result of:

- Conferring sustained cellular multiplication
- Advancement of ►cell cycle progression
- Decreased requirement for ►growth factors
- Focus formation under conditions of cell culture
- Ability of cells to grow under more restricted experimental conditions, such as in soft agar
- Tumorigenic conversion, such as in experimental animals
- Conversion of cells to form tumors that undergo ►metastasis
- Escape from ►apoptosis

The precursors of oncogenes (proto-oncogenes) are present in their normal structure and expression activity in all eukaryotic cells, they represent potential "enemies within," but perform normal, usually vital, functions. Their oncogenic potential can be activated by any one of the following mechanisms (Fig. 2)

- Expression deregulation, by which the normal expression pattern is altered by a variety of mechanisms
- Mutation within the gene, which results in an abnormal protein that has a different biological activity (e.g. ►RAS)
- Translocation, by which DNA of two genes on two different chromosomes can recombine with the result of a fusion gene and a fusion protein (e.g. BCR/ABL [►BCR-ABL1]) or a deregulated gene expression, when gene expression signals are replaced by other DNA sequences



Oncogene. Figure 1 Model for the transduction by retroviruses. The process begins when the provirus of a retrovirus integrates into the vicinity of a cellular oncogene. The characteristic "long terminal repeats" (LTR) are drawn as black and white boxes. A deletion enables the c-onc and the provirus to fuse into a single genetic unit, one of the proviral LTR plus regions of both the provirus and the c-onc, are deleted. Transcription from the hybrid unit generates a hybrid RNA, introns have been removed by splicing. This RNA can be packaged, together with a wild type retroviral RNA, to form a virion (retroviruses have two RNA molecules). Infection of a cell initiates reverse transcription of viral RNA. Beginning at the 5′-end, the reverse transcriptase can jump to the 3′-end to continue chain propagation along the retroviral genome. Reverse transcriptase can also jump to the hybrid RNA and generate a new retrovirus genome, containing the c-onc.

Oncogene. Figure 2 Molecular pathways for activating the oncogenic potential of cellular oncogenes. Translocation defines exchange of genetic material between two non-homologous chromosomes.

- ►Amplification, where the number of gene copies multiplies, with the consequence of enhanced gene expression (e.g. ►MYCN)

Oncogene Cooperation

Experimental approaches have shown that alteration of a single oncogene is insufficient to achieve full tumorigenic conversion of a normal cell. Only when at least two altered oncogenes are introduced can a normal cell assume a tumorigenic phenotype. Oncogene cooperation is well in line with the multiple genetic changes that a tumor acquires during its evolution to metastatic disease (►Multistep development). Oncogenes can also cooperate with ►tumor suppressor genes.

Pathway addiction

Definition

►Oncogene addiction describes the phenomenon in which some cancers that contain multiple genetic, epigenetic, and chromosomal abnormalities remain dependent on (addicted to) one or a few genes for both maintenance of the malignant phenotype and cell survival.

Characteristics

Multistage Carcinogenesis and Oncogene Addiction

There has been considerable progress in the systemic treatment of cancer due to the rapid development and

clinical application of molecular targeted agents (►Molecular Therapy). Although patients with a particular type and stage of cancer are often treated as a single group, more specific therapy is being considered, as subsets of patients who are more likely to benefit from treatment with particular agents are being identified. It is now an axiom in oncology that human cancers often evolve through a multistage process that extends over a period of decades. The marked increase in molecular biology studies has revealed that this process is driven by the progressive accumulation of mutations, and epigenetic abnormalities in expression (►Epigenetics), of multiple genes that have highly diverse biochemical functions. Malignant carcinomas of the lung (►Lung Cancer), colon, breast, and other organ sites often display mutations in multiple oncogenes (►Oncogene) and ►tumor suppressor genes, harbor epigenetic abnormalities that result in increased or decreased expression of hundreds of genes, and contain chromosomal abnormalities that include ►aneuploidy and ►loss of heterozygosity at numerous loci. Therefore, it is surprising that despite this extensive disruption in the genomes of cancer cells there are multiple examples in both experimental systems and in patients with cancer whereby the reversal of only one or a few of these abnormalities can profoundly inhibit the growth of cancer cells and in some cases lead to improvements in patient survival (Table 1). We previously introduced the concept of "oncogene addiction," to emphasize the apparent dependency of some cancers on one or a few genes for maintenance of the malignant phenotype.

Evidence for Oncogene Addiction

Evidence that supports the concept of oncogene addiction has been obtained in three diverse systems: genetically engineered mouse models of human cancer, mechanistic studies in human cancer cell lines, and ►clinical trials involving specific molecular targeted agents (Table 1). Several investigators have generated transgenic mice that overexpress an oncogene in a specific target tissue under conditions in which the oncogene can be switched on or off. Switching on the ►c-*myc* oncogene in the hematopoietic cells of mice led to the development of T-cell and myeloid leukemias (►Acute Myeloid Leukemia); however, when this gene was subsequently switched off the leukemia cells stopped dividing and displayed differentiation and ►apoptosis. Dependence on continued expression of a single oncogene for maintenance of the neoplastic state has also been seen in similar murine models of other tissues, including: myelocytic leukemia induced by the ►*Bcr-Abl* oncogene; ►melanoma induced by the *H-ras* oncogene (►RAS); lung tumors induced by the *K-ras* oncogene; pancreatic β-cell tumors and osteogenic sarcoma (►Osteosarcoma) induced by the *c-myc* oncogene; and breast (mammary) tumors induced by the ►Her-2/neu, *c-myc*, and Wnt (►Wnt Signaling) oncogenes. In the *c-myc* ►breast cancer model when the *c-myc* oncogene was switched off although 50% of the breast tumors regressed, the remaining 50% showed only partial regression. Furthermore, breast tumors that recurred were found to be *c-myc* independent and some of these displayed an activated *K-ras* oncogene. Similarly, in the Her-2/neu breast tumor model tumors that recurred were found to be Her-2/neu independent, and this was recently found to be due to increased expression of the transcription factor *Snail* (►Snail Transcriptional Factor). In the Wnt-1 murine model even though downregulation of Wnt-1 resulted in rapid and extensive regression of aneuploid and invasive breast tumors and pulmonary metastases, a number of breast tumors recurred that were Wnt-independent. Apparently this was due to acquisition of mutations in the ►*p53* tumor suppressor gene. The relevance of these examples of "escape from oncogene addiction" will be discussed later with respect to human cancers and combination therapy.

A variety of studies using human cancer cell lines also indicate that although these cells are aneuploid and carry numerous genetic and epigenetic abnormalities, they can also be highly dependent on the activity of a single oncogene for maintaining the malignant phenotype. Blocking expression of the oncogenes *Her-2*, *cyclin D1* [►Cyclin D], *K-ras*, β-catenin, *cyclin E*, β-raf, or microphthalmia transcription factor (*MITF*) using either antisense DNA (►Antisense DNA Therapy) or RNA interference (RNAi) strategies (►RNA Interference) can markedly inhibit the *in vitro* growth of various types of human cancer cells. In some cases blocking oncogene expression also increases the sensitivity of these cells to specific chemotherapy agents and inhibits their tumorigenicity in mice. Because of the efficacy of the RNAi method for inhibiting the expression of specific genes the list of such examples of oncogene addiction is now rapidly expanding.

The most convincing and clinically relevant evidence for the concept of oncogene addiction comes from the increasing number of examples (i.e. prospective randomized trials) of the therapeutic efficacy of antibodies or drugs that target specific oncogenes in human cancers. One of the earliest examples is the use of the antibody ►trastuzumab (►Herceptin), which targets the receptor tyrosine kinase ►Her-2/neu (►Receptor Tyrosine Kinases). This membrane associated receptor is overexpressed in 20–30% of breast cancers, and it is now established that use of trastuzumab in these patients can markedly inhibit tumor growth and prolong patient survival in both the adjuvant (►Adjuvant Therapy) and metastatic settings. We should, however, emphasize that the therapeutic effects of trastuzumab may be

Oncogene Addiction. Table 1 Oncogene addiction: studies in mice, studies in human cancer cell lines, and clinical evidence

Studies in mice[a]

mediated at least in part via immune mechanisms. Within the past few years several low molecular weight drugs have been developed that target and inhibit the activity of other specific protein kinases that have key roles in the growth and survival of human leukemia and carcinoma cells. The remarkable therapeutic efficacy of some of these compounds provides direct evidence for the concept of oncogene addiction. Examples include ►imatinib that targets the oncogenic ►BCR/ABL protein in ►chronic myeloid leukemia (CML) and also targets the product of the oncogene *c-kit* in gastrointestinal stromal tumors (GIST) (►Gastrointestinal Tumors), and the EGFR targeted drugs ►gefitinib (►Epidermal Growth Factor Receptor Inhibitors) and ►erlotinib in ►non-small cell lung carcinoma (NSCLC), ►pancreatic cancer, and glioblastoma (►Glioblastoma Multiforme). ►Cetuximab, a monoclonal antibody (►Monoclonal Antibody Therapy) that targets the EGFR, may have significant antitumor activity in head and neck and colorectal carcinomas;

and ►bevacizumab, a monoclonal antibody to ►VEGF, may have significant antitumor activity in carcinomas of the breast, colon and kidney. These clinical studies also provide insights into the phenomenon of oncogene addiction. For example, in a subset of patients with CML who initially responded to imatinib but later suffered a relapse, examination of the leukemic cells showed a *de novo* mutation in the kinase domain of the BCR/ABL protein, which blocked the inhibitory activity of imatinib. Likewise, it was recently found that the tumor from a patient with NSCLC who relapsed 2 years after an initial dramatic response to gefitinib, had acquired a second point mutation in the kinase domain of the EGFR, which blocked the binding of gefitinib. The strong selective pressure for emergence of cells that carry *de novo* mutations in the respective oncogenes indicates the remarkable dependence of these neoplastic cells on these oncogenes, and provides further evidence for the concept of oncogene addiction. At the same time these findings reveal the emergence of resistance mechanisms to molecular targeting agents. Studies in progress indicate that in the case of the *Bcr/Abl* oncogene there are other drugs that can inhibit the kinase activity of the mutant Bcr/Abl protein, and it may be possible to develop similar drugs that act on resistant mutants of the EGFR and resistant forms of other protein kinases. Furthermore, it might be possible to suppress the emergence of these types of resistant cells by combining a specific protein kinase inhibitor with an agent that inhibits cell proliferation via a different mechanism; this would limit the likelihood of emergence of mutant clones. This aspect is further discussed later in the section on combination therapy.

The concept of oncogene addiction is also relevant to both ►tumor suppressor genes and tumor-stromal interactions. We have emphasized the roles of dominant acting oncogenes that enhance cell proliferation and cell survival. The disordered circuitry of cancer cells, however, is also a consequence of inactivation or loss of expression of tumor-suppressor genes, which normally inhibit proliferation or enhance apoptosis. Experimental studies indicate that reintroducing a wild-type tumor-suppressor gene (e.g. those encoding ►p53, ►Rb, or ►APC) into human cancer cells where the respective endogenous gene was inactive usually caused marked inhibition of growth, induction of apoptosis and/or inhibition of tumorigenesis in mice. These results would not be expected if cancer cells evolved simply through the stepwise addition of genetic abnormalities, because in this setting correction of just one mutagenic event should have only a modest inhibitory effect. Thus, some cancer cells seem to be "hypersensitive" to the growth-inhibitory effects of specific tumor suppressor genes. We postulate that, like oncogene addiction, this effect also reflects the bizarre circuitry of cancer cells, and have termed this phenomenon "tumor suppressor gene hypersensitivity". This phenomenon can also be exploited in cancer therapy by ►gene therapy, for example the use of an adenovirus that encodes a normal p53 protein or by targeting a downstream signaling pathway that was activated as a result of loss of activation of a tumor suppressor gene. Alternatively, if a tumor suppressor gene is inactivated by histone deacetylation (►Histone Deacetylases) or DNA ►methylation (which frequently occurs in cancer cells; e.g. ►$p16^{INK4}$ gene), drugs that inhibit histone deacetylase enzymes (e.g. depsipeptide, suberoylanilide hydroxamic acid) or cause demethylation of cellular DNA (e.g. 5-azacytidine, zebularine) may reactivate silenced tumor suppressor genes and thereby inhibit tumor growth. Synergistic or additive effects on tumor growth inhibition might be obtained by combining drugs that exploit both oncogene addiction and tumor suppressor gene hypersensitivity.

Activated oncogenes like *EGFR* or *ras* stimulate signaling pathways that can also affect tumor-stromal interactions by increasing expression of matrix metalloproteinases (enhancing tumor ►invasion and ►metastasis) and of the angiogenic factor VEGF. Inactivation of these genes in cancer cells can inhibit tumor invasion, ►angiogenesis, and even recurrence. The neovasculature associated with tumor-induced angiogenesis is abnormal compared with normal vasculature, and the circuitry that regulates the growth and function of endothelial cells in this neovasculature may differ from that of normal vasculature. Bevacizumab provides a promising example of preferentially targeting abnormal tumor vasculature, and its use has led to improved disease-free and overall survival rates in patients with ►colon cancer.

Mechanisms of Oncogene Addiction

The phenomenon of oncogene addiction was a consequence of the fact that the ►multistep development of ►carcinogenesis may not simply a summation of the individual effects of activation of multiple oncogenes and inactivation of multiple tumor suppressor genes. This is consistent with the fact that the proteins encoded by these genes often have multiple roles in complex and interacting networks, which display both positive and negative feedback control. The functions of these proteins are also influenced by their levels of activity and the context in which they are expressed. Thus, a given oncogene can enhance cell proliferation but it can also enhance apoptosis. Furthermore, throughout the multistage carcinogenic process, the evolving cancer cell must maintain a state of homeostasis between positive- and negative-acting factors in order to maintain structural integrity, viability, and the capacity to replicate. For these reasons, the intracellular circuitry

or "wiring diagram" that regulates ►signal transduction and gene expression in cancer cells is very different, i.e. "bizarre," when compared to that of normal cells. Therefore, in cancer cells a given oncogene may play a more essential and qualitatively different role in a given pathway or "module" compared with its role in normal cells. Thus, cancer cells may be much more dependent on the activity of a specific oncogene than normal cells.

Within the context of disordered cell circuitry, specific mechanisms have been proposed to explain why inactivation of an oncogene might lead to selective growth inhibition, differentiation and/or apoptosis in cancer cells but not in normal cells that express the same oncogene. One explanation is that in order to maintain homeostasis, the proliferation enhancing effects of a specific ►oncogene in cancer cells may be partially buffered through negative feedback mechanisms, through increased expression of proliferation inhibitory factors. If this oncogene is then inactivated the cancer cells might suffer a relative excess of the latter inhibitory factors and thus undergo apoptosis, before a new level of homeostasis can be achieved. The apparent propensity of some cancer cells to undergo apoptosis when stressed could enhance this process.

A second mechanism is based on the concept of "synthetic lethality" originally derived from studies in lower organisms. According to this concept two genes are said to be synthetic lethal if mutation of one of the two genes is compatible with survival but mutation of both genes causes cell death. For example, certain cancer cells might be highly dependent on a given oncogene because during their development they lost the function of another gene that normally performs a similar function. Therefore, a drug that inhibits the activity of the oncogene would selectively target the cancer cells and spare the normal cells. Furthermore, because of the bizarre circuitry of cancer cells, pairs of genes in cancer cells that have a synthetic lethal relationship may differ from those in normal cells, thus, increasing the dependence of tumor cells on a specific oncogene. A related explanation for oncogene addiction is that during the multistage carcinogenesis process, cancer cells become highly dependent on specific oncogenes and their related pathways because of the large numbers of mutated and inactivated genes that function in other pathways. This could render cancer cells less adaptable than normal cells.

Only a subset of patients with NSCLC (about 10–20%) display favorable and often impressive clinical responses to the EGFR inhibitor gefitinib, and this is often associated with tumors that have specific activating mutations in the kinase domain of EGFR. For reasons that are not understood patients with these activating mutations are also more likely to have adenocarcinomas, be female, non-cigarette smokers, and of Japanese origin. Thus, addiction to a specific oncogene might occur only in a subset of specific types of cancers with a distinct etiology, and only when that oncogene is mutated and not simply activated. Normal EGFR activation results in induction of multiple downstream signaling pathways some of which enhance cell proliferation and others that enhance cell survival (i.e. inhibit apoptosis). An experimental study indicated that mutations in the *EGFR* can preferentially enhance activation of the survival, Akt-associated pathway (►AKT Signal Transduction Pathway). This may explain why NSCLC cells that harbor this mutation in EGFR are highly dependent on this activated oncogene for survival. Similarly, the presence of specific deletion mutations in the EGFR gene in glioblastoma was recently shown to correlate with clinical responses to an EGFR inhibitor. These data fit the paradigm that oncogene addiction can be due to the establishment of distorted pathways of signal transduction (i.e. bizarre circuitry) during tumor development. Recent studies suggest that in addition to point mutations in the gene encoding the EGFR other factors may influence the sensitivity of NSCLC tumors to EGFR inhibitors, including *EGFR* gene ►amplification, the activation state of the EGFR protein, specific downstream signaling pathways, and pharmacologic factors.

Future Directions and Clinical Applications

Identification of the Critical Oncogene or "Achilles' Heel" in Specific Human Cancers

Human cancers display multiple genetic and epigenetic abnormalities. Furthermore, it is now apparent that these abnormalities frequently differ between different types of cancer, and also between subsets of the same type of cancer. In view of this complexity how can we identify the specific oncogene or oncogenes that have a critical role in maintaining the malignant phenotype in these different cancer types, or within individual cases? In other words how do we identify the "Achilles' heel" in specific cancers so that each patient can be treated with the appropriate molecular targeted agent? At the present time there are no methods to fully assess the total circuitry that controls cell proliferation, differentiation and apoptosis in normal or cancer cells. Advances in network theory, systems biology, and computer modeling, may eventually make this possible.

Currently, several empiric approaches can be used to help identify the Achilles' heel of specific types of human cancer. One is to use high throughput screening of thousands of compounds in chemical libraries to identify specific compounds that preferentially inhibit *in vitro* growth or induce apoptosis in specific types of human cancer cells. A related approach that is being rapidly expanded is to use a library of ►siRNAs, which are low-molecular weight RNAs that are taken up by

cells and inhibit the expression of specific genes, to identify which genes are required to maintain the proliferation and/or survival of specific types of cancer cells. Once such genes are identified drugs can be designed to target the related protein(s). A recent study in mice suggests that it might become feasible to administer to patients a specific siRNA preparation that knocks down the expression of a critical oncogene in the tumor, thus providing a novel approach for delivering cancer therapy.

In addition, specific criteria might be used to assist in identifying genes that are most likely to be critical for maintaining the malignant phenotype. For example, oncogenes that are mutated early in the multistage process of tumor development might be favored candidates because they played a critical role in determining subsequent aspects of the abnormal circuitry in the evolving cancer cells. Oncogenes that are mutated and not simply overexpressed might also be more likely targets for therapy since they reflect the "hard-wiring" of cancer cells, rather then epigenetic abnormalities. Mutated oncogenes may therefore be more likely to be present in the stem-cell population of tumors rather than just in the progeny cells. In addition, mutated oncogenes might be more likely to have qualitatively different roles than oncogenes that are only overexpressed. This aspect is exemplified by the properties of a mutated EGFR receptor in NSCLC cells. Specific cancers display increased expression of genes that normally have critical roles in ►stem cells, or during normal tissue development and differentiation. These include the genes that encode proteins involved in the Wnt, Hedgehog (Hh) (►Hedgehog Signaling), TGFβ/BMP, Notch, Snail, Slug, and MITF signaling pathways, and inhibition of the Hh and MITF pathways have led to growth inhibition in murine ►medulloblastoma and human ►melanoma models, respectively. It is possible that dependence of a cell on a specific oncogene may be different in the stem cells than in the progeny cells in a given tumor, because of differences in their intracellular circuitry. Optimal therapy would then require developing molecular targeted agents that target only the critical oncogene in the stem cells of a specific cancer. Further characterization of stem cells in specific tumors should clarify this aspect of oncogene addiction, and the potential limitations of specific molecular targeted agents.

Advances in microarray (►Microarray (cDNA) Technology) and proteomic (►Proteomics) methods have compared expression profiles of thousands of genes and proteins between normal tissues, cancers, and subtypes of specific cancers. "Network theory" and the emerging field of systems biology may eventually provide methods for conceptualizing and analyzing the entire circuitry of specific types of normal and cancer cells, and thus facilitate identification of specific pathways of oncogene addiction. Networks in mammalian cells share similar principles with networks that are relevant to engineering and other disciplines. Thus, by viewing the cancer cell as a "complex" or "complicated" system, genes and proteins as "nodes", and groups of interacting proteins in a signal transduction pathway as "modules", engineering tools and concepts can be used to analyze large datasets to generate an holistic view of the regulatory network of normal and cancer cells. Furthermore, a concept called Boolean genetic network theory can be used to study the cancer cell as a dynamic system. By analyzing the myriad of individual and interacting genes in a cancer cell in a Boolean fashion (i.e. active = "on", inactive = "off"), the overall activity state ("attractor state") of specific cancer cells (e.g. proliferation, apoptosis, differentiation) might be determined or predicted. Thus, in the future it could be possible to use network theory to describe and predict the existence of an "addicted" attractor state, and to also predict the specific oncogene responsible for this addicted state. A more detailed understanding of these networks might also provide insights into tumor resistance and the appropriate choice of combination therapy for specific patients.

Combination Therapy

Although the concept of oncogene addiction may apply to a given cancer at a particular time or stage, it is apparent from some of the mouse model experiments and from clinical experience with molecular targeted agents, that cancers can "escape" from a given state of oncogene addiction. Presumably, this reflects the genomic instability of cancers. It could also reflect epigenetic changes in gene expression that lead to an altered state of cell circuitry; for example, ongoing changes in DNA methylation and chromatin structure in a cancer cell population. It is not known whether this escape leads to secondary addiction to another oncogene or to the growth of a population of "non-addicted" cancer cells. For these reasons, as well as the likelihood of heterogeneity within tumors, it is unlikely that the use of a single molecular targeted agent will achieve long lasting remissions or cures in human cancers, especially for late-stage disease. Combination therapy will, therefore, be required, which raises several unresolved questions. Can such combinations be rationally designed? Should the individual agents act on the same molecular target but by different mechanisms, or on different targets in the same pathway; or should each agent target a different pathway or cellular mechanism? The first approach may prevent emergence of the types of resistance recently seen with imatinib and gefitinib. The second approach also seems rational because it is likely that cancer cells may be addicted to

specific signaling pathways rather than a single oncogene. A drug combination that targets proteins that function at different stages in the same pathway may, therefore, be more likely to inactivate that pathway, than a single drug. The third approach can also be justified because of the disturbance of multiple pathways in cancer cells. It is becoming increasingly apparent that certain molecular targeted agents are actually promiscuous, i.e. they target more than one molecule, and this may enhance their therapeutic efficacy. For example the drug sorafenib appears to have activity against ►renal carcinomas by targeting both a mutant *Raf* oncogene and the VEGF receptor, thus inhibiting both cancer-cell proliferation and angiogenesis. Clinical studies indicate that the efficacy of certain molecular targeted agents can be enhanced by combining them with cytotoxic agents, i.e. agents that often act by inhibiting DNA or chromosomal replication. Trastuzumab that targets HER2 can improve response and survival rates if given in combination with ►paclitaxel to patients with metastatic breast cancer. The combination of bevacizumab or cetuximab with cytotoxic chemotherapy agents can also improve response rates in patients with metastatic breast and colon cancer, respectively (►Chemotherapy of Cancer, Progress and Perspectives). Furthermore, when bevacizumab was added to a combination chemotherapy regimen it improved overall survival rates in patients with metastatic colon cancer. As with chemotherapy, the efficacy of targeted therapy will likely be greater in patients with minimum residual disease. Thus, treatment with trastuzumab after adjuvant chemotherapy significantly improves disease-free survival in patients with early-stage breast cancer.

Conclusion

At the present time the choice of the best molecular targeted agent and the appropriate combination therapy for a specific patient with cancer is largely empirical. Nevertheless, the rapid development of diverse molecular targeted agents coupled with further mechanistic studies, and advances in profiling the molecular circuitry of specific subsets of human cancer, should make it possible to further exploit the concept of oncogene addiction to achieve more effective and selective therapies for several types of human cancer.

Oncolytic Adenovirus

Masatoshi Tagawa
Division of Pathology, Chiba Cancer Center Research Institute, Chiba, Chuo-ku, Japan

Synonyms

Conditionally replicating adenovirus; Conditionally replicative adenovirus; Replication-competent adenovirus; Replication-selective adenovirus; Replication-activated adenovirus

Definition

Oncolytic ►adenoviruses are recombinant adenoviruses that can replicate preferentially in tumor cells and consequently destroy the tumors. ►Virotherapy is a term primarily used for cancer therapy with oncolytic viruses.

Characteristics

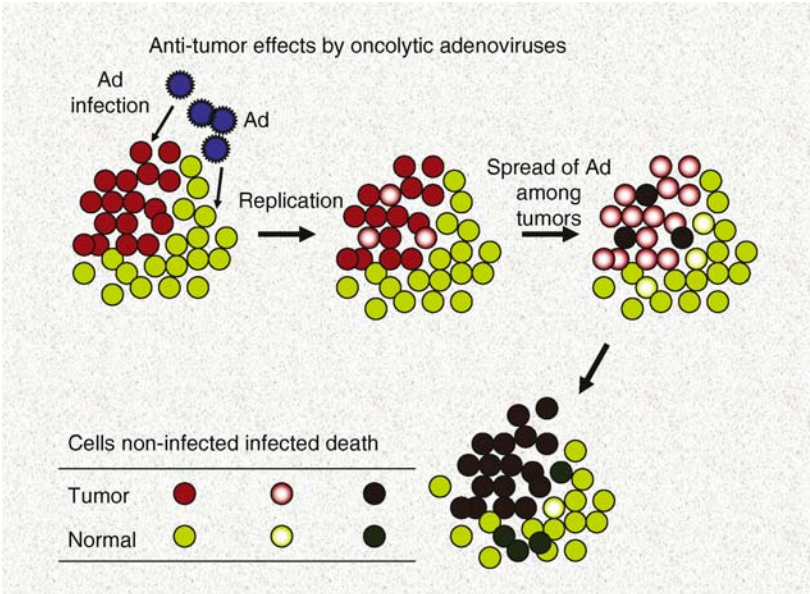
General Description

Adenoviruses, nonenveloped double-stranded DNA viruses with about a 38-kb genome, cause respiratory infection, pharyngitis and keratoconjunctivitis depending on their ►serotypes. Adenoviruses are not oncogenic to human but cytotoxic to human cells. The viral replication induces cell death; consequently, adenoviruses are released from the burst cells and spread to other target cells in the vicinity. Recombinant adenoviruses are widely used as a vehicle to express an exogenous gene in target cells. These adenoviruses used for gene transfer cannot replicate in target cells (replication-defective) because they are devoid of the genes encoded in the E1 region, which are required for viral replication. HEK 293 cells, which are frequently used for production of replication-defective adenoviruses, constitutively express the genes mapped in the E1 region and thereby can support the viral replication. In contrast, oncolytic adenoviruses are replication-competent in target tumors and killed tumor cells but scarcely or to less extent are cytotoxic to nontumorous cells (Fig. 1). Historically speaking, clinicians experienced tumor regression after infection of a certain type of viruses and later viruses with cytotoxic activities were demonstrated to destroy rodent and human tumors. The wild-type viruses used for cancer treatments in fact produced a limited benefit in clinical settings due to antiviral immune responses and the therapy with such viral agents was abandoned. Advent of recombinant DNA technology however enables us to modify viral genomes and to produce viruses as a tool for gene transfer and therapy. Oncolytic adenoviruses are renewed and preclinical and clinical developments have been primarily pioneered by bioventure companies. In 2005, Chinese Food and Drug Administration firstly approved ONYX-015-type oncolytic adenoviruses for cancer treatment.

Mechanism

Understanding of tumor-selective replication of adenoviruses needs to know the functions of the *E1A* and *E1B* genes mapped in the E1 regions. The *E1A* gene is firstly transcribed after the viral infection (immediate early gene) and the product bind to the ►RB1 ►tumor suppressor gene product which binds to transcription factor ►E2F. Binding of E1A to ►pRB releases E2F and facilitates S-phase entry of the infected cells to transactivate both viral and cellular genes that are necessary to produce viral progenies. The *E1B* gene encodes 19 and 55 kDa molecules. The E1B-55kDa molecules bind to the ►p53 ►tumor suppressor gene and accelerate ►p53 degradation; subsequently, the E1B-55kDa inhibits transactivation of the downstream genes and ►apoptosis mediated by p53.

Currently there are two major strategies to produce oncolytic adenoviruses. One is to utilize molecular defects of tumor cells, which render tumors more permissive for the viral replication, and the other is to activate the *E1A* gene with a transcriptional regulatory region that has a tumor-specificity. The typical type to use the molecular lesion is adenoviruses defective of E1B-55kDa molecules, which are also known as *dl*1520, ONYX-015, and Cl-1042. The viruses take advantage of p53 defects in tumors that are frequently found in various types of human cancer. Since adenoviruses induce p53 expression in infected cells, the viruses need to inactivate p53 to avoid p53-mediated cell cycle arrest and apoptosis for continuous viral replication. ONYX-015 fails to degrade p53 because of E1B-55kDa deficit; thereby, the viral replication is not halted. In normal cells, replication of ONYX-015 is immaturely terminated due to p53-mediated apoptosis. The initial idea that ONYX-015 could replicate in p53-mutated or -defective tumor cells but not in cells with wild-type 53 was evidenced experimentally but subsequent studies showed that replication of ONYX-015 was not related with the p53 status of infected cells. The results of clinical trials of ONYX-015 also suggested that the outcomes were not linked with the p53 status of tumors. The discrepancy could be due to the complexity of p53



Oncolytic Adenovirus. Figure 1 Concept of oncolytic adenoviruses. Adenoviruses (Ad) infect tumors as well as normal cells but the viral replication occurs preferentially in tumors. The progenies released from burst cells subsequently infect tumor masses in the vicinity.

regulation. The overall p53 functions are influenced by a number of molecules including p14 and ►Mdm2. The genetic information of the p53 therefore cannot predict whether the p53 pathways are intact or not. Nonetheless, ONYX-015 shows cytotoxic activities to tumors and produces antitumor effects in clinical trials. Precise mechanisms of preferential cytotoxicity of ONYX-015 to tumor cells remain uncharacterized. Recent studies suggest that selective cytotoxicity to tumor cells of ONYX-015 is attributable to defective export of late viral RNAs to cytoplasm in tumors but not in normal tissues. Tumor cells through unidentified mechanism support the viral RNA migration that is a novel function of E1B-55kDa whereas normal cells cannot activate transport of the viral RNAs and consequently cannot induce lytic viral replication.

Another type of oncolytic adenoviruses with transcriptional regulation of the *E1A* gene was developed by incorporating so-called tumor-specific promoters. The expression of E1A and E1B is controlled by the viral E1A promoters located in the upstream of the *E1A* gene and these oncolytic adenoviruses are produced by replacing the viral E1A promoter with an exogenous transcriptional regulatory region of the gene that is highly expressed in tumors but scarcely in nontumorous cells. In the adenoviruses, expression of the *E1A* and *E1B* gene is subjected to the specificity of the putative tumor promoter such as ►carcinoembryonic antigen, ►ERB82 and ►alpha-fetoprotein. It could use a tissue-specific promoter and subsequently replication-competent adenoviruses can destroy the target cells depending on the specificity of the promoter activity. The initial clinical studies were performed for ►prostate cancer using the ►PSA gene promoter to activate both *E1A* and *E1B* genes. Subsequent studies showed that control of the respective *E1A* and *E1B* genes with different promoters bearing similar specificity such as probasin could enhance the cytotoxicity for prostate cancer with tumor-specificity. Further investigations demonstrated that integration of such exogenous promoter regions could sometimes suppress viral replication although the adenoviruses kept the specificity for their cytotoxicity.

The concept of oncolytic adenoviruses is intriguing but several points have to be considered to achieve better clinical outcomes. Tumor masses consist of a number of normal cells such as ►stroma cells and these cells hamper efficient viral spread into tumors in the vicinity. The virotherapy is essentially a local therapy and may not be a systemic therapy although systemic administration is under investigation. Antibody against adenoviruses produced by repeated injections decreases the efficacy of virus infection. ►Humoral immunity could rather increase the safety by inhibiting wide spread of the viruses to whole body. Interestingly, many clinical studies suggested that humoral immune responses did not suppress the infectivity of adenoviruses to target cells when locally administered.

Clinical Applications

Although oncolytic adenoviruses have been yet commercially unavailable except in China, a number of clinical studies have been conducted in particular in combination with conventional ►chemotherapy. ONYX-015 has been examined for the clinical feasibility especially head and neck cancer because it is relatively easy to approach to the tumor sites

and to estimate the tumor growth. Most of the patients could tolerate ONYX-015 despite adverse effects such as flu-like symptoms. These primary data of clinical studies need further investigations and large-scale randomized studies are required to evaluate the clinical efficacy. Recent reports demonstrated that H101, ONYX-015-type adenoviruses approved in China, produced antitumor effects for head and neck cancer in combination of an anticancer agent ►cisplatin. The clinical data obtained in China are similar to those conducted in USA, suggesting potentiality of the viral agent for cancer therapy.

The tumor promoter-mediated oncolytic types have been also clinically tested but most of them did not proceed to further trials. The clinical reports currently obtained showed the evidences of viral replication in human tumor tissues and limited adverse effects.

Future Directions

There are about 50 kinds of serotypes of human adenoviruses discovered and the type 5 is most frequently used as a vector for gene transduction and oncolytic adenoviruses. The type 5 adenoviruses use the coxsackie and adenovirus receptor and ►integrin (αvβ3, αvβ5) as cellular receptors and bind to them with their fiber and penton regions, respectively. In human cancer, however, the expression of their cellular receptors is often down-regulated and consequently the infectivity of type 5 adenoviruses often decreases. In order to circumvent the lower infectivity, several strategies have been examined. One of them is to replace the fiber region with that of other types such as type 3 and type 35, which use different receptor molecules with a higher expression level in tumors. Incorporation of a binding motif such as ►RGD sequences, which bind to integrin, enhanced the infectivity. Antibody-mediated "retargeting" is also examined. Preparation of adenoviruses covered with antibody against cell surface molecules which are expressed highly on tumor cells facilitates the infectivity.

Enhancement of cytotoxic activity by oncolytic adenoviruses is important from a clinical standpoint. Since oncolytic adenoviruses replicate within the infected cells, an exogenous gene incorporated in the viruses is amplified together with the viral replication and thereby the gene product increases. For example, increased expression level of a ►suicide gene enhances the sensitivity of infected cells to a ►prodrug. Enhanced systemic immunity can be achieved by integrating the ►cytokine gene such as interleukin-12, which belongs to T helper type 1 cytokines. These modifications are currently being examined preclinically.

Synonyms

Virus therapy of cancer; Oncolytic therapy with viruses

Definition

Oncolytic virotherapy is the experimental treatment of cancer patients based on the administration of replication-competent viruses that selectively destroy tumor cells but leave healthy tissue unaffected. Oncolytic viruses currently being characterized include vaccine strains of human viruses and apathogenic human and animal viruses. Moreover, viruses are being genetically modified to increase their tumor specificity and oncolytic efficacy.

Characteristics

Viruses as Therapeutics: Clinical Trials of Oncolysis

Although infections can be a serious threat for cancer patients, it was observed at the end of the nineteenth century that some patients experience remissions of their disease after natural infections. Starting in the 1920s, many experiments involving the treatment of tumor-bearing animals with viruses like vaccinia virus, herpes virus, ectromelia virus and fowl plague virus were carried out. Between 1940 and the early 1970s, many types of viruses were inoculated into cancer patients, including rabies vaccine virus, West Nile virus, ►adenoviruses, mumps virus, Sendai virus, ►Newcastle

disease virus, influenza virus, Semliki Forest virus and Sindbis virus. Although some encouraging results were reported, oncolytic virotherapy never became a standard treatment. Reasons for this include lack of predictable efficacy, regrowth of tumors with appearance of neutralizing antibodies against the viruses, limited availability of standardized virus preparations for the administration to patients, and the great enthusiasm that initially accompanied the development of ►radiotherapy and ►chemotherapy.

Since the beginning of the 1990s, there has been a renewed interest in using viruses for cancer treatment. The renewed enthusiasm was based on a better understanding of the mechanisms of virus replication and oncolytic specificity, and on the availability of genetic methods to modify viruses.

Viruses currently tested in clinical trials include the DNA viruses ►herpes simplex virus, ►adenovirus, and vaccinia virus as well as the RNA viruses ►reovirus, ►Newcastle disease virus, ►measles virus and Coxsackievirus.

Herpes simplex virus type 1 (HSV-1) was the first virus to be genetically engineered for selective replication in tumor cells in 1991. Different genetic modifications that selectively disable viral replication in non-dividing cells have been described, among them mutations in the thymidine kinase, the ribonucleotide reductase and the γ34.5 gene. Additionally, up to 30 kbp of foreign DNA can be inserted into the HSV-1 genome. Several antiherpetic drugs are available and can be used to treat possible unwanted side-effects of infection. On the other hand, the majority of the population has neutralizing antibodies against HSV-1, interfering with the delivery of the virus.

Since HSV-1 has a natural ►tropism for neural cells, the initial phase I clinical trials focused on the treatment of patients with malignant glioma. Two vectors, HSV 1716 and G207 have been stereotactically injected into the tumors of glioma patients. Up to 3×10^9 plaque forming units (pfu) were well tolerated without major side effects. Additionally, two small pilot studies with ►melanoma and liver ►metastasis in colorectal carcinoma were performed that also showed no significant toxicity. Further studies focus on the combination of virotherapy with radiation and the insertion of therapeutic transgenes into viral vectors.

Adenoviruses (Ads) have been tested in several phase I and II trials since 1996 (►Virotherapy). The most widely tested virus, ►ONYX-015, has a deletion in the E1B region that confers tumor selectivity. Adenoviruses can easily be genetically manipulated, have the capacity to carry up to 10 kb of foreign genetic material while maintaining replication competence, and can be grown to very high titers (up to 10^{12} pfu/ml). While the first clinical studies involved direct intratumoral injections of Ads in patients with head and neck ►squamous cell carcinoma, Ads were later also applied intraperitoneally, intravenously, and by hepatic artery infusion. Many tumors have been treated, including ►pancreatic cancer, ►glioblastoma, ►colorectal cancer, hepatobiliar cancer, sarcomas and ►prostate cancer. One phase III study executed in China that used a virus slightly different from ONYX-015, H101, showed a 79% response rate for virotherapy in combination with chemotherapy as opposed to 40% for chemotherapy alone. This trial led to the approval of H101 for the treatment of late-stage refractory ►nasopharyngeal cancer by China's regulatory authorities.

Reovirus is a double-stranded human RNA virus that does not appear to cause any serious disease. It can not yet be genetically modified but has a natural tropism for transformed cells. A phase I study investigating intratumoral injections of the type III Dearing strain (Reolysin®) into cutaneous lesions showed some promising responses and no dose-limiting toxicity for up to 10^{10} pfu per injection. Studies involving patients with glioma, prostate cancer and other malignancies are ongoing. The virus will also be applied intravenously, and virotherapy will be combined with radiation.

Newcastle disease virus (NDV) is a negative strand RNA virus of the Paramyxovirus family that naturally infects poultry. It is apathogenic for humans and had been investigated previously for the generation of so called oncolysates, a suspension of tumor cells that are explanted, infected with NDV, inactivated, and given back to the patient to induce an immunological response. Oncolysates do not contain replicating viruses and thus are not discussed in more detail. In another line of research, the replicating NDV strain PV701 was administered to patients with various solid tumors. When very high doses (up to 1.2×10^{11} pfu) were administered, the patients experienced flu-like side effects. Extensive studies showed that these side-effects are well tolerated when the patient is treated with non-steroidal anti-inflammatory drugs and when dosing starts low ("desensitization"). In one study, a patient with previously compromised lung function and pulmonary metastases died from respiratory failure after the treatment with PV701, the only treatment-related death in the field of oncolytic therapy so far. Some patients experienced stabilization of their disease for several months, suggesting that therapy with PV701 might be efficacious for some cancer patients. Phase II studies with the virus are in course.

Infection with another Paramyxovirus, measles virus (MV) was sporadically associated with cancer regression in lymphoma and leukemia patients, and the live attenuated MV vaccine is under development as an oncolytic agent. A small phase I study of intratumoral injections in patients with cutaneous T-cell lymphomas has demonstrated the safety of this approach as well as some clinical responses. Another phase I study involving intraperitoneal injection of a genetically

modified virus that secretes a marker peptide into patients with ►ovarian cancer is under way. Further studies involving a virus expressing the sodium-iodine-symporter as a therapeutic gene in combination with radioactive iodine for the treatment of myeloma patients and a study with glioma patients are planned, and several genetic modifications to improve viral efficacy and safety are currently tested in preclinical studies.

Targeting Viruses to Tumor Cells

The molecular basis for the preferential replication of many viruses in tumor cells is currently active focus of research, and ►targeted viruses are created by genetic modifications. There is increasing evidence that many genetic changes in tumor cells that result in malignant transformation also undermine cellular antiviral defense mechanisms. For example, the susceptibility of cell lines to human reovirus infection correlates with activation of the ►RAS-pathway, and the process of malignant transformation of murine embryonic fibroblasts leads to an impaired cellular response to interferon that results in susceptibility to vesicular stomatitis virus.

Restriction of viral ►tropism to tumor cells can occur, or be engineered, at different stages in viral replication. Efficient targeting of the first infection stage, cell entry, has been achieved for MV. Small ligands, single-chain antibodies or T-cell receptors displayed on the viral attachment protein can efficiently mediate entry through targeted receptors; entry through natural receptors can also be avoided by modifications of the attachment protein. Proteins on tumor cells that have been successfully used as a receptor by retargeted MV include carcinoembryonic antigen, CD20 and CD38. Alternatively, a targeting system based on selective activation of the viral fusion protein by tumor-specific proteases has been described. Genetic modification of the receptor-binding proteins has also been attempted with other viruses such as adeno-associated viruses, adenoviruses and retroviruses, but the efficiency of these targeting systems is not yet optimal.

Selective replication of naturally oncolytic viruses in tumor cells is often based on post-entry events, especially defects in innate defenses of cancer cells. Many viruses encode accessory proteins that are not strictly required for viral replication but counteract innate defenses, and their genes have been deleted to engineer viruses selectively replicating in tumor cells, e.g. E1A and E1B deleted adenoviruses and NS1-deleted influenza viruses. The VSV M protein counteracts cellular innate immunity. This essential gene cannot be deleted, but M protein mutations confer to viruses greater selectivity for tumor cells because the mutant viruses cannot block interferon production in infected cells.

For viruses that rely on cellular polymerases for transcription, promoters driving essential genes can be replaced by promoters that are only active in tumors, e.g. the carcinoembryonic antigen promoter for ►colon cancer, the alpha-fetoprotein promoter for ►liver cancer and the ►mucin-1 promoter for breast cancer. This approach has been widely used with adenoviruses but also with herpesviruses and retroviruses.

"Armed" Oncolytic Viruses

Even with targeted oncolytic viruses, it might not be possible to infect and thereby kill all tumor cells of a patient. Strategies to destroy uninfected transformed cells are therefore required, and attempts have been made to increase efficacy of tumor cell killing by insertion of therapeutic genes into the genome of oncolytic viruses, generating "►armed viruses." Arming can be based on ►suicide genes, which encode proteins that toxify systemically administered prodrugs, resulting in killing of not only the transduced cell but also neighboring cells. Local production of toxic substances in tumors is expected to result in fewer side effects than systemic administration. Similarly, transduction with the sodium-iodine symporter leads to the uptake of radioactive iodine that kills the tumor cell and some surrounding cells.

Another important approach to improve the efficacy of oncolytic virotherapy are strategies that enhance the reactivity of the immune system against cancer cells. In oncolytic virotherapy, the patient's immune is a double-edged sword: on the one hand, it will fight the oncolytic viruses like any other infection, thereby protecting malignant cells. On the other hand, viral replication in cancer cells might cross-prime the immune system and favor elimination of cancer cells. A variety of transgenes improving the activation of the immune system have been used, including interleukin (IL)-2, IL-4, IL-12 and granulocyte-macrophage colony-stimulating factor.

Perspectives

The concept of ►virotherapy has been revived by the availability of reverse genetics systems for many virus types and the better understanding of the molecular mechanisms of carcinogenesis. Many oncolytic viruses are currently developed and tested in clinical trials, and the results of phase I and II studies indicate that this form of treatment can be well tolerated and safe. Although these trials were not designed to demonstrate efficacy, efficacy appears to be low. However, a great variety of new approaches, including genetic modification of viruses to carry transgenes, new methods to monitor viral replication, improved dosing schemes, combinations with other treatment modalities like chemotherapy and radiation, and application of immunosuppressive drugs during virotherapy are currently tested in preclinical models and clinical studies. Genetic modifications and treatment combinations have to be tailored to the different forms of cancer, taking into account the natural tropism of different viruses. The

recent approval of the oncolytic adenovirus H101 for the treatment of late-stage refractory nasopharyngeal cancer in China may be the prelude of a new, much needed treatment modality for cancer.

Synonyms

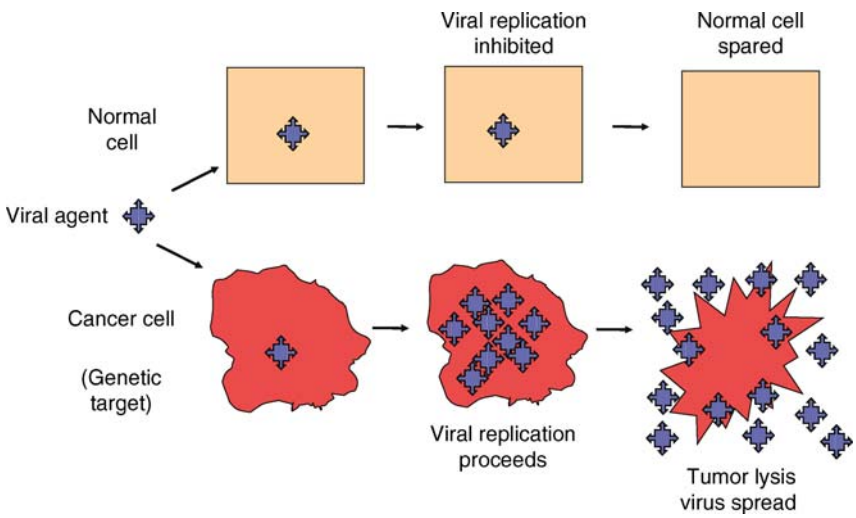
Therapeutic viruses; Virotherapy; Replication-selective viruses; Targeted viruses

Definition

Oncolytic viruses are viruses that replicate (multiply themselves) selectively in cancer cells, and are attenuated (crippled) in normal cells, and as a result destroy cancer cells ("onco" cancer, "lysis" cell destruction through necrosis) and tumors with minimal toxicity to normal cells and tissues.

Characteristics

Therapeutic oncolytic viruses (virotherapeutics) constitute a platform of targeted anti-cancer agents that have unique mechanisms of action compared with other cancer therapeutics, such as chemotherapy or radiotherapy. Oncolytic viruses are viruses that replicate (multiply themselves) selectively in cancer cells, and are attenuated (crippled) in normal cells, and as a result destroy cancer cells and tumors with minimal toxicity to normal cells and tissues. The development of virotherapeutics has evolved from the use of *in vitro*-passaged strains (first generation), to genetically-engineered



Oncolytic Virus. Figure 1 Schematic of oncolytic virotherapy mechanism-of-action: viral replication, cell killing, virus release and spread within cancer tissue but not normal tissues. (Reproduced with permission from REF. 28. © (2001) Nature Publishing Group).

selectivity-enhanced viruses (second generation) and finally to genetically-engineered transgene expressing "armed" oncolytic viruses (third generation). Descriptions of cancer remissions following virus infections date back to a century ago. Initial patient treatment publications, written up to 50 years ago, consisted of case reports or case series of treatment with first-generation, non-engineered viruses. Over the past decade, hundreds

of cancer patients have been treated on prospectively designed clinical trials (including phase III), evaluating over ten different engineered second- and third-generation viruses (Fig. 1).

Selectivity and Cancer-Targeting Mechanisms

Oncolytic viruses are by definition cancer-selective. Cancer selectivity is based on genetic differences between cancer cells and normal cells. Many genetic targets in cancer can activate the replication of oncolytic viruses and their cancer-specific cytolysis capacity. Examples include the loss of anti-viral mechanisms in cancer cells such as type-I interferon induction and anti-viral activity. Deletion of the interferon genes can block induction of interferon expression from the infected cancer cell. The interferon response pathway can be blocked by ras pathway (►RAS activation) activation or by loss of p53 (encyclopedia link) function. Other genetic abnormalities in cancer that can be targeted include cell cycle abnormalities (►Cell-cycle targets for cancer therapy), cell surface virus receptors and tissue-specific promoters.

Viruses can target these cancer genetic abnormalities naturally (or inherently) without genetic engineering. Once example is the vesicular stomatitis virus (VSV) that is hyper-sensitive to type-I interferon-mediated clearance in normal cells, but can replicate and lyse cells in tumors that have inactivated interferon responses. Other oncolytic viruses must be engineered genetically to make their replication and cytolysis dependent on genetic targets in cancer. Examples include the deletion of viral genes that are necessary for replication of the virus, but whose function can be supplied in *trans* by the cancer cell. For example, deletion of the vaccinia viral thymidine kinase (TK) gene markedly attenuates (weakens) the vaccinia virus in normal cells, whereas in cancer cells the ►E2F transcription factor is activated and drives high-level expression of the cellular TK. Cellular TK in cancer cells supports and activates vaccinia replication and cytolysis. JX-594 (Jennerex Biotherapeutics Inc, SF, CA, USA) is an oncolytic vaccinia virus with a TK deletion that also is "armed" (engineered to express) with human GM-CSF; the virus is in Phase II clinical trials. Other examples of gene deleted viruses are in Table 1. Viruses that replicate in the nucleus of infected cells can also be targeted by expressing critical viral genes under control of a cancer tissue-specific promoter (e.g. E2F promoter-enhancer and telomerase promoter).

Efficacy and Anti-Cancer Mechanisms

The primary mechanism-of-action (MOA) for oncolytic viruses is direct cell lysis as a result of viral replication cycle completion. However, this primary MOA can be complemented and augmented by additional MOA. These secondary MOA can be a direct result of the direct virus replication-dependent oncolysis or can be engineered into the virus therapeutic. Direct oncolysis can also lead to induction of cancer-specific antitumoral cell-mediated immunity. In addition, oncolysis can result in the blockage of tumor-associated blood vessels (also known as "vascular shutdown"). In addition, these agents can be engineered to express therapeutic transgenes to express proteins selectively in tumors that have anti-cancer MOA. Examples include prodrug-activating enzymes that activate chemotherapy locally in tumor tissue, and immune response activators such as GM-CSF (see JX-594 above).

Virus Species

Oncolytic viruses can be made from a diverse array of viral species. Each species has distinct characteristics that give them specific spectra of activity and behaviors in cancer patients. Examples include enveloped viruses such as vaccinia, herpes simplex virus (HSV) and measles, as well as non-enveloped viruses such as adenovirus and reovirus. These viruses represent the equivalent of the chemical "pharmacophore" (starting material for a therapeutic agent) that can then be engineered to optimize efficacy and safety. Species-dependent differences can be profound. For example, whereas vaccinia virus is a blood-borne virus that can naturally spread via blood to disseminated tumor sites in the body, other viruses such as ►adenovirus (Ad5) or HSV that are not naturally blood-borne are limited to local-regional applications in cancer patiens.

Onconase

Definition

Is a ribonuclease-type enzyme inhibitor found in the oocytes of the frog *Rana pipiens*. It is being studied in the treatment of ►mesothelioma.

►Ranpirnase

Oncopeptidomics

Harald Tammen
Digilab BioVisioN GmbH, Hannover, Germany

Definition

Oncopeptidomics is defined as application of peptidomics technologies to the field of oncology. Peptidomic technologies encompass the systematic, comprehensive multiplex analysis of native or endogenous peptides in a biological sample with respect to temporal and spatial resolution.

Characteristics

Peptides

The proteome is the set of all proteins encoded by the genome and present within an organism for a specific time frame. While the genome remains relatively stable, the proteome is remarkable dynamic with multiple mechanisms of up and down regulation as well as different mechanisms of post-translation modifications. One important, irreversible proteomic control mechanism is the proteolytic processing of proteins by proteases that initiate, modulate and terminate many important cellular functions through highly specific and limited substrate cleavages. One important result of proteolytic activity is the generation of peptides. The Greek origin of the term "peptide" (from the Greek terms "peptos," meaning digestible, and "poly-saccharide," referring to its composition of two or more amino acids) reflects the fact that peptides are the products of proteolytic cleavage events. It is estimated that there are 500 genes that encode proteases and approximately 150 protease inhibitors have been identified in the human genome.

The role of bioactive peptides in biology and their importance for therapeutic applications has been known for several decades. Insulin, for example was the first peptide used to treat a disabling and life-threatening disease, Type 1 diabetes. In general, the function (or bioactivity) of peptides is linked to some defined molecular interaction that invokes a change of physicochemical state (e.g. a signal transduction). But peptides are also often produced during metabolic processes and, as such, represent or mirror that process as an objective ►biomarker. Due to their involvement in almost all biological processes, peptides are highly relevant as biomarkers.

Peptide Biomarker

In the field of clinical diagnostics, there is increasing interest in native peptides as potentially useful biomarkers. The discovery of tumor biomarkers useful for early detection of cancer is one main goal in cancer research, since the 5-year survival rate of cancer patients shows a high correlation to the tumor stage. Consequently the axiom of "the earlier the diagnosis, the better the chance of effective treatment" is still regarded to be true.

Since the peptidome (or the low-molecular weight proteome) reflects proteolytic processing of precursor molecules, a close connection to tumor pathophysiology exists. Increased or altered expression and secretion of proteases (e.g. ►matrix metalloproteases (MMP) and ►cathepsins) exerting proteolytic activity inside the cells or extracellularly in the tumor tissue is associated with tumor cell growth, invasion, angiogenesis and metastasis. Peptides, as proteolytic reaction products of these altered expression are capable to reflect these changes in enzymatic activity. In contrast to cell-associated proteases or precursor proteins, peptides exhibit better permeability between tissue compartments due to the relative low molecular weight. Therefore, the probability of detecting proteolytic fragments from tissue-born proteins in body fluids is significantly higher than that of the protein precursor. Taken together, endogenous peptides can be regarded as versatile biomarkers that are capable of revealing the different pathologies and heterogeneity of diseases by reflecting changes in the expression of their precursor proteins or activity of the corresponding enzymes.

For example, ►fibrinogen degradation products (FDP) have long been known to be increased in plasma of cancer patients. It is likely that FDPs are produced by plasmin, which is generated from plasminogen around neoplastic cells due to enhanced release of plasminogen-activator by these cells.

Peptide Biomarker Discovery

►Multiplex profiling technologies for peptides are most often based on ►mass spectrometry which offers the analytical comprehensiveness required to monitor peptides, and thus proteolytic events, in an efficient way. Differences can be linked to altered regulation of protein synthesis and degradation which, in turn, are representative of altered cellular mechanisms associated with the advent and growth of tumors. There are two basic approaches for peptide biomarker discovery: broad-shallow and narrow-deep.

The broad-shallow approach uses the entire information content (peptide pattern) present in a given dataset for stratification of healthy individuals from cancer patients by use of ►multivariate statistics. One prominent example of this approach was published in 2002. In the study, the authors describe the application of bioinformatics tools (e.g. genetic algorithms) to mass spectrometric data patterns acquired from serum samples of patients with ►ovarian cancer or healthy individuals. The results were used as a basis for stratifying cancer patients from controls with exceptionally high specificity and sensitivity. Although the study

initialized a controversial debate around the lack of ►sequence identification of the discriminatory peaks and the utility of abstract patterns with the risk of data over-fitting, it initiated a conceptual breakthrough for mass spectrometry in biomarker research.

The narrow-deep approach aims at the discovery of a very limited set of marker candidates for a given problem but with extensive biological and analytical characterization of these candidates. The identification of the protein or peptide sequence not only allows the generation of antigen specific antibodies as the part of the major prevailing form of in vitro diagnostic (IVD) assays, but also the validation of these biomarkers with independent approaches. The differences in peptide expression levels can be analyzed in different biological sources such as tissue and plasma, the test validation can be performed on various other detection systems (e.g. gene expression, immunohistochemistry, immunoassays), and a biological hypothesis can be generated and tested. Even more important, the biomarker can be transferred to multiple sites and approved clinical validation procedures can be used.

Challenges and Limitations in Oncopeptidomics

Currently most of the applied multiplex technologies for discovery of biomarkers do not allow detecting concentrations of endogenous peptides in the low picomolar to the high femtomolar range – a sensitivity level required for the measurement of classical tumor markers in blood. Most published results describe fragments of liver proteins as biomarker candidates. These highly abundant (micromolar concentrations) plasma proteins (e.g. apolipoprotein A-I, serum-amyloid protein, hemoglobin, transthyretin) or their fragments have been proposed to discriminate between controls and cancer patients. Since many of these proteins originate from the liver and not from the diseased tissue itself, it is a matter of the current debate whether markers reflecting a tumor host response (e.g. acute phase proteins) will eventually have sufficient sensitivity and specificity to bring them from discovery through the rigorous clinical validation process. Nevertheless, concepts have been proposed, that fragments derived from high abundant plasma proteins are tailored by tumor exopeptidases during serum generation. Until now a definitive assessment has not been made, since direct measurements of these postulated peptidases has not been carried out yet. As a result, current peptidomics discovery strategies should integrate the analysis of model systems, tumor and control tissue, and the consequent use of active controls as well as body fluids to enhance sensitivity. The challenge of the next years is to further promote such integrative approaches and to improve the sensitivity of mass spectrometric based multiplex systems to extend the analytical range beyond highly abundant components.

Conclusion

Peptide biomarker bear the potential of adding high value for the diagnosis and stratification of cancer and different peptidomics technologies in the field of oncology are currently under broad investigation. At present, a definitive assessment on the hitherto obtained results cannot be made, since most candidates are not validated yet. The complexity of clinical validation of proteomic biomarkers is a challenge and the time requirement has typically been underestimated. The objective to establish more reliable biomarkers for the stratification of patients, the determination of clinical or therapeutic outcomes (►prognostic biomarkers or ►predictive biomarkers), or the early detection of cancer necessitate a more holistic viewpoint and will presumably require a duration comparable to the drug development process.

Oncoplastic Surgery

Gail S. Lebovic
Director of Women's Services, The Cooper Clinic, Dallas, TX, USA

Definition

Oncoplastic surgery is an evolving surgical subspecialty that combines the principles and techniques of surgical oncology (removal of cancer) with aesthetic and reconstructive surgery.

Characteristics

Historical Background

►Breast cancer is not a new disease. Historical documents as early as the Egyptian Papyrus writings have noted its existence. Since that time, women have lived in fear of this dreaded disease, the lethal nature of its course and the often disfiguring surgery that accompanies treatment.

Today, many of those fears can be alleviated. A broad range of new and innovative techniques are now used in

the diagnosis and treatment of breast cancer which has changed the stage of disease that physicians are treating to a much earlier stage. In turn, this has allowed for new surgical modalities such as minimally invasive biopsy, ►breast conservation. The advances in surgical care and the development of new and successful reconstructive techniques have all stimulated the development of oncoplastic surgery as a new surgical subspecialty.

The surgical history of breast cancer treatment dates back to the late 1800s when Dr. William Halsted and others realized that removal of the breast and surrounding tissues resulted in an improved quality of life for breast cancer patients. Unfortunately, since the majority of these women were diagnosed at a late stage of disease, even this dramatic and extensive surgery did not necessarily extend their lifespan. This type of surgery (the ►Halsted radical mastectomy) required complete removal of the tissues surrounding the breast, including the entire breast itself, all of the overlying muscle, the skin of the chest wall and most of the auxiliary lymph nodes and tissue. While the advent of anesthesia and antibiotics made this surgical procedure possible for the removal of cancer, the "radical mastectomy" resulted in a horribly disfiguring appearance (Fig. 1a) and left many women feeling ashamed.

As mammographic screening programs became more available, and as women became more familiar with the signs and symptoms of breast cancer, the medical community began to see smaller, earlier tumors. Ultimately, research proved that with breast cancers diagnosed at an earlier stage, women have improved survival rates even when less radical surgery is performed. This led to promotion of the "modified radical mastectomy" which surgically removed the breast and auxiliary contents, but preserved the underlying muscle and more of the skin (Fig. 1b). This procedure was much less invasive than the radical mastectomy, and resulted in a better contour and appearance of the chest wall allowing women to wear a breast prosthesis more easily and feel less deformed. It also enabled surgeons to develop methods for reconstructing the breast, and by the mid to late 1980s many women were able to have immediate ►breast reconstruction at the time of ►mastectomy (Fig. 2a–d) or undergo delayed reconstruction using tissue expansion with ►breast implants (Fig. 3a, b). Thus, they were saved the physical and psychological discomfort of living without their breast.

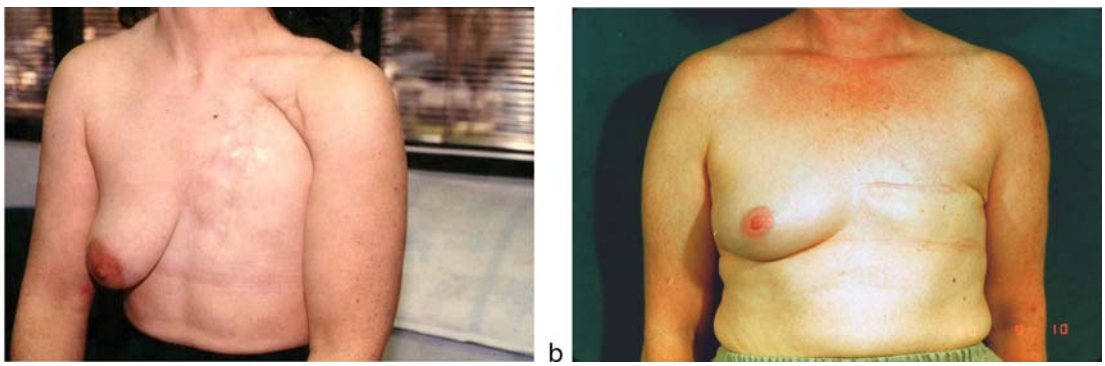
Additional intensive research studies in the United States and Europe ultimately revealed that small tumors in the breast could effectively be removed while preserving the surrounding tissue and saving the nipple and areola. This became known as "breast conservation" surgery and now is used to treat over 50% of breast cancers that are diagnosed. Depending upon the type, size and location of the tumor, breast conservation surgery is often followed by additional treatments such as ►radiation therapy and/or chemotherapy. These changes in the surgical management of breast cancer have provided the impetus for continued improvement and have led to the recent expansion of oncoplastic surgery.

Clinical Impact of Oncoplastic Surgery

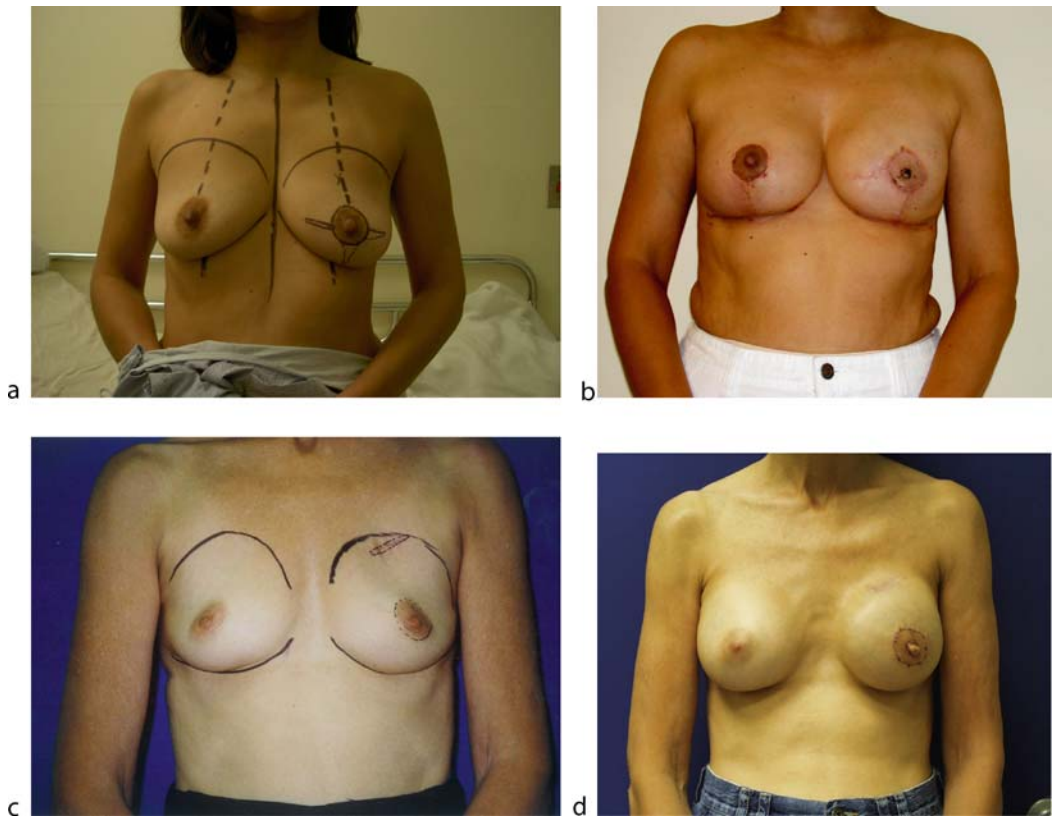
The term "oncoplastic surgery" was first used by Dr. Werner Audretsch to describe a new surgical approach – one in which the breast surgeon considers cancer treatment in conjunction with aesthetics. Thus, the clinical objectives of oncoplastic surgery are to optimize patient outcomes by combining the principles of surgical oncology with those of aesthetic and reconstructive surgery. First and foremost, there must be no compromise in the primary cancer treatment. Aesthetic outcome of the surgery is critically important, but follows as "secondary" after all consideration for cancer treatment. For example, ►breast reduction can be performed to remove the tumor and improve the overall appearance of the breast (Fig. 4a, b).

Pre-operative assessment of the patient begins with the following:

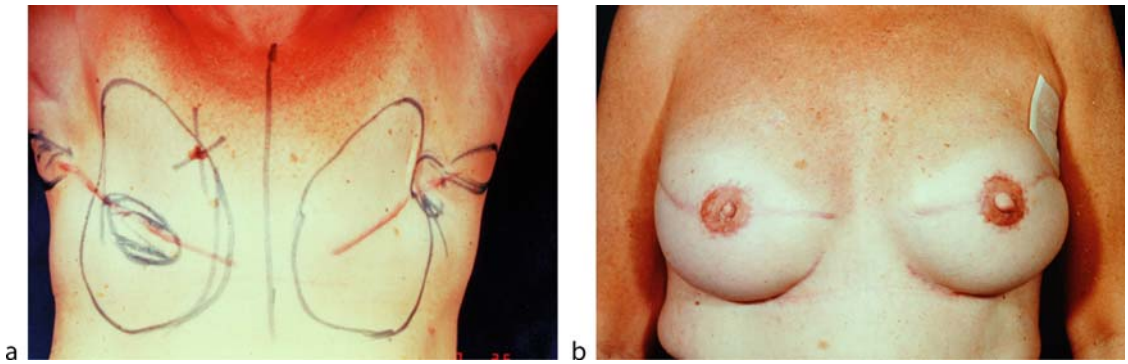
Complete and thorough history and physical examination



Oncoplastic Surgery. Figure 1 (a) Radical mastectomy and (b) modified radical mastectomy.



Oncoplastic Surgery. Figure 2 (a) Breast cancer patient prior to removal of the left breast, (b) same patient following removal of the left breast and immediate reconstruction, (c) breast cancer patient prior to removal of the left breast, and (d) same patient following removal of the left breast, immediate reconstruction, ►nipple construction and augmentation of the right breast.



Oncoplastic Surgery. Figure 3 (a) Breast cancer patient following removal of both right and left breasts and (b) same patient following reconstruction of both right and left breasts with nipple reconstructions.

Diagnostic imaging studies with tissue biopsies as needed

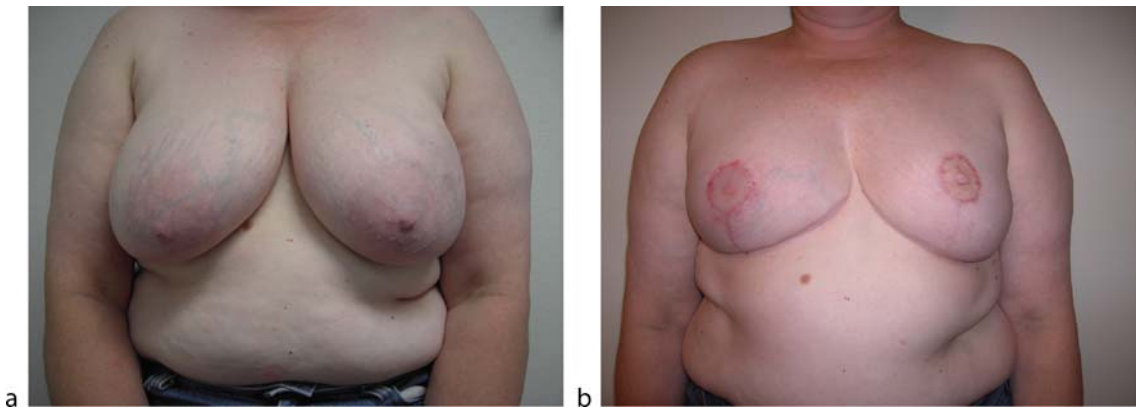
Risk assessment – including risk of recurrence and risk of a new cancer occurring in the opposite breast

Surgical objectives are then determined and must take into consideration:

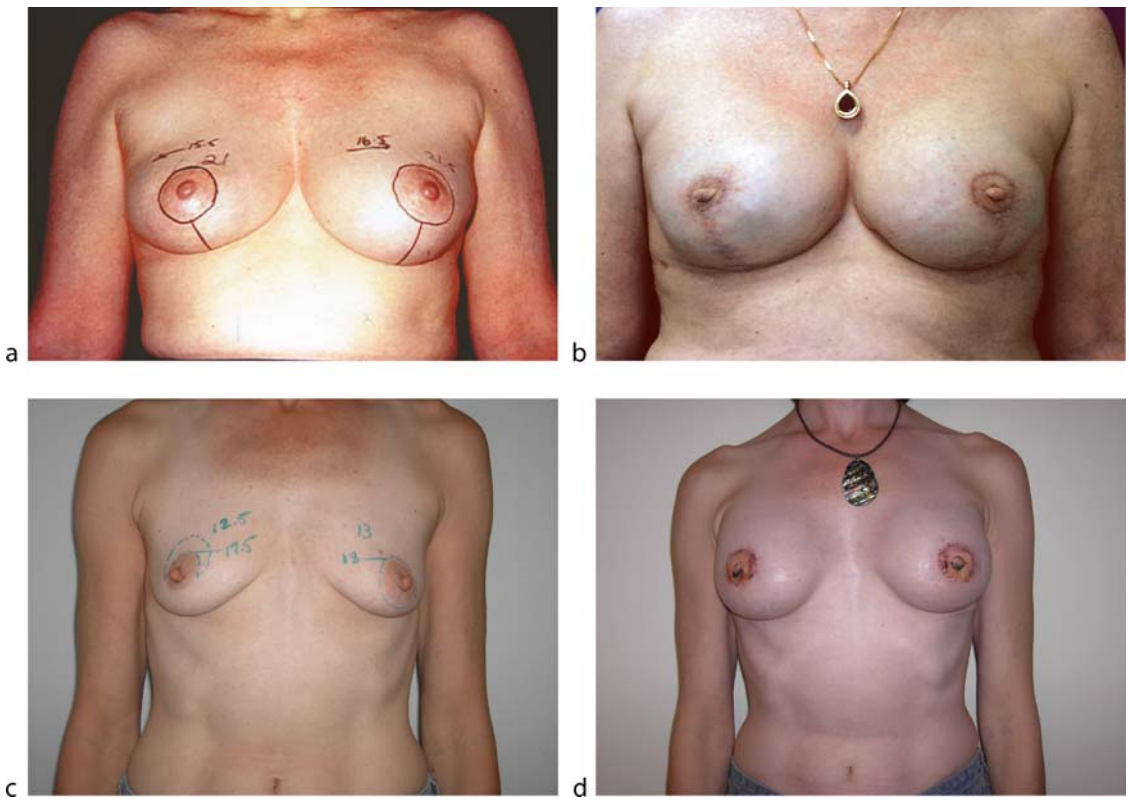
Optimizing removal of involved tissue with clean margins and appropriate staging

Preservation of non-affected tissues (i.e. skin, muscle, etc.)

Consideration of additional therapy that may be necessary (i.e. radiation)



Oncoplastic Surgery. Figure 4 (a) Breast cancer patient with large breasts and (b) same patient following removal of left breast, immediate reconstruction, left nipple reconstruction and reduction of the right breast.



Oncoplastic Surgery. Figure 5 (a & c) Patients with strong family history of breast cancer and genetic predisposition to the disease. (b & d) Same patients following prophylactic removal of the breasts with immediate reconstruction of the breasts and nipples.

Optimizing aesthetic appearance of the breasts (reconstruction, reduction, etc.)

In order to achieve these objectives, the pre-op testing of patients at risk or diagnosed with breast cancer can be extensive. Various imaging modalities are commonly employed for diagnosis, such as mammography, ultrasound and magnetic resonance imaging (MRI), and should include thorough assessment of both breasts using minimally invasive tissue sampling for any suspicious lesions.

In addition, patients with a family history of breast cancer should undergo genetic testing for BRCA mutations (►BRCA1/BRCA2 Germline Mutations and Breast Cancer Risk). These genetic mutations are

predictors of patients at high risk for developing breast cancer during the course of their lifetime. Often patients with this known predisposition to breast cancer will choose to have the breasts surgically removed as a precautionary measure since surgery will markedly decrease and/or prevent their lifetime risk of breast cancer. This procedure is termed a "►prophylactic mastectomy". Oncoplastic surgery is particularly beneficial for these patients since the elective removal of the breasts can be done in an anesthetically pleasing fashion, preserving almost all of the skin and in some cases even preserving the nipple and areola. This procedure is combined with immediate breast reconstruction providing a nice appearance to the new breasts with a markedly decreased risk of development cancer (Fig. 5a–d).

After evaluation and consideration of all aspects of each patients' cancer care, the surgeon explores the desires and needs of the patients' aesthetic/reconstructive desires and applies them to the surgical plan. This provides for a comprehensive surgical approach and often requires fewer surgeries to achieve the desired surgical outcome.

Summary

Although at present the field of Oncoplastic surgery is in its' embryonic growth phase, breast surgeons around the world have recognized the benefits of providing this type of care to breast cancer patients and hopefully soon these techniques will be available to women throughout the world.

Oncostatin M

Nick Underhill-Day
School of Biosciences, University of Birmingham, Birmingham, UK

Synonyms

OSM; Oncostatin M Precursor

Definition

Oncostatin M (OSM) is a member of the hemopoietic ►interleukin-6 (IL-6) cytokine subfamily and is most closely related structurally and functionally to ►leukemia inhibitory factor (LIF).

Characteristics

Human Oncostatin M is a multifunctional, 28-kDa glycoprotein which was originally isolated from histiocytic lymphoma cells treated with phorbol 12-myristate 13-acetate (►PMA). Oncostatin M was identified and cloned on the basis of its ability to inhibit the growth of ►melanoma cell lines but is now known to exhibit unique biological functions in hemopoiesis, neuropoiesis, ►inflammation, bone remodeling, muscle proliferation and embryonic development.

OSM is produced by activated T-lymphocytes, ►macrophages, monocytes and neutrophils and is a member of the glycoprotein 130 (gp130) cytokine family which exert their actions via a shared signal-transducing receptor, gp130. Members of this family include ►interleukin-6 (IL-6), interleukin-11 (IL-11), ►leukemia inhibitory factor (LIF), ciliary neurotrophic factor (CNTF), cardiotrophin-like cytokine (CLC), cardiotrophin-1 (CT-1) and neuropoietin (NP). The genes for oncostatin M and LIF occur in tandem on human chromosome 22q12 and share similar gene structures thus probably arose through gene duplication. The human OSM gene is approximately 4 kb in length and contains three exons encoding a 2 kb transcript. Oncostatin M is most closely related structurally and functionally to LIF, exhibiting 22% sequence identity to LIF.

Oncostatin M Protein Structure

Oncostatin M and other IL-6 cytokines belong to the 'long chain four helix bundle' subgroup of cytokines together with ►granulocyte colony stimulating-factor (G-CSF), growth hormone and ►erythropoietin. This subgroup exhibits four helices (A-D) joined together by polypeptide loops in an UP-UP-DOWN-DOWN topology. The IL-6 cytokine family can be further subdivided into straight chain and kinked chain cytokines (IL-6 and IL-11 belong to the straight chain subgroup while OSM, LIF and CNTF have a kink in

helix A). This structural divergence reflects differences in receptor recruitment.

Oncostatin M has an N-terminal secretory signal sequence of 25 amino acids and a basic hydrophilic C-terminus of 31 amino acids. Both are cleaved off during protein processing but there may be slight differences in post-translational modification depending upon the cell line hence generating differently sized mature Oncostatin M protein. The unprocessed OSM precursor is 28 kDa (252 amino acids) while the N-and C-terminal modifications make the mature and fully active form of OSM approximately 22 kDa (196 amino acids).

Oncostatin M Ligand-Receptor Interactions

Different members of the gp130 family signal either by the formation of homodimeric gp130 complexes (facilitated in some cases by non-signaling co-receptors) or via heterodimeric receptor complexes containing gp130 and a second signaling receptor. Human OSM is unusual in that it can form two types of heterodimeric signaling complexes. The type I OSM receptor complex consists of the gp130 receptor and the LIF receptor α (gp130/LIFRα). This configuration is also utilized by LIF. As a consequence, human OSM and LIF can exhibit similarities in biological activity. The type II OSM receptor complex comprises gp130 and the OSM receptor β (gp130/OSMRβ) and this is activated by OSM only. The type II receptor complex may activate signaling pathways distinct from the OSM type I complex thus conferring OSM–specific signaling functions.

OSM ligand has two receptor binding sites; II and III. Site II (as with all the IL-6 cytokines) binds to gp130 via conserved residues within the A and C helices. Site III binds to either the LIFRα or OSMRβ via conserved residues at the N-terminus of the D-helix (two conserved amino acids, phenylalanine-160 and lysine-163, referred to as the FK motif). All the other LIFR binding ligands contain this FK motif.

Oncostatin M Signaling

The generic features of gp130 cytokine signaling are well defined. The formation of a high affinity transmembrane signaling complex results in activation of the receptor associated Janus kinase family (Jak1, ►Jak2 and Tyk2) leading to phosphorylation of gp130, OSMRβ and LIFRα. Phosphorylated tyrosine residues in the receptor C-terminal regions recruit phosphotyrosine binding (PTB) and Src homology-2 (►SH2 domain) domain containing proteins such as the adaptor protein Shc to OSMRβ and phosphatase Shp2 to gp130 and LIFRα. Both these associations result in activation of the mitogen-activated protein kinase (MAPK) cascade. The second target of receptor activated Jak kinases are the ►signal transducers and activators of transcription (STAT) family of transcription factors (STATs-1, -3 and -5) which, upon Jak-mediated phosphorylation, migrate to the nucleus and activate the transcription of downstream gene targets.

Clinical Relevance of Oncostatin M in Cancer

The clinical manifestations of oncostatin M within the tumor ►microenvironment are poorly understood and are further complicated by virtue of its multiple roles in ►inflammation, tissue remodeling and wound healing processes. In normal physiological processes OSM is implicated in a variety of cellular functions in immune, hemopoietic, neural, bone and hepatic systems. Many of these functions are shared by other members of the interleukin-6 cytokine family while some are restricted to oncostatin M. The role of OSM in cancerous tissues is controversial as some actions are considered anti-tumorigenic while others may potentially contribute to tumor progression, ►angiogenesis and increased metastatic potential. OSM-induced growth inhibition of tumor cells is clearly beneficial while some of the pro-inflammatory actions (e.g. increased ►cyclo-oxygenase-2 expression) coupled with stimulation of proteolytic pathways involved in extracellular matrix (ECM) degradation and associated localized tissue damage could be detrimental. The biological activities of oncostatin M most likely to have implications in tumor biology are outlined below.

OSM inhibits the growth of normal primary mammary epithelial cells and stimulates proliferation of dermal fibroblasts, endothelial cells, vascular smooth muscle cells and T-cells. In addition OSM modulates the growth of a number of solid tumor-derived cell lines exhibiting antiproliferative effects on breast tumor-derived cell lines, lung carcinoma cells, melanoma cells, ►neuroblastoma cells, glioma cells and ovarian carcinoma cells while stimulating the proliferation of primary ►plasmacytoma and myeloma cells, prostate carcinoma cells and cells derived from acquired immunodeficiency syndrome-related ►Kaposi sarcoma (AIDS-KS). Oncostatin M has also been shown to inhibit *in-vivo* glioma formation after intracerebral inoculation of mice with ►glioblastoma cells. In many of these tumor cell lines (e.g. melanoma, breast tumor) the specific OSMRβ is a prerequisite for the effects on growth. However, some cell lines derived from advanced-stage cancers can become refractory to OSM growth inhibition and may undergo OSM autocrine growth stimulation (e.g. melanoma cells).

OSM treatment of breast-cancer cell lines and normal breast epithelial cells reduces the proportion of cells in the S-phase of the cell cycle while increasing the proportion of cells in G0/G1 phase. Both MAPK and STAT signaling are implicated in the anti-proliferative effects (and gene regulatory anomalies) of OSM on most of these tumor cells. OSM-mediated growth responses involve alterations in protein expression and

may include gene targets such as ►c-myc, p53, p21, cyclins A and D and c/EBPδ.

OSM stimulates differentiation of hemopoietic cells (T-cells, megakaryocytes) and vascular endothelial cells. OSM also induces morphological changes in several tumor cell lines which, in some reports (breast cancer, glioma, lung cancer and myeloblastic M1 murine leukemia) are associated with cell differentiation processes. In the MCF-7 breast tumor cell line, OSM stimulation results in increased expression of epithelial membrane antigen, a component of milk fat-globule proteins and differentiation marker. However, morphological changes involving loss of cell-cell and cell-matrix interactions (breast tumor cells and lung cancer cells) coupled with modulation of adhesion receptor expression and increased cell motility have also been reported and associated with tumor cell detachment from the substratum and enhanced invasive capacity.

OSM secretion by immune cells leads to a range of effects involved in both pro- and anti-inflammatory processes. OSM is known to be expressed during initiation of immune responses along with other cytokines such as interleukin-2 (IL-2) and ►tumor necrosis factor-α (TNFα). OSM mediates the expression and/or activity of other cytokines, for example, in ►Kaposi sarcoma cells OSM induces expression of IL-6 while in endothelial cells OSM stimulation results in increased IL-6, GM-CSF and G-CSF expression. OSM also has the capacity to act synergistically with other inflammatory cytokines (e.g. IL-1, TNFα) for example in the stimulation of ►prostaglandin E_2 synthesis in astrocytes and astroglioma cells. OSM induces synthesis of CXC and CC subfamilies of ►chemokines such as growth regulated protein (GRO-α, GRO-β) production by endothelial cells, stromal cell-derived factor 1 (SDF-1) production by mesenchymal stem cells or monocyte chemoattractant protein 1 (MCP-1) expression by synovial fibroblasts. In addition, OSM protein acts as a chemoattractant for leukocytes, neutrophils and capillary endothelial cells thus may act to recruit immune cells to sites of inflammation and help revascularization during the wound healing process. OSM can also inhibit expression of some cytokines and chemokines.

OSM stimulation of mammary adenocarcinoma cells, endothelial cells, astroglioma cells and ►neuroblastoma cells results in increased ►prostaglandin (PG) synthesis due to upregulation of cyclooxygenase-2 expression. PGE_2 acts as an inflammatory mediator and stimulates further expression of cytokines and growth factors by immune cells localized to the area of inflammation.

Vascular endothelial cells are one of the main targets of oncostatin M due to their high expression of gp130 family receptors including OSMRβ. OSM induces endothelial cell surface expression of adhesion receptors (e.g. P- and ►E-selectin, ICAM-1, VCAM-1) which aid in the recruitment, adhesion and transmigration of leukocytes and neutrophils across the endothelium. In addition, OSM also alters fluid (and cell) movement in and out of the vasculature by inducing expression of vasodilators (vasoactive intestinal peptide) or vasoconstrictors (►endothelins).

One of the earliest defined characteristics of OSM and all gp130 family cytokines is stimulation of acute phase protein (e.g. serum amyloid A, α1-antichymotrypsin, complement factors) production both in local tissues at sites of inflammation and by liver hepatocytes. Thus, as well as exhibiting pro-inflammatory properties, OSM is a prominent cytokine during immune attenuation and probably aids in the re-establishment of tissue homeostasis.

OSM is involved in ►extracellular matrix remodeling and contributes to the degradation and reformation of stroma in wound healing processes. This is achieved by mediating the expression of proteolytic enzymes, their associated receptors and inhibitors. For example, OSM modulates expression of components of the ►plasminogen activating system (►urokinase-type plasminogen activator (uPa), uPa-receptor, tissue-type plasminogen activator (tPa) and plasminogen activator inhibitor (PAI-1)) in endothelial cells, fibroblasts, astrocytes and lung carcinoma cells. OSM also regulates the balance between ►matrix metalloproteinases (e.g. MMP1, MMP2, MMP3 and MMP9) and ►tissue inhibitors of matrix metalloproteinase (TIMP) in a variety of normal and tumor cell lines. OSM induces expression of additional proteolytic enzymes (e.g. ►cathepsins) and stimulates production of ►ECM components such as ►fibronectin, laminin and vitronectin presumably during formation of new stroma. OSM can also stimulate expression of angiogenic regulators including ►vascular endothelial growth factor (VEGF) and ►basic fibroblast growth factor (bFGF) by several different cell types so can potentially promote ►angiogenesis.

Lastly, OSM has been implicated in modulation of tumor cell ►drug resistance. On exposure to oncostatin M, ►prostate cancer-derived (PC-3) cells acquire enhanced resistance to both ►etoposide and ►cisplatin. OSM is also known to mediate downregulation of ►cytochrome P450 enzyme expression in hepatocytes thus may impair drug metabolism in both normal and cancerous tissues during inflammatory processes. OSM may also override growth responses of tumor cells to drug treatment. For example, myeloma cells normally undergo growth inhibition in response to dexamethasone but this response is reversed by OSM.

Oncostatin M Precursor

►Oncostatin M

ONYX Vector

Definition

Refers to a human gene therapy vector based on a modified adenovirus, with deletion of the E1B 55-kDa gene, that renders the virus incapable of replication in cells with normal p53 genes. By contrast, in cancer cells with mutated p53 genes, ONYX vector can replicate and lyse the host cell, perhaps contributing to effective tumor control. As many human tumors have a mutated p53 genes, they are potentially vulnerable to lysis by ONYX-vector approach.

Open Reading Frame

Definition

Orf; Region of a gene that is translated into a protein; typically flanked by a start and stop codon.

Opportunistic Infections

Definition

Infection induced by a microorganism that normally does not lead to a disease, but becomes pathogenic when the body's immune system is compromised.

►Inflammation

Opsonin

Definition

Is any molecule that acts as a binding enhancer for the process of ►phagocytosis, for example, by coating the negatively-charged molecules on the membrane. ►Opsonization.

Opsonization

Definition

Refers to a process that makes bacteria or other cells more susceptible to the action of phagocytosis. Is the process where particles such as microorganisms become coated with molecules that allow them to bind

to receptors on phagocytes. Antibodies (especially IgG) and complement proteins like C3b can opsonize and are therefore referred to as ►opsonin.

Opsonize

Definition

To coat an organism with antibodies or a complement protein so as to make it palatable to phagocytes.

►Opsonin
►Opsonization

OptiBerry

Definition

A synergistic combination of six edible berry extracts including wild blueberry, wild bilberry, cranberry, elderberry, raspberry seed, and strawberry.

►Chemoprotectants

Optic Glioma

Definition

Grade 1 pilocytic ►astrocytoma, a tumor that arises from glial cells and grows in and along the optic nerve or optic tract.

Optical Mammography

K. Thomas Moesta, Peter M. Schlag
Klinik für Chirurgie und Chirurgische Onkologie, Charité, Universitätsmedizin, Berlin, Germany

Synonyms

Light tomography; Breast transillumination

Characteristics

Optical mammography is an imaging modality using transilluminated light in the visible and near infrared wavelength range, which is used to detect or to differentiate neoplastic lesions of the breast.

Description

Many attempts to detect ►breast cancer by transillumination have failed in the past due to the strongly diffusive nature of light transport in tissues. Lasers might initiate a technical revolution in this field. The use of several wavelengths may enable differential spectroscopy, leading to functional and tissue composition information. High frequency intensity modulation or pulsed laser systems provide additional information of the length of the photon path in tissue, eventually enabling differentiation between absorption and scattering properties of breast tissue or even three-dimensional reconstruction of optical properties.

Application

Two-frequency domain instruments have been clinically evaluated in Germany. The Fig. 1 demonstrates the Carl Zeiss instrument "LIMA" that uses two laser diodes

Optical Mammography. Figure 1 Prototype of a Frequency Domain optical mammograph. The instrument uses two intensity modulated (110 MHz) laser beams at wavelengths of 690 and 810 nm to scan a breast. Images are calculated from amplitude and phase data.

at 690 nm and 815 nm, and a modulation frequency of 110 MHz. A clear improvement in image quality compared to conventional imaging was demonstrated. Furthermore, the approach enabled the characterization of individual tumors with regard to size, position and tissue-optical properties. However, no significant improvement in sensitivity appears to result from the frequency domain approach.

Actual research focuses on time domain instruments using laser pulses in the picosecond range. Entire flight time distributions are registered. By using only the first photons leaving the tissue, contrasted pictures of differentially absorbing tissue formations may become possible. However, the probability for a photon to pass a 4–7 cm layer of breast tissue without any scattering (ballistic photon) is zero. Thus, image contrast will always be inferior to X-ray images. On the other hand, additional and quantitative information can be obtained by the use of different wavelengths such as tissue oxygenation parameters or tissue composition information, which may compensate for the lack of contrast and detail resolution. Such time domain instruments are entering initial clinical testing. Furthermore, for the purpose of enhanced specificity in detectable lesions, contrast agents may prove useful in the future.

Oral Cancer

Cathie Garnis[1], Wan L. Lam[2]
[1]MIT Center for Cancer Research, Cambridge, MA, USA
[2]British Columbia Cancer Research Centre, Vancouver, BC, Canada

Synonyms

Lesion on tongue, lip and other areas in the mouth

Definition

Oral cancer is cancers of the mouth. It is a common form of head and neck cancer.

Characteristics

Etiology

Oral cancer is amongst the most commonly diagnosed cancers worldwide and its incidence high in developing countries. The main etiological factors for oral cancer are tobacco and alcohol use, with 75% of those diagnosed with disease described as current or ex-smokers. Regular combined use of tobacco and alcohol significantly increases the chance of developing this type of tumor; those who both smoke and drink have a 15 times greater risk of developing oral cancer than the overall population. While the majority of people are over the age of 40 at the time of diagnosis, oral cancer may also occur in younger individuals. Exact causes for those affected at a younger age have been linked to young men and women who use "smokeless" chewing or spit tobacco. It is also a possibility that those in this younger age group have a causal link which is viral-based, as their exposure to tobacco and other known causative agents is short in time. The ►human papillomaviruses, particularly versions 16 and 18, is implicated in the increasing incidence of young non-smoking oral cancer patients. This is the same virus that is the causative agent in more than 90% of all ►cervical cancers.

Oral cancer carries a poor prognosis and a high rate of recurrence; second primary tumors are estimated to occur at an annual rate of 3–10% and their presence is known to greatly impact survival. Despite the development of new therapeutic options, the overall survival rate for oral cancer has not changed in the last two decades.

Progression

Oral cancer progresses through various histopathological stages – from hyperplasia, various stages of dysplasia, and carcinoma *in situ* (►CIS) to invasive disease. There are two types of precancerous oral lesions: ►leukoplakia and ►erythroplakia. Both show varying degrees of dysplastic change. In general, erythroplakia contains more severe ►dysplasia and is more likely to progress, while incidence of leukoplakia is much higher.

Oral leukoplakia is a white-plaque mucosal lesion that confers increased risk for the development of ►oral squamous cell carcinoma (OSCC). Five to 15 percent of oral white patches are classified as dysplasia. Of these, only 15–20% develop into invasive carcinoma. Treatment for oral leukoplakia is removal via surgery or laser. Because histology of low grade dysplastic lesions is of limited prognostic value, therapeutic intervention is considered only where there is evidence of transition to CIS or invasion. Hence there is a need to identify

molecular markers that predict progression for individual pre-invasive lesions.

Genetics

Oral tumors have been proposed to arise through "►field cancerization", a process where whole tissue exposure to a carcinogen leads to increased risk of multiple pre-malignant lesions or invasive tumors. The frequent occurrence of tumors with dissimilar histology in the same individual, as well as distinct genetic signatures in these tissues are evidence for this phenomenon. With field cancerization, each tumor is thought to arise by clonal evolution of a cell population that is accumulating cancer-causing genetic and epigenetic changes.

Oral cancer generally arises through dysregulation of ►oncogenes and ►tumor suppressor genes (TSGs) that drive cell proliferation. Oncogenes are altered growth-promoting regulatory genes that govern cell signal transduction pathways. Mutation of these genes leads to either overproduction or increased function of the resulting protein. TSGs, on the other hand, are "gatekeepers" of cellular proliferation. They can either inhibit cell growth or promote cell death. Mutations in a number of TSGs and oncogenes are commonly observed in oral cancer. These include ►*RAS*, ►*MYC*, ►*CCND1 (CyclinD1)*, ►*EGFR* (*Epidermal Growth Factor Receptor)*, ►*TP53, CDKN2A* (*Cyclin Dependent Kinase Inhibitor 2A*), and ►*FHIT* (*Fragile Histidine Triad*).

►Allelic loss involving chromosome arm 3p is one of the most frequent and earliest genetic events in the development of ►HNSCC. This loss is significant as several potential TSGs fall in this region. For oral cancer, multiple discontinuous regions of allelic loss support the idea that there are multiple TSGs on this chromosome arm. There is evidence that several genes residing on chromosome 3p are important for tumorigenesis, however the exact role each of these genes plays in the development of disease is still being determined. One gene residing on chromosome 3p that has been implicated in oral cancer is *FHIT*. This large gene, located at 3p14.2, also spans one of the most widely characterized ►fragile sites in the human genome, FRA3B. The *FHIT* gene, a member of the histidine triad gene family, is a target of tyrosine phosphorylation by the SRC protein kinase.

Treatment

Treatment for oral cancer is usually surgery and ►radiotherapy. Chemotherapy may be added to sensitize the malignant cells to radiation, to decrease the possibility of metastasis, or to treat patients with confirmed distant metastases. The stage of the disease at diagnosis dictates which treatment modality is used. Patients who are treated for early-stage cancer may have little in the way of post treatment disfigurement. For those diagnosed with later stage cancer, the results of surgical removal of the disease may require reconstruction of portions of their oral cavity or facial features.

Oral Squamous Cell Carcinoma

Gareth J Thomas
Institute of Cancer, Bart's and the London School of Medicine and Dentistry, Queen Mary University of London, London, UK

Synonyms

Oral cancer

Definition

Over 90% of malignant tumors affecting the mouth (including lips, mouth and oropharynx) are ►squamous cell carcinomas (SCC) arising from the lining mucosa. Other types of malignant tumor also develop within the mouth (e.g. salivary gland adenocarcinomas, melanoma, lymphoma); however, the term 'oral cancer' tends to be used synonymously with SCC.

Characteristics

Epidemiology

Oral cancer is estimated by the WHO to be the eighth most common cancer worldwide, with approximately 400,000 new cases each year. It accounts for around 4% of all cancers (5% of cancers in men, and 2% of cancers in women) and 2% of all cancer deaths. Oral cancer

most commonly occurs in middle-aged and older patients, and over 95% of patients are older than 40 years at time of diagnosis (mean age of diagnosis of around 60 years).

The incidence of oral cancer shows striking geographical variation, with around two thirds of all cases arising in the developing world, particularly the Indian subcontinent, which accounts for about a third of all cases. Oral cancer is less common in the western world (USA 30,000 new cases each year, Europe 66,500 new cases each year). Males are affected more commonly than females (worldwide male:female ratio 2:1), although this also varies geographically.

The incidence and mortality from oral cancer is rising in several regions of Europe, Australia, Japan and Taiwan. For example, the oral cancer incidence in the United Kingdom has risen by 19% in the last decade, with an increasing number of young people affected, and 25% of cases having no known risk factors. Nonsmokers are more likely to present with oral cancer at relatively young or relatively old age compared with smokers.

Etiology

It is estimated that around 80–90% of oral cancer cases are due to tobacco use (►tobacco-related cancers) and alcohol abuse (►alcohol-mediated cancers), which act both separately and synergistically. Epidemiological studies suggest that the risk for developing mouth cancer is five to nine times greater for smokers than non-smokers, and may be even higher in heavy smokers. Patients who are both heavy smokers and drinkers can have over a hundred times greater risk for developing a malignancy. Such patients often have a poor diet, and a low consumption of fruits and vegetables is also regarded as a risk factor for oral cancer development.

In India and South East Asia, tobacco may be chewed in the form of ►betel quid (paan). This habit is associated with a vastly increased risk for developing oral cancer, and accounts for the much higher incidence of the disease in these countries. The quid typically, is chewed over a period of many hours and is held in the buccal pouch within the mouth. Typically, tumors arising in betel chewers tend to arise on the buccal mucosa or retromolar area.

►Human papillomavirus (HPV) also has been postulated to play a role in oral cancer pathogenesis. A subset of mouth cancers (particularly oropharyngeal tumors) may result from infection with the oncogenic papillomaviruses, HPV16 and HPV18.

Long-term exposure to ►UV radiation is a major risk factor for lip cancer, due to actinic radiation damage. It is more common therefore in outdoor workers, people who regularly holiday abroad, and who live in sunny climates.

Several conditions are associated with increased risk of developing oral cancer: Submucous fibrosis has a malignant transformation rate of around 7–13%. Whether ►lichen planus is premalignant is more controversial, but it appears that oral cancer may arise in 0.5–2% of patients with this disease. Other rare precancerous conditions, such as syphilitic glossitis and sideropenic dysphagia, are now rare in developed countries.

Genetics

Like most epithelial cancers, oral cancer develops in a multistep process, through the accumulation of genetic and ►epigenetic alterations. Studies have demonstrated multiple genetic abnormalities including amplification or over-expression of various ►oncogenes (*CCND1* (►cyclin D1), ►*MYC*, ►*RAS*, and epidermal growth factor receptor), and deletion, mutation or promoter ►methylation of ►tumor suppressor genes (►*FHIT*, ►*P53*, ►*INK4A* [p16], *RAR-β*). No one change is found in 100% of tumors.

►Loss of heterozygosity (loss of genomic material from one of a pair of chromosomes) occurs at numerous chromosomal loci. Common sites of loss of heterozygosity include 3p, 9p and 17p, sites of tumor suppressor genes encoding proteins involved in the regulation of cell cycle and/or apoptosis (*FHIT, INK4A* and *P53* respectively). The most common genetic changes involve loss of chromosomal region 3p21. This results in inactivation of the p16 gene and occurs early in the development of oral cancer.

Approximately half of oral cancers also contain mutations of the *P53* gene, and the prevalence of mutations is greater in patients who smoke and drink alcohol compared with non-smokers/drinkers. Mutations in ►*RAS* are observed more frequently in patients from India whose cancer is linked to quid chewing.

Genes may also be silenced by promoter methylation. This occurs through epigenetic mechanisms rather than direct loss or mutation of DNA. Studies indicate that the genes most commonly methylated in oral cancer are *INK4A, CDH1* (►E-cadherin), *MGMT* (methylguanine-DNA methyltransferase) and *DAPK1* (death-associated protein kinase 1).

Several rare inherited cancer syndromes predispose to the development of oral (and other) cancers. Cancer predisposition may be caused by alterations in one of three groups of genes: tumor suppressor genes, oncogenes and DNA stability genes. Generally, oral cancer arises in syndromes resulting from defects in DNA stability genes. These include ►Fanconi anemia, ►Bloom syndrome, ►ataxia telangiectasia and ►xeroderma pigmentosum. With the exception of ►Li–Fraumeni syndrome (P53 mutation) oral cancer does not develop in syndromes caused by defective tumor suppressor genes.

►Polymorphisms in genes involved in the metabolism of carcinogens found within tobacco and alcohol have been linked to individual susceptibility to oral cancer. ► It is suggested that people with a null genotype for the ►gluthione *S*-transferase enzymes (*GSTM1* and *GSTT1*) have an increased risk of oral cancer. Other enzymes are implicated in oral cancer susceptibility, including ►cytochrome p450, the N-acetyltranferases and alcohol dehydrogenase, but their role has not been clearly determined. First-degree relatives of people with oral cancer have been reported to be at greater risk of developing the disease, and it is suggested that this possibly is associated with a greater susceptibility to genetic damage by environmental mutagens.

Premalignancy

Oral cancer develops in a multi-step process requiring a step-wise transition from normal mucosa through pre-malignant lesions to overt malignancy. This transition occurs as cells accumulate genetic damage and may alter the appearance of the oral mucosa both clinically and histologically.

Pre-malignant lesions usually present as a white patch (leukoplakia), less commonly as a red patch (erythroplakia) or a mixed red/white patch (speckled leukoplakia). Microscopically, the oral mucosa may show pre-malignant dysplastic changes, graded as mild, moderate or severe dysplasia. The risk of a cancer developing from such lesions is though to be around 10–15%. However, ability to predict the malignant potential of these lesions based on pathologic findings is very limited; transformation does not always correlate with the degree of dysplastic change and, additionally, tumors can develop from histologically normal mucosa. Several studies have found that early genetic changes do not result in observable changes in tissue morphology.

In an effort to predict malignant transformation more effectively, attempts have been made to use molecular biological markers to assess cancer risk. These have included biomarkers of genomic instability such as ►aneuploidy (abnormal number of chromosomes) and allelic imbalance (loss of heterozygosity). Although studies suggest that these approaches may be better than current histological practice, no single method is yet regarded as powerful enough to predict the risk of oral cancer development.

Treatment of premalignancy usually involves excision of lesions, which are graded as moderately or severely dysplastic (although studies suggest that this does not significantly alter the risk of future malignancy). However, patients may have wide fields of genetically altered mucosa, which are too extensive to be treated surgically. Researchers have investigated chemopreventive agents in an attempt to prevent both malignant progression and recurrence of cancer after surgery. Synthetic ►vitamin A derivatives (►retinoids), such as isoretinoin and fenretinide, have been tested, sometimes in combination with interferon-α and vitamin E. Results have been variable; there has been some success in reversing clinically and histologically evident dysplasia, however, genetic abnormalities persist. Compounds such as the PPARγ inhibitor, Rosiglitazone, and ►non-steroidal anti-inflammatory drugs (NSAIDs) which inhibit the cyclooxygenase enzymes (COX) currently are being investigated. The conditionally replicating ►adenovirus, ►ONYX-15, which destroys cells containing defective p53 protein has also been tested.

Clinical Features

The majority of oral cancers present as a non-healing ulcer or growth. The sites most commonly affected are the tongue and floor of mouth. Patients with posteriorly-located tumors have a decreased 5-year survival, mostly because of increased risk of ►metastasis to cervical lymph nodes.

Symptoms vary according to site and include pain, bleeding, paraesthesia, anaesthesia, restriction of tongue movement, limitation of mouth opening, loosening of the teeth and enlarged lymph nodes in the neck. However, patients may experience few symptoms, possibly explaining why around two thirds of cancers are diagnosed when the disease is at an advanced stage.

Clinically tumors are staged using the TNM classification. Tumor size and status of lymph nodes are the most reliable clinical prognostic indicators. A large tumor size at presentation (greatest tumor surface diameter) is associated with increased risk of lymph node metastasis, local recurrence, and poor survival.

Multiple cancers may develop synchronously or metachronously in the upper aerodigestive tract, and the reported frequency of second (or subsequent) primary tumors in patients with oral cancer lies between 10–30%. Evidence suggests that secondary tumors may develop through two different mechanisms; either arising independently in a field of defects (►field cancerization) or via clonal spreading of transformed cells from the primary site.

Pathology

Although various ►biomarkers have been suggested as being useful for predicting prognosis and determining treatment, post-operative management of the patient still, to a large extent, is determined through detailed pathological examination of the tumor resection specimen. Most importantly, this determines whether the tumor has been completely removed; positive excision margins are regarded as one of the main causes of local recurrence and poor outcome. Other pathological parameters of the primary tumor, which are discussed

below, also have a bearing on patient prognosis. Additionally, a ►neck dissection involving the removal of cervical lymph nodes often is performed, and these nodes are examined for evidence of metastatic spread.

There are different pathological subtypes of oral cancer. Most cancers are of conventional type; other less common variants include verrucous, basaloid, papillary, spindle, acantholytic, adenosquamous and carcinoma cuniculatum. Prognosis may vary according to subtype. For example verrucous carcinomas rarely metastasize and have a better prognosis than conventional SCC. On the other hand, basaloid squamous cell carcinomas are aggressive tumors that metastasize widely.

Conventional oral cancers are graded as well, moderately or poorly differentiated depending on the degree of keratin production and cell/nuclear pleomorphism. It is now recognized that histological grading of the whole tumor is a poor predictor of patient outcome, probably because around 90% of oral cancers are designated moderately differentiated. However, several studies have shown that the grade and pattern of invasion of the deep advancing edge of the tumor has prognostic value. This 'invasive front' grading has been shown to be useful in predicting local recurrence, lymph node metastasis and survival. Spread of tumor along nerves or into vessels (perineural and lymphovascular invasion respectively) may also have roles in predicting patient outcome.

Although clinically the tumor diameter is used to TNM stage the patient, tumor thickness (depth of invasion) is a more accurate predictor of overall survival. Critical tumor thickness appears to vary according to site affected within the mouth. However on average, tumors greater than 4 mm in thickness have a fourfold increased risk of metastasis compared with thinner tumors.

The number of positive lymph nodes containing tumor and the size of the metastatic deposit are used in TNM staging, and are the most important factors in determining prognosis. Generally, prognosis is halved if metastases are present, and halved again if extracapsular spread is present (spread of metastatic tumor beyond the lymph node into adjacent tissues).

Treatment and Management

A number of different imaging techniques may be used to determine the extent of the primary disease and the possible involvement of neck nodes. These include plain radiography, computed tomography (CT), magnetic resonance imaging (MRI), ultrasound and positron emission tomography (PRT). At present, patients with oral cancer usually have a staging CT or MRI scan. There is debate about whether the chest should be included (CT chest) since the incidence of chest metastasis is quite low.

Despite many advances in imaging technology, surgical techniques, radiotherapy, and chemotherapy, oral cancer remains associated with marked morbidity and a 5-year survival rate of less than 50%, which has not improved for decades. This may possibly reflect the fact that most patients are diagnosed when the disease is in an advanced stage (III and IV). Surgery and radiotherapy either alone or in combination are the main primary treatment modalities. The role that chemotherapy has to play is more controversial.

Treatment typically is stage related and the most important factors in determining the type of treatment is the site and size of the primary tumor, and the status of the cervical lymph nodes. Early disease may be treated either surgically or with definitive radiotherapy with similar efficacy. Radiotherapy is avoided if the tumor lies close to, or involves, bone because of the risk of osteoradionecrosis. In advanced disease and for patients at high risk of local recurrence combined therapy is used with surgery combined with postoperative radiotherapy. Chemotherapy may also be used and several studies have shown that the addition of ►cisplatin to postoperative radiotherapy improves the outcome among high-risk patients. Treatment-related morbidity, particularly of advanced tumors, is a significant problem and includes problems with swallowing, and speech as well as cosmetic deformities.

Patients with metastatic disease in cervical lymph nodes require a neck dissection. If multiple nodes are involved and/or there is evidence of extracapsular spread this usually is followed by radiotherapy. The management of patients that do not have clinically detectable disease in the neck is more debatable; the choices being an elective neck dissection, radiotherapy or close monitoring of the patient.

Future Directions

It is clear that the current treatments available for oral cancer are, to a certain degree, inadequate. The overall survival rate of oral cancer patients has not improved for decades and surgery, radiotherapy and chemotherapy all are associated with significant morbidity, damaging normal tissues, as well as tumor cells. A number of different molecules are over-expressed in oral cancer and have been suggested as potential therapeutic targets. These include the epidermal growth factor receptor (EGFR), COX-2 and the integrin αvβ6. Reagents developed to target these proteins include NSAIDS, monoclonal antibodies and chemical tyrosine kinase inhibitors. Adenoviral gene therapy and immunotherapy using autologous dendritic cells also are being considered.

Orchiectomy

Definition

A surgical procedure to remove one or both testicles, the main source of male hormones, to decrease hormone production. It has the same efficacy and same side effects as LHRH analogs therapy.

►Adjuvant Chemoendocrine Therapy
►LHRH Agonists

ORG 2766

Definition

A neuroprotective chemoprotectant that slows down ►cisplatin- and ►taxol-induced neuropathy, neurotoxicity, and ototoxicity.

►Chemoprotectants

Organ Cultures

Definition

Tissues generally cultured, often within a network of perfused artificial capillaries or other bioreactor, so that functional systems may be studied. They have been used to study tumor invasion and have potential for studying tumor cell and normal tissue drug metabolism and toxicity and complex microenvironmental interactions involved in tumor physiology.

►Organotypic cultures
►Three-Dimensional Tissue Cultures

Organotypic Cultures

Definition

Aggregates of cells usually grown as cultures embedded in a porous extracellular matrix that promotes tissue like architecture and cell-cell interactions. They are considered to more accurately reflect the tumor microenvironment than monolayer cultures. They give consistent results, are more easily manipulated than organ culture, and many human cell lines may be used. Cancer cells are generally co-cultured with syngeneic stromal immune and endothelial cells to provide further approximation to the in vivo physiology. They do not fully integrate physiological function such as pressure gradients or blood flow and do not model therapeutic index in therapeutic studies. They are used to study cancer cell biology, cell interactions, migration and invasion. They have potential for studying drug mechanism of action and drug screening.

►Three-Dimensional Tissue Cultures

Origin of Replication

Definition

Is the site where the DNA helix is melted and initiation of DNA synthesis occurs. Mammalian cells are estimated to use between 50,000 and 100,000 origins of replication per cell cycle.

►S-Phase Damage-Sensing Checkpoints

Origin Replication Complex

Definition

Orc; A complex of six proteins originally discovered in yeast. Genetic and biochemical data strongly suggests Orc is required for initiation of replication from chromosomal origins.

►S-Phase Damage-Sensing Checkpoints

Orlistat

Definition
A potent natural inhibitor of pancreatic lipases. It was isolated from the bacterium Streptomyces toxytricini and has been used to treat obesity. Orlistat is also a selective inhibitor of fatty acid synthase by binding the thioesterase domain of fatty acid synthase.

►Fatty Acid Synthase

Ornithine Cycle

Definition
►Urea Cycle

Ornithine Decarboxylase

Definition
ODC; The rate limiting enzyme of polyamine biosynthesis. ODC converts ornithine (itself derived from arginine) to putrescine and the other polyamines. This enzyme is irreversibly inhibited by the chemopreventive agent, difluoromethylornithine (DFMO).

►Arginine

Ornithine Transcarbamylase

Definition
OTC; synonym ornithine carbamoyltransferase; Is an enzyme that catalyzes the reaction between carbamoyl phosphate and ornithine to form citrulline and phosphate. In mammals it is located in the mitochondria and is part of the urea cycle.

►Arginine-Depleting Enzyme Arginine Deiminase

Orphan GPCR

Definition
Orphan G-protein coupled receptors are members of the GPCR family of transmembrane receptors based on their sequence homology, but have no known ligand.

►Orphan Nuclear Receptors

Orphan Nuclear Receptors

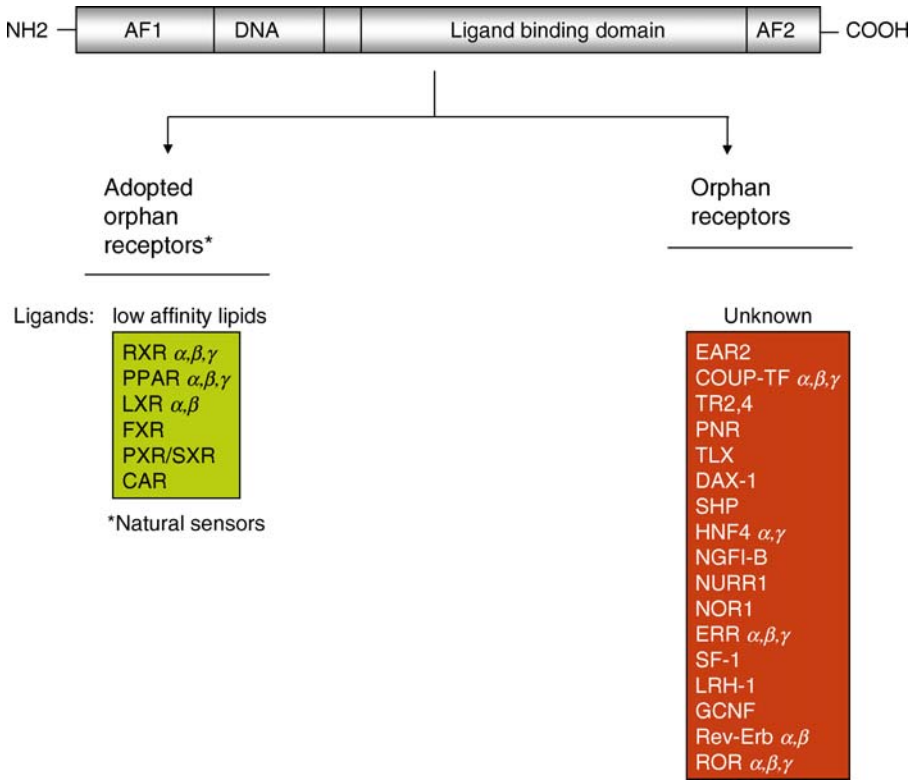
Animesh Rathore, Sridhar Mani
Department of Medicine, Oncology and Molecular Genetics, Albert Einstein College of Medicine, NY, USA

Synonyms
Adopted orphan nuclear receptors; Receptors with no ligand-binding pocket; Receptors with empty ligand-binding pockets; Receptors with structural ligands; Receptors regulated by ligands

Definition
The word "orphan" means lacking "support, supervision or care" (The American Heritage® dictionaries) and when applied as an adjective to ►nuclear receptors implies that these receptors do not have a defined ►ligand (for which no ligand is known). This definition is paradoxic in the sense that a "receptor" implies that there is a physiologic ligand even though that ligand has not been discovered. At present, there is no consensus in the field with regard to the presence or absence of ligands for all orphan receptors. Once a physiologic ligand is discovered for a particular receptor, then that receptor no longer belongs in the "orphan" category (adopted orphan receptors); however, there are examples of liganded receptors (e.g., RXR, PPARs) where the controversy surrounds the identity of the true physiologic ligand (Fig. 1).

Characteristics
Orphan nuclear receptors are a diverse group of nuclear receptors characterized by one or more of the following features:

1. Lacks a ligand that defines a physiologic or pathophysiologic phenomenon. Compounds have been found inside the ligand binding pocket of some



Orphan Nuclear Receptors. Figure 1 Schematic structure of orphan nuclear receptor superfamily present in human, mouse and rat. A schematic structure of a typical nuclear receptor is shown describing the activation factor domains (AF 1 and 2), the DNA binding domain (DNA) and the ligand binding domain (which incorporates AF-2). Low affinity dietary lipids serve as natural ligands to receptors classified under the adopted orphan status ▶in *green* (these receptors are natural sensors of the environment) and receptors whose ligands have not yet been characterized as orphan receptors ▶in *red* (figure is adapted and modified from Chawla A et al Science 30 November 2001:vol 294, no 5548, pp 1866–1870).

receptors (e.g., SF-1, LRH-1) but its physiologic relevance is unknown.

2. The ligand binding pocket is larger than that observed for classic nuclear receptors (e.g., steroid receptors) and this feature allows them to bind to a diverse group of molecules with lower affinity (usually in the micromolar range).
3. Domain variations are the largest amongst those seen with nuclear receptors. For example, in vertebrates, DAX-1 and SHP do not have a classic DNA binding domain (DBD) but only a ligand binding domain (LBD).
4. There is extreme diversity of these receptors in terms of their mode of binding to DNA. Most bind as homo dimers on direct repeat (DR) elements (e.g., HNF-4, TR2/4), others interact with RXR (e.g., NGFI-B, NURR1) while others like GCNF oligomerize upon binding to hexameric repeat AGGTCAAAGGTCAA. Monomeric binding to half-site DNA sequences defines orphan nuclear receptors (e.g., SF-1, LRH-1, ERRs bind to TCAA/GGGTCA elements). In all monomeric interactions with DNA, the interaction between DBD of the receptor and DNA is in the A/GGGTCA motif. There is a recognition helix in the C-terminus of the first zinc finger interacting with the major groove of DNA. The second helix in the second zinc finger stabilizes the interaction with the DNA, which then allows for dimerization with its partner proteins. The C-terminal portion of the receptor is able to interact with the extended 5′ element (e.g., in the structural analysis of Rev-erb DBD associated with DNA, there is a core DBD and an A box beyond this core which forms a third helix of the DBD and is implicated as a recognition site for 5′ extension DNA element).
5. The biological functions of orphan receptors are diverse and yet not fully characterized. However, two principles have emerged. One, these receptors have an important function that is unique to each receptor. Two, these receptors play an important role in modulating the function of classic liganded receptors.

6. The biological function of orphan receptors is clear and unambiguous. A summary of this with regard to individual orphan receptors is shown in Table 1.

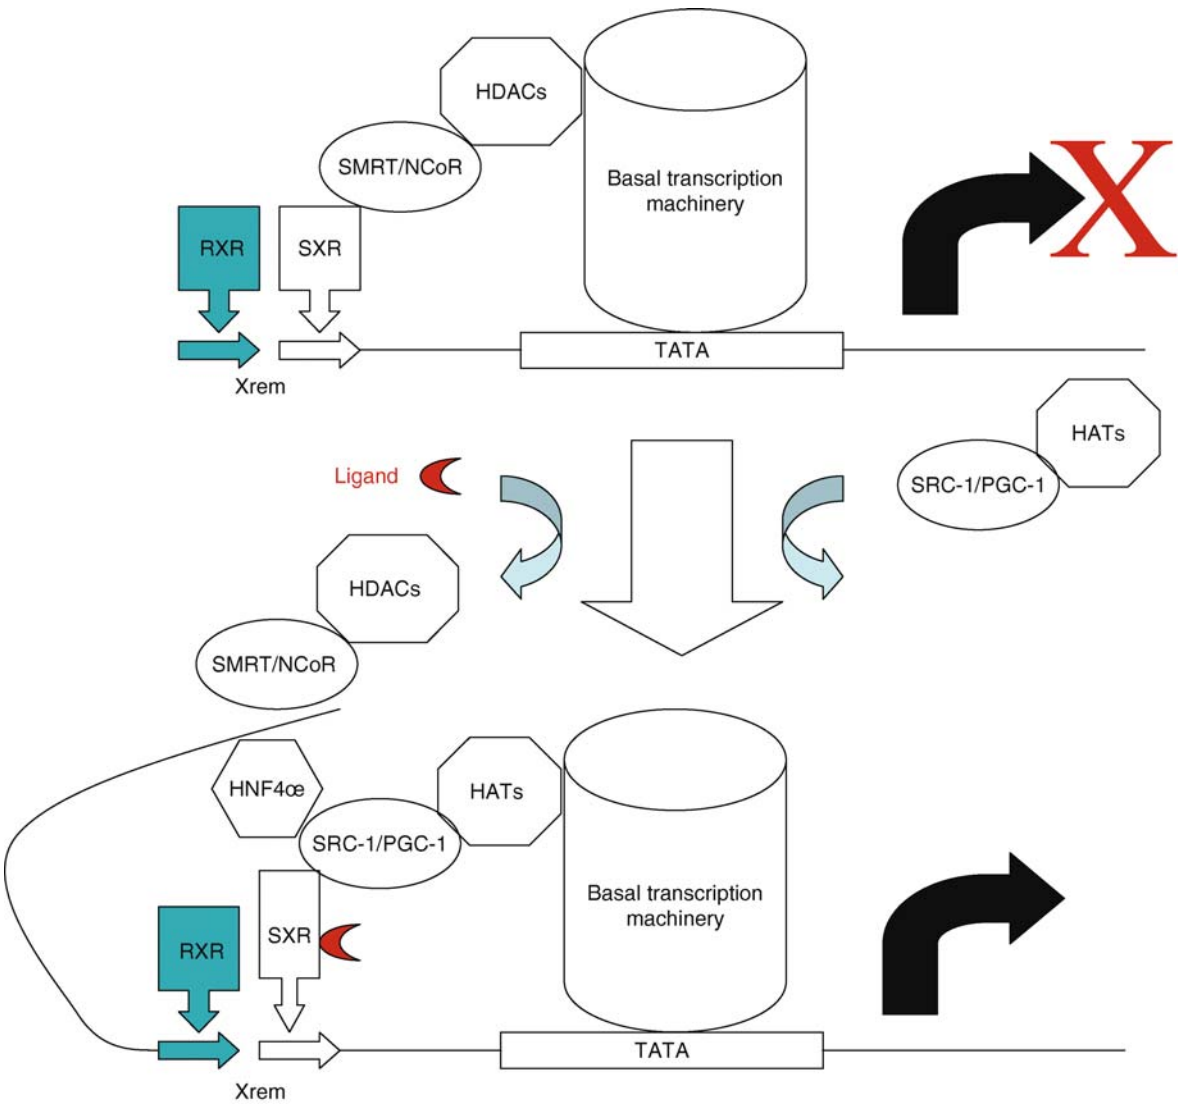
Mechanism

Orphan receptors, like their classical receptor counterparts, reside or translocate to the nucleus upon ligand binding. They are either basally repressed or more commonly constitutively active and their activity may be enhanced upon binding to their cognate ligand. A classical model for nuclear receptor action implies that these receptors also bind to co-repressors and other ►co-regulators (►transcriptional coregulators). In this model, co-repressor complexes that can recruit and alter histone deacetylases mediate basal repression. Several known co-repressors that are involved include silencing mediator of retinoid and thyroid receptor, (SMRT), and nuclear receptor co-repressor (NCoR), and their associations are tissue specific. N-CoR and SMRT are paralogs of each other and are encoded by distinct genetic loci and exert overlapping biological functions. Both N-CoR and SMRT operate by tethering to their ►transcription factor partners and nucleating the assembly of a larger, functional co-repressor complex. SMRT and N-CoR tether to nuclear receptors through a set of C-terminal "CoRNR box" motifs. A secondary

Orphan Nuclear Receptors. Table 1 Orphan nuclear receptor phenotype and its biologic implications to human disease. The mutant phenotype is almost always characterized in mice either as a knock-out phenotype or a Cre/Lox knock-out (*Mouse Models)*

EAR2 (NR2F6)	Circadian gene expression/behavior	Human disease
COUP-IF1 (NR2F1)	Non-viable at birth	?
COUP-TFII (NR2F2)	Embryonic lethal (day	?
TR2 (NR2C1)	Fertile	?
TR4 (NR2C2)	Reduced spermatogenesis	?
	Defective reproduction	
	Growth retardation	
PNR (NR2E3)	Retinal degeneration	Enhanced S-cone syndrome
		Retinitis Pigmentosa
		Goldmann-Favre syndrome
TLX (NR2E1)	Reduced forbrain size, increased aggression	?
DAX- 1 (NR0B1)	Delayed testis development, DS S syndrome	Hypogonadotropic hypogonadism
SHP (NR0B2)	Increased bile acid synthesis	Obesity
HNF-4(NR2A 1) α, β	Embryonic lethal; adults increased hepatic lipids decreased serum cholesterol and triglyceride	Early-onset type II diabetes
NGFI-B (NR4A1)	No clear phenotype	?
NURR1 (NR4A2)	Loss of ventral dopaminergic neurons; death at birth	Parkinson's disease
NOR1 (NR4A3)	Inner ear defects; bidirectional circling behavior	Extraskeletal myxoid chondrosarcoma
ERRα (NR3B 1)	Reduced body weight and peripheral fat; resistant to high-fat diet obesity	Osteoporosis
SF-1 (NR5A 1)	Lack adrenal glands and gonads	Adrenocortical insufficiency
LRH- 1 (NR5A2)	Embryonic lethal; adults (+/-) are hypercholesterolemic	?
GCNF (NR6A 1)	Cardiovascular abnormalities, defective trunck development, embryonic lethal; aberrant estrous cycle (crc-Lox knockouts)	?
Rcv-Erb α	Cerebellar abnormalities; cicadian rhythm changes	?
Rcv-Erb β	?	?
ROR α	Stagger phenotype (cerebellum)	?
ROR β	Duck-like gait, disrupted reproduction in males, blindness, abnormal circadian rhythm	?
RORγ	Lack peripheral and mesenteric lymph nodes and Pcyer's patches	?

hierarchy of co-repressor subunits, including histone deacetylases, TBL-1, TBLR-1, GPS-2, and a number of other modulatory and effector proteins are recruited through docking surfaces (repression domains, RDs) located principally in the N-terminal and central regions of SMRT and N-CoR. Co-activator recruitment after ligand binding is complex and tissue-specific and includes, but may not be limited to, SRC-1, PGC-1 and other regulators like SHP and HNF-4. There is cross talk between distal CAR/PXR sites and HNF4α binding sites in the CYP2C9 promoter and the HNF4α sites are required for maximal induction of the CYP2C9 promoter. Ligand-activated PXR interferes with HNF-4 signaling by targeting the common co-activator PGC-1, which underlies physiologically relevant inhibitory cross talk between drug metabolism and cholesterol/glucose metabolism (►Receptor cross-talk). SHP is defined as a negative regulator of PGC-1-hNF-4 interactions on PXR. This observation suggests that perhaps HNF-4 directly interacts as a co-activator of the SXR-PGC-1 complex (Fig. 2). There are other modes of gene transcription mediated by orphan receptors and involved in trans-repression or activation (e.g., SHP), and these modes vary from receptor to receptor.



Orphan Nuclear Receptors. Figure 2 Cartoon schema of transcriptional repression and activation by SXR and its co-regulators. In the absence of ligands, denoted as a red half moon, SXR, steroid and xenobiotic receptor (also known as human (h) PXR) is repressed. In the presence of a ligand, significant structural changes alter SXR-co-regulator interface, resulting in the recruitment of co-activators and the histone acetyltransferase (HAT) complex. The net result is transcriptional activation).

Orphan receptors are critical in development and ►cell differentiation. For example, HNF-4 is critical in liver development but in adults alterations lead to significant changes in hepatic lipid accumulation. TFs are fundamental to the development of the nervous system, NURR members for brain development, GCNF for silencing of pluripotency gene expression during gastrulation and ES cell differentiation, and TLX and PNR in retina formation. Orphan receptors are key regulators of cellular metabolism, adipogenesis and energy metabolism. For example, LRH-1 regulates cholesterol metabolism and SF-1, steroidogenesis. A more recently explored physiologic phenomenon is that of regulating ►circadian rhythm. In this context, Rev-erbs and RORs are key members of the circadian pacemaker system within peripheral tissues and supra-chiasmatic nucleus. Furthermore, orphan receptors modulate liganded receptor activity. Receptors such as COUP-TFs, TR2, and TR4 repress activation mediated by liganded receptors like RAR, TR and PPAR. DAX-1 and SHP regulate the activity of several orphan and non-orphan receptors like PXR and steroid receptors.

Clinical Aspects

The role of orphan receptors in cancer is still evolving. A clear example of the role orphan receptors may play with regard to cancer therapeutics is their effect on controlling drug metabolism. For example, paclitaxel metabolism is significantly impacted by the activation of PXR and such paclitaxel serves as an agonist of PXR activity (►Xenobiotics). Paclitaxel mediated activation of PXR may accelerate its own metabolism through induction of CYP3A4 and CYP2C8 genes, lowering blood levels and the activity of the drug. A recurrent t (9; 22) (q22; q12) ►chromosome translocation has been described in extraskeletal myxoid chondrosarcoma (EMC) and both NURR1 and NOR1 have been implicated as an example of the oncogenic conversion of a nuclear receptor and the first involving the orphan subfamily. Chimeric fusions of NOR-1 with ►EWS, TCF12 and TAF2N have been linked to ►extraskeletal myxoid chondrosarcoma. The oncogenic activity of EWS/FLI1 in ►Ewing sarcoma may be mediated in part by upregulation of DAX-1. Furthermore, the role of the NR4A subfamily members in cancer is also largely defined by the implication of the subfamily in the regulation of ►apoptosis. Apoptosis in many tumor types, including colon, breast, prostate, lung, and gastric cancers, have been shown to involve the NR4A family members. In another example, RORs have been implicated in mitigating the proliferative effects of fatty acids on androgen dependent and independent ►prostate cancer cells. DAX-1 may inhibit endometrial carcinomatosis through its interactions with ER. In liver carcinogenesis, the orphan receptor, CAR, is essential for liver tumor promotion by phenobarbital. Thus orphan receptors can regulate the process of carcinogenesis. Cellular translocation of nuclear receptors may underlie the pathophysiology of apoptosis inducing agents in cancer. For example, the orphan receptor NURR77 translocates to mitochondria in the early phases of apoptosis induced by chenodeoxycholic acid in stomach cancer cells. All-trans ►retinoic acid (ATRA), a primary mode of therapy for ►acute promyelocytic leukemia, is a ligand for the orphan receptor RORβ. TR3 orphan receptor may play an important role in modulating drug-induced prostate cancer apoptosis. COUP-TFII is required for ►angiogenesis and may play an important role in cancer-mediated angiogenesis. ERRs play a role in human breast cancer, as its expression is associated with certain biomarkers predicting outcome. LRH-1 has been implicated in breast carcinogenesis and regulates the activity of P450 aromatases in surrounding adipose tissue and hence serves as an important target for therapy in breast cancer. More recently, LRH-1 has been implicated in intestinal tumorigenesis through effects on cell cycle and intestinal inflammation, both linked to carcinogenesis. The PPARs have been widely known to be associated with a variety of tumor types, in which it may represent a link between diet and increased risk of cancer. Furthermore, PPARs may serve as targets for cancer therapy as agonists are known to induce apoptosis in a variety of cell lines (e.g., breast, colon).

In patients with breast cancer, ERR and ERR status may be predictive of sensitivity to hormonal blockade therapy, and ERR status may also be predictive of ErbB2-based therapy such as ►Herceptin. Moreover, ERR and ERR status are candidate targets for therapeutic development. Synthetic agents blocking RXRs (e.g., bexarotene) have been approved for treatment of ►cutaneous T-cell lymphoma. They serve as examples of translational capabilities, as we begin to find out more about the biologic function of orphan receptors.

Orthologue

Definition

Synonym ortholog; Describes the same gene in different species, e.g. c-R*mil* in chicken *versus* *BRAF* in mammals. Genes in different organisms that are direct evolutionary counterparts, i.e., they are related by descent from a common ancestor. As orthologues often retain their biological function during evolutions they are subject to less sequence variation than a ►paralogue.

Orthotopic

Definition

Refers to the implantation of ►xenografts of cancer cells in the organ where the primary colony of cells were originated.

Orthotopic Model

Definition

Tumor models produced by transplanting cancer cells into an anatomically appropriate location in the host organism, which is usually a mouse. The transplanted cells can be xenografts (from a different species) or allografts (from the same species).

►Ultrasound Micro-Imaging

OSF-1

►Pleiotrophin

OSM

►Oncostatin M

Osmotic Pump

Definition

A small, implantable and non-mechanical device that regulates the continuous dosing of a chemical into the body via the process of osmotic displacement.

►Bioluminescence Imaging

Osteoblast

Definition

Mononucleated cell that produces bone matrix proteins and take charge of bone mineralization. Osteoblasts share a common progenitor, the undifferentiated mesenchymal cell, with chondrocytes, myocytes and adipocytes.

►Bisphosphonates

Osteoblast Specific Factor

►Pleiotrophin

Osteoblast-specific Factor-2

►Periostin

Osteoblastic Bone Disease

►Bone Loss, Cancer Mediated

Osteoblastic Bone Lesion

Definition

Are characterized by mineralized or calcified deposition into the lesional tissues. The most current malignant osteoblastic lesions are bone metastases from ►prostate cancer. These lesions are associated with a deregulation of osteoblast activities, the specialized bone forming cells.

►Zoledronic Acid
►Bone Loss, Cancer Mediated

Osteoblastic Metastasis

Definition

►Metastasis that is characterised by the ability to promote the formation of bone.

►Bone Loss, Cancer Mediated

Osteochondroma

Definition

Benign peripheral cartilaginous tumor. Osteochondromas arise at the surface of bone and consist of a reactive bony stalk containing a marrow cavity that is continuous with that of the underlying bone, covered by a neoplastic cartilaginous cap. A exophytic growth composed of a cap of proliferating hyaline cartilage that transforms to bone by the process of endochondral ossification during the time of active growth.

►Bone Tumors
►Chondrosarcoma

Osteochondromyxoma

Definition

►Osteochondroma containing myxoid elements.

Osteoclast

Definition

Are multinucleated cells specialized in the bone degradation process. Differentiated cells of the mononuclear phagocytic lineage that resorb bone. Secretes acid and hydrolytic enzymes which dissolve the mineralized and organic components of the bone matrix. Osteoclasts are closely to the ►macrophage lineage, are located in the bone marrow and are formed by fusion of mononuclear precursors.

►Bone Loss, Cancer Mediated
►Zoledronic Acid

Osteogenic Sarcoma

►Osteosarcoma

Osteolysis

Definition

Is a bone disease originate from various aetiologies (tumor, infection, trauma) characterized by focal or multi-focal bone destruction associated with an excessive ►osteoclast activity.

►Bone Loss, Cancer Mediated
►Zoledronic Acid

Osteolytic Bone Disease

►Bone Loss, Cancer Mediated

Osteolytic Metastasis

Definition
Metastasis that is characterised by the ability to promote ►osteolysis.

►Bone Loss, Cancer Mediated

Osteoma

Definition
Is a benign, local growth usually confined to the facial skeleton of patients with ►familial adenomatous polyposis (FAP), in particular in mandibular and maxillary bones. It is often visible by X-ray, more seldom as external swellings, and is a good diagnostic predictors for FAP.

►APC Gene in Familial Adenomatous Polyposis

Osteomimicry

Definition
The acquisition of bone cells' genotypic and phenotypic properties by cancer cells with ►bone tropism.

Osteonectin

Definition
Is a glycoprotein in the bone that binds calcium.

►Doublecortin
►Secreted Protein Acidic and Rich in Cysteine

Osteopetrosis

Definition
Skeletal abnormality characterized by increased bone mass.

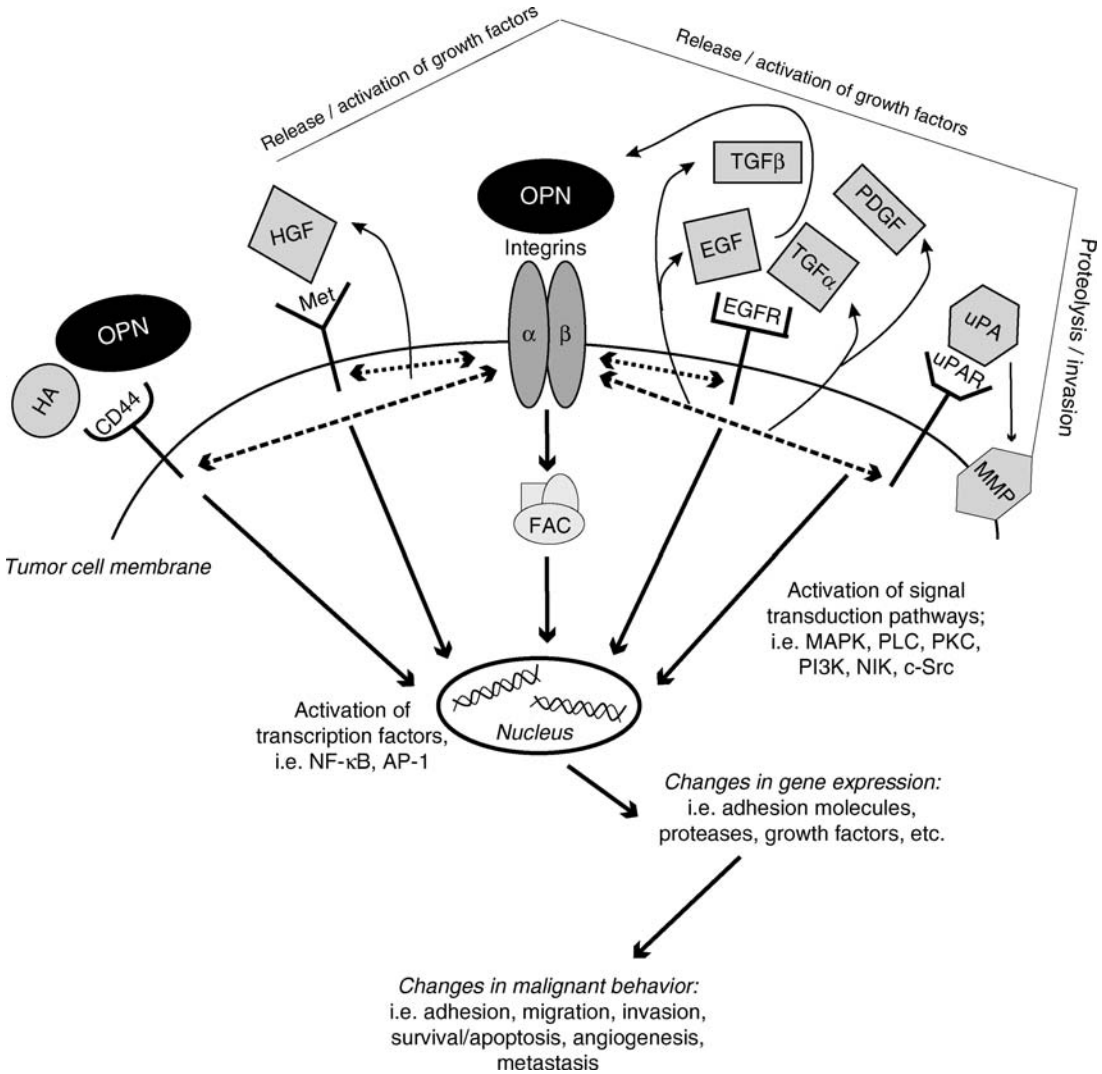
Definition
Osteopontin (OPN) is an acid-rich, phosphorylated mammalian ►glycoprotein that is a member of the small ►integrin-binding N-linked glycoprotein (SIBLING) family of proteins. Osteopontin is synthesized and secreted by tumor cells and by many normal cell types, including cells in the mammary gland, the vasculature, the bone, the immune system, and the kidney.

Characteristics
OPN Gene Structure and Regulation of Gene Expression
The OPN gene has been identified in many different species, including human, mouse, rat, rabbit, cow, and pig, with approximately 40% homology of nucleic acid sequence between species. The human OPN gene is located on the long arm of chromosome 4 (4q21–4q25) and contains seven exons spanning approximately 11.1 kb. The OPN promoter contains several potential regulatory sequences that can mediate transcription of OPN in response to a wide variety of stimuli in different tissue types. These sequences include GATA-1, TATA-like and CCAAT-like motifs, as well as a ►Ras-activated enhancer sequence and ►vitamin-D-responsive elements (VDREs). Many other potential binding sites for ►transcription factors such as ►AP-1, PEA3, ►Ets-1, TCF-1, ►E2A, E2BP, ►Myb, AP2, SP1, and Oct-1 have also been characterized. The

number and diversity of regulatory elements present in the OPN promoter are reflective of the fact that OPN expression is controlled by complex regulatory pathways that influence both normal and malignant cell behavior. In particular, the expression of OPN can be upregulated by a number of cancer-related ►growth factors, including ►epidermal growth factor (EGF), ►scatter factor/►hepatocyte growth factor (HGF), ►platelet-derived growth factor (PDGF), ►vascular endothelial growth factor (VEGF), and ►transforming growth factor β (TGFβ), and this upregulation often results in increased OPN-mediated malignancy of tumor cells (Fig. 1).

OPN Protein Structure and Interaction with Other Proteins

The human OPN protein contains approximately 314 amino acid residues, and is particularly rich in aspartate, glutamate, and serine residues. The molecular weight of OPN and associated isoforms has been reported to vary between 41 and 98 kDa depending on the cellular source. Extensive post-translational modifications in the form of ►sulfation, ►phosphorylation, and/or ►glycosylation can lead to cell type and condition-specific differences, and likely accounts for variability in molecular weights. The OPN protein contains several conserved structural elements including heparin- and



Osteopontin. Figure 1 Functional contribution of OPN to malignant cell behavior. This schematic diagram is a representation of how OPN can help tumor cells to both respond to and influence the tumor microenvironment. As discussed in the text, OPN-mediated molecular cross-talk between itself and other tumor-derived and host-derived factors such as integrins, proteases, and growth factor/receptor pathways has the potential to influence tumor and host cell behavior through multiple different signaling pathways.

calcium-binding domains, a thrombin-cleavage site, a CD44 binding site, and an ►RGD (Arg-Gly-Asp) integrin-binding sequence. Based on the presence of these domains, it is not surprising that the functional importance of OPN lies in its ability to interact with a diverse range of factors, including cell surface receptors (►integrins, ►CD44), ►growth factor/receptor pathways (►VEGF, ►HGF/Met, TGFα/EGFR), and secreted ►proteases (►urokinase-type plasminogen activator (uPA), ►matrix metalloproteinases (MMP)). These complex signaling interactions can result in changes in gene expression which ultimately lead to increased malignant cell behavior and cancer progression (Fig 1).

Functions of OPN in the Context of Cancer

OPN is involved in a number of normal and pathologic conditions, including mammary gland development, lactation, bone remodeling, vascular remodeling, immune reactivity/inflammation, renal disease, and cancer. OPN can be produced by many cell types, such as bone cells (osteoblasts, osteocytes, osteoclasts), fibroblasts, inflammatory cells (►T-cells, ►natural killer (NK) cells, ►macrophages), endothelial cells, epithelial cells, and tumor cells. In the context of cancer, OPN can functionally contribute to several types of malignant cell behavior which are discussed below. OPN-mediated tumor cell malignancy is largely dependent on its interaction with other factors such as integrins, proteases, and growth factor/receptor pathways (Fig 1). Additionally, highly aggressive tumor cells tend to not only express high levels of endogenous OPN, but also seem to be more responsive to exogenous OPN produced by other cells in the tumor ►microenvironment.

OPN-Mediated Cell Adhesion

OPN plays an important role in cell ►adhesion through direct interaction with cell surface integrins such as αvβ1, αvβ5, αvβ3, α4β1, α8β1, and α9β1. These interactions serve to activate downstream integrin signaling and subsequently increase cell adhesion and malignancy of tumor cells. In addition, OPN can also directly interact with another cell surface receptor, CD44, in order to mediate cell adhesion.

OPN-Mediated Cell Migration and Invasion

OPN can promote cell ►migration and ►invasion, two important components of the ►metastatic process. Experimental studies have demonstrated that OPN-mediated migration is dependent on its interaction with cell surface integrin receptors (as described above), in particular the αvβ3 integrin. In addition, OPN can upregulate ►uPA and members of the MMP family, and these proteases provide cells with the ability to generate localized proteolytic activity at the tumor-host interface in order to mediate cell invasion and migration through the ►extracellular matrix. The growth factor/receptor pathways ►EGF/►EGFR and ►HGF/►Met are upstream and downstream effectors of OPN and have also been shown to influence OPN-mediated migration and invasion.

OPN-Mediated Cell Survival/Resistance to Apoptosis

OPN can confer resistance to ►apoptosis in cancer cells through a variety of mechanisms related to evasion of ►immune surveillance. Direct interaction between OPN and the αvβ3 integrin or CD44 can protect tumor cells in the circulation through inhibition of ►complement-mediated cell death. Furthermore, OPN can inhibit induction of inducible ►nitric oxide synthase (iNOS) by immune cells, thus protecting the tumor cell against nitric oxide-mediated cell death and allowing tumor progression.

OPN and Angiogenesis

OPN can contribute to neovascularization and ►angiogenesis in various animal models of cancer. The mechanisms by which this occurs are largely hypothetical, but are believed to involve molecular cross-talk between OPN, the αvβ3 integrin, and/or VEGF. In particular, signaling through αvβ3 is critical for endothelial cell survival, and OPN can enhance this survival.

OPN and Metastasis

Given the involvement of OPN in all of the malignant behaviors described above, it is clear that OPN plays a central role in cancer as a ►metastasis-promoting factor. OPN has been shown to contribute to experimental metastasis in a number of animal models of cancer, in particular to ►breast cancer metastasis to the lymph nodes and the bone via interactions with integrins and/or growth factors. Furthermore, OPN-deficient mice injected with ►melanoma tumor cells show reduced experimental metastasis compared to wild-type controls. Taken together with clinical observations (described below), these experimental studies indicate that OPN is not merely associated with cancer and metastasis, but that it actually plays a multifaceted functional role in malignancy.

OPN Expression in Human Tumors and Prognostic Significance

OPN has been shown to be overexpressed by a number of human tumors, including ►breast cancer, ►prostate cancer, ►colon cancer, ► lung cancer, ►liver cancer, ►gastric cancer, ►esophageal cancer, ►ovarian cancer, ►cervical cancer, renal and ►brain cancer. In many cases, OPN has also been correlated with poor prognosis, reduced survival, and/or increased metastatic burden in cancer patients. OPN can be measured in tumor samples by ►immunohistochemistry or measured as a secreted protein in the blood by ►ELISA. In tumor samples, it has been observed that OPN can be expressed by both tumor cells and ►tumor associated macrophages, although only tumor cell-expressed OPN has been correlated with prognosis. In blood samples,

the cellular source of OPN is not known, since multiple cell types including tumor cells, activated immune cells, and remodeling vasculature may be secreting OPN in the tumor microenvironment. However, a growing number of clinical studies have demonstrated a value for OPN as a blood marker in oncology, suggesting that regardless of the cellular source, OPN can provide prognostic information and potentially provide indications of treatment response in cancer patients.

Pediatric Oncology Branch, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA

Synonyms

Osteogenic sarcoma

Definition

Is a rare malignant tumor of the bone. It arises in the bone (osteo) from mesenchymal cells (sarcoma).

Characteristics

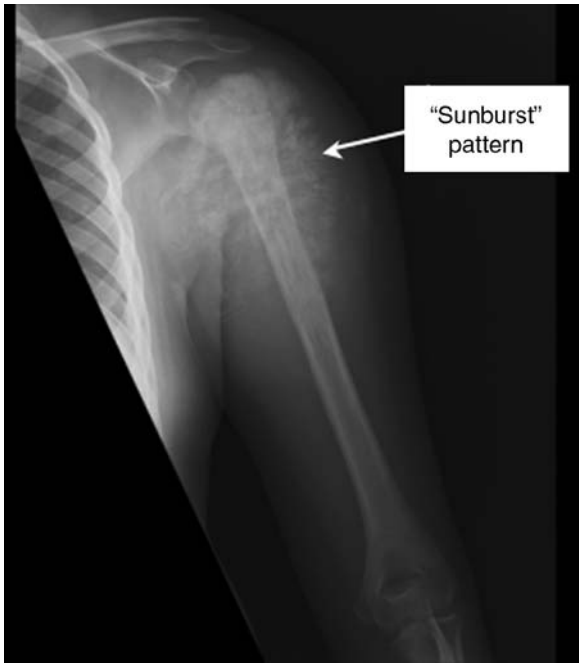
Historically, osteosarcoma was once a fatal diagnosis. Patients had only a 15% chance of cure despite the use of aggressive surgical techniques to remove the primary tumor. With the increasing use of chemotherapy in the 1970s, survival rates increased dramatically. Currently, patients have a 65% chance of survival.

Epidemiology

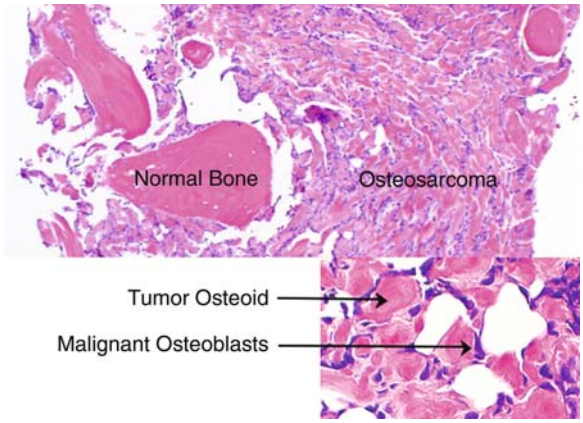
Osteosarcoma is the most common primary ►bone tumor. World-wide incidence rates are not known; however, ~800 patients are diagnosed with osteosarcoma in the United States annually. Half of these patients are teenagers. Men are affected more than women (60% vs. 40%) and African-Americans slightly more than Caucasians. Osteosarcoma has a propensity to affect rapidly growing bones. Half of all tumors occur around the knee and 10% occur in the shoulder. In addition, almost all tumors affect the metaphysis (the distal growing end) of the bone. Teenagers with osteosarcoma also tend to be slightly taller than their peers, suggesting the involvement of growth factors in this tumor.

Clinical Course

The first symptom that patients notice is usually pain. Due to the active nature of teenagers and the lack of systemic signs (such as fever, weight loss, or fatigue) in the early course of disease, most patients are treated with pain medications. The average time from the initial symptom to diagnosis is three months. The presence of a mass or progressive signs of discomfort usually leads



Osteosarcoma. Figure 1 An x-ray of the shoulder reveals the presence of ossification in the soft tissue that surrounds the cortex of the bone. This results in a classic "sunburst" pattern suggestive of osteosarcoma.



Osteosarcoma. Figure 2 Areas of normal bone (left) are being infiltrated by osteosarcoma cells on the right. The inset, at higher magnification, shows malignant osteoblasts that produce tumor osteoid, the defining feature of osteosarcoma.

to obtaining x-rays. These may reveal soft tissue ossification, resulting in the classical "sunburst" pattern (Fig. 1). An MRI of the affected area is required to delineate the extent of the mass and the amount of bone involvement. A definite diagnosis requires a biopsy, preferably obtained by an orthopedic surgeon who specializes in oncology. The ►biopsy should be performed in such a way that future limb salvage surgery will not be adversely affected. The biopsy must show frankly malignant sarcomatous stroma, with production of tumor osteoid, as shown in Fig. 2. Once the diagnosis of osteosarcoma is established, workup to determine whether there has been spread of the tumor (►Metastasis) include a chest cat scan (75% of metastases are to the lungs) and a bone scan (10% of metastases are to the bone, an additional 10% are to both sites). Other tests that are useful to monitor toxicity of chemotherapy agents include a hearing test, an echocardiogram and liver and kidney function tests. Serum alkaline phosphatase and LDH levels are elevated in 40% of patients, high levels of the former correlate with poor prognosis.

Treatment

Following the histological diagnosis of osteosarcoma and workup for metastatic disease, treatment is initiated. Current regimens utilize a neo-adjuvant (►chemotherapy given prior to surgery) (►Neoadjuvant therapy) approach. Four drugs with demonstrated activity against osteosarcoma include, ►methotrexate (M), ►adriamycin (A), ►cisplatin (P) and ifosfamide (I). A common current treatment regimen employs AP followed by M, for two cycles, lasting 8–10 weeks. There are many side effects associated with the use of chemotherapy, included nausea and vomiting, loss of hair and bone marrow suppression, which leads to increased chances of infection, bleeding and fatigue. Side effects that are specific for the agents named above include liver and kidney toxicity (M), decrease in heart function (A), hearing loss (P) and bladder damage (I). The severity of side effects cannot be predicted for any one patient. Protective agents may be considered to ameliorate some of these side effects.

Following the initial course of chemotherapy, definitive surgery is performed. It is imperative that the entire tumor is removed. Patients who have residual tumor have only a 10% chance of long-term survival. Prior to 1970, all patients with osteosarcoma underwent amputation of the affected extremity if possible. Thanks to advances in orthopedic surgery, the vast majority of patients have the option of undergoing limb salvage. This entails removal of the area involved with tumor. The bone that is removed is then replaced with modular metallic rods. These are adjustable, thus reducing the chance of leg length discrepancy. The only instances when amputation is absolutely required are when the blood and nerve supply to the distal extremity is compromised. The rare occurrence of osteosarcoma in the hand or foot also requires amputation due to the lack of prostheses that function well in these small bones.

Following surgery, patients continue with chemotherapy to complete a total of 30–40 weeks of treatment. These patients are then monitored for five years after the

completion of therapy. Patients with localized disease (those who did not have signs of spread) have a 70% chance of cure.

Osteosarcoma has been referred to as a "radioresistant" tumor. This is not quite accurate in that radiation can destroy osteosarcoma cells. However, the doses required to do so are so large (>50 Gy) that conventional radiation approaches would lead to too much damage to the surrounding normal cells. Radiation is used in cases of osteosarcoma of the pelvis when surgery has not been able to remove the entire tumor. Recent advances in radiation delivery techniques such as intensity-modulated and proton-based therapy may increase survival in these patients. Radiation is also used in palliation, in cases to relieve pain due to impingement of the tumor against vital sites.

Metastases

Twenty percent of patients have detectable spread of disease at the time of diagnosis. Unfortunately, these patients have only a 25% chance of cure. The management of these patients is similar to those of patients with non-metastatic osteosarcoma, removal of the primary tumor and all sites of tumor spread, in conjunction with chemotherapy. There have been many efforts to increase the intensity of chemotherapy drugs given to these patients in an attempt to increase the survival rate. As expected, the number of side effects increased greatly, but there has not been an increase in survival.

Recurrence

Another group of patients who do poorly are those who have recurrence of the tumor following treatment. These patients have only a 20% chance of cure. Over 90% of recurrences are in the lung. Patients who do not achieve a second surgical remission have greatly diminished prognosis. Those who are able to have all of their tumor nodules removed have a 40% chance of cure. Again, attempts to increase survival by giving more chemotherapy or radiation to the lung have not been very successful. If any of the four chemotherapy drugs that have activity against osteosarcoma have not been used in the original treatment, those agents should be given in conjunction with surgery. Unfortunately there is still no effective salvage regimen for these patients.

Genetics

The cause of osteosarcoma remains unknown with most patients having no defined genetic risk factors. The risk of developing osteosarcoma increases two-fold over the general population for patients who receive radiation or chemotherapy (especially alkylating agents and anthracyclines) for treatment of other cancers. Two groups of patients have a much higher risk of osteosarcoma however, those with hereditary retinoblastoma (►Retinoblastoma, cancer genetics) and those with ►Li-Fraumeni syndrome. These syndromes occur due to mutations in the tumor suppressor genes *Rb* (►Retinoblastoma protein, biological and clinical functions) and *p53* (►p53 Protein, biological and clinical aspects), respectively. Analysis of patient tumor samples reveals that over 50% of samples have mutations in either *Rb* or *p53*. Other populations that have increased risk of developing osteosarcoma are geriatric patients with ►Paget disease and children with ►Rothmund-Thomson syndrome who have truncating mutations in the *RecQL4* gene. When karyotypes of patient samples are prepared, all samples show ►aneuploidy (more than the normal chromosome number of 46), suggesting that a defect in DNA replication may prove important in the etiology of osteosarcoma.

Future

Research in osteosarcoma has focused on metastatic disease due to the poor prognosis associated with both metastases and recurrence. The futility of efforts aimed at targeting the tumor through intensification of chemotherapy has led to efforts aimed at other targets. In particular, agents that decrease the blood supply to the tumor (angiogenesis inhibitors) (►Antiangiogenesis) and agents that target the reactive cells that surround the tumor (stromal inhibitors) are receiving increased focus, both in the laboratory and in clinical trials.

Outer Edge of the Tumor Mass

Definition
Consists of the path-leading cells that interact with the surrounding tissue and form the invasive front of the tumor. The molecular expression profile of cells at the outer edge of the tumor can differ from that of cells in the interior. Nuclear localization of ►β-catenin, and upregulation of β1-integrin, the L1 ►adhesion molecule and ►podoplanin were specifically reported in cells of the tumor rim.

►Podoplanin

Ovarian Ablation

Definition
►Ovarian Function Suppression.

Ovarian Adenocarcinomas

Definition
Are malignant ovarian neoplasms classified according to the histology of the tumor. Surface epithelial-stromal tumors are the most common and prototypic ovarian cancers, and include serous cystadenocarcinoma and mucinous cystadenocarcinoma. ►Ovarian cancer staging is by the ►FIGO staging system.

Ovarian Cancer

Pat J. Morin[1], Ellen S. Pizer[1]
Laboratory of Cellular and Molecular Biology, National Institute on Aging, NIH, Baltimore, MD, USA

Definition
A heterogeneous group of malignant tumors derived from the ovary (there are also a wide assortment of benign tumors derived from the ovary). Approximately 90% of malignant ovarian tumors originate from the ovarian surface celomic epithelium and are therefore designated epithelial ovarian cancer (EOC). Germ cell tumors and stromal tumors account for the remaining cases.

EOC can be divided according to histological appearance:

- Serous, the most common type (composed of epithelium resembling that of fallopian tubes)
- Endometrioid (composed of epithelium resembling that of the endometrium)
- Clear cell (composed of clear cell epithelium and resembling gestational endometrium)
- Transitional cell tumors (composed of epithelium resembling urothelial cells)
- Mucinous (composed of epithelium resembling that of the endocervix)
- Squamous cell (squamous epithelial cells)
- Mixed epithelial tumor (mixture of two or more of the above subtypes)
- Undifferentiated (no recognizable differentiation features)

Ovarian cancer is staged according to the following International Federation of Gynecology and Obstetrics (►FIGO) guidelines. Grading of EOC is based on degree of differentiation, cytologic ►atypia and mitotic index.

- Stage I: restricted to the ovaries
- Stage II: involvement of ovaries and pelvic extension
- Stage III: involvement of ovaries with peritoneal implants outside the pelvis
- Stage IV: involvement of ovaries with distant ►metastasis, such as liver, lung or brain

Characteristics
In westernized countries, ovarian cancer is the sixth most common cancer in women. Over half of the women diagnosed with ovarian cancer are over 65 years of age. The age-adjusted incidence for ovarian cancer is ~15 per 100,000 and the total number of cases is expected to increase as the overall population ages. Overall, ovarian cancer prognosis is poor. In spite of the

recent introduction of aggressive treatments, five year survival rates for patients with advanced ovarian cancer (stage III and IV) has remained low and ranges between 5 and 30%. However, the outcome is much more favorable for stage I patients where 5-year survival can reach 90–95%. Unfortunately, because of lack of symptoms, only 25% of the women with ovarian cancer are diagnosed with stage I disease. These facts make ovarian cancer a disease for which early detection represents an intervention of choice in reducing morbidity. Several putative ovarian cancer serological markers have been identified, including ►CA125, ►TATI, ►CEA and ►CA19-9. Of those, CA125 has proven to be the most clinically useful. Unfortunately, studies have exhibited mixed results, with some studies detecting only 23% of stage I ovarian carcinoma with CA125. CA125 may be useful when used in combination with pelvic ultrasound assessment, and CA125 has been used in monitoring recurrence in patients with CA125-positive tumors. Overall, CA125 lacks the specificity and sensitivity required for the screening of the general population.

The etiology of ovarian cancer is not well understood but the following risk factors have been identified:

- Age: half the cases occur in women of 65 years or older
- Menstrual history: ovarian cancer risk increases with increasing numbers of menstrual cycles
- Birth control pills: the use of which, for at least five years, lowers the risk of ovarian cancer
- Pregnancy and breastfeeding: lowers the risk of ovarian cancer
- Family history

Typical treatment for ovarian cancer is surgery followed by chemotherapy. The exact details of treatment depend on the tumor type, grade and stage, the age, as well as the general health of the patient.

In spite of recent advances in the field of cancer genetics and molecular biology, little is known about the mechanisms of ovarian tumorigenesis. Chromosome abnormalities are frequent in ovarian cancer and allelic losses have been observed in chromosomes 4p, 6p, 6q, 7p, 7q, 8p, 8q, 9p, 11q, 12p, 12q, 13q, 16p, 16q, 17p, 17q, 19p, 19q, 22q and Xq. These observations suggest the presence of several tumor suppressor genes important in ovarian cancer, but very few have been unambiguously identified. The tumor suppressor ►p53 is inactivated in a large number of ovarian cancers. Although the tumor suppressor genes ►BRCA1 and ►BRCA2 have been implicated in familial breast and ovarian cancer syndromes, the vast majority of ovarian cancers are sporadic and may have a different natural history.

The K-►Ras, ►Her-2/neu and c-►myc ►oncogenes have all been implicated in EOC. The frequencies of alteration of these different oncogenes varies according to the subtype of ovarian cancer. No clear association has been reliably observed between the activation of these oncogenes and survival. Indeed, stage and grade have been the only factors consistently shown to predict outcome of ovarian cancer.

Ovarian Function Suppression

Definition

Synonym Ovarian ablation; Includes the use of surgery, radiation therapy, or a drug treatment to stop the functioning of the ovaries.

►Adjuvant Chemoendocrine Therapy

Ovarian Steroid Hormones

Definition

Refer to the female sex steroid hormones 17β-►estradiol and ►progesterone, secreted by the ovary and by the placenta during pregnancy. Steroid hormones are lipid molecules derived from a common cholesterol precursor (cholestane, C27). Based on the distance between the site of hormone synthesis and secretion and the target tissue, their mechanism of action can be classified as ►endocrine (distant

target), ►paracrine (neighboring cells), or ►autocrine (same cell).

►Progestin

Ovarian Stroma

Definition

Solid inner part of the ovary consisting of various secretory cells.

►Granulosa Cell Tumors

Ovarian Surface Epithelium

Definition

The tissue covering the outer surface of the ovary, from which epithelial ovarian tumors arise.

►Endometriosis

Ovarian Teratoma

Definition

Synonym dermoid cyst; most frequent ovarian germ cell tumor. Mature ovarian teratomata develop from postmeiotic germ cells and present as cystic tumors limited to the ovary with no metastatic spread. In contrast, immature teratomata may show considerable infiltration into neighboring organs and may be a component of mixed malignant ►germ cell tumors.

Synonyms

Dysgerminomas – Dysgerminoma, Embryonal carcinoma, Yolk sac tumor, Choriocarcinoma, Teratoma, mature/immature (cystic teratoma, syn.: dermoid cyst); Sex cord stromal tumors – Granulosa cell tumor, juvenile type, adult type, Sertoli-Leydig cell tumor (syn. gynandroblastoma), Sclerosing stromal cell tumor, Sex cord stromal tumor with annular tubules, Steroid tumor, Brenner tumor; Ovarian small cell carcinoma, hypercalcemic type; Cystadenoma; Ovarian carcinoma

Definition

Primary ovarian neoplasms derived from the germinative, stromal or epithelial component of the ovary during infancy, childhood and adolescence.

Characteristics

Ovarian tumors of childhood and adolescence include a broad variety of clinically, histologically and biologically different entities. The epidemiological patterns differ significantly from those in adult patients. The classical epithelial ►ovarian carcinoma of adults constitutes a rarity in childhood and adolescence. In contrast, ►germ cell tumors (GCT) prevail in young patients and represent the most frequent ovarian tumor during childhood and adolescence.

The histologic variability of ovarian tumors is related to the varying histogenesis of the different entities, because ovarian tumors may develop from all different histologic components of the ovary. Among the largest group of ovarian tumors, the GCTs, ovarian cystic ►teratomas are distinguished from malignant GCTs, which may sometimes include mature or immature teratomatous components. Less frequent histologic entities during childhood and adolescence include ►sex cord stromal tumors (SCST), ►granulosa cell tumors, ovarian small cell carcinoma of the hypercalcemic type (OSCC) as well as epithelial tumors such as cystadenomas, borderline tumors and classical ovarian carcinomas (►Ovarian cancer).

Epidemiology

Among ovarian tumors of childhood and adolescence, GCTs constitute the largest group, with a peak incidence during adolescence and young adulthood. Ovarian tumors account for ~1% of all registered childhood cancers. In addition, an unknown number of unregistered ►ovarian teratomas and rare ovarian tumors must be considered.

In contrast to ►testicular GCTs, which show a bimodal incidence distribution according to age with a first peak during infancy and a second during young adulthood, ovarian GCTs show their peak incidence during adolescence and young adulthood, with no distinct cohort during infancy.

►OSCSTs represent the second largest groups of ovarian tumors during childhood and adolescence. During infancy, the almost exclusive histology is juvenile granulosa cell tumor. With the onset of puberty, ►Sertoli-Leydig cell tumors become more prevalent. The other histologic subentities are too rare to allow for the evaluation of epidemiological patterns.

Epithelial cancers such as OSCC and borderline lesions and the classical carcinoma are diagnosed almost exclusively during adolescence and are rarely reported to pediatric registries.

Histology and Biology

Ovarian tumors may develop from any histologic component of the ovary. The histologic appearance of ►GCTs is interpreted in the light of the holistic concept first proposed by Teilum. Accordingly, GCTs may show pure germ cell differentiation on one hand (►dysgerminoma, in analogy to the seminoma and germinoma of the testis and CNS, respectively) or somatic differentiation on the other. Morphologically, dysgerminomas resemble immature germ cells and express immature stem cell markers such as c-kit, human placenta like alkaline phophatase and OCT3/4. They may develop in the presence of gonadoblastomas; thus indicating underlying disorders of gonadal development, e.g. related to Ullrich-Turner syndrome of testicular feminization with streak gonads.

Among the non-seminomatous GCTs, immature embryonal structures may be observed in embryonal carcinomas (EC) that morphologically remind of the embryoid bodies of embryonal stem cell cultures. The distinct histologic subentities of nonseminomatous GCTs can be distinguished by clinical, histopathologic and immunohistochemic analysis. Embryonal carcinoma may be CD30 and OCT3/4 positive. In contrast, yolk sac tumors express alpha fetoprotein (AFP) and may stain positive for CD34, while choriocarcinoma is detected by staining for ß-human chorionic gonadotropin (ß-HCG). These two markers may be measured in the patient's serum and may therefore be valuable for diagnosis and follow-up of such secreting GCTs.

Teratomas show a higher degree of organoid differentiation with presence of mature or immature structures that may be derived from all three germ layers such as hair, squamous and mucous epithelium teeth, cartilage, bone, glial or thyroid tissue. Characteristically, such mature teratomas contain large tumors cysts and have therefore been named dermoid cyst. These tumors are biologically distinct in that they show an isodisomic chromosome count, related to their development from rather mature germ cells that have already undergone meiotic recombination. Immature teratomas present with varying components of immature tissue that mostly resembles immature neural tissue with neurotubular structures. In immature teratomas, the grade of immaturity can be determined according to the relative amount of immature tissue.

In conventional cytogenetic analysis, differences between GCTs in children and in adults can be detected: The ►isochromosome 12 p (designation: i(12p)), which is the result of a centromeric junction of two short arms of chromosome 12 and loss of the long arms, constitutes the pathognomic cytogenetic abnormality in adult GCTs and can be seen in more than 80% of tumors. The remaining "i(12p)-negative" GCTs show gain of regions from 12p, either as double minutes or homogeneously staining regions. In contrast, the i(12p) can not – or only rarely – be detected in GCTs that arise before the onset of puberty. During childhood, deletions (resulting in ►LOH) of the short arm of chromosome 1 and the long arm of chromosome 6 can be found frequently. According to the unimodal age distribution of ovarian GCTs, no such childhood genetic pattern can be detected in ovarian GCTs of young girls, but the characteristic pattern of adult GCTs including i(12p) may be detected in girls as young as four years of age.

GCTs may arise in the context of constitutional sex chromosomal abnormalities. Ovarian GCTs can be associated with Ullrich-Turner syndrome (45,X0), gonadal dysgenesis (Swyer Syndrome) and/or testicular feminization. Characteristically, these tumors arise in the presence of gonadoblastomas, which has therefore been proposed as the ovarian equivalent of the testicular intratubular neoplasia (TIN, syn. carcinoma in situ).

Sex cord stromal tumors (SCSTs) may include granulosa-, Sertoli-, Leydig- and theka-cells as well as their respective immature progenitor cells and fibroblast that are derived from the specialized gonadal stroma Granulosa Cell Tumors. In the developing gonads, granulosa and Sertoli cells show a sex-specific differentiation. As a morphologic correlate of their hormonal activity, a positive immunohistochemical staining constitutes the diagnostic hallmark of SCSTs.

SCSTs may develop in association with several defined hereditary disorders. In juvenile granulosa cell tumors, there is an association with multiple enchondromatosis, syn. Ollier disease. In addition, there is a pronounced association of ►Peutz-Jeghers syndrome with sex cord tumors with annular tubules. These tumors usually develop at a younger age than in otherwise healthy patients, and they may develop bilaterally. In contrast, testicular large cell calcifying Sertoli Cell tumors can be found in boys with Peutz-Jeghers syndrome.

Genetic analysis of sporadic juvenile ovarian granulosa cell tumors with ►comparative genomic hybridization has not revealed frequent or characteristic chromosomal imbalances. The majority of tumors show balanced karyotypes, and in approx. 25% of patients chromosomal imbalances such as gain of the whole chromosome 12 can be found.

The ovarian small cell carcinoma of the hypercalcemic type (OSCC) represents a rare ovarian neoplasm with enigmatic histogenesis that most commonly develops after the second decade of life. The histologic diagnosis is complicated by the pronounced morphologic similarity between JGCT and OSCC; however, the lack to demonstrate Inhibin by immunohistochemistry strongly argues for the diagnosis of OSCC, if additional characteristic morphologic features are present. The clinical presence of hypercalcaemia in approximately two thirds of patients does not substitute the histologic diagnosis, since a variety of other ovarian neoplasms such as clear cell carcinoma or serous carcinoma may also be associated with hypercalcemia. Clinically, OSCC are characterized by a usually very aggressive clinical behavior associated with fatal outcome in the vast majority of patients.

Adolescent girls may rarely present with large cystic serous tumors, histologically resembling either a simple or papillary cystadenoma. These tumors show a clinically benign behavior after complete resection, but serous adenocarcinoma, which represents the malignant form of papillary serous cystadenoma, must be distinguished histologically. In analogy, mucinous adenocarcinoma constitutes the malignant counterpart of the mostly huge but clinically benign mucinous cystadenomas. The majority of Brenner tumors are benign and occur as small solid and well-circumscribed nodules. Again, a malignant variant (malignant Brenner tumor, pure transitional cell carcinoma) has to be distinguished.

Ovarian adenocarcinomas rarely develop during adolescents; however these tumors often take a malignant clinical course. Particularly in young patients and in patients with frank familial history, these tumors are associated with inherited BRCA mutations. CA125 can be used as tumor marker following tumor resection, but the vast majority of patients will require adjuvant chemotherapy.

Clinical Diagnosis

Ovarian tumors are commonly detected as large tumors which may have led to a visible swelling of the abdomen or fatigue. In some patients, tumor related torsion of the ovary or tumor rupture may result in severe acute abdominal pain and require emergency laparatomy.

Yolk sac tumors secrete alpha1-fetoprotein (AFP) and choriocarcinoma human chorionic gonadotropin (HCG), which can be detected in the serum. In

Ovarian Tumors During Childhood and Adolescence. Table 1 Clinical and biologic characteristic of ovarian tumors correlated with histology

Histology	Clinical behavior	Tumor markers in Serum				Sensitivity to	
		AFP	HCG	Inhibin	Ca++	Chemo	Irradiation Gy
Germinoma	Malignant	–	(+)	–	–	+++	24
Embryonal CA	Malignant	–	–	–	–	+++	45
Yolk sac tumor	Malignant	+++	–	–	–	+++	45
Choriocarcinoma	Malignant	–	+++	–	–	+++	45
Teratoma	Benign (potentially malignant)	–/(+)	–	–	–	>54[b]	>54[b]
SCSTs	Malignant	–/(+)[a]	–	(+)[b]	–	++	n.d.[b]
Ovarian small cell carcinoma, hypercalcemic type	Malignant (presumably fatal)	–	–	–	++	++*	n.d.[b]
Cystadenoma	Benign (potentially malignant)	–	–	–	–	–	–

[a]Some poorly differentiated Sertoli-Leydig cell tumors may secrete AFP.

Abbreviations: n.d., no data.

combination with characteristic radiographic findings such as calcifications in mixed tumors with teratomatous elements, these markers can be indicative of malignant GCTs, after other rare diagnoses that may be associated with elevated tumor markers have been excluded. Pure embryonal carcinomas and teratomas are usually not associated with specific serum tumor markers. In ~20% of dysgerminomas, serum levels of placenta like alkaline phosphatase may be elevated. Syncytiotrophoblastic cells in germinoma may produce as well human chorionic gonadotropin (ß-HCG), which therefore can also be elevated (►Serum biomarkers).

SCSTs often induce clinical symptoms that are related to the production of sex hormones by the tumor. Characteristically, infants and children present with signs of isosexual precocity, including breast enlargement, pubarche and vaginal bleeding. In (post-)pubertal girls, tumors may lead to primary or secondary amenorrhea and unspecific signs of virilization. As other steroid hormone producing cells SCSTs also produce Inhibin. Free Inhibin can be measured in the serum and may serve as a serological tumor marker during follow-up.

In rare but well documented cases of poorly differentiated ovarian Sertoli-Leydig cell tumors, ►AFP production has been reported, which may interfere with clinical diagnosis. Histologically, most of these tumors resemble SLCT with retiform, often hepatoid differentiation and heterologous elements.

►CA125 constitutes a rather unspecific marker of ovarian tumors that may be elevated in different histologic entities. CA125 may provide useful information regarding the response to treatment and for follow-up in tumors that are otherwise tumor marker negative.

Ovarian small cell carcinoma may present with significant hypercalcemia, which is not related to skeletal metastasis. However, hypercalcemia has also been reported in some patients with ovarian GCTs, SCSTs and cystadenoma or other epithelial tumors.

The staging system of the World Health Organization and the International Federation of Gynecologic Oncology (►FIGO) can be applied. Tumors confined to the ovary (stage I) are distinguished from tumors with locoregional spread in the small pelvis (stage II) and the abdominal cavity (stage III) and distant metastases (stage IV). Microscopic spread may have occurred even in stage I tumors, if malignant ascites is noted or if pre- or intraoperative violation of the tumor pseudocapsule occurred (stage Ic). Tumors with no microscopic spread on complete staging are categorized as stage Ia (unilateral tumor) or stage Ib (bilateral tumors).

Peritoneal gliomatosis constitutes a specific phenomenon in teratomas and mixed malignant GCTs that refers to glial nodules in the peritoneal surface. Although gliomatosis imposes like wide-spread metastases, it represents a reactive and non-neoplastic disorder so that upstaging is inadequate.

Surgical Therapy

All ovarian tumors require surgical resection. In most patients, a primary tumor resection constitutes the standard approach and will result in complete tumor resection, because most tumors are encapsulated. In metastatic tumors with peritoneal spread, an up-front chemotherapy followed by delayed tumor resection is recommended as it may significantly facilitate complete tumor resection. Therefore, diagnosis must be made on the basis of imaging and tumor markers, and only in tumor marker negative tumors, an initial biopsy will be required.

A median ►laparatomy is considered the classical standard approach to ovarian tumors in childhood and adolescence, as it will allow for preparation and exstirpation of the tumor in one piece. With the modern advances in laparascopy, more patients will undergo laparoscopic surgery. However, the safety of this approach has not been prospectively evaluated in ovarian tumors of childhood. By no means, tumors should be punctured or resected in separate pieces in order to facilitate removal through the laparoscope, because this would not comply with the oncological criteria of complete resection and may thus be associated with an increased risk of relapse.

For the same reasons, organ sparing surgery (e.g. enucleation of a cystic tumor) should be avoided, and might only be reserved to those rare patients with bilateral tumors, which are additionally treated with consolidating chemotherapy.

Tumor resection may be restricted to ovarectomy, if surgical staging indicates a stage I tumor. Only in stage II or III tumors, unilateral adnectomy is indicated. In general, hysterectomy is considered unnecessary.

Surgical staging limited to resection of suspicious lymph nodes only does not adversely affect outcome in the presence of cisplatin containing combination chemotherapy. Thus, routine sampling of unsuspicious nodes is not recommended.

In non-metastatic tumors, omentectomy and appendectomy are not required for oncological reasons, but in specific situations may be performed on the basis of individual judging by the surgeon.

Last, resection of glial nodules in gliomatosis peritonei is not generally recommended due to the non-malignant nature of this disorder. However, resection of large nodules may become necessary if they result in local complications such as mechanic ileus.

Adjuvant Therapy

After resection, a choice regarding the indication for adjuvant therapy has to be made. ►Adjuvant therapy may be chosen from a broad and risk-stratified panel of chemotherapeutic strategies, which may include two to four cycles of a two- or three-agent chemotherapy

as well as strategies with locoregional or systemic treatment intensification. The adequate choice of treatment does not only require the individual skill and experience but must always consider a careful clinical and histopathologic assessment, preferably by a central reference pathologist. Therefore, all children and adolescents with ovarian GCTs should be enrolled into cooperative protocols, which will provide the treating physician with the required infrastructure for diagnosis and risk-assessment.

While previously, adjuvant chemotherapy has been widely used even in completely resected stage I tumors, recent experience has shown that a careful watch-and-wait strategy may be justified in stage I tumors. In analogy to testicular GCTs, it is advisable to administer adjuvant chemotherapy to those patients with histological evidence of vessel-invasion. A watch-and-wait strategy must always include a careful and close follow-up schedule, which specifically includes the assessment of the paraaortal lymph nodes, the most frequent site of relapse. In addition, the patients should be informed that there is a general risk of relapse under a watch-and-wait strategy that is ~20–30%. However, with delayed chemotherapy, there is an excellent salvage rate, so that the overall survival exceeds 90%. Nevertheless, although ►chemotherapy can be avoided in two thirds of patients, those who relapse will have to bear a higher therapeutic burden.

Adjuvant therapy generally consists of platin-based combination chemotherapy. Previously, irradiation has also been administered in dysgerminomas, however, compared to chemotherapy, it will result in infertility of the contralateral ovary without better cure rates. Therefore, irradiation is reserved to salvage treatment only.

Current modern platin-based chemotherapy usually consists of a three-agent combination including ►cisplatin (100 mg/m^2/cycle) and ►etoposide (300–500 mg/m^2/cycle) in combination with ►bleomycin (15–30 U/m^2/cycle) or ifosfamide (7500 mg/m^2/cycle) ►platinum drugs. The comparably effective ►vinblastin is less commonly used because of vascular complications, in particular in combination with bleomycin.

Cisplatin can be substituted by ►carboplatin (600 mg/m^2/cycle) with similar cure rates. However, carboplatin at lower doses (400 mg/m^2/cycle) results in unacceptably high relapse rates. In general, carboplatin is assumed to have a better toxicity profile than cisplatin with lower nephro- and ototoxicity but higher hematotoxicity. Intensification of cisplatin with 200 mg/m^2/cycle) results in significant ototoxicity, however also yields a survival advantage in high risk patients.

The other drug consistently administered in GCTs is ►etoposide. In general, etoposide is associated with an increased risk of secondary malignancies, in particular acute myelogeneous leukemia. However, at the doses usually administered for GCTs and in the absence of concomitant radiotherapy, the risk is acceptably low and does not exceed 1%.

In the different national protocols, different choices of the third drug have been made. In the UK and the USA, platin-compounds and etoposide are combined with bleomycin, thus resembling the traditional ►BEP chemotherapy for testicular GCTs. In contrast, the national groups in France, Brazil and Germany are administering ifosfamide. The toxicity profiles of these two drugs differ significantly. Bleomycin in combination with cisplatin may result in pneumopathy, which in rare patients may be lethal. In contrast, ifosfamide has a more pronounced hematotoxicity and may result in chronic renal tubulopathy.

As for both drugs, the risk is highest in neonates and infants, both have not been administered in this age group. Thus, the two-agent regimen has been extended to a larger group of patients with a moderate risk profile, with promising treatment response.

Some tumors may show an only insufficient response to conventional three agent chemotherapy and should therefore be selected for treatment intensification. In tumors with locoregional (i.e. peritoneal) spread, treatment intensification may be achieved by combination of chemotherapy with locoregional hyperthermia ►Hyperthermia. Metastatic tumors however may be selected for dose intensified chemotherapeutic strategies (►Platinum-refractory testicular germ cell tumors).

In contrast to the more frequent GCTs, the experience regarding the adjuvant chemotherapy in the rare tumor entities such as SCSTs and OSCCs is much more limited and awaits prospective evaluation. The overall prognosis of SCSTs is favorable and cure rates exceed 80%. Patients with stage I tumors are followed expectantly, while patients with peritoneal spread are selected for adjuvant chemotherapy (e.g. cisplatin, etoposide, ifosfamide). Patients with stage Ic tumors and malignant ascites of preoperative tumor rupture should also be selected for chemotherapy, since the outcome of this specific group was comparable to that of stage II and III tumors.

Experience regarding the optimal treatment of OSCC is extremely small and mostly derived from retrospective clinico-pathological surveys and single case reports, indicating for an extremely aggressive natural course of this disease with an almost invariable fatal outcome. Regardless of stage, all patients with ►ovarian small cell carcinoma, hypercalcemic type require multi-agent chemotherapy during first-line treatment. High-dose chemotherapy can be used to consolidate the therapeutic success.

The guidelines for the treatment of other epithelial tumors such as cystadenoma and adenocarcinomas follow those for the corresponding tumors in adults. If necessary, a combination of carboplatin and ►taxol is considered the current standard chemotherapy ►ovarian cancer.

Overexpression

Definition

Gene overexpression refers to the increased expression of a gene. This can occur either endogenously by regulotary pathways, by genomic ►amplification of a gene or exogenously by experimentally introducing DNA-constructs (plasmids) encoding the respective gene into cells.

Ovulation

Definition

The process by which an ovum is released from within the ovary in a cyclical manner. The fluid-filled follicle containing the ovum distends the surface of the ovary until it breaks down, and the ovum is released.

►Endometriosis

Oxaliplatin

Definition

Chemotherapeutic agent; platinum-containing; causes DNA disruption.

►Peripheral Neuropathy

Oxidation

Definition

The chemical process involving removal of electrons. If dithiols are oxidized with two electrons, they may form disulfides.

►Thioredoxin System
►Reactive Oxygen Species

Oxidative DNA Damage

Andrew R. Collins
Department of Nutrition, University of Oslo, Oslo, Norway

Definition

Represents free radical damage to DNA. Oxidation essentially involves the addition of oxygen or removal of hydrogen atoms from a molecule. Oxidation of DNA may simply result in a small change to one of the bases, or a deoxyribose in the backbone of the molecule may be altered to such an extent that the continuity of the backbone is broken. Single-strand breaks are more common than double-strand breaks.

Characteristics

DNA is thought of as a very stable molecule and yet it readily undergoes damage, by a variety of agents that can be either endogenous or exogenous in origin. Ionizing radiation (e.g. X-rays), ►ultraviolet radiation and various chemicals, including some present in tobacco smoke (►Tobacco carcinogenesis), cause the release of free radicals, and if DNA is not protected, oxidative damage can occur. Free radicals (►Reactive oxygen species) also occur within the cells of the body, arising as a minor product during the cycle of oxidation of carbohydrates in the mitochondria. The hydroxyl radical, *OH, is particularly reactive with DNA.

In addition to single- and double-strand breaks, many different oxidation products of the four bases (►Adducts to DNA) have been identified in DNA treated with radiation or other free radical-generating chemicals. Some of these modified bases are potentially capable of giving rise to a ►mutation. For instance, ►8-oxoguanine, if present in the DNA when it is replicating, may lead to the incorporation of adenine rather than cytosine into the newly synthesized complementary strand, thus changing the DNA sequence.

Some oxidation is detectable in the DNA of normal human cells. It is usually measured by gas

chromatography (►GC-MS) or high performance liquid chromatography (►HPLC). Normally for GC-MS, the DNA is acid-hydrolyzed to bases (guanine etc.), while for HPLC the DNA is enzymically hydrolyzed to nucleosides (deoxyguanosine (dG) etc.). Both of these methods have given relatively high values for the extent of conversion of guanine to 8-oxoguanine, with up to 300 or more 8-oxo-guanines for every 10^6 unaltered guanines. However, recently it has been recognized that guanine tends to oxidize during preparation of samples for analysis and so the early estimates of 8-oxoguanine are considered to be excessive. Values as low as 3 per 10^6 have been reported from HPLC analysis of anaerobically prepared samples.

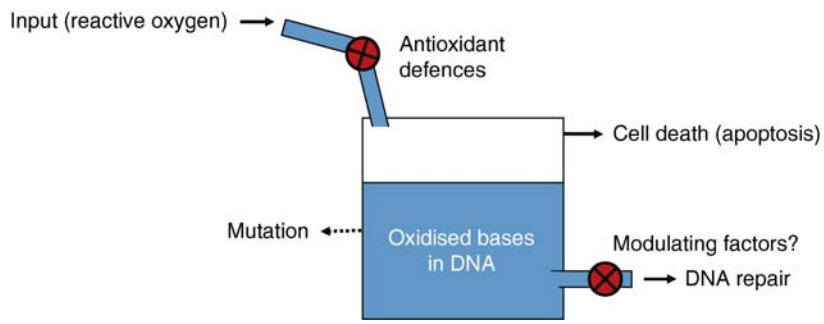
There is another approach to measuring oxidized bases using bacterial repair endonucleases, which recognize the damage and make a corresponding break in the DNA. The enzyme FPG (formamidopyrimidine DNA glycosylase) recognizes 8-oxoguanine. DNA breaks can then be measured in various ways, including the ►comet assay (Fig. 1). This approach gives values for 8-oxoguanine that are even lower, with around 0.5 per 10^6 guanines.

The extent of background DNA oxidation in normal cells remains an important question. Methodological problems must be solved before a consensus can be reached.

Oxidative DNA Damage. Figure 1 The comet assay. Cells are embedded in agarose on a microscope slide, lysed, and electrophoresed at high pH. This view is of the DNA from one cell, stained with DAPI and visualized by fluorescence microscopy. The percentage of DNA fluorescence in the tail of the "comet" is proportional to the frequency of breaks – such as breaks introduced at 8-oxoguanine sites by the enzyme FPG.

Mechanisms

Measurement is made of the steady state level of DNA damage, which is a dynamic equilibrium between input of damage and its repair (Fig. 2). In the case of oxidative damage, input is controlled by ►antioxidant defenses. The tripeptide glutathione is present at high concentration in the nucleus and "mops up" free radicals before they can cause damage. Superoxide dismutase and catalase are enzymes that convert superoxide and hydrogen peroxide (two reactive forms of oxygen) ultimately to non-harmful products. Other enzymes combine various organic free radicals with glutathione, thus inactivating them. Fruits, vegetables and grains in the diet are a source of ►antioxidants, including ►vitamin C, ►vitamin E, ►carotenoids and flavonoids. These ►natural products have the ability to quench or scavenge free radicals; whether they act as antioxidants in vivo depends on whether they are taken up from the gut in sufficient amounts, and has been the subject of recent human intervention trials. In general, it is possible to detect a significant decrease in the steady state level of base oxidation (and/or an increased resistance to in vitro oxidation of DNA) in white blood cells of volunteers taking individual antioxidant



Oxidative DNA Damage. Figure 2 DNA damage: a steady state. There is a constant inflow of damage, caused by free radical attack and attenuated by antioxidants. This is normally balanced by cellular DNA repair processes, which remove the damage and restore the DNA sequence. Little is known about what modulates repair activity.

supplements or antioxidant-rich foods, ranging from fried onions to kiwifruit.

However effective the antioxidant defenses, some DNA oxidation does occur. The turnover of this damage is achieved by ►repair of DNA. Small base damage, which includes base oxidation, is repaired primarily by base excision repair. Here, the damaged base is removed, followed by the base-less sugar-phosphate residue and perhaps a few neighboring nucleotides. A small repair patch of new nucleotide(s) is inserted and ligated.

As well as being present in cellular DNA, 8-oxodG is detectable in urine as free nucleoside. The idea that urinary 8-oxodG represents the accumulated product of DNA repair in all the cells of the body is attractive but flawed; base excision repair releases the base not the nucleoside. Even if this 8-oxodG originates in the oxidation of broken down DNA from dead cells passing through the kidneys, it still reflects ►oxidative stress, and it has given useful information about oxidative stress related to exercise, smoking and nutrition. Most impressively, consumption of 300 g a day of brussels sprouts led to a decrease of 28% in urinary 8-oxodG concentration.

Clinical Aspects

It is commonly stated that oxidative DNA damage is a significant cause of cancer, and that fruits and vegetables protect against cancer because the antioxidants they contain decrease the amount of base oxidation in the cellular DNA. However, there is little evidence that this is true. In two large scale human intervention trials, smokers and/or ►asbestos workers were given β-carotene (a carotenoid antioxidant) daily for several years. The ►lung cancer incidence was actually higher in these subjects compared with those taking placebo (or other supplement). Other intervention trials have shown no beneficial or harmful effect of supplementation with antioxidant micronutrients in terms of cancer risk – in spite of their ability to decrease oxidative damage.

In an experimental animal system, a high level of oxidative DNA damage is not necessarily marked by an elevated cancer risk. In a ►knockout mouse model, which is defective in the murine equivalent of FPG, there is a slight increase in the steady state level of 8-oxoguanine, but no increase in cancer incidence. It seems that there is a back-up repair pathway that deals (more slowly, but adequately) with oxidative damage.

Oxidative stress is a feature of many other diseases, including heart disease, diabetes, cataract, and rheumatoid and arthritic conditions. It may be a cause of the clinical condition, or an effect. A common theory of ageing argues that the accumulation of free radical-induced damage to biomolecules – lipids, proteins and nucleic acids – is responsible for the general cellular dysfunction and deterioration of body processes in later life, but the evidence for accumulation of oxidative DNA damage is weak.

The importance of fruits and vegetables in a healthy diet is not in doubt. But it is clear that antioxidants are not their only feature, and we should be looking at other effects that phytochemicals might have on metabolism to account for their capacity to prevent disease.

Oxidative Metabolism

Definition

Consists of replacing a carbon hydrogen bond in a drug by a carbon oxygen bond or the breaking of a carbon nitrogen bond (N-dealkylation).

►ADMET Screen

Oxidative Phosphorylation

Definition

Biochemical reactions in the mitochondria that generate ATP. Is an oxygen-dependent process by which aerobic cells obtain energy (ATP) in the mitochondria. In this process, electrons from NADH and $FADH_2$ are passed along the electron-transport chain to oxygen. This electron transport generates an electrochemical proton gradient across the inner mitochondrial membrane that is used by ATP synthase to phosphorylate ADP and form ATP.

►Hydrogen Peroxide

Oxidative Stress

Jérôme Alexandre, Carole Nicco, Frederic Batteux
Faculté de Médecine Paris – Descartes, UPRES 18-33, Groupe Hospitalier Cochin – Saint Vincent de Paul, Paris, France

Definition

Is caused by an imbalance between the production of reactive oxygen and a biological system's ability to readily detoxify the reactive intermediates or easily repair the resulting damage. It is defined as a disturbance in the prooxidant–►antioxidant balance in favor of the former leading to potential damage. Oxidative stress is believed to contribute to the development of several diseases, including cancer.Corresponding author.

Characteristics

The complex of oxidative stress involves a number of cell-chemical elements:

►Free radicals include any species that contain one or more unpaired electrons, generating electrons singly occupying an atomic or molecular orbital. The presence of unpaired electrons confers a considerable degree of reactivity upon a free radical. Dioxygen is the main source of intracellular free radicals.

►Reactive oxygen species (ROS) is a collective term that includes both oxygen free radicals such as superoxide anion ($O_2^{\bullet -}$) and hydroxyl radical ($OH^{\bullet}$) and other reactive molecules as ►hydrogen peroxide (H_2O_2). H_2O_2 is not a free radical but is also reactive and easily converted into radicals.

ROS are physiological byproducts of normal aerobic metabolism. 90% of intracellular superoxide anion comes from the mitochondrial electron transport chain. Other significant sources of superoxide anion include ►NADPH oxidase (NOX), ►xanthine oxidase, and NADPH-►cytochrome P450 reductase. NOX are a family of multimeric membrane oxidases tightly regulated by various stimuli including growth factors.

Superoxide anion is considered as the "primary" ROS. The chemical reactivity of superoxide anion is weak in aqueous medium. Moreover, its negative electronic charge makes it unable to diffuse through lipid membranes. That's why superoxide anion by itself has little cellular effects.

The conversion of $O_2^{\bullet -}$ into H_2O_2 is catalyzed by enzymes of the ►superoxide dismutase (SOD) family. Three isoforms of SOD have been identified in humans: CuZn-SOD, which is located in the cytosol, Mn-SOD, located in the mitochondria, and extracellular (EC)-SOD. H_2O_2 is able to go trough cellular membranes and can diffuse relatively far from its production origin. At physiological concentrations, H_2O_2 reacts mainly with sulfydril radicals, inducing reversible alterations of cysteines. Thus, H_2O_2 is able to specifically alter activity of proteins containing cysteine residues in their enzymatic sites, especially tyrosine phosphatases.

The hydroxyl radicals are formed through the Fenton or Haber-Weiss reaction that converts $O_2^{\bullet -}$ and H_2O_2 into $OH^{\bullet}$ in the presence of Fe^{2+} or Cu^{2+}. $OH^{\bullet}$ is extremely reactive and induces severe cellular oxidative damages as DNA alterations, being thus highly mutagenic. It leads to polyunsaturated fatty acids peroxidation, increasing cellular membrane permeability. $OH^{\bullet}$ is also able to react with proteins, inducing irreversible inactivation.

Several antioxidant enzymes can detoxify the whole cascade of ROS and protect normal cells from the potential damages implicated by oxidative stress. SOD catalyses the conversion of $O_2^{\bullet -}$ into H_2O_2, which is further detoxified by catalase or by enzymes of the glutathione peroxidase family using reduced glutathione. This complex enzymatic antioxidant system is completed by exogenous compounds such as arginine, vitamins A, C, E, β-carotene, glutathione, polyphenols, and minerals (selenium and zinc).

Oxidative Stress is Involved in Oncogenesis

There are several evidences that ROS play a key role in the oncogenesis process. In vitro exposure to chronic oxidative stress is associated with oncogenic ►transformation and tumor growth. Overexpression of NOX1 (the catalytic subunit of NOX) stimulates the generation of O_2^- and induces the transformation of mouse ►NIH 3T3 cells. Patients carrying specific polymorphisms on GSH-peroxidase 1 gene associated with decreased antioxidant activity present an increased risk of lung and breast cancers. An excessive production or a defective detoxification of ROS may favor the promotion and the development of cancer during chronic infection or ►inflammation which is considered to cause one third of world cancers.

The tumoral transformation induced by ROS, especially by $OH^{\bullet}$, is at least in part consecutive to their ►mutagenic effects. They can act directly on DNA structures leading to single- or double-strand breaks, to point and frame-shift mutations, and to chromosome abnormalities. ROS can also promote proliferation and survival of cancer cells and tumor angiogenesis by means of ►epigenetic effects. By altering activity of several tyrosine phosphatases, including ►PTEN and ►MAPK phosphatases, H_2O_2 activates mitogenic and survival pathways. This molecule has also been reported to stimulate ►VEGF production by tumor cells.

Increased Oxidative Stress in Cancer Cells

Under basal conditions of culture, various cancer cell lines produce more $O_2^{\bullet -}$ and H_2O_2 than nontransformed

cells. The presence of oxidative modifications of DNA in primary human cancer cells has also been demonstrated. The oxidative stress observed in cancer cells mostly results from the increase production of superoxide anion. The overexpression of ►Myc oncogene has been associated with increased production of superoxide by mitochondrial respiratory chain, while ►RAS oncogene mutations induce NOX activation. A decrease activity of antioxidant enzymes could also contribute to oxidative stress since tumor cells, compared with normal cells, often express lower levels of catalase, glutathione peroxidase, reductase and their respective cofactors.

The overproduction of ROS in cancer cells contributes to the genetic instability, leading to nuclear and mitochondrial DNA mutations and more aggressive phenotype. Thus, oxidative stress is part of a positive amplification loop where ROS induce malignant transformation and transformation is itself associated with more ROS production.

Therapeutic Perspectives of Oxidative Stress Modulation

Differential Effects of Oxidative Stress in Normal and Cancer Cells

Growing evidence suggests that ROS can induce a wide-type of cellular responses from proliferation to senescence and cell death. Adding increasing amounts of exogenous H_2O_2 or increasing its intracellular levels by overexpression of SOD leads to a dose-dependent decrease in proliferation and tumor cell death. H_2O_2 can stimulate proapoptotic signal molecules such as apoptosis signal regulating kinase 1, c-Jun-NH2-kinase, and p38; activation of the p53 protein pathway; startup of the mitochondrial apoptotic cascade. When adding ROS to cells culture media, differential cellular effects have been observed in normal and cancer cells. In normal cells, persistent ROS production leads to activation of the ►JNK pathway and apoptosis, whereas low concentrations or transient high levels of ROS induce the proliferation of those cells, through the activation of the ERK pathway. In sharp contrast, similar expositions to ROS cause tumor cell growth arrest and apoptotic death because of their high basal level of ROS that is close to the threshold of cytotoxicity. Thus, the fate of tumor cells exposed to oxidative stress is tightly correlated with the duration of ROS stimulation and depends on the basal redox status of the cell.

Use of Antioxidant Agents in Cancer Patients

Clinical data regarding the effects of antioxidant molecules in cancer patients have been controversial. Because oxidative stress induced DNA damages and is involved in malignant transformation, the hypothesis was made that antioxidant agents could have preventive effect against cancer. Numerous clinical trials were performed using various antioxidants (N-acetylcysteine (NAC), β-carotene, vitamin A, vitamin C, vitamin E, …), but failed to show any protective effect. Furthermore, a doubt has been cast on the possibility that some of these molecules, especially NAC might trigger tumor growth. These results should be viewed in light of the biological effects of antioxidants in cancer cells. Indeed, we previously observed that NAC, which is endowed with catalase and glutathione-like activities, decreases intracellular H_2O_2 concentration and increases the proliferation of tumor cells in vitro and in vivo, probably because tumor cells are submitted to detrimental oxidative stress.

Antioxidant molecules probably play a protective role against cancer in healthy individuals by preventing DNA damages linked to the oxidative stress. However, once cancer cells have emerged, a cancer-promoting effect could result from the administration of agents that decrease intracellular H_2O_2 level. Therefore, antioxidant should be used with caution in cancer patients.

Anticancer Agents Increase Oxidative Stress in Cancer Cells

The most commonly used anticancer agents, such as ►cisplatin, ►adriamycin, ►fluorouracil, ►irinotecan, or ►paclitaxel, are able to induce ROS production in cancer cells. Hydrogen peroxide and superoxide accumulation are observed within few hours of drug exposure and occur before the commitment of the cells into apoptosis. Moreover, antioxidants such as NAC and catalase are able to decrease their cytotoxicity. These results strongly suggest that oxidative stress is involved in the cytotoxicity of most anticancer agents. However, the underlining mechanisms seem to differ from an agent to the other. For example, ►5-FU and ►anthracyclins induce ROS production by a p53-dependent pathway involving the activation of several mitochondrial oxidoreductases such as proline oxoreductase and ferrodoxine reductase. On the other hand, membrane NOX activation is induced by ►paclitaxel and ►arsenic trioxide.

Tumor cells have higher levels of ROS than normal cells and could therefore be more sensitive to the additional oxidative stress generated by anticancer agents. This hypothesis offers a new explanation to the observation that anticancer agents are usually more toxic to cancer cells than to normal cells.

Finally, cellular antioxidant enzymes may influence the sensitivity of tumor cells to anticancer agents. Thus, high levels of reduced glutathione, the cofactor of glutathione peroxidase, in tumor cells have been associated with a ►multidrug resistance phenotype. A correlation was found between resistance of breast cancers to docetaxel and the overexpression of several genes controlling the cellular redox environment.

Using Oxidative Stress Modulators as Anticancer Agents

The fundamental differences between normal and tumor cells in terms of responses to H_2O_2 overproduction

provide new possibilities in the treatment of cancer, taking into account the tumor cell susceptibility to ROS-induced apoptosis. Overexpression of SOD in cancer cell lines induces an increase in H_2O_2 production and reduces tumor growth. However, the SODs are polypeptides of high molecular weight that are not able to cross the cellular membranes and therefore have a limited interest for clinical use. Several nonpeptidyl SOD mimics with lower molecular weight have been developed, such as (Cu(II)(3,5-diisopropylsalicylic acid)2) (CuDIPS), Mn(III) tetrakis(4-benzoic acid) porphyrin (MnTBAP), or mangafodipir. The SOD mimics increase the concentration of H_2O_2, resulting in the abrogation of tumor cells proliferation in vitro. Similar results have been observed in vivo.

Increasing the Therapeutic Index of Anticancer Agents by SOD Mimics

Several reports have suggested that compounds that increase intracellular hydrogen peroxide concentration could enhance the activity of anticancer agents. For example, buthionine sulfoximine (BSO), a glutathione synthesis inhibitor, can increase the cytotoxicity of melphalan by inhibiting glutathione peroxidase activity and increasing H_2O_2 level. Similarly, we previously showed that the antitumor activity of oxaliplatin and paclitaxel is enhanced by SOD mimics. A potential limitation to the clinical development of such compound is that they could also increase the toxicity of anticancer agents on normal cells. As an example, BSO depletes glutathione in both normal and cancer cells, increasing melphalan's hematologic toxicity and thus abrogating any enhancement of the therapeutic index of this anticancer agent. Mangafodipir has SOD-, catalase- and glutathione reductase-like properties, allowing it to act at multiple steps of the ROS cascade. We showed that mangafodipir protects mice treated with paclitaxel from developing leucopenia and also amplifies the antitumoral effect of paclitaxel on implanted tumor, increasing its therapeutic index. These opposite effects of mangafodipir in normal and cancer cells may be related to the differences in the redox status of these cells, as described above.

Clearly, oxidative stress modulators, especially SOD mimics, warrant further development in anticancer treatment.

Synonyms

Oxygen partial pressure distribution in tumor; Oxygen tension distribution in tumor; Oxygenation status and tumor oxygen level

Definition

Tumor oxygenation, which reflects the distribution of oxygen (O_2) partial pressures (pO_2 values) or O_2 concentrations, results from O_2 availability (O_2 supply) to the tumor tissue, the ►diffusional flux of O_2 from the microvessels to the cells and the ►respiration rate (O_2 consumption rate) of the parenchymal and stromal cells making up the tissue. O_2 supply is mainly influenced by the efficacy of blood flow, diffusional O_2 flux and blood hemoglobin (Hb) level.

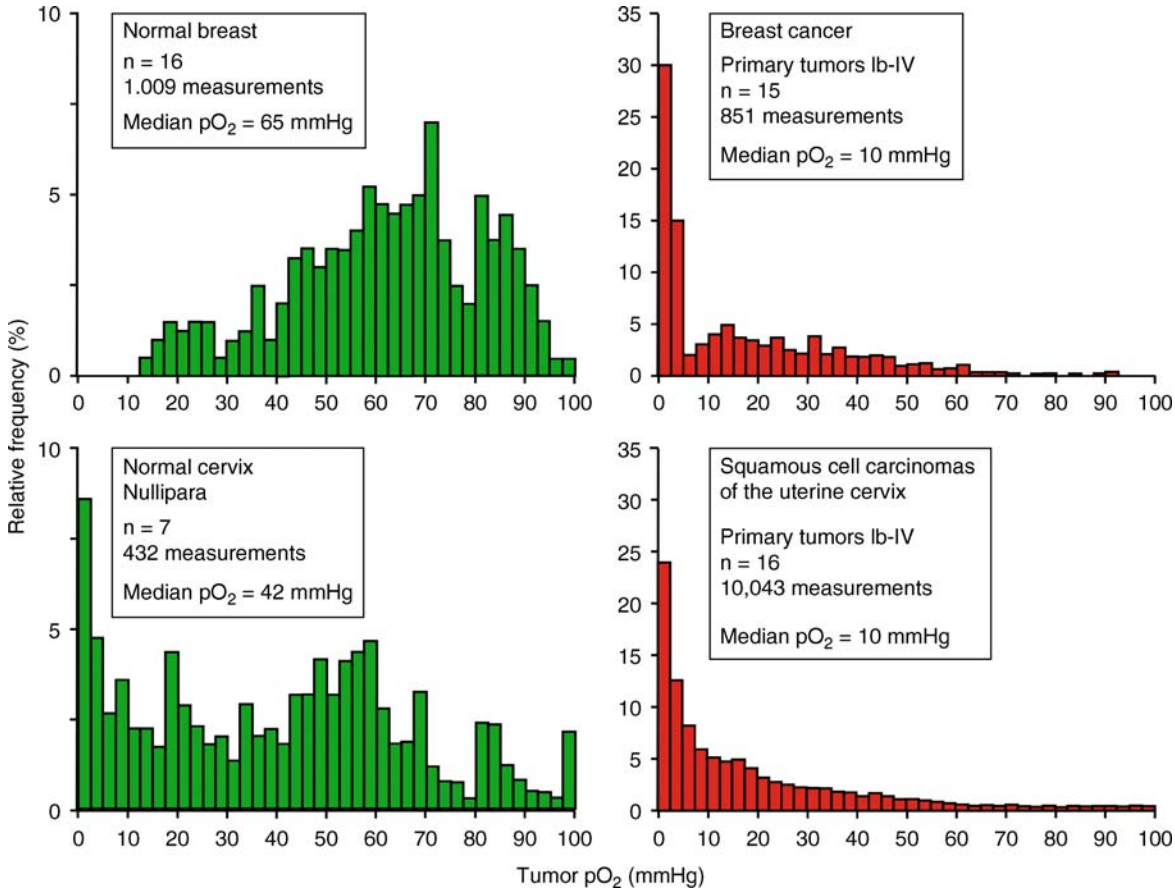
Characteristics

Whereas in normal tissues the O_2 supply meets the metabolic demands, in many solid tumors the respiration rate may outweigh an insufficient O_2 supply and result in the development of tissue areas with very low O_2 levels (►hypoxia, O_2 depleted tissue areas) or even areas completely lacking O_2 (►anoxia).

Considerable evidence demonstrates that in most human tumors oxygenation is compromised as compared to normal tissues, which are characterized by "normal" O_2 partial pressure distributions (►normoxia). Oxygenation is extremely heterogeneous within an individual tumor (intra-tumor heterogeneity). Furthermore, considerable heterogeneity of oxygen-depleted areas (hypoxic areas) has been shown between tumors of the same clinical size, stage, grade or histological type (inter-tumor heterogeneity). Tumor oxygen supply is not regulated according to the metabolic demand, as is the case in the physiological situation. On average, the median pO_2 values in tumors are substantially lower than in normal tissues at the site of tumor growth (Fig. 1). Tumor oxygenation is independent of clinical size, stage, grade, histology and various oncologic parameters or patient demographics. In some cancer entities, the oxygenation status significantly deteriorates in ►anemia (as a result of a decreased O_2 capacity of the blood) and at Hb concentrations above the median Hb level (most probably due to rheological problems within the chaotic tumor microvessels). Metastatic lesions seem to have an oxygenation status comparable to that of the primaries, whereas local recurrences have a poorer oxygenation status than the primary tumors.

Pathomechanisms of Tumor Hypoxia

Tumor hypoxia results from an inadequate O_2 delivery to the respiring neoplastic as well as stromal cells. Limited and even abolished O_2 supply is due to severe structural and functional abnormalities of the ►microcirculation, as well as due to a deterioration of diffusion geometry. In addition, cancer-related and/or therapy-induced anemia and carboxyhemoglobin formation (in heavy smokers) can lead to a reduced O_2 content of the blood. As a result, areas with very low (down to zero) O_2 partial pressures exist in solid tumors. These very low pO_2 microregions are heterogeneously distributed within the tumor mass and may be located next to regions with pO_2 values corresponding to the normal tissue from which the tumor has been derived. In



Oxygenation of Tumors. Figure 1 Oxygenation status of normal tissues (*left panels*) and solid tumors (*right panels*). Frequency distributions of measured pO_2 values (pO_2 histograms) for normal breast tissue and uterine cervix are compared with the respective cancer tissues (clinical stages Ib – IV). Oxygen partial pressures (pO_2) in the tissue were measured with a computerized polarographic microsensor technique which enables direct assessment of the pO_2 data with an O_2 sensitive needle-electrode. Oxygen partial pressures were measured along several electrode tracks in each individual tumor. Pooled data presented here are derived from pre-treatment measurements in conscious patients.

addition, significant temporal variations in the oxygenation status have been observed in tumors.

Methods of Measurement

Assessment of the tumor oxygenation status in experimental tumors and in the clinical setting has been performed using various techniques. So far, the most direct and often used method for description of oxygenation is the polarographic measurement of O_2 partial pressures. With this invasive microtechnique, frequency distributions (►histograms) of measured intratumor pO_2 values can be obtained with a relatively high spatial resolution. Other direct procedures include fiber-optic O_2 sensors and electron paramagnetic resonance oximetry. This latter technique is minimally invasive requiring only application of the paramagnetic material.

Measurement of intravascular oxyhemoglobin (HbO_2) saturation is another method that has the potential to allow a characterization of the oxygenation status of human tumors. However, it only provides information related to the vascular compartment and thus the situation in the extravascular space can only be inferred (e.g., BOLD-MRI).

Tumor oxygenation can be measured in tomographic images in the clinical setting upon inhalation of radiolabeled ^{15}O-gas in ►positron emission tomography (PET) studies. However, as with magnetic resonance imaging (MRI) procedures, limitations include poor quantification and sparse spatial resolution. The parameter measured with these non-invasive techniques is not directly interpretable as a tumor pO_2 value or O_2 concentration.

Non-invasive methods for detection of tumor hypoxia include the binding and the retaining of radiolabeled ►bioreductive drugs, such as fluoromisonidazole (labeled with ^{18}F and detected by positron emission

tomography) and iodoazomycin-arabinoside (labeled with ^{123}I and detected with single photon emission computerized tomography, SPECT).

Several techniques for assessment of tumor oxygenation require the analysis of tumor biopsy specimens. Using immunohistochemistry with exogenous hypoxia markers (such as misonidazole, pimonidazole, etanidazole or nitroimidazole-theophylline), detailed information concerning hypoxia at the cellular level can be obtained. Disadvantages include the need for injection of a hypoxia marker and possible sampling errors. The role of HIF-1α, GLUT-1 or CA IX as endogenous markers of tumor hypoxia is questionable.

Clinical Relevance

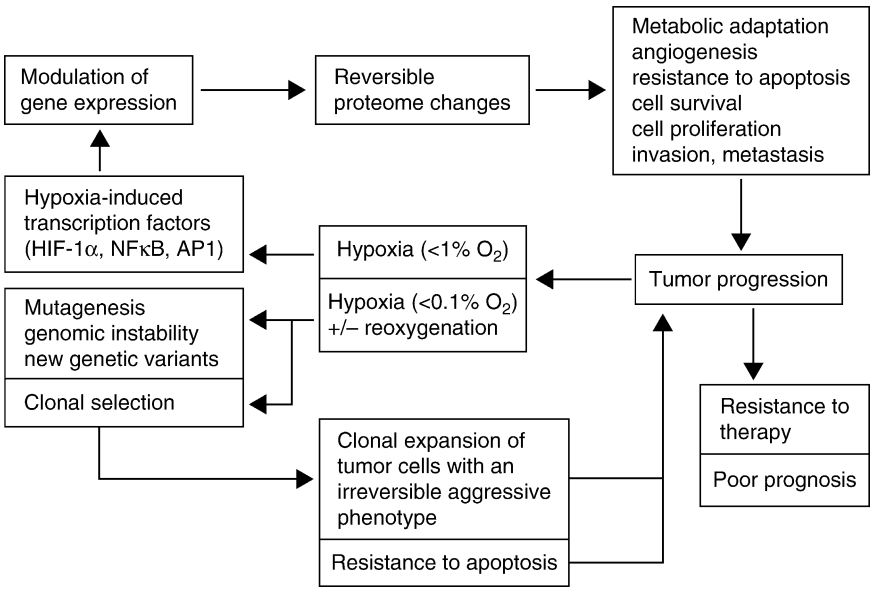
Tumor hypoxia has been considered to be a therapeutic problem since it renders solid tumors resistant to sparsely ionizing radiation (X- and γ-rays), some forms of chemotherapy (e.g., cyclophosphamide, carboplatin) and photodynamic therapy. Oxygen levels may furthermore influence a series of biological parameters, which in turn may markedly increase the malignant potential of a tumor irrespective of tumor treatment modalities.

Hypoxia is a common characteristic of locally advanced solid tumors that has been associated with malignant ►progression, that is, an increasing probability of recurrence, locoregional spread, and distant ►metastasis. Emerging evidence indicates that the effect of hypoxia on malignant progression is mediated by a series of hypoxia-induced proteomic (<1% O_2) and genomic changes (<0.1% O_2) leading to an activated ►angiogenesis, anaerobic metabolism, local invasive growth, metastasis, loss of apoptotic potential, and other processes that enable tumor cells to survive or escape their oxygen-deficient environment. The transcription factor ►hypoxia-inducible factor 1 (HIF-1) is a key regulator of tumor cell adaptation to hypoxic stress. Tumor cells with proteomic and genomic changes favoring survival under hypoxic conditions will proliferate, thereby further aggravating the hypoxia. Mutagenesis, genetic instability, the selection and expansion of new (and more aggressive) clones which eventually become the dominant tumor cell type, lead to the establishment of a vicious circle of hypoxia and malignant progression (Fig. 2). According to recent observations, malignant progression is most probably promoted by iterative cycles of hypoxia and reoxygenation episodes which have emerged as pivotal factors of the tumor pathophysiome.

Hypoxia-associated resistance to radio- and chemotherapy is multifactorial. Besides direct effects (e.g., DNA damage) and hypoxia-induced genome and proteome changes, indirect effects may also play a pivotal role. For example, inhibition of cell proliferation or tissue ►acidosis which often coincides with hypoxia in tumors that show a high glycolytic rate.

Tumor Oxygenation as a Prognostic Parameter

Clinical trials have been conducted in more than 700 patients with locally advanced cervical cancer, in squamous cell carcinomas of the head and neck and in soft tissue sarcomas. In these studies, pretreatment



Oxygenation of Tumors. Figure 2 Schematic representation of the mechanisms causing hypoxia-induced proteomic and genomic changes leading to tumor aggressiveness, malignant progression, treatment resistance, and poor prognosis.

tumor oxygenation has turned out to be a very powerful prognostic factor. Tumor hypoxia adversely affects locoregional control, disease-free survival and overall survival (cancers of the uterine cervix and head & neck tumors). This effect is independent of other known prognostic variables. Hypoxia also diminishes disease-free and overall survival in soft tissue sarcoma.

Modulation of Tumor Oxygenation

Manipulations of the tumor oxygenation status for therapeutic benefit have been performed for many years. A number of strategies to improve tumor oxygenation and to increase its uniformity have been considered. These include enhancing O_2 availability and/or reducing cellular respiration rate. The former can be achieved either by increasing the O_2 content in the tumor microvessels or by improving tumor blood flow. A reduction in the O_2 consumption rate would permit further diffusion of O_2 from blood vessels into distant cell layers to meet the needs of those tumor cells far away from the "O_2 source," i.e., from microvessels perfused with red blood cells.

Considering the data accumulated so far on strategies to improve tumor oxygenation, it seems unlikely that there is a single solution to overcoming tumor hypoxia. A more rational approach may be to combine a number of these means since many of the factors contributing to tumor hypoxia work in parallel rather than in series with one another.

p8; Candidat of Metastasis 1; NUPR1; *Homo sapiens* nuclear protein 1

Definition

The *p8* gene, first described as overexpressed in the ►pancreas during the acute phase of pancreatitis, encodes a ubiquitous nuclear and cytoplasmic ►stress protein. Expression of the p8 mRNA is rapid, strong and transient in response to several stresses. The human p8 gene was assigned to chromosome 16, at position p11.2, and the gene is organized in three exons interrupted by two introns. The sizes of exons I, II and III are 214, 150, and 329 nucleotides, respectively, and the complete mRNA sequence comprises 693 nucleotides (exclusive of the poly A tail) and has only one open reading frame.

Characteristics

The *p8* gene was cloned from human, rat, mouse, and *Xenopus laevis*, conceptually translated from the *Drosophila melanogaster* genome or deduced from EST libraries (*Bos taurus*, *Xenopus tropicalis*, *Zebrafish*, *Oryzias latipes*, *Bombyx mori* and *Paralichthys olivaceous*). p8 is a highly basic 82-aa polypeptide, with a theoretical molecular mass of about 8 kDa, containing a canonical bipartite domain of positively charged amino acids typical of ►nuclear localization ►signals (NLS) and a nuclear/cytoplasmic location has been demonstrated for human p8. Importantly, the nuclear or cytoplasmic localization of p8 depends on growth conditions. When cells are growing p8 is nuclear whereas it is at the cytoplasm when cell growth is arrested. The transport to the nucleus is ►ATP-dependant and localization is also regulated by its p300-dependent acetylation.

The p8 protein contains an N-terminal ►PEST region (Pro/Glu/Ser/Thr-rich), suggesting a regulation of p8 expression by the ubiquitin (Ub)/proteasome system. Homology searching in databases yielded no homology of p8 with other proteins of known function. Biochemical properties of the mammalian p8 proteins are a high isoelectric point (9.6–10.4), 14% of acidic amino acids, 20–24% of basic amino acids, 14–17% of phosphorylable amino acids (serine, threonine, and tyrosine), and a high abundance of proline (6–9%) and glycine (5–6%). The negatively charged residues appear located at the amino-terminal region, and all the positive residues accumulate in the carboxy-terminal portion of the molecule. All these features are shared by some of the ►high mobility group proteins (HMG), particularly by the HMG-I/Y, family. The overall identity of human p8 with human HMG-I/Y is only around 35%, but the molecular mass, isoelectric point, the percentage of Arg + Lys, Glu + Asp, Ser + Thr, Gly + Pro, hydrophilicity plot, and charge separation (despite a reverse orientation) are very similar. A characteristic property of these HMG proteins, also shared by p8, is that they are neither denatured by heating at 100°C, nor precipitated by 2% trichloroacetic acid. NMR and CD

analyses of p8 showed absence of stable secondary structure. The protein binds DNA weakly and is a substrate for protein kinase A (PKA). The phosphorylated p8 (PKAp8) has a higher content of secondary structure than the nonphosphorylated protein and PKAp8 binds DNA strongly. Moreover, secondary structure prediction methods indicated that within the high homology region of others proteins, there is a basic helix-loop-helix secondary structure motif, characteristic of some classes of ►transcription factors. An architectural role in transcription is proposed and several apparently unrelated functions have been ascribed to p8.

p8 is described as a stage-specific component of the gonadotrope transcriptome that may play a functional role in the initiation of LHβ gene expression during embryonic cellular differentiation. p8 is also a transcriptional regulator critical to two key cellular events in heart failure: cardiomyocyte hypertrophy and cardiac fibroblast matrix metalloproteases (MMP) expression. Furthermore, p8 is an important component of the defense program. For example, inactivation of the p8 gene increases liver sensitivity to CCl4 or increases sensitivity to systemic LPS treatment. Thus, p8 is an important element in the ►stress response. Finally, p8 and p53 are involved in an autoregulatory loop, p8 regulating p53 transactivation activity and p53 acting as a strong repressor of p8 expression. Also, p8 is involved in two major mechanisms, ►cell cycle regulation and ►apoptosis. To account for these various functions, it is suggested that the small size of the protein, its lack of ►specific tri-dimensional structure, and its nuclear-cytoplasm localization allow its interaction with several partners to target different signaling pathways. Several partners have been identified by yeast two-hybrid screening cDNA libraries.

Tumor Establishment and Progression

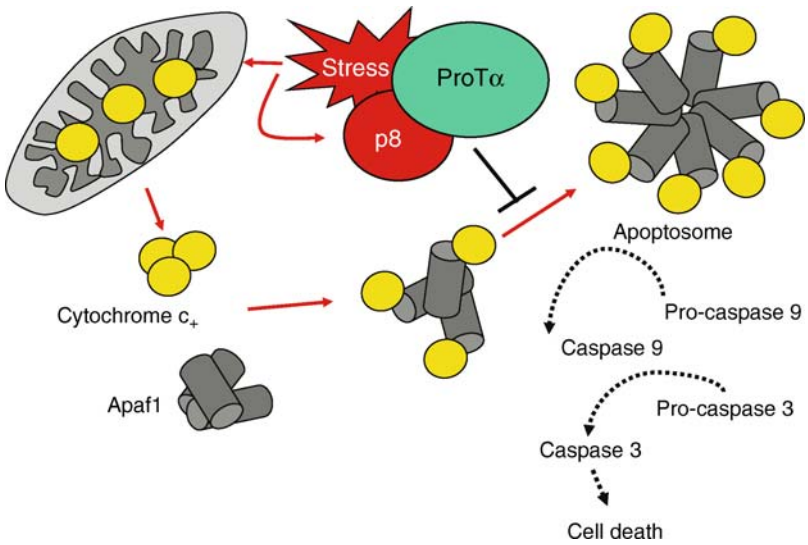
Tumor cells form ►metastasis to distant organs in a selective manner, and the organ specificity of the metastatic process is assumed to be governed, at least in part, by interactions between the malignant cells and local microenvironmental factors. It is currently admitted that development of metastases is primarily the result of the ability of disseminated tumor cells to initiate and continue growth in the target organ. In fact, cancer progression occurs in several steps; during transformation some cancer cells are positively selected within the tumor on the basis of their growth capacity, low response to apoptotic signals, and ability to escape the immunological survey of the host. After leaving the primary tumor, transformed cells migrate through the body. Yet, metastasis will not develop in all tissues. Capacity for invading the target organ is a first limitation. But once within the organ, metastasis will develop only if transformed cells can cope with their new microenvironment. Therefore, invading cells are exposed to the stress induced by the new microenvironment and their capacity to react by activating stress-associated genes should be determinant in metastasis formation. Supporting this hypothesis, several stress-associated genes were found overexpressed in tumors and their expression level often correlated with aggressiveness. Therefore, the stress-associated genes might facilitate tumor progression and metastasis formation by helping cell adaptation to the microenvironment of the host tissue. p8 is overexpressed in many human ►cancers. Its expression is crucial for tumor development and the stress-response mechanisms governed by p8 are required for tumor establishment and progression. Impossibility for p8-deficient cells to form colonies in soft-agar, to develop as subcutaneous tumors, or to generate intraperitoneal spreading strongly suggest that expression of p8 is required for the organization and development of tumors. Furthermore, p8 mediates the growth of tumor cells after metastatic establishment in a secondary organ, indicating that activated expression of p8 in metastatic cells is required for tumor progression. Some clinical data indicate that p8 expression in breast and pancreatic cancers correlates with aggressiveness and that metastatic cells express high levels of p8. However, the molecular mechanisms by which p8 allows tumor progression is still unknown but its contributions to cell cycle regulation and apoptosis are probably involved.

p8 and Cell Cycle Regulation

In response to stress agents, cells activate various intracytoplasmic pathways, depending on cell type and on the nature of the agent, that eventually reach the nucleus to modulate gene expression. By regulating genomic response, these stress-associated pathways will determine whether a cell re-enters the cell cycle, undergoes cell cycle arrest, or enters a cell-death program. *p8* is a stress gene, regulating cell cycle progression. It can act as a growth-promoting factor when it is overexpressed in pancreatic or HeLa cells or as a growth inhibitor when expressed in MEF (murine embryonic fibroblasts) or breast cancer-derived cells. These functions seem to involve regulation of the cyclin-dependant kinase inhibitor p27Kip1, in part through its interaction with JAB1.

p8 and Apoptosis

p8 expression has been inversely correlated to apoptosis in samples obtained from human pancreatic and breast cancers. According to this antiapoptotic effect, the interaction p8/Prothymosin alpha (ProTα), one of the molecular partners of p8, is very exciting. This ►natively unstructured protein was originally considered as a thymic hormone but, like p8, it was eventually attributed several other functions. p8 and ProTα are two



p8 Protein. Figure 1 p8 and prothymosin alpha (ProTα) are required for caspase inhibition in stressed cells. In response to apoptogenic stimuli, Apaf1 oligomerizes with cytochrome c to form the apoptosome that recruits and activates caspase 9 that, in turn, activates effector caspase 3. Following a stress p8 and (ProTα) complex impedes apoptosome formation, which prevents caspase 9 activation and blocks the apoptotic cascade.

small proteins without stable secondary structure in solution, showing opposite electrostatic charges at neutral pH. They interact and promote mutual stabilization of their structures in a particular conformation, the resulting p8/ProTα complex becoming able to block staurosporine-induced apoptosis. In other words, two natively unfolded proteins, p8 and ProTα, which had been attributed an antiapoptotic function, are in fact inactive if alone and require interacting with each other to exert that function, probably because the active complex has acquired stable secondary structure. Moreover, p8 is involved in the effect of ►gemcitabine, the only chemotherapeutic treatment presently available for pancreatic cancer. It was demonstrated that in pancreatic cancer cells, a large part of gemcitabine-induced apoptosis results from the inhibition of the constitutive antiapoptotic activity of p8 (Fig. 1).

p8 can also act as a proapoptotic protein. In fibroblast, the presence of p8 sensitizes cells to apoptosis induced by DNA damage. Moreover, recent works demonstrate a link between p8 and the antitumoral effects of ►cannabinoids. 9-tetrahydrocannabinol (THC) is the most abundant compound of *Cannabis sativa*, with potential therapeutic applications in patients with cancer. This antitumoral action of THC relies, at least in part, on its ability to induce p8 expression and subsequent p8-mediated apoptosis of tumor cells.

Conclusion

In conclusion, p8 is a small, highly basic and natively unfolded protein whose expression is induced by several stresses. p8 interacts with numerous partners to regulate transcription, cell cycle, and apoptosis. Functions of p8 depend on its molecular partner, its cellular location, the cell-type, and its level of expression. Of particular interest is its role on tumor development. Finally, p8 might be a new drug-targetable gene whose blockade would prevent cancer progression and metastasis development.

Definition

The p21 protein has been defined as an inhibitor of ►cyclin-dependent kinases (CDKs). Inhibition of this group of enzymes by p21 leads to the cessation of cell proliferation. Additionally, p21 also binds to and inhibits the activity of ►PCNA (proliferating cell nuclear antigen, which is a subunit of DNA polymerase), which results in the termination of DNA replication. Because both of these functions lead to cell cycle arrest, p21 is also called an inhibitor of the ►cell cycle.

Additional functions of p21 are known that are unrelated to its ability to inhibit cell proliferation. For example, p21 can regulate transcription, restrain ►apoptosis, impose on cell motility, interfere with cellular differentiation and ►senescence, act as cytoplasmic regulator of nuclear import, and may affect DNA methylation status. These multiple functions rely on different cellular localizations and different targets that are present either in the cytoplasm, in the nucleus, or on DNA. Because of this pleiotropic nature of p21 function, its traditional definition as a "CDK inhibitor" or "cell cycle inhibitor" is incomplete; the well-informed investigator should not consider p21 merely as an inhibitor of the cell cycle.

Characteristics

Because p21 has been discovered by diverse experimental approaches, it has received different suffixes, including wildtype p53-activated fragment 1 (Waf1), senescent-derived inhibitor-1 (Sdi1), CDK2-interacting protein (Cip1), CDK2-associated 20K protein (CAP20) or melanoma differentiation-associated protein (mda-6). Most commonly, it is called p21Waf1 ($p21^{Waf1}$) or p21Cip1 ($p21^{Cip1}$).

The p21 gene is called CDKN1A (cyclin-dependent kinase inhibitor 1A). It is composed of three exons that are located on human chromosome 6 (6p21.2). Its 2.1 kb transcript encodes a 21 kD polypeptide (hence its name), which consists of 164 amino acids. The p21 protein is primarily located in the nucleus, although it may relocate to the cytosol where it exerts important

functions as well. ►Orthologues of this gene have been cloned from mouse, rat, cat, and *Xenopus*, and are likely to exist in organisms as diverse as insects, plants and yeast.

Cell Cycle Inhibition by p21

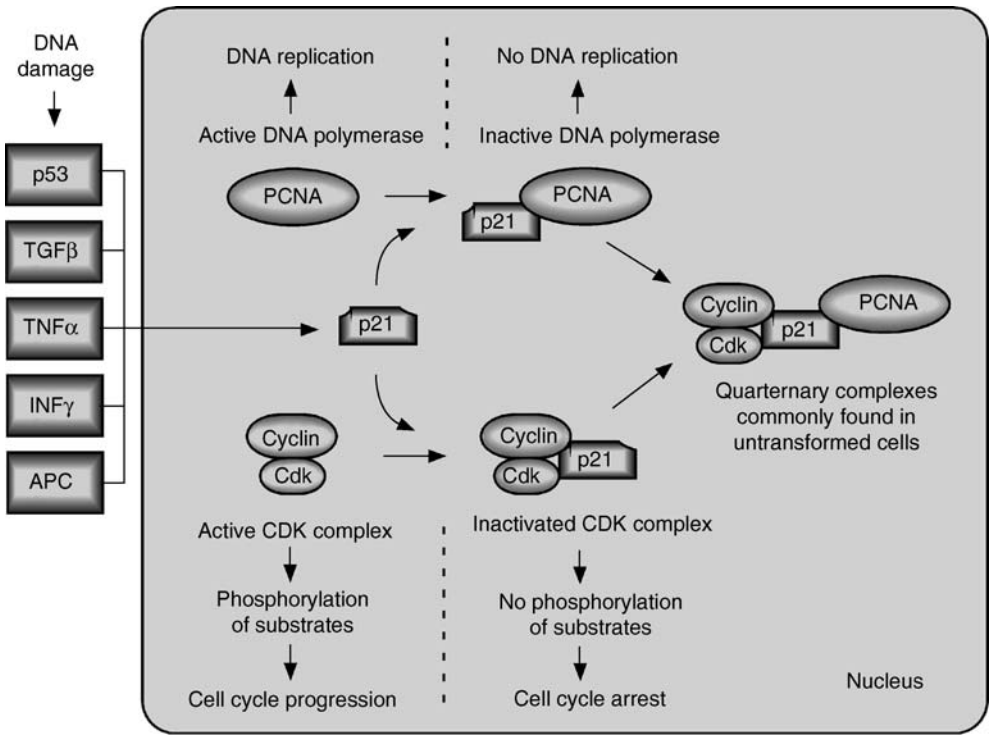
The activity of CDKs is required for cell cycle progression, while PCNA is essential for the execution of DNA replication. Therefore, the inhibition of CDK and PCNA activity by elevated levels of p21 causes cell cycle arrest, in that way defining p21 as a negative regulator of cell proliferation (Fig. 1). In extension, p21 has been implicated in several other processes that are related to cell growth, such as differentiation, senescence, and carcinogenesis.

The major targets of p21, the cyclin-dependent kinases, are considered the "engine of the cell cycle," and they direct the events required for cellular proliferation. Each CDK consists of two parts: one part is a cyclin protein (which acts as a regulatory subunit) and the other part is the actual cyclin-dependent kinase (cdk, which constitutes the catalytic subunit). The complex, composed of one cyclin subunit plus one cdk subunit, is called CDK. Several different ►cyclin proteins (cyclin A, cyclin B, etc.) as well as several different ►cdk (►cyclin-dependent kinases) subunits (cdk1, cdk2, etc.) exist and can combine to form different combinations of CDK heterodimers. For cell cycle progression and cell division to occur, the following CDK complexes are absolutely required: cyclin D together with cdk4 or cdk6 (cyclin D/cdk4 and cyclin D/cdk6), cyclin E/cdk2, cyclin A/cdk2, cyclin A/cdk1, and cyclin B/cdk1. The enzymatic activity of all CDK complexes, and thus their ability to drive cells through the cell cycle, is strictly regulated by post-translational modifications (phosphorylation and dephosphorylation) and by their interaction with inhibitory proteins, the cyclin-dependent kinase inhibitors (abbreviated CKI or CDI).

There are two families of ►CKIs:

- one is the Cip/Kip (CDK inhibitory protein) family that is constituted of p21 itself, p27Kip1, and p57Kip2
- the other is the INK4 (inhibitor of kinase 4) family, of which the tumor suppressor p16INK4a is the best-studied member.

While the INK4 proteins bind to and inhibit the activity of only two CDKs, namely cdk4 and cdk6, members of the ►Cip/Kip family are rather indiscriminatory and affect all of the further above mentioned CDK complexes. p21 in particular has been labeled as a universal inhibitor of CDKs.



p21 (Waf1/Cip1/Sdi1). Figure 1 Cell cycle-inhibitory function of p21.

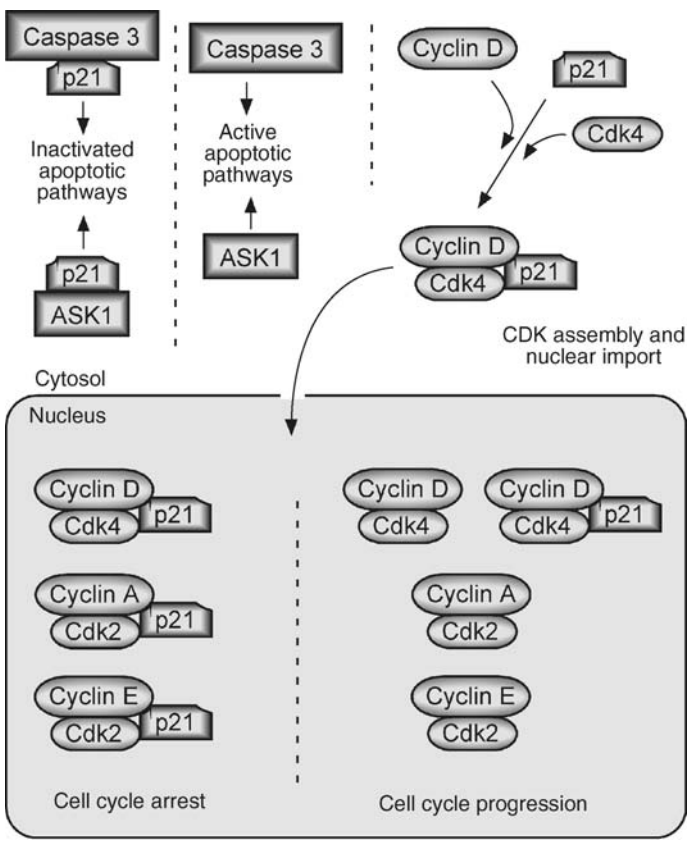
P

Positive Regulation of Proliferation by p21

The major critical function of p21, in particular at elevated expression levels, is the inhibition of CDK activity, which subsequently causes cell cycle arrest and inhibition of cell division. However, at rather low concentrations, p21 does not inhibit all CDKs with the same efficiency. In the case of cyclin E/cdk2 and cyclin A/cdk2, a single molecule of p21 is sufficient to completely inhibit the respective catalytic activity. Thus, in this instance, p21 fully conforms to its reputation as a potent CDK inhibitor. However, in the case of cyclin D/cdk4 and cyclin D/cdk6, two molecules of p21 are required for inhibition; at equimolar concentrations (one molecule of p21 plus one cyclin/cdk complex) p21 does not inhibit cyclin D/cdk4 or cyclin D/cdk6 activity. Rather, under these conditions, p21 stimulates the assembly and nuclear targeting of these complexes (Fig. 2). Moreover, the binding of p21 by cyclin D/cdk4 and cyclin D/cdk6 sequesters this inhibitor away from cyclin E/cdk2 and cyclin A/cdk2, thus indirectly promoting activation of these latter CDK complexes. As a consequence, the relatively low concentrations of p21, which are present in most cells, do not act cell growth inhibitory. For these reasons, the widely accepted definition of p21 as a general CDK inhibitor may have to be modified to accommodate its recognized role as a differential regulator of individual cyclin/cdk combinations.

p21's activity as an assembly factor for cyclin D/cdk4/6 is counter-intuitive and in contrast to its function as a CDK inhibitor. In this context, the complete repression of p21 repression of p21 leads to impairment of cell cycle progression due to decreased cyclin D/cdk4/6 complex formation. This outcome clearly does not support the simplified expectation that repression of p21 should result in growth promotion, as predicted from its traditional role as a CDK inhibitor. The biological rationale behind this aspect of p21 function is not yet completely understood, and further studies are required to illuminate this conundrum.

The p21 gene is a transcriptional target for multiple proliferation-inhibitory signaling cascades, including p53 (which can be activated in response to DNA damage), TGFβ (transforming growth factor beta), TNFα (tumor necrosis factor alpha), IFNγ (interferon gamma), or APC (adenomatosis polyposis coli) (Fig. 1).



p21 (Waf1/Cip1/Sdi1). Figure 2 Inhibitory and stimulatory functions of p21 protein.

p21 binds to the DNA polymerase subunit of ►PCNA and inactivates its DNA-replicative function. As a consequence, DNA replication, but not DNA repair, is blocked. p21 also binds to cyclin/cdk complexes and inhibits their enzymatic activity. As a result, the substrates of the cyclin/cdk complexes are not being phosphorylated, and the cells become arrested in the cell cycle. Thus, through the increase of p21 levels, the cells are able to stop proliferation. This process can be reversed: a reduction in the amount of p21 protein will release the inhibition of PCNA and of cyclin/cdk, and the cells resume growth.

Binding of p21 to Target Proteins

The CDK- and PCNA-inhibitory activities of p21 are functionally independent and reside in separate parts of the protein. The amino-terminal region, which is strongly conserved among the ►Cip/Kip family members contains distinct cyclin- and cdk-interacting domains; amino acids 17–24 (the Cy1 site) constitute the binding site for cyclin, whereas residues 53–58 (K site) in conjunction with amino acids 74 to 79 (the 3_{10} helix) contact the cdk. Thus, p21 simultaneously binds to both subunits of the CDK complex, whereby the interaction with the cyclin subunit serves to stabilize the ternary complex. As deduced from the crystal structure of the cyclinA/cdk2/p27Kip1 complex, the mechanism through which Cip/Kip proteins inhibit the kinase is through blocking the binding of ATP. This is achieved by a two-fold process: first, the inhibitor inserts a small helix inside the catalytic cleft of the cdk subunit that directly blocks ATP binding; second, the inhibitor causes a conformational change within the amino-terminal region of the cdk subunit that results in the loss of many ATP-interacting elements. Together, these processes result in the efficient, yet reversible, inhibition of kinase activity. It remains to be established why binding of one molecule of p21 to complexes containing cdk4 or cdk6 does not result in a similar inhibition of kinase activity.

Cytoplasmic p21 can bind to caspase 3 and ASK1 (apoptosis signal-regulating kinase 1) and thereby inhibit apoptosis (Fig. 2). Moreover, cytoplasmic p21 functions as an assembly factor that promotes the association of cyclin D with cdk4 (or cdk6) and supports nuclear entry of this complex, thereby stimulating cell cycle progression at low concentrations (Fig. 2). Increased levels of nuclear p21 inhibit cyclin A/cdk2 and cyclin E/cdk2 complexes, leading to cell cycle arrest.

In addition to modulating CDK activity, p21 protein is able to inhibit DNA synthesis through its ability to bind to and block the activity of ►PCNA, which is an accessory protein of the major replication enzymes DNA polymerase δ and ε. The interaction with PCNA is achieved via a high-affinity binding site that stretches from amino acids 143–160 in the carboxy-terminal domain of p21. As a result, p21 masks contact sites on PCNA that are required for interaction with other proteins of the polymerase assembly. The interaction of PCNA with DNA, however, is not impeded by p21 binding. It is interesting to note that by binding PCNA, p21 inhibits DNA replication but not DNA repair. Rather, it appears that p21 actually stimulates PCNA-dependent nucleotide excision repair. Thus, by interacting with PCNA, p21 executes a two-fold task: it blocks replicative DNA synthesis, which allows time for DNA repair to take place before the errors are duplicated, and at the same time it helps the repair to be executed.

Regulation of p21 Expression and Activity

Low amounts of p21 protein are present in most cell types. However, the expression levels can be increased significantly in response to a wide spectrum of diverse external stimuli and through the activation of different intracellular signal transduction pathways. In general, p21 expression can be regulated at multiple levels. The promoter of the p21 gene contains numerous binding sites for various transcription factors; most prominent among these is the tumor suppressor ►p53. In addition, enhanced expression of p21 can be mediated post-transcriptionally through the increased stability of its mRNA, and post-translationally through alterations in p21 protein half-life, degradation through the ubiquitin/proteasome pathway and cleavage by caspases. Moreover, the ability of p21 to interact with its respective targets can be modified by phosphorylation of p21, as well as by alterations in its subcellular localization.

The p21 protein contains a variety of phosphorylation sites that are targeted by several distinct kinases. The best characterized of these sites is threonine-145 (T145), which is phosphorylated by the pro-survival kinase ►Akt (also known as protein kinase B, PKB) and possibly also by protein kinase A (►PKA). As a result of T145 phosphorylation, p21 loses its ability to interact with PCNA and furthermore relocalizes from the nucleus to the cytoplasm. Restriction of p21 to the cytosol would be expected to severely limit its access to nuclear CDK complexes and thereby interfere with its ability to inhibit the cell cycle machinery; on the other hand, cytosolic p21 would be available to support the assembly of cyclin D/cdk4/6 complexes, which takes place in the cytosol. Although these consequences could not be demonstrated unequivocally in all cell types, they are entirely consistent with the growth-stimulatory and pro-survival role of Akt/PKB. In this context, it has been noted that p21 functions that take place in the cytosol are generally growth-stimulatory, whereas nuclear p21 dictates cell

cycle inhibitory outcomes, primarily via the inhibition of PCNA and CDK complexes, and the direct transcriptional repression of the cyclin B gene.

Besides T145, at least six additional phosphorylation sites have been described in the p21 protein: T57, S998, S130, S146, S153, and S160. Their precise functions are less well understood, but might play a role in regulating the interaction of p21 with other proteins and/or might impinge on its role as a transcriptional cofactor. Besides interacting with CDK complexes and PCNA, more than a dozen other proteins have been identified as binding partners for p21. Although many details remain to be established, it is evident that phosphorylation of p21 has profound consequences for its function. For instance, phosphorylation of serine-130 (S130) prevents the interaction of p21 with cdk2, which in effect neutralizes its function as a CDK and cell cycle inhibitor.

Role of p21 in p53 Pathway

The best understood regulation of p21 is in response to stress conditions that generate DNA damage, such as during cellular exposure to certain chemotherapeutic drugs, oxidants or irradiation. These insults activate the tumor suppressor ►p53 (►p53 Protein, Biological and Clinical Aspects), which binds to the p21 promoter and increases p21 expression. Elevated levels of p21 cause cell-cycle arrest and provide the cells with the opportunity to repair the DNA damage. In this sense, p21 exerts a protective function against stress, which relies on its ability to suppress cell proliferation. Cells that were engineered to lack the p21 gene have been found to inefficiently arrest in the cell cycle after DNA-damaging insults and are much more prone to cell death (apoptosis). Thus, p21 is a major executioner of p53 functions and contributes to cellular survival after exposure to harmful stimuli. In cells that are deficient in p53 function, as is the case in more than 50% of all human cancers, the transcriptional induction of p21 is not observed in response to many DNA-damaging agents.

Role of p21 in Differentiation and Senescence

The expression of p21 is highly modulated during the course of cellular differentiation and development. At least in some tissues, the exit from the cell cycle during terminal differentiation is mediated by p21, and this function of p21 is regulated by pathways that are independent of p53. Thus, these differentiation-inducing signals act through pathways that target transcription factors other than p53. One such factor is MyoD, which is a central regulator of myogenesis that induces myocytes to exit the cell cycle and fuse to form myotubes. A binding site for MyoD has been identified in the p21 promoter and shown to mediate p21 induction during myogenesis. Furthermore, the ability of p21 to be induced in a p53-independent manner has been established for various differentiation models in vitro as well as during development in vivo. From these studies it has been determined that the induction of p21 is a primary mediator of differentiation. Moreover, in the case of hematopoietic stem cells, p21 has been shown to be the molecular switch that keeps these cells in relative quiescence; proliferative restriction is critical to the survival of these cells as increased cycling causes their premature depletion.

Most normal cells that are cultured in vitro cease to proliferate after a finite number of doublings, a process called ►senescence. It has been shown that p21 accumulates as cell cultures age and approach senescence. In parallel with the increase in p21, the enzymatic activity of cyclinE/cdk2 complexes is decreased and PCNA activity is inhibited. In addition, probably through indirect mechanisms, p21 has been implicated in the negative regulation of ►telomerase, which is an enzyme that is required for the extension of cellular life span. In this regard, it has been shown that the inactivation of the p21 gene delayed cellular senescence, i.e., the cells underwent more doublings before they reached senescence. In other studies, it was shown that the experimental inhibition of p21 function in early senescent cells stimulated the cells to re-enter S-phase and replicate their DNA, although the cells did not undergo cell division. This finding is consistent with the fact that in early senescent cells, cyclinE/cdk2 complexes and PCNA are inhibited by p21. Upon removal of p21, both enzymes resume their function and drive cells through S-phase. Overall, p21 appears to be a critical initiator of the senescent process. However, once cells are fully senescent, other proteins, such as the CKI p16INK4a, take over for the long-term maintenance of this arrest.

Role of p21 in Apoptosis

The p21 protein protects cells from genotoxic and other cellular stresses. It was described above that after DNA damage, p53 transcriptionally activates the p21 gene, and elevated levels of p21 protein protect cells from apoptosis by arresting the cell cycle and permitting DNA repair. Moreover, cytoplasmic p21 can act as an anti-apoptotic component in a more direct manner (Fig. 2). It can bind to pro-caspase 3 and prevent its activation, thereby providing resistance to ►Fas-mediated apoptosis. Furthermore, p21 interacts with and inhibits the pro-apoptotic kinase ►ASK1 (apoptosis signal-regulating kinase 1), which phosphorylates p21 at serine-98 (S98). Both of these events are enhanced by the pro-survival kinase Akt/PKB (and possibly PKA), which phosphorylate p21 on T145,

thereby stabilizing the protein and maintaining its location outside the nucleus.

The pro-survival and anti-apoptotic function of p21, which is executed in the cytoplasm, seems to be in contrast to its primary nuclear function, which is inhibition of CDK and PCNA activity with ensuing cell cycle arrest and inhibition of cell growth. Thus, the tumor suppressor-like characteristics of nuclear p21 appear to conflict with its cytoplasmic purpose, which rather resembles typical oncoprotein function.

Tumor-Suppressing Function of p21

Clinical Relevance

In theory, every cyclin-dependent kinase inhibitor should be a tumor suppressor. By virtue of their ability to arrest cells in the cell cycle and prevent their proliferation, CKIs are crucial negative regulators of cell growth. The elimination of CKI activity, for example by mutation or deletion, should release CDK complexes from this form of inhibition and promote unrestricted, inappropriate cellular growth. Conversely, the artificially increased expression of CKIs in tumor cells, for example through a gene therapy approach, should lead to the cessation of tumor cell proliferation.

In reality, a tumor suppressor function of p21 has been difficult to prove. Unlike p16INK4a, which is a *bona fide* tumor suppressor and frequently found inactivated in human cancers, p21 has not yet convincingly revealed such a function. Efforts to find tumors that harbor mutations in the p21 gene yielded such events only at a very low rate. However, polymorphisms of p21 have been observed in various cancers and one of them (at position 149) was found to be associated with human esophageal cancer.

Initially, the generation of mice with a homozygous deletion of the p21 gene yielded disappointing results; these mice did not exhibit an increased rate of spontaneous tumor formation. This was surprising because p21 is one of the major executioners of the tumor suppressor p53, and mice without the gene for p53 have a rapid rate of early tumor formation. Nonetheless, keratinocytes that were established from the p21-deficient mice exhibited increased susceptibility to transformation by the ►ras oncogene, and the resulting tumors grew much more aggressively as compared to ras-transformed keratinocytes from mice that contained the normal p21 gene. Thus, it appears that the lack of p21 function contributes to the promotion of malignant tumorigenesis, and that the absence of p21 may become obvious and detrimental to cellular function only under conditions of stress, such as in response to genotoxins or aggravated growth-stimuli by oncogenes.

When artificially introduced and overexpressed in either normal or tumor cells, all CKIs tested to date cause cell cycle arrest. This effect could be useful in gene therapy-based treatments of human cancers in the future, after the numerous difficulties associated with gene therapy approaches have been solved. Two different approaches can be envisioned: First, CKIs could be used to complement defects in the tumor cells and either restore normal growth control or completely suppress tumor cell growth. Second, CKIs could be used to selectively, and reversibly, block the growth of only normal cells; this would permit the use of high doses of chemotherapeutic drugs to efficiently kill and eliminate the rapidly dividing tumor cells. The normal cells, due to their transiently arrested state, would be protected from the cytotoxic drugs. After termination of the chemotherapy, the elevated amount of CKI activity would have to return to pre-treatment levels in order to allow resumption of normal cell growth. Although still far from reality, such CKI-based gene therapy approaches could one day supplement our arsenal of anti-cancer weapons.

p53

Definition

Synonym: TP53; A protein encoded by a tumor suppressor gene that is frequently mutated in many types of cancer. This 53-kilodalton phosphoprotein mediates a key cell cycle regulatory checkpoint in response to DNA damage or activation of certain oncogenes and, thereby, is able to cause potentially cancerous cells to repair or destroy themselves.

Definition

The p53 family consists of ►p53 and its two homologues, p63 and p73. All three proteins are transcription factors that bind specific DNA sequences to mediate gene expression involved in cell cycle arrest, apoptosis, and differentiation. *p63* and *p73* map to chromosomes 3q27 and 1p36, respectively. The three p53 family genes and their protein products share many characteristics, including some "p53-like activities." However, some differences in structure and function suggest that each protein has unique roles in various biological and pathological processes from development to oncogenesis.

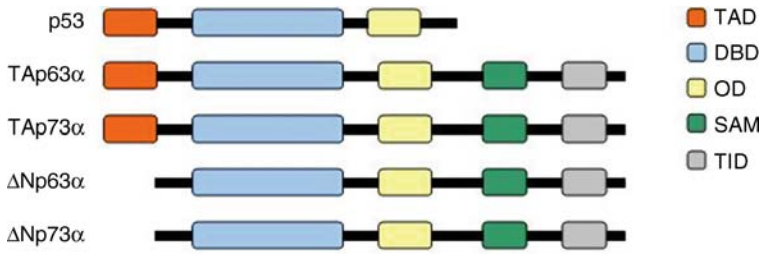
Characteristics

Molecular Structure and Function

In the late 1990s, two decades after the initial discovery of the ►p53 tumor suppressor protein, the p53 homologues p63 and p73 were identified. The *p63* and *p73* genes give rise to multiple mRNA, which are translated into several distinct isoforms (Fig. 1). Different isoforms result from the utilization of two promoters as well as alternative splicing. The three p53-family proteins have a common modular architecture with an N-terminal ►transactivation domain (TAD or TA), a ►DNA-binding domain (DBD), and an ►oligomerization domain (OD). The full-length p63 and p73 proteins that are translated from the first promoter are most similar to p53 and are referred to as TAp63 and TAp73, respectively. Like p53, TAp63 and TAp73 form oligomers and can induce apoptosis and cell cycle arrest. TAp63 and TAp73 regulate many of the same downstream target genes as p53 by binding to p53-responsive elements in genes such as ►*p21*, ►*PUMA* and *BAX*. In addition, some unique target genes have been identified for p63 and p73, likely reflecting different promoter binding sequence preferences as well as unique tissue patterns of expression. Known TAp63 and p73 target genes are summarized in Table 1.

p63 and *p73* also encode N-terminally truncated isoforms, ΔNp63 and ΔNp73, that lack the TAD. These ΔN variants are transcribed from the second promoter located within the third intron of both genes. Although the lack of TAD renders ΔN proteins transcriptionally inactive, they retain the ability to bind DNA and thus compete with transactivation-competent p53-family proteins for promoter-binding sites. They can also form ►hetero-oligomers with TA proteins, preventing the formation of functional tetramers. Therefore, ΔNp63 and ΔNp73 are not only unable to induce downstream target genes, but they can act as dominant-negative proteins that block TAp63, TAp73, and p53 activities and thus, have anti-apoptotic properties.

Alternative splicing at the C-terminus adds further to the complexity of p63 and p73, resulting in unique coding sequences (Fig. 1). The longest p63 and p73 proteins (p63 and p73 alpha) have a ►sterile-α-motif (SAM) domain not found in p53. SAM domains are known to serve as protein-protein interaction modules, raising the possibility that p63 and p73 splice variants with SAM domains are capable of recruiting isoform-specific binding proteins. A transcriptional inhibitory domain (TID) is also found in a subset of the different C-terminal isoforms. Thus, differential splicing of the C-termini influences the ability of these proteins to



p53 Family. Figure 1 The structure of the p53-family of proteins. Shown are the transactivation (TAD, orange), DNA-binding (DBD, blue) and oligomerization (OD, yellow) domains for p53, p63 and p73. These p63 and p73 domains show significant homology to p53 (TAD, ~25%, DBD ~60%, and OD ~40%). Alternative splicing at the C-terminus of p63 and p73 generates multiple isoforms (p63 α, β, γ and p73 α, β, γ, δ, ε, Φ, ζ, η) that are identical through the OD. The longest p63 and p73 isoforms (alpha) are shown in the figure and contain a SAM (green) and transinhibitory domain (grey) not found in most other C-terminal isoforms.

p63 and p73 can induce many p53-target genes that are involved in cell-cycle arrest and apoptosis (upper panel). However, both proteins can also upregulate novel target genes that cannot be activated by p53 (lower panel). Noted in parentheses are genes only regulated by p63 or p73, but not both.

transactivate target genes. For example, in comparison to TAp63α, TAp63γ more strongly induces downstream pro-apoptotic genes. Thus, the differences in coding sequences and isoform specific binding partners result in different activities of the various isoforms.

Various upstream pathways and stimuli, including DNA damaging agents and oncogenes, such as ►E2F1 and ►Ras, regulate the expression and stability of p63 and p73 isoforms (summarized in Table 2). In addition, like p53, p63 and p73 are regulated by post-translational modifications including phosphorylation, acetylation, and ubiquitination. Interactions with binding partners, such as ►p300 and ►MDM2, as well as heterotypic interactions with each other, further modulate the activities of the p53-family proteins.

Roles in Development

Unlike p53, which is ubiquitously expressed, p63 and p73 are expressed in a tissue-specific fashion and each play roles in critical developmental processes. In contrast to p53 null mice in which only a small percentage have developmental defects in neural tube closure, p63 and p73 mutant mice have significant developmental abnormalities. *p63*−/− mice that lack all TA and ΔN isoforms have significant limb and craniofacial malformations as well as failed development of epithelial tissues including the skin. In humans germline *p63* mutations have been detected in patients with characteristics reminiscent of the *p63* knockout mice. Heterozygous *p63* mutations have been found in 6 different human ►ectodermal dysplasia syndromes characterized by combinations of skin, hair, mammary gland, craniofacial and limb abnormalities. Studies into these disorders have provided important clues as to which tissues express p63 and have revealed that p63 is essential in epithelial morphogenesis and involved in senescence. Studies of *p73*−/− mice have demonstrated that ΔNp73 is crucial in the development of the nervous system. *p73* knockout mice have significant neurologic abnormalities due to the absence and/or loss of specific populations of neurons. ΔNp73 promotes cell survival by the inactivation of the full-length p53 family proteins and thus, the loss of ΔNp73 leads to enhanced apoptosis in ►cortical and ►sympathetic ganglia neurons. The relative balance between the TA and ΔN forms of p63 and p73, as well as p53, are important in these developmental processes and similarly, in cancers that arise from these tissues.

The p53-family is regulated by a number of proteins and signaling pathways. These upstream regulators can affect the p63 and/or p73 at the transcriptional or the post-translational level. Some regulators have been shown to affect all three p53-family members (denoted with *).

Role in Cancer: Tumor Suppressor or Oncogene?

The high incidence of p53 mutations in human tumors coupled with the chromosomal locations of *p63* and *p73* led to the prediction that p63 and p73 were also tumor suppressor genes that are inactivated by mutations in certain human malignancies. Surprisingly, despite the functional similarities among the p53 family proteins, and specifically their ability to induce p53-responsive pro-apoptotic genes, only rare *p63* and *p73* mutations have been detected in both cell lines and primary tumors. Although the lack of mutations initially raised doubts as to whether these two genes have roles in human cancers, many studies have reported high levels of p73 and p63 expression in human cancers. However, many of these studies did not distinguish between the various isoforms. More recent evidence from mouse models and human tumors suggests that the relative expression levels of the different TA and ΔNp63 and p73 isoforms are important in tumor development and progression, as well as the response to treatment.

Knockout mice lacking one or both copies of p53, as well as mice that express specific p53 point mutations, develop a wide range of tumors at a young age. In contrast, *p63*+/− and *p73*+/− mice develop pre-malignant and cancerous lesions only when aged. Furthermore, in *p53* mutant mice, the additional loss of *p63* or *p73* leads to different tumor types, and higher tumor burden with more metastatses. Importantly, tumors from p63 or p73 heterozygous mice were shown to have ►loss of heterozygosity (►LOH) of the remaining allele, suggesting that p63 and p73 have recessive properties of a classical tumor suppressor gene. However, the relative contribution of the different TA and ΔN isoforms is difficult to determine since these knockout mice lack the expression of all p63 or p73 isoforms.

Loss of p63 and p73 has been described in several human tumor types. Loss of p63 expression is associated with bladder cancer progression and correlates with poor prognosis. TAp73 silencing by methylation in leukemias and lymphomas has also been described. Furthermore, low expression of p63 and p73 has been reported in breast cancer due to a number of mechanisms including LOH and allele silencing.

In addition to missense mutations, p53 is inactivated by binding to inhibitory proteins such as the papilloma virus E6 oncoprotein in cervical cancer and MDM2 in sarcomas. While TAp63 and p73 can likewise bind to MDM2, as well as other modulatory proteins such as MDMx, iASPP, YAP and PML (see Table 2), the relative role of these complexes in human cancers has not been elucidated. However, there is growing evidence that inactivation of the putative tumor suppressor TA forms of p63 and p73 is mediated by hetero-oligomerization with a subset of p53 mutant proteins found commonly in tumors. These mutants include the p53 conformational mutants with "►gain-of-function" properties. These mutant p53 proteins bind to and inhibit TAp63-and TAp73-dependent transactivation and apoptosis, leading to enhanced survival and growth. Furthermore, this binding affinity of mutant p53 for TAp73 is influenced by the status of a p53 polymorphism at codon 72. In certain tumors, such as head and neck squamous cell carcinoma presence of arginine, instead of proline, at p53 codon 72 is associated with worse prognosis due, at least in part, to more potent binding to TAp73. Therefore, although cancer-associated missense changes are almost never found in the new p53-family members, other mechanisms exist to inactivate the tumor suppressor like forms, TAp63 and TAp73.

Ironically, despite the focus on p63 and p73 as tumor suppressors, there is perhaps more evidence supporting roles for ΔNp63 and p73 isoforms as oncogenes. Amplification of the genomic region encompassing *p63* and overexpression of the ΔNp63 protein have been detected in several epithelial-derived tumors. In head and neck squamous cell carcinomas (HNSCCs)

and breast cancers, ΔNp63 promotes the survival of transformed cells by blocking TAp73-dependent apoptosis. Thus, ΔNp63 behaves as a potent oncogene and highlights how perturbations in the equilibrium between ΔN and TA p63 and p73 proteins are important in tumorigenesis. Whether this holds true for other tumors that express high p63 levels including cervix, nasopharynx and bladder, remains to be determined.

Much like p63, p73 is but highly expressed in several types of human malignancies. Overexpression of p73 has been reported in numerous cancer types including neuroblastoma, breast, lung, esophagus, bladder, ovarian, liver, colon and certain types of leukemias. There is emerging evidence that when carefully studied, like p63, the upregulation of the ΔNp73 forms are relevant in the pathogenesis of these cancers. However, to date specific overexpression of ΔNp73 transcripts and/or protein has only been shown in a few tumor types including mesenchymal or precursor-derived tumors such as rhabdomyosarcoma and neuroblastoma as well as breast, colon and hepatocellular carcinomas. The tissue specificity of these findings is likely due to the fact that p73 has a restricted pattern of expression throughout development. The mechanisms responsible for p73 overexpression and specific mechanism(s) by which ΔNp73 promotes cancer development remain unknown. However, there is some evidence that ΔNp73 promotes immortalization of primary cells and can cooperate with oncogenes such as Ras to enhance transformation. Furthermore, the binding of ΔNp73 to p53 andTAp73 and TAp63 has been proposed to modulate differentiation in neuroblastoma and rhabdomyosarcoma.

Clinical Relevance p63 and p73-Prognosis and Chemosensitivity

Evidence in cell and animal systems supporting a role for the different isoforms in tumorigenesis has led to the assessment of p73 and p63 expression as a marker for clinical prognosis. The relative ratio of TA versus ΔN isoforms as measured at the transcript level is linked to prognosis in several tumor types, including breast and colon cancers. High levels of ΔNp73 protein have also been correlated with poor prognosis in small series of patients with neuroblastoma and breast cancers. Immunohistochemistry for p63 has also begun to be used as a marker in several tumor types including prostate and breast. However, large analyses of primary tumor samples will be required to determine if the relative expression of TA and ΔN isoforms of p63 and p73 can be linked to clinical prognosis. Nevertheless, roles for these two p53 family proteins in the response to DNA damaging agents such as chemotherapies suggest that their expression has important therapeutic implications.

Currently, the two major treatments for cancer, radiation and ►chemotherapy, both exert their cytotoxic effects by stabilizing and activating p53. However, these therapies are also capable of killing cancer cells harboring p53 mutations, suggesting that p53-independent mechanisms exist to initiate apoptosis. Many studies support a role for the p53 family proteins in chemosensitivity. TAp73 is induced by ►γ-irradiation and many chemotherapeutic drugs and in a variety of cancer cell types, including those with mutant and wild-type p53. Studies using cells in which p73 or p63 is inactivated by genetic deletion, use of dominant-negative proteins, and short interfering RNA (►siRNA) demonstrate that loss of p63 or p73 leads to chemoresistance. Similar to their effect on p53 many chemotherapies also induce p73 and p63 post-translational modifications that stabilize and enhance their ability to induce apoptosis. These include c-abl mediated phosphorylation in response to cisplatin and irradiation. p73 is also upregulated at the transcriptional level by some drugs. For example, doxorubicin treatment leads to E2F1 mediated induction of TAp73. Similar to p53, TAp73 and TAp63 mediate the expression of genes that control cell-cycle arrest and apoptosis (Table 1). Thus, in response to anti-cancer treatments, TAp73, and perhaps TAp63, can substitute for and in certain cases, cooperate with other p53 family proteins to eradicate transformed cells and promote tumor regression.

The interactions among the p53 family proteins also modulate their ability to induce chemotherapy induced apoptosis. The expression of various tumor derived p53 mutant proteins leads to chemoresistance via the ability of these mutant proteins to bind to and inactivate TAp73 and p63. Experiments in cell lines demonstrate that manipulation of the levels of these p53 mutant proteins by overexpression or siRNA leads to chemoresistance or chemosensitivity, respectively. Some chemotherapies also affect the levels of ΔNp73 and p63. Furthermore, overproduction of ΔNp73 or ΔNp63 in cell lines also leads to chemoresistance, and this is likely due to hetero-oligomerization and inactivation of the full length p53 family proteins. This paradigm has been best studied in head and neck squamous cancers where downregulation of ΔNp63 in response to cisplatin results in diminished ΔNp63-TAp73 complex formation and enhanced apoptosis. Given the importance of ΔN proteins in cancer cell survival, this represents a second potential mechanism through which chemotherapeutic drugs induce apoptosis. Although the mechanisms by which chemotherapies downregulate ΔNp63 and p73 are not known, it is clear the balance between ΔN and TA proteins, as well as mutant forms of p53, are important determinants of chemosensitivity of tumor cells.

Given the importance of p53 in tumor suppression, ►small-molecule inhibitors are actively being designed

to activate p53. However, since p53 is non-functional in approximately half of all human cancers recently there has been interest in developing therapeutic strategies to activate p73 and p63 to induce tumor cell death. Several different approaches might lead to enhanced p73 or p63 activity. Panels of drugs and small molecules can be screened for agents that either directly increase TAp73 or p63, or enhance their activation by upstream pathways (e.g. via E2F1 activation). Furthermore, in tumors with high levels of ΔNp73 or ΔNp63 strategies might be aimed at donwregulating these anti-apoptotic isoforms. Drugs that interfere with proteins that inactivate TAp73 and p63 can also be targeted. To this end, small peptides have been designed to modulate the interactions between the iASPP proteins and p63 and p73. Furthermore, therapeutic strategies using drugs and siRNA designed to interfere with the interaction between "gain of function" mutants of p53 and TAp73 have been successful in vitro. Finally, many drugs have been designed to interfere with p53 binding to its negative regulator MDM2. It is predicted that some of these drugs might also interfere with MDM2 binding to TAp73 and TAp63, raising the possibility that these small-molecule inhibitors may be useful for a broad spectrum of cancers.

Concluding Remarks

Since their discovery, studies of p63 and p73 have been focused on comparisons to p53. While the prospect of TAp63 and TAp73 compensating for the loss of p53 in tumor suppression and treatment is exciting, it is equally important to recognize very significant differences in their roles in both cancer and development. Not all tissues and cancers exhibit the same expression pattern of p63 and p73. The levels and balance between the various pro and anti-apoptotic p53 family proteins appear to play important roles in both development and cancer. Given the importance of p63 and p73 in physiological apoptosis as well as in tumors and their response to chemotherapies, understanding how they function will likely lead to the development of better cancer treatments.

Definition

P-glycoprotein (Pgp), the product of the human ►MDR1 gene responsible for a major form of ►multidrug resistance in tumor cells, is a transmembrane protein that carries out ATP-dependent efflux of various lipophilic compounds, including many anticancer drugs. Pgp renders tumor cells resistant to such drugs, and Pgp expression has been shown to correlate with clinical drug resistance or negative prognosis in several types of cancer.

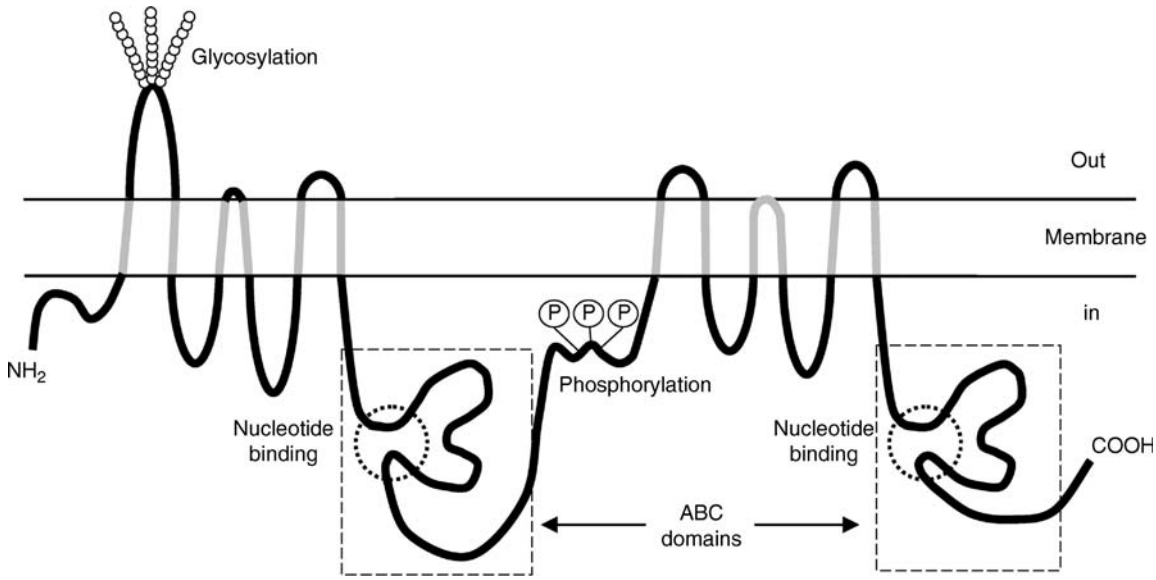
Characteristics

The best known form of multidrug resistance in mammalian cells involves cross-resistance to a large group of lipophilic drugs with different structures and mechanisms of action. Cellular targets of such drugs include microtubules (►vinblastine, ►vincristine, ►taxol, ►colchicine), ►topoisomerase II (►doxorubicin, ►etoposide), RNA polymerase (►actinomycin D), ribosomes (puromycin), plasma membrane (gramicidin D) and mitochondria (rhodamine 6G). This multidrug resistant phenotype is due to increased expression of the gene termed MDR1 (multidrug resistance 1). Expression of the MDR1 gene in drug-sensitive cells is sufficient to produce the full pattern of multidrug resistance. Rodent cells carry two homologs of the human MDR1 gene, both of which confer multidrug resistance. Another member of the MDR gene family, which is alternatively called MDR2 or MDR3 in humans, is closely related to MDR1 but does not confer detectable multidrug resistance (the product of the gene functions as a phosphatidylcholine translocase).

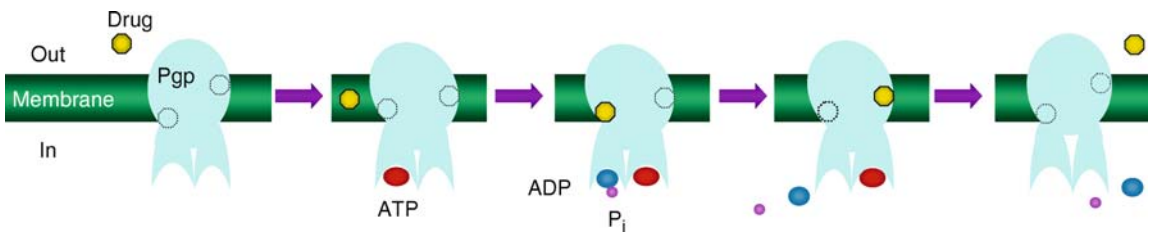
The resistance of MDR1-expressing cells was shown to result from decreased intracellular accumulation of the drugs, associated with an increased rate of drug efflux. Many lipophilic fluorescent dyes (e.g. Rhodamine 123, Hoechst 33342, calcein AM) also show decreased accumulation in MDR1-expressing cells. The exclusion of such dyes provides a convenient approach to the detection of multidrug resistant cells. The MDR1 gene encodes a glycoprotein with a mobility of ~170 kD. This protein was originally found to be elevated in the membranes of multidrug resistant cell lines and was termed P- (for permeability) glycoprotein (Pgp). Pgp, encoded by the human MDR1 gene, contains 1,280 amino acids and consists of two similar halves separated by a short linker region containing multiple charged residues and phosphorylation sites (Fig. 1). Each of the two halves of Pgp contains a N-terminal hydrophobic and a C-terminal hydrophilic region. Each hydrophobic region includes six membrane spanning α-helices. The transmembrane segments were originally deduced through hydrophobicity analysis and subsequently confirmed by epitope mapping studies. Some studies suggest, however, the existence of one or more alternative transmembrane orientations for Pgp, which may coexist with the orientation shown in Fig. 1. Pgp conformation can be altered through the binding of different ligands, as indicated by differential immunoreactivity, altered patterns of proteolytic digestion and some other assays. However, it is unknown whether these conformational transitions involve changes in the transmembrane orientation of Pgp.

The hydrophilic regions of Pgp contain nucleotide binding sites and display the characteristic sequences of the ATP-binding cassette (ABC), a conserved domain shared by a large superfamily of proteins known as ►ABC transporters. Some other ABC transporters are also involved in multidrug resistance, including the ►multidrug-resistance protein (MRP) family and the MXR/BCRP/ABCP1 protein. The ABC domains of Pgp are responsible for its ATPase activity, which enables the pumping of Pgp transport substrates against the concentration gradient (Fig. 2). The ATPase activity of Pgp is strongly stimulated by many of its transport substrates. The presence of functional nucleotide binding sites in both ABC domains is required for both the ATPase activity and the drug efflux by Pgp.

All the documented Pgp transport substrates are lipophilic or amphiphilic, but not all the lipophilic compounds are transported by Pgp. A common functional feature of Pgp substrates is their entry into a cell by passive diffusion through the lipid bilayer and not through a specialized carrier. In agreement with this



P-glycoprotein. Figure 1 Scheme of the two-dimensional structure and transmembrane orientation of Pgp.



P-glycoprotein. Figure 2 A simplified hypothetical scheme of drug efflux by Pgp.

mode of uptake, there is substantial evidence that the initial binding of many substrates to Pgp occurs within the lipid bilayer rather than on the cytoplasmic surface of the plasma membrane. Photoaffinity labeling assays have implicated the transmembrane domains of Pgp as the primary sites for substrate binding. The ability of Pgp to transport different substrates can be increased or decreased by point mutations of specific amino acid residues. Most (but not all) of such residues localize to transmembrane domains. Mutations that affect the specificity of Pgp-mediated transport were found to affect substrate binding or release and the ability of individual substrates to stimulate the ATPase activity of Pgp.

In addition to its function as an efflux pump for different lipophilic compounds, Pgp was shown to act as a short chain lipid translocase in the plasma membrane. Pgp also confers resistance toapoptosis induced by different agents (which need not be transported by Pgp), through an unknown mechanism. Other changes associated with Pgp expression in some cell lines include stimulation of volume regulated chloride channels, alteration of intracellular pH and increased ATP release. However, the putative role of Pgp in these phenomena requires further documentation.

Expression

Pgp is normally expressed in a variety of human tissues, including the adrenal cortex, lumenal surfaces of the kidney, liver, colon and jejunum, and endothelial capillaries of the brain, testes and papillary derma. It is also expressed in placental trophoblasts, in certain types of lymphocytes (particularly CD56-positive ►natural killer cells and CD8-positive T-cells) and in early hematopoietic progenitor cells of the bone marrow, where Pgp expression is positively correlated with the stem cell marker CD34. Analysis of mice with a knockout of one or both of their MDR1 homologs revealed some of the physiological functions of Pgp. Pgp ►knockout mice show a large increase in the accumulation of different drugs in the brain, indicating that Pgp in brain endothelial capillaries plays an important role in the blood-brain barrier. The knockout mice also show an increase in drug accumulation in the intestine and cardiac tissue, indicating that Pgp plays a physiological barrier role in several types of tissues.

Cellular and Molecular Regulation

Overexpression of Pgp in multidrug resistant cell lines, isolated after multistep selection with chemotherapeutic drugs, is frequently associated with the ►amplification of the MDR1 gene. Such amplification, however, appears to be specific for in vitro selection, since it occurs rarely if at all in Pgp expressing tumors. Similarly, point mutations of the MDR1 gene that increase its ability to transport specific drugs have been found in vitro but not in vivo. Another mechanism of MDR1 gene activation in vitro involves genetic rearrangements that bring the previously silent MDR1 gene into proximity with a strongly transcribed gene, sometimes providing MDR1 with an alternative transcription initiation site. There is evidence that such rearrangements may also occur in certain lymphoid malignancies. In most cases, however, increased MDR1 mRNA expression does not involve any detectable genetic changes. Several in vitro studies and in vivo observations with tumors undergoing chemotherapy indicate that the MDR1 gene can be activated epigenetically in response to different forms of cytotoxic stress or after treatment with ►protein kinase C-inducing agents. This activation may occur both at the level of transcription and of RNA stability. In particular, two CCAAT box-binding proteins, NF-Y and YB-1, were reported to mediate the induction of the MDR1 promoter by genotoxic stress, but it is still unknown to what extent these transcription factors are responsible for MDR1 activation during cancer chemotherapy.

At the protein level, Pgp undergoes post-translational modification through N-linked ►glycosylation in the first extracellular loop and ►phosphorylation by protein kinase C and protein kinase A in the linker region (Fig. 1). Neither of these Pgp modifications appear to be essential for the drug efflux function, as indicated by the activity of glycosylation- or phosphorylation-deficient mutants of Pgp in drug resistance assays. The phosphorylation mutants, however, show some quantitative changes in the stimulation of their ATPase activity by Pgp transport substrates. Another potential level of Pgp regulation is suggested by the observed variability in the percentage of Pgp that localizes to the plasma membrane (as opposed to Golgi or endoplasmic reticulum) in different cells. Modulation of the Pgp transport to the plasma membrane may represent another mechanism of its regulation.

Clinical Relevance

Pgp expression in clinical cancers has been extensively analyzed both at the RNA and protein level. These studies showed that, with regard to Pgp expression, most tumors can be divided into two classes. The first class is represented by those tumors that arise from Pgp expressing normal tissues, such as renal cell carcinomas, hepatomas, adrenocortical tumors or colorectal cancers. Pgp is commonly expressed in such tumors whether treated or untreated, and Pgp levels in some of these cancers show a positive correlation with morphological differentiation. ►Acute myeloid leukemias (AML) may also belong to the same category. As stated above, Pgp expression in normal hematopoietic progenitor cells correlates with the expression of the ►stem cell marker ►CD34, and similar correlations for CD34 and Pgp were also reported in AML. Higher Pgp expression in more primitive hematopoietic cells might also account for the high levels of Pgp observed in the blast crisis of chronic myelogenous leukemia, in contrast to low or undetectable expression in the chronic phase.

The second class of tumors arise from normal tissues with low Pgp expression (carcinomas of the lung, ovary or breast, sarcomas, some types of leukemias). Pgp expression in untreated tumors of this class is usually low and it is often undetectable even by the most sensitive assays. Pgp expression in such tumors is frequently increased after chemotherapeutic treatment. It is unknown, however, whether this increase represents the selection of drug-resistant cells by anticancer drugs, results from ►epigenetic MDR1 induction by cellular damage or perhaps even represents a treatment-unrelated parameter of tumor progression. A number of studies showed a strong correlation between MDR1 expression, on one side, and clinical drug resistance or the overall negative prognosis, on the other side. The strongest correlations of this type were reported in pediatric solid tumors (►neuroblastoma, ►sarcoma, ►retinoblastoma). There are also many reports that Pgp is a negative prognostic factor in various adult cancers, such as ovarian, breast, esophageal and small cell lung cancers, as well as myelomas, leukemias and lymphomas. Not all investigators, however, have observed such correlations for Pgp, a conundrum which probably reflects the variability and poor standardization of diagnostic methods for Pgp detection.

Given the clinical significance of Pgp expression, considerable efforts have been placed into developing and testing agents that reverse Pgp-mediated multidrug resistance, as non-toxic supplements to chemotherapeutic drugs. Many agents (some of which are themselves transported by Pgp) were found to inhibit drug binding or transport by Pgp and to sensitize Pgp-expressing cells to anticancer drugs in vitro and in animal models. The first generation of agents to undergo clinical trials included Pgp inhibitors that had already been used in clinical practice, such as verapamil or cyclosporin A. The second generation comprises much more potent compounds developed specifically for Pgp inhibition, such as Valspodar (PSC-833), a non-immunosuppressive ►cyclosporin analog. Clinical trials of Pgp inhibitors showed a moderate but significant improvement in the treatment response of several ►hematological malignancies, but solid tumor trials have not yet shown unambiguous

benefits. Pgp inhibitors in clinical trials were found to increase the plasma drug concentrations, apparently through the inhibition of Pgp function in secretory organs. There are also reports of increased systemic toxicity in the presence of Pgp inhibitors, but such side effects appear to be clinically manageable. It remains to be determined whether the relatively disappointing results of the Pgp inhibitor trials may be improved through the use of inhibitors with different pharmacokinetic properties (such as inhibitory anti-Pgp antibodies) or different clinical protocols. It is also possible that the inhibition of only one of several mechanisms of drug resistance that exist in tumor cells may be insufficient to achieve clinical benefit.

Another Pgp-based therapeutic approach that has entered phase I clinical trials involves the use of the MDR1 gene for gene therapy aimed at chemoprotection of hematopoietic stem cells. Several animal studies with MDR1-containing retroviral vectors have shown that this approach can provide chemoprotection against Pgp-transported drugs (principally ►taxol). It is conceivable, however, that some of the observed effects may not only be due to the effects of Pgp on taxol but to a general effect of MDR1 on stem cell maintenance, possibly due to the antiapoptotic effect of Pgp. While the animal studies have been promising, substantial technical improvements in the methodology of gene transfer into human hematopoietic stem cells are needed to elucidate the clinical potential of this approach.

Other Pgp-oriented therapeutic approaches are being explored in preclinical studies. One such strategy is aiming Pgp inhibitors not at the multidrug-resistant tumor cells but rather at the blood-brain barrier, which may be permeabilized by inhibiting Pgp in brain endothelial cells. Such permeabilization would allow Pgp-transported drugs to be delivered into the brain, a known pharmacological "sanctuary" of tumor metastases. Another potential strategy aims to prevent the conversion of Pgp-negative tumors to Pgp-positive. MDR1 expression is induced epigenetically in response to cellular damage with chemotherapeutic drugs. This induction may be prevented in vitro by combining cytotoxic drugs with the inhibitors of protein kinase C and several other signal transduction pathways. The potential in vivo utility of these novel approaches remains to be explored.

Paclitaxel

Keith Skubitz
Division of Hematology, Oncology and Transplantation, University of Minnesota Medical School, Minneapolis, MN, USA

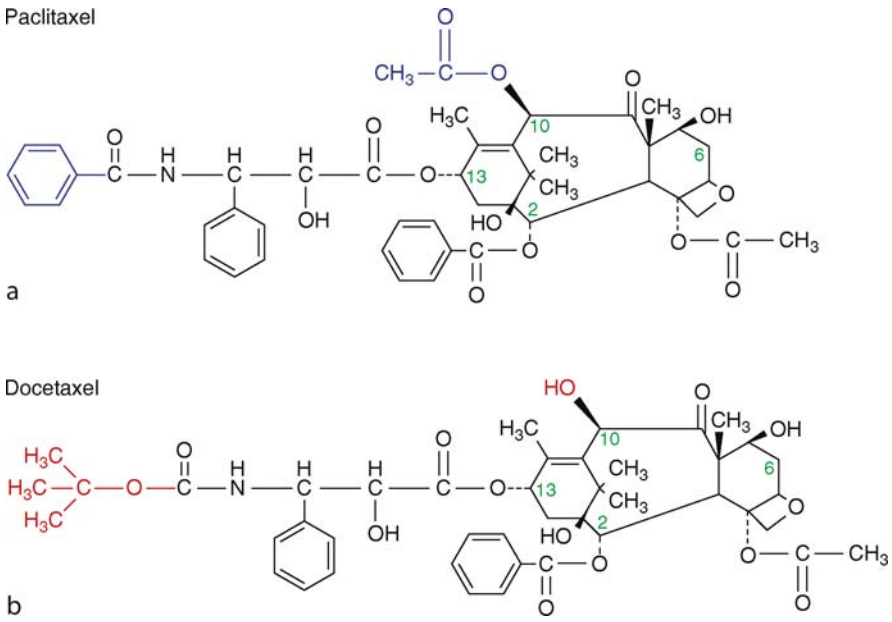
Definition

Paclitaxel is an anti-cancer agent derived from the North America Pacific yew tree (Taxus brevifolia) that is used in the treatment of a number of common malignancies including ►lung, ►ovarian, and ►breast cancer.

Characteristics

Paclitaxel is a cancer chemotherapeutic agent that is widely used for several types of malignancies (Fig. 1a and b). It is a natural product produced from the pacific yew tree. While first isolated from the bark of the Pacific yew, it is now commonly synthesized from a compound obtained from yew needles or cell culture systems.

Paclitaxel is a member of the ►taxane class of drugs, and was the first taxane to enter clinical trials and receive FDA approval. Another commonly used taxane



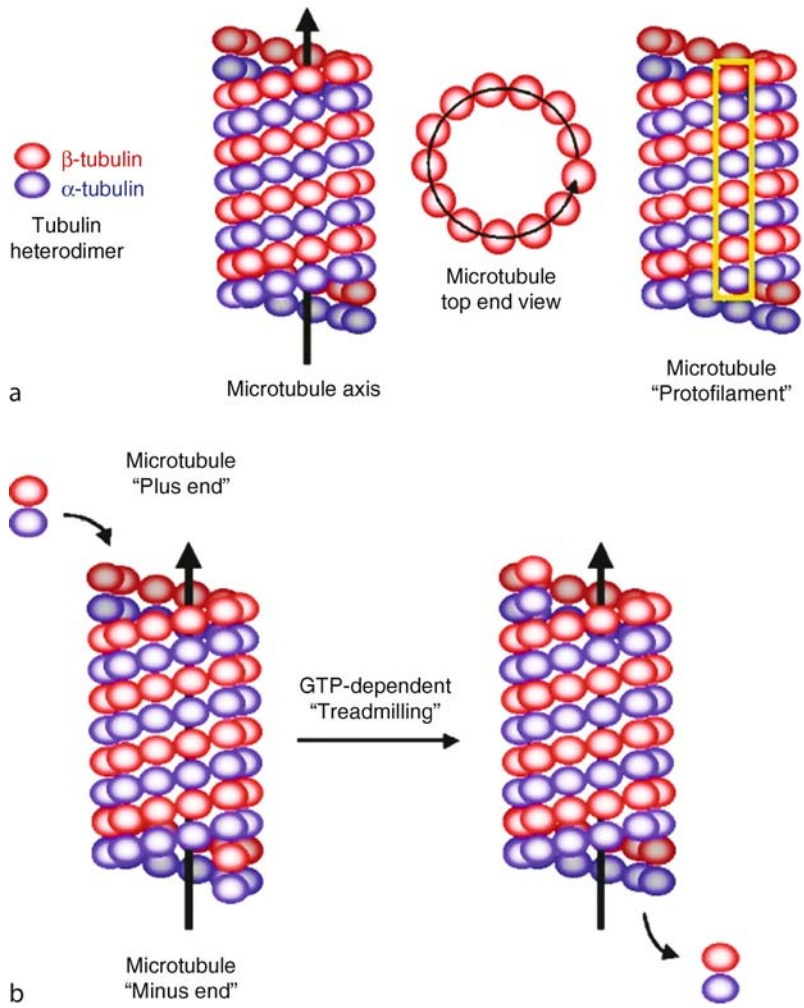
Paclitaxel. Figure 1 Structure of paclitaxel and docetaxel. Molecular structure of paclitaxel (a) and docetaxel (b). Dissimilarities are marked in blue (a) and red (b). Reproduced from Andersen et al (2006) BMC Clin Pharmacol 6(1):2, with permission per BMC Central policy.

is taxotere, which is derived from the English yew tree. Although paclitaxel was identified in the 1970s, its development was limited by ►hypersensitivity reactions. It is poorly soluble in water, and it is therefore commonly administered in a vehicle known as ►Cremophor EL, which may contribute to the hypersensitivity reactions observed when administered. Premedication with drugs such as anti-histamines and glucocorticoids, and slower administration of the drug, allowed the practical use of paclitaxel in patients, but in some people this reaction prevents its use. It is administered by intravenous infusion over times ranging from a few hours to several days.

Paclitaxel is commonly used as first line therapy in many common malignancies, including lung cancer, breast cancer, ovarian cancer, and head and neck cancer. It also has high activity in some specific uncommon malignancies such as angiosarcoma and kaposi sarcoma. Paclitaxel is also used as a component of drug-eluting vascular ►stents, where slow local release of the drug inhibits ►restenosis.

Mechanism of Action

Paclitaxel binds the beta-subunit of ►tubulin and stabilizes tubulin polymerization (Fig. 2a and b). ►Microtubules are composed of polymerized alpha- and beta-tubulin monomers, and play important roles in cell function. Tubulins are guanosine triphosphate (GTP) binding proteins. Beta-tubulin has ►GTPase activity while alpha-tubulin does not. During the formation of microtubules, dimers of alpha- and beta-tubulin bound to GTP attach to the growing (+) end of the microtubule. After incorporation into the microtubule, the GTP is cleaved to GDP. The stability of the tubulin dimer in the microtublules is determined by whether it is bound to GDP or GTP, with GTP favoring assembly while GDP favors disassembly. Thus, microtubules are in a dynamic state. One important role of microtubules is the formation of the ►mitotic spindles, which pull the chromosomes apart during mitosis. Microtubules also contribute to cell shape as a critical component of the ►cytoskeleton. The cytoskeleton is composed of microtubules, actin, and intermediate filaments, and plays an important role in the control of cell shape and locomotion. Microtubules are also involved in the movement of intracellular organelles. Paclitaxel binds polymerized tubulin and inhibits the dissociation rate of the tubulin subunits from the tubule to free monomer, thus stabilizing the microtubule. Paclitaxel administration to cells at micromolar concentrations results in the formation of microtubule bundles and ►asters, and arrests cells in mitosis. However, much lower concentrations (1–20 nM) can be ►cytotoxic or ►cytostatic. In vitro studies suggest that the time a cell is exposed to paclitaxel above a threshold concentration may be an important determinant of biologic effect. While other mechanisms may also be involved, it is generally believed that the stabilization of tubulin polymerization is the major mechanism by which paclitaxel exerts its anti-tumor activity.



Paclitaxel. Figure 2 Schematic structure of a microtubule. The tubulin dimers associate to form a hollow tube known as a microtubule. The tubulin dimers are arranged in a helical manner with 13 dimers of tubulin per turn. When viewed from the side, the tubulin dimers form microtubule "protofilaments." The arrangement of the dimers results in the exposure of an alpha-tubulin surface on one end of the microtubule, and a beta-tubulin surface on the other. The microtubules are dynamic structures, with tubulin dimers being added to the "+" end and dissociating from the "−" end. (Courtesy of Dr. Michael Blaber, Department of Biomedical Sciences, Florida State University, Tallahassee, Florida).

Mechanism of Resistance

More than one mechanism of resistance to paclitaxel occurs. One clearly defined mechanism is mutations in the tubulin gene that result in altered paclitaxel binding. Other less well-defined mechanisms exist, at least one of which may include over-expression of transmembrane pumps, such as ►P-glycoprotein family members, that actively remove drug from the cell.

Pharmacokinetics

Paclitaxel is highly protein bound. Pharmacokinetic studies suggest a very large volume of distribution (~50–180 l/m^{2}of body surface area), possibly reflecting binding to tubulin or another intracellular compartment. While renal elimination does not appear to be an important route of paclitaxel clearance, the liver plays a more important role in drug removal, and drug doses should be modified when liver function is abnormal.

Common toxicities of paclitaxel include, ►myelosuppression, hair loss, myalgias, fatigue and peripheral ►neuropathy. The toxicities of paclitaxel depend on dose and time of administration. Paclitaxel is commonly given as a 1- or 3-h intravenous infusion, although a variety of infusion times ranging up to several weeks have been described. Different infusion times are associated with different maximally tolerated doses. Longer infusions may be associated with less hair loss, neuropathy, myalgia, and hypersensitivity reaction.

Newer formulations of paclitaxel have been developed that do not require cremophor for solubility, and have additional desirable properties. One such formulation is nanoparticle paclitaxel, in which paclitaxel is bound to albumin; this formulation has been FDA approved and is in clinical use. A second formulation is a polymer form in which paclitaxel is linked to poly-L-glutamic acid; this formulation is in late-stage clinical trials. Other formulations and analogs are also in development.

Palliative

Definition

A treatment approach, usually employed in the care of terminally ill patients, aimed at relieving symptoms caused by disease rather than actual treatment of the disease itself. Treatment of tumor to only minimize tumor symptoms or to increase quality of life, without trying to cure the disease.

Palliative Care

►Supportive Care

Palliative Therapy

Michael MacManus
Department of Radiation Oncology, Peter MacCallum Cancer Centre, East Melbourne, Victoria, Australia

Definition

The term "Palliative" (from the Latin palliare, to cloak) is often applied to treatment that is given with the intention of reducing the severity of the symptoms of cancer, or is intended to slow the progress of the disease. Palliative treatment is given without the intention of providing a cure. Much of the care that is provided to cancer patients is effectively palliative in nature and represents an enormous expenditure of resources by health agencies in developed countries.

Characteristics

A decision to use palliative therapy in cancer implies that the patient has a malignant disease process that has been recognized as being impossible to cure. The use of "radical" or aggressive therapies with curative intent would be futile for such patients. Palliative therapies for cancer are therefore given without any real expectation of permanently eradicating the disease process causing the symptoms, although very rarely, long-term survival and even cure can be an unintended but welcome consequence. Palliative therapies for cancer work by inducing regression of all or part of the malignant disease process. This is in distinction to the disciplines of "Palliative Care" and ►"Supportive Care," which stress the skilful relief of pain and other physical and psychological symptoms in cancer and other chronic diseases, usually without direct treatment of the chronic illness responsible for the symptoms.

In the course of the illness of a patient with cancer, the character of the treatment may become progressively more palliative in nature when initial treatment fails and the disease is gradually recognized as being incurable. In some diseases, such as ►non-small cell lung carcinoma, the majority of patients present with disease that is already too-advanced for cure and all therapy is palliative in nature at the outset. Palliative therapies are often, but not always, less intense or toxic than treatments given with curative intent. Palliative therapies often require that the patient experiences a temporary worsening of quality of life due to transient toxicity from the treatment, in exchange for the hope or expectation of a later improvement in the symptoms caused by the cancer. Alternatively the patient with incurable malignancy may have few symptoms at the outset but may still be offered palliative treatment in an effort to prevent an impending catastrophe, such as obstruction of a major airway, or to achieve longer survival due to a temporary reduction in the burden of disease.

The range of symptoms that can be relived by palliative therapies is wide. This is a reflection of the enormous differences between different types of malignant disease and the endless possibilities for variation of patterns of disease progression between different patients with the same type of cancer. The best method of palliation varies widely between the different malignant disease types and the site of the disease responsible for the symptoms. The symptoms may reflect local anatomical problems, such as pain from bone destruction, or be systemic in nature, such as fevers or anemia.

The most commonly used palliative therapies for cancer patients are radiotherapy (►Ionizing radiation therapy), ►chemotherapy, hormonal therapy and surgery, but a wide range of additional palliative anticancer therapies can have important roles in specific clinical situations. Examples of these other therapies include radionuclide therapy for bone metastases or thyroid cancer, immunotherapy and ►radioimmunotherapy for B-cell lymphoma, laser coagulation of bleeding bronchial carcinomas, radiofrequency ablation for liver tumors, and psoralen combined with ultraviolet light treatment (PUVA) in the treatment of some skin lymphomas. Surgical interventions can play a major role in the palliation of symptoms, such as placement of an esophageal stent to allow swallowing to resume in esophageal cancer, relief of intestinal obstruction by bowel diversion procedures, relief of spinal cord compression or resection of a solitary or dominant brain metastasis. The most widely used palliative therapy modalities will be discussed in a little more detail below.

Palliative Radiotherapy

Palliative radiotherapy (also often known as Radiation Therapy) is a widely used and highly effective treatment for localized tumor lesions that are causing symptoms or are about to do so. Most palliative radiotherapy is now given using high energy photons from linear accelerators or telecobalt machines. For more superficial tumors, electron beams or orthovoltage of superficial X-ray machines may be used. For some accessible tumors, radioactive sources may be placed directly into the tumor or adjacent to the tumor to provide local symptom-control with a very low radiation dose to normal tissues more that a few centimeters from the source. Palliative radiotherapy differs from potentially curative radical or "definitive" radiotherapy, not only in the intent of the treatment but also in some technical aspects. Because cure is not the intention, lower total doses are often used than in radical radiotherapy, fraction sizes are usually larger and fewer treatments are given so that overall treatment

time is as short as possible to achieve the goal of timely palliation. Simpler and less costly beam arrangements may be used. It is not always necessary to include all of the disease in the treatment field to obtain a benefit and the treatment intensity should ideally be just enough to provide relief of the symptoms for the duration of the patient's remaining lifespan. For very ill patients with a very short anticipated lifespan, a single fraction of radiotherapy may be sufficient to relieve symptoms. However, most treatments are fractionated (that is given in separate small increments) on a daily basis. Most of the widely used fractionation schedules in common cancers involve treatment of consecutive week days for approximately one or two weeks. There is a wide spectrum of radiosensitivity between different cancers and this is considered when planning treatment. Some malignancies, such as follicular lymphoma, an often indolent type of ►malignant lymphoma, can be exquisitely radiosensitive and respond completely to doses as low as 4 Gy, without any toxicity. Others, such as recurrent rectal cancer may be relatively radioresistant and require doses of radiation in excess of 40 Gy to obtain durable relief of pain, often with significant treatment related side effects.

Palliative radiotherapy is used across virtually the complete spectrum of cancers and plays a large role in all of the most common malignancies, including lung, breast, prostate and bowel cancers, brain tumors and ►multiple myeloma. Many of the most common consequences of these diseases are effectively treated with palliative radiotherapy, including pain caused by bone metastasis, breathlessness and hemoptysis caused by bronchial tumors, brain impairment caused by central nervous system metastases or malignant spinal cord compression. Radiotherapy can reach any part of the body and is useful in situations where other treatments cannot gain access; for example brain metastases may be relatively protected from chemotherapy by the blood brain barrier but are often effectively treated with radiation.

The toxicity of radiotherapy varies with the dose and fractionation and the region of the body treated. Because palliative doses are usually lower than radical doses, side-effects are usually relative mild and transient, but commonly include fatigue, some skin redness, inflammation of mucous membranes in the treatment field and localized hair loss.

Palliative Chemotherapy

The term chemotherapy in oncology usually means the delivery of cytotoxic drugs to kill cancer cells. Chemotherapy drugs are often very powerful agents targeted at proliferating cells. Most, but not all, have a relatively narrow therapeutic window, meaning that the difference between an effective dose and a dangerously toxic dose is relatively small. For this reason drugs with overlapping toxicities are often given together in combinations of two or more agents. Many of these drugs suppress bone marrow function and therefore need to be given in "cycles" some weeks apart, allowing bone marrow recovery to occur before the next cycle can be given.

Malignant diseases show a very wide range of sensitivities to chemotherapy. In those diseases with the highest sensitivity to chemotherapy, including malignant lymphomas and ►germ cell tumors, chemotherapy is often given with curative intent at the outset. After relapse or after failure of salvage therapy, the patient may be recognized to have disease that is no longer curable. Chemotherapy may then play an important role in palliation. Sometimes the distinction between curable and incurable disease may not be clearly made and chemotherapy may serve both a palliative role, to relieve symptoms, but also provide a small hope for long-term survival. In advanced follicular lymphoma, which is highly chemo-sensitive but is usually considered incurable, patients may survive for many years following palliative chemotherapy. Relapse or progression after initial palliative chemotherapy is usual and second line chemotherapy may be considered. Subsequent courses of chemotherapy are usually more difficult to tolerate than early courses. In the late stages of an initially chemo-sensitive illness the patient may be faced with the dilemma of choosing further chemotherapy associated with a high risk of toxicity and a low probability of response, or concentrating solely on supportive care.

There is a larger group of moderately chemotherapy-sensitive cancers where chemotherapy can play a significant role in palliation when the patient is known to have incurable disease. These diseases are not generally considered to be curable with chemotherapy alone. They include multiple myeloma and many epithelial cancers such as advanced non-small cell ►lung cancer, extensive stage small cell lung cancer, ►ovarian cancer, ►breast cancer and advanced head and neck cancers. Patients most likely to benefit from palliative chemotherapy are those with a good performance status and without serious concomitant illnesses. In advanced non-small ►cell lung cancer, for example, chemotherapy provides such patients with a significant but relatively short improvement in overall survival, perhaps 6 weeks on average. Some patients may consider the risk of toxicity excessive for a relatively short prolongation of their lives in this situation. However quality of life is a major consideration when deciding whether or not to use palliative chemotherapy and well conducted studies have shown that quality of life is actually better in lung patients who receive chemotherapy than in those who do not. In other cancers such as breast cancer where response rates are usually

higher and patients are often younger and fitter when palliative chemotherapy is needed, greater benefits may be obtained with chemotherapy and initial decision making about whether or not to have chemotherapy is easier.

There is a further group of diseases that are relatively unresponsive to chemotherapy, in that the majority of patients do not have a response and randomized trials have shown that overall survival is not improved compared to patients who do not receive chemotherapy. Nevertheless, even in this group excellent responses to chemotherapy are sometimes seen. This group includes diseases like malignant ►melanoma, renal cell carcinoma and some soft tissue sarcomas.

Like radiotherapy, chemotherapy can be a double-edged sword. In cancers with low chemo-sensitivity it can often produce toxicity without any benefits whatsoever, unlike radiotherapy, which at least causes a response in most tumors that are treated even if they are chemo-resistant. However, unlike radiotherapy chemotherapy is a whole body treatment and often is the only available means for modifying the overall course of a widely disseminated cancer and improving overall survival.

Hormonal Therapy

Breast cancer and prostate cancer are very common malignancies that are often responsive to palliative hormonal therapies when patients are known to have incurable advanced disease. In both diseases, hormonal therapy can also play a role as adjuvant therapy for patients with potentially curable localized disease. Breast cancer cells commonly have receptors on the cell surface for ►estrogen and progesterone that indicate that the cells may behave more aggressively in the presence of estrogen in the bloodstream. In patients with advanced, receptor-positive breast cancer, the disease can often be made to regress by manipulating the patient's hormonal environment. In the past this was commonly accomplished by inducing an artificial menopause by oophorectomy or radiation to the ovaries. In modern practice, oestrogen receptor antagonists such as ►tamoxifen or ►aromatase inhibitors such as letrozole are most commonly used, and are effective in both pre- and postmenopausal women. Compared to chemotherapy, these drugs have low toxicity. Response rates are high in receptor-positive cancers and may last several years, with regression of painful bony lesions or symptomatic soft tissue tumors.

In advanced prostate cancer, often associated with widespread painful bone metastasis, tumor cells are usually dependent on presence of circulating androgens which stimulate tumor growth by binding to ►androgen receptors on the cell surface. By inducing a reduction in the circulating level of androgens, as in bilateral orchidectomy, or by blocking the pituitary secretion of hormones that stimulate androgen production by the testis using LH-RH agonist drugs such as Zoladex or by using drugs that block androgen receptors on the tumor cells such as Bicalutamide, advanced prostate cancer can be made to regress in many cases. Such regressions last on average a little less than two years but in individual cases may last for many years and may be achieved with acceptable side effects.

Conclusion

The palliative treatment of cancer is complex and should ideally be coordinated in a multidisciplinary team setting where a range of palliative therapies is available together with access to appropriate supportive care. Patients may benefit from the concurrent or sequential use of a range of different palliative treatments to achieve the best quality of life for the longest possible time. Treatments must be tailored both to the disease extent and to the wishes and personal philosophy of the patient, always bearing in mind that the dignity and autonomy of the suffering person should be paramount.

PAMPA

Definition

Is an acronym for Parallel Artificial Membrane Permeability Assay. In PAMPA a measurement is made

of the speed with which a chemical crosses a porous material like fritted glass or plastic soaked with a fat or a mimic of the gastrointestinal tract wall.

►ADMET Screen

Pancreas

Definition

Is involved in the digestive and endocrine system. It is both exocrine (secreting pancreatic juice containing digestive enzymes) and endocrine (producing several important hormones, including insulin, glucagon, and somatostatin).

Pancreas Cancer, Clinical Oncology

Daniel D. von Hoff
Arizona Cancer Center, Tucson, AZ, USA

Definition

Pancreatic cancer is an adenocarcinoma of the pancreas (carcinoma of the pancreas). Cancer of the pancreas is usually lethal. The pancreas is a gland that secretes both digestive enzymes and insulin (from special cells called islet cells).

Characteristics

Anatomy

The pancreas is located on the upper abdomen located in the midst of many vital organs, including the liver, spleen, stomach, small bowel and large bowel. Because of its central location, it is very problematic when cancer spreads from the pancreas directly into the adjacent organs. In addition, the head of the pancreas (the portion on the patients' right side) covers the common bile duct. The common bile duct is the duct through which bile runs from the liver and gall bladder, is mixed with pancreatic juices and then emptied into the small bowel. Blockage of this common bile duct can lead to one of the early symptoms of pancreatic cancer.

In addition, the location of the pancreas near the back (in an area called the retroperitoneum) is problematic as that is the area which contains important vessels, such as the superior mesenteric artery and veins and the celiac plexus. This means that a cancer in the pancreas will frequently (and very early in the course of the disease) invade these vessels, which enables the tumor to spread to distant sites by these vessels (such as to the liver or lung). Vessel invasion also makes the pancreas cancer inoperable (see below). There are also many nerves that are located behind the pancreas and those nerves frequently affected by cancer of the pancreas.

Etiology (Cause of the Disease)

The cause of pancreatic cancer is unknown. In about 8% of patients, the disease appears to be inherited (familial pancreatic cancer). The primary risk factor for pancreatic cancer that is not inherited is ►smoking. Other risk factors include ►alcohol consumption, a history of surgical procedures for peptic ulcer disease and a history of ►inflammation of the pancreas (pancreatitis). Diabetes is frequently associated with cancer of the pancreas. However, it is unclear if diabetes is a risk factor for the development of pancreatic cancer or whether it is just a result of the pancreatic cancer damaging the insulin-producing (islet cells) cells of the pancreas.

Pathology

It is very important to determine what type of cancer of the pancreas one is talking about. The types of cancer involving the pancreas are as follows:

- Ductal adenocarcinoma of the pancreas: This is the most common (accounts for more than 90%) and the most lethal form of the disease. It is believed that this type of cancer arises in the cells that line the ducts of the pancreas. Ductal adenocarcinoma rapidly invades blood vessels, nerves and other organs. It is frequently at an advanced stage when it is diagnosed and has a bad prognosis.
- Mucinous cystadenocarcinoma: This pathologic type is an uncommon form of pancreas cancer. It tends to be less invasive and mainly causes problems because of its size. The usual treatment is surgical removal, unless other vital organs, blood vessels or nerves are involved. It is not a benign condition.
- Islet cell tumor: These are cancers that appear to arise from the small clusters of cells called islets, which are scattered throughout the normal pancreas. Islets have cells capable of making many different hormones including insulin and glucagon. Islet cell tumors can cause symptoms as the excessive hormones that they make (such as insulin) can cause severe physiologic problems (such as hypoglycemia or low blood sugar). In general, islet cell tumors have a far better prognosis than other types of cancer of the pancreas.

The sections below will only deal with the most common type of pancreas cancers – ductal adenocarcinoma of the pancreas.

Symptoms

Unfortunately, the symptoms associated with ductal adenocarcinoma of the pancreas are fairly non-specific

and appear late. They include pain in the midepigastric (stomach area) or the back (usually due to nerve invasion by the tumor), nausea and/or vomiting, fatigue, loss of appetite and weight loss. A change in bowel habits with light colored stools is also a sign of the disease, as is a severe darkening of the urine. One rather drastic symptom is the appearance of jaundice (a yellowness of the whites of the eyes and skin), which is caused by the tumor closing off the bile drainage such that the bile (containing the pigment bilirubin) cannot be secreted, builds up in the blood and is deposited in the skin.

Making the Diagnosis

The most effective way to determine whether or not there is a mass in the pancreas is via a special X-ray known as a spiral CT scan. Another, perhaps more sensitive method, is called an endoscopic ultrasound (or EUS) in which a tube (endoscope) is passed through the mouth into the stomach and an ultrasound device at the end of the tube sends out signals that are used to detect a mass in the pancreas. If a mass is detected, it is critical to obtain a histologic diagnosis to determine if the mass is cancer (or just a benign inflammation). A histologic diagnosis is obtained by inserting a needle into the mass to look for tumor cells, or the histologic diagnosis is obtained by performing an open surgical procedure and biopsy of the pancreas.

Staging of the Disease

Pancreatic cancer is staged as being localized, locally advanced or metastatic (with distant spread).

- Localized: This stage means the tumor is confined within the pancreas with no major blood vessel involvement or involvement of areas outside of the pancreas.
- Locally advanced: Tumor involves major blood vessels or regional lymph nodes, but no cancer in other organs. In general, the tumor can be encompassed by a radiotherapy port. There can be no spread to distant organs.
- Metastatic: The pancreatic cancer has spread beyond the pancreas (usually into the liver, other surrounding organs or lung).

Prognosis

Pancreatic cancer has the worst survival of any cancer. The overall 1-year survival for all patients is about 18% with fewer than 2% of patients living 5 years. For patients with localized pancreatic cancer who have surgical resections of their disease and no evidence of tumor spread beyond the pancreas in their pathology resections there may be as many as 20% who survive 2 years. However, it is rare to find that the pancreatic cancer is truly localized. For patients with locally advanced pancreatic cancer, the average survival is about 10 months if the patient is treated with radiation to the area in addition to chemotherapy. For patients with advanced metastatic pancreatic cancer, the average survival (with treatment) is about 6 months.

Thus, the diagnosis of pancreatic cancer comes with a terrible prognosis. In order to make progress against the disease, it is important that new therapies be developed.

Treatment

- For patients with localized disease, the treatment is surgical resection. This gives the patient their only chance for prolonged survival (if the patient is fortunate to have truly localized disease). The surgical resection of the pancreas with surrounding organs and bowel reconstruction is frequently referred to as the Whipple procedure. Even with localized disease with no invasion noted on scans at the time of surgery, the pancreatic cancer frequently is found to have spread beyond the pancreas. Therefore, an important area of research is to use a ►neoadjuvant therapy approach. The idea with neoadjuvant therapy is to give therapy, such as radiation therapy, chemotherapy, or both, before surgery to try to 'down stage' the disease. Hopefully, this approach will help make more patients truly operable with complete removal of their tumor.
- For patients with locally advanced disease, there is controversy in terms of what constitutes the best treatment. The standard treatment is considered to be radiation plus chemotherapy (usually the drug, 5-fluorouracil) to sensitize the tumor to the radiation. This treatment has been reported to increase the average survival for a patient with locally advanced disease from 5 months up to 10 months. However, the radiation plus chemotherapy regimen is associated with substantial side effects. Therefore, a better approach (perhaps chemotherapy alone) for patients with locally advanced pancreatic cancer is being investigated.
- For patients with metastatic pancreatic cancer, treatment is usually chemotherapy or supportive care (pain control and treatment of other medical problems) only. Until recently there has been no chemotherapy that has improved patient survival. The anticancer agent, ►gemcitabine, has been shown to improve the survival of patients with advanced pancreatic cancer, plus improve the quality of life of the patient (decreased pain, improvement of performance status). When patients with advanced pancreatic cancer were treated with gemcitabine, their survival was improved from 2% (in the control arm treated with 5-fluorouracil) up to 18% for patients receiving gemcitabine. Currently, investigators are building on this modest advance against advanced disease by combining gemcitabine with other new cancer therapy approaches.

Familial Pancreatic Cancer

Only about 3–8% of pancreatic cancers is thought to be familial. It is an area of intense study to determine if you have a parent or brother and/or sister with the disease, what type of monitoring and/or treatment is necessary. It is clear that some type of monitoring, such as endoscopic ultrasound, should be performed at special centers.

Pancreatic Cancer, Basic and Clinical Parameters

B. Michael Ghadimi, Heinz Becker
Department of General and Visceral Surgery, University Medical Center, Göttingen, Germany

Definition

Epithelial malignancies of the pancreatic gland that originate in more than 85% from ductal cells. In rare cases tumors may also arise from acinar or endocrine cells.

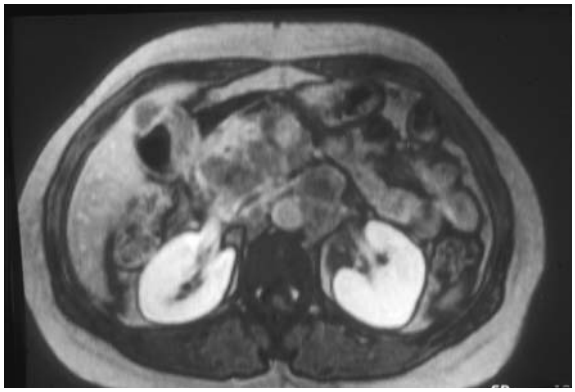
Characteristics

Pancreatic adenocarcinoma is one of the most aggressive human malignancies reflected by a mortality rate which closely follows that of the incidence. Its incidence is steadily increasing and today it is the fifth leading cause of cancer related deaths in the western hemisphere. Most patients are diagnosed with pancreatic cancer in the late course of the disease with unspecific symptoms such as fatigue, weight loss, jaundice and upper abdominal pain. At this stage pancreatic cancer frequently has invaded surrounding organs such as the duodenum and stomach, and the retroperitoneal tissue and blood vessels (Fig. 1). Lymph node metastases occur in most cases and reflect a high metastatic potential.

Most patients present between the fifth and eighth decade of life with a male/female ratio of ~1.5:1. The etiology of pancreatic cancer remains unclear. However, environmental factors such as cigarette smoking and a high fat diet may predispose patients to the development of pancreatic malignancies. Chronic inflammatory diseases such as chronic pancreatitis might also increase the risk for pancreatic adenocarcinoma. Genetic factors, such as p16 germline mutations and mutations in the mismatch-repair system may also increase the probability to develop pancreatic adenocarcinoma. However, less then 10% of patients belong to a hereditary pancreatic cancer syndrome.

Pathology

The most frequent site of pancreatic cancer is the head of the pancreatic gland (~60%). The remainder of cases arise in the body (15%), the tail (5%) or disseminated throughout the pancreas (20%). The vast majority of pancreatic cancers are of ductal origin. Rarely, they originate from acinar or endocrine cells. Ductal adenocarcinoma of the pancreas are desmoplastic malignancies composed of mucin-producing glandular cells infiltrating a non-neoplastic stroma which accounts for more than 50% of the tumor tissue. In addition to the fibrocytic stroma, cancer cells are also admixed with inflammatory cells, including lymphocytes. The histological progression from benign to malignant pancreatic disease starts from flat mucinous lesions, to papillary lesions without atypia to lesions with atypia, to in-situ carcinoma and finally to infiltrating adenocarcinoma.



Pancreatic Cancer, Basic and Clinical Parameters. Figure 1 Pancreas cancer, basic and clinical parameters. Abdominal magnetic resonance imaging (MRI) picture. The MRI depicts a huge mass in the upper abdomen that originates from the corpus of the pancreas.

At the time of diagnosis, pancreatic cancer generally has invaded the peripancreatic fat tissue and lymph nodes or adjacent organs such as the duodenum, stomach, peritoneum and vessels. Cancers restricted to the pancreatic gland are rare. In particular, carcinomas located in the body and tail are diagnosed at a more advanced stage due to unspecific symptoms. Sites of hematogenous metastases formation are primarily the liver, rarely the lung. However, local tumor recurrence due to remaining microscopic tumor foci even in smaller tumors seems to be the determining factor for patients survival.

Staging

The UICC staging system is based on the size of the primary tumor (T), the extent of regional lymph node involvement (N) and the presence of metastases (M).

Primary tumor (T):

- TX Primary tumor cannot be assessed
- T0 No evidence of primary tumor
- Tis Carcinoma in situ
- T1 Tumor <2 cm
- T2 Tumor >2 cm
- T3 Tumor extends directly to the duodenum, bile duct or peripancreatic tissues
- T4 Tumor extends directly to the stomach, spleen, colon, or adjacent vessels.

Regional lymph nodes (N):

- NX Regional lymph nodes cannot be assessed
- N0 No regional lymph node metastasis
- N1 Regional lymph node metastasis

Distant metastasis (M):

- MX Presence of distant metastasis cannot be assessed
- M0 No distant metastasis
- M1 Distant metastasis

Genetics

An array of technologies has been applied to investigate relevant chromosomal and genetic changes in pancreatic cancer over the last couple of years. The detection of specific chromosomal changes and altered tumor suppressor genes and oncogenes has significantly improved our understanding of the development and progression of this dismal disease (Fig. 2).

Cytogenetics

The application of modern fluorescence-in-situ technologies (FISH) such as comparative genomic hybridization (CGH) or spectral karyotyping (SKY) for the study of numerical and structural chromosomal aberrations have revealed new insights into pancreatic tumorigenesis. Pancreatic carcinoma cells have a surprisingly high degree of chromosomal instability but also have recurrent pattern of chromosomal alterations. Genetic losses usually involve chromosome arms and chromosomes 8p, 9p, 17p, 18q, 19p and 21, whereas gains can be mapped to 3q, 5p, 7p, 8q, 12p and 20q. These chromosomal regions are affected in up to 90% of pancreatic adenocarcinomas and correlate very well with those regions harboring oncogenes and tumor suppressor genes such as *DPC4* at 18q, *p16* at 9p, *p53* at 17p and *Kras* at 12p.

Oncogenes

The K-ras oncogenes codes for a GTP-binding protein and plays a major role in pancreatic cancer. Activating point mutations of the K-ras oncogene occur in 70–90% of all ductal adenocarcinomas and are largely restricted to codon 12 and 13 of the K-ras gene at 12p12. Due to these mutations, the K-ras oncogene cannot be inactivated and the signal transduction pathway remains active stimulating proliferation and cellular transformation. K-ras mutations have been found in proliferative, non-invasive ductal lesions indicating that K-ras might play a role during early carcinogenesis. However, K-ras mutations have also been found in inflammatory and normal pancreatic tissue without neoplastic potential. This finding might limit the development of a gene based test system using K-ras mutations as an indicator for neoplastic or malignant cells in pancreatic juice, blood or stool of patients with pancreatic disease.

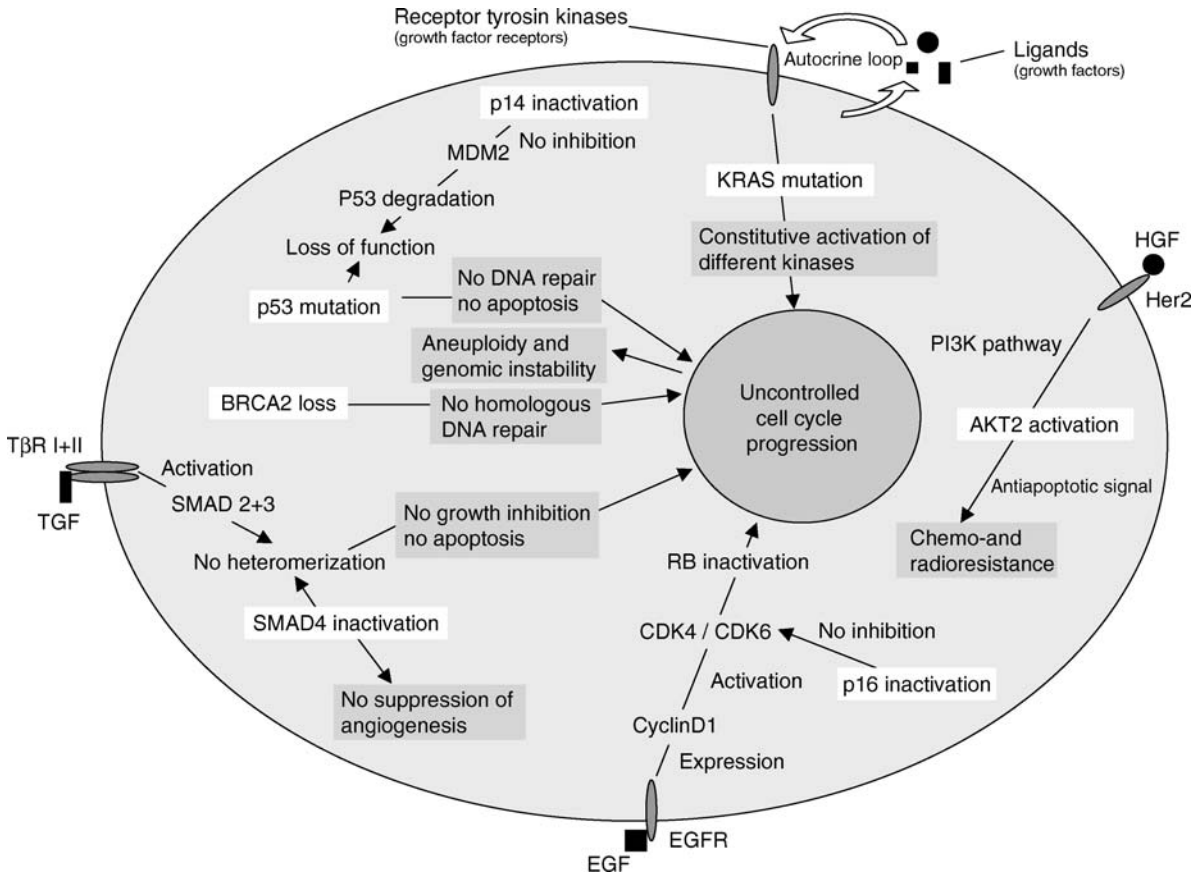
EGFR (epidermal growth factor receptor) and Her-2/neu (heregulin-, neuregulin- or glial growth factor-receptor) belong to the *ERBB*-family. In normal pancreatic tissue and chronic pancreatitis HER-2 expression remains unaffected, whereas in patients with pancreatic cancer over-expression of HER-2 can be found in early morphologic duct lesions. Using immunochemistry, over-expression of HER-2 ranges from 21% to 80%, and only 27% of the immunohistochemical positive cases showed amplification of *HER-2* as detected by FISH.

The *EGFR* gene is located on chromosome 7p12. Expression of EGFR can be detected in about 50% of pancreatic carcinomas. EGFR expression seems to play an important role in the metastatic potential.

Tumor Suppressor Genes

The relevant tumor suppressor genes in pancreatic cancer are p53, p16 and DPC4.

p53 is a nuclear binding protein that arrests cells at the G1/S checkpoint and also plays an important role in the induction of apoptosis after DNA damage. P53 resides on chromosome 17p13. It is inactivated by allelic loss and inactivating mutations in about 50% of pancreatic cancers. Therefore, loss of p53 function results in a disturbed cell cycle and loss of programmed cell death.



Pancreatic Cancer, Basic and Clinical Parameters. Figure 2 Pancreas, basic and clinical parameters. Schematic diagram of major pathways in the development of pancreatic adenocarcinomas which finally lead to the loss of cell cycle control.

p16 has been identified at 9p21 and is inactivated in about 90% of pancreatic cancers via allelic loss, inactivating mutations and/or hypermethylation of the promoter have been found. p16 inhibits the promotion of the cell cycle by binding to the cyclin-CDK4 complex and preventing CDK4 activation of RB protein. Therefore, inactivation of p16 in pancreatic cancer disregulates another relevant cell cycle checkpoint.

The tumor suppressor gene DPC4 is biallelically inactivated in about 50% of pancreatic cancers. Located on chromosome 18q, DPC4 codes for a peptide which is closely related to the MAD family of proteins (SMAD). These molecules play an integral part in the signal transduction from TGF-β superfamily cell surface receptors. Since it is known that TGF-β inhibits cell growth and proliferation, inactivation of DPC4 and loss of its inhibitory function may bestow a growth advantage upon cancer cells.

Epigenetic Changes

Another cause of gene expression changes in the development of pancreatic cancer is DNA-methylation. The methylation of the promoter regions of different genes (e.g., *p16, RB, VHL, hMLH1, hMSH2*) was also found in pancreatic carcinomas. Beside *p16,* the gene Preproenkephalin (*ppENK*), which has growth inhibiting function, was found methylated in 90% of the pancreatic cancers. Methylation of genes with a significant role in carcinogenesis occur early in cancer development. The methylation of *p16* can be observed in up to 50% of such cancers. The number of methylated loci increases with the size of the tumor and the age of the patients. Non-neoplastic epithelium is not methylated.

Hereditary Pancreatic Cancer

Several family studies have suggested that between 5 and 10% of pancreatic cancer may have a hereditary basis. A predisposition to the development of pancreatic cancer has been shown for several genetic syndromes including hereditary pancreatitis, hereditary non-polyposis colorectal cancer (HNPCC) and the familial atypical mole-multiple melanoma (FAMMM) syndrome.

Hereditary pancreatitis is an autosomal-dominant disorder which is characterized by an early onset of age.

P

Patients suffer from recurrent acute pancreatitis which leads subsequently to chronic pancreatitis carrying its significant risk factor for the development of pancreatic cancer. In the disorder, a mutation in the trypsinogen gene at 7q35 results in the inability to deactivate trypsin which results in autodigestion of pancreatic tissue.

Hereditary non-polyposis colorectal cancer (HNPCC) syndrome is another syndrome that predisposes individuals to pancreatic cancer. It is an autosomal transmitted disease, caused by germline mutations in the mismatch-repair system. Besides pancreatic cancer, patients also inherit a predisposition to other cancers, including colonic, breast, ovarian and endometrial carcinomas.

Patients with the FAMMM syndrome have an elevated risk for the development of multiple atypical nevi, malignant melanomas and pancreatic cancer. In a subset of patients, a germline mutation in the p16 tumor suppressor gene is implicated.

Diagnosis of Pancreatic Cancer

There are unfortunately no early signs or symptoms to identify pancreatic cancer as gastrointestinal obstruction and other compromising sequellae occur. Patients that are worked up for abdominal pain or jaundice suspicious for pancreatic cancer typically undergo the following diagnostic procedures.

Abdominal Ultrasound

Transabdominal pancreatic ultrasonography (US) is performed using high-resolution real-time linear array or sector scanners combined with Doppler examination. The sensitivity of US in pancreatic cancer is as high as ~85%. Lesions in the head are more visible than lesions in the body or tail of the gland, due to intestinal gas. Computer tomography (CT) is clearly superior in terms of sensitivity and specificity compared to ultrasonography. In summary, US is a reliable screening method for the detection of pancreatic masses and liver metastases but is not recommended for examining patients if a malignant disease is strongly suspected.

Computed Tomography (CT)

Current techniques including high resolution spiral CT provide detailed images of the pancreas, the pancreatic and biliary duct system, the peripancreatic vessels and surrounding organs. Several studies have reported a sensitivity of 92%, a specificity of ~100% with spiral CT. However, only 65% of all tumors which were staged as resectable with spiral CT scans were actually candidates for resection. Therefore, laparotomy or surgical laparoscopy remain the only specific approaches to determine resectability.

Magnetic Resonance Imaging (MRI)

The importance of MRI in pancreatic cancer diagnostics, despite the advantage of avoiding ionizing radiation, is still to be determined. In most centers MRI is used to differentiate between malignant and benign disease when US or CT are equivocal or the administration of intravenous contrast agents is contraindicated.

Magnetic Resonance Cholangiopancreatography (MRCP)

Although the exact role of MRCP has not yet been determined it has demonstrated its potential to display changes in the pancreatic duct pathology. MRCP and ERCP findings correlate with pathology in 80–90% of the cases.

Endoscopic Retrograde Cholangiopancreatography (ERCP)

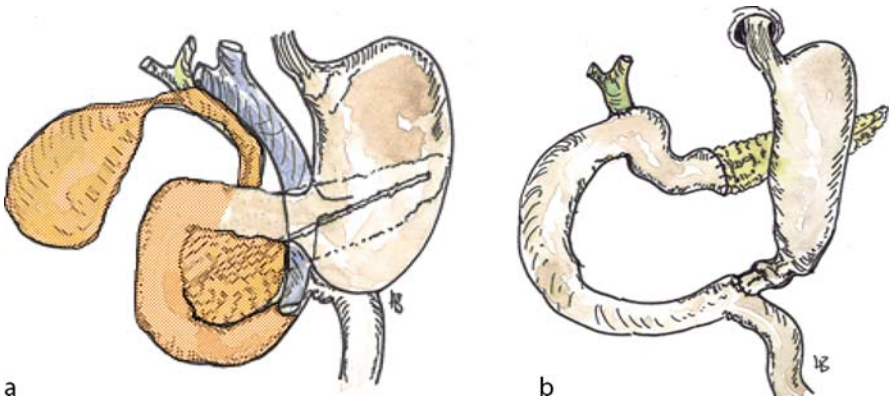
Endoscopic techniques, such as ERCP, can be applied for diagnosis and interventional management for patients with pancreatic disorders with a sensitivity and specificity of 90%. Endoscopic pancreatographic features of malignant disease include stenosis or displacement of the pancreatic and bile duct (e.g. double duct sign), alteration of secondary branches and extravasation of contrast dyes due to necrosis. An additional major role of ERCP is the opportunity to provide drainage of an obstructed common bile duct by facilitating the insertion of stents into the biliary system. Also tissue sampling can be performed during ERCP, using brush cytology, direct biopsy, endoscopic needle aspiration and aspiration of pancreatic and bile fluid. The opportunity to obtain tumor material during endoscopic procedures might become an important step since molecular markers can be applied to these samples and might assist in the differential diagnosis of pancreatic disease.

Therapy of Pancreatic Cancer

Although there has been considerable progress in the biological understanding and diagnostic tools of pancreatic cancer, the neoplasms continues to have one of the poorest prognoses of all human cancers. Surgical resection of small tumors is the only option for curative treatment. The 5-year survival is below 5% and due to advanced tumor stage at time of diagnosis, therapies remain palliative for the vast majority of patients. Five-year survival rates increase to 30% when tumors smaller than 2 cm are resected.

Surgical technique is dependent on location of the tumor and includes local excision in papillary tumors and left hemipancreatectomy in tumors of the pancreatic tail.

However, the majority of pancreatic cancers are located in the pancreatic head on which two methods of resection are most commonly employed. The classical method, the Whipple-Kausch pancreatectomy, involves en-bloc removal of (i) the distal third of the stomach and the right half of the greater omentum, (ii) the gall bladder including the distal bile duct system, (iii) the



Pancreatic Cancer, Basic and Clinical Parameters. Figure 3 Pancreas, basic and clinical parameters. Pylorus-preserving pancreatectomy (PPPD) (a) Intraabdominal Situs before surgical resection – areas in orange color mark the organs which will be removed. (b) Intraabdominal Situs after resection according to PPPD.

duodenum and the proximal 10 cm of the jejunum, (iv) the head and parts of the body of the pancreas and (v) the peripancreatic and hepatoduodenal lymph nodes. The surgical therapy of choice and modern technique is the so called the pylorus-preserving pancreatectomy (PPPD). Instead of resection of the distal stomach, the pylorus is attached directly to a jejunal loop in PPPD (see Fig. 3). It remains unclear if either method is superior but advocates of PPPD claim better nutritional outcomes and shorter operative times compared to standard Whipple-Kausch pancreatectomy. Therefore, the PPPD is considered as state-of-the-art in the major surgical centers in Europe.

In patients with advanced disease, multidisciplinary approaches are needed involving the surgeon, endoscopist and radiologist to optimize palliative therapy in the setting of a limited life expectancy. Operative bypasses including choledochojejunostomies and gastroenterostomies have many advantages and remain as highly acceptable choices in the management of terminal disease. Non-operative stenting should be reserved for elderly patients or patients with very advanced disease who are poor operative candidates.

The resistance of pancreatic cancer to adjuvant, neoadjuvant and palliative chemo- and/or radiotherapy has remained a consistent disappointment over the last decades. Trials with gemcitabine, a cytidin analogue, have shown a decrease of disease-related symptoms thus benefiting patient's quality of life and have resulted in very modest prolongation in survival. Recently, oral 5-Fu (Capecitabine) has been added to gemcitabine and some oncologist recommend additionally EGFR-blockers. Overall, there are no convincing data about any drugs significantly increasing patient's survival. Such results emphasize the importance of developing new diagnostic methods of pancreatic cancer to allow surgical resection at an earlier tumor stage.

Definition

Pancreatic cancer is a virulent disease with no effective therapy besides surgical resection. The possibility for

surgical tumor removal is limited by early metastatic spread of tumor to sites outside the pancreas. The survival for patients with metastatic pancreatic cancer is less than 1 year following diagnosis. Clinicians must translate the available knowledge of the molecular basis of this disease into rationale and effective therapeutic strategies for treatment.

Pancreatic cancer is one of the tumors with the highest number of genetic mutations of any solid malignancy. These include oncogenes, tumor-suppressor genes and DNA-stability genes. The stability genes include mismatch repair (MMR) and base-excision repair (BER) genes, which control the mutation rate of other genes. A number of genetic alterations have been, and still is being, tested as molecular target for antipancreatic cancer therapy. It is clear that novel molecular targets and strategies need to be developed for the treatment of pancreatic cancer.

Characteristics

Pancreatic cancer ranks thirteenth in incidence but eighth as a cause of cancer death worldwide. In the United States and Europe, pancreatic cancer is the fourth leading cause of cancer death in both men and women. Chemotherapy and radiation therapy have had little impact on survival, prompting the National Cancer Institute to declare that survival for pancreatic cancer has remained unchanged for three decades and its treatment has consistently been identified as an area of unmet medical need.

Oncogenes

K-Ras Oncogene

The *K-Ras* proto-oncogene is the most commonly mutated gene in pancreatic cancer. K-ras is a member of the RAS family GTP-binding proteins and has intrinsic GTPase activity. The Ras proteins mediate a wide variety of cellular functions including proliferation, differentiation, and survival by transduction of growth-promoting signals from the cell surface tyrosine kinase receptors to intracellular pathways. Activating K-Ras point mutations at codon 12 results in substitution of amino acids and are early genetic alterations, occurring in 30% of early pancreatic neoplasms and with a frequency approaching 100% in advanced pancreatic adenocarcinoma.

Ras has been considered an important therapeutic target in pancreatic cancer due to its frequency of mutation and possible role in the initiation of this malignancy. Unfortunately, Ras inhibitors to date have not been clinically effective. Most studies have focused on the efficacy of farnysltransferase inhibitors (FTIs) which inihibit posttranslational modification of Ras by interfering with lipid modification of the C terminus of Ras. Despite showing promise in vitro and in xenograft models, FTIs have failed to significantly improve survival of patients with pancreatic cancer, possibly due to compensatory geranyltransferase activity preserving Ras function. A phase II trial of FTI alone on 53 patients with locally advanced or metastatic pancreatic cancer showed a median survival of 2.6 months and a 6-month survival rate of 19%. Another phase II trial on 20 patients with metastatic disease showed a median survival of 19.7 weeks and a 6-month survival rate of 25%. A phase III trial combining the FTI tipifarnib with gemcitabine chemotherapy did not lead to any improvement in median survival compared with gemcitabine chemotherapy alone. Therefore, at the present time, the role of FTIs in the treatment of pancreatic cancer remains uncertain.

Activated K-Ras signals to multiple critical pathways including the RAF-mitogen-activated kinase (MAPK), phosphoinositide-3-kinase, and Ral GDS pathways. These downstream targets are logical alternative points of study for therapeutic intervention.

Signaling Pathways of Ras

Raf-MAPK

The Raf serine/threonine kinases lead to MAP kinase activation resulting in proliferative behavior in a variety of cell types. Activating B-Raf mutations have been demonstrated in a variety of malignancies including melanoma, colorectal, thyroid, and ovarian cancers. However, B-Raf and Ras mutations appear to be mutually exclusive in these cancers. Pancreatic cancers rarely have B-Raf mutations, except for a low incidence in the histologic subtype of pancreatic medullary carcinoma. Nevertheless, inhibition of MAP kinase leads to pancreatic cancer cell cycle arrest and decreased proliferation. This arrest may be mediated through increased expression of p27KIP1.

Phosphoinositide 3-Kinase (PI3K) Pathway

The PI3K pathway regulates cell size, survival, and proliferation via several downstream effectors including AKT. Activating mutations in the catalytic subunit of PI3K and loss-of-function mutants of the *PTEN* tumor suppressor have been frequently seen in some cancers but not in human pancreatic adenocarcinoma cells. However, the PI3K pathway appears to have general importance in pancreatic adenocarcinoma. Decreased PTEN expression in pancreatic adenocarcinoma, possibly due to promoter hypermethylation, has been reported. In addition, activation of the PI3K pathways appears necessary to maintain Ras-transformed tumors growth in nude mice after Ras expression is abolished. Finally, inhibition of PI3K appears to increase the sensitivity of pancreatic adenocarcinoma cells to chemotherapy. These observations have made the PI3K pathway an interesting potential target for drug development, but no successful clinical trials have been reported to date.

Activation of the serine/threonine kinase AKT is common in pancreatic cancer; inhibition of which sensitizes cells to the apoptotic effect of chemotherapy. Inhibition of either phosphatidylinositol-3 kinase or AKT led to a decreased protein level of the anti-apoptotic gene *BCL-2* and an increased protein level of the proapoptotic gene *BAX*. Furthermore, inhibition of AKT decreased the function of nuclear factor κB (NF-κB), which is capable of transcriptional regulation of the *BCL-2* gene. Inhibiting this pathway had little effect on the basal level of apoptosis in pancreatic cancer cells, but increased the apoptotic effect of chemotherapy. The antiapoptotic effect of AKT activation in pancreatic cancer cells may involve transcriptional induction of a profile of BCL-2 proteins that confer resistance to apoptosis; alteration of this balance allows sensitization to the apoptotic effect of chemotherapy.

Nuclear Factor κB

The NF-κB transcription factor is an important mediator of mutated K-Ras signaling in pancreatic adenocarcinoma cells. This pathway is activated by a variety of cellular stresses through stimulation by cytokines and growth factors and subsequently aids in the control of apoptosis and immune responses. Most primary pancreatic cancers and cell lines demonstrate constitutive NF-κB activity. NF-κB induction has been shown to be necessary for Ras transformation of several cell types. NF-κB helps to regulate cell survival genes, VEGF, urokinase, and other proinvasive and angiogenic factors. The NF-κB pathway may also contribute to chemoresistance which is widespread amongst pancreatic adenocarcinomas possibly due to the ability of NF-κB to upregulate BCL-2 and BCL-XL. The diverse roles of NF-κB have led to the development of inhibitors that have been studied in patients with advanced pancreatic cancer.

The phosphorylated form of I-κB is degraded by the 26S proteasome and inhibition of the proteasome prevents I-κB degradation, thereby preventing the activation of NF-κB. Bortezomib (PS-341, Velcade) is a 26S proteasome inhibitor that causes cell cycle arrest of pancreatic cancer cells via accumulation of cyclin-dependent kinase inhibitor $p21^{cip1/waf1}$ and apoptosis via downregulation of BCL-2. In vivo experiments have shown that PS-341 increases the cytotoxicity of gemcitabine. However, despite encouraging preclinical data, neither PS-341 alone nor combined with gemcitabine is considered of any benefit to patients with metastatic pancreatic cancer. This is due to findings from a randomized phase II trial involving 87 patients with metastatic pancreatic adenocarcinoma, where the use of PS-341 alone or in combination with gemcitabine, resulted in a median survival of only 2.5 and 4.8 months, respectively.

Ras Family GTPases

The Ras family of GTPases has more than 150 members and is divided into five groups: Ras, Rab, Arf, Rho, and Ran. Some of the best characterized proteins include the Rho family. Activating mutations of Rho family members have not been demonstrated in human pancreatic tumors; however, overexpression of Rho has been shown to correlate with pancreatic cancer metastasis.

Ral GTPases are downstream of Ras and are members of the Ras subfamily. Ral A has been shown to be activated in several pancreatic cancer cell lines and RAL A inhibition suppressed tumorigenicity of Ras-transformed human cells. Much evidence supports K-Ras and many of its downstream effectors in both the initiation and maintenance of pancreatic cancer. While agents that target FTIs have not shown to be of benefit in pancreatic cancer, ongoing studies are investigating the possibility of targeting Ras-directed downstream signaling mediators.

Tumor Suppressor Genes

CDKN2A/INK4A/p16

Chromosomal alterations in the 9p21 region that contains the gene for *CDKN2A/INK4A/p16* are frequently observed in pancreatic cancer. These alterations typically result in cellular inactivation through deletion or mutation, although gene silencing by hypermethylation does also occur. The *CDKNA2A* gene encodes a cyclin-dependent kinase inhibitor that induces cell cycle arrest at G1 in cooperation with normal retinoblastoma function. In animal models, loss of CDKNA is an early event in pancreatic cancer that functions to enhance the oncogenic effect of K-Ras.

SMAD4 and TGF-β

The *SMAD4* gene plays an important role in signaling pathways involving transforming growth factor beta (TGF-β), bone morphogenetic protein, and activin. Inactivation of SMAD4 is noted in approximately 50% of pancreatic cancers. SMAD4 has been termed a progression allele for pancreatic adenocarcinoma as it is lost in later stages of pancreatic intraductal neoplasms. Recent reports suggest that wild-type SMAD4 restricts activated K-Ras initiated neoplasms that would otherwise progress to frank invasive disease in the context of SMAD4 deficiency.

TGF-β is the prototypic member of a superfamily of proteins that upon ligand binding phosphorylate receptor-regulated SMAD proteins regulating a variety of cellular functions including proliferation, migration, differentiation, and apoptosis. In numerous cell lines, TGF-β exerts a growth inhibitory effect that involves cell cycle regulators, repression of c-Myc, and induction of apoptosis. Elevation in TGF-β signaling inhibits epithelial cancer initiation in vivo and defects in

this pathway promote pancreatic tumorigenesis. Recent evidence suggests that SMAD4 deficiency inhibits TGF-β-induced cell cycle arrest and cell migration, thereby, altering TGF-β signaling from one of tumor suppression to tumor promotion.

p53

Loss of activity of the transcription factor p53, which plays a critical role in cell cycle arrest and apoptosis, has been reported in pancreatic tumors. Missense mutations in part of the *p53* gene encoding the DNA-binding domain of this tumor suppressor protein result in the production of a protein that is able to translocate to the nucleus but is unable to function in DNA binding and therefore accumulates in the nucleus. This accumulation has been described in high grade tumor and late intraepithelial lesions, suggesting that these mutations contribute to the later stages of pancreatic tumorigenesis. As with SMAD4 deletions, loss of p53 activity induces further chromosomal instability in the context of mutated, activated K-ras.

Growth Factors

Epidermal Growth Factor Receptor (EGFR)

The EGFR is a family of transmembrane glycoproteins that has four members. Upon phosphorylation, the activated receptor subsequently signals to a variety of intracellular adaptor molecules and mediators. These allow EGFR to play a role in a range of cellular functions including proliferation, survival, and motility. Two major downstream pathways in normal EGFR signaling are the Ras–Raf–MAPK and the PI3K/Akt pathways. Constitutive activation of EGFR promotes oncogenic cellular processes including uncontrolled proliferation with migration, invasion, angiogenesis, and resistance to apoptosis.

Overexpression of EGFR has been observed in many pancreatic tumors and appears to correlate with poor prognosis and disease progression. Preclinical studies have shown that antagonizing EGFR signaling inhibits growth and metastasis of pancreatic tumors in xenograft animal studies. Two therapeutic approaches have been utilized to interfere with EGFR signaling. The first involves blocking ligand binding with monoclonal antibodies specific to epitopes within the ligand-binding domain. Once bound to the domain, these antibodies prevent receptor dimerization and subsequent tyrosine phosphorylation. The second approach to inhibit EGFR signaling uses small-molecule tyrosine kinase inhibitors (TKIs) that function inside the cell. These TKIs inhibit the kinase activity of the receptor independent of ligand binding through competition with ATP binding, thereby preventing receptor activation. The advantage of kinase inhibitors over receptor antibodies is that cross reactivity with the ATP-binding domain of other EGFR family members as well as the ability to inhibit truncated receptor mutants that lack a functional extracellular domain may allow for more thorough receptor inhibition with TKIs. The disadvantage of TKIs is that other kinases can be inhibited leading to increased toxicity or death of normal cells.

A small molecule EGFR TKI, erlotinib, has been evaluated in randomized studies of patients with advanced pancreatic cancer. Patients were randomized to gemcitabine chemotherapy with placebo or gemcitabine with erlotinib. The latter treatment was well tolerated and resulted in a small but significant improvement in survival. This study validated EGFR as a target in pancreatic cancer and provides further rationale for ongoing studies of targeted molecular agents in this disease.

Vascular Endothelial Growth Factor Receptor (VEGFR)

Angiogenesis refers to the process by which new blood vessels develop from existing vasculature. Tumor blood vessels are highly disorganized and structurally abnormal resulting in irregular blood flow, increased permeability, poor nutrient and drug delivery, and areas of hypoxia. VEGFR is one of the central mediators of angiogenesis and is overexpressed in pancreatic cancer. Recent preclinical data suggest that this growth factor has mitogenic activity on endothelial as well as tumor cells, making it a target for dual cancer therapy intended to produce both antiangiogenic and antitumor effects.

Angiogenesis has prognostic importance in pancreatic cancer, a disease in which VEGF expression correlates positively with local recurrence, metastatic potential, and overall survival. The VEGF pathway has been most commonly targeted with monoclonal antibodies that bind the ligand (e.g., bevacizumab) or small molecule VEGFR TKIs. Bevacizumab has been shown to suppress pancreatic tumor growth in preclinical models. Subsequently, a phase II study evaluated the combination treatment of bevacizumab with gemcitabine in 52 patients with metastatic pancreatic cancer. Results showed a 21% partial response rate with a median survival of 8.8 months. Overall, the treatment was well tolerated but plasma VEGF levels did not correlate with outcomes. The response rates and survival results from this phase II study were considered encouraging and this treatment regimen was evaluated in a phase III study. In this double-blinded randomized trial in 602 patients with pancreatic cancer, bevacizumab plus gemcitabine treatment was compared with gemcitabine plus placebo therapy. Unfortunately, bevacizumab plus gemcitabine treatment failed to show a survival benefit compared with gemcitabine monotherapy.

An alternative approach to targeting the VEGF pathway involves the use of TKIs that operate on an intracellular level. Such agents have already been approved for use in other cancers and include sunitinib

in renal cell and gastrointestinal stromal tumors and sorafenib in advanced renal cell carcinoma. The knowledge obtained with the use of targeted anticancer molecular agents suggests that less selective inhibitors with multiple targets may be more efficacious than inhibitors of single targets. This is likely due to the crosstalk and redundancy in molecular pathways that promote essential functions such as proliferation and survival. In addition, a single inhibitor with multiple targets may promote fewer drug interactions, potentially inducing less toxicity than combinations of more specifically targeted agents.

Sorafenib is a multitargeted TKI of Raf-1, VEGR-2, and the platelet-derived growth factor receptor. Proposed antitumor activity of sorafenib targets both antiangiogenic and antiproliferative mechanisms. A phase I study in 23 patients with advanced pancreatic cancer demonstrated encouraging results with a 57% incidence of disease stability. Subsequently, a phase II study of gemcitabine with sorafenib was performed and preliminary results have been reported. Unfortunately, there were no objective responses to this combination with a median survival of 4 months.

Cytoplasmic Tyrosine Kinases

Several agents targeting a variety of pathways are in early clinical testing in pancreatic cancer and include those directed at src and focal adhesion kinase (FAK). *Src* was the first reported proto-oncogene and encodes a nonreceptor tyrosine kinase with involvement in the regulation of proliferation, differentiation, survival, motility, angiogenesis, and cell–cell interactions. Malignant Src activity is related to the overexpression of the wild-type protein rather than expression of a mutated genotype. Src activity may contribute to both constitutive and EGF-induced VEGF expression and, therefore, to angiogenic potential. This has been shown in pancreatic cancer cells in vitro and in animal models growing human pancreatic tumors. Src inhibitors are in phase I and II clinical testing, and clinical trials combining an oral Src inhibitor with gemcitabine are in process.

FAK is a cytoplasmic protein tyrosine kinase that, as its name suggests, is localized to focal adhesions, which are contact points between a cell and its extracellular matrix (ECM). Tyrosine phosphorylation of FAK occurs in response to clustering of integrins, during formation of focal adhesions and cell spreading, and upon adhesion to fibronectin. FAK does not function as a classic oncogene, affecting cell transformation. Rather, it promotes a more invasive and metastatic phenotype of an established malignancy. FAK appears to have many functions in cells, linking integrin signaling to downstream targets, acting as part of a survival signal pathway and having a connection with cell motility. FAK is phosphorylated following activation of a number of transmembrane receptors. FAK functions not only as a kinase, but also as a scaffolding protein for the assembly of a number of cellular signaling molecules, suggesting that FAK is a critical mediator of cell-ECM signaling events.

Our laboratory group has played an important role in defining the biology of FAK in human tumors, including pancreatic cancer. We have demonstrated in pancreatic cancer cells, as well as in vivo models, that FAK inhibition is an effective antineoplastic strategy by inducing apoptosis and sensitizing tumor cells to chemotherapy. FAK inhibitors are currently in phase I testing.

Matrix Metalloproteinases

Tissue invasion and the ability to metastasize are among the hallmarks of cancer. Disruption of cellular junctions and the interactions between cells and the ECM are essential prerequisites for cell detachment from the primary tumor, invasion of the blood stream, and growth at distant sites. Several families of proteases are implicated in these processes. The largest and best characterized is the family of matrix metalloproteinases (MMPs), which are zinc-dependent proteolytic enzymes with different substrate specificities for ECM molecules (eg, collagen, fibronectin, laminin, and elastin). Among the various family members, MMP-2 and MMP-9 are most commonly implicated in tumor angiogenesis. The activity of MMPs may be inhibited by members of the family of proteins known as tissue inhibitors of metalloproteinases (TIMPs). In pancreatic cancer, overexpression of several MMPs has been demonstrated in several studies. It has been suggested that an imbalance between MMPs and TIMPs plays a role in pancreatic tumor progression and that MMP-2 activation correlates with more-advanced pathologic stages and with early recurrence after resection.

Synthetic MMP inhibitors (MMPIs) have been developed and tested against a variety of tumors. One such MMPI is marimastat, an orally bioavailable drug that is active against several MMPs. In preclinical models, marimastat and other MMPIs delay tumor growth and prolong animal survival, but no cytotoxic effect is observed. Phase I studies found an inflammatory polyarthritis to be the dose-limiting toxicity of marimastat. Pharmacokinetic analyses showed that marimastat is rapidly absorbed and eliminated, with time to maximum concentration of 1–2 h and an elimination half-life of 4–5 h.

In a dose-finding study among patients with pancreatic cancer, marimastat doses of 5 mg, 10 mg, and 25 mg twice daily were considered adequate. CA19-9 changes in that study suggested evidence of activity, which was also noted in a phase II trial in which patients who had CA19-9 stabilization or responses (30% of cases) lived longer than patients with a rising tumor marker. Based on these findings, randomized trials of marimastat were performed.

Bramhall et al. randomized 414 patients with advanced pancreatic cancer to receive either gemcitabine or marimastat. Although the median survival in the 25-mg marimastat group was lower than that in the gemcitabine group (125 days vs. 167 days), the log-rank analysis showed no difference between the survival curves of the two groups. Survival of patients treated with the other doses of marimastat (5 mg b.i.d. and 10 mg b.i.d.) was much lower than that of patients given gemcitabine. A subgroup analysis of patients with metastatic disease (approximately 65% of the cases) suggested an interaction between marimastat and disease stage; the median survival of patients with nonmetastatic disease was longer than that of patients with metastatic disease. In the gemcitabine group, there was no difference in median survival between patients with and without metastases. Consistent with the mode of action of these two drugs, the median progression-free survival among patients treated with marimastat, which has no cytotoxic effect, was approximately half that of patients treated with gemcitabine. Likewise, the reported response rates were lower in the marimastat arms of the trial (3% vs. 26% for gemcitabine). Musculoskeletal toxicity was reported in 39–55% of patients across different dose levels of marimastat, but this toxicity was grade 3 or 4 in only 7–12% of cases.

A different approach was taken in a second phase III trial, in which 239 patients were treated with gemcitabine and were concurrently randomized to receive marimastat (10 mg b.i.d.) or placebo. The median and 1-year survival was nearly identical in the two groups. Likewise, the log-rank comparison between the two survival curves yielded no differences in overall or progression-free survival. In this trial, there was no interaction between marimastat and disease stage.

The results of these trials indicate that marimastat, alone or in combination with gemcitabine, has no role in the treatment of advanced pancreatic cancer. Furthermore, another MMPI, BAY12-9566 proved inferior to gemcitabine in a randomized trial of 277 patients with advanced pancreatic cancer. Therefore, the currently available studies of MMPIs show that these agents have no role in the treatment of advanced pancreatic cancer. However, due to their cytostatic effect, it is conceivable that the administration of marimastat or other MMPIs to patients with tumors in earlier stages could improve on the existing therapies. The suggested interaction between marimastat and disease stage in one of the trials is in line with this hypothesis.

Pancreatic Cancer Stem Cells

Cheong J. Lee[1], David G. Heidt[1], Diane M. Simeone[1,2]
[1]Department of Surgery, University of Michigan Medical Center, Ann Arbor, MI, USA
[2]Department of Physiology, University of Michigan Medical Center, Ann Arbor, MI, USA

Definition

A subpopulation of highly tumorigenic cells that possess the stem cell-like properties of the ability to self-renew and generate differentiated tumor cell types found in pancreatic cancer.

Characteristics

Pancreatic cancer is an aggressive malignancy arising from the exocrine pancreas. Greater than 30,000 people per year are affected by the disease in the United States alone where it is the fourth leading cause of cancer death. Pancreatic cancer portends the worst prognosis of any solid tumor malignancy, with a 5-year survival rate of less than 3%. Conventional therapies, such as chemotherapy and ionizing radiation often produce minimal clinical response in tumor shrinkage and cancer regression. While our understanding of the molecular mechanisms underlying the development and progression has significantly improved by examining genomic and proteomic profiling of human pancreatic cancers, these studies do not account for the heterogeneity of cancer cells within a particular tumor.

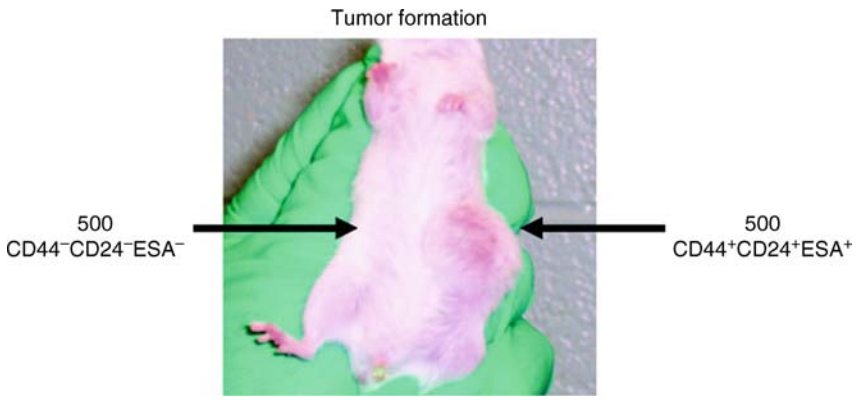
Recently, there has been a paradigm shift in our understanding of how cancers develop and propagate termed the ►cancer stem cell theory. In the traditional model of how cancer develops and propagates, it is though that all cells within the cancer are able to

proliferate extensively and form new tumors. In the cancer stem cell theory, tumors arise from a small population of cancer cells, usually less than 5% of cells, that have properties of adult stem cells; particularly the abilities to self-renew and differentiate into the multiple cell types found in the tumor. Of clinical relevance, this model may explain why standard chemotherapy and ionizing radiation therapy may result in tumor shrinkage, but do not prevent cancer recurrence, since cancer stem cells are resistant to standard types of therapies. Conventional treatments may be able to target the bulk of the tumor, but not necessarily these tumor-initiating cells, subsequently leading to recurrence or disease progression following standard treatment.

The existence of cancer stem cells was originally demonstrated in acute myelogenous leukemia and now has been well established in a several types of solid tumors, including breast cancer, brain cancer, prostate cancer, colon cancer, head and neck cancer, lung cancer, and melanoma. Identification of cancer stem cells within human tumors has been facilitated by the development of ►xenografts (or implants) of human tumors into immunodeficient mice for study. Using this model system, either primary tumors derived directly from patients or implanted and expanded in mice can be dissociated into single cell suspensions. These cells then undergo ►flow cytometry and are isolated based on differential cell surface marker expression and implanted into mice with monitoring of tumor growth (Fig. 1).

Study of human pancreatic cancers have identified a subpopulation of cells that express cell surface markers ►$CD44^{\pm}$ ►$CD24^{\pm}$ ►$ESA^{\pm}$ as putative pancreatic cancer stem cells. In pancreatic cancer, less than 1% of the cancer cells are $CD44^{+}$ $CD24^{+}$ ESA^{+}. As few as 100 $CD44^{+}$ $CD24^{+}$ ESA^{+} cells injected into immune incompetent ►NOD-SCID mice form tumors (Table 1) while 10,000 unsorted primary bulk pancreatic cancer cells were required to initiate tumor growth, revealing a greater than 100-fold enhanced tumorigenic potential in the triple surface marker positive cell population compared to bulk pancreatic cancer cells.

The $CD44^{+}$ $CD24^{+}$ ESA^{+} pancreatic cancer cells possess the stem cell properties of self-renewal and the ability to produce differentiated progeny that recapitulate the phenotype of the parent tumor. Tumors formed in NOD-SCID mice as xenografts derived from pancreatic cancer stem cells are histologically identical to patient's primary tumor from which the cells were derived (Fig. 2). While some different types of tumors may have common cell surface makers that best define the cancer stem cell population, it is likely that different tumor types each have their own "best" set of makers that identify cancer stem cells. In addition, the secondary tumors that form from implantation of the primary tumor's $CD44^{+}$ $CD24^{+}$ ESA^{+} cells reproduce the surface expression pattern of



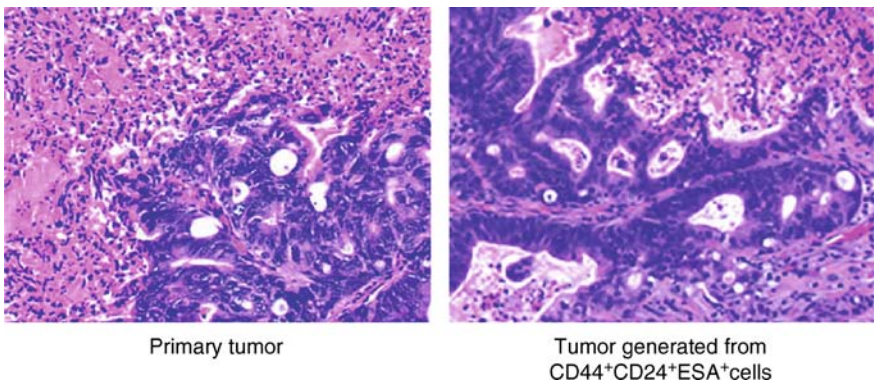
Pancreatic Cancer Stem Cells. Figure 1 Tumor formation in NOD/SCID mice injected with 500 $CD44^{+}$ $CD24^{+}$ ESA^{+} cells, with no tumor formation seen at the injection site of 500 marker negative $CD44^{-}$ $CD24^{-}$ ESA^{-} cells.

Pancreatic Cancer Stem Cells. Table 1 Tumor formation ability of sorted pancreatic cancer cells using cell surface markers

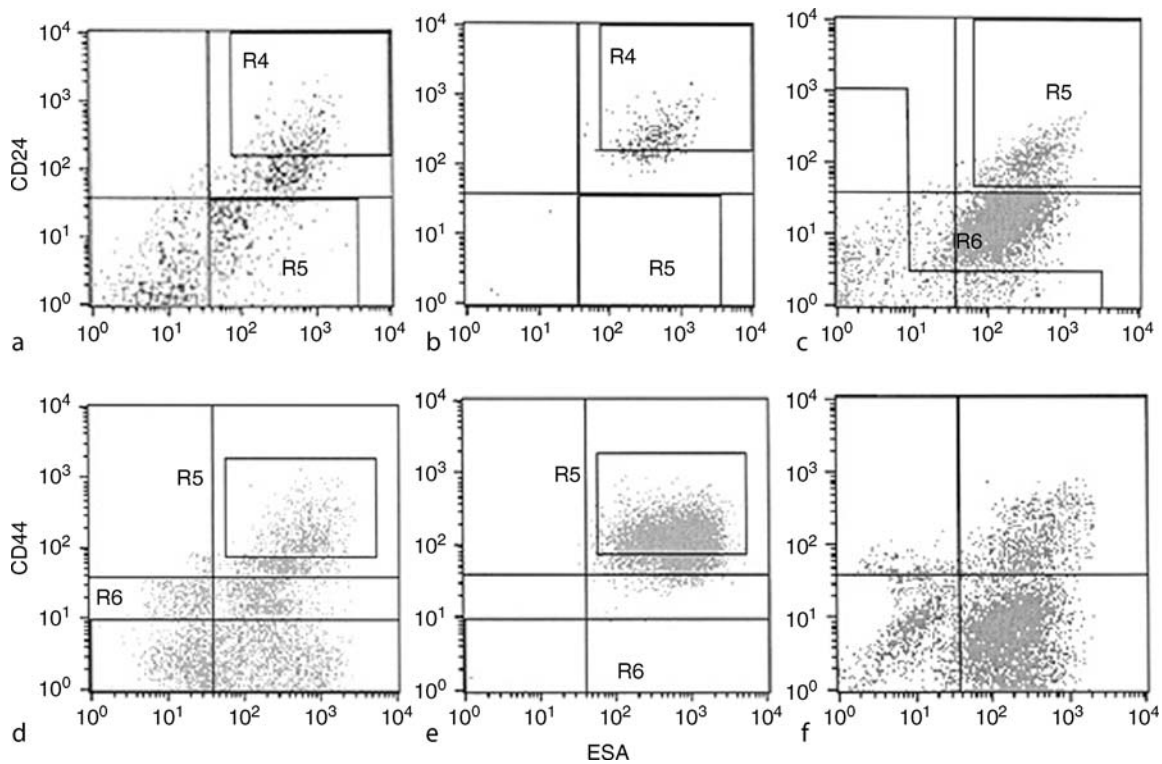
Cell number	10K	1K	500	100
Unsorted	4/6	0/6	0/3	0/3
$CD24^{+}$ ESA^{+}	6/8	5/8	5/8	2/8
$CD24^{-}$ ESA^{-}	2/8	1/8	0/8	0/8
$CD44^{+}/CD24^{+}/ESA^{+}$	10/12	10/12	7/12	6/12
$CD44^{-}/CD24^{-}/ESA^{-}$	1/12	0/12	0/12	0/12

commonly expressed proteins seen in the original tumor (Fig. 3). The capacity of these highly, tumorigenic $CD44^+$ $CD24^+$ ESA^+ pancreatic cancer cells to both self-renew and produce differentiated progeny highlight their stem cell properties.

It is not known at present whether these pancreatic cancer stem cells arise from a mutated stem cell, or a differentiated cell that has regained stem cell-like properties because of genetic alterations. Several studies examining other cancers have supported the



Pancreatic Cancer Stem Cells. Figure 2 H&E staining of the tumor generated from $CD44^+$ $CD24^+$ ESA^+ cells (*right*) has similar histologic features to the corresponding patient's primary pancreatic tumor (*left*). Magnification, 200×.



Pancreatic Cancer Stem Cells. Figure 3 Highly tumorigenic pancreatic cancer cells display stem cell-like properties. (a–f) Phenotypic diversity in tumors arising from $CD44^+$ $CD24^+$ ESA^+ cells. Plots are representative of the CD44, CD24, and ESA staining patterns of human pancreatic cancer cells. (a and d) Staining pattern from a patient tumor. $CD44^+$ $CD24^+$ ESA^+ tumorigenic cells from the tumor were then isolated (b and e) and injected into the flank of NOD/SCID mice. (c and f) The staining pattern of the resultant tumor that arose from the $CD44^+$ $CD24^+$ ESA^+ cells. The tumorigenic cells formed tumors that contained phenotypically diverse cells (c and f) similar to those seen in the original tumor (a and d).

concept that cancer stem cells likely arise from self-renewing adult stem cells which are transformed by dysregulation of a self-renewal pathway. Characterizing normal pancreatic stem cells will greatly enhance our understanding of pancreatic cancer stem cells. Unfortunately, despite extensive effort, isolation of normal pancreatic stem cells has not yet been achieved to date.

A critical consequence of the identification of pancreatic stem cells is the potential impact this may have on approaches to treatment of pancreatic cancer. It is likely that therapies specifically targeting this stem cell population will be needed to improve the likelihood of long-term cure for patients with pancreatic cancer. Approaches targeting markers expressed specifically on the cell surface of pancreatic cancer stem cells (i.e. CD44) or drugs that target signaling pathways that are specifically altered in these pancreatic cancer stem cells, such as ►sonic hedgehog, are likely to lead to significant improvements in outcome for pancreatic cancer patients. In short, a better understanding of pancreatic cancer stem cells will aid in refining current anti-cancer therapies, and ultimately help to identify novel diagnostic markers and therapeutic targets.

Pancreatic Ductal Adenocarcinoma

Definition

DA; Is the most important of the ductal neoplasia and constitutes the vast majority of pancreatic tumors. DA is one of the most aggressive cancers and is produced by progressive mutations in cancer-related genes that can appear early or late in the evolution of the disease.

►Pancreatic Cancer

Pancreatic Islet Cells

Definition

The pancreas is organized into the exocrine and endocrine tissues. The endocrine pancreas consist of islands i.e. islets, of cells that secrete a number of hormones that include, insulin, gastrin, glucagon, pancreatic polypeptide, VIP, and somatostatin.

Panitumamab

Definition

In September of 2006, FDA approved panitumumab, a recombinant human monoclonal antibody that binds the human epidermal growth factor receptor (EGFR), for the treatment of patients of patients with EGFR-expressing metastatic adenocarcinoma of the colon or rectum (MCRC) after disease progression on or following fluoropyrimidine-, oxaliplatin-, and irinotecan-containing chemotherapy regimens. The efficacy of panitumumab was demonstrated in a phase III randomized, open-label, controlled trial comparing panitumumab plus best supportive care (BSC) versus BSC alone in a total 463 patients with 5-FU, irinotecan and oxaliplatin refractory disease. Nineteen of 231 (8%) subjects in the panitumumab arm had a partial response, and there was significant prolongation of progression free survival in the panitumumab arm.

Pannexins

Charles P. K. Lai, John F. Bechberger, Christian C. Naus
Department of Cellular and Physiological Sciences, The University of British Columbia, Vancouver, BC, Canada

Definition

Pannexins are a second family of ►gap junction genes, distinct from ►connexins. However, in function they are similar to connexins, forming ►hemichannels,

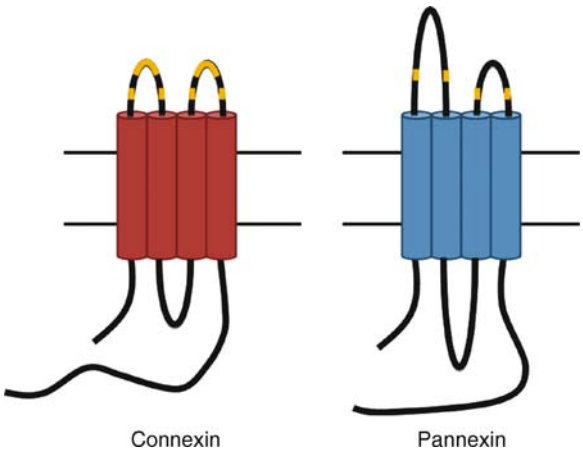
proteinaceous cylinders spanning the plasma membrane and encompassing a hydrophilic channel.

Characteristics

Overview. Until quite recently, only one mammalian family of gap junction genes had been identified, namely the connexins. However, a novel family of mammalian gap junction genes with low sequence similarity to the invertebrate gap junctions, ►innexins (Inxs), has been discovered in chordates and termed pannexins (Panxs). Currently, three pannexin members (►Panx1, ►Panx2 and ►Panx3) have been identified in vertebrates. Previous studies on Inx mutants in *Drosophila* have demonstrated Inx-specific functions including synaptogenesis in the giant-fiber system, epithelial organization and morphogenesis, and germ cell differentiation processes. The role of pannexins in mammalian cells and tissues has yet to be fully explored.

Similarities Between Connexins and Pannexins. Despite sequence dissimilarity between connexins and pannexins, the two protein families share structural resemblance. Similar to connexins, pannexins have a predicted topology of four membrane-spanning domains, two extracellular loops, a cytoplasmic loop, and cytoplasmic amino- and carboxy-termini. Intriguingly, whereas connexins contain three regularly spaced cysteine residues in the two extracellular loops, pannexins, like innexins, only have two such residues. Numerous studies have suggested the importance of the cysteine residues in facilitating functional connexin-based gap junctions and hemichannels, and therefore the variation in the number of cysteine residues may underlie functional differences between pannexin and connexin functions. Analogous to connexins, pannexin hemichannel and intercellular channel formation are pannexin-specific. Although the two channels have similar characteristics, their differences imply that they could exhibit unique functions via different mechanisms (Fig. 1).

Pannexins as tumor suppressors. Gap junctions, and their constituent connexin proteins, have long been considered to play a role in the control of cell proliferation, with disruptions in expression and gap junctional coupling correlating with cell transformation. However pannexins have just been recently identified and their implication in cancer is only now being examined. Indeed, like connexins, pannexins are now emerging as being ►tumor suppressors. Panx1 is normally expressed in brain ►astrocytes, and has been shown to be reduced in brain tumors, specifically ►gliomas. Panx2 has also been suggested as a tumor-suppressor gene in glial cells. Thus transfection of either Panx1 or Panx2 suppresses the tumorigenic phenotype of glioma cells. High-throughput microarray analysis of human brain tumor samples has also shown an overall reduction of Panx2 gene expression in gliomas. Furthermore, a correlation between Panx2 up-regulation and post diagnosis survival in patients with glial tumors was found using a brain cancer gene expression database (REMBRANDT). In addition, the Panx2 gene is located within chromosomal region 22q13.3 where deletion was often found in human astrocytomas and ependymomas.



Pannexins. Figure 1 Comparison of the topology of connexin versus pannexin proteins. They are both tetraspan transmembrane proteins with two extracellular loops, one intracellular loop and intracellular amino and carboxy termini. While connexins possess three cysteine residues (*yellow regions*) in each extracellular loop, pannexins only have two.

Summary. Targeting some of the cellular mechanisms controlling proliferation, migration and invasion would constitute effective therapeutic strategies. One such mechanism involves intercellular communication through gap junctions. Gap junctions and their constituent proteins, connexins and pannexins, have been shown to play a role in controlling proliferation in many cell types. This has been exploited for possible therapeutic potential by directly targeting cell proliferation, or by utilizing properties of connexins/pannexins and/or gap junction channels to augment ►suicide gene therapy. While the clinical application of therapies targeting Cx/Panx pathways has not yet been realized, valuable approaches to such therapy remain fertile territory.

►Papanicolaau Test

Papain

Definition

Papain is a cysteine protease originally derived from papaya (*Carica papaya*). The tertiary structure of papain consists of two distinct structural domains with a cleft between them. This cleft contains the active site, which contains a catalytic triad made up of three amino acids – cysteine-25 (from which it gets its classification), histidine-159, and asparagine-158.

►Calpain
►Stefins

Papanicolaou Test

Definition

A polychrome staining method originally developed by George N. Papanicolaou. Routinely used in all cytology labs for staining cells so that they can be seen microscopically. Is excellent for evaluating nuclear and cytoplasmic structure. Is the microscopic examination of exfoliated cells obtained by swabs from the uterine cervix (cytology). Abnormal cells showing morphologic signs of papillomavirus infection and/or malignant changes can be identified, in which case usually a direct inspection of the cervix (colposcopy) is performed, eventually followed by biopsy and histological diagnosis. Cytology is currently used as the method in cervical cancer screening programs. Because of the relatively high false negative rate of cytology, it is being evaluated if detection of papillomavirus infection may become a supplementary method in cancer screening.

►Human Papillomaviruses

Papillary Carcinoma

►Follicular Thyroid Tumors

Papillary Carcinoma, Oncocytic Variant

Definition

Papillary carcinoma of the thyroid characterized by an oncocytic cytoplasm that is not large. The cell has the characteristic nuclear features of papillary carcinoma.

►Hurthle Cell Adenoma and Carcinoma

Papillary Thyroid Carcinoma

Definition

Papillary thyroid carcinoma (PTC) derives from the follicular thyroid cells. It is the most common type of thyroid cancer. PTC usually occurs sporadically. However, familial occurrence has been noted. Patients with familial ►adenomatosis polyposis (FAP), which is caused by mutations in the ►*APC* gene, seem to have an

increased risk developing PTC. Patients with ►Cowden syndrome, an inherited hamartoma syndrome caused by mutations in the tumor-suppressor gene ►*PTEN*, also have an increased risk developing thyroid cancer, specifically follicular thyroid carcinoma but PTC has also been reported. Somatic rearrangements in *RET* have most often been found in about 10–40% of PTC. In transgenic mice, these rearrangements are capable causing PTC. Recently, a somatic point mutation in *BRAF* (V600E; previously designated as V599F) has been identified as the most common (35–70%) genetic change is PTCs.

Paracentesis

Definition
Insertion of a thin needle or tube into the abdomen to remove accumulated fluid from the peritoneal cavity.

►Acites

Paracetamol

Definition
Synonym acetaminophen; has analgesic and antipyretic properties, but, unlike aspirin, it is not a very effective anti-inflammatory agent. It is well tolerated, lacks many of the side-effects of aspirin, and is commonly used for the relief of fever, headaches and other minor aches and pains. Paracetamol has not been shown to be carcinogenic in any way.

Paracrine

Definition
Is a factor acting on the immediate neighbors of the cells that produce it. Following interaction with the related

receptor(s), a paracrine activation is obtained (autocrine; receptor tyrosine kinases). Refers to a short-range biologic action mediated by a soluble factor produced by one cell type that acts on another cell type. For example, it was initially thought that scatter factor was produced only by mesenchymal cells such as fibroblasts and acted solely in a paracrine fashion on nearby epithelial cells through their c-Met receptors. However, scatter factor may promote tumorigenesis by autocrine as well as paracrine loops. An example of the latter is the ability of scatter factor produced by primary tumor cells (e.g., glioma or breast cancer cells) to stimulate tumor growth by inducing angiogenesis in the host stroma in experimental mouse and rat tumor models.

►Gut Peptides
►Scatter Factor

Paracrine Stimulation

Definition

production of a factor that stimulate cells in the immediate environment of the producer cell.

Paraesthesia

Definition

Unpleasant sensation of tingling, pricking or numbness.

►Peripheral Neuropathy

Parallel Gene Expression Analysis

►Microarray (cDNA) Technology

Paralogue

Definition

Synonym: Paralog; Describes a set of closely related genes within one species, e.g. the human MDM, RAS and MYC genes. Paralogues share a common evolutionary origin and have been generated by gene or genome duplication events followed by sequence diversification. The products of paralogues often fulfill similar or redundant functions, however, they also display isoform-specific functions with increasing sequence diversification.

►BORIS
►CCCTC-Binding Factor (CTCF)

Parametric

Definition

Parametric, as a statistical term, refers to analyses that assume an underlying mathematical model for the population of interest, like the normal distribution, that is fully characterized by typically unknown constants.

►Kaplan–Meier Survival Analysis

Paraneoplastic Neuropathy

Definition

Malfunction of peripheral nerves associated with an underlying malignant disease.

►Peripheral Neuropathy

Paraneoplastic Syndromes

Definition

The term paraneoplasic syndrome refers to a clinical picture produced by organ damage in areas remote from the tumor and not produced as a direct consequence of the tumor itself. There are many types of paraneoplastic syndromes. A group of paraneoplastic syndromes have an immunologic basis. As an example, several neurologic syndromes have been described in association with small cell lung cancer, including paraneoplastic encephalomyelitis and sensory neuropa-

thy, paraneoplastic cerebellar degeneration, cancer-associated retinopathy, opsoclonus-myoclonus, and Lambert–Eaton myasthenic syndrome. Nearly all these paraneoplastic syndromes are associated with the presence of autoantibodies in the sera. Anti-Hu antibodies are associated with paraneoplastic encephalomyelitis, sensory neuronopathy, cerebellar degeneration, and autonomic neuropathy. These antibodies are generated against the Hu antigen found in neurons. Anti-Hu antibodies may be found in the sera of patients with small cell lung cancer, but they are not useful diagnostic biomarkers of this malignancy, because although most small cell lung cancers express the Hu antigen, <20% of all patients with small cell lung cancer have detectable levels of anti-Hu antibodies. Two thirds of patients with anti-Hu antibodies have other autoantibodies not yet characterized. Although anti-Hu antibodies have been found in ovarian, breast, prostate, and colon cancer, the presence of anti-Hu antibodies is almost always indicative of an underlying small cell lung cancer. Autoantibodies that bind to ganglionic acetylcholine receptors have been reported in patients with various forms of autoimmune autonomic neuropathy. The correlation between high levels of ganglionic-receptor antibodies and the severity of autonomic dysfunction suggested that the antibodies may have a pathogenic role. Autoantibodies may be directly responsible for tissue injury. Examples of autoantibodies that have been thought to be associated with tissue injury are those of cancer-associated retinopathy. Also, anti-Hu, and anti-Yo antibodies which have been shown to react with tumor antigens, and bind proteins of the endoplasmic reticulum in Purkinje cells in patients with paraneoplastic cerebellar degeneration in breast and ovarian carcinomas. In addition, although these paraneoplastic syndromes are rare, they provide clear examples of autoantibodies preceding the clinical diagnosis of breast cancer and ovarian cancer.

►Autoantibodies

Parathyroid Glands

Definition

Consist of usually two pairs of endocrine glands, situated near the thyroid gland in the neck. The parathyroid glands secrete a hormone – parathyroid hormone (PTH) – which acts on the kidneys and bone to regulate calcium in the extracellular fluid.

►Multiple Endocrine Neoplasia Type 1

Parathyroid Hormone-Related Protein

Jürgen Dittmer
Clinic for Gynecology, University of Halle, Halle, Germany

Synonyms

PTHrP; PTHLH; PLP

Definition

PTHrP was discovered as a humoral factor that induces hypercalcaemia of malignancy. PTHrP shares with parathyroid hormone (PTH), a protein that regulates calcium homeostasis, the ability to interact with the parathyroid hormone receptor 1 (PTH1R), a ►G-protein coupled receptor. Activation of PTH1R in bone, kidney and intestine leads to increased calcium blood levels.

Characteristics

Protein Structure

Three isoforms of the PTHrP protein exist, containing 139, 141 or 173 amino acid, each of which is coupled to a prepropeptide of 36 amino acid on its N-terminus. The mature PTHrP consists of a least three functional domains, the N-terminus, the mid-region domain and the C-terminal domain. In the 173 amino acid isoform, the last 34 amino acids may form a fourth functional domain. Following post-transcriptional cleavage of PTHrP, these domains are able to act separately. The N-terminus shows similarities to the N-terminus of PTH and is a secretory peptide that interacts with PTH1R. This interaction gives rise to an increase in cellular cAMP levels, but can also lead to activation of calcium (►Calcium Binding Proteins and Cancer)- or ►protein kinase C-dependent pathways. The mid-region domain translocates into the nucleus and is able to accumulate in the nucleolus. Nuclear translocation is blocked upon phosphorylation of this domain by CDK1/2 (►Cyclin-Dependent Kinases). The import of the mid-region domain into the nucleus is therefore thought to be regulated in a cell cycle dependent manner. The C-terminal domain (osteostatin) antagonizes the bone-absorbing action of the N-terminal domain of PTHrP, probably by interfering with PTH1R internalization. The C-terminal domain contains four serine phosphorylation sites that are required for its mitogenic activity on vascular smooth muscle cells. The last 34 amino acid of the 173 amino acid isoform has been shown to interfere with nuclear localization of PTHrP and to raise the cellular cAMP level. PTHrP mRNA undergoes extensive splicing. N-terminal splicing of PTHrP mRNA varies depending on the promoter that initiated

transcription. C-terminal splicing of the PTHrP mRNA that give rise to the different protein isoforms seems to be independent of promoter usage. All PTHrP transcripts contain the coding exons for the three functional domains (Fig. 1).

Regulation of PTHrP Expression

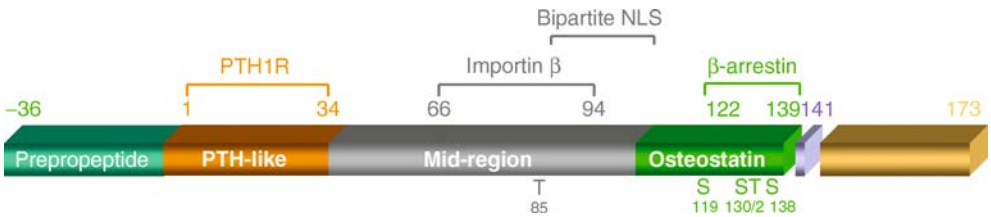
PTHrP expression is mainly regulated on the transcriptional level. In humans, three different PTHrP promoters (P1, P2 and P3) have been identified. The best characterized promoter is the proximal P3-promoter. It contains functional binding sites for ►Ets transcription factors, Sp1 and for the TGFβ (►transforming growth factor β)-regulated Smads. The Ets binding site is required for the activation of PTHrP by the ►Ras/Raf/MEK-1/ERK1/2 pathway. This signaling cascade is used by tyrosine receptor kinases, such as EGFR (►Epidermal Growth Factor Receptor Ligands), and ►G-protein coupled receptors, such as the calcium sensing receptor, to activate PTHrP transcription. TGFβ upregulates PTHrP gene transcription by recruiting Smad proteins to the Smad site of the PTHrP P3 promoter where the Smad proteins cooperate with Ets and Sp-like proteins. A number of cytokines, including IL-1β, IL-2, IL-4 and IL-6, also activate PTHrP expression on the transcriptional level. In addition, the interaction of cells with particular ►extracellular matrix proteins can trigger PTHrP expression. Inhibition of PTHrP transcription is achieved by treatment with nuclear receptor ligands, such as vitamin D, retinoic acid and glucocorticoids. Vitamin D represses PTHrP transcription through a vitamin D response element in the P1 promoter.

Normal Functions

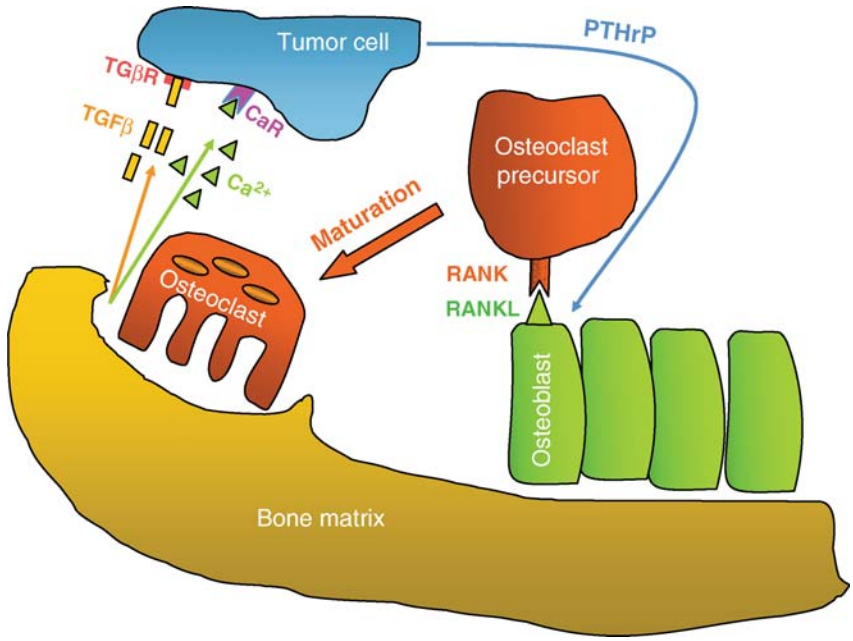
The normal function of PTHrP is to regulate many biological processes critical in embryonal development and adult physiology. PTHrP usually acts locally as a paracrine or autocrine factor. As a paracrine factor, PTHrP plays a crucial role in bone development where it is expressed by the periarticular perichondrium to activate proliferation of PTH1R-expressing condrocytes, thereby preventing premature ossification. PTHrP knockout mice die shortly after birth because of fatal skeletal dysplasia. Of similar importance is PTHrP for mammary gland development. PTHrP is required for ductal morphogenesis and sexual dimorphism as it triggers formation of mammary-specific mesenchyme. A number of other processes have been linked to PTHrP function, such as lactation and tooth development. In tooth development, PTHrP stimulates bone resorption of the alveolar bone, a process needed for tooth eruption. By interfering with keratinocyte differentiation, PTHrP likely plays a role in skin development. Proliferative or antiproliferative effects on regeneration processes, such as wound healing, have been attributed to PTHrP. An important role of PTHrP in controlling the vascular tone is emerging. As a vasorelaxant PTHrP regulates the contractility of many different vascular beds, including kidney microvessels and the arteries and veins of the mammary gland. During pregnancy, PTHrP is essential for the fetal–placental calcium transport, an activity that seems to be dependent upon the mid-regional part of PTHrP. Furthermore, a role of PTHrP in the survival of neurons is discussed (Fig. 2).

PTHrP and Cancer

PTHrP is expressed by many tumors, including carcinomas of breast, kidney, prostate, colon, stomach and lung. In hematopoietic malignancy, it is predominantly found in HTLV-I (►Human T-cell Leukemia Virus) induced adult T-cell leukemia, probably as a result of the ability of the HTLV-1 protein Tax to strongly induce PTHrP transcription. Cancers can secrete PTHrP at levels that are sufficient to raise PTHrP blood levels and to induce hypercalcaemia of malignancy, a disease that complicates cancer. Besides this endocrine cancer-related function, PTHrP displays autocrine and paracrine activities that



Parathyroid Hormone-Related Protein. Figure 1 The human parathyroid hormone-related protein. The three initial translational products (-36/139, -36/141 and -36/173) of human PTHrP contain a prepropeptide of 36 amino acid at their N-termini. The mature protein consists of three functional domains, the PTH-like N-terminal domain, the mid-region domain and the C-terminal domain (osteostatin). The PTH-like domain interacts with the PTH1 receptor. The mid-region domain harbors two sequences that mediate its translocation into the nucleus. The first sequence interacts with importin β, the other is a bipartite nuclear localization sequence (NLS). T and S denotes threonine- and serine-based phosphorylation sites, respectively. Thr^{85} can be phosphorylated by CDK1/2. The β-arrestin interaction domain of osteostatin is indicated. Arrestins are involved in internalization and inactivation of ligand-stimulated G-protein coupled receptors, such as PTH1R.



Parathyroid Hormone-Related Protein. Figure 2 Involvement of PTHrP in skeletal metastasis. PTHrP produced by breast cancer cells that metastasized to bone may fuel a vicious cycle by stimulating osteoblasts to interact with osteoclast precursors via RANK/RANKL (►RANK-RANKL Signaling). As a result, the osteoclast precursors will mature to osteolytic osteoclasts. Following its destruction, the bone matrix releases TGFβ and calcium which then activate their corresponding receptors on the tumor cells (TGβR and CaR). The activated receptors further stimulate PTHrP production and more osteoclasts are recruited for bone degradation. This positive feedback loop is thought to facilitate metastasis growth by providing space for tumor expansion.

seem to influence tumor progression and metastasis. One of the best characterized examples for the importance of PTHrP in cancer is its involvement in breast cancer growth in the bone. By secreting PTHrP, breast cancer cells that metastasized to bone induce osteoclastic bone-absorption leading to bone destruction and release of TGFβ which then acts back on the cancer cells and further boosts PTHrP expression in these cells. This positive feedback fuels a vicious cycle that accelerates osteolysis and facilitates expansion of the metastatic cells in the bone environment. It is likely that calcium is supporting this process. Calcium is also released upon bone degradation and stimulates PTHrP expression in the tumor cells by activating the calcium sensing receptor CaR. PTHrP secreted into the bone may also interfere with hematopoiesis by stimulating the activity of hematopoietic stem cells. Other studies show that PTHrP protects cancer cells from apoptosis, stimulate their proliferation and triggers their ability to migrate and invade extracellular matrix. A number of genes that are targeted by PTHrP in cancer cells have been identified. Among them are genes encoding integrin α6 (►Integrin Signaling and Cancer), PAI-1 (►Plasminogen Activating System), CDK1 (►Cyclin-Dependent Kinases) and ►KiSS-1. Activation of the PI3K/AKT pathway (►AKT Signal Transduction Pathway in Oncogenesis) by PTHrP has also been shown. The PTHrP domain that mediates these effects varies with the targeted gene. For example, integrin α6 is activated via the mid-region domain, whereas the N-terminal domain seems to be important for the repression of CDK1. Supporting the notion that PTHrP is a tumor-promoting factor, many survival analyses of cancer patients revealed that PTHrP expression in the tumor increases the risk of a relapse und is linked with unfavorable prognosis. In breast cancer, coexpression of PTH1R along with PTHrP further reduced disease-free survival. It should be noted, however, that the value of PTHrP as a prognostic factor of breast cancer is still a matter of debate, as also data have been published that show that PTHrP expression in breast cancer correlates with a more favorable prognosis.

Paresthesia

Definition

An abnormal sensation in the skin, including tingling, prickling, or burning, that has no objective cause, and is usually due to injury to a sensory nerve.

►Taxotere

Parity

Definition

The number of pregnancies a woman has had which have gone beyond 24 weeks gestation.

►Endometriosis

Parkinson Disease

Definition

A progressive neurodegenerative disorder characterized the loss of dopamine neurons, resulting in tremor, rigidity, slowness of movement, and postural instability.

►Synuclein

Parosteal Lipoma

Definition

Is a rare benign neoplasm of adipose tissue that exhibits a contiguous relationship with the periosteum. These lipomas of the bone share some histopathologic features with their commonly occurring soft tissue counterparts. While the latter ones are one of the most common mesenchymal tumors, only slightly over 100 cases of parosteal lipoma have been reported in the literature.

►Lipoma Preferred Partner

PARP

Definition

►Poly(ADP-ribose) polymerase.

PARP Inhibitors

Definition

Poly(ADP-ribose) polymerase inhibitors are a large number of low molecular weight compounds (NAD+ analogs) that competitively inhibit PARP activity. Amongst the first to be described were nicotinamide, benzamide and 3-aminobenzamide. However, their potency and specificity is rather low. Subsequently, more sophisticated new compounds have been developed such as 4-amino-1,8-naphthalimide, 3,4-dihydro-5-methoxyisoquinolin-1(2H)-one (PD 128763), 8-hydroxy-2-methylquinazolin-4(3H)-one (NU1025) or 2-methylbenzimidazole-4-carboxamide (NU1064), to name but a few. These are much more potent than the first generation inhibitors and possess an improved pharmacokinetic profile.

With respect to specificity, while all inhibitors inhibit PARP-1 (by definition), at least some of the first generation inhibitors also interfered with other ADP-ribosyl transfer reactions, such as mono-ADP-ribosylation of proteins or NAD+ glycohydrolases, albeit at different IC50 levels. Furthermore, the novel poly (ADP-ribose) polymerases recently identified are likely to be inhibited as well, perhaps at similar IC50 levels as PARP-1.

►Poly(ADP-Ribosyl)ation

Particle-induced Cancer

Anne Thoustrup Saber[1], Ulla Vogel[1], Steffen Loft[2], Håkan Wallin[1]
[1]National Research Centre for the Working Environment, Denmark
[2]Institute of Public Health, Department of Occupational and Environmental Health, Denmark

Definition

Particle-induced cancer refers to cancer arising after exposure to particles.

P

Introduction

Particles are here defined as solid spherical or fibrous materials suspended in air. It has been documented that particle-induced cancer occurs in animals and humans after inhalation of solid insoluble particles. The ►International Agency for Research on Cancer (IARC) has classified a number of particles according to their carcinogenicity. Group 1 agents are carcinogenic to humans. Group 2A agents are probably carcinogenic to humans, while group 2B agents are possibly carcinogenic to humans.

In the outdoor environment ►ultrafine particles are formed by the combustion processes e.g. of diesel (group 2A) and biomass (group 2A). Indoor sources of particle pollution include smoke from tobacco (group 1), cooking fires, wood stoves, fireplaces and candles (smoky coal is classified as group 1 carcinogen). Some occupational exposures to aerosols of solid particles have been associated with ►cancer in the respiratory tract. Examples are quartz (group 1), asbestos (group 1), soot (group 1), welding fumes (group 2B) and wood dust (group 1).

The effects of particles deposited in the lung may be related to carcinogenic effects that have been noted in animals after surgical implantation of some stable solid materials such as thin films of polymeric or metallic materials or solid metallic bodies of specific compositions.

In the hitherto largest study, in which 500,000 persons from 51 urban areas in USA were followed for over 16 years, the incidence of lung cancer correlated with long-term exposure to fine particulate matter: For every 10 $\mu g/m^3$ increase in fine particles (PM2.5) lung cancer mortality increased by approximately 8% each year. The study provides the strongest evidence yet for linking ►lung cancer to air pollution in urban areas.

Particle Size and Form

Particles in urban air tend to have a multimodal distribution, partly reflecting the sources. Particles are traditionally divided in three different size fractions: the ultrafine (<0.1 μm), fine (<2.5 μm) and coarse (>2.5 μm). In relation to traffic sources the fine and ultrafine fraction are generated by combustion from motor vehicles, whereas the coarse fraction consists of particles generated by mechanical processes. The ultrafine particles (UFP) aggregate fast, forming larger accumulation particles. For equivalent masses of inhaled particles, ultra-fine particles provide a greater surface area per mass unit for adsorption of potentially toxic agents, and present a greater capacity for the formation of ►free radicals and oxidants on the particle surface than do the larger sized particles. This means that they have a greater potential of reacting with the lung cells.

Another group of particles are the engineered ►nanoparticles which have been produced in a multitude of forms and sizes, ranging from spherical fullerenes to nanotubes.

Fibers, such as asbestos, exist in different lengths and diameters. The size and shape of the asbestos fibers are important determinants for their toxicity. Fibers with a diameter of less than 3 μm and a length of more than 5 μm are considered to be most hazardous to health (diameter: length = 1:3).

Deposition and Clearance of Particles in the Lungs

The deposition of particles in the lungs depends on particle size. Particles with a diameter greater than 10 μm, are deposited primarily in the upper airways (nose, nasopharynx), whereas smaller particles are able to deposit in greater number and deeper down in the lungs, in the bronchia. The ultrafine particles are able to reach the alveoli. The retention of particles depends on many factors, including particle characteristics (such as size, shape, solubility and surface chemistry) and anatomical factors.

There are a number of defence mechanisms in the respiratory tract that manage to keep the mucosal surfaces free from foreign materials deposited after inhalation. In the ciliated airways in the nose, trachea, the bronchia and bronchioli, deposited materials, such as insoluble particles, are effectively removed by transport of the mucus blanket by the beating of cilia towards the pharynx, where the foreign material is swallowed. Mucociliary clearance is fast; however, if the insoluble materials are deposited in the alveoli, where there is no mucociliary transport, the clearance is much slower. Moreover, ultrafine particles in bronchia and bronchioli have a slow mucociliary clearance. Usually particles deposited in the alveoli are cleared by phagocytosis by alveolar macrophages. The macrophages are capable of crossing the lung epithelium or phagocytized material may be dissolved by the macrophage. It is unclear if particles are able to pass over the lung epithelial cells by other mechanisms. Sometimes particles are trapped in the lung for a very long time and may be concentrated in foci at which interstitial fibrosis may develop.

Mechanisms

Different kinds of particles have been shown to induce genotoxic damage after deposition in the lung. This may result in cancer if the ►DNA damage is not repaired or if selective ►apoptosis of the damaged cells fails.

1. A primary mechanism of particle-induced ►genotoxicity has been attributed to the surface characteristics. Urban air pollution particles and diesel exhaust particles consist of a carbon core onto which ►polycyclic aromatic hydrocarbons (PAHs), ►quinones,

and ►transition metals are adsorbed. Transition metals, quinones and PAHs on the surface or released from the particles are able to generate ►reactive oxygen species (ROS) thereby causing DNA damage.
2. Another direct way of action is due to the surface activity of the particles to generate ROS extracellularly or intracellularly via activation of mitochondria and ►NADPH oxidase.
3. A decade ago another indirect pathway for genotoxicity was proposed on the basis of the finding that carbon black exposed rats developed tumours similar to DEP exposed rats, despite the fact that carbon black is almost devoid of PAH's on the surface. The fact that tumour formation in rats has been found to be paralleled by the degree of chronic neutrophilic ►inflammation led to the idea about a relationship between particle-induced inflammation and genotoxicity. Likewise, most human cancers are accompanied by the infiltration of inflammatory cells and a wide range of chronic inflammatory diseases predispose to cancer in the affected organ. The genotoxic effect of particle-induced inflammation is related to the release of reactive oxygen species by the inflammatory process. It has been demonstrated that the inflammatory response depends on the particle size. Exposure studies have shown that ultrafine particles cause more inflammation in the lungs of rodents than exposure to the same mass concentration of fine particles. The greater surface area has been suggested to be responsible for the greater inflammatory response of the ultrafine particles. This is based on a linear correlation between surface area of relatively inert particles and inflammatory response measured by the total number of neutrophils in rats.
4. Chronic inflammation and fibrosis are pathological changes in the cellular and ultrastructural composition of tissues. Fibrosis is a type of scarring reaction that involves excess fibrous connective tissue. Such changes in the tissue environment may promote the growth of cellular growth and carcinogenetic transformation. There is a clear association between the occurrence of cancer and fibrosis in the lung and other tissues. However, it is unclear if the tissue changes are a part of carcinogenic transformation or if it is a parallel process.

Thus, the genotoxic effects of PM can either be directly due to surface properties of the particles or due to ROS released by the inflammatory process.

The mechanisms behind the carcinogenic effects of particles at present are still poorly understood. The importance of obtaining more knowledge about the mechanisms behind the carcinogenic effect of particles is underlined by the emerging nanotechnology. Nanotechnology may lead to the release of persistent nanosized particles, and must be considered as an important contributor to the exposure of particles at the work place and the environment in the future.

Particulate Matter

Definition

Is suspension of tiny solid (a smoke) or liquid (an aerosol) particles suspended in a gas.

►Xenobiotics

Parvovirus

Definition

Eukaryotic virus family characterized by unusually small size of viral capsid (~20 nm) and viral DNA genome (~5,000 nucleotides).

►AAV

Passive Cell Death

Definition

►Necrosis.

Passive Immunity

Definition

Immunity resulting from the transfer of antibodies or antiserum produced by another individual.

Passive Targeting

Definition

A mechanism by which drugs and drug delivery vectors can be preferentially delivered to target cells *in vivo*, especially cells in tumor tissue. Based on their physicochemical properties (small size and/or surface modification with polyethylene glycol), drugs or drug delivery vectors can escape from nonspecific trapping by the reticuloendothelial system and accumulate in target tissues after circulating in the blood. Because cancer tissues are characterized by a high interstitial pressure, enhanced vascular permeability, and the lack of functional lymphatic drainage, passive targeting has become a popular approach for drug delivery.

►Non-viral Vector for Cancer Therapy
►Targeted Drug Delivery

Patch-Clamp Technique

Definition

Is an electrophysiological method in which a seal is formed between the tip of a glass pipette and a cell membrane. The technique allows the recording of ion channels activity and is widely used in pharmacology, for example studying chemotherapeutic drugs and ion channels involved in cancer.

►Ether à-go-go Potassium Channels

Patched

Definition

PCTH; Is a member of the patched gene family. The protein is the receptor for sonic hedgehog, a secreted molecule implicated in the formation of embryonic structures and in tumorigenesis. This gene functions as a tumor suppressor. Mutations of this gene have been associated with ►naevoid basal cell carcinoma syndrome, esophageal squamous cell carcinoma, trichoepitheliomas, and transitional cell carcinomas of the bladder.

►Hedgehog Signaling

Pathogen-Associated Molecular Pattern

Definition

PAMP; Collective term for biochemically diverse substructures of pathogenic origin recognized by the target cells of the respective hosts. Usually bind to so-called pattern recognition receptors (PRR) on the cell surface or in the cytoplasm of the target cell and initiate an immediate (antimicrobial) cellular response.

►Bacillus Calmette-Guérin

Pathogenesis

Definition

Pathogenesis is the mechanism by which a certain etiological factor causes disease.

►Gastrointestinal Stromal Tumor

Pathological Tumor Cell-Platelet Interaction

►Tumor Cell-Induced Platelet Aggregation

Pathology

Saul Suster
Department of Pathology, Medical College of Wisconsin, Milwaukee, WI, USA

Synonyms

Surgical pathology; Diagnostic pathology; Oncologic surgical pathology; Tumor pathology; Tumor typing; Molecular pathology

Definition

The study of human tissues to establish a diagnosis and determine the nature, extent, optimal therapy and possible future behavior of a disease process.

Characteristics

The traditional role of the surgical pathologist has been to analyze tissues obtained from various biopsy procedures in human subjects to establish the type of disease. Due to advances in modern science, the role of the surgical pathologist has been considerably expanded, and we currently act as highly specialized consultants who not only are responsible for rendering a diagnosis, but also for mapping the extent of the disease, determining its degree of aggressiveness, predicting response to therapy and advising the clinician as to the possible biologic behavior of the lesion.

The most basic method used by the pathologist for the study of tumors is conventional histology. This technique involves processing representative tissue samples in a standard fashion to produce thin tissue sections that are stained with special chemical dyes (hematoxylin and eosin) and then examined under transmitted light in a microscope. The information obtained from this simple and basic technique will permit answering most routine questions in 70–80% of cases in most pathology laboratories. A series of other ancillary techniques has been traditionally employed to expand our ability to understand and identify the processes being studied, including ►histochemistry, ►electron microscopy, ►immunohistochemistry, ►cytogenetics, ►flow cytometry, and ►molecular pathology. In recent years, immunohistochemistry and molecular pathology have largely superseded histochemistry and electron microscopy in the routine practice of surgical pathology, although there still remain many valid indications for their use.

The most central role of diagnostic pathologists remains tumor typing. Another important role of the pathologist is to provide proper ►staging and ►grading information for malignant neoplasms. Proper staging and classification requires determining the type of tissue and anatomic site of origin of the tumor (i.e. breast, colon, etc). In the past, human neoplasms were traditionally classified on the basis of their purported cells of origin (histogenesis). In recent years there has been a shift towards classifications based on the realized lines of differentiation of the tumor cells rather than on a hypothetical cell of origin. Based on a given tumor's realized lines of differentiation, several broad categories of tumor types or tumor families are identified including epithelial, mesoderm-derived (i.e. ►mesenchymal tumors), ►neural tumors, ►neuroectodermal tumors, ►neuroendocrine tumors, ►germ cell tumors, ►blastemal tumors, ►hematolymphoid tumors, ►melanocytic tumors and mixed tumors showing combinations of the above. Finally, tumors of unknown or uncertain histogenesis constitute another important category (Table 1).

Pathologic Factors Involved in the Prognostication of Human Neoplasms

Factors that provide important prognostic information for the management of human neoplasms include the histologic type of the tumor, the grading, the staging, and the status of resection of the tumor. The grading of a tumor is generally established by determining the degree of cytologic atypia (or deviation from the normal) of the tumor cells, which is usually manifested by increasing nuclear size and aberrations of nuclear components (i.e. enlarged nuclei, hyperchromatism, prominent nucleoli, mitotic figures, etc). Alternatively, grading can be also done by determining the degree of differentiation of the tumor cells (i.e. the extent to which the tumor cells resemble their normal counterparts). As such, tumors may be categorized as well, moderately or poorly-differentiated, with progressive loss of differentiation (i.e. higher grade) generally implying a more aggressive biologic potential.

Staging of malignant neoplasms has been found to directly correlate with prognosis in the majority of human cancers. The staging for most tumor systems utilizes a combination of clinical and pathologic parameters to determine how advanced or localized a disease process is. A variety of staging systems has been proposed over the years; the most commonly employed is that based on the assessment of the size of the tumor, the presence or absence of lymph node metastases, and the presence or absence of distant metastases (so-called T-N-M staging). The most widely used ►TNM staging system is the one proposed by the American Joint Commission on Cancer (AJCC), although other systems also are employed. Staging in combination with grading has historically been the most reliable prognostic parameter for the assessment of biologic behavior in human neoplasms.

Determination of the status of resection for a given neoplasm is another important piece of information provided by the surgical pathologist that plays an important role in the management of cancer patients. This is done by histologically examining the surgical resection margins of a specimen. Another important function of the surgical pathologist is to offer guidance to the surgeon during the operative act to determine the extent of resection and the status of the margins. This intraoperative consultation is done utilizing a frozen section technique which consists of rapid freezing of the tissues which are immediately cut, stained and read by the pathologist to provide a rapid interpretation of the findings. This method is often used during surgery to determine the status of the surgical margins. Newer

Pathology. Table 1 Classification of solid tumors

Epithelial neoplasms
General
Adenoma/adenocarcinoma
Squamous cell carcinoma
Papilloma/papillary carcinoma
Transitional cell carcinoma
Clear cell carcinoma
Large cell carcinoma/giant cell carcinoma
Spindle cell (sarcomatoid) carcinoma
Anaplastic carcinoma
Organ/tissue specific
Adenoid cystic carcinoma (salivary glands and other organs)
Adenomatoid tumor (serosal surfaces and other organs)
Acinar cell carcinoma (pancreas)
Acinic cell carcinoma (salivary glands and other organs)
Ameloblastoma/ameloblastic carcinoma (mandible)
Adrenal cortical adenoma/Adrenal cortical carcinoma
►Basal cell carcinoma (skin and other organs)
Brenner tumor (ovary)
Calcifying epithelial odontogenic tumor (Pindborg tumor) (mandible)
Ceruminous gland carcinoma (ear)
Cholangiocarcinoma (liver)
Choroid plexus papilloma/Choroid plexus carcinoma (brain)
Collecting duct carcinoma (kidney)
Craniopharyngioma (brain)
Epi-myoepithelial carcinoma (salivary gland and other organs)
Follicular adenoma/Follicular carcinoma (thyroid)
Glassy cell carcinoma (cervix, uterus)
Hepatoma (liver)
Hepatoid adenocarcinoma (endometrium, stomach and other organs)
Hurthle cell adenoma/Hurthle cell carcinoma (thyroid)
Metanephric adenoma (kidney)
Mucoepidermoid carcinoma (salivary glands and other organs)
►Mesothelioma (serosal surfaces)
Myoepithelial carcinoma (salivary glands and other organs)
Polymorphous low-grade adenocarcinoma (salivary gland and skin)
Serous papillary carcinoma (ovaries, uterus, peritoneum)
Thymoma, atypical thymoma, thymic carcinoma (thymus)
Mesenchymal neoplasms
Fibroblastic/myofibroblastic/fibrohistiocytic
Fibroma/fibrosarcoma
Fibromyxoid sarcoma/myxofibrosarcoma
Myofibroma/myofibroblastic sarcoma
Myofibroblastoma
Dermatofibrosarcoma protuberans
Malignant fibrous histiocytoma
Cartilage
Chondoma/chondrosarcoma
Chondroblastoma
Extraskeletal myxoid chondrosarcoma
Mesenchymal chondrosarcoma
Bone
Osteoma
Osteoid osteoma
Osteoblastoma
Osteosarcoma
Osteoclastoma (giant cell tumor)
Chondromyxoid fibroma
Smooth muscle
Leiomyoma/leiomyosarcoma
Glomus tumor/glomangiosarcoma
Skeletal muscle
Rhabdomyoma/rhabdomyosarcoma
Adipose tissue
Lipoma/liposarcoma
Lipoblastoma
Vascular endothelium
Hemangioma
Hemangioendothelioma
Angiosarcoma
►Kaposi sarcoma
Organ specific
Meningioma/meningeal sarcoma (meninges)
Meningeal hemangiopericytoma (meninges)
Sex cord/stromal tumors (gonads)
Solitary fibrous tumor (serosal surfaces and other organs)
Cystosarcoma phyllodes (breast)
Gastrointestinal stromal tumor/sarcoma (gastrointestinal tract)
Cementoma/cementoblastoma (mandible)
Embryonal sarcoma (liver)
Endometrial stromal sarcoma (uterus)
Hemangiopericytoma-like intranasal tumor (nasal cavity)
Juxtaglomerular cell tumor (kidney)
Papillary fibroelastoma (heart)
Neural neoplasms
Schwannoma
Neurofibroma
Perineurioma

Pathology. Table 1 Classification of solid tumors (Continued)

Granular cell peripheral nerve sheath tumors
Malignant peripheral nerve sheath tumors
Neuroblastoma
Esthesioneuroblastoma
►Medulloblastoma
►Retinoblastoma
Ganglioneuroma
Ganglioneuroblastoma
Gliomas
Glioblastoma multiforme
Ganglioglioma
Oligodendroglioma
Astrocytoma
Ependymoma
Hemangioblastoma
Neurocytoma
Hematopoietic neoplasms
►Malignant lymphoma
►Hodgkin disease
Granulocytic sarcoma (myelosarcoma)
Plasmacytoma/anaplastic plasmacytoma
True histiocytic sarcoma
Dendritic reticulum cell tumors
Malignant mastocytosis
Langerhans cell histiocytosis/sarcoma
Neuroendocrine neoplasms
Neuroendocrine carcinomas (carcinoid, atypical carcinoid, small cell carcinoma, large cell neuroendocrine carcinoma)
Paraganglioma
Tissue/organ specific
Medullary carcinoma (thyroid)
Pheochromocytoma (adrenal)
Pituitary adenoma/Pituitary carcinoma
Parathyroid adenoma/Parathyroid carcinoma
Merkel cell carcinoma (skin)
Glomus jugulare tumor (ear)
Goblet cell carcinoid
Islet cell tumors (pancreas)
Struma ovarii (ovaries)
Neuroectodermal neoplasms
Ewing sarcoma
Primitive neuroectodermal tumor (PNET)
Melanotic progonoma (melanotic neuroectodermal tumor of infancy)
Blastemal neoplasms
Pulmonary blastoma
Mesoblastic nephroma (kidney)
Wilms tumor (kidney)

Pathology. Table 1 Classification of solid tumors (Continued)

►Hepatoblastoma (liver)
Gonadoblastoma (testis and ovaries)
Pancreatoblastoma (pancreas)
Polar spongioblastoma (brain)
Melanocytic neoplasms
Melanocytic nevi
►Malignant melanoma
Clear cell sarcoma of soft parts
Germ cell tumors
Teratoma (benign, immature and malignant)
Seminoma/dysgerminoma
Yolk sac tumor
Choriocarcioma
Embryonal carcinoma
Combined germ cell tumors
Tumors of mixed histogenesis
Benign mixed tumor (skin, salivary gland and other organs)
Fibroadenoma (breast)
Lipoadenoma (parathyroid and other organs)
Myelolipoma (adrenal and other organs)
Myolipoma/lipoleiomyosarcoma
Dendritic fibromyxolipoma
Lipoleiomyoma (uterus and other organs)
Adenofibroma/adenosarcoma (uterus, ovaries and other organs)
Malignant mixed Mullerian tumors (uterus, ovaries and other organs)
Mixed epithelial and stromal tumor (kidney)
Carcinosarcoma (various organs)
Germ cell tumors with malignant hematopoietic elements
Myomelanocytic tumors (PECOmas)
Angiomyolipoma
Mesenchymoma/malignant mesenchymoma
Ectomesenchymoma
Gangliocytic paraganglioma
Gliosarcoma
Malignant “triton” tumor (malignant schwannoma with rhabdomyosarcoma)
Tumors of uncertain or unknown histogenesis
Clear cell “sugar” tumor (pulmonary and extrapulmonary)
Small round cell desmoplastic tumor
Synovial sarcoma
Epithelioid sarcoma
Rhabdoid tumor
Alveolar soft part sarcoma
Chordoma/parachordoma
Solid pseudopapillary tumor of pancreas

molecular methods have more recently been applied to the determination of residual disease in certain tumor systems, thus enhancing the capability of the oncologic team to detect and treat such lesions at an early stage prior to recurrence.

Techniques in Diagnostic Pathology

Immunohistochemistry is the most widely used ancillary technique for the diagnosis of human tumors. A large variety of tumor-associated surface, cytoplasmic and nuclear antigens have been developed that are amenable to detection in routinely processed human tissue samples. Specific immunophenotypes of neoplasms help characterize their properties and identify their realized lines of differentiation. In addition to serving to establish the correct diagnosis, immunohistochemistry can also be used to determine prognosis and response to therapy. Although a few fairly specific markers have been developed over the years, no truly specific marker exists and it is therefore better to talk of tumor-associated markers for diagnosis. Because of this lack of absolute specificity, antibodies are best used in panels rather than singly. Immunohistochemistry is merely an ancillary technique and the selection of markers must be always guided by the histologic features of the tumor in concert with the clinical background; tumor diagnosis should never be primarily based on the results of immunohistochemical stains independent of the morphologic findings and clinical history.

There is a large variety of tumor-associated or differentiation antigens employed in routine practice for diagnosis. These include ►epithelial-associated antigens (epithelial membrane antigen, ►carcinoembryonic antigen, etc); ►intermediate filaments (keratins, vimentin, desmin, glial fibrillary acidic protein, neurofilaments); ►muscle-associated antigens (actin, myosin, myogenin, etc); ►neural associated markers (►S-100 protein, nerve growth factor receptor, etc); ►endothelium-associated markers (►von Willebrand factor, CD31, etc); ►melanocyte-associated antigens (HMB45, Melan-A, tyrosinase, etc); ►hematolymphoid markers (►cluster-designation [CD] lymphoid markers such as CD3, CD5, CD10, CD20, CD30, CD45, etc.; plasma cell and myeloid-associated markers, etc.); ►germ cell markers (alpha-fetoprotein, placental-like alkaline phosphatase, human chorionic gonadotropin hormone, etc); neuropeptides and hormones (calcitonin, somatostatin, thyroglobulin, etc); ►neuroendocrine markers (chromogranin-A, neuron specific enolase, etc); and others.

Immunohistochemical markers that identify specific oncogenes, growth factors and receptors have also been utilized both for diagnosis and prognosis of tumors. These include ►Her-2-neu (c-erb-b2 proto-oncogene), ►estrogen receptor and ►progesterone receptor, ►bcl-2, ►c-mic^2 (CD99), ►kit (CD117), p16, ►p53, p63, ►epidermal growth factor receptor (EGFR) and others. Overexpression of some of these markers has been associated with certain tumor types, or can correlate with a particular behavior for such tumors. Detection of overexpression of some of these markers is now also being utilized to guide targeted therapy, for example with ►cyclin-dependent kinase inhibitors, such as CD117, whose expression is linked to favorable response to imatinib mesylate, a tyrosine-kinase inhibitor drug with potent antitumor properties that has been applied with success in the treatment of gastrointestinal stromal tumors.

Immunohistochemical markers can also be applied for predicting response to therapy. A variety of tumors are known to be under the regulation of steroid sex hormones (estrogen, progesterone, etc). Response to therapy in such tumors can be monitored and predicted from the status of hormone receptors by immunohistochemistry. Expression of p53 oncoprotein has also been linked to drug resistance and can be utilized to assess chemosensitivity in certain types of tumors. Detection of ►MDR-1 (►P-glycoprotein) has been associated with a multidrug resistant phenotype, whereby tumor cells are able to reduce intracellular accumulation of chemotherapeutic drugs. Her-2-neu expression in ►breast cancer has been shown to predict resistance to hormone therapy in estrogen-receptor-positive tumors and resistance to some types of chemotherapy. Another valuable application of immunohistochemistry is for the detection of proliferation markers, such as ►MIB-1, ►Ki-67, etc. Such markers can provide prognostic information about a variety of tumor processes and have been associated with good predictive value in several tumor systems.

Flow cytometry is a technique that has been proven valuable for the establishment of cell clonality and for aiding specific cell typing and classification in hematopoietic malignancies. This technique can be utilized with body fluids, tissues, peripheral blood and bone marrow. ►Hematological malignancies, lymphomas and leukemias can be immunophenotyped as to their cell lineage (lymphoid, myeloid, plasma cell) and their degree of differentiation. Flow cytometric analysis can also be used for the evaluation of minimal residual disease in hematopoietic neoplasms. DNA flow cytometric analysis of tissues has also been successfully applied to obtain prognostic information for certain types of tumors, such as breast cancer and ►colon cancer.

Molecular pathology and genetic analysis has had an important impact in the management of cancer patients. The application of molecular cytogenetic analysis of human tumors has acquired an important role in recent years not only for diagnosis but also as a tool for determining the extent of disease, provide prognostic

information, and monitor patients for recurrence. Molecular cytogenetic analysis has elucidated specific chromosomal abnormalities associated with hematopoietic and non-hematopoietic neoplasms. A variety of molecular techniques are applied by pathologists for the study of tumors, including ►polymerase chain reaction (PCR), reverse-transcriptase polymerase chain reaction (RT-PCR), ►Southern blot and ►in-situ hybridization. These techniques allow the detection of gene rearrangements, gene fusion products for chromosomal deletions and oncogene analysis. Traditional cytogenetic metaphase studies using cell culture is being slowly replaced in modern surgical pathology laboratories by interphase cytogenetic analysis by fluorescence in-situ hybridization (FISH).

One of the most common applications of molecular pathology is in the diagnosis of hematolymphoid neoplasms. Diagnosis of T cell lymphomas and B cell ►lymphomas can be aided by the demonstration of clonal ►immunoglobulin gene rearrangement or ►T-cell receptor gene rearrangements. Similarly, demonstration of specific ►chromosomal translocations by a variety of molecular techniques are used for the diagnosis of ►follicular lymphoma [t(14;18)], ►chronic myeloid leukemia [t(9;22)], ►mantle cell lymphoma [t(11;14)], ►anaplastic large cell lymphoma [t(2;5)] and others.

Another area in which molecular pathology has made significant advances has been in the molecular genetic characterization of soft tissue sarcomas. In contrast with most epithelial cancers, many soft tissue sarcomas have shown consistent molecular alterations, particularly chromosomal translocations. Identification of such translocations can be of aid in the diagnosis of these tumors. The majority of such translocations often affect genes involved in coding of transcription factors and results in the creation of a unique fusion product that can be detected by PCR or FISH techniques. These fusion proteins can be assayed in small formalin-fixed paraffin-embedded tissue samples, making molecular diagnosis a viable and useful adjunct for pathologic diagnosis. An example of this is the demonstration of the t(X;18)(p11;q11) in ►synovial sarcoma, which involves the fusion of the SYT gene from chromosome 18 to one or two homologous genes on the X chromosome, SSX1 or SSX2. Identification of the SST/SSX chimeric transcript will help establish the diagnosis of synovial sarcoma. This characteristic translocation does not appear to occur in histologically similar soft tissue sarcomas that enter in the differential diagnosis.

Another family of lesions for which molecular analysis has proved helpful is ►Ewing sarcoma and related tumors, such as primitive neuroectodermal tumor (PNET), peripheral neuroepithelioma and the ►Askin tumor. These tumors share a genetic alteration in which the EWS gene fuses with at least five different ETS genes, most commonly Fli-1 on chromosome 11, producing an ►EWS/Fli-1 fusion protein. A similar pattern has also been detected in several other unrelated soft tissue tumors, such as clear cell sarcoma, desmoplastic small round blue cell tumor, and extraskeletal myxoid chondrosarcoma. In clear cell sarcoma, the EWS gene combines with another transcription factor unrelated to the ETS family, ATF1. In desmoplastic small round cell tumor, the EWS gene recombines with the ►Wilms tumor suppressor gene WT1 resulting in a t(11;22)(p13;q12) with the creation of a characteristic ►EWS fusion protein, EWS/WT1. In extraskeletal myxoid chondrosarcoma, a consistent translocation is identified, t(9;22), resulting in the EWS/CHN fusion protein. Some of these fusion products, however, have also been detected in other unrelated neoplasms, somewhat reducing their specificity. Other types of sarcomas associated with distinctive genetic alterations include alveolar ►rhabdomyosarcoma, which is associated with t(13;2) resulting in a ►Pax/FKHR fusion product; dermatofibrosarcoma protuberans, characterized by t(17;22)(q22;q13); and myxoid and round cell liposarcomas, characterized by t(12;16)(q13;p11).

Another area in which molecular diagnosis has been useful is in the detection of minimal or residual disease, and for the assessment of metastases or recurrence. For example, in Ewing sarcoma, the extent of disease at diagnosis represents one of the most powerful predictors of prognosis. In patients with otherwise localized disease, RT-PCR can identify occult tumor cells in the bone marrow. Detection of the Pax/FKHR fusion product in the bone marrow by RT-PCR has also been used for the staging and monitoring of therapy in patients with alveolar rhabdomyosarcoma. PCR has also been used for the detection of occult epithelial metastatic cancer cells in lymph nodes that were negative for malignant cells by routine histologic examination. The clinical significance of such findings, however, has not yet been determined.

Finally, molecular pathology can also play a role in the assessment of prognosis of malignant tumors. For example, determination of ►mismatch repair in colon cancer, typing of ►human papillomavirus in cervical cancer, ►amplification of *MYCN* in ►neuroblastoma, and p53 overexpression in Wilms tumor are but a few examples of this application to tumor pathology.

Pathway Addiction

►Oncogene Addiction

Patient Generated Subjective Global Assessment

Definition

PG-SGA; A nutrition screening tool that incorporates patient solicited data with an evaluation by the healthcare team to identify and quantify nutrition risk.

►Nutrition Status

PAX

Definition

Refers to Paired box genes; PAX genes encode nuclear transcription factors that are regarded as major controllers of developmental processes in both vertebrates and invertebrates. Nine members of the family have been described in mammals, with orthologues present in worms, flies, frogs, fish and birds. PAX genes have been implicated in several human cancers on the basis of their expression level, although the mechanistic implications for expression levels in tumorigenesis are not clear. In alveolar rhabdomyosarcoma (ARMS), chromosome translocations involving juxtaposition of *PAX3* or *PAX7* and the forkhead transcription factor gene, *FKHR* (forkhead box M1) are often seen. These translocations are associated with t(2;13) in 55–73% of cases or t(1;13) in 22% of cases, respectively, and yield chimeric *PAX3-FKHR* or *PAX7-FKHR* genes.

PAX5

Definition

Is a member of the paired box (PAX) family of transcription factors, encodes the B-cell lineage specific activator protein (BSAP) that is expressed at early stages of B-cell differentiation. It is also expressed in developing central nervous system and testes. Alterations of the gene contribute to the neoplastic transformation of B-cell progenitors.

►Acute Lymphoblastic Leukemia

Paxillin

Definition

Is an adaptor protein that is found mainly in sites of integrin-based cell substrate contacts (termed focal adhesions). It plays a role in the turnover of cell-substratum adhesions during motility. It is also present in invadopodia.

►Cortactin

PBPC

Definition

Peripheral blood progenitor cells obtained from peripheral blood by apheresis after mobilizing stem cells by administration of hematopoietic growth factors.

►Ewing Sarcoma

PBX

Definition

The Pre-B cell leukemia transcription factor family (PBX1-3) belongs to the TALE (three amino acid loop extension)-class of homeodomain protein and has a wide functional diversity during development. PBX is

required for hematopoiesis as well as for multiple developmental processes such as skeletal patterning and organogenesis. A conserved YPWM motif in the HOX protein is necessary for cooperative binding with PBX. It has furthermore been shown that PBX1 functions as a HOX cofactor during development. A and B-like HOX proteins form trimeric DNA-binding complexes with PBX and TALE superclass proteins MEIS1A and MEIS1B. The DNA binding affinity and sequence selectivity of HOX homeodomain proteins are increased by the formation of cooperative complexes with the PBX homeodomain protein. A conserved YPWM motif in the HOX protein is necessary for cooperative binding with PBX. More recent data suggest that PBX1 may act even more broadly by modulating the activity of non-homeodomain transcription factors.

►NUP98-HOXA9 Fusion

PCNA

Definition

Proliferating cell nuclear antigen. An accessory protein of the major replication enzymes DNA polymerase δ and γ that is required for DNA synthesis. Commonly used as an indicator of active cell proliferation.

►p21(Waf1/Cip1/Sdi1)

PCP

Definition

Planar cell polarity; the organization of cells within the plane of a single layered sheet of cells.

►Wnt Signaling

PCR

Definition

Polymerase chain reaction; Molecular biological enzymatic technique to amplify DNA sequences from few copies to easily detectable quantities by repeated cycles of melting the DNA double helix, annealing synthetic oligonucleotides complementary to the ends of the DNA sequence to be amplified, and de-novo DNA synthesis by a heat-stable polymerase using the annealed oligonucleotides as anchors.

Definition

►Platelet-derived growth factor.

PDGFR

Definition

►Platelet-derived growth factor receptor
►PDGF.

PDK1

Definition

phosphoinositide-dependent kinase-1; Is a master protein kinase that activates other kinases (e.g., PKB/Akt, SGK) by phosphorylation thereby controlling multiple signaling pathways.

►BCL3

PDMP

Definition

D-threo-1-phenyl-2-decanoylamino-3-morpholino-1-propanol, a cationic ceramide analog that inhibits the ►glycosylation of ►ceramide (to form glucosylceramide), thereby forcing accumulation of ceramide and sphingomyelin. It also inhibits the conversion of glucosylceramide to GalGlcCer and the conversion of the latter to α-GalGalGlcCer (globotriaosyl ceramide) and ganglioside GM3 (NeuAcGalGlcCer). The enzyme that cleaves the ceramide–glucose linkage in GSLs (ceramide glycanase) and the enzyme that transfers fatty acid from phosphatidylcholine and phosphatidylethanolamine to form fatty acyl-1-O-ceramide (lysosomal phospholipase A_2) are also inhibited by PDMP. All of these effects add up to increased levels of ceramide.

►Sphingolipid Metabolism
►Glycobiology

PDZ Domain

Definition

Domain named after the three proteins PSD-95, Dlg and ZO-1. Is a modular protein interaction domain that often occurs in scaffolding proteins that bind in a sequence-specific fashion to the C-terminal peptide sequence or at times the internal protein sequences of target proteins. These domains of approximately 90 amino acids are known by an acronym of the first three PDZ-containing proteins identified including the postsynaptic protein PSD-95/SAP90, the Drosophila septate junction protein Discs-large, and tight junction protein ZO-1. In addition to their interaction with membrane proteins and receptors, the PDZ domain-containing proteins also interact with F-actin cytoskeleton through ezrin–radixin–moesin (ERM) proteins

►Calcitonin

PDZ Ligand

Definition

A small peptide sequence (4–6 amino acids) that binds to ►PDZ domain, which are peptide-binding modules, and are usually embedded in large scaffolding proteins along with additional PDZ domains and/or peptide-binding modules. PDZ domains function to assemble their ligands into large complexes with other scaffold-associated molecules

►Calcitonin

PEA3

Definition

PEA3, ER81 and ERM form the PEA3 subfamily of ►ETS transcription factors. PEA3 activates gene expression and is thought to play an important role in promoting tumor metastasis.

►Lipoma Preferred Partner

PEBP2αB

►Runx1

PEComas

Definition

►Neoplasms with Perivascular Epithelioid Cell Differentiation.

PEG

Definition

Polyethylene glycol.

►Microcell-Mediated Chromosome Transfer

Pegylated Interferons

Definition

Are interferons that are chemically modified by the covalent attachment of poly-ethylene glycol (►PEG), which are used in antiviral therapies.

►Hepatitis C Virus

Pegylation

Definition

Is the act of covalently coupling a polyethylene glycol (►PEG) structure to another larger molecule, for example, a therapeutic protein (which is then referred to as Pegylated).

►Arginine-Depleting Enzyme Arginine Deiminase (ADI)

Pemphigus

Definition

A rare, grave skin disease of unknown cause characterized by the development of bullae on the skin and mucous membrane.

►Rituximab

Penetrance

Definition

Is a genetic term that describes the proportion of individuals with a specific genotype who express that character in the phenotype; the frequency with which a genetic trait is expressed phenotypically. The penetrance is often reduced for example, if by age 70, a disease had occurred in 60% of carriers of a particular mutation in gene, the penetrance would be 60% at age 70.

►APC Gene in Familial Adenomatous Polyposis

Pentakisphosphate

Marco Falasca
Head Inositide Signalling Group Institute of Cell and Molecular Science Center of Diabetic and Metabolic Metabolism, Bart's and the London, Queen Mary's School of Medicine of Dentistry A NewYork Street, London

Definition

Inositol pentakisphosphate (abbreviated IP_5) is a molecule derived from inositol containing five phosphate groups and possessing anti-cancer properties.

Characteristics

Inositol Phosphates Family

Inositol is a polycyclic polyalcohol whose structure forms the backbone for all ►inositol polyphosphates (IPs) and ►phosphatidylinositol lipids (phospholipids). Over 30 different inositol polyphosphates have been identified so far in mammalian cells yet, despite their importance, the majority of these remain completely uncharacterized.

Many inositol derivatives play a key role in eukaryotic cells and are involved in a large number of biochemical processes mostly acting as second messengers in intracellular signaling. The best example is represented by ►inositol 1,4,5-trisphosphate (IP_3), which plays a very important role in many signaling pathways and also serves as a precursor for the synthesis of several highly phosphorylated inositol polyphosphates such as ►inositol tetrakisphosphate (IP_4), inositol pentakisphosphate (IP_5), and ►inositol hexakisphosphate (IP_6), also known as phytic acid.

Inositol Pentakisphosphate (IP_5)

IP_5 is a derivative of IP_3 possessing two additional phosphate groups. It is present in nearly all eukaryotic cells at levels of 15–50 μM and can be generated through phosphorylation of IP_4 or dephosphorylation of IP_6. The intracellular distribution of IP_5 is, to date, unknown although the fact that the inositol polyphosphate kinases (the enzymes responsible for the synthesis of IP_5 and IP_6) are localized in the nucleus may suggest that these inositol polyphosphates accumulate in the nuclear compartment. IP_5 is present at a very high concentration in several foods, including cereals, beans and nuts. For example IP_5 concentrations range from 0.4 g/kg in corn to 1.6 g/kg in millet and from 0.1 to 1.3 g/kg in beans. High levels of IP_5 have also been found in nuts, in particular in cashews (1.5 g/kg) and peanuts (0.6 g/kg).

IP_5 Intracellular Functions

The intracellular functions of IP_5 are just beginning to be appreciated. It has been shown that IP_5 can modulate the human immunodeficiency virus (HIV) type 1 and Gag protein assembly and therefore IP_5 may contribute to the pathogenicity of HIV-1 infection.

IP_5 has also been identified as essential in the regulation of chromatin remodeling and for transcription of some phosphate-responsive genes, possibly by affecting the ability of these complexes to interact with specific molecules and/or chromatin. One report illustrates a novel pathway of modulation of vascular L-type voltage-gated Ca^{2+} channels, in which IPs (mainly IP_5 and IP_6) help in their activation. IP_5 is also known to be involved in vascular L-type Ca^{2+} channel activation via stimulation of the protein kinase C pathway. These results indicate that IP_5 may act as intracellular messengers in modulating L-type Ca^{2+} channel activity and so could be implicated in mediator-induced contractions of vascular smooth muscle cells.

More evidence for the role of IP_5 as second messenger derives from genetic studies in mice. Deletion of *Ipk2*, a gene that encodes an inositol polyphosphate kinase enzyme, whose function includes the conversion of IP_3 and IP_4 to IP_5 and IP_6, is required for proper development of the mammalian embryo.

IP_5 Anti-Cancer Properties

The use of IPs as potential anti-cancer agents has been supported by several studies indicating that IP_6 possesses anti-tumor activity *in vitro* and *in vivo*. However the very high concentrations required for IP_6 to be active (1–5 mM) suggest a lack of selectivity of this compound, although it is noteworthy that, even at these concentrations, IPs do not appear to have any toxic effects. Little is known about the mechanisms by which IP_6 exerts its anti-cancer actions. The recent observation that IP_6, when taken up into cancer cells, becomes dephosphorylated to lower IP forms (mainly IP_5) and that in these cells IP_5 is more active than IP_6, strongly suggests that the anti-cancer activity of IP_6 is due to its dephosphorylation to IP_5. Indeed, increasing evidence indicates that IP_5 itself possesses anti-tumor properties. It has been clearly shown that IP_5 significantly reduces growth of ovarian cancer cells implanted in mice. Strikingly, the efficiency of IP_5 in these experiments was comparable to cisplatin, the most commonly used drug for ovarian cancer treatment. Data indicates that the anti-tumor activity of IP_5 is mostly due to its pro-apoptotic properties (i.e. it promotes death of cancer cells) combined with an anti-angiogenic activity (i.e. it inhibits formation of new blood vessels therefore blocking the supply of nutrients and oxygen to cancer cells).

Mechanism of Action of IP_5

It is now well established that the enzyme ►phosphoinositide 3-kinase (PI3K) is a key mediator of tumor development and progression. This enzyme catalyses the phosphorylation of position 3 in the inositol ring of phospholipids leading to formation of 3-phosphorylated compounds, among which the trisphosphate ►phosphatidylinositol-3,4,5-trisphosphate (PIP_3) is the most studied. PIP_3 activates several proteins that in turn regulate many intracellular processes crucial for cell survival, proliferation, migration etc. Key targets of PIP_3 action are the enzymes ►phosphoinositide-dependent kinase-1 (PDK1) and ►protein kinase B (PKB) also known as ►Akt. In normal conditions the PIP_3-dependent activation of such enzymes is time-restricted and specific regulators turn off the signal therefore processes like proliferation and migration are tightly regulated and

limited in time. Dysregulation of this signal is often observed in cancer cells, mostly due to a constitutive activation of PI3K/generation of PIP_3 or loss of the enzymes responsible for "switching off" PIP_3. As a consequence there is a permanent activation of Akt (amongst other enzymes) and processes like proliferation and migration remain activated.

The mechanism of PDK1/Akt activation downstream of PI3K activation is based on a physical interaction between a region in both PDK1 and Akt known as the ►pleckstrin homology domain (PH domain) and PIP_3. PH-domain containing proteins often bind both inositol phosphates and inositol lipids, and the subcellular distribution of these proteins can be affected by changes in the degree of competition between the two classes of ligands.

Being a phospholipid, PIP_3 possesses a lipid structure enabling it to be inserted into the cellular membrane. As a consequence its interaction with the PH domains of PDK1 and Akt triggers the relocation of both enzymes to the cell surface where Akt can be activated. IP_5 possesses the core structure necessary for binding PDK1 and Akt PH domains but it lacks the membrane anchor. Because of this, IP_5 remains in the cytosol and, by interacting with PDK1 and Akt, inhibits their relocation to the membrane and therefore Akt activation.

Such a mechanism of action is supported by data indicating that IP_5 is able to selectively inhibit Akt activity in cancer cell lines whereas other inositol phosphates tested have no effect. Data confirm a strict correlation between the IP_5-dependent pro-apoptotic rate and the degree of inhibition of Akt signaling. In fact, the specificity of IP_5 activity is confirmed by evidence indicating that this compound is active in human cancer cell lines characterized by an elevated PI3K/Akt activity, whereas it is inactive in other cell lines that do not possess such increases in Akt activation. More importantly, a complete inhibition of Akt activation has been observed in IP_5-treated mice demonstrating that IP_5 can inhibit Akt activation *in vivo* and block tumor growth. These data therefore indicate that IP_5 is a very specific inhibitor of this pathway both *in vitro* and *in vivo*.

It is of note that the derangement of this pathway is believed to be involved in the molecular mechanisms underlying *Salmonella* pathogenicity. When *Salmonella*, an important enteric pathogen of humans, invades cells, this leads to the rapid depletion of the cellular IP_5 pool. It has been proposed that the loss of cellular IP_5 may underlie the ability of *Salmonella* to activate Akt and promote cell survival during infection.

Clinical Perspective of IP_5

As discussed above, dysregulation of PI3K-dependent function (mostly the PI3K/Akt pathway) is common in cancer therefore PI3K is a key target for development of novel anti-cancer drugs. Being such a critical enzyme in many different cellular functions it should not be surprising that strategies based on a blockade of PI3K itself have resulted in many toxic effects. At the moment therefore, there is an urgent need to find specific and selective inhibitors of PI3K signaling that block specific downstream targets without interfering with other PI3K-mediated signals.

In this respect, the specific action on Akt of IP_5 might prove beneficial in reducing toxic side effects. Indeed, even at concentrations ten times higher than those used in the *in vivo* experiments (50 mg/kg) IP_5 did not appear to have any toxic effects. These properties, together with the fact that IP_5 is a water-soluble, natural compound, suggest that IP_5 may overcome problems concerning solubility, chemical stability and toxicity that limit the use of other potential inhibitors of the PI3K/Akt pathway.

IP_5 has also been shown to sensitize breast, ovarian and lung cancer cell lines to other, commonly used anti-cancer drugs. For example, IP_5 enhances the pro-apoptotic effect of cisplatin in ovarian cancer cells and etoposide in lung cancer cells. These data suggest that combination therapy of IP_5 with other commonly used drugs might enhance their activity. This would ultimately prove beneficial in terms of lowering the toxic effects of these drugs and the cost of their use.

PEP Syndrome

Definition

►POEMS Syndrome.

Peptide

Definition

A compound that is made up of two or more amino acids joined by covalent bonds.

►Modular Transporters

Peptide Vaccines for Cancer

Esteban Celis
H. Lee Moffitt Cancer Center and Research Institute, University of South Florida, Tampa, FL, USA

Synonyms

Active immunization using synthetic peptides corresponding to T cell epitopes.

Definition

An immunogen composed of synthetic peptides (small protein sequences) administered with the intent of eliciting antitumor immune responses for treating cancer.

Characteristics

Principles of Antitumor Immunity

The immune system has the capacity to recognize tumor cells and in many instances this recognition results in antitumor effects such as slowing the tumor growth or tumor eradication. In view of this, many approaches have been made to develop ►cancer vaccines, and other modes of ►immunotherapy. ►Cytotoxic T lymphocytes (CTL) are considered the most effective elements of the immune system that can kill tumor cells. CTL recognize small fragments (peptides of 8–10 residues) derived from the proteolytic processing of a tumor antigen. These peptides are presented to the CTL antigen receptor in the context of products of the class I ►major histocompatibility gene complex (►MHC) known as ►HLA class I in humans. Recognition of peptide/MHC class I complexes that are expressed on the surface of antigen-presenting cells leads to CTL activation and subsequently to an effector antitumor function such as cytotoxicity or the production of ►lymphokines that have antitumor effects. Because the MHC is highly polymorphic (i.e., there are many alleles within a species), a particular peptide may only bind to one MHC allele (i.e., MHC restriction). Effective CTL responses require the participation of ►T helper lymphocytes that recognize slightly larger peptides (12–15 residues), which associate with MHC class II molecules. Helper T lymphocytes can augment CTL activity by increasing their capacity to proliferate and by facilitating the generation of memory CTL responses that will prevent tumor recurrences. In view of this, there is a general consensus that vaccination strategies against cancer should attempt to concurrently stimulate tumor-reactive CTL and T helper cells.

Tumor Antigens for T Lymphocytes

Almost any protein expressed by a tumor cell (or by a normal cell) will generate MHC-binding peptides, but only some peptides can be recognized by tumor-reactive CTL and T helper lymphocytes. Multiple mechanisms involved in the development of immune tolerance operate to prevent the induction of T cell responses against normal cells, which would lead to autoimmune pathology. However, the immune system has the capacity to detect alterations that take place on cancer cells. There are many types of alterations that take place in cancer cells that lead to the generation of peptides that can be recognized as tumor antigens by T lymphocytes. Proteins derived from products of ►oncogenic viruses such as ►human papillomaviruses, ►Epstein–Barr virus, ►human T cell leukemia virus or products of mutated genes could generate MHC-binding peptides that would function as tumor-specific antigens (TSA). In these circumstances, no immune tolerance or potential autoimmunity will exist because these peptides are absent in normal cells. However, in many instances tumor-reactive T lymphocytes can recognize peptides that are derived from proteins that are also present in normal cells. These tumor-associated antigens (TAA) can be the products of overexpressed genes (e.g., ►HER-2/neu, ►CEA, ►p53 protein, ►biological and clinical aspects), developmental genes such as ►oncofetal antigen, members of the cancer-testes gene family such as ►MAGE, ►GAGE proteins, NY-ESO-1, which have been identified using techniques such as ►SEREX, or tissue differentiation proteins such as ►prostate specific antigen (PSA) and ►prostate-specific membrane antigen (PSMA) both applicable for prostate cancer and various ►melanoma antigens (gp100. MelanA/MART1, tyrosinase), many of which have already been used in developing a ►melanoma vaccine. Both TSA and TAA are considered as candidates for developing antitumor vaccines and at the present time there is no final word of which one will generate more effective antitumor responses.

Selection of Peptides for Vaccination

CTL and T helper peptide epitopes have been identified through two main strategies. The first approach relies in the isolation of tumor reactive T cells from cancer patients that are used to screen cDNA expression libraries or peptide fractions eluted from MHC

molecules both prepared from tumor cells recognized by the T cells. The second strategy is a predictive approach commonly known as "reverse immunology" where a putative TSA or TAA of known amino acid sequence is analyzed for the presence of peptides capable of binding to specific MHC molecules. Several peptide/MHC binding algorithms have been constructed to predict the likelihood of a peptide to bind to a particular MHC allele based on the presence of conserved MHC binding anchors situated at specific positions within the peptide sequence (motifs). These algorithms are readily available to investigators through the Internet, where the amino acid sequence of a potential TAA/TSA can be analyzed for the existence of peptides with high MHC binding predictive scores to one or several alleles. Performing peptide-MHC binding assays can help confirm the results from these algorithms and narrow down the number of potential T cell epitopes. The last step of the predictive approach is to assess whether the predicted MHC binding peptides function as epitopes for tumor-reactive T cells. Synthetic peptides representing the predicted epitopes are prepared by organic chemistry methodologies and are tested for their capacity to stimulate T cell responses *in vitro* using lymphocytes from peripheral blood of normal individuals. In this process, the naïve T lymphocytes are "vaccinated" *in vitro* with peptide-pulsed autologous ►antigen-presenting cells (APCs) to generate CTL (or T helper) antigen-specific cell lines that can be propagated in tissue culture. These peptide-reactive T cells are then tested for their ability to recognize tumor cells that express the corresponding TAA/TSA (from where the peptide sequence was first generated). Recognition of tumor cells by the peptide-reactive T cell lines validates that the tumor cells through natural antigen- processing pathways generate the MHC binding peptide, and this serves as the final and most significant selection criteria for a peptide to be used as a vaccine. This information can also be valuable for the design of ►DNA vaccines.

Immunization Strategies Using Synthetic Peptides

Antigen stimulation of naïve T cells can lead to either activation (proliferation and differentiation into effector cells) or tolerance (lack of function and cell death). The outcome of the T cell response is dictated in great part by the type of APCs and its activation status. The most potent type of APCs are ►dendritic cells (DCs), which have the unique functions of harvesting antigens in peripheral organs (skin, gut, lungs), processing the antigens into MHC-binding peptides and migrating into secondary lymphoid organs (lymph nodes, spleen) where they present the antigen to naïve T lymphocytes. When DCs receive proinflammatory signals they become stimulatory APCs, while DCs not receiving these signals will behave as a toleragenic APCs. The proinflammatory signals that activate DCs can be in the form of cytokines (interleukin-1 and tumor necrosis factor) or molecules that function as ligands for any member of the ►toll-like receptors (TLR) family. The most common type of TLR ligands are pathogen-associated molecular patterns (PAMPS) commonly found in infectious agents, such as double stranded ribonucleic acid (dsRNA), lipopolysaccharide (LPS) and prokaryotic DNA containing unmethylated cytosine-guanine motifs (CpG). Many immune cells including DCs express TLRs and through their interaction with TLR ligands, the cells will become activated and functional. Thus, to generate an effective immune response against a TAA, peptides must be combined with a proinflammatory signal such as a TLR ligand. For example, synthetic polynucleotides such as deoxyoligonucleotides containing CpG motifs, or double strand polyinosinic-polycytidylic acid (poly-I:C), which stimulate TLR-9 and TLR-3, respectively are ideal candidates to be used as ►immune adjuvants for antitumor vaccines based on peptide T cell epitopes. Immunization using synthetic peptides with the aim of stimulating antitumor T cell responses can be achieved through two different methods. For the first approach, a cell-based vaccine is generated using autologous APCs such as DCs or macrophages that are pulsed *ex vivo* with synthetic peptides. In some instances, the APCs can be stimulated (or matured) with proinflammatory factors before they are administered into the patients. The second approach is to directly administer the synthetic peptide (together with an adjuvant) to the patient via an injection, which most frequently is done through a subcutaneous or an intradermal route. Direct administration of peptide vaccines can also be accomplished in a "needleless" fashion, through a transcutaneous route using a topical vaccine formulation that may include immune adjuvants.

The main advantage of APC-based peptide vaccines is that the T cell epitope is efficiently delivered onto the APCs, presumably decreasing the possibility of peptides being presented to naïve T cells by nonactivated APCs, which could generate T cell tolerance. The main disadvantage of the cell-based vaccines is their high cost associated to amount of labor required to produce the autologous APCs suitable for human use. On the other hand, the direct administration of peptides via an injection or topically, may not be an efficient way to deliver the epitopes to APCs but it is certainly more cost effective than cell-based vaccines. Using mouse tumor model systems both vaccination approaches have shown to induce strong T cell responses that translate into antitumor effects. However, at the present time neither peptide-pulsed cell-based vaccines nor direct peptide vaccination have yielded conclusive positive results in the clinic. Among the possible explanations for these divergent observations are that many of the mouse tumor models are not truly representative of human disease and that the vaccines are usually

tested in mice at earlier disease stages as compared to the clinical studies done in humans, where most of the patients are in advanced stages of cancer.

Remaining Challenges for Developing Effective Antitumor Peptide Vaccines

Without any doubt the overall clinical performance of most therapeutic cancer vaccines including those composed of synthetic peptides remains far from optimal. In first place, the strength of immune responses, measured by the percentage or total numbers of CTL induced by most antitumor peptide vaccines is in reality meager as compared to the intensity of T cell responses observed during the organism's successful battle against infections. Many factors will contribute towards an effective expansion of T cells during an immune response such as the duration of the antigenic stimuli. For instance, peptides that are rapidly cleared by the organism may not be able to sustain the T cell activation level leading to successful expansion, while peptides that remain for extended periods of time may generate T cell exhaustion or tolerance. Successful T cell expansion by peptide vaccines will also depend on presence of APC-derived costimulatory signals that are either expressed on the cell surface (CD80, CD86, CD70, CD137L, CD252) or are in the form of ►lymphokines (interleukin-12, type I interferon). As mentioned above, concurrent activation of helper T cells will also contribute towards the expansion of CTL and will enhance the generation of memory CTL responses. A successful peptide vaccination strategy must also deal with the inhibitory signals that the immune system utilizes to prevent or terminate CTL responses. For example, ►T regulatory cells that normally function to prevent autoimmune diseases are also known to inhibit antitumor CTL responses. In addition, several molecular interactions such as those derived from the stimulation of CTLA-4 and PD-1 on CTLs will lead to inhibitory signals that will arrest CTL expansion and effector function. The successful design of a peptide vaccination strategy leading to the generation of large numbers of effector T lymphocytes may not be sufficient by itself to ensure a clinical benefit against cancer. Unfortunately, tumors count on many defensive mechanisms against the immune system. In some instances tumors may cease to express the TSA/TAA or MHC molecules and will no longer be recognized by the CTLs. Tumors may also generate an inhospitable microenvironment by producing T-cell inhibitory substances such as transforming growth factor-beta (TGF-β) and inteleukin-10, or by recruiting immune suppressor cells like regulatory T lymphocytes and myeloid derived suppressor cells. Thus, the likelihood of an immunogenic peptide vaccine to deliver the desired antitumor effectiveness will depend in great part in the patient's disease stage, since advanced tumor burden will be accompanied by more immune suppressive activity. In view of these issues, it seems logical that peptide vaccines should be used in patients with minimal residual disease and perhaps in the adjuvant setting, combined with other therapies that would reduce tumor burden. Even if these issues are solved, one major limitation for the use of peptide vaccines is due to fact that each peptide epitope will only offer coverage to subset of patients that have the corresponding MHC allele and have tumors that express appropriate TSA/TAA. Future polyepitope peptide vaccination strategies either using peptide cocktails or multiepitope peptide constructs will lead to broadening patient population coverage.

Peptidomimetic

Definition

Is a compound that mimics the biological action of a peptid. It is a molecule containing non-peptidic structural elements and is capable of mimicking or antagonizing the biological action(s) of a natural parent peptide. These modifications involve changes to the peptide that will not occur naturally, such as altered backbones and the incorporation of nonnatural amino acids that are not recognized by cellular degradation systems. A peptidomimetic does not longer have classical peptide characteristics such as peptidic bonds that can be degraded by cellular enzymatic activities. This approach is important in ►drug design aiming to develop anticancer drugs that are not rapidly degraded by the organism and that specifically bind to target in the cell.

►Anti-HER2/Neu Peptide Mimetic (AHNP)

Perforin

Definition
Perforin is a protein that can polymerize to form the membrane pores that are an important part of the killing mechanism in cell-mediated cytotoxicity. Perforin is produced by cytotoxic T cells and natural killer cells and is stored in granules that are released by the cell when it contacts a specific target cell.

►Natural Killer Cell Activation
►Immunoediting
►Cystatins

Performance Status

Definition
An index that measures the overall health status of a patient as defined by his/her ability to perform ordinary tasks and activities of daily living.

(Peri-) Hilar Cholangiocarcinoma

►Klatskin Tumors

Pericardium

Definition
Membranous sac surrounding the heart.

Pericellular Matrix

Definition
The zone immediately surrounding a cell, and the interface between the plasma membrane and extracellular matrix. The site where integral membrane proteins can interact with the meshwork of proteoglycans, glycolipids and hyaluronan immediately surrounding a cell.

►Hyaluronan Synthases

Pericyte

Definition
A mesenchymal-like cell, associated with the walls of small blood vessels. As a relatively undifferentiated cell, it serves to support these vessels, but it can differentiate into a fibroblast, smooth muscle cell, or macrophage as well if required. Specialized support cells that are precursors to smooth muscle cells and coat blood vessels and some portions of lymphatic vessels.

►Lymphangiogenesis
►Lymphatic Vessels
►Vascular Disrupting Agents

Periodontium

Definition
Tooth-supporting tissue consisting of bone, periodontal ligament, cementum and gingiva.

►Dental Pulp Neoplasms

Periostin

Yasusei Kudo, Takashi Takata
Department of Oral and Maxillofacial Pathobiology, Division of Frontier Medical Science, Graduate School of Biomedical Sciences, Hiroshima University, Hiroshima, Japan

Synonyms
Osteoblast-specific factor-2 (Osf2)

Definition

Periostin, originally named as osteoblast-specific factor-2 (Osf2) (genebank D13664), first identified in bone, is implicated in regulating ►adhesion and differentiation of osteoblasts. Periostin is a secreted protein that shares a structural homology to the axon guidance protein ►fasciclin I (FAS1) in insects. Proteins that share homology with FAS1 include βig-h3, stablin I and II, MBP-70, Algal-CAM, Periostin, and Periostin-like factor (PLF). An approximately 90 kDa periostin has an NH_2-terminal secretory signal peptide, followed by a cysteine-rich domain, four internal homologous repeats, and a COOH-terminal hydrophilic domain. In N-terminus, periostin has an ►EMI domain, which is a small cysteine-rich module of approximately 75 amino acids. Periostin binds to αvβ3, αvβ5, and α6β4 ►integrins, ►fibronection, ►tenacin-C, collagen V, and periostin itself. Mouse and human *periostin* gene (POSTN) share 89.2% amino acid identity overall and 90.1% identity in their mature forms. The human periostin gene is located on chromosome13q.

Characteristics

Periostin expression is observed in a wide range of normal adult tissues, including aorta, thyroid, lung, breast, stomach, colon, placenta, uterus, vagina, ovary, testis, and prostate. Periostin overexpression is found in various types of human ►cancer including ►neuroblastoma, head and neck cancer, ►nasopharygeal carcinoma, thyroid carcinoma, ►non-small cell lung carcinoma, ►breast cancer, ►colon cancer, pancreatic ductal adenocarcinoma, and ►ovarian cancer. In addition, elevated levels of periostin are detected in sera of patients with thymoma, non-small cell lung carcinoma, breast cancer, and pancreatic ductal adenocarcinoma, and in ►ascites from ovarian cancer patients. Overexpression or elevated serum levels of periostin appear to be associated with poorer prognosis of various cancers. Although the detailed function of periostin is still unclear, it plays important roles for tumor progression including ►invasion, ►angiogenesis, cellular survival, and ►metastasis. In vivo studies revealed that periostin is associated with a phenotype of greatly accelerated tumor metastatic growth through invasiveness, cancer cell survival, and angiogenesis by using the animal model system of metastasis.

Peripheral Lymph Node Addressin Molecule

Definition

PNAd; A family of sialomucins expressed on high endothelial venules and serving as a receptor for L-selectin mediated homing of lymphocytes to peripheral lymph nodes.

►Omental Immune Aggregates

Peripheral Lymphoid Organs

Definition

►Secondary Lymphoid Organs.

Peripheral Membrane Proteins

Definition

Synonym: extrinsic membrane proteins or amphitropic proteins. They bind reversibly to membranes through lipid co/post-translational modifications or through specific amino acid regions that provide the right context for electrostatic and/or hydrophobic interactions.

They are relevant in the context of signal transduction and cellular physiology as they can propagate messages from the plasma membrane to intracellular membranous or aqueous compartments.

►Membrane-Lipid Therapy

Peripheral Nervous System

Definition

The part of the nervous system that lies outside of the brain and spinal cord, and serves the limbs and organs.

►Synuclein
►Neuroblastoma

Peripheral Neuropathy

Stephan Mielke
Division of Hematology and Oncology Department of Internal Medical II Wuerfburg University Medical Center, Wuerfburg, Germany

Synonyms

Neuropathy; Mononeuropathy; Plexopathy; Polyneuropathy

Definition

Peripheral ►neuropathy is a general term indicating the malfunction of peripheral nerves due to various causes. Peripheral neuropathies can be categorized by location (distal, proximal), distribution pattern (unilateral, bilateral, symmetrical), underlying cause (toxic, metabolic, vascular, autoimmune, paraneoplastic), impaired neuronal quality (motor, sensory, autonomic), dynamics of manifestation (acute, subacute, chronic) and underlying histopathology (axono-, myelino- and ganglionopathies).

Characteristics

Depending on the type of peripheral neuropathy and the impaired neuronal qualities, sensory, motor and autonomic symptoms may appear. Sensory symptoms may include ►paraesthesia, numbness, tingling, burning and pain while motor symptoms may range from mild muscular weakness to paralysis. Appearance of orthostatic hypotension, cardiac arrhythmia and paralytic ileus may reflect autonomic involvement. Diagnosis is usually made based on clinical examination. This includes evaluation of the vibration sense by the tuning-fork test, deep tendon reflexes, muscle strength and sensory symptoms. Additional neurophysiologic evaluations such as measurements of distal latencies, conduction velocities and amplitudes improve diagnostic sensitivity. Nerve biopsies, usually obtained from the sural nerve, provide a further but rather invasive diagnostic tool. Novel approaches include the examination of intraepidermal fibers in skin biopsies and magnetic resonance imaging (MRI) of the spinal cord dorsal columns to detect ganglionopathies.

In cancer patients ►mononeuropathies and ►plexopathies are often caused by local tumor-associated compression while ►polyneuropathies are frequently caused by the systemic anti-tumor treatment itself. These treatment-related, toxic peripheral neuropathies need to be distinguished from other forms such as pre-existing neuropathy or ►paraneoplastic neuropathy. Furthermore, overlaps between different forms of peripheral neuropathy can be observed frequently, especially in elderly cancer patients with additional metabolic disorders.

Mononeuropathies and Plexopathies

Local tumor or metastatic growth infiltrating or compressing peripheral nerves can cause neuronal malfunctions and pain in a circumscribed area. Diagnosis is usually established clinically but may be supplemented by computed tomography (CT) and magnetic resonance imaging (MRI). Treatment options include systemic anti-tumor therapy and from case to case local surgical or radiotherapeutical intervention.

Paraneoplastic Neuropathies

Mild forms of mixed sensory and motor peripheral neuropathies can be observed among many patients suffering from cancer and are often attributable to weight loss, nutrition deficits, organ failure or disease progression. True paraneoplastic syndromes of the peripheral nervous system are rather rare but represent an important differential diagnosis as neurological symptoms my precede those of the tumor. Paraneoplastic neuropathies

Peripheral Neuropathy. Table 1 Typical neuropathic symptoms associated with the application of selected, broadly applied chemo therapentic agents

►Cisplatin, Carboplatin	Predominantly sensory neuropathy; large sensory fibers are affected; impaired vibration and proprioception; carboplatin is considered less neurotoxic than cisplatin
►Oxaliplatin	Two forms of peripheral neurotoxicity:
	►1. *Acute*: occurs in a majority of the patients; sensory neuropathy; causes paraesthesia; may involve mouth and throat; appears within minutes to days; usually self-limiting; often triggered by cold temperatures
	►2. *Chronic*: cumulative, dose-limiting sensory neuropathy
►Paclitaxel, ►Docetaxel	Cumulative, dose-limiting sensory neuropathy; usually causes numbness, paraesthesia, tingling and burning in a symmetrical stocking-and-glove distribution; rarely causes motor neuropathy with mild distal weakness; autonomic involvement possible; incidence increased with dose-dense schedules; presumably combined axono-, myelino- and ganglionopathy; docetaxel is considered less neurotoxic than paclitaxel
►Thalidomide	Sensory peripheral neuropathy; distal paraesthesia with or without sensory loss; may be dose-related; usually late onset
►Vincristine, ►Vinorelbine	Predominantly cumulative sensory neuropathy; dose-limiting for vincristine; impaired or lost pain and temperature sensation; stocking-and-glove distribution; may cause motor and autonomic neuropathy (paralytic ileus, prophylaxis with stool softeners suggested)

can appear in various cancer types including lung cancer, ►malignant ►lymphoma and ►multiple myeloma. The majority of cases have been described in patients with small cell lung cancer presenting a severe sensory loss attributable to a dorsal root ganglionitis. In some of these patients' sera anti-onconeuronal (►anti-Hu) antibodies can be detected. A paraneoplastic brachial neuritis and an acute rapidly progressive sensorimotor ►polyneuropathy have been described in patients with ►Hodgkin disease. Treatment of paraneoplastic neuropathies requires systemic anti-tumor therapy of the underlying disease. However, rapidly progressive sensorimotor ►polyneuropathies may require plasma exchange and immunoglobulin infusions.

Toxic, Treatment-Related Neuropathies

Development of peripheral neuropathy following systemic chemotherapy can be frequently observed in cancer patients. The majority of patients receiving neurotoxic chemotherapeutics are prone to developing cumulative ►polyneuropathies. The exact incidence is presumably underestimated and varies significantly depending on the used chemotherapeutic regimens. The specific characteristics of broadly applied chemotherapeutic agents known to cause peripheral neuropathies are listed in Table 1.

Therapy for peripheral neuropathy is limited und includes symptomatic treatment with tricyclic antidepressants and anticonvulsants to control the neuropathic pain. The tricyclic antidepressant nortryptiline, the norepinephrine-and-serotonin-reuptake-inhibitor venlafaxine and the anticonvulsant gabapentin, have shown moderate clinical activity. Unfortunately, dose reduction of the chemotherapeutic agent and treatment interruptions are associated with the risk of losing therapeutic efficacy. Several neuroprotective agents such as acetyl-L-carnitine and ►amifostine are under evaluation. Their clinical value needs to be determined in further trials. Taken together, a close monitoring of all patients receiving neurotoxic substances is suggested, especially in the palliative setting where quality-of-life can be significantly compromised by severe peripheral neuropathy.

Peripheral Primitive Neuroectodermal Tumor

►Ewing Sarcoma

Peritoneal Carcinomatosis

►Carcinomatosis

Peritoneal Debulking Surgery

Definition

Synonym: Cytoreductive Surgery; Refers to an operation to remove as much tumour or tumour cells as possible from the peritoneal cavity. This may involve removing all or a portion of tumour-infiltrated peritoneal organs as well e.g. omentum, uterus, ovaries, appendix and portions of bowel.

►Transcoelomic Metastasis

Peritoneal Dissemination

Definition

The spread of cancer from the primary site within the appendix or other intraabdominal organ to the peritoneal surfaces. Intraabdominal and intrapelvic dissemination may follow a characteristic pattern.

►Appendiceal Epithelial Neoplasms

Peritoneal Malignancy

►Carcinomatosis

Peritoneal Metastasis/Dissemination

►Transcoelomic Metastasis

Peritoneal Mucinous Carcinoma

Definition

PMCA; A mucinous appendiceal neoplasm in which the cancer cells have an invasive component resembling a mucinous adenocarcinoma from the colon or other site.

►Appendiceal Epithelial Neoplasms

Peritoneal Tumor

►Carcinomatosis

Peritonectomy

Definition

Removal of peritoneal surface using electrosurgical dissection in order to resect ►carcinomatosis.

►Appendiceal Epithelial Neoplasms

Peritoneovenous Shunt

Definition

Surgical insertion of a shunting tube to achieve the continuous emptying of ascitic fluid into the venous system.

►Acites

Peritoneum

Definition

The peritoneum (derived from Greek meaning "stretched over") is the serous membrane of the

abdominal and pelvic cavity which covers and supports the abdominal and pelvic organs, and serves as a conduit for their blood and lymphatic vessels and nerves.

►Transcoelomic Metastasis

Peritoneum as the First Line of Defense

Definition

The ►peritoneum is an anatomic barrier to further dissemination of ►carcinomatosis. If surgical procedures remove peritoneum with free cancer cells remaining within the abdomen or pelvis, the first line of defense against carcinomatosis has been violated.

►Appendiceal Epithelial Neoplasms

PERK

Definition

An endoplasmic reticulum (ER) transmembrane protein kinase that phosphorylates the α subunit of translation initiation factor 2 (eIF2α) in response to ER stress and anoxia. PERK is maintained in an inactive state by the binding of the ER chaperone BiP, that under conditions of ER stress dissociates from PERK.

►Anoxia
►Endoplasmic Reticulum Stress

Perlman Syndrome

Definition

Characterized by fetal gigantism, renal dysplasia, nephroblastoma, islet cell hypertrophy, multiple congenital anomalies, and mental retardation.

►Nephroblastoma

Permeases (for Import Systems)

►ABC-Transporters

Peroxisome

Definition

Dynamic ubiquitous cellular organelle involved in the metabolism of hydrogen peroxide (generation and elimination) and lipids (fatty acid α- and β-oxidation).

►Autophagy

Peroxisome Proliferator-Activated Receptor

Thomas Barz, Dietmar Spengler
Max-Panck-Institut für Psychiatrie, München, Germany

Synonyms

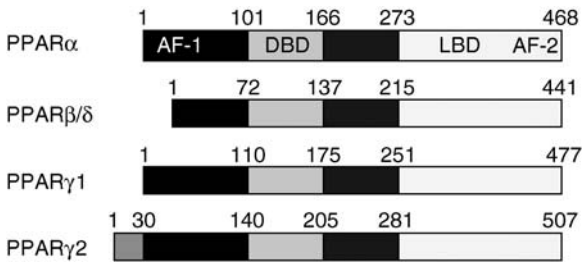
PPAR; NR1C

Definition

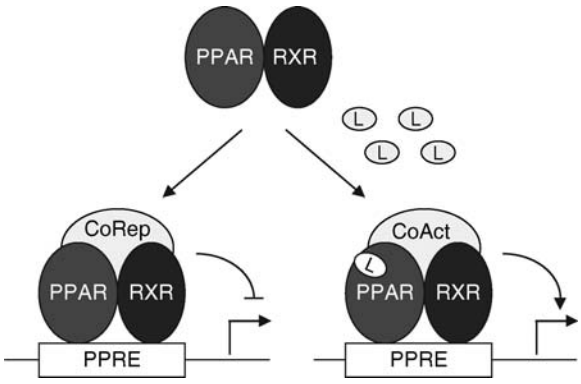
Peroxisome proliferator-activated receptors (►PPARs) are nuclear hormone receptors originally identified as molecular targets of synthetic compounds inducing peroxisome proliferation. As ligand-dependent transcription factors PPARs mediate the effects of fatty acids and their derivatives, and thereby regulate proliferation, differentiation and cell survival.

Characteristics

The three peroxisome proliferator-activated receptor isoforms PPARα, ►PPARβ/δ; and PPARγ are encoded by different genes and belong to the largest family of transcription factors, the nuclear hormone receptors (NHRs). PPARs possess a modular structure composed of a central DNA binding domain (DBD) with two zinc fingers and a ligand binding domain (LBD), including the ligand binding pocket and the ligand-dependent activation domain AF-2 in its C-terminus (Fig. 1). A ligand-independent, poorly characterized transactivation function at the N-terminus is known as AF-1.



Peroxisome Proliferator-Activated Receptor.
Figure 1 The PPAR receptor family. Human PPARs share a common modular structure typical for the nuclear receptor superfamily. The highly conserved central DNA binding domain (DBD) contains two variant zinc fingers. By each of them one zinc ion is bound by a tetrahedral arrangement of cysteine ligands. The C-terminal ligand binding domain (LBD), as well as the ligand-independent and ligand-dependent activation domains (AF-1 and AF-2, respectively) are less conserved and confer transcription regulation via their interaction with coactivator and corepressor complexes. Amino acid numbers are indicated for each receptor isoform.



Peroxisome Proliferator-Activated Receptor.
Figure 2 Transcriptional activity of PPAR-RXR heterodimers. *Left*, in the unliganded state, PPAR-RXR heterodimers bind to PPREs in the promoter region of target genes and inhibit their transcription by recruiting co-repressors (Co-Rep). *Right*, upon ligand (L) binding, co-repressors are released and co-activators (Co-Act) such as p300/CBP are recruited to cooperatively activate transcription of PPAR target genes.

PPARs control gene expression by binding to specific PPAR response elements (PPREs) corresponding to the consensus motif 5′-AACT AGGNCA A AGGTCA-3′ typically located in the promoters of their target genes. Like many other NHRs, PPARs bind DNA as obligatory heterodimers by interacting with one of the ►retinoid acid receptors (RXRs). In the unliganded form, PPAR-RXR dimers can actively silence gene expression by recruiting co-repressor complexes. Conformational changes upon ligand binding promote interaction with coactivators such as ►p300/CBP, leading to transcriptional activation of PPAR target genes (Fig. 2). Endogenous ligands are fatty acids and their derivatives, for which PPARs act as intracellular sensors and thereby regulate pathways involved in lipid and glucose metabolism. Correspondingly, synthetic PPAR ligands such as fibrates and ►thiazolidinediones (TZDs) are used for the treatment of dyslipidemia and type II diabetes, respectively. Beside their role in metabolism, PPAR functions are also associated with other processes of clinical importance, such as arteriosclerosis, ►inflammation and especially cancerogenesis.

PPARα

PPARα is expressed in the liver, kidney, heart, intestine, skeletal muscle, brown fat tissue, adrenal gland and pancreas. It was the first PPAR family member identified in a screen for molecular targets of peroxisome proliferators (PPs) using a mouse liver cDNA library. PPs are liver-targeting chemically unrelated compounds, including natural lipids and steroids as well as ►xenobiotics, industrial plasticizers, pesticides and solvents. Chronic PP administration in rodents leads to liver ►hypertrophy, ►hyperplasia and eventually to ►hepatocellular carcinoma. The exclusive role of PPARα in mediating these processes was deduced from PPARα-null mice that are resistant to the effects of PP treatment, including the development of hepatocellular carcinomas. The exact mechanisms underlying the tumorigenic PPARα function are unclear but several explanations have been proposed: PP-activated PPARα triggers DNA replication and proliferation of hepatocytes, accompanied by an induction of cell cycle regulators such as ►cyclin dependent kinases CDK-1 and -2 as well as c-►myc. Further, PPs attenuate hepatocytic ►apoptosis in vitro and in vivo. PPARα appears to be critical to this effect since inhibition of apoptosis can be prevented by a dominant-negative PPARα protein. Another PPARα-mediated mechanism reported is the production of reactive oxygen species as by-products of β-oxidation, possibly leading to ►DNA damage and increased proliferation of hepatocytes.

Despite the clear evidence for PPARα-mediated PP action in rodent hepatocarcinogenesis, the situation in humans appears to be different. Studies did not reveal activated peroxisome proliferation in the liver or any increased incidence of hepatocellular carcinoma in patients treated with hypolipidemic fibrate drugs. Consistently, in vitro experiments with human cells showed a reduced transcriptional response to activated PPARα compared with rodents. A lower level of hepatocytic PPARα expression (1–10%), different cofactor availabilities and PPREs of target genes, as well as a reduced activation efficiency and bioavailability of certain PPs are discussed as possible explanations for

these species differences. Nevertheless, as many humans are constantly exposed to PPs (e.g. hypolipidemic drugs, pesticides, plasticizers) it is very important to constantly resurvey the cancerogenic potential of these compounds.

PPARβ/δ (NUC1, FAAR)

PPARβ/δ is expressed in a wide range of tissues with high levels in brain, skin, adipose tissue and colon. Although the role of PPARβ/δ in cancer is controversial, its involvement in processes related to tumorigenesis such as proliferation, differentiation and survival is well accepted. For example, a role for PPARβ/δ in the differentiation of adipose tissue and oligodendrocytes was concluded from the phenotype of PPARβ/δ-null mice, exhibiting a decreased fat mass and myelination defects in the corpus callosum, respectively. In keratinocytes, PPARβ/δ inhibits proliferation but promotes cell migration and survival via activation of ILK, PDK1 and AKT1. A role for PPARβ/δ as a mediator of proliferation in hepatic stellate-cells and vascular smooth-muscle cells has been reported. The strongest link to cancerogenesis has been demonstrated in murine colorectal cancer cells where PPARβ/δ expression is repressed by the ►APC/β-catenin tumor suppressor pathway. Aside from the APC pathway, PPARβ/δ is also targeted by the ►Ras pathway, as it becomes activated in response to an overexpression of oncogenic Kras. For both pathways, regulation of cyclooxygenase 2 (COX2) levels might be the underlying mechanism, as COX2 is the rate-limiting factor in the generation of some natural PPARβ/δ ligands (►prostaglandins). PPARβ/δ activation in human hepatocellular carcinoma cells increases proliferation and COX2 expression, suggesting a growth-promoting positive feedback loop. Consistent with a direct role in colorectal tumorigenesis, PPARβ/$\delta^{-/-}$ ►colon cancer cells show a significantly decreased tumorigenic potential in xenograft mouse models. Moreover, PPARβ/δ upregulates VEGF in colon carcinoma cells, which directly promotes colon tumor epithelial cell survival through activation of ►PI3K-Akt signaling. The repression of PPARβ/δ activity by the ►non-steroidal anti-inflammatory drug (NSAID) sulindac might explain NSAID-mediated chemoprevention of colon cancer.

The role of PPARβ/δ in tumors other than colon cancer is far from being clear. Significant upregulation of PPARβ/δ has been observed in head and neck ►squamous cell carcinomas, endometrial adenocarcinomas and breast cancer cell lines. A growth inhibiting activity of PPARβ/δ has been suggested in lung cancer cells. In summary, pro- and anti-cancerogenic PPARβ/δ functions seem to exist, depending on the cell- and tissue-specific context.

PPARγ

PPARγ exists as two protein isoforms, expressed from different promoters and alternatively spliced at the 5′ end of the gene, resulting in 30 additional amino acids at the NH_2 terminus of PPARγ2 compared with PPARγ1. Whereas expression of PPARγ2 is mainly restricted to adipose tissue, PPARγ1 has also been detected in other tissues, including heart, skeletal muscle, pituitary, brain, kidney, liver and colon.

The concept of PPARγ playing a role in tumorigenesis and therefore being a potential target in cancer therapy was developed from its antiproliferative activity in fibroblasts during adipogenesis. Also in other cell types PPARγ activation induces programs of gene expression that reflect the differentiation potential of progenitor cells. For instance, its expression in epithelium-derived cells stimulates the production of markers of epithelial differentiation/maturation, such as keratin 20 and krüppel-like factor 4. Additionally, PPARγ inhibits cell proliferation through induction of cyclin-dependent kinase inhibitors (i.e. ►$p21^{Cip1}$ and $p18^{Ink4c}$) and attenuates ►E2F/DP DNA-binding activity via down-regulation of PP2A protein phosphatase. Consistent with an integrating role coupling cell differentiation and growth arrest, loss of one allele of PPARγ predisposes to carcinogenesis in wild-type mice, while loss-of function mutations in PPARγ associate with human colon cancer. Additional evidence for the impact of PPARγ on tumorigenic processes comes from the identification of a chromosomal translocation in a subset of ►follicular thyroid carcinomas, resulting in a PAX8-PPARγ fusion protein which abolishes the ligand activation of the wild type PPARγ protein. Building up on these findings, intense clinical interest has been raised in the possible application of synthetic PPARγ ligands as effective chemotherapeutic agents. Indeed, PPARγ ligands have been shown *in vitro* to induce cell cycle arrest and/or apoptosis in a variety of cancer cell types, including liposarcoma, breast adenocarcinoma, prostate carcinoma, ►neuroblastoma, pancreas and colon carcinoma cells. However, the role of PPARγ ligands – which have also PPARγ-independent effects – in the regulation of neoplastic transformation *in vivo* remains controversial: In contrast to the reduction of aberrant crypt foci and the inhibition of colon cancer growth in wild-type mice, PPARγ ligands in APC^{Min} mice not only failed to suppress polyp formation but also led to a small although significant increase in colon tumors. Moreover, epidemiological data emphasize that the development of colorectal cancer is promoted by prostaglandins, which are potential ligands of PPARγ. In mice with mutations in the cyclooxygenase gene or in animals and humans treated with COX inhibitors, decreased production of prostaglandins prevents or attenuates colon cancer development. Furthermore, the intake of fatty acids from animal origins strongly correlates with colon tumors, suggesting that PPARγ possibly links high-fat diet and colon cancer. Studies aimed to find an explanation for the contradictory results with PPARγ

in colon cancer revealed that the tumor-suppressor function of PPARγ entirely depends on the presence of an intact adenomatous polyposis coli (APC) gene. The cross-regulation of ►Wnt/β-catenin/Tcf ligands, kinases, and transcription factors with members of the nuclear receptor family has emerged as clinically and developmentally important area of endocrine cell biology. Wnt/β-catenin can modulate NRs activity, and NRs ligand dependently inhibit the Wnt/β-catenin/Tcf cascade. As a case in point, PPARγ can suppress β-catenin levels in wild-type mice whereas in the presence of a mutant APC the ability of PPARγ to regulate β-catenin and colon tumorogenesis is completely lost. In normal cells, PPARγ targets β-catenin to the proteasome partly through a process possibly involving PPARγ induction of ►PTEN and activation of the downstream effector GSK3-β. β-Catenin and PPARγ interact with each other through the TCF/LEF binding domain of β-catenin and the putative coactivator binding sites of PPARγ to influence each other's activity. As a result, in normal untransformed cells, PPARγ additionally induces the proteasomal degradation of β-catenin through complex formation independent from GSK3-β, while in transformed cells, oncogenic β-catenin escapes its PPARγ-associated degradation and inhibits in turn PPARγ activity. In this model, the oncogenic form of β-catenin is dominant over PPARγ activity, thus explaining why PPARγ is capable of suppressing tumorigenesis only in cells that have a functional APC to facilitate the GSK3-β-mediated inactivation of β-catenin. As a further indication for a role of PPARγ in suppressing the oncogenic activity of β–catenin, NSAIDs have been reported to antagonize β-catenin function via high levels of PPARγ and its co-receptor RXR-α, which is independent from the presumed role of NSAIDs in COX inhibition. Finally, epidemiological studies demonstrate long-term ingestion of various NSAIDs to associate with a reduced incidence of colorectal cancer, and probably of prostate and breast tumors. Taken together, the multilayered and cell type specific activity of PPARγ as well as its interconnection with the Wnt/β-catenin/Tcf pathway argue against the indiscriminately and broad use of PPARγ ligands in cancer treatment. Thus, despite the substantial progress being made in the understanding of the role of PPARγ in cancerogenesis during the last decade, further investigations appear necessary to elucidate and refine indications for a PPARγ-targeted therapy.

Synonyms

Individualized treatment

Definition

►Personalized medicine is defined as the application of the right treatment for the right patient, at the right dose, and at the right time. Personalized medicine is therefore a model of the way medicine will evolve through the use of specific treatments and therapies best suited to an individual's genotype and is driven by patient demand for safer and more effective medicines and therapies.

Characteristics

The concept of individualizing treatment is not new and the study of hereditary influences on the response to drugs (►pharmacogenetics) is reflected in the scientific literature from the 1960s. The number of articles published remained constant until 1996 when technical

developments and new insights into the highly complex nature of many diseases resulted in the advent of ►pharmacogenomics. Pharmacogenomics is closely related to pharmacogenetics but the emphasis is on the influence of a whole set or complement of genes on the response to drugs, with the aim of improving drug efficacy rather than simply being concerned with drug safety. Subsequent growth in the new field of pharmacogenomics-based personalized medicine has been exponential.

The term "personalized medicine" is mainly used in the context of pharmacogenomics and although pharmacogenomics is one of the main drivers of this new area, it is important to realize that this view can be rather narrow, and personalized medicine also includes areas such as disease susceptibility in addition to the molecular traits and mechanisms underlying individual characteristics. Applications range from personal risk profiles leading to personal preventative measures, such as vaccination and personalized health planning leading to early diagnosis, to genetic counseling, databases and decision support tools. This essay focuses on the role of personalized medicine in cancer and explores its use in current clinical practice and its likely application in the future.

Why is Personalized Medicine Important in Cancer?

Personalized medicine is more important for cancer patients than for those with other diseases for several reasons. Firstly, cancer is a highly heterogeneous disease with significant molecular differences in the expression and distribution of tumor cell makers among patients with the same type and grade of tumor. Secondly, cellular mutations tend to accumulate as cancer progresses, further increasing tumor heterogeneity. Thirdly, currently used cancer therapies are often toxic to normal cells resulting in severe side effects rarely seen in other diseases. Finally, cancer patients have limited time to try one kind of treatment and, if it does not work, to try others until the right medicine is found. Therefore, cancer therapy presents a unique example of personalized medicine in which an individual's genotype not only determines the therapeutic and toxic responses to a drug (the ►pharmacogenotype), but also that of the tumor.

To what Extent is Cancer Medicine Already Personalized?

Over the past 20 years, a large amount of the fine detail of the basic biological processes that become disturbed in cancer has been amassed. We now know the key elements of growth factor binding, signal transduction, gene transcription control, cell cycle checkpoints, apoptosis, angiogenesis and metastasis. The new paradigm is to develop agents that target the precise molecular pathology driving the progression of individual cancers. Investment in ►genomics, genetics and automation has already resulted in a large number of rationally designed anti-cancer drugs with a record number of novel compounds currently in clinical trials. High profile drugs such as Gleevec (►imatinib), ►Herceptin (trastuzumab), Tarceva (►erlotinib) and Avastin (bevacizumab) specifically target underlying molecular lesions and are in widespread clinical use. Patients are selected to receive treatment based on the detection of a precise molecular lesion and the likelihood of benefit with subsequent drug treatment. These agents have provided important proof-of-principle evidence for the benefits of targeted therapy in cancer and represent a significant advance towards achieving personalized medicine.

One of the consequences of using targeted therapy against a defined molecular lesion is that a move to target rather than disease based drug clinical development is required as a defined molecular lesion may occur in more than one type of cancer. An example among the new approved agents for targeted therapy in cancer is the use of imatinib (Gleevec). Imatinib was originally developed to target the ►BCR/ABL receptor tyrosine kinase, formed by the fusion of the head of the *bcr* gene with the body of the *abl* gene, in chronic myelogenous leukemia cells. The chimeric ►BCR/ABL molecule transforms primary myeloid cells to leukemic cells via its ABL receptor tyrosine kinase activity. Imatinib is a competitive inhibitor of the ABL tyrosine kinase activity resulting in 89% overall survival of patients after 5 years. Subsequent analysis has also revealed activity against the tyrosine kinases associated with the ►KIT protein (stem cell factor receptor) and ►platelet-derived growth factor receptor. The KIT tyrosine kinase is abnormally expressed in gastrointestinal stromal tumor (GIST), a rare neoplasm for which there had been no effective systemic therapy. Clinical trials subsequently demonstrated imatinib to be an effective therapy in GIST with 1 year survival rates of 88% and imatinib is now licensed for treatment of GIST.

To achieve the goal of personalized medicine, in addition to developing drugs with defined molecular specificities, it is essential to have ►biomarker and imaging tests to identify the molecular targets in a patient's tumor and the patient's pharmacogenotype. ►Biomarkers act as molecular signposts of the physiological state of a cell and are determined by the genes, proteins and other organic chemicals made by the cell. A related objective of the same tests is to enable monitoring of the effect of a defined drug on its molecular target and to assess early response so that a non-responding patient can be spared unnecessary treatment and be offered alternative therapies. Biomarkers can also provide essential information regarding how much drug is needed to inhibit a particular

molecular target in a tumor and whether there is a benefit to giving more drug. Ideally these tests should be non-invasive as biopsy of solid tumors is expensive and subjects patients to additional invasive procedures with associated risks. Although recent advances in non-invasive techniques, such as buccal cell isolates offer potential as viable sources of biomarkers, traditional sources such as serum or plasma are currently in routine use.

The advantage of using biomarkers to identify patients likely to benefit from a particular treatment is demonstrated by the success of the monoclonal antibody Herceptin (trastuzumab) in breast cancer. Herceptin targets the receptor tyrosine kinase ►HER2/neu which leads to increased cell growth, decreased cell death and increased metastasis to distant sites when mutated. Patients likely to benefit from Herceptin are selected using ►immunohistochemistry test kits or fluorescence in-situ hybridization assays which detect the presence of the protein. Patients whose tumors do not express HER2/neu are spared futile treatment and potential treatment-related side-effects and offered alternative therapy saving precious time and resources.

The newly emerging area of cancer ►phenomics can be used as a practical illustration of how genetic studies can be successfully integrated with phenotypic data to improve the specificity of personalized medicine. Cancer phenomics refers to the systematic and detailed collection, objective documentation and cataloguing of phenotypic data at many levels, including clinical, molecular and cellular phenotype. Data is most mature for germline mutations in the receptor tyrosine kinase "rearranged during transfection," ►*RET*. *RET* plays a crucial role in transducing growth and differentiation signals in tissues derived from the neural crest. Germline mutations in *RET* which lead to a constitutively active receptor tyrosine kinase or decreased specificity for its substrate predispose to the cancer-associated syndrome ►multiple endocrine neoplasia-2 (MEN2). MEN2 is a clinical syndrome involving predisposition to medullary thyroid cancer and phaeochromocytoma in addition to other endocrine, mucocutaneous and skeletal features. MEN2-asociated tumors are more often bilateral and multifocal, and occur at a much younger age than their sporadic counterparts. Meticulous characterization of *RET* phenomics at the clinical and biochemical levels has revolutionized management of families with MEN2. When a mutation is identified in an individual, predictive testing can be performed on family members and only those who carry the mutation require further MEN2 management. The correlation between genotype and phenotype in MEN2 has lead experts to suggest individualized recommendations for the timing of prophylactic thyroidectomy (surgical removal of the thyroid gland) on the basis of the *RET* mutation genotype. For other mutations in *RET,* phenomics has suggested a specific routine surveillance program for early detection is a more appropriate management route. Knowledge of the molecular pathways that are deregulated as a result of *RET* mutations will enable targeted therapies to be explored that might prove useful in treating tumors arising as a result of *RET* mutations.

The Future of Personalized Medicine in Cancer

The Human Genome Project, and its successor the Cancer Genome Project and related activities are expected to identify the majority of genes in most of the common human cancers over the next 5 years. Together these projects will provide a vast repository of comparative information about normal and malignant cells. Instead of licensing drugs for empirical use in different types of cancer with relatively poor response, new therapies will require the identification of specific molecular lesions resulting in improved response rates. Reduced toxicity due to increased selectivity will allow new therapies to be given over prolonged periods of time, in some cases for the rest of the patients' life, a concept unthinkable with current cytotoxic therapy. More complete knowledge of tumor biology and the role of target pathways in normal physiology will reduce the likelihood of unexpected toxicities that can limit or even curtail a drug's usefulness. The recent example of unexpected cardiotoxicity in some patients treated with imatinib is an example.

Detailed analysis of the differences between normal and malignant cells also allows the possibility of individual cancer risk assessment leading to tailored prevention programs and specific screening programs to detect early cancer. Although cancer prevention currently absorbs only 2% of the total current funding of cancer care and research, this percentage is likely to increase in the post-genomic era. Currently it is accepted that approximately 100 genes are associated with the development of a range of cancers. However, the detection of ►polymorphisms in low-penetrance cancer-related genes – or a combination of changed genes – will allow identification of people at increased risk and demand for prevention strategies will increase. It is predicted that within 20 years most people will be genetically mapped with the information easily stored on a smart card. Thus, predisposition to some cancers will be found in early adult life with potential for correction well before manifestation of the disease.

Multiple technologies exist to achieve the goal of personalized treatment in cancer and molecular diagnosis can be established at multiple levels where molecular differences can be found between individuals with identical clinical manifestations. Currently available diagnostic procedures are insufficient to determine

which patients will primarily benefit from rational tumor therapy. In the future, gaining information on the morphology, genetic, ►proteomic, and ►epigenetic alterations will be essential to provide clinicians with relevant information for individualized medicine to be prescribed. DNA ►microarrays are the first approach close to being used in routine diagnosis. These consist of thousands of DNA fragments specific for individual genes which are used to ultimately obtain a genetic expression profile indicating over-expression, under-expression, no change, or complete absence for each gene in the tissue sample. Patterns of gene changes or novel genes associated with disease development or clinical outcome of an individual tumor can then be identified by specialist ►bioinformatic programs which use statistical methods to evaluate the complex information, and translate molecular information into clinically relevant data. Similar analysis of proteins as proteomic patterns also appears on the horizon. The development of high throughput methods for investigation of the methylation status of DNA provides a further level of information. It is likely that individually none of these technologies will provide all the information required for an efficient individualized approach, therefore a "multiplex" approach combining the different biological levels of DNA, RNA, and protein, may be necessary to functionally classify malignant tumors.

The Challenges for Achieving Personalized Medicine

One of the major limitations to achieving personalized medicine is our incomplete knowledge of tumor biology. Our understanding will continue to be supplemented by data from The Human Genome Project and The Cancer Genome Project and their related activities. However, continued investment in technical developments and ►bioinformatics is necessary to develop special methods capable of detecting the entire spectrum of rate-limiting oncogenic pathways in tumors before and after therapy to identify those patients who will benefit from novel therapies. These include the broad profiling of human tissue for morphology, genetic, proteomic, and epigenetic alterations as described above. Before establishment of such an integrated approach into daily routine can occur, extensive research needs to be performed to allow a firm prediction on the activation of a certain pathway in clinical material.

More insidious challenges stem from the way cancer drugs are currently developed. The simplest being that currently drugs frequently enter clinical trials without a "validated" biomarker or imaging test to select patients most likely to respond or for identifying response to treatment. "Validated" means that the test is standardized and has been shown to be reproducible across institutions, if not in patients, then at least in animal models. Instead of being an after-thought, these tests need to be developed early in the development of a drug and be ready for use in clinical trials. Additionally, current requirements for disease-specific drug trials mean that responding patients must be identified by separate trials for each disease group. A move to target rather than disease-based drug clinical development will require a paradigm shift in the way cancer drugs are developed.

A further challenge for drug development results from the likely need to give the newer types of cytostatic cancer drugs (which arrest cell growth but do not shrink tumors) in combination. A rational way to develop molecularly targeted cancer drugs is to use combinations that attack different points in the same or parallel signaling pathways. However, the reluctance of pharmaceutical companies to test their experimental agents in combination with a competitor's agent is a frustration for many clinical investigators. A framework for providing intellectual property protection to companies that test drugs in combination has recently been provided by the US National Cancer Institute Cancer Therapy Evaluation Program (CTEP) with a number of CTEP-sponsored drug combination studies underway. This type of model will need to be extended and made more readily available in the future.

Other challenges for drug development include the widespread frustration with the cost and time that it takes to bring a new cancer drug to trial. Initiatives are in place to help to speed up the drug development process both in the drug discovery pipeline and in the design of clinical trials. The implementation of chemical biology, which provides experimental techniques for linking together elements from all stages of what was previously viewed as a linear pathway from gene to drug, may help to speed up the drug development process. To encourage the more rapid introduction of drugs into clinical trial, the Federal Drug Agency recently introduced the concept of phase 0 or micro-dose trials at less than one-one hundredth of the dose calculated to yield a pharmacologic effect, thus allow the collection of human ►pharmacokinetic and ►bioavailability data earlier in the drug development process. These human data can then be combined with preclinical data to select the best candidates to advance to further, more expensive and extensive clinical development. However, much work needs to be done in this area to ensure personalized medicine becomes a reality.

Finally, there has been much discussion of the economic, social, and ethical considerations of personalized medicine. Although these discussions are outside the scope of this essay, it is important to note that although the post-genomic era provides the molecular tools needed to provide personalized medicine, it may not provide for the risks involved. These include privacy, protection of data, and prevention of

discrimination. Information and communication management is also required to handle the wealth of personal information and link to global medical knowledge.

Summary

We are at one of the most exciting times in modern cancer therapy with the development of rational therapy and the move towards ►personalized treatment for cancer. The concepts to be tested are well established, the drugs are becoming available, and new emerging technologies in target identification, drug discovery, molecular markers, and imaging can finally make the goal a reality: personalized health planning, early diagnosis, the right drugs for the right patient, with predictable side effects.

Peutz-Jeghers-Syndrome

Tilman Vogel
Department of Surgery, Krankenhaus Maria Hilf, Mönchengladbach, Germany

Synonyms

Peutz-Touraine-syndrome; Hereditary hamartosis Peutz-Jeghers; Hutchinson-Weber-Peutz-syndrome; Lentiginosis polyposa Peutz; PJS

Definition

Peutz-Jeghers-syndrome is an autosomal dominantly inherited disorder that is characterized by the combination of:

1. Lentiginosis, i.e., typical pigmented lesions.
2. Hamartomatous polyposis that occurs mainly in the small intestine but also in the colon and the stomach. Extraintestinal hamartomas are rare; possible localizations include the gallbladder, the urinary bladder, the heart, and the respiratory tract.
3. Increased risk for various types of cancer (e.g., pancreas, gastrointestinal tract, bilateral breast cancer, rare gynecological tumors).

The clinical diagnosis is considered established when either two or more hamartomas or at least one hamartoma together with pigment spots or one hamartoma and positive familial history are found (Fig. 1).

Peutz-Jeghers-Syndrome. Figure 1 Typical pigmented lesions perioral and on the lips.

Characteristics

Although Peutz-Jeghers-syndrome is autosomal dominantly inherited, a large number of sporadic cases (possibly new mutations) occur. The disease is equally distributed between the sexes and the races. The clinical problems are bleeding, pain, and intussusception caused by the intestinal hamartosis and the increased risk for various tumors. Initial studies showed mutations in the coding region or splice sites of the *LKB1/STK11* gene in 35–70% of PJS cases. A second (yet unknown) gene that also causes PJS was therefore discussed. Since then, the ability to identify large deletions provided evidence suggesting that all PJS cases may be due to STK11 germline mutations.

Lentiginosis (Pigment Spots)

The typical pigmented spots occur mainly around the mouth, on the lips, and in the buccal mucosa but may also be found on the hands, the fingers, the feet, and around nose and eyes. In size the spots range from few millimeters up to up to ~1 cm in diameter. They are not elevated above skin level. Their color may vary from light brown to nearly black. They may be present at birth or can emerge during the first years of life, although in some cases first spots appear in higher age. In most patients the spots change during life, loosing intensity with increasing age. Histopathologically they show an increase of melanin and melanocytes in the basal layer of the epidermal epithelium. No malignant transformation has ever been reported. If they represent a cosmetical problem, laser treatment is possible. Of the PJS-patients 5–50% have no pigmented spots.

Hamartomatous Polyposis

The hamartomatous polyps are mainly localized in the jejunum followed by the duodenum, the ileum, the colon, and the stomach. Other localizations like the esophagus, the gall bladder, the urinary bladder, the heart, and the respiratory tract have been described but remain extremely rare.

The main problems caused by the intestinal polyps are intussusception, bleeding, and pain. Intussusception leading to bowel obstruction and necrosis is the main cause for emergency surgery in those patients. The age range where symptoms are initiated reaches from newborn babies to old age. Initial clinical symptoms first occur in 33% of patients in the first decade of life, further 33% in the second.

The polyps in the intestine show a typical histopathological picture: intact intestinal goblet cell rich mucosa covers branching bundles of smooth muscle from the lamina muscularis mucosa. These polyps are usually benign but in some cases adenomatous and carcinomatous changes have been reported, leading to the suggestion of a hamartoma-adenoma-carcinoma sequence.

Increased Risk for Malignant Tumors

An increased risk for a wide variety of malignant tumors in PJS-patients has been reported by several authors. In a Meta analysis, the risk ratio for all cancers was 15.2 with a cumulative risk of 93% from age 15 to 64 years old. The most frequent tumor sites include the gastrointestinal tract (stomach, small intestine, colon), the pancreas, the lung, and the female breast (often bilateral). Furthermore, many patients develop tumors of the urogenital tract. In males Sertoli-cell tumors are found. In females rare tumors, such as the benign bilateral form of the sex cord tumor with annular tubes (SCTAT) and the adenoma malignum of the uterine cervix, are found next to the normal carcinomata of the ovaries, the cervix, and the myometrium. Furthermore, malignant tumors in PJS-patients have been found in almost all organ systems. It is therefore impossible to exclude any tumor from the spectrum found in PJ-syndrome.

Pathogenesis

In most cases of PJS an inactivating mutation in the *STK11* or *LKB1* gene can be shown. Initial studies showed mutations in the coding region or splice sites of the *LKB1*/*STK11* gene in 35–70% of PJS cases. A second (yet unknown) gene that also causes PJS was therefore discussed. Since then, the ability to identify large deletions provided evidence suggesting that all PJS cases may be due to *STK11* germline mutations. But still, a second gene responsible for PJS remains possible.

The gene product has a strong homology to the serine–threonine protein kinase XEEK1 from Xenopus. The STK11/LKB1 protein is nuclear as well as cytoplasmic. Furthermore, LKB1 is involved in other human disorders like diabetes and lung adenocarcinoma. The gene has been also investigated in many other sporadic tumors like colorectal, gastric, testicular, pancreatic, ovarian, and breast cancer, in malignant melanoma as well as in different tumor cell lines. Mutations of the *STK11*/*LKB1* gene were rare in these tumors, suggesting a minor role in the evolvement of sporadic tumors besides lung adenocarcinoma.

Loss of heterozygosity of the wild-type allele has been demonstrated in the hamartomatous polyps and in 70–100% of the malignant tumors investigated from PJS-patients.

Therapy

Besides surgical or endoscopic removal of polyps and tumors, there is no established therapy for PJS. However, recent results give reason for hope that in the future medications will be able to favorably influence the course of disease. One possible target for medication could be the cyclooxygenase-2 (COX-2), an enzyme which is frequently elevated in PJS hamartomas. Pharmacological suppression of COX-2 is possible and leads to encouraging results in mouse model and a small series of patients by reducing polyp burden in some cases. Due to adverse events reported from patients treated with COX-2 inhibitors, further studies are on hold.

Screening Recommendations

Regular examinations of PJS-patients have two different aims: (i) to avoid complications caused by intestinal polyps such as bleeding, pain, intussusception, and bowel obstruction and (ii) the early diagnosis of cancer or precursor lesions.

For the first aim, regular screening of the gastrointestinal tract is recommended. The second one is more difficult to achieve since malignant tumors have been reported in virtually all organ systems of PJS-patients. To date, there is no consensus what is the most adequate screening program for people at risk.

The "Deutsche Krebshilfe" (German Cancer Aid Society) recommends annual physical examinations, starting at age 12. Endoscopy of colon and stomach and imaging of the small intestine by either capsule endoscopy, MR-Sellink procedure, or double balloon enteroscopy should start at age 12 and be repeated every 2 years.

However, in a case report, first symptoms of PJS have been described as early as within the first days of life. It has also been shown that one third of patients become symptomatic during the first decade of life. The 12-year of age threshold as a starting point for regular examinations is therefore debatable.

Should symptoms occur in people at a younger age that carry the gene or that are, with an otherwise unknown genetic status, at risk, immediate clarification is warranted.

In female patients, regular gynecological examination including vaginal ultrasound should start at the age of 18 and be repeated on an annual basis. In male patients, regular examination of the genital organs is required in order to detect Sertoli-cell tumors.

At the age of 25, bilateral breast sonography in females should commence on an annual basis. At age 35, bilateral mammography or MRT of the female breast and pancreaticobiliary MRT (MRCP) is recommended to be carried out every other year.

Synonyms

Bacteriophage display

Definition

►Phage display is a molecular technique used to select molecules with specific binding characteristics out of a large pool of genetically engineered ►bacteriophages

displaying combinatorial libraries of proteins via fusion to outer coat proteins of viruses that contain the genes encoding the displayed proteins.

Characteristics

Phage display is very effective way for producing large numbers of diverse peptides and proteins and isolating molecules with specific binding and functional characteristics. Filamentous phage was the first to be used, and currently remains the most commonly employed bacterial viruses for phage display. Phage display involves the expression of polypeptides on the surface of ►bacteriophage. Typically foreign proteins are incorporated into the amino-terminus of pIII, pVIII and, less frequently, pVI coat proteins in filamentous phage display. The lytic bacteriophage vectors such as lambda, T4, and T7 have also been used, especially for displaying ►cDNA expression libraries. Corboxy-terminal display is more common when expressing cDNA library and other proteins for studying protein–protein interactions. Polypeptide libraries in phage display system are encoded by a degenerate oligonucleotide that has been introduced into a location in a phage or ►phagemid genome such that the encoded proteins are displayed or expressed as a fusion to one of the proteins on the outer surface of the bacteriophage. The source of DNA coding for the expressed protein may either be synthetic random or biased sequences, especially for short peptides, or may come from pooled genetic sequences that code for the relevant proteins. During phage assembly process, the fusion proteins are incorporated into the phage particle, and the DNA encoding the displayed fusion protein is packaged inside the same particle. This provides a physical linkage of each polypeptide in the library to its encoding nucleic acid sequence, which can be amplified and decoded. Each phage clone displays a single protein, thus billions of phage particles created from batch-cloned gene libraries express large numbers of diverse proteins constituting phage-displayed polypeptide library. The most popular molecules that are displayed on phage combinatorial libraries today are based on the framework of constrained peptide loop or an antibody fragment. The antibody libraries may be classified as "naïve" or "synthetic" repertoire. A naïve library contains combinatorially assembled ►V-gene from unimmunized animals or human donors to create arrays of antibodies. In "synthetic" repertoire, the combinatorial diversity is generally introduced by appending degenerate complimentary determining regions to a fixed antibody sequence. Single chain variable fragments (scFv), in which variable heavy (V_H) and light (V_L) chain domains of an antibody are sequentially joined by an interdomain peptidic linker, have been the most commonly displayed format for phage antibody libraries. The affinity selection of peptides and antibodies for diagnostic and therapeutic purposes are today the most widely used and commercially most successful applications of phage display libraries. In addition, phage-displayed enzymes, receptors, protein domains, and high complexity cDNA expression libraries have been used for identifying interacting partners.

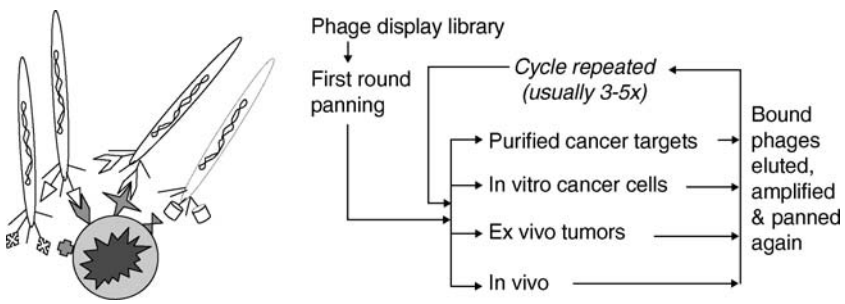
The rapid enrichment and identification of target-binding phages is achieved by affinity selection of phage library on the immobilized target, through a process known as panning. In this process, binding phages are captured and nonbinding clones are washed away. The target-bound phages, following elution with acids, bases, denaturants, or proteases, are amplified in the appropriate host bacterial cells and exposed to the target again for binding. This panning cycle of phage binding, elution, and amplification is usually repeated 3–5 rounds for an optimal enrichment of binding phages. The phages that show considerable binding on individual screening are analyzed for their DNA sequences for identification of the polypeptides they represent. Using similar approach, in vivo panning of injected phage display libraries identified several target-specific binders in human and animal studies also. An ability to select affinity-based ►ligands from a diverse library of polypeptides against any target in a relatively easy way is the key for an extensive utilization of this technology in the cancer research.

Development of Therapeutic and Imaging Agents for Cancer

Developing medications that can target cancer cells without harming the rest of the body is one of the most important challenges for cancer researchers today. It is believed that an ability to home in on cancer cells makes targeted therapy both more effective and less likely to cause side effects. A variety of strategies are being evaluated to achieve this goal. The development of targeted therapeutic methodologies relies in most cases on the availability of binding molecules specific for cancer cell-associated targets. Phage display technology offers a potential tool for developing anticancer agents for both therapeutic and diagnostic applications. Phage display technology has been used to identify peptides and antibodies against a diverse population of known tumor targets. In the cases where ligands isolated from phage-displayed libraries do not show enough affinity and specificity for efficient tumor targeting, phage display techniques are usually combined with affinity maturation methods for optimizing such ligands. In a majority of the cases, ligands have been identified by in vitro panning a phage-displayed library against purified proteins of known cancer-specific targets. Using this approach, ligands have been obtained to an incredibly wide variety of cancer-specific targets

including cell membrane receptors, tumor-associated antigens, ►cellular messengers, matrix-related elements, tumor vasculature targets, etc. However, the approach of developing ligands only to known targets leaves out a variety of other possible targets including novel ones that may uniquely be present in cancer cells. Screening intact cells, tissues, or whole organisms without prior information of the specific molecular targets is a promising strategy to identify cell-specific ligands against an array of targets. Phage-displayed random libraries can be defined as "all-purpose" ►ligand libraries, since expressed polypeptides that have different shapes and properties can interact with linear peptides or folded protein domains, and even with nonprotein molecules. An exposure of the entire library to tumor should identify out of the millions of different shapes at least a few polypeptides that fit specifically to attachment spots on the cancer-specific targets (Fig. 1). In recent years, in vitro and ex vivo selection of phage-displayed ligands on highly complex and diverse target as whole cancer cells, endothelial cell surface of the tumor neovasculature, and whole tumors has been successfully accomplished. In vivo approaches, where phage library has been injected intravenously, have been reported to identify promising ligands against tumor targets in several animal studies with established xenograft tumors. In few studies, the administration of these ligands in conjugation with a cytotoxic agent to tumor-bearing animals resulted in considerable reduction in tumors, lower systemic toxicity, and increased survival time. The benefits of performing in vivo procedure include the presence of a vast number of possible targets in their native configuration, subtraction of the pools of ligands binding to normal tissue, identification of ligands that are stable in blood, and the possibility of identifying unique targets for individual tumors. Recently, the first series of cancer patients who received phage library for serial panning of tumor-targeting ligands have been reported. Patients with Stage IV cancer including breast, melanoma, and pancreas had phage-displayed random peptide or scFv library administered intravenously, tumors excised and tumor-homing phages recovered. In a subset of patients, repeat panning was possible using phage recovered and amplified from that same patient's tumor. No serious side effects, including allergic reactions, were observed with up to three infusions. Several tumor-homing clones from a subset of the patients were identified that specifically bound to a tumor from the same patient in whom clones were recovered. The lack of toxicity and the ability to recover clones with favorable characteristics is a first step for further research with this technology in cancer patients.

A wide variety of options are available to utilize tumor-binding ligands for cancer treatment. Whichever strategy is subsequently chosen, it will vastly benefit if tumor-binding ligands for any patient are reliably available. The application of ligands derived from a phage-displayed library panning is believed to be an important component of a modularized drug. One module is the antiproliferative component and the other is the tumor-binding element. The possibilities of the antiproliferative module include virtually every current anticancer drug category in which increased accumulation of drug at the cancer site would be advantageous. Thus there are several therapeutic options for advancing this technology to the clinic. Cancer-specific ligands identified by phage display technology have been successfully exploited for the ►targeted drug delivery in ►gene therapy, ►radioimmunotherapy, ►photodynamic therapy, prodrug therapy, etc. In general, these ligands act as a delivery vehicle in different forms of therapies to transport therapeutic agents, including genes, ►radionucleotides, ►cytotoxins, ►photosensitizers, ►immunotoxins, ►apoptotic, ►antimetabolic, ►antiangiogenic, enzymes, ►liposomes, ►nanoparticles, etc to cancer site. Cancer cell-targeting ligands



Phage Display. Figure 1 Left side figure shows schematic representation of phages from a filamentous phage library displaying amino-terminal polypeptides fusion to phage outer coat protein pIII. When phage-displayed library is exposed to targets, e.g., cancer cell in this presentation, certain phages depending on their affinity bind to cell surface molecules (targets) and rest are washed away. Right side figure shows the process of panning with cancer targets in different forms, where phages bound to targets are eluted, amplified, and exposed to targets again. The repetition of this process leads to an enrichment of phages that bind to targets with considerable affinity. DNA analysis of target-binding phages decodes the sequences of polypeptides they represent.

isolated from phage display technology also find use in imaging, diagnosis, and monitoring of cancer. The ligands against cancer-specific targets including those associated with ►angiogenic tumor vasculatures can be attached to an imaging agent for localizing tumors. Possible agents for imaging applications are radioisotopes such as ^{99m}TC for scintography, fluorophores for infrared photodetection, gadolinium-loaded liposomes for magnetic resonance imaging, etc.

Identification Cancer-Specific Antigen, Interacting Partners and Immune Response

Affinity-based selection by phage display is also used for tumor profiling, identification of cancer ►biomarkers, to probe protein–protein interactions, and to identify interacting partners and binding domains. This leads to a better understanding of cancer at molecular level and provide information on novel targets proteins, their pathways and networks, and their role in carcinogenesis. Identifying valid cancer cell-specific targets is a difficult challenge as the genetic and biochemical changes that cause disease are often quite subtle, perhaps involving many minor modifications in several genes. Therefore, the success of targeted therapy heavily depends on the identification of appropriate targets under such a complex situation. cDNA expression libraries of cancer cells in filamentous and T7 bacteriophage have been used for identifying partners in protein–protein interactions. Such libraries are also exploited for the analysis of humoral immune responses in cancer patients. Serological analysis of cDNA expression libraries of human tumors with autologous serum (►SEREX) has been used for identifying relevant tumor antigens. The panning of tumor cDNA expression library on serum antibodies from cancer patients can select IgG-binding phages, which subsequent to phage DNA analysis helps in identifying cancer-specific proteins. Alternatively, the use of a phage-displayed peptide library for panning serum antibodies of cancer patients leads to the identification cancer-related ►epitopes that may have diagnostic and/or prognostic value. Phage display technology has also been used to isolate human antitumor antibodies. It is a powerful strategy in which phage-displayed scFv libraries constructed from the peripheral blood lymphocytes of cancer patients are panned against tumor cells. Such a screening of antibody repertoire of cancer patients helps in identifying the human monoclonal antitumor antibodies with clinical and research potential.

The knowledge of cancer-specific cell surface markers is very useful in targeted delivery of therapeutic and diagnostic agents to cancer cells; however, the heterogeneity in the expression and distribution of biomarkers among different cancer patients results into variable patient responses to targeted anticancer therapies. Phage display repertoire may be useful in identifying a panel of very specific cancer cell-binding ligands in high throughput manner without any prior knowledge of the cell surface. Such a panel of binding molecules reflects the expression of whole cell membrane markers and thus helps to generate functional profile of a tumor. Future technological advances may allow functional profiling of individual tumors rapidly in a cast-effective manner, which may lead to the development of ►personalized cancer therapy.

Phagemid

Definition

Is a plasmid vector that carries within its ►sequence a ►bacteriophage replication origin (ori), desired phage capsid protein gene with appropriate cloning sites for fusion polypeptide, and a phage packaging signal. The phagemid encoding the polypeptide-capsid protein fusion is packaged into phage particles following infection of a host bacterium with a helper phage that supplies all the structural proteins.

►Phage Display

Phagocyte

Definition

A white blood cell that can engulf particles such as bacteria, other microorganisms, aged red blood cells,

foreign matter. Executes phagocytosis. The principal phagocytes include the neutrophils and monocytes. The prefix "phago" comes from the Greek "phagein," meaning "to eat."

Phagocytic Glycoprotein-1

►Adipose Tumors

Phagocytosis

Definition

A process by which cells, such as immune cells, bind to and internalize foreign objects, for example, bacteria by macrophages. Tissue macrophages are typical scavenger cells, which have the capacity to engulf other cells, cell debris, extracellular matrix, or foreign bodies by a mechanism termed phagocytosis. The intracellular phagosomes formed this way fuse with lysosomes leading to complete digestion of the engulfed material. Some aggressive tumor cells have the capacity to phagocytose neighboring normal cells and extracellular matrix, leading to tumor invasion and local spread. Refers to a journal to the process by which a particle contacts a cell, and the cell then invaginates its membrane around the particle and internalizes the phagocytic vesicle containing the nickel particle. This results in delivery of a large amount of particles inside the cell.

►Cystatins

Phakomatoses

Definition

Familial cancer syndromes that have the characteristic of benign hamartomatous tumors in common. Includes ►neurofibromatosis Type 1 and ►neurofibromatosis Type 2 (NF1, NF2), ►tuberous sclerosis complex (TSC), von Hippel–Lindau disease (VHL), ►nevoid basal cell carcinoma syndrome (NBCCS), ►Cowden syndrome, ►Peutz–Jeghers syndrome, juvenile polyposis (JP), and ►familial adenomatous polyposis (FAP).

Pharmacodynamics

Definition

Is the study of the biochemical and physiological effects of drugs and the mechanisms of drug action, and the relationship between drug concentration and effect.

►Hollow Fiber Assay
►Pharmacokinetics/Pharmacodynamics

Pharmacogenetics

Definition

Discipline in which DNA analysis is used to predict or explain the pharmacokinetic behavior of drugs. Used to indicate the analysis of a limited number of selected genes, known to be involved in drug metabolism. The field in which multiple genes and genetic variants are investigated in relation to drug metabolism or efficacy of drugs is termed ►pharmacogenomics.

Pharmacogenomics in Multidrug Resistance

Toshihisa Ishikawa
Department of Biomolecular Engineering, Graduate School of Bioscience and Biotechnology, Tokyo Institute of Technology, Meguro-ku, Tokyo

Definition

►Multidrug resistance in cancer is the major obstacle to long-term, sustained patient response to ►chemotherapy. It has been long recognized that the effectiveness of anticancer drugs can vary significantly among individual patients. It is obvious that the susceptibility of cancer cells to particular anticancer drugs cannot be predicted by a single factor but is determined by many factors that influence overall sensitivity. Cancer cells appear to have the capacity to generate variants resistant to anticancer drugs, as part of biological responses to external challenges. Tumors, and even individual cancer cells, can exhibit multiple mechanisms of resistance simultaneously. High-speed ►genotyping and the acquisition of clinical pharmacogenomic data will

be of importance to improve the efficacy and safety of pharmacotherapy of cancer.

Characteristics

Cancer is one of the gene-associated diseases, involving multiple factors in its cause and development. Despite enormous efforts spent on the development of cancer chemotherapies, these therapies are often effective only in a relatively small proportion of cancer patients. Acquired and intrinsic drug resistance in cancer is the major obstacle to long-term, sustained patient response to chemotherapy. It has been convincingly documented that several ATP-dependent drug transporters can cause drug resistance in cancer cells by actively extruding the clinically administered chemotherapeutic drugs. By far the best known major drug transporters, i.e., ABCB1 (P-glycoprotein/MDR1), ABCC1 (MRP1/GS-X pump), ABCC2 (MRP2/cMOAT), and ABCG2 (BCRP/MXR1/ABCP), have been characterized in detail with respect to their structure and function. These drug transporters belong to the ATP-binding cassette (ABC) transporter gene family.

To realize the promise of ►personalized medicine in cancer chemotherapy, it is critically important to understand the molecular mechanisms underlying inter-individual differences in drug response, namely, the pharmacological effect vs. side effect. The differences in response to medications are often greater among members of a population than they are within the same person or between monozygotic twins at different times. The existence of large population differences with small intra-patient variability is consistent with the idea of heredity inheritance as a determinant of drug response. It is estimated that genetic factors can account for 20–95% of variability in drug disposition and effects. ►Genetic polymorphisms in drug metabolizing enzymes, transporters, receptors, and other drug targets (*e.g.*, toxicity targets) are linked to inter-individual differences in the efficacy and toxicity of many medications.

The pharmacological effect of a drug depends on both pharmacodynamics (interaction with the target or the site of action) and pharmacokinetics (absorption, distribution, metabolism, and elimination). While drug metabolism has long been recognized as one of the major determinants of drug clearance and the factor that is responsible for individual differences in pharmacokinetics, it is now widely accepted that the drug transport process plays a major role in drug absorption, distribution, and elimination.

Pharmacogenomics has significantly contributed to our understanding of genetic causes underlying differences in drug metabolism (*e.g.*, cytochrome P-450 mediated drug metabolism). In fact, recent technological advances allowing massive DNA sequencing have in turn allowed us to identify single nucleotide polymorphisms (SNPs) as one possible cause of variable drug response among individuals. In light of such advances, it is important to carefully examine the clinical significance of polymorphisms in drug response genes.

Single Nucleotide Polymorphism (SNP)

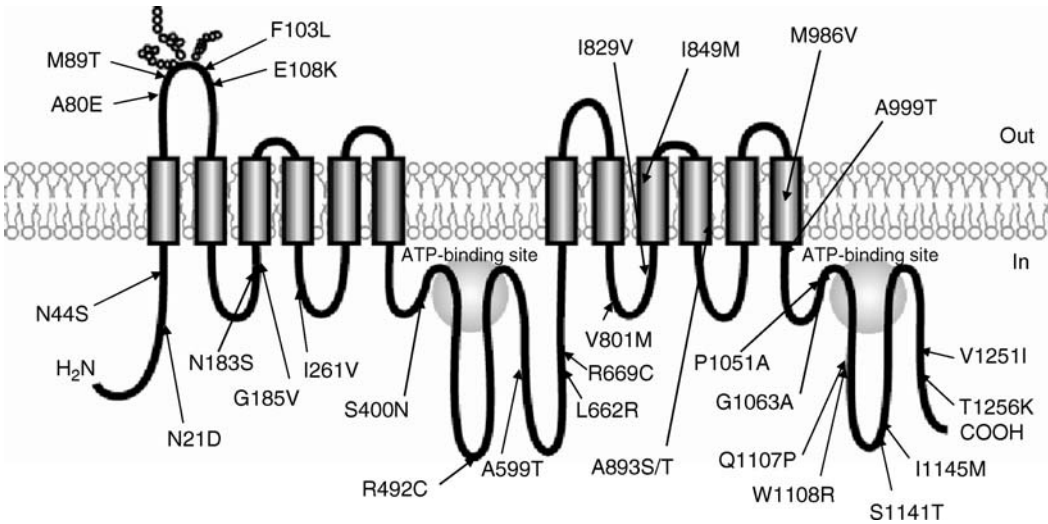
Genetic polymorphisms relevant in a population aspect are usually defined as variants present in more than 1%. It was originally estimated that single nucleotide polymorphisms (SNPs) in the human genome occur at a rate of 1 in every approximately 1,000 base pairs, a recent report indicates a much higher rate of polymorphism that averages one SNP in every 185 nucleotides. The rate of polymorphism within gene encoding regions was estimated at 3.4 per kilobase. Therefore, it is likely that a large number of coding region SNPs exist among drug transporter genes. Many of those SNPs are expected to cause amino acid changes that directly alter protein function. Furthermore, the rate of SNPs in non-coding regions such as promoter, introns, splice junctions, and 3′-untranslated regions is greater than within exons, suggesting that genetic polymorphisms invoking alterations in transcriptional activation and splicing may also prove to be relevant in determining the function of proteins encoded by the corresponding genes.

ABC Transporters

The ABC transporter gene family form one of the largest protein families encoded in human genome. Hitherto more than 48 human ABC protein genes have been identified and sequenced. It has been reported that mutations of ABC protein genes are causative in several genetic disorders in humans. Many of human ABC proteins are involved in membrane transport of drugs, xenobiotics, endogenous substances or ions, thereby exhibiting a wide spectrum of biological functions. Based on the arrangement of molecular structure components, i.e. nucleotide binding domains and topologies of transmembrane domains, hitherto reported human ABC proteins are classified into seven different sub-families (A to G). The HUGO Human Gene Nomenclature Committee developed a new system of nomenclature for the human ABC-transporter family. The new nomenclature scheme was implemented in 1999, and detailed information is available on the web site at http://www.gene.ucl.ac.uk/nomenclature/genefamily/abc.html.

ABCB1 (P-glycoprotein/MDR1)

Human ABCB1 (P-glycoprotein/MDR1) was identified because of its overexpression in cultured cancer cells associated with an acquired cross-resistance to multiple anticancer drugs (Fig. 1). ABCB1 is expressed not only in cancer cells but also in many normal tissues. For



Pharmacogenomics in Multidrug Resistance. Figure 1 Schematic representation of ABCB1 and nonsynonymous polymorphism. The positions of amino acid substitutions are indicated by arrows. G185V is an acquired mutation.

example, it is located in the apical domain of the enterocytes of the gastrointestinal tract (jejunum and duodenum) and limits the uptake and absorption of drugs and other substrates from the intestine into the systemic circulation by excreting substrates into the gastrointestinal tract. In addition, ABCB1 is expressed in the endothelial cells lining the small vessels of the human cortex, in which the transporter appears to be concentrated within the luminal cellular compartment. The expression of ABCB1 on the luminal membrane of capillary endothelial cells of the brain restricts drug distribution into the central nervous system. This function of ABCB1 appears to be very important for protecting the central nervous system from attack by toxic compounds. However, such function becomes critical in the case of chemotherapy of brain tumors, since ABCB1 expressed in the ►blood–brain-barrier limits the penetration of anticancer drugs into the central nervous system.

To date, genetic variations of the human *ABCB1* gene have been most extensively studied. Hitherto, more than 50 SNPs and several insertion/deletion polymorphisms in the *ABCB1* gene have been reported. Preclinical and clinical studies have provided evidence for naturally occurring polymorphisms in ABCB1 and their effects on drug absorption, distribution, and elimination. It has been reported that the 2677G>T/3435C>T haplotype is of clinical importance. Recent reports as well as the NCBI dbSNP database show a tri-allelic polymorphism of ABCB1 (2677G>T/A) and one rare mutation (2677G>C). Functionally evaluation showed that nonsynonymous polymorphisms (2677G>T, A, or C) at amino acid position 893 (Ala>Ser, Thr, or Pro) have a great impact on both the activity and the substrate specificity of ABCB1. The polymorphisms of 2677G>T (893 Ala>Ser) is reportedly associated with high risk of lung cancer.

ABCC1 (MRP1/GS-X pump) and ABCC2 (MRP2/cMOAT)

Human ABCC1 (MRP1) gene is located on chromosome 16p13.1 and spans at least 200 kb consisting of 31 exons. The ABCC1 gene encodes a 1531 amino acid protein which has a molecular weight of 190 kDa in its mature glycosylated form. In the promoter region of the ABCC1 gene, there are a number of putative transcription factor motifs, such as the activator proteins AP1 and AP2 (Sp1), glucocorticoid response element (GRE), and also estrogen response element (ERE) and cAMP response element (CRE). Human ABCC2 (MRP2 or cMOAT) is a 1545 amino acid protein whose exon gene is located in chromosomal region 10q23–24. Although there is limited sequence similarity between ABCC1 and ABCC2 (49%), the primary structure and membrane topology of the two proteins are similar. In addition, the two transporters also have similar substrate characteristics. Both ABCC1 and ABCC2 transport a wide range of organic anions, including glutathione disulfide (GSSG), glutathione-metal complexes, glutathione conjugates, as well as glucuronate and sulfate conjugates.

Elevated expression of ABCC1 mRNA and/or protein levels have been observed in many multidrug resistant cancer cells. Transfection of ABCC1 cDNA in cultured cells resulted in enhanced resistance to many cytotoxic agents including doxorubicin, vincristine and VP-16. ATP-dependent transport of these

anticancer drugs can be enhanced by the presence of ►glutathione (GSH) in membrane vesicles prepared from ABCC1-overexpressing cells, suggesting that ABCC1 co-transports anticancer drugs and GSH. In patients, human colorectal cancers frequently overexpress ABCC1 and ►γ-glutamylcystein synthetase (γ-GCS), a rate-limiting enzyme of GSH biosynthesis, as compared to the surrounding normal tissue. The frequency of ABCC1 expression in carcinoma was higher than that in adenoma ($p<0.0001$). The ABCC1 up-regulation and the *p53* status were significantly correlated.

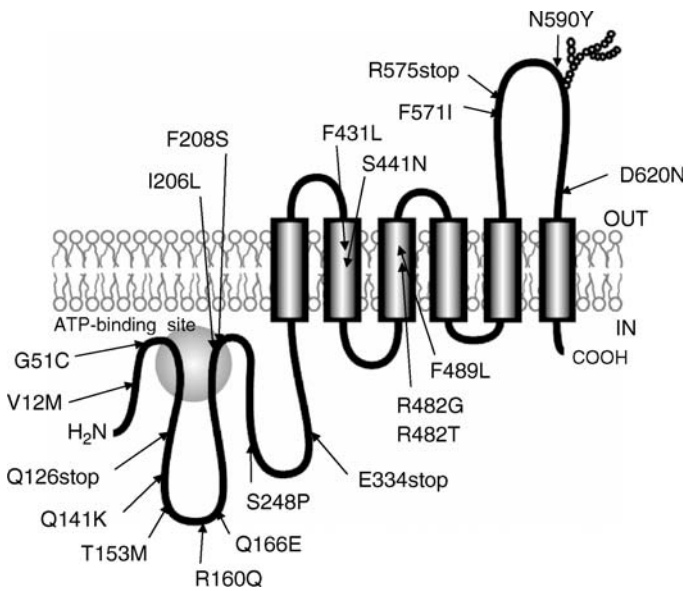
ABCG2 (BCRP/MXR1/ABCP)

Human ABCG2 (BCRP/MXR1/ABCP) is another member of the ABC transporter gene family, ant its overexpression in cancer cells is related with cellular resistance to anticancer drugs, such as mitoxantron, topotecan, and ►SN-38, an active metabolite of irinotecan (Fig. 2). SNPs of ABCG2 have been documented to be a significant factor in the patients' responses to medication and/or the risk of diseases. Sequencing of the ABCG2 gene from human samples has revealed over 80 different, naturally occurring sequence variations. Drug resistance profiles of ►Flp-In-293 cells expressing two major SNP variants, i.e., V12M, and Q141K, toward SN-38 demonstrated that the IC_{50} value for Q141K was about 50% of that for the wild-type (WT). The contributions of the minor SNP variants, i.e., F208S, S248P, F431L, S441N, and F489L, to drug resistance toward SN-38, mitoxantrone, doxorubicin, daunorubicin, or eroposide were significantly lower than that of WT.

The Q141K polymorphism located in exon 5 (c.421C>A) leads to the replacement of the negatively charged glutamic acid residue with a positively charged lysine residue. This polymorphism affects the ATP-binding domain, between the ►Walker A motif (amino acid residues 83–89) and the signature region (amino acid residues 186–189). The Q141K variant was also detected in all ethnic groups tested: the allele frequency ranged between 0% and 35%, (the Africans in North of Sahara, the Africans sub-Saharan, and African-American subjects with low; the Japanese and Chinese populations with high allele frequencies). The SNP (Q141K) was postulated to cause increased sensitivity of normal cells to anticancer agents that are ABCG2 substrates such as topotecan, diflomotecan, and SN-38.

Perspectives

Drug transporters as well as drug-metabolism play pivotal roles in determining the pharmacokinetic profiles of drugs and, by extension, their overall pharmacological effects. There are an increasing number of reports addressing genetic polymorphisms of drug transporters. Information is still limited, however, regarding the functional impact of genetic polymorphisms in drug transporter genes. Detailed functional analysis *in vitro* is critically important to provide clear insight into the biochemical and therapeutic significance of genetic polymorphisms. Functional validation of SNPs and



Pharmacogenomics in Multidrug Resistance. Figure 2 Nonsynonymous polymorphisms of human ABCG2. Schematic illustration of the structure of ABCG2 protein and the locations of amino acid changes. R482G and R482T are acquired mutations.

their linkage with clinical data would provide a new approach to individualized pharmacotherapy in the 21st century.

Definition

Pharmacokinetics

►Pharmacokinetics (PK) is the study of how a drug is absorbed, distributed, metabolized, and excreted over time.

Pharmacodynamics

►Pharmacodynamics (PD) is the study of how a drug affects its target(s) in a dose- and time-dependent fashion.

Characteristics

To maximize the chance of successful drug development, a comprehensive knowledge of the compound under investigation is required. Assuming the drug target has been correctly selected, drug efficacy requires delivery into the patient such that adequate drug concentration is achieved within the plasma and tumor (measured by PK studies) to effect target modulation (measured by PD studies) resulting in anticancer effect(s). These principles have been incorporated into a pharmacological audit trail consisting of a series of questions that should be addressed during drug design and development. These can be summarized as:

- Is the drug target expressed in the tumor of interest?
- Are adequate plasma and tumor drug levels achieved?
- Does this level of drug exposure result in target modulation?
- Can effects be demonstrated on the biochemical pathway downstream of the target?
- Are the desired biological effects achieved, e.g., cell cycle arrest, induction of apoptosis or inhibition of angiogenesis?
- What are the therapeutic consequences of drug exposure and target modulation?

Related to these questions, it is valuable to determine if biomarkers of sensitivity or resistance can be identified.

From these questions it is obvious that PK and PD studies form an important part of the knowledge base required for modern drug development. The advantage

of using PK/PD biomarkers, and of implementing the pharmacological audit trail, is that decisions in drug development can be made on a rational basis, therefore making the process more effective.

Pharmacokinetics

It is usual to assume that the therapeutic and toxic effects of a drug are related to its concentration at the site of action. Previously it was estimated that around 40% of drugs failed clinical development due to poor PK properties. Inappropriate PK can lead to inadequate or variable drug exposure, and hence to lack of therapeutic activity or undesirable toxicity. This figure has fallen to around one in ten, due mainly to more thorough preclinical PK modeling.

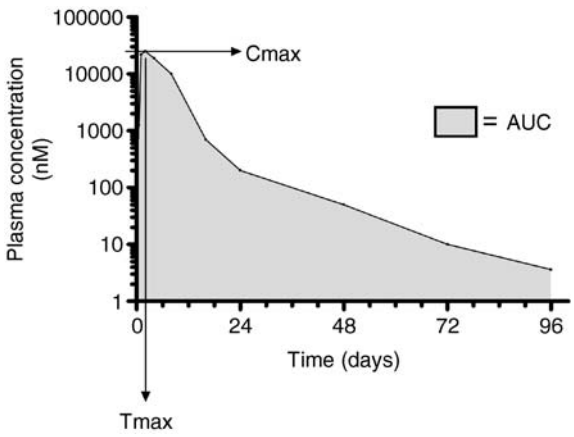
Early in drug discovery, physicochemical properties need to be addressed, in order to maximize the chance of the final molecule possessing appropriate drug-like properties. The Lipinski rule of five provides a useful guide. This is based on the fact that most marketed drugs have a molecular weight of less than 500 Da, partition coefficient cLog P < 5 (a measure of lipophilicity), <5 hydrogen bond donors, and <10 hydrogen bond acceptors. Algorithms can be applied and experiments performed to predict oral bioavailablity or metabolic liability as well as unwanted toxic effects.

Additional related studies that are carried out alongside preclinical PK include the potential for adverse interactions with cytochrome P450 enzymes, potentially leading to variable drug levels and drug-drug interactions, and with hERG channels, potentially predictive of side effects on the heart.

During preclinical testing it is valuable to determine PK in tumor-bearing animals where drug concentrations in plasma and tumor tissue can be determined after both single and multiple doses. These data can be used to predict human exposures and to guide initial clinical trials. The drug concentration measured over time is a function of:

- Drug entry into the body; for an oral drug this relates to absorption across the gastrointestinal tract or for intravenous delivery whether a bolus is given or an infusion over prolonged period
- Distribution into body tissues, including tumor
- Metabolism, most frequently by liver enzyme systems
- Excretion of drug, usually by the liver or kidneys

In patients, plasma samples are usually collected and analyzed over a time-course following drug administration. From these data it is possible to calculate maximum plasma concentration (C_{max}), time to reach C_{max} (T_{max}) and the area under the plasma drug concentration curve (AUC); Fig. 1 shows a hypothetical example. The time taken for half the drug to be eliminated from plasma can also be determined (t½).



Pharmacokinetics and Pharmacodynamics in Drug Development. Figure 1 Hypothetical graph plotting the concentration of drug in plasma versus time from start of an intravenous infusion. Key measured parameters are indicated, namely maximum concentration of drug (Cmax), time to reach Cmax (Tmax) and area under the curve (AUC).

Other PK variables can be derived from the data such as steady state volume of drug distribution (V_{SS}), total body clearance (CL) and oral bioavailability (F_{PO}) if applicable. V_{SS} is the amount of drug in the body divided by the drug concentration in plasma. Clearance of a drug is the volume of plasma from which the drug is completely removed per unit time. F_{PO} represents the fraction of the administered dose that reaches the systemic circulation.

Determination of a drug's PK properties facilitates the selection of the correct drug dose and administration schedule in patients. This requires consideration of:

- Preclinical information on the drug exposures (both concentrations and exposure times) required for the desired anticancer effect
- Concentrations (C_{max} and AUC) of drug and any metabolites in the circulation and ideally the tumor if data are available
- Protein binding, which may limit tissue uptake
- If applicable, oral bioavailability

An important objective is to determine if it is possible to achieve levels of exposure that would be required for a significant therapeutic effect.

The extent of PK studies performed in early clinical trials varies. In phase I testing where safety is paramount and few prior data are available, the relationship between drug dose administered and patient exposure (C_{max} and AUC) is examined and PK parameters may be linked to toxic and therapeutic events. Once the dose of drug for future study has been determined, it may be useful to perform additional studies to address specific

issues. Examples might be to determine possible effects of food on oral drug absorption or the impact on organ (e.g., liver or kidney) dysfunctions on the PK profile. Thorough absorption, distribution, metabolism and excretion (ADME) studies using radiolabeled drug in small groups of patients are sometimes beneficial but these are time-consuming and resource intensive as they require measurement of all input into, and output from, the patient.

In modern drug development, PK measurements are usually made by mass spectrometry coupled to liquid chromatography.

Pharmacodynamics

In association with PK data, PD biomarkers can be valuable in answering further questions in the pharmacological audit trail.

In the development of a modern molecularly targeted cancer drug, PK and PD biomarker assays will usually be developed during the preclinical discovery phase. These biomarkers are used to demonstrate proof of mechanism in model systems, i.e. target modulation, for example in human tumor cell lines and human tumor xenografts in immunosuppressed mice. Careful studies must be carried out to demonstrate that any PD assay is able to measure changes in the predicted endpoint, for example kinase inhibition. If sufficiently robust and reproducible, the assay can be applied to measure PD changes in human trials.

PD endpoints may be measured in surrogate normal tissue, such as buccal mucosa, skin, peripheral blood mononuclear cells (PBMCs) or hair follicles, which have the advantage of being readily available and safe to obtain. For example, in the development of the epidermal growth factor receptor (EGFR) inhibitors gefitinib and erlotinib, skin biopsies were used to provide surrogate tissue to confirm inhibition of phosphorylation of EGFR itself and of downstream markers such as ERK 1/2, as measured by immunohistochemistry.

Although PD data from surrogate normal tissue can be valuable, the gold standard remains to measure the effects of the drug in the tumor. However, the acquisition of tumor tissue is complicated by logistical and ethical issues. Hence there is increasingly a need for minimally invasive techniques such as functional imaging, e.g., using positron emission tomography (PET) scanning. Use of serum markers or circulating tumor cells is also attractive.

Demonstrating the PK-PK-Clinical Relationship

Based on the premise that to obtain a beneficial clinical effect (e.g., tumor stabilization or shrinkage) a drug must be effective on its target (assuming the target is a bona fide anticancer target), it is valuable to define a relationship between PK, PD and clinical effect. As set out in the pharmacological audit trail, adequate drug exposure must occur in plasma and tumor which is measured by PK studies (using plasma). Both concentration and time of exposure may be important.

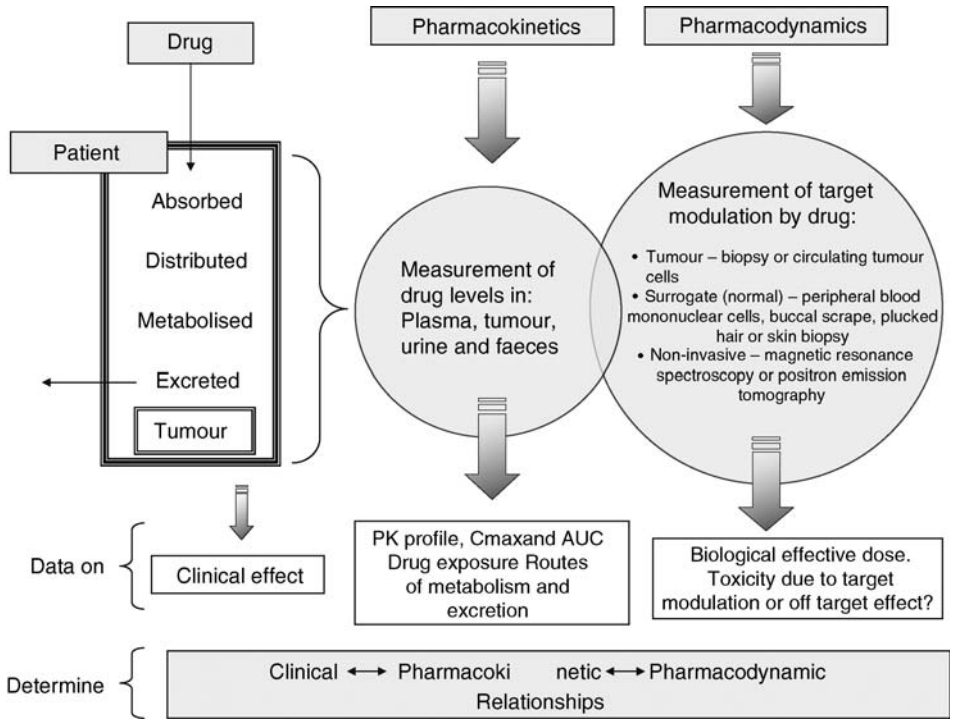
Drug effects on the target are determined using PD endpoints. Fig. 2 summarizes the integration of PK and PD studies with examples of substrates for analysis. The approach is exemplified in the development of heat shock protein 90 (HSP90) inhibitors such as tanespimycin 17-Allylamino, 17-Demethoxygeldanamycin (17-AAG).

A series of orchestrated interactions between the molecular chaperone HSP90 and other proteins (client proteins) occur within a cell to maintain normal cellular functions. Inhibition of HSP90 function disrupts these interactions and targets client proteins, many of which are oncogenic (e.g., CDK4, ERBB2, CRAF or BRAF) for destruction by the proteasome. Other heat shock proteins, such as heat shock protein 70 (HSP70), are induced in response. These changes can be detected by methods including western blotting or enzyme linked immunosorbant assay (ELISA). To follow the PD effects of HSP90 inhibition by tanespimycin, a panel of relevant proteins was chosen, including CDK4, CRAF, ERBB2 and HSP70. These were based on candidate markers derived from early mechanistic work, cDNA microarray gene expression and proteomic profiling studies. Preclinical determination of PK-PD-tumor response relationships were undertaken in a human tumor xenograft model. PK studies in these models confirmed that tanespimycin concentrations were achievable, in both plasma and tumor, that had been shown to inhibit proliferation of tumor cells in culture. PD measurements proved HSP90 inhibition by demonstrating that the client proteins CRAF, CDK4, and ERBB2 were depleted and that HSP70 was induced, as predicted. These changes in protein expression can be regarded as a pharmacological signature of HSP90 inhibition after being reproduced in multiple models and by several independent investigators.

PBMCs were investigated as a surrogate normal tissue in which to measure HSP90 inhibition. Previously, reversible occurrence of the PD signature of HSP90 inhibition was confirmed in PBMCs from mice with human tumor xenografts, as well as ex-vivo human PBMCs exposed to tanespimycin. Similar HSP0 inhibition was seen in the xenograft tumor tissue, and then subsequently in tumor biopsies from treated patients.

Building on the preclinical data, multiple phase I trials using a variety of dosing schedules with tanespimycin demonstrated that it was possible in patients to:

- Achieve adequate plasma concentrations of tanespimycin and metabolites compared to preclinical models



Pharmacokinetics and Pharmacodynamics in Drug Development. Figure 2 Summary of the role of PK and PD in drug development.

- Inhibit HSP90, based on the PD signature
- Observe early indicators of antitumor activity, e.g., tumor stabilization
- Demonstrate that toxicity was manageable

HSP90 inhibitors, such as tanespimycin, are now in Phase II and III clinical trials and future studies will aim to complete unanswered questions, such as how to determine which patients will respond and how tumors might develop resistance, in order to guide clinical use of these agents.

These studies of HSP90 inhibitors provide scientific validation of PK and PD biomarker assays. In addition, it is increasingly important that validation is performed to the requisite, technical level to ensure compliance with regulatory requirements. This should be done in a phased, fit for purpose fashion.

Although current PD studies mainly involve measurement of a single marker or a small group of them, more complex measurements can also be made, including global mRNA, proteomic and metabonomic profiling.

Conclusions

A comprehensive understanding of a drug's properties involves study of both PK and PD. Both the safety and success of clinical trials are reliant to a large extent on such information. Use of PK and PD biomarkers provides a rational basis for drug development and increases the likelihood of a successful outcome.

Pharmacophore

Jürgen Bajorath
Department of Life Science Informatics,
B-IT University of Bonn, Germany

Definition

The precise arrangement of atoms, groups, or functionalities in a small molecule required for specific interactions with its biological target and its activity.

Characteristics

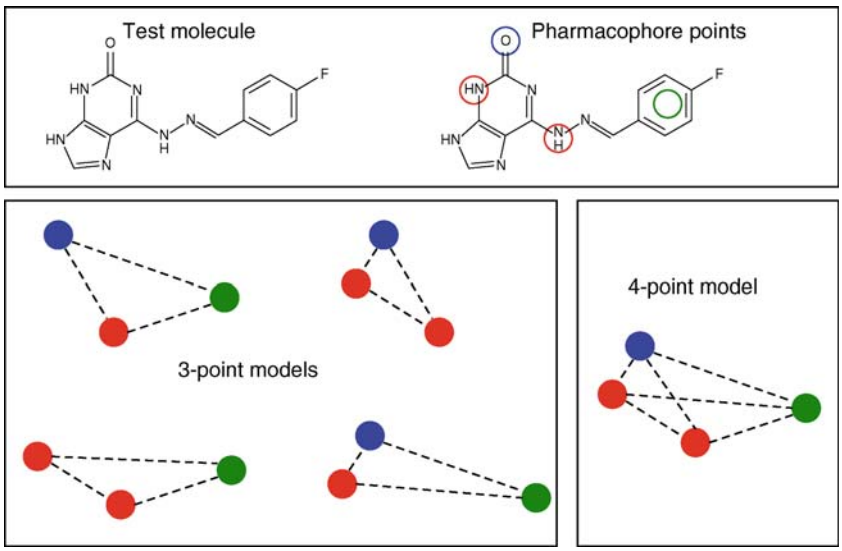
Specific binding to biological targets, mostly proteins, is a necessary but not sufficient requirement for the biological activity of small molecules and their ability to ultimately become drugs (►Small molecular drugs). Pharmacological parameters (►Pharmacokinetics/pharmacodynamics) and ADMET properties (►Absorption, ►distribution, ►metabolism, ►excretion, ►toxicity, ►ADMET screen) are equally important determinants for synthetic compounds or natural molecules to become drug candidates. However, specific target-ligand interactions (►Druggable target) are a pre-requisite of inhibitory, antagonistic, or agonistic effects of small molecules. The discovery of such interactions and their exploration present an essential starting point for drug development. The pharmacophore concept, formulated in the 1970s, aims to define critical interactions at the small molecule level, often without detailed structural knowledge of the underlying receptor-ligand interactions. Together with ►QSAR (►Quantitative structure activity relationship) and molecular similarity analysis, the pharmacophore concept is one of the major paradigms in ligand-based drug design (►Drug design).

In general terms, a pharmacophore is best defined as the arrangement of those substructures or functional groups in an active compound that are crucial for its activity. Pharmacophores can be derived from two- or three-dimensional (2D, 3D) molecular representations, but 3D-pharmacophores are most popular (considering the fact that molecules are active in three dimensions). Accordingly, a 3D-pharmacophore refers to the precise spatial arrangement of activity-determining parts of a molecule. This geometric arrangement is a consequence of the conformation and orientation of a ligand within its receptor binding site. Although experimentally determined structures (►X-ray crystallogaphy, ►nuclear magnetic resonance) of receptor-ligand complexes would provide the best possible basis to derive pharmacophore models, they are often not available. In fact, as a ligand-based approach, pharmacophores are most often deduced from active compounds. This is typically accomplished by comparing the structures of series of analogs or more distantly related compounds and predicting their binding conformations. As a consequence, accurate prediction of the bioactive conformation of a small molecule is critically important for the validity of a pharmacophore model and often presents a major bottleneck.

An important advancement of the pharmacophore concept has been the transition from an atom-centric representation to pharmacophoric functions. This means that important atoms or groups are replaced with different "features," which represent functionalities important for binding. The most relevant pharmacophore features include hydrogen bond acceptors (e.g. hydroxyl or carbonyl groups), hydrogen bond donors (e.g. hydroxyl or amide groups), positively charged (e.g. guanidines) or negatively charged groups (e.g. carboxylates), and hydrophobic (e.g. cyclohexyl or isopropyl groups) or aromatic moieties (e.g. phenyl ring or other aromatic ring systems). In pharmacophore models, features are represented as points; for example, for five- or six-membered rings, the centroid position is used as a point. Feature points are separated by inter-feature distances, which represent the second major component of pharmacophore models. The combination of features and inter-feature distances captures the chemical nature of a pharmacophore and its geometric arrangement.

As any predictive approach, pharmacophore modeling has intrinsic limitations. First, pharmacophores implicitly account only for direct binding interactions and not other parameters that determine protein-ligand interactions such as, for example, de-solvation or entropic effects. Furthermore, pharmacophore models are by design qualitative in nature; they do not take the relative strengths of binding contributions into account and do not include other energetic parameters. Therefore, pharmacophores are best rationalized as a ligand-centric approximation of short-range interactions and molecular complementarity.

Originally, most pharmacophore models were three-point pharmacophores but during the late 1990s, they were extended to 4-point pharmacophores. Thus, the three or four most important centers for binding are extracted from a molecule and their pairwise intramolecular distances are measured. Accordingly, a three-point pharmacophore is determined by three feature points and three inter-feature distances and a four-point pharmacophore by four features and six inter-feature distances. Distances between feature points are usually divided into different ranges or bins, for example, six to ten distinct intervals per inter-feature distance. This is done to permit a certain degree of flexibility in evaluating pharmacophore patterns, taking into account, for example, that corresponding hydrogen bonds might have slightly different lengths or that differently sized rings or groups might engage in similar interactions (a concept termed "bioisosterism") (Fig. 1).



Pharmacophore. Figure 1 Model pharmacophore. For an arbitrary test molecule, pharmacophore points and features are assigned (red, hydrogen bond donor; blue, hydrogen bond acceptor; green, aromatic center) and potential three-point pharmacophores combining these features and the corresponding four-point pharmacophore model are shown. Dashed lines are inter-feature distances.

Pharmacopohore models containing more than four features can, in principle, be easily defined, but there are both conceptual and practical reasons to limit the number of feature points. First, only a few parts or functional groups of a small molecule and the interactions they form determine binding and biological specificity. This suggests that one should be conservative in assigning features and not artificially complicate models. Second, from a practical point of view, a systematic evaluation of potential pharmacophore patterns is currently computationally infeasible for pharmacophores containing more than four feature points and increasing numbers of inter-feature distances, as further discussed below.

Major applications of pharmacophore models include 3D database searching, the design of active compounds and target-focused libraries (►Combinatorial libraries), and the derivation of models for 3D-QSAR. Searching databases of 3D structures of small molecules has been one of the original applications of pharmacophores and continues to be a major focal point. For database search calculations, pharmacophore queries consist of specific features and distance constraints. The goal of 3D database searching is the identification of molecules that meet the pharmacophore constraints but are chemically distinct from the query compounds. For these applications, it is important that pharmacophore queries have some degree of flexibility in terms of features and, in particular, inter-feature distances. This rationalizes the introduction of distance binning schemes, as described above. A pharmacophore search using single values for inter-feature distances would be overly rigid and likely fail to produce hits because no database compound might exactly fit all the distance constraints, although some molecules might share the pharmacophore arrangement. In addition to database searching, another original application of pharmacophores has been the design of analogs of active compounds. Once a pharmacophore has been derived from a series of active molecules, medicinal chemists often utilize 2D pharmacophore representations and apply chemical knowledge to predict compound modifications that are consistent with the pharmacophore (e.g. bioisosteric replacements) but perhaps lead to an improvement in the biological activity of lead compounds or their ADMET properties.

Pharmacophore models have increasingly been used to design combinatorial libraries that are focused on biological target families. Among others, important target families for pharmacophore-based library design include G-protein-coupled receptors (►G-proteins, ►GPCRs) and protein kinases (►Tyrosine kinase). In both cases, so-called "privileged" structural motifs have been identified that are highly recurrent in active compounds. For GPCRs, which represent approximately 50% of current drug targets, abundant information about active small molecules is available, but very little target structure information, which is a typical application scenario for pharmacophore modeling. Combinatorial or other compound libraries can be focused on target families such as GPCRs by using pharmacophore models derived from known ligands as filters for the evaluation of candidate compounds. By filtering out compounds that do not fit pharmacophore constraints and accepting those that do, libraries can be significantly enriched with molecules having an increased probability to be active. In

addition to pharmacophore filters, specialized pharmacophore models have been introduced for the purpose of compound design. These models are used to orient substituents relative to core structures of molecules in order to fulfill pre-defined pharmacophore requirements and then select suitable building blocks (scaffold and R-groups) for combinatorial synthesis. Finally, pharmacophore models also serve as starting points for the generation of 3D-QSAR models and the calculation of descriptors that form steric or electrostatic fields surrounding compounds having similar activity. In 3D-QSAR, pharmacophores serve as anchor points for the generation of compound conformations and their spatial alignment.

As stated above, a principal limitation of pharmacophore modeling is the difficulty to accurately predict bioactive conformations of small molecules from first principles. A prediction is typically attempted on the basis of systematic conformational analysis of active compounds and classification and energetic evaluation of sets of similar conformations. Given these uncertainties, modifications of the pharmacophore concept have been introduced that alleviate the need to predict single bioactive conformations. This has been accomplished by a systematic exploration and comparison of potential pharmacophore patterns in molecules, which is called "pharmacophore fingerprinting" and requires the generalization of pharmacophore models. Generalization involves the assignment of alternative features to each point in a three- or four-point pharmacophore (i.e. the six features described above) and the division of inter-feature distances into different intervals. Alternative features and distance ranges are systematically combined and the presence or absence of each unique combination in a molecule is examined using a conformational ensemble and recorded in a bit string format (where "1" indicates its presence and "0" its absence). The overlap between the resulting pharmacophore fingerprints of different molecules is quantified using a similarity metric. The more pharmacophore patterns two molecules share, the more similar they are, at least in "pharmacophore space."

Pharmacophore fingerprinting is computationally by far the most expensive pharmacophore calculation because distance and feature combinations can quickly become very large. For example, given six alternative features at each point and ten distance intervals for each inter-feature distance, a three-point pharmacophore model would produce 33,000 distinct pharmacophore arrangements, whereas a corresponding four-point model would produce 9.7 million potential pharmacophores. This explains why systematic exploration of possible pharmacophores is currently limited to four-point models. Furthermore, for each test molecule in a database a complete conformational search must be carried out as a pre-requisite for pharmacophore fingerprinting, which adds to the computational expense of large-scale database searching. Other recent extensions of the pharmacophore concept include the introduction of "fuzzy" features that further generalize or simplify pharmacophore functions. The goal of such efforts is to enable pharmacophore searching to identify molecules having increasingly diverse structures but similar binding characteristics and activities.

Since their introduction, pharmacophores have played an important role in medicinal chemistry and small molecule-based drug design. Pharmacophore models of very different complexity have been successfully applied on a case-by-case basis, ranging from simple "paper drawn" 2D pharmacophores to elaborate 3D pharmacophore fingerprints that literally capture millions of potential pharmacophore patterns. Pharmacophore modeling continues to be a highly active area in computer-aided pharmaceutical research, as exemplified by recent advancements such as the introduction of fuzzy pharmacophores or the derivation of complementary pharmacophores from binding site features of target proteins.

Phase I and II Clinical Trials

Definition

The clinical development of a new drug or treatment is along a series of clinical trials called Phase I, II, and III. In Phase I clinical trials, a new drug or treatment is tested in a small group of people (20–80) for the first time to evaluate its safety, determine a safe dosage

range, and identify side effects. In Phase II clinical trials, the study drug or treatment is given to a larger group of people (100–300) to see if it is effective, i.e. if it works against a particular disease like cancer, and to further evaluate its safety. Phase III trials include a large group of patients (often more than 1000) comparing a new treatment to standard treatment.

Synonyms

Phase 2 detoxification enzymes; Phase 2 drug-metabolizing enzymes; Phase 2 proteins

Definition

Phase 2 enzymes in principle are part of the cellular ►biotransformation machinery. Cellular biotransformation of ►xenobiotics and endobiotics, including ►carcinogen metabolism, may be divided into two sequential phases: phase 1 (oxidation, reduction and hydrolysis reactions) and phase 2 (conjugation reactions). Phase 2 enzymes traditionally refer to the enzymes catalyzing the conjugation reactions, such as ►glutathione *S*-transferase (GST), UDP-glucuronosyltransferase (►UGT), *N*-acetyltransferase (NAT) and ►sulfotransferase (SULT). However, the term has gradually become broader in scope as it has also been used by an increasing number of investigators for a number of enzymes that catalyze phase 1 reactions, such as epoxide hydrolase (►EH), heme oxygenase-1 (►HO-1), NAD(P)H:quinone oxidoreductase type 1 (►NQO1), and enzymes that are not directly involved in the biotransformation process, such as glutamate cysteine lygase (►GCL) which is critical in glutathione biosynthesis. The term "phase 2 proteins" is more inclusive, as it also refers to certain antioxidant proteins that have no known catalytic activities such as ►ferritin, which is the main intracellular iron storage protein. A major reason for this seemingly ambiguous classification is that many of these enzymes/proteins are often coordinately induced by a variety of chemical agents through the Keap1-Nrf2-ARE signaling pathway, as will be briefly described later, and that all of them play important roles in cytoprotection and cancer prevention. However, some "classic" phase 2 enzymes such as NAT and SULT are not known to be regulated by this signaling pathway. Examples of Keap1-Nrf2-ARE-regulated phase 2 genes include EH, ferritin, GST, GCL, HO-1, NQO1 and UGT.

Characteristics

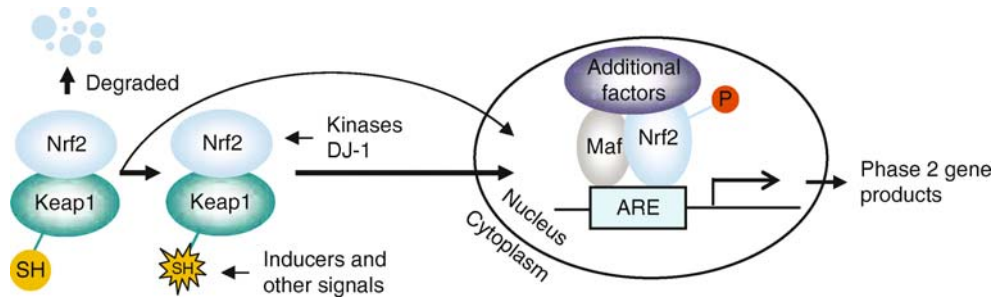
Many phase 2 enzymes/proteins have multiple isoforms. For example, GST is a super family of enzymes comprised of cytosolic (five known classes: alpha, mu, pi, theta and zeta), mitochondrial (kappa) and membrane-bound members; UGT is divided into two families: UGT1 and UGT2, each of which comprises a long list of isoforms; NAT has two isoforms (NAT1 and NAT2), and eleven human SULT isoforms are known; there are three known isoforms of heme oxygenase (HO-1, HO-2 and HO-3) and two isoforms of NAD(P)H:quinone oxidoreductase (NQO1 and NQO2). Moreover, a number of phase 2 genes are polymorphic in humans, and the genetic variants may yield either a null or sub-optimal phenotype. The best-known examples of genetic variants regarding this family of enzymes are GST mu1-null, GST theta1-null, NQO1-null, and NAT1/NAT2 slow acetylators.

Phase 2 enzymes are major ►detoxification enzymes and an important part of cellular defense against carcinogens, oxidants and other toxic chemicals. The cancer-preventive role of many phase 2 enzymes has been well documented. For example, epidemiological studies have shown that individuals deficient in a phase 2 enzyme (e.g. GST, NAT or NQO1) are at considerably higher risk of developing certain cancers; likewise, susceptibility to cancer increases in rodents if a phase 2 gene (e.g. GST or NQO1) is knocked out; moreover, forced over-expression of a phase 2 enzyme through gene transfection in cultured cells protects cells against carcinogen-induced DNA damage and/or cytotoxicity. However, it is also known, perhaps not surprising in view of their cytoprotective activities, that some phase 2 enzymes (e.g. GST pi-1) have been shown to contribute to drug resistance in cancer cells. Moreover, it has also been reported that catalysis of certain substrates by a phase 2 enzyme may actually result in bioactivation of the compounds. For example, several anticancer quinones (e.g. ►mitomycin C and streptonigrin) depend on NQO1 for bioactivation and anticancer activity.

Although the mechanisms by which each phase 2 enzyme prevents cancer are complex and not fully understood, it is clear that cellular protection offered by these enzymes as a group is versatile and far-reaching. For example, enzymes such as GST and UGT have low substrate specificities, each of which is capable of catalyzing the detoxification of a diverse group of carcinogenic chemicals; GCL is the major biosynthetic enzyme of GSH, which serves as an important cellular antioxidant and is also critical for the normal function of GST and other enzymes; NQO1 not only detoxifies carcinogenic quinones but also stabilizes tumor suppressor p53 and strengthens cellular antioxidant capacity. It is important to consider phase 2 enzymes as a group, because many of them not only are readily inducible but also are often coordinately induced in cells and tissues both in vitro and in vivo by chemical inducers. Many cancer chemopreventive agents (or ►chemoprotectants), including dietary ►phytochemicals (e.g. certain isothiocyanates and polyphenols), are inducers of these enzymes, and a number of phase 2 inducers (e.g. oltipraz and ►sulforaphane) when tested in animal models inhibited tumor development. It is now a widely held view that dietary or pharmacological induction of phase 2 enzymes is an important strategy for prevention of chemical carcinogenesis.

Regulation

While each individual phase 2 gene may potentially be subjected to regulation through multiple mechanisms, it is the Keap1-Nrf2-ARE signaling system (Fig. 1) that unifies many phase 2 genes and is the most relevant to cancer prevention. ►Nrf2, nuclear factor erythroid 2-related factor 2, is a transcription factor that is normally sequestered by its repressor ►Keap1, Kelch-like ECH-associated protein 1. Binding to Keap1 promotes proteasomal degradation of Nrf2. Dissociation of Nrf2



Phase 2 Enzymes. Figure 1 A brief scheme for the induction of phase 2 genes through the Keap1-Nrf2-ARE pathway. Binding of Keap1 to Nrf2 in the cytoplasm targets Nrf2 for proteasomal degradation, but some Keap1-Nrf2 complexes may translocate to the nucleus, where Nrf2 may be released. Disruption of the association of Keap1 with Nrf2 by phase 2 inducers or other stress signals, through interaction with critical Keap1 cysteine residues, Nrf2 phosphorylation by kinases, and Nrf2 stabilization by DJ-1, causes increased nuclear accumulation and ARE binding of Nrf2, leading to increased transcription of phase 2 genes and increased cellular protection.

from Keap1 allows the former to heterodimerize with partners such as small muscle aponeurotic fibrosarcoma (Maf) protein, bind to a *cis*-acting DNA regulatory element, and promote transcription of the downstream gene. The DNA regulatory element to which the Nrf2 hetrodimer binds and activates is termed the antioxidant response element (►ARE) or electrophile response element (►EpRE). This element was so named because it was initially discovered to respond to phenolic antioxidants but subsequently found to respond broadly to agents that contain an electrophilic center. One or more copies of the typical ARE sequence (5′TGACnnnGC-3′, where n represents any nucleotide) is known to exist in the 5′-flanking region of phase 2 genes including GCL (both catalytic and regulator subunits), several GST isozymes, HO-1, NQO1, and ferritin heavy subunit. A functional ARE may also operate in the following phase 2 genes: EH, ferritin light subunit and UGT (1A1, 1A6 and 1A10), as it was shown that Nrf2 deletion or silencing inhibited both basal and inducible response of EH and UGT genes and that the genes for both ferritin heavy and light subunit were induced by phase 2 inducer 1,2-dithiole-3-thione. However, to the knowledge of this author, there has been no report that Nrf2 may up regulate HO-2, HO-3, NAT1, NAT2, NQO2 or SULT isoforms. Interestingly, there seems to be a certain degree of degeneracy in the ARE sequence, as a recent study of mouse NQO1 gene showed that the ARE spans 24 bp and comprises 5′-GAGTCACAGTGAGTCGGCAAAATT-3′, where the underlined nucleotides are those with mutation resulting in a complete loss of its function.

While the traditional view about Nrf2 activation has been that Nrf2 is repressed by Keap1 in the cytoplasm and that inducers cause dissociation of the complex leading to Nrf2 nuclear translocation and ARE activation, more recent studies have revealed the presence of a cytoplasmic-nuclear shuttling mechanism of Keap1-Nrf2 complex and indicated that dissociation of the complex within the nucleus might contribute to Nrf2/ARE activation. Studies show that Nrf2 dissociation (activation) from Keap1 occurs upon alkylation or oxidation of critical cysteine residues on Keap1 by chemical activators or other signals. Two cysteine residues in mouse Keap1 (C273 and C288) were shown to be critical for the inducer-sensing function of Keap1 and for its Nrf2-repressing activity. Electrophilic inducers are believed to directly interact with these cysteine residues, causing conformational change in Keap1 and subsequent release of Nrf2. However, other studies show that modifying specific cysteines of Keap1 might be insufficient for Nrf2 activation, and additional mechanisms contribute to Nrf2 activation. It was shown that phosphorylation at Ser40 in Nrf2 by protein kinase C promoted Nrf2 dissociation from Keap1. Additional factors, including p160 family coactivators and cyclic AMP-responsive element binding protein/p300 factors, appear to bind to Nrf2-Maf-ARE complex and enhance transcription. Kinase such as mitogen activated protein kinases and phosphatidylinositol-3-kinase also were shown to play a role in Nrf2 activation, although detailed information is not yet available. Moreover, DJ-1/PAMK7, a cancer- and Parkinson's disease-associated protein was recently reported to stabilize Nrf2.

Phase II Metabolism

Definition

A conjugation reaction that links a endogenous moiety to a Phase I metabolite or polar functionality on an unmetabolized drug to facilitate its excretion.

►Lead Optimization

Phase 2 Proteins

Definition

Phase 2 Enzymes.

►Phase 2 Enzymes

Phenomics

Definition

Is the systematic and detailed collection, objective documentation and cataloguing of phenotypic data at many levels, including clinical, molecular and cellular phenotype.

►Personalized Cancer Medicine

Phenotype

Definition

The physical properties (e.g., eye color and height) of an organism or the detectable manifestation of a specific trait (e.g., disease and DNA repair), as distinguished from genotype (the genetic makeup of a cell, either of the entire cell or more commonly for a certain gene or a set of genes). The entire physical and biochemical constitution of an organism as determined both genetically and environmentally.

►Mutagen Sensitivity

Phenotype-Orientated Screens

Definition

A procedure in which molecules are systematically tested for their ability to produce or inhibit a biological process or characteristic of interest.

►Small Molecule Screens

Phenylalanine Mustard

Definition

►Melphalan.

Phenylalanine Nitrogen Mustard

Definition

►Melphalan.

Phenylaminopyrimidine

Definition

Chemical structure of ►imatinib and ►nilotinib.

Pheocromocytoma

Definition

Synonym: Pheocromocytoma; Is a rare tumor in the adrenal glands that causes excess secretion of catecholamines. This leads mainly to hypertension but can also lead to hyperglycemia and diabetes-like symptoms. Only about 1 in a 1000 people with hypertension have a pheochromocytoma

►Adrenomedullin

Philadelphia Chromosome

Definition

Refers to the chromosome 22 lacking approximately half of its long arm due to a reciprocal translocation between the long arms of chromosomes 9 and 22 [t(9;22)(q34;q11)], resulting in a chimeric gene (►BCR ABL1). The fusion protein product is a constitutive tyrosine kinase that alters signaling pathways that control the proliferation, survival, and self-renewal of hematopoietic stem cells. The Philadelphia chromosome is found in chronic myeloid leukemia (CML) cells in nearly every patient with this disease, and a subset of patients with acute lymphoblastic leukemia (ALL), where it connotes a worse prognosis.

►Chronic myeloid leukemia

Phlegm Dampness

Definition

Is a term in Chinese medicine. It refers to phlegm produced from the accumulation of turbid fluid retained in the body. Different from the concept of Western medicine, spleen represents a macroscopic concept of digestion, absorption, and nutrition metabolism in Chinese medicine. Phlegm dampness often results from the dysfunction of spleen in transporting and distributing nutrients and water, as well as the accumulation and stagnation of dampness due to deficient spleen. It is manifested as profuse frothy sputum, nausea, or fullness in the chest, cough with dyspnea, and plump tongue with slippery or greasy coat.

►Chinese versus Western Medicine

Phorbol Ester

Definition

Belongs to a class of tumor promoters that stimulate protein kinase C by acting as analogs of diacylglycerol. They can be used to stimulate T lymphocytes.

►TPA

Phorbol 12-Myristate 13-Acetate

Definition

PMA; synonym: 12-O-Tetradecanoylphorbol-13-acetate (TPA). A very potent tumor promoter and activator of protein kinase C.

►Protein Kinase C Family

Phosphatase and Tensin Homolog Deleted on Chromosome 10

Definition

PTEN; A tumor suppressor which acts as both a lipid and a protein phosphatase. PTEN gene is deleted or mutated in diverse human cancers including glioblastoma, endometrial, breast, and prostate cancers and dominantly inherited hamartoma syndromes such as Cowden and ►Bannayan–Riley–Ruvalcaba syndrome.

Phosphatase

Definition

Is an enzyme that removes a phosphate group from its substrate by hydrolyzing phosphoric acid monoesters into a phosphate ion and a molecule with a free hydroxyl group. This action is directly opposite to that of a ►kinase, which attach phosphate groups to their substrates by using energetic molecules like ATP. A common phosphatase in many organisms is alkaline phosphatase. Serine and threonine protein phosphates are stable under physiological conditions, so a phosphatase has to remove the phosphate to reverse the regulation. There are four known groups: PP1 (α, β, γ1, γ2), PP2A, PP2B (AKA calcineurin), PP2C, PP4, and PP5. The first three have sequence homology in the catalytic domain, but differ in substrate specificity. Ser/Thr-specific protein phosphatases are regulated by their location within the cell and by specific inhibitor proteins.

Phosphatidic Acid

Definition

An intracellular second messenger generated by the phospholipase D enzyme.

►Laminin Signaling

Phosphatidyl Inositol 3-Kinase

Definition

PI3k; PI3 Kinase; A kinase activated by a variety of receptor associated protein tyrosine kinases that phosphorylates inositol lipids in the plasma membrane.

Such phosphatidyl inositols can then serve as docking sites for proteins with pleckstrin homology domains.

►PI3k Signaling

Phosphatidylinositol-3,4,5-trisphosphate

Definition

Second messenger produced by the enzyme phosphoinositide-3 kinase through the addition of a phosphate group to the 3 position in the inositol ring of phosphatidylinositol-4,5-bisphosphate (PIP_2).

►Pentakisphosphate

Phosphatidylinositol 3-kinase

►PI3K Signaling

Phosphatidylinositol Lipids

Definition

A family of molecules present in cellular membranes. They contain a polar phosphate head group attached to an inositol sugar, a glycerol backbone and two hydrophobic fatty acid tails. The conversion between phosphatidylinositol lipids forms an important step in several signaling cascades.

►Pentakisphosphate
►Inositol Lipids

Phosphatidylserine

Definition

An abundant acidic phospholipid at cell membranes, capable of activating ►protein kinase C. Phosphatidylserine transfer to the external surface of the plasma membrane is a key signal of apoptotic cell recognition for phagocytes.

►Protein Kinase C Family

Phosphodiesterase

Definition

Group of enzymes which hydrolyze the phosphodiester bond in cyclic nucleotides like cAMP and cGMP to form AMP or GMP. Main inactivation mechanism for cyclic nucleotides involved in signal transduction

►G-Proteins

Phosphoinositide-Dependent Kinase-1

Definition

PDK-1; Enzyme possessing a ►pleckstrin homology domain able to target it to intracellular domains rich in PIP_3 where it can activate Akt by phosphorylating it on a threonine amino acid residue. By its activation of ►Akt, PDK-1 can be involved in carcinogenesis.

►Pentakisphosphate

Phosphoinositide 3-kinase

►PI3K Signaling

Phosphoinositides

Definition

Are glycerophospholipids containing a phosphorylated inositol polyalcohol chain at the sn-3 position of glycerol. They are source either of inositoltrisphosphate and diacylglycerol upon hydrolysis by phospholipase C or phosphoinositide-3,4,5-trisphosphate (PIP3) upon phosphorylation by PI3kinase.

►Lipid Mediators

Phospholipase

Definition

PL; Is an enzyme that converts phospholipids into fatty acids and lysophospholipids. There are four major families, termed A1, A2, C and D that specifically hydrolyse the ester linkage at a defined position of glycerol; PLA1 clives the chain at the sn-1, PLA2 at the sn-2 and PLC (before phosphate), PLD (after phosphate) at the sn-3 position of glycerol. Lysophospholipase D, called autotaxin specifically cleaves the phosphocholine moiety of lysophosphatidylcholine leading to lysophospatidic acid (LPA).

PLA2 cleaves arachidonic acid (also called arachidonate) a substrate for eicosanoids. PLC cleaves inositolbisphosphate from phosphatidylinositol and generates inositoltrisphosphate (IP3), instrumental in Ca^{2+} mobilization and diacylglycerol (DAG) involved in selective activation of isoforms of ►protein kinase C (PKC).

►Lipid Mediators
►Phospholipase A2

Phospholipase A1

Definition

PLA1; Is an enzyme that hydrolyzes the *sn*-1 fatty acids from phospholipids resulting in the formation of 2-acyl-lysophospholipids.

►Lysophosphatidylcholine

Phospholipase A_2

Qihan Dong
Central Clinical School, The University of Sydney, Department of Endocrinology and Sydney Cancer Centre, Royal Prince Alfred Hospital, NSW, Australia

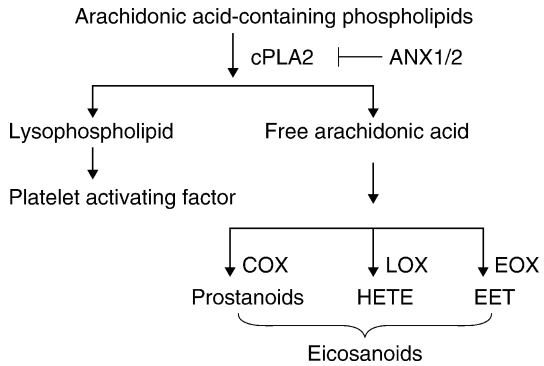
Definition

Phospholipase A_2 (PLA_2) enzymes are a family of proteins and to date at least 20 members have been identified in mammals. The family can be classified into four classes on the basis of their nucleotide and amino acid sequence homology. First, there are at present ten secreted phospholipase A_2 enzymes ($sPLA_2$-IB, -IIA, -IIC, -IID, -IIE, -IIF, -III, -V, -X, and -XII), which are of low molecular weight (13–18 kDa) with a catalytic histidine in their active site and a requirement for calcium for enzyme activity. Second, there are three characterized human cytosolic PLA_2 enzymes ($cPLA_2$-α, -β, and -γ, also known as Group IVA, IVB, and IVC PLA_2) that use a catalytic serine in their active site. $cPLA_2$-α and -β contain a C2 calcium binding domain and enzyme activity is calcium-dependent while $cPLA_2$-γ lacks this domain and is thus a calcium-independent PLA_2. Recently, a comprehensive homology search against the murine genome and EST databases using conserved sequences of $cPLA_2$ as the query, led to the identification of $cPLA_2$-δ, $cPLA_2$-ε, and $cPLA_2$-ξ (also known as Group IVD, IVE, and IVF PLA_2), all of which are calcium-dependent enzymes. Third, three calcium-independent cytosolic PLA_2 enzymes ($iPLA_2$-α, -β, and -γ also known as Group VIA-1, VIA-2, and VIB) with an active-site serine, and fourth, four platelet-activating factor acetylhydrolase (PAF-AH) enzymes (Group VIIA, VIIB, VIIIA, and VIIIB) also involve a catalytic serine. Many of the different forms of PLA_2 are differentially expressed in a tissue-, species-, and/or genotype-specific manner.

Characteristics

Function

Much research has focused on $cPLA_2$-α because of its central role in the initiation of arachidonic acid metabolism. $cPLA_2$-α enzymes catalyze the hydrolysis of the *sn*-2 position of membrane glycerophospholipids, leading to the production of free fatty acids and lysophospholipids (Fig. 1). If the esterified fatty acid is arachidonic acid (AA), this is converted to ►prostaglandins (PGs) by ►cyclooxygenases (COX), hydroxyeicosatetraenoic acids (HETEs) by lipoxygenases (LOX), or epoxyeicosatrienoic acids (EETs)



Phospholipase A_2. Figure 1 Diagram depicting the role of cytosolic $cPLA_2$-α.

P

by P450-dependent epoxygenase (EOX). By binding to ►G-protein-coupled receptors, these eicosanoids are central mediators of ►inflammation and could be mitogenic. The other reaction products of $cPLA_2$ action, lysophospholipids, are also biologically active via binding to ►G-protein-coupled receptors and, in some settings, are the precursors of platelet-activating factor.

A direct role for $sPLA_2$ in supplying arachidonic acid to downstream enzymes for eicosanoid synthesis has now been demonstrated in vivo. $sPLA_2$ enzymes have been implicated in a number of biological processes, such as ►inflammation and host defence. $sPLA_2$-IIA found in inflammatory fluids, tissue exudates, or serum, and is believed to propagate inflammation in response to proinflammatory cytokines including interleukin-1, ►interleukin-6, and tumor necrosis factor. A gene deletion experiment in mice shows that knockout of the *sPLA*$_2$-V gene reduces eicosanoid production in response to inflammatory stimuli. There are also reports describing the necessity of *sPLA*$_2$-V in eicosanoid production in murine mast cells.

Biological roles for the other $cPLA_2$ enzymes including the newly identified $cPLA_2$-δ, $cPLA_2$-ε, and $cPLA_2$-ξ have not yet been clearly defined. The Ca^{2+}-independent iPLA2 appears to play a role in phospholipid remodeling, regulation of store-operated calcium channels, ►apoptosis, and release of arachidonic acid.

Regulation

For cPLA2-α, Ca^{2+} binding to the N-terminal C2 domain is required for translocation of the enzyme from the cytosol to the endoplasmic reticulum, golgi apparatus, and perinuclear membranes – where $cPLA_2$-α associates with the preferred substrate, arachidonoyl phospholipids, resulting in eicosanoid biosynthesis, as well as brings close proximity to eicosanoid-producing enzymes such as COX and LOX. $cPLA_2$-α activity is also regulated by phosphorylation on serine residues with protein kinases including ►MAPK. The main site of cPLA2 phosphorylation is Ser-505 and replacement of Ser-505 with Ala abolishes agonist-stimulated arachidonate release.

Annexin 1 (ANX1, also known as lipocortin I and calpactin II) and annexin 2 (ANX2, also known as lipocortin II and calpactin I) are naturally inhibitors of $cPLA_2$-αin various cell types. There are 13 members in annexin family and inhibition of $cPLA_2$-α appears to be specific and not a general phenomenon for all ANXs. Although the exact mechanism for the inhibition of $cPLA_2$ is not clear, it is unlikely due to competition with cPLA2 for substrate. Some in vitro studies have shown that secreted phospholipase A_2 can also be inhibited by annexins due to substrate sequestration by annexins.

A homeodomain-interacting protein kinase-2 (HIPK2), also a corepressor for homeodomain transcriptional factors, is capable to retrain $cPLA_2$-α gene expression through interacting with histone deacetylase-1.

Some studies suggest that $sPLA_2$ can mediate indirect activation of $cPLA_2$-α via mobilization of calcium and/or ►MAP kinase-mediated phosphorylation. There are two possible mechanisms underlying this mediation. It is possible that $sPLA_2$ binds to the external cell surface resulting in the release of fatty acid and lysophospholipid. Arachidonic acid released in this manner will be metabolized to HETE and/or PGE_2. These metabolites and/or lysophospholipid, may in turn activate $cPLA_2$-α by mobilization of calcium intracellularly and/or by activation of the ►MAP kinase pathway. Alternatively, $sPLA_2$ could exert its action on $cPLA_2$ by binding to heparan sulphate proteoglycans (e.g., glypican) leading to internalization.

Cancer Relevance

Eicosanoid pathway is activated in many types of cancers, and contributes to disease progression by promoting cell proliferation, ►motility, ►invasion, and ►angiogenesis. As the predominant source of intracellular AA for eicosanoid synthesis, $cPLA_2$-α is induced and/or activated in a range of human tumor types, such as colon and lungs. In ►prostate cancer, ANX1 and ANX2, the negative regulator of $cPLA_2$-α, are lost and secreted PLA_2-IIA, the potential positive regulators of $cPLA_2$-α, is increased in prostate cancer. Thus, in addition to ►COX and LOX enzymes, PLA_2 enzymes are dysregulated and could contribute to the pathogenesis of cancer. Considering the fact that (i) COX and LOX inhibitors suppress the production of PGs or HETEs only, (ii) platelet activating factors produced from the remaining lysophosphoplipid after AA cleavage by $cPLA_2$-α are oncogenic in the breast and colon, and can stimulate angiogenesis and ►NF-kB, and (iii) blockade of PLA_2 enzymes is expected to block AA supply to both COX and LOX pathways as well as the production of platelet-activating factors, PLA2s represent potential targets for the treatment of cancer.

Phospholipase C

Definition

PLC; Ubiquitous enzyme which catalyses the cleavage of phosphatidyl inositol 4,5-bisphosphate in inositol 1,4,5 triphosphate (IP_3) and diacylglycerol (DAG). IP_3 releases intracellularly stored Ca^{2+} resulting in an increase in the free cytosolic Ca^{2+} concentration, while DAG regulates various effectors like some isoforms of protein kinase C. While β-isoform of phospholipase C are regulated by G-proteins, γ-isoforms are primarily regulated through receptor tyrosine kinases.

►G-Proteins

Phospholipase D

Definition

PLD; Represents a family of enzymes responsible for the hydrolysis of phosphatidylcholine (PC) into phosphatidic acid (PA) and choline. It is regulated by growth factors and cytokines receptors, as well as GTPases of the Ras superfamily, mostly Rho, Ral and Arf proteins. At least two members in mammalians have been identified that are involved in secretion and cell growth control. At least PLD1 has been shown to have oncogenic potential.

►GTPase

Phospholipid Bilayer

Definition

Plasma membrane.

Phospholipids

Definition

Are a major component of all biological membranes and are a class of lipids contaning: fatty acids, a negatively-charged phosphate group, nitrogen containing alcohol and a backbone. Phospholipids with a glycerol backbone are known as glycerophospholipids or phosphoglycerides. The unique phospholipid with a sphingosine backbone is named sphingomyelin. Lipids containing one or more phosphate groups, particularly those derived from either glycerol or sphingosine (sphingolipids). They are polar lipids that are of great importance for the structure and function of cell membranes and are the most abundant of membrane lipids.

►Fatty Acid Synthase
►Lipid Mediators

Phosphoprotein Enriched in Diabetes/ Phosphoprotein Enriched in Astrocytes-15kDa

Definition

PED/PEA-15 is a protein of 131 amino acids and 15 kDa that consists of one N-terminal death-effector-domain (DED) and two phosphorylation sites for PKC (Ser 104) and calcium calmodulin kinase II (Ser 116). PED/PEA-15 inhibits apoptosis by interfering with the recruitment of caspase-8 to activated death receptors and also promotes MAPK signaling pathways.PED/PEA-15

►Caspase-8

Phosphorylation

Definition

Is the addition of a phosphate (PO_4) group to a protein molecule or a small molecule. The process of phosphorylating a compound (e.g., chemical, protein) either by a reaction with an inorganic phosphate or by transferring a phosphate from another organic phosphate. This process can be used to regulate biological processes in cells. Another way to define it would be the introduction of a phosphate group into an organic molecule. In eukaryotes, protein phosphorylation is probably the most important regulatory event. Many enzymes and receptors are switched "on" or "off" by

phosphorylation and dephosphorylation. Phosphorylation is catalyzed by various specific protein kinases, whereas phosphatases *de*phosphorylate. Phosphorylation is observed on serine, threonine, tyrosine and histidine residues.

Photoactivation

Definition

A chemical process that is induced by a photosenstizer upon light irradiation.

►Hypericin

Photocarcinogenesis

Farrukh Afaq
Department of Dermatology, University of Wisconsin, Medical Sciences Center, Madison, WI, USA

Synonyms

Solar light induced cancer; Ultraviolet radiation induced cancer; Sun light induced cancer

Definition

Photocarcinogenesis is a complex multistage process of tumor growth and development involving three distinct stages exemplified by initiation, promotion and progression.

Characteristics

Ultraviolet Radiation and Skin Cancer

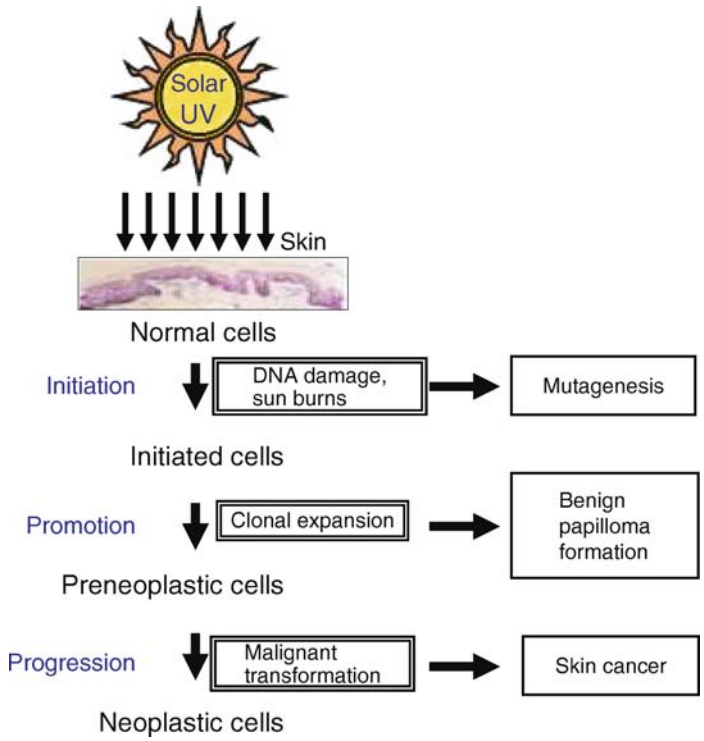
Skin, the largest body organ, situated at the interface between the body and its environment, directly suffers from the deleterious effects of xenobiotics and genotoxic agents including solar ultraviolet (UV) radiation. Solar UV radiation has been implicated as the main cause for skin cancer. The prevalence of UV-induced skin cancer is rapidly increasing, accounting for more than 40% of all human cancers in the United States, with about 1.2 million new cases being diagnosed each year.

Solar UV radiation is divided into three regions depending on wavelength, short wave UVC (200–280 nm), mid wave UVB (280–320 nm) and long wave UVA (320–400 nm). UVC has the highest energy and, hence, is the most biologically damaging region of UV radiation. However, it is effectively blocked from reaching the Earth's surface by the stratospheric ozone layer and therefore its role in human pathogenesis is minimal. It is unknown how its physiological significance will change with depletion of the ozone layer and continuous influx of UVR at the earth's surface. The only wavelengths that reach the earth surface are comprised of UVB (1–10%) and UVA (90–99%). Currently UVB and to a much lesser extent, UVA radiation are considered to be responsible for inducing various skin disorders including skin cancer. UVA radiation constitutes the majority of solar radiation at the earth's surface but only accounts for 10% of the carcinogenic dose of sunlight. Conversely, UVB radiation is a minor but active constituent of solar light and has direct and indirect adverse biological effects on the skin. In UV skin tumorigenesis approximately 90% of the carcinogenic dose of sunlight is derived from UVB.

Exposure to UVB (mid wave) plays a major role in the development of non-melanoma skin cancers (NMSCs) comprising of basal cell carcinomas (BCCs) and squamous cell carcinomas (SCCs), the most frequently diagnosed cutaneous malignancies and account for approximately 80% and 16% of all skin cancers, respectively. Both BCCs and SCCs are derived from the basal layer of the epidermis of the skin. SCCs are invasive and more than 10% of these cancers metastasize. On the other hand, BCCs do not metastasize but can be locally invasive and destructive. Malignant melanoma, the deadliest form of skin cancer has reached epidemic levels and continues to increase at the rate of 4% annually. In the year 2006, 62,190 new cases of melanoma were diagnosed, resulting in 7,910 deaths while 2,800 deaths were expected to occur from non-epithelial skin cancers.

Ultraviolet Radiation-induced Skin Cancer or Photocarcinogenesis

Solar UV radiation-induced skin cancer or photocarcinogenesis is a complex multistage phenomenon involving three distinct stages exemplified by initiation, promotion and progression (Fig. 1). Each of these stages is mediated via alterations in various cellular, biochemical, and molecular changes. Initiation, the first step in the carcinogenesis process is essentially an irreversible step in which genetic alterations occur in genes that ultimately leads to DNA mutation in normal cells. Tumor promotion is the essential process in cancer development involving clonal expansion of initiated cells giving rise to premalignant and then to



Photocarcinogenesis. Figure 1 Stage of solar UV radiation induced skin carcinogenesis.

malignant lesions, essentially by alterations in signal transduction pathways. Tumor progression involves the conversion of premalignant and malignant lesions into an invasive and potentially metastatic malignant tumor. To name a few, the processes of skin cancer development involve stimulation of DNA synthesis, DNA damage and proliferation, ►inflammation, ►immunosuppression, epidermal hyperplasia, cell cycle dysregulation, depletion of antioxidant defenses, impairment of signal transduction pathways, increase in prostaglandin synthesis, and induction of ornithine decarboxylase and cyclooxygenase.

Oxidative Stress and Photocarcinogenesis

The major role of skin is to afford a protective covering at the crucial interface between the body and its environment. The skin directly suffers from the deleterious effects of UV radiation and exogenous chemicals. Environmental factors may stimulate the skin responsive system through their oxidizing properties. UV radiation jeopardizes the integrity of the skin that is critical for cellular homeostasis. UV exposure results in an increased generation of reactive oxygen species (ROS) that overwhelms the antioxidant defense mechanisms of the cells. This condition of prooxidant/antioxidant disequilibrium is defined as "►*oxidative stress*."

The epidermis is composed mainly of keratinocytes, which are rich in ROS detoxifying enzymes such as superoxide dismutase, catalase, thioredoxin reductase and glutathione peroxidase, and in low-molecular-mass antioxidant molecules such as tocopherol, glutathione and ascorbic acid, and thus provides some natural protection against ROS. Skin spontaneously responds to increased ROS levels; however the capacity of these detoxifying enzymes is not unlimited and can be overwhelmed by excessive generation of ROS. Studies have shown that UV radiation to the skin results in the formation of ROS and can act both as an initiator and promoter of tumors by damaging critical cellular molecules such as proteins, lipids and DNA, and by acting as a stimulator or inducer of cell-signaling molecules. Studies have demonstrated that oxidative stress elicited by UV irradiation activates redox-sensitive transcription factors, including nuclear factor kappa B (NF-κB), mitogen activated protein kinases (MAPK), and members of the activator protein-1 (AP-1) complex, such as c-Fos and c-Jun. The induction of oxidative stress and imbalance of antioxidant defense system have been associated with the onset of several disease states including inflammation, rheumatoid arthritis, immunosuppression, photoaging and skin cancer. Accumulating body of evidence suggests that ROS are involved in all three stages of

photocarcinogenesis process. The cause of these events is contingent upon the UV dose, time of exposure and the wavelength.

DNA Damage and Photocarcinogenesis

DNA contains purine and pyrimidine bases and their absorption maxima lies between 230 and 300 nm. Therefore, DNA is a major UVB-absorbing cellular chromophore in the skin. The most common and frequent photoproducts that are formed in the skin after UVB exposure are cyclobutane pyrimidine dimmers (CPDs) and pyrimidine (6–4) pyrimidone photodimers. UVB irradiation to the skin also results in photoisomerization of trans- to cis-urocanic acid, DNA strand break, DNA crosslinks and DNA-protein crosslinks. Formation of CPDs, if not repaired through nucleotide excision repair, replication leads to signature mutations. These mutations are in the form of C to T and CC to TT transition and have been observed in tumor suppressor gene p53 in large population of human SCCs, BCCs and actinic keratoses. Studies suggest that most of the UVB-induced CPDs are found in the epidermis but a significant amount is also found in the dermis. Pharmacokinetic studies reveal that UVB-induced DNA damage in the form CPDs in human skin declines over the period of time and this may occur because cells with damage DNA undergo apoptosis or has been repaired. CPDs are primarily produced in keratinocytes and Langerhans cells following UVB exposure, and also in dendritic cells in lymph nodes draining the irradiated sites. CPDs have been implicated in UVB-induced immunosuppression and initiation of photocarcinogenesis.

p53 and Photocarcinogenesis

Apoptosis is regarded as an ideal way of elimination of damaged cells. It is now well established that uncontrolled cellular growth that may be a result of defects in cell cycle and apoptotic machinery, is responsible for the development of skin cancer. Therefore, to maintain the integrity of the cells after DNA damage, several cellular responses are activated that include mechanisms for removal of DNA damage, delay in cell cycle and DNA repair or apoptosis by transcriptional activation of *p53*-related genes. The *p53* tumor suppressor gene plays a crucial role in protecting cells from DNA-damage as a consequence of UVB exposure. It has also been suggested that p53 can directly or indirect regulate UVB-induced, transcription-coupled DNA repair. An important function of p53 protein is to act as a transcription factor by binding to a p53-specific DNA consensus sequence in responsive genes. The increased level of p53 protein after DNA damage is associated with enhanced apoptosis, presumably in cells that are too damaged for adequate DNA repair. High doses of UVB have been shown to be associated with the formation of sunburn cells, initiated via a p53-dependent pathway, and cause the removal of damaged cells, thus minimizing the risk of skin cancer. Lower doses of UVB allow cell survival and repair of genetic damage, but the cell survival response is a state of local and systemic immunosuppression, which in itself may be deleterious and contribute to the process of formation of skin cancers.

Mutations in the p53 gene have been detected in 50% of all human cancers and in almost all skin carcinomas. Studies have shown that early responses in the skin of mice after an acute UVB exposure included an increased number of cells expressing both p21 and p53. Chronic UVB exposure to these mice resulted in modulation of the expression of cell cycle markers, with increased expression of p53 and cyclin D_1 correlating with the development of skin tumors. It has been suggested that increased expression of cyclin D_1 in SCCs contributes to the tumor phenotype even in the presence of elevated p53 levels. Studies have also demonstrated that elevated cyclin D_1 expression occurs in squamous carcinoma and papillomas, while decreased expression leads to reduce skin carcinogenesis. SCCs developed in SKH-1 mice after chronic exposure to UVB showed increase in cyclin D_1 protein levels.

Studies have shown that overexpression of $P16^{INK4A}$ reduces the proliferation of human and murine squamous epithelial cells. Transcriptional upregulation of $p16^{INK4A}$ has also been shown in melanoma cells following UVB irradiation. Induction of $P16^{INK4A}$ in human keratinocytes was reported in human epidermis and in cultured keratinocytes after UVB irradiation. UV-induced mutations of $p16^{INK4A}$ and $p14^{ARF}$ genes have been reported in epithelial skin tumors from sporadic patients and from Xeroderma Pigmentosum patients who suffer from strong UV hypersensitivity. There is considerable evidence that p53, $p16^{INK4A}$, $p21^{waf1/cip1}$ and $p14^{ARF}$ proteins are part of parallel pathways that control cell cycle and responses to UV-DNA damage.

Inflammation, Immunosuppresion and Photocarcinogenesis

Skin inflammation that includes the release of growth factors, proinflammatory cytokines, erythema, edema, hyperplasia, infiltration of inflammatory cells and ROS production in response to UVB plays an important role in skin cancer development. Chronic UVB-mediated inflammation causes the induction of the COX-2 enzyme resulting in increased prostaglandin E_2 (PGE_2) levels in the skin. Increased PGE2 levels have been associated with skin cancer development and spread. Increased myeloperoxidase activity is associated with neutrophils infiltration that plays an important role in inflammation.

UVB exposure initiates a cascade of events that modify gene expression profiles and alters the immune system of the skin. There is ample experimental and clinical evidence to suggest that immune factors contribute to the pathogenesis of solar UV-induced skin cancer. Chronically immunosuppressed patients living in regions of intense sun exposure experience and exceptionally high rate of skin cancer. Exposure to UVB radiation results in inhibition of contact hypersensitivity (CHS) induced by contact allergens that is a prototypic T-cell mediated immune response. UVB-induced infiltration of $CD11b^+$ cells (cell surface markers of macrophages and neutrophils) upregulates interleukin (IL)-10 and downregulates IL-12 in the skin and/or draining lymph nodes. IL-10 possesses immunosuppressive activity, whereas IL-12 is immunoregulatory cytokine. In UVB exposed skin, IL-10 is primarily secreted by activated macrophage and inhibits antigen presentation, thereby down regulating CHS responses. IL-12 by stimulating the production of interferon-γ regulates the growth of T-cells and enhances T helper cell type 1 functions.

Defects in Signaling Pathways and Photocarcinogenesis

UVB radiation to mammalian skin results in alterations in a variety of signaling pathways that are responsible for maintaining a balance between cell proliferation and death. NF-κB is a ubiquitously expressed transcription factor that belongs to the Rel family and regulates genes involved in inflammation, immunity, cell cycle progression, tumor promotion, angiogenesis and metastasis. NF-κB is present in the cytosol as a heterodimer usually consisting of its p50 and p65 subunits bound to its inhibitory proteins IκB. UVB activates IκB kinases (IKK) either directly or indirectly that are central to NF-κB activation. The activated IKK phosphorylates the inhibitory κB proteins on either serine residue 32 or 36 of IκBα. The released NF-κB then moves from the cytoplasm to the nucleus and activates transcription of target genes. Phosphorylation and activation of IκB kinase is controlled by an NF-κB-inducing kinase.

MAPK encompasses a large number of serine/threonine kinases involved in regulating a wide array of cellular processes including proliferation, differentiation, stress adaptation, and apoptosis. The MAPKs are divided into three multimember subfamilies: the extracellular signal-regulated kinases (ERK), the c-Jun N-terminal kinases (JNK), and the p38 kinases and are activated in response to oxidant injury and therefore could potentially contribute to influence cell survival. Studies have shown that UVB activates ERK1/2 and p38 signaling pathways via ROS generation. Low-dose UVB irradiation of normal human skin induces rapid and reversible phosphorylation of JNK and p38. Studies have demonstrated that both p38 and ERK were required for UVB induced c-*fos* expression, a member of the AP-1 transcription factor complex. AP-1 transcription factor is a protein dimer that consists of either heterodimers between *fos* and *jun* family gene products or homodimers of *jun* family gene products. There are three Jun proteins (c-Jun, Jun B and Jun D) and four Fos proteins (c-Fos, Fos B, Fra-1 and Fra-2). There is growing evidence that the AP-1 family of proteins is involved in cell proliferation and survival by regulating the expression and function of a number of cell cycle regulatory proteins. Sublethal doses of UVB produce strong induction of c-jun and c-fos transcripts in primary human keratinocytes. Studies have demonstrated that both p38 and ERK are required for UVB induced c-*fos* expression. Inhibition of both p38 and ERK simultaneously completely abrogated UVB induced c-*fos* transcription and down regulated basal transcription of the c-*fos* gene.

Conclusions and Recommendations

In recent year there is a significant increase in the incidence of skin cancer due to greater amount of UV radiation reaching the surface of the earth because of depletion of ozone layer, out door recreational activities and extensive use of sun tanning devices for cosmetic purposes. For primary prevention of photodamage and cutaneous disease, education about the harmful effects of UV radiation present in the sunlight, the need to avoid its excessive exposure by wearing protective clothing and the use of sunscreen has been persistently emphasized, but for many reasons these primary prevention approaches have had limited success. Therefore, additional efforts are needed to prevent skin cancers that result as a consequence of UVB exposure. UVB radiation to mammalian skin is known to alter cellular function via DNA damage, oxidative stress, p53 mutation, generation of ROS, inflammation, immunosuppression and skin cancer. Many signaling molecules and pathways have been found to play a role in UVB induced skin damages.

Accumulating data consistently support the view that a wide variety of botanical agents (such as green tea polyhenols, resveratrol, pomegranate, curcumin, genistein, apigenin and silymarin) possess substantial anti-photocarcinogenic and anti-mutagenic activities because of their antioxidant and anti-inflammatory properties. The use of these botanical agents alone or in the form of a formulation could be developed for chemoprevention. The concept of chemoprevention is to control the occurrence of cancer by slowing, blocking, or reversing the development of the disease by the administration of naturally occurring or synthetic compounds. One of the excitements of chemoprevention is that agents can be targeted for intervention at

the initiation, promotion, or progression stage of the multistage photocarcinogenesis process. Since multiple pathways are involved in photocarcinogenic response, a mixture of several botanical agents working through different mechanisms could be an effective strategy. Skin care products supplemented with botanicals, in conjunction with the use of sunscreens and educational efforts may be an effective approach for reducing UVB-generated ROS-mediated photodamage, inflammatory responses, immunosuppression and skin cancer in humans.

Photochemical Reaction Type-I

Definition

Of an activated photosensitizer after intersystem crossing to the triplet state. The photosensitizer transfers electrons to a target molecule, often molecular oxygen. Photochemical reactions type-I and type-II cause the production of reactive oxygen (ROS), the cytotoxic product employed in photodynamic therapy for destruction of tumor cells.

►Photodynamic Therapy

Photochemical Reaction Type-II

Definition

Of an activated photosensitizer after intersystem crossing to the triplet state. The photosensitizer transfers energy to triplet oxygen, which is activated to the reactive singlet state. Photochemical reactions type-I and type-II cause the production of reactive oxygen (ROS), the cytotoxic product employed in photodynamic therapy for destruction of tumor cells.

Photochemoprevention

Anne M. VanBuskirk
Medical Affairs Department, TAP Pharmaceutical Products, Inc. Lake Forest, IL, USA

Definition

"Photochemoprevention" has 2 very different meanings. The term was first coined in 2001 to describe ►chemoprevention of skin damage, including skin ►carcinogenesis (►Photocarcinogenesis), due to ►ultraviolet (UV) light (►Solar Ultraviolet light, ►UV radiation). A second use of the word "photo-chemoprevention," as defined in 2003, is to refer to the combination therapy of ►pulsed dye laser (PDL) to inhibit ►angiogenesis and chemoprevention to block both proliferation of cancer cells and tumor revascularization (►vascular targeting agents in cancer). The comments below will describe the term "photochemoprevention" as originally used.

Characteristics

Photochemoprevention can refer to the use of any chemopreventive agent, either ingested or topically applied, to block the damaging effects of UV light. UV light, in particular UVB light, is directly responsible for much of the damage leading to skin cancer development, especially basal cell (►Basal Cell Carcinoma) and ►squamous cell carcinomas, both of which are considered to be non-melanoma skin cancers. Preventive agents block the action of UV light in one or more ways, including (i) acting as a sunscreen, (ii) acting as an anti-oxidant, and/or (iii) inhibiting signaling and ►signal transduction pathways activated by UVB light. Through these activities, chemopreventive agents can prevent or slow the emergence of mutated cells (►Repair of DNA) and their ►progression to malignant tumors. Several targets for chemopreventive agents have been identified, including inhibition of: (i) polyamine or ►prostaglandin synthesis, (ii) oxidation (►Oxidative DNA damage), (iii) specific retinoid receptors (►Retinoid Receptor crosstalk in Cancer), and (iv) components of the ►NFkB (Nuclear Factor *f* ÛB), ►Ras (►Rat Sarcoma) (►RAS, ►RAS Activation) and ►MAP kinase signaling pathways.

Although photochemoprevention can refer to the use of any agent to prevent, ameliorate or repair

►photodamage associated with skin cancer, it has generally come to mean the use of natural products, especially botanicals, as skin cancer chemopreventive agents. There are numerous reports of natural products reducing UV damage and preventing skin carcinogenesis. A few of the commonly studied natural products are green tea (►Epogallocatechin), grapes (►Grape Seed Extract), berries and brown algae (►Polyphenols and Cancer). The majority of these entities have both sunscreen and anti-oxidant properties, depending on how they are used (►Phytochemicals and Cancer Prevention).

Photodynamic laser therapy; Photodynamic tumor therapy

Definition

Photodynamic Therapy (PDT) uses the action of visible, low energetic light on a ►photosensitizer to activate its destructive potential in a target tissue. PDT is a selective treatment modality since the photosensitizer shows preferential accumulation in target (e.g., tumor) cells and the light application can be restricted to the target area. By light activation the photosensitizer forms cytotoxic compounds, mainly ►reactive oxygen species (ROS), destroying the target. The emission of ►fluorescence light is employed in ►Fluorescence Diagnosis for tumor diagnosis. PDT is applied for malignant and several nonmalignant diseases.

Characteristics

Historical Perspective

Photodynamic effects have been known for a long time from substances enhancing the healing effect of sunlight. It lasted until 1904 when the term "photodynamic" was used for light-induced cytotoxic action and fluorescence of a photosensitizer. Modern PDT started in the 1970s with the investigation and usage of ►hematoporphyrin derivative (HPD) as a photosensitizer. ►Photofrin (a HPD) became the first drug approved for clinical oncologic treatment in 1993. In recent years, also nononcologic diseases such as bacterial or fungal infections or nonmalignant skin diseases became a potential application of PDT. The following sections refer to PDT as a tumor therapy, although the basics also apply to the nononcologic indications.

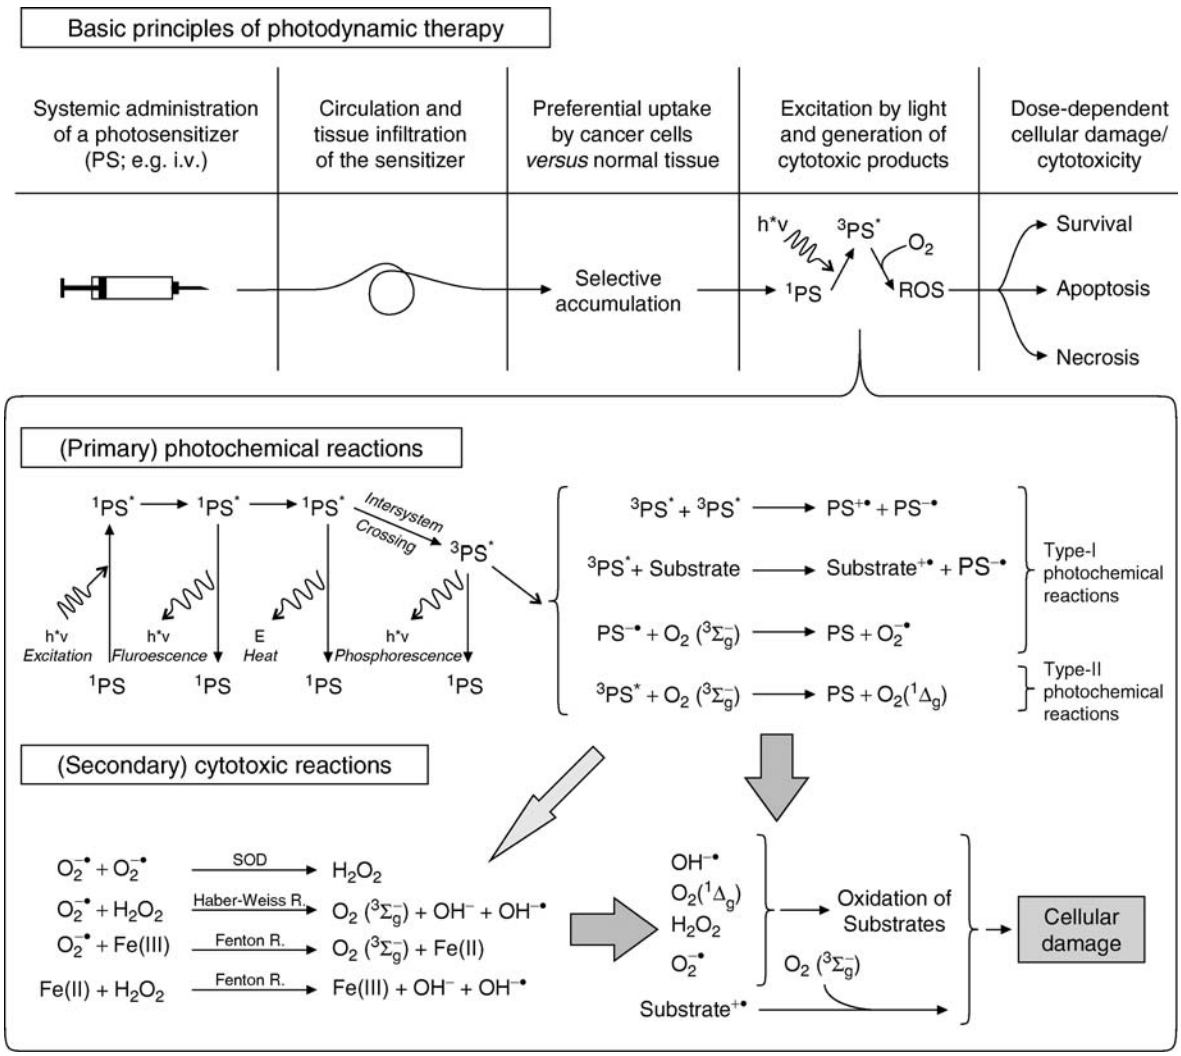
Principle of PDT

The principle of PDT is a two-step procedure with accumulation of a nontoxic photosensitizer in a target and activation of the molecule by harmless visible irradiation according to the photosensitizer's absorption spectrum. The photosensitizer is excited by the light from its electronic ground state, S_0, to the first excited

state (referred to as singlet state), S_1. This is followed by fluorescence emission, heat dissipation or a radiation-free conversion to the electronic triplet state, T_1. The triplet state is relatively long lasting (about 10^{-3} s) and allows the excited photosensitizer to interact with surrounding molecules (molecular oxygen or cellular constituents) and transfer energy or electrons, resulting in generation of cytotoxic products. Reactions involving transfer of electrons or energy are referred to as ►photochemical reactions type-I or ►photochemical reactions type-II, respectively (see Fig. 1).

Available Photosensitizers

An ideal photosensitizer for PDT should (i) be nontoxic in the absence of light, (ii) have a high quantum efficiency (i.e., a high efficiency in absorbing light energy and transferring it to other molecules), (iii) be able to absorb light above 600 nm for deep penetration



Photodynamic Therapy. Figure 1 Basic Principle of Photodynamic Therapy. Following administration the ►photosensitizer (PS) accumulates preferentially in tumor tissue and causes cellular damage and cell death subsequent to irradiation with light of the appropriate wavelength (h*v). Excitation of the photosensitizer from its ground state (^{1}PS) to its first activated singlet state (^{1}PS*) is followed by either ►fluorescence emission or a transition into the activated triplet state of the photosensitizer (^{3}PS*). ►Photochemical reaction type-I of ^{3}PS* with other photosensitizer molecules, substrates or molecular oxygen $\left(O_2\left(^3\Sigma_g^-\right)\right)$ via hydrogen atom abstraction or electron transfer or ►photochemical reaction type-II with oxygen via energy transfer yields radical molecules or – following further (secondary) reactions – various types of ►reactive oxygen species (ROS). These reactive species oxidate a number of cellular substrates causing overall oxidative stress and damage. H_2O_2, ►hydrogen peroxide; SOD, ►superoxide dismutase; *, activated state; •, radical species.

of tissue, (iv) accumulate preferentially within the target, and (v) clear rapidly from normal tissue and the whole body. As sensitizers serve several ►porphyrin-like substances, artificial photosensitizers like different ►phthalocyanines or plant-extracted dyes like ►hypericin (from St. John's wort, *Hypericum perforatum*). A special endogenously formed substance is the strong photosensitizer and fluorescence dye ►protoporphyrin IX (PpIX). PpIX is a precursor of ►heme, which represents the prosthetic group of several proteins, such as ►hemoglobin. PpIX forms in the heme pathway in ►mitochondria starting with the precursor ►δ-aminolevulinic acid (ALA). If ALA is externally given in excess to a cell, PpIX is accumulates due to its slow conversion to heme.

For tumor eradication, excitation of the photosensitizer would be most beneficial at high wavelengths since light penetration into tissues increases with the wavelength due to absorption of $\lambda<600$ nm by tissue chromophores (oxy- and deoxyhemoglobin and melanin). Light absorbance by water becomes significant at a wavelength $\lambda>1{,}300$ nm; this gives an "optical window" for optimal photosensitizer excitation with respect to minimal absorbance and maximal tissue penetration.

Up till now, several countries have approved the use of PDT for various types of tumors and precancers (see Table 1).

Principles of Clinical Application

PDT is minimally invasive, prevents scarring, exhibits excellent cosmetic outcome, and is only minimally ►mutagenic. It can be applied repeatedly and in combination with other therapies. Side effects are light sensitivity of the skin after systemic application, vertigo, and nausea, and also local pain during PDT with ALA-induced PpIX. The mechanisms of photosensitizer excretion and its elimination rate via liver to bile, kidney to urine, or/and via intestine to feces represent important factors in determining the grade and duration of light sensitivity.

PDT is applied after approval or in the case of failure of a conservative therapy or if resistance toward conventional tumor treatments is present. Since its damaging mechanisms differ from those of ►chemotherapy and ►radiotherapy, PDT does not interfere with those therapies. Finally, from an economical point of view, PDT is simple, useful, effective, and relatively cheap.

In clinical applications, the photosensitizer is applied either systemically (e.g., by intravenous injection or orally) or topically (e.g., as an ointment) and accumulates in the target tumor tissue. Irradiation is usually performed at a time, when the sensitizer shows the optimum accumulation and the greatest ratio between diseased and normal surrounding tissues. For many photosensitizers, a differential (tumor-selective) accumulation has been proven. Selective enrichment may be supported by delivery of a photosensitizer coupled to suitable carriers such as liposomes or antibodies.

As light sources for PDT serve different kinds of lasers, various lamps (e.g., tungsten filament or xenon arc lamps) equipped with filter systems, semiconductor diode lasers, and conventional light-emitting diodes. Irradiation in inner organs is generally carried out by fiber optics connected with an organ-specific shaped applicator coupled to a light source and at the skin by a conventional lamp, equipped with a cut-off filter to mask out ultraviolet and infrared wavelength portions.

Three general mechanisms contribute to the tumoricidal action of PDT: (i) direct tumor cell killing by light-induced production of cytotoxic compound (ROS), (ii) effects on the tumor vasculature (attachment of the photosensitizer to the tumor endothelial walls and PDT-mediated vascular shutdown, vessel constriction, blood flow stasis, and ►hypoxia), and (iii) immunological effects such as the stimulation of the immune system, which could even be employed to generate a PDT vaccine based on the induction of a cytotoxic T-cell response. Especially in the case of vascular targeting by PDT the pharmacokinetics of the photosensitizer are of utmost importance in defining a drug-to-light interval optimal for induction of vascular damage.

Molecular Mechanisms

Photosensitizers or the prodrug ALA enter the cell or vessel by several mechanisms, ranging from passive diffusion to active uptake via receptors. There is evidence that some photosensitizers (e.g., HPD) are taken up by ►low-density lipoprotein receptors (LDL). The fact that several types of tumor cells bear extensive amounts of LDL receptors could partly explain the tumor selectivity of PDT. ALA seems to enter the cell via the ►Gamma-aminobutyric acid (GABA) receptors. In general, the uptake of photosensitizers into tumor cells is influenced by several factors such as the administration protocol and vehicle, the chemical properties of the photosensitizer, pH, tumor architecture, and cellular parameters (e.g., cell cycle).

As mentioned above, molecular oxygen represents an important reaction partner as the activated photosensitizer reacts with the singlet state oxygen resulting in different forms of ROS. Therefore, the grade of tumor vascularization and the oxygenation of tumors affects the efficiency of the photodynamic process; as a consequence, in some cases, lowering the irradiation intensities and prolonging the irradiation times or fractionating the light dose increases the effectiveness of PDT. However, the benefits of these protocols depend on the tumor type and architecture since fractionated irradiation may also allow recovery of the

Photodynamic Therapy. Table 1 Current Indications for Photodynamic Therapy

Generic name	Chemical name	Activation wavelength	Approval	(Potential) indications
Benzvix	Benzyl δ-aminolevulinic acid	635 nm	No[1]	►Gastrointestinal Tumors
BOPP	Boronated protoporphyrin	630 nm	No[1]	►Brain tumors
Levulan	δ-aminolevulinic acid, ALA	635 nm	Yes[2]	►Actinic keratosis
			No[1]	Head and neck tumors, gynecological tumors
Lu-Tex	Lutetium texaphyrin	732 nm	No[1]	►Cervical Cancers, Prostate Cancer and ►Brain tumors
Metvix	δ-aminolevulinic acid methyl ester	635 nm	Yes[3]	►Basal cell carcinoma
Pc-4	Phthalocyanine-4	670 nm	No[1]	Cutaneous/subcutaneous lesions from diverse solid tumor origins
Photochlor	2-(1-hexyloxyethyl)-2-devinyl pyropheophorbide-alpha	665 nm	No[1]	Basal cell carcinoma
Photofrin, Porfimer sodium,	Hematoporphyrin derivative, polyhematoporphyrin	630 nm	Yes[4]	►Barrett's high-grade dysplasia
			Yes[5]	Cervical dysplasia and Cervical Cancers
			Yes[6]	Endobroncheal cancer
			Yes[7]	►Esophageal Cancer
			Yes[5]	►Gastric cancer
			Yes[8]	Papillary ►Bladder Cancer
			No[1]	Brain tumors cholangiocarcinoma
Photosense	Tetrasulfonated Aluminium Phthalocyanine	672 nm	Yes[9]	Head and neck cancer
SnET2	Tin ethyl etiopurpurin	664 nm	No[1]	►Breast cancer, Basal cell carcinoma, ►Kaposi Sarcoma, prostate cancer
Foscan, Temoporfin	Meso-tetrahydroxyphenyl chlorine	652 nm	Yes[10]	►Palliative Therapy of head and neck cancer
			No[1]	Prostate cancer, ►Pancreas Cancer, cholangiocarcinoma
Visudyne, Verteporfin	Benzoporphyrin derivative-monoacid ring A	689 nm	No[1]	Basal cell carcinoma

[1] Not yet approved, [2] EU, U.S., [3] EU, [4] Canada, EU, UK, U.S., [5] Japan, [6] Canada, Denmark, Finland, France, Germany, Ireland, Japan, The Netherlands, UK, U.S., [7] Canada, Denmark, Finland, France, Ireland, Japan, The Netherlands, UK, U.S., [8] Canada, [9] Russia, [10] EU, Iceland, Norway.

tumor cell's repair systems causing reduced PDT effects.

The intracellular localization and redistribution of the photosensitizer in the cell or vessel determines the primary damage, since ROS have short half-lives, i.e. typical diffusion lengths are 10–20 nm. Consequently, the localization of the photosensitizer determines the cellular target such as specific organelles. The intracellular localization of the photosensitizers depends on their chemical characteristics (e.g., lipophilic dyes accumulate in various membrane systems), the route of internalization, and the time. Except a few photosensitizers used in specialized clinical fields (such as toluidine blue for caries treatment), the dyes do not localize in the nucleus, and therefore PDT does not seem to have a mutagenic potential.

PDT induces damage to target cells via generation of ►oxidative stress and oxidative damage to cellular constituents such as proteins and lipids; this is reflected by the frequently observed increased expression of stress genes coding for proteins such as ►JUN and ►FOS. The resulting cellular response is essentially dose dependent, that is, with increasing PDT dose a transition of survival and repair over induction of ►apoptosis to necrotic cell death (►necrosis) can be observed. The cytotoxic action of PDT is antagonized by the cellular antioxidative defense mechanisms such as antioxidative enzymes and low molecular weight

scavengers. Since PDT does not specifically affect single proteins or cellular mechanisms like most chemotherapeutics, no resistance of tumor cells is induced, even following repeated applications of PDT.

Severe damage caused by massive production of ROS by PDT, results in necrotic cell death, which is characterized by plasma membrane disruption, leak of intracellular material, and immediate and passive cell death. Cell death by apoptosis is induced and executed by a complex cell death machinery, which is reflected by active regulation and complete reorganization of the cellular material. Several models of ►Apoptosis Signaling describe the events and regulation points of apoptosis; the mitochondrial pathway of apoptosis induction and execution is very common following PDT-induced cellular damage. This pathway often involves ►Mitochondrial Membrane Permeabilization (MMP) caused by transformation of the adenine nucleotide translocator into an unspecific pore in the mitochondrial membranes accompanied by reduction of the mitochondrial membrane potential, mitochondrial swelling, and release of proapoptotic factors such as ►cytochrome c, apoptosis-inducing factor (AIF), and ►procaspases. Association of cytochrome c, APAF-1 (apoptosis protease activating factor-1), ATP (adenosine triphosphate), and procaspase-9 results in activation of ►caspase-9. Caspases are endoproteases involved in apoptosis executing the apoptotic programme by cleavage of cellular proteins. The active initiator caspase-9 itself activates caspase-3 (an effector caspase) and triggers the execution of apoptosis. Beside the mitochondrial pathway, also the receptor-mediated, and the stress-induced, ►endoplasmic reticulum (ER)-mediated pathway of apoptosis induction was found. In those cases, different subsets of initiator caspases are induced, all activating the executing caspase-3, -6, or -7. An important class of regulatory proteins is represented by the ►Bcl-2 protein family members (named after ►B-cell lymphoma), which interact with components of the apoptotic pathways at several stages (e.g., mitochondrial pore opening, activation of caspases). Eventually, activation of caspases generates a reaction chain leading to the induction of a cascade of caspase activity, which finally deconstructs the cell and the nucleus, packs it to vesicles (apoptotic bodies), and offers it to immune and neighboring cells for uptake and recycling. Several other (signaling) systems such as intracellular calcium, cathepsins, ceramides, arachidonic acid metabolites, or cyclic nucleotides have been reported to be involved in the cytotoxic action of PDT depending on the model system and photosensitizer used. These data may be further exploited for the design of more efficient combined therapeutic approaches.

In general, the induction and execution of apoptotic cell death depends on several factors such as the damage quantity and quality (dose and intracellular targets), susceptibility of the cell (e.g., antioxidative status), and the availability of cellular energy for execution of apoptosis.

Beside the above mentioned acute stress response, several other effects of PDT on the gene expression of treated tumor cells could be found. Following detailed functional studies and in vivo experimentation, these observations help providing therapeutic strategies that could further enhance the efficiency of PDT.

PDT is known to cause acute inflammation (expression of inflammatory cytokines ►interleukin-1 and ►interleukin-6), invasion of inflammatory cells (neutrophils, mast cells, and macrophages), attraction of antigen presenting cells, and possible development of a systemic immune response with generation of an immunological antitumor memory. Due to induction of a cytotoxic ►T-cell response involving expression of ►interleukin-12, PDT could have potential as a systemic immune therapy or as an in situ ►cancer vaccine. The effects on the immune system represent a potentially important side action of PDT, however, intensive detailed trials have to prove whether this is a useful phenomenon or in which cases it is practical to pay special attention to PDT-mediated antitumor immune effects.

Nononcological indications of PDT include condyloma, warts, psoriasis, acne, skin rejuvenation, sterilization of blood cells, treatment of local bacterial, fungal, viral and parasitic infections, rheumatic arthritis, age-related macular degeneration, caries, dermatophytic fungi, malaria, vascular diseases such as intimal hyperplasia, arteriosclerosis, and prophylaxis of restenosis after ►angioplasty.

Photodynamic Tumor Therapy

►Photodynamic Therapy

Photofrin

Definition

Synonym porfimer sodium; Is the trade name of hematoporphyrin derivatives. It is used as a photosensitizer in ►photodynamic therapy and fluorescent diagnosis due to its photochemical and fluorescent properties.

►Photodynamic Therapy

Photolithography

Definition

Is the process of transferring geometric shapes on a photomask to the surface of a light-sensitive chemical on the substrate. It is used in microfabrication to selectively remove parts of a thin film or the bulk of a substrate. The steps involved in the photolithographic process include wafer cleaning, barrier layer formation, photoresist application, soft baking, mask alignment, exposure, and development, as well as hard-baking.

►Proteinchip

6,4-Photoproduct

Definition

A ►DNA photoproduct that is generated upon covalent linkage between the C-6 position of one pyrimidine and the C-4 position of the 3υ adjacent pyrimidine.

►Solar Ultraviolet Light

Photosensitivity

Definition

Is the increased sensitivity to the development of edema and/or erythema by ultraviolet (UV) light; ►xeroderma pigmentosum.

►Fluorescence Diagnostics
►UV Radiation

Photosensitizer

Definition

A substance that induces photosensitivity normally to a light insensitive chemical or physical process. This may be an adverse effect of many drugs or a desired effect in ►photodynamic therapy. Upon light irradiation in the presence of oxygen found in living tissues, a photosensitizer is excited to produce fluorescence that can be used in ►photodynamic diagnostic of cancer.

►Hypericin
►Photodynamic Therapy

Photothermal Ablation

Definition

The process of destroying tumor cells by activating nanoparticles inside tumors with light which results in heating of the particles and subsequent destruction of the tumor.

►Nanotechnology

Phthalocyanines

Definition

Are artificial photosensitizers consisting of an extensive ring system based on pyrrole groups. Phthalocyanines are used as photosensitizers in ►photodynamic therapy and fluorescent diagnosis due to their photochemical and fluorescent properties.

►Photodynamic Therapy

Phytoalexin

Definition

Plant-derived natural antibiotic.

Phytochemicals in Cancer Prevention

Andreas J. Gescher, Karen Brown, William P. Steward
Cancer Biomarkers and Prevention Group, Department of Cancer Studies, University of Leicester, Leicester, UK

Synonyms

Plant-derived agents; Nutraceuticals

Definition

Phytochemicals are molecules which occur in the plant kingdom; the prefix phyto- is used in words related to botany. Strictly speaking, the term phytochemical encompasses compounds belonging to a large range of chemical classes, from essential minerals such as selenium to large organic molecules such as plant proteins, fats and carbohydrates, which serve as nutrients. Most people would probably associate the term phytochemical with small non-nutrient organic molecules contained in edible fruits and vegetables. Representative examples of potentially cancer chemopreventive phytochemicals (with their dietary precursors in brackets) are genistein (soya), vitamin c (fruits, vegetables), β-carotene (fruits, vegetables), curcumin (curry spice turmeric), lycopene (tomatoes), tea catechins such as epigallocatechin gallate (green tea), resveratrol (red grapes, other fruits) and apigenin (leafy vegetables) (see Fig. 1).

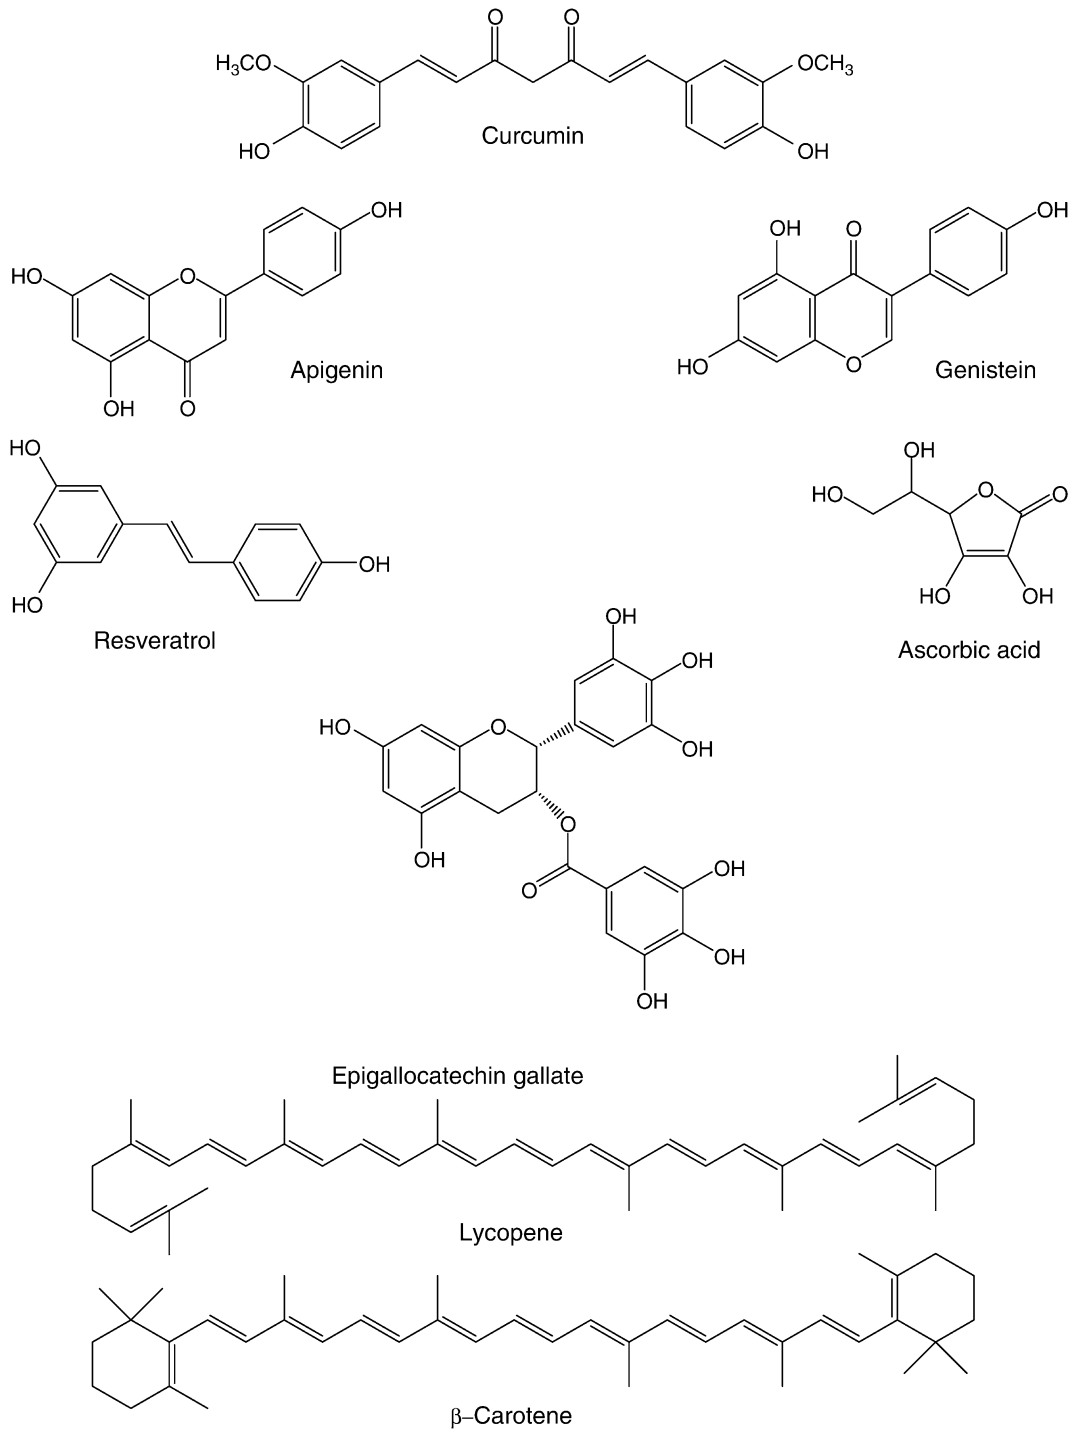
Characteristics

Epidemiology. There is epidemiological evidence which links the incidence of cancer in people in certain areas of the world to the geography of their origin. Often emigrants from areas characterized by a low incidence of a particular cancer, who move to an area with a high prevalence of that cancer, rapidly adopt the high risk of the indigenous population of their chosen immigrant country. For example, Japanese women, who traditionally have a low risk of developing breast cancer, adopt the high breast cancer risk pattern prevalent in the USA within a generation. The low risk of breast cancer in Japan has been tentatively linked to the ubiquitous consumption of plentiful amounts of soya. During the last two decades many attempts have focused on the chemical isolation and pharmacological characterization of dietary constituents, exemplified by those shown in Fig. 1, which may be responsible for the cancer-preventive properties of the parent foodstuff. In the case of soya, constituent chemicals which have been hypothesized to cause, or contribute to, the cancer-preventive properties, are the isoflavones genistein and diadzein.

Cancer Chemopreventive Mechanisms

Research on chemopreventive mechanisms of phytochemicals has primarily focused on their ability to modulate the following biochemical processes: activation/detoxification of chemical carcinogens by xenobiotic enzymes, DNA repair, cell cycle progression, cell proliferation, differentiation, ►apoptosis, expression and functional activation of ►oncogenes or tumor suppressor genes, ►angiogenesis, ►metastasis and hormonal and growth-factor activity. It is important to note that phytochemicals engage pharmacological mechanisms in a species- and tissue-specific manner. Table 1 shows the spectrum of mechanisms in cells *in vitro* activated by curcumin as a paradigm of polyphenolic phytochemicals.

Cancer Chemopreventive Activity in Rodents. Phytochemicals have been shown to possess preclinical cancer chemopreventive efficacy in two types of rodent model. Within weeks of continued exposure to carcinogens such as azoxymethane or benzanthracene, rodents develop cancer in a variety of tissues depending on dose and route of administration. These are the so-called "carcinogen-induced models of carcinogenesis." They contrast with "genetic models," rodents (usually mice) which harbor a gene defect, deletion or mutation, which predisposes them to the formation of malignancies. Particularly interesting for cancer chemoprevention research are rodent models with the propensity to develop cancer caused by a genetic defect, which resembles the genetic fault underlying the corresponding disease in humans. Two examples of genetic mouse models are the Apc^{Min} and the TRAMP (transgenic adenocarcinoma of the mouse prostate) mice. Apc^{Min} mice harbor a functionally inactive mutated *Apc* tumor suppressor gene. All mice with the min genotype develop tumors in the small intestine. The Apc^{Min} mouse is a model of an inherited human disease called Familial Adenomatous Polyposis Coli (FAP) characterized by an ►*APC* gene mutation not unlike that seen in Apc^{Min} mice. FAP patients present with colorectal adenomas early in life, which ultimately progress to colorectal carcinomas. In TRAMP mice expression of the SV40 transforming sequences is targeted to the prostate, and all male TRAMP mice develop prostate tumors. In chemoprevention efficacy testing experiments, carcinogen-induced or genetic models receive the phytochemical under study usually



Phytochemicals in Cancer Prevention. Figure 1 Examples of chemopreventive phytochemicals.

added to the diet, and the number and size of tumors which develop are compared with those in animals which received control diet only. The chemopreventive phytochemicals shown in Fig. 1 have been demonstrated to possess cancer chemopreventive activity in a variety of carcinogen-induced and genetic preclinical models.

Clinical Trails. Definitive phase III clinical trials which show without doubt that a specific isolated phytochemical (rather than a dietary mixture) can prevent cancer in humans have yet to be published. Two randomized trials with a lung cancer endpoint, the α-tocopherol, β-carotene (ATBC) prevention study

Phytochemicals in Cancer Prevention. Table 1 Chemopreventive mechanisms of curcumin in cells *in vitro*

Pharmacological effect	Molecular target	Model system
Inhibition of carcinogen activation/DNA binding	↓CYP1A1 activity	Human breast cancer cells
	↓Carcinogen-DNA adduct formation	
Stimulation of carcinogen detoxification	↑Detoxifying enzymes (e.g. GST, QR)	Rodent liver; human hepatoma cells
Control of cell cycle and proliferation	↓Cyclin D1 expression	Prostate/breast/squamous carcinoma cells, lymphoma cells, murine epidermal cells
	↓Rb phosphorylation	
	↓NF-κB activation	
	↓c-Jun, c-Fos expression	
Inhibition of oncogen product activity	↓c-Myc, c-Jun, c-Fos expression	Mouse epidermis
Induction of apoptosis/ differentiation	↓NF-kB, IKK activation	Human myeloma/breast cancer/ leukemia cells
	↓BCl-2; ↑p53 and BAX expression; ↑caspase activity; ↑BID cleavage; ↑Cytochrome C release	
Inhibition of angiogenesis, metastasis, invasion	↓VEGF; ↓MMP-2 mRNA expression; ↑TIMP-1 mRNA expression	Human breast carcinoma cells

Abbreviations: CYP: cytochrome P450; GST: glutathione S-transferase; QR: quinone reductase; Rb: retinoblastoma tumor suppressor; NFκB: nuclear factor κB transcription factor; IKK: I κB kinase; VEGF: vascular endothelial growth factor; MMP: matrix metalloproteinase; TIMP: tissue inhibitor of metalloproteinase.

and the β-carotene and retinol efficacy trial (CARET) were conducted in the early 1980s. Their outcome suggests that β-carotene was not only devoid of imparting any health benefit, but that it might have even exacerbated the risk of lung cancer. A meta-analysis of all randomized trials conducted up to 2004, in which antioxidant supplements including vitamins A, C and E, carotenes and selenium were compared with placebo for prevention of gastrointestinal cancers failed to find evidence for efficacy. Results like these intimate that ultimate incontrovertible clinical proof of the ability of isolated phytochemicals to prevent a particular malignancy will be exceedingly difficult to obtain. In order to gather indirect evidence for anticarcinogenic efficacy of phytochemicals, ►pharmacodynamic markers reflecting chemopreventive efficacy are under intense exploration.

Compelling evidence for testing specific phytochemicals in the prevention of certain malignancies comes from secondary findings of clinical trials. For example, the Nutritional Prevention of Cancer study, a randomized controlled trial of selenium for prevention of non-melanoma skin cancer conducted in the 1990s in regions of the USA where selenium intake is low, showed a 63% reduction in risk of prostate cancer. This finding provided the rational for the SELECT trial of selenium and vitamin E for prostate cancer prevention, which is currently ongoing in the USA. There have also been a few intriguing small pilot studies in humans, which hint at the ability of certain phytochemicals to delay cancer onset, exemplified by the finding that consumption of green tea catechins delayed the progression of high-grade prostate intraepithelial neoplasia to prostate cancer. Studies like this hint at the prospect that certain phytochemicals may turn out to be really useful in clinical cancer chemoprevention.

Phytoestrogens

Valerie Speirs
Leeds Institute of Molecular Medicine, University of Leeds, Leeds, UK

Definition

Phytoestrogens are natural chemicals of plant origin which have similar action to the mammalian ►hormone estrogen.

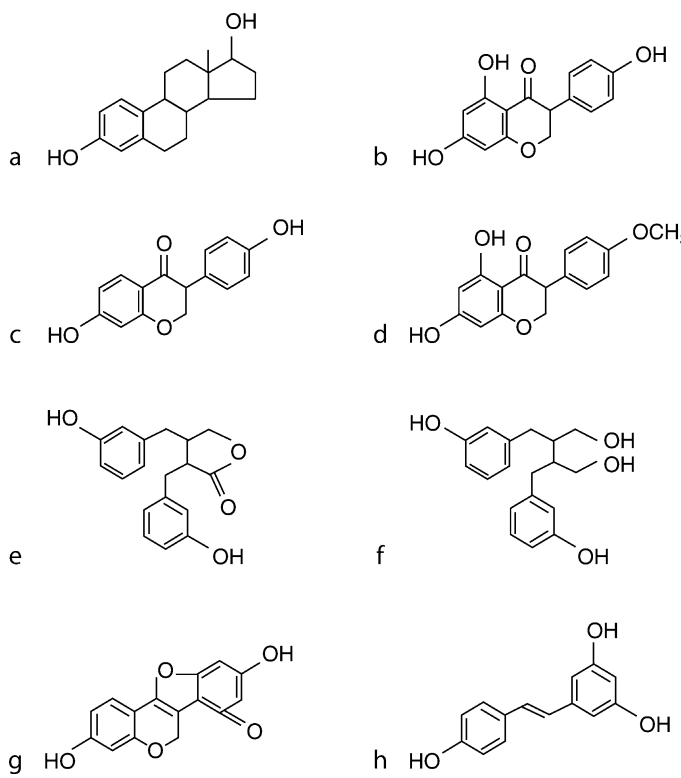
Characteristics

Phytoestrogens are non-steroidal ►polyphenolic compounds. They are found naturally in many edible plants and have structural similarity to the mammalian steroid hormone ►17β-estradiol (Fig. 1). This permits binding to ►estrogen receptors (ERs), but they have a much higher affinity for ERβ than ERα. Based on their chemical structure, phytoestrogens can be broadly divided into four distinct categories: the ►isoflavones (►genistein, daidzein, biochanin A), the ►lignans (enterolactone, enterodiol), the ►coumestans (coumestrol) and the ►stilbenes (►resveratrol).

Phytoestrogens are found in a range of plant products consumed in the diet although their concentrations depend largely on the food type. Isoflavones are found mainly in soy-based products including soybeans, tofu, soy milk, textured soy protein and miso. Of these, the best studied are genistein and daidzein. The coumestans are found in plants less frequently consumed in the human diet e.g. alfalfa sprouts, clover and pinto beans. Lignans are present in flaxseed and are ingested as plant lignan precursors from most fruits and vegetables. These are then converted by gut microflora and into mammalian lignans. Stilbenes are found mainly in peanuts but also in the skin of grapes and as a component of red wine.

Potential Benefits of Phytoestrogens

Many putative health benefits of phytoestrogens have been proposed, the most interesting of which include their potential role as anti-cancer agents (►Phytochemicals and cancer prevention), especially in hormonally-regulated ►cancer (►Estrogenic hormones and cancer). This stems from ►epidemiological (►Epidemiology of cancer) evidence revealing a much higher incidence of breast cancer in Asian populations who consume a soy-rich diet and where the average daily intake of phytoestrogens is 30mg/day compared to



Phytoestrogens. Figure 1 Structural comparison of 17β-estradiol (a) with the principal classes of phytoestrogen, the isoflavones genistein (b), daidzein (c) and biochanin A (d), the lignans enterolactone (e) and enterodiol (f), the coumestan coumestrol (g) and the stilbene resveratrol (h).

<10mg/day in Western countries. Increasing epidemiological evidence suggests that the perceived ►chemoprotectant effects of phytoestrogens are dependent upon a critical period of exposure to these agents pre-puberty and that consumption later in life will have little chemopreventative benefit. This has also been borne out in animal studies which showed neonatal but not postnatal administration with phytoestrogens afforded protection against ►breast cancer development.

Although much of the work on phytoestrogens has been done on breast cancer, these agents have also been implicated in the prevention of prostate (►Prostate cancer, clinical oncology) and colon (►Colon cancer) cancer through a dose-dependent reduction of circulating hormones but data remain inconclusive.

Phytoestrogens bind to and activate ERs but are weak estrogens compared to natural hormones (►Hormones and cancer). It is believed that by ER binding, phytoestrogens prevent the biologically more potent systemic estrogens binding to and activating the receptors. Other more indirect modes of action of phytoestrogens have been reported and include: suppression and/or inhibition of enzymes involved in steroid hormone biosynthesis, inhibition of ►neovascularization required for tumor growth and the inhibition of growth factor signaling. There are additional reports of their action as ►antioxidants by preventing formation of free radicals that can cause cell damage.

Potential Drawbacks of Phytoestrogens

As well as potential protective effects of phytoestrogens, other studies suggest that these agents may actually promote cancer with studies on breast cancer cells showing growth stimulatory effects. This seems to be concentration dependent with low levels exerting estrogenic effects while high levels seem to be more protective. However levels of the latter are non-physiological and considerably higher than plasma levels achieved after a soy-rich meal. Overall further experimental studies, especially prospective epidemiological, are required to advance our understanding of beneficial effects (or otherwise) of phytoestrogens in ►carcinogenesis.

P

Definition

PI3Ks are members of a unique and conserved family of intracellular lipid kinases that catalyze the phosphorylation of phosphatidylinositol and phosphoinositides at the D3 position of the inositol ring, generating new intracellular second messengers such as phosphatidylinositol-3-phosphate (PI-3-P), phosphatidylinositol-3,4-bisphosphate (PI-3,4-P2), and phosphatidylinositol-3,4,5-trisphosphate (PI-3,4,5-P3 or PIP3) (►inositol lipids). This reaction leads to the activation of many intracellular signaling pathways through the binding of these proteins to these lipid products. As a consequence PI3K regulates functions as diverse as cell metabolism, survival and polarity, and vesicle trafficking.

Characteristics

PI3K Classification and Signaling Pathways

PI3Ks are grouped in three classes (I–III) according to their substrate preference and sequence homology (Fig. 1). The Different classes of PI3K have distinct roles in cellular signal transduction.

Class IA PI3K

p85 regulatory isoforms have a common core structure consisting of a p110-binding domain flanked by two Src-homology 2 (SH2) domains. p85 isoforms also have an extended N-terminal region containing an Src-homology 3 (SH3) domain and a BCR homology (BH) domain flanked by two proline-rich (P) regions. p110 catalytic subunit isoforms possess an N-terminal p85-binding domain, a Ras-binding domain that mediates a C2 domain, a phosphatidylinositol kinase (PIK) homology domain and a C-terminal catalytic domain. The PIK and catalytic domains of p110 are homologous to domains found in a family of protein kinases that includes ►mTOR (mammalian target of rapamycin), ataxia telangiectasia-mutated, ataxia telangiectasia Rad3-related, and DNA-dependent serine/threonine protein kinase.

Class IB PI3K

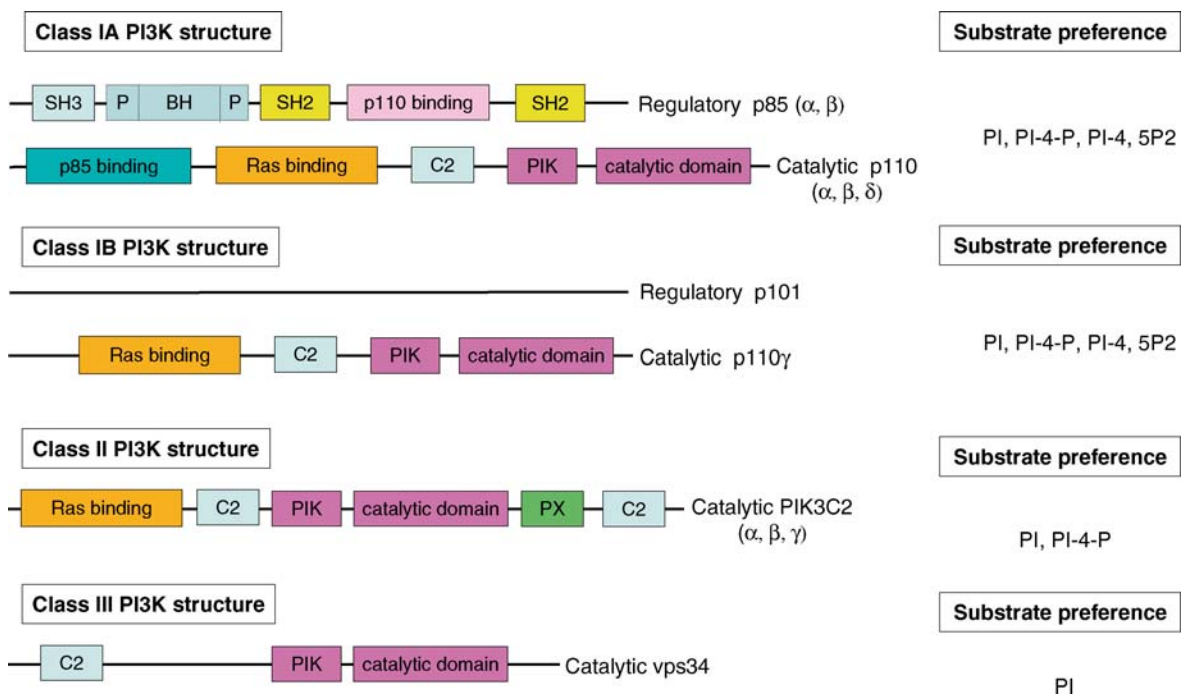
Although p110γ shares extensive homology with the class IA p110 proteins, p101 is distinct from p85 proteins.

Class II PI3K

All three p110-like catalytic subunit isoforms share significant sequence homology with the class I p110 subunits. In addition, class II PI3Ks have an extended divergent N-terminus, and additional PX and C2 domains at the C-terminus.

Class III PI3Ks

This class only displays an N–terminal. C2 domain a PIK domain and a C-terminal catalytic domain.



PI3K Signaling. Figure 1 Classification of PI3K members and substrate preference.

Class I PI3Ks

This class is divided into two subfamilies depending on the receptors to which they couple. Class IA PI3Ks are heterodimers of a p85 regulatory subunit (α or β) and a p110 catalytic subunit (α, β, or δ) and are activated by growth factor receptor tyrosine kinase (RTKs), whereas class IB PI3Ks are heterodimers of a regulatory subunit p101 and a p110 catalytic subunit (γ) and are activated by G-protein-coupled receptors. This binding both relieves the basal inhibition of p110 by p85 and recruits the p85-p110 heterodimers to its substrate (PI-4,5-P2) at the plama membrane. Class I PI3K are involved in many important physiological mechanisms including metabolism and longevity such as glucose homeostasis, cell migration, growth and proliferation.

Class II PI3Ks

This class consists of a single p110-like catalytic subunit (α, β, or γ). Class II PI3Ks bind to clathrin and localize to coated pits, indicating a function in membrane trafficking regulation and receptor internalization.

Class III PI3Ks

This class consists of a single member, vps34 (vacuolar protein defective 34).

In budding yeast, vps34 was originally found to have a role from trafficking vesicles from the golgi apparatus to the vacuole. In mammals, this class seems to be crucial for controlling cell growth.

Two commonly used PI3K inhibitors, wortmannin and LY294002, inhibit class I and II and at a lesser extent class II as well as other PI3K-like protein kinases.

PI3K Signaling Pathways

PIP3 is a lipid second messenger that activates many downstream molecules by binding to their pleckstrin-homology (PH) domains. The protein serine/threonine kinase AKT (also known as PKB) (►AKT signal transduction pathway in oncogenesis) is a principal target of PIP3. Binding of PIP3 to AKT leads to the membrane recruitment of AKT and subsequent phosphorylation by the mTOR–rictor kinase complex and by PDK1 (3-phosphoinositide-dependent kinase). This leads to the full activation of AKT, which in turn phosphorylates many target proteins, thereby regulating a range of cellular functions. An important AKT target is the forkhead (FOXO) family of transcription factors. AKT-mediated phosphorylation of FOXO proteins leads to their inactivation through cytoplasmic sequestration by 14-3-3 proteins. The main biological functions of these signaling pathways are described later (Fig. 2) [2, 3].

Cell metabolism: In muscle and fat, AKT promotes glucose uptake by stimulating the membrane translocation of the glucose transporter GLUT4. In addition, AKT activates glycogen synthase through the inhibition of glycogen synthase kinase 3 (GSK3) and regulates fatty acid synthesis by activating ATP citrate lyase (ATP-CL). In the liver, AKT inhibits gluconeogenesis by blocking FOXO-mediated transcription of gluconeogenic enzymes, such as phosphenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase (G6Pase).

Cell cycle and cell survival: AKT promotes G1–S cell-cycle transition by blocking FOXO-mediated transcription of cell-cycle inhibitors, such as p27Kip1 and RBL2 (retinoblastoma-like 2). AKT might also directly phosphorylate and inactivate p27Kip1. In addition, AKT indirectly stabilizes the cell-cycle protein c-Myc (►Myc oncogene) and cyclin D1 (►cyclin D) through the inhibition of GSK3. AKT promotes cell survival by blocking FOXO-mediated transcription of proapoptotic proteins such as FasL (Fas-ligand) and Bim (BCL2-like 11). AKT can also directly phosphorylate the proapoptotic protein BAD (BCL2-antagonist of cell death), causing its inactivation by 14-3-3 binding. Furthermore, AKT can phosphorylate MDM2 (transformed 3T3 cell double-minute 2 p53-binding protein), leading to p53 degradation (►p53 protein, biological and clinical aspects). Finally, AKT can phosphorylate some PKC isoforms (PKCζ) (►protein kinase C family) which activate IKK leading to IκB degradation and NF-κB activation (►nuclear factor κB).

Protein synthesis: AKT phosphorylates the tuberous sclerosis complex 2 (TSC2) protein tuberin, and therefore inhibits the GTPase-activating protein (GAP) activity of the TSC1–TSC2 complex toward Rheb (small G-protein Ras homologue enriched in brain). This allows GTP-bound Rheb to accumulate and activate the mTOR–raptor kinase complex, which in turn mediates phosphorylation of 4E-BP1 (eukaryotic translation initiation factor 4E-binding protein 1) and p70S6Kinase, ultimately leading to increased protein synthesis.

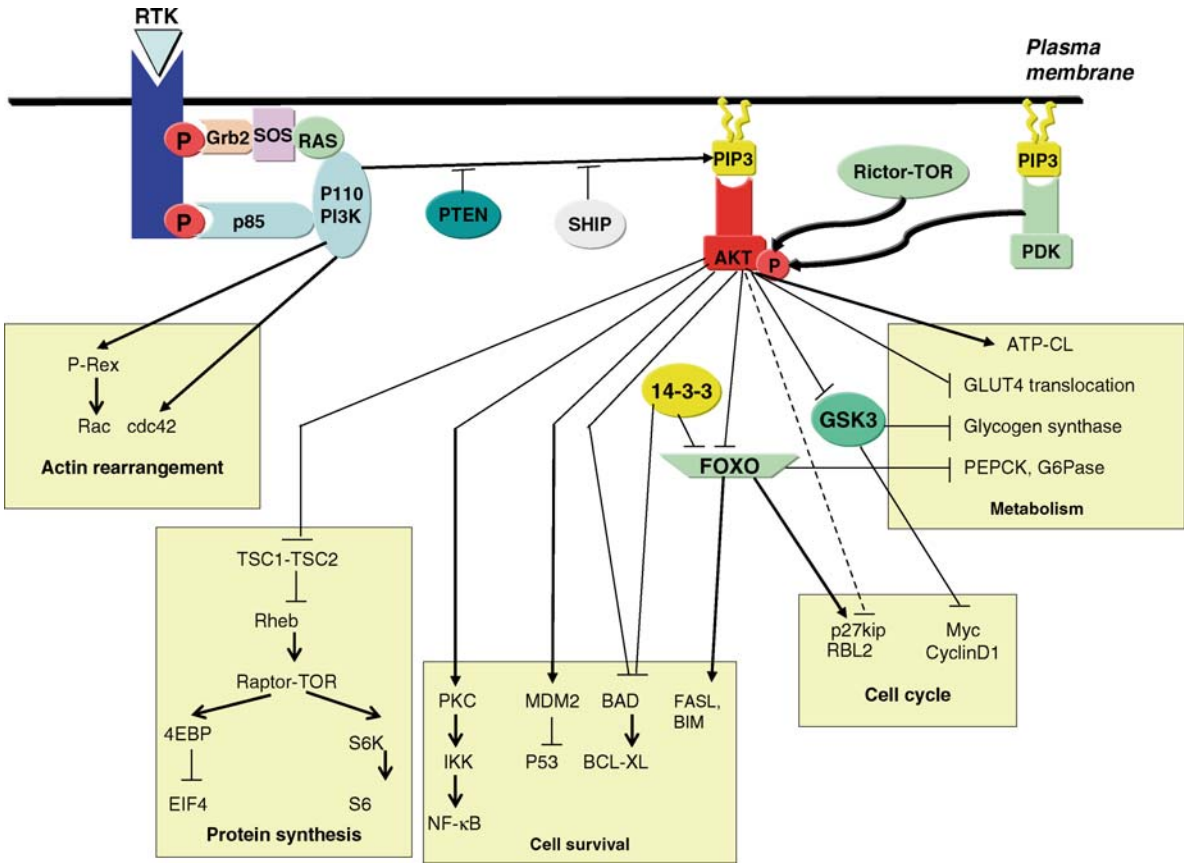
Cell polarity and motility: PI3K, together with the small GTPase Rac and Cdc42, regulates cell polarity and motility by controlling actin dynamics in motile cells.

Vesicle sorting: Class III PI3K regulates proper intracellular vesicle trafficking and may mediate aminoacid-induced mTOR activation.

Negative Regulation of PI3K Signaling Pathways

Two main phosphatases are involved in PIP3 dephosphorylation: PTEN (phosphatase and tensin homologue deleted on chromosome ten) and SHIP (SH2-domain, containing inositol 5-phosphatase).

►PTEN dephosphorylates phosphoinositides at the 3′ position of inositol leading to PI-4,5-P2. As a consequence, PTEN negatively regulates all signaling pathways induced by PI3K activation. Germline mutations in the *PTEN* gene result in Cowden disease and Bannayan–Riley–Ruvalcaba syndrome (also known as macrocephaly, multiple lipomas, and haemangiomata), which are two familial diseases characterized by benign



PI3K Signaling. Figure 2 Class I PI3K signaling pathways activated by RTK. Many pathways are activated leading to regulation of metabolism, cell cycle, cell survival, protein synthesis, and actin rearrangement. Figure derived from Engelman et al (2006).

tumors and high risk of cancer. Somatic mutations, gene deletion or gene inactivation of *PTEN* occurs in a sizeable fraction of glioblastomas, prostate cancers, breast cancers, and melanomas.

SHIP contains a centrally located phosphoinositide phosphatase domain that selectively hydrolyzes the 5′-phosphate from PIP3 leading to PI-3,4-P2 which interact at a lesser extent with AKT. SHIP may act as a tumor suppressor in hematopoietic progenitors, since inactivating mutation in the catalytic domain was found in acute myelogenous leukemia.

Main Phenotypes Induced by PI3K Signaling Pathways

The *in vivo* functions of the various isoforms of PI3K in mammals have begun to be addressed by gene deletion studies in mice. These studies highlight the importance of class IA PI3K signaling in regulating growth and metabolism. Furthermore, dysregulation of this pathway is crucial for the pathophysiology of several human diseases: mutations that lead to the amplification of PI3K signaling are among the most common mutations in human cancers, whereas attenuated PI3K signaling downstream of the insulin receptor is a major contributor toward type-2 diabetes (also known as noninsulin-dependent diabetes mellitus). Most of our understanding of PI3K signal transduction is based on studies of class I PI3Ks.

PI3K Signaling and Cell Growth

In myocytes, PI3K signaling controls cell growth (i.e., cell size). For example, overexpression of either a constitutively active form of p110α or a constitutively active form of AKT in the heart results in increased organ and cell size, whereas overexpression of a dominant-negative form of p110α reduces heart size. Furthermore, the expression of a dominant-negative form of p110α suppresses the growth induced by IGF1 receptor in the heart. Accordingly, tissue-specific deletion of PTEN leads to increased cell size, whereas mice with germline deletion of AKT1 or AKT3 show growth retardation.

PI3K Signaling, Tumorigenesis, and Cancers

In the 1980s, PI3K was discovered because of its association with onco proteins. Mutants of polyoma middle T that failed to bind PI3K were compromised in their ability to transform fibroblasts and polyoma middle T-transformed cells had elevated levels of PIP3. A few years later, the p110α catalytic subunit of PI3K was identified as an avian retrovirus-encoded oncogene that could transform chick embryo fibroblasts *in vitro*. Genetic analyses of human tumors performed in the 1990s showed that a locus on chromosome 10q23 was frequently deleted in advanced cancers. PTEN was located in this region indicating that it functioned as a tumor suppressor because of its ability to turn off the PI3K pathway. This idea has been further strengthened by the recent discovery of several genetic alterations in the pathway in human cancers, including p85, p110α, PTEN, and AKT. The *PIK3CA* (phosphatidylinositol 3-kinase, catalytic, α-polypeptide) (►PIK3CA oncogene) gene that encodes p110α is frequently amplified in several human cancers, such as head and neck cancers, cervical cancers, gastric cancers, and lung cancers. Recently, point mutations in p110α were identified in significant fractions of brain cancers, colon cancers, breast cancers, and hepatocellular cancers. Interestingly, most point mutations in p110α cluster around two hotspots: E545 in the helical PIK homology domain and H1047 near the end of the catalytic domain. These mutations increase *in vitro* PI3K activity of the holoenzyme. The expression of these p110α mutants in cells confers AKT activation in the absence of growth factor stimulation. Significantly, these mutants can transform fibroblasts and mammary epithelial cells, and drive tumor formation in mouse xenografts. Interestingly, mutations in other p110 isoforms have not been identified in cancers, indicating that p110α harbors more oncogenic potential. Amplification of AKT2 has also been found in human cancers, indicating that the tumorigenic effect of aberrant PI3K signaling is at least partly mediated through AKT. Recently, AKT2 mutations and IRS2 amplifications were also observed in colon cancers.

PI3K, Insulin Signaling, and Diabetes

In mammals, the PI3K–AKT signaling pathway has a central role in the regulation of downstream metabolism of the ►insulin receptor and IRS adaptor molecules. Indeed, insulin can mediate glucose uptake and membrane translocation of the glucose transporter GLUT4 in adipocytes and myocytes. In hepatocytes, PI3K–AKT signaling inhibits the FOXO-mediated transcription of gluconeogenic enzymes and therefore suppresses hepatic glucose production. Knockout and transgenic mice have ascertained the role of class IA PI3K in mediating insulin signaling *in vivo*. Mice with germline deletion of either p110α or p110β die early during embryogenesis, whereas mice that are doubly heterozygous for p110α and p110β, and mice that are heterozygous for a kinase-dead knock-in allele of p110α, exhibit glucose intolerance. In addition, tissue-specific deletion of PTEN in muscle, fat, or liver leads to enhanced insulin sensitivity in these tissues. Besides, mice deficient in all p85 isoforms in either muscle or the liver exhibit severely impaired insulin signaling in these tissues. These findings show that class IA PI3K is essential in mediating insulin action *in vivo*. Interestingly, the loss of PI3K signaling in the muscle results in impaired muscle glucose uptake, whole-body glucose intolerance, hyperlipidaemia, and adiposity, whereas the loss of PI3K signaling in the liver leads to unregulated hepatic gluconeogenesis, hyperglycaemia, hyperinsulinaemia, and reduced circulating lipids. Moreover, several polymorphisms in the human gene coding for p85α are associated with increased risk of type-2 diabetes. Elevated levels of p85, but not p110, were observed in muscles of type-2 diabetic individuals. The importance of the PI3K pathway in the regulation of metabolism has been confirmed by mutations of other components of the pathway. For example, germline deletion of AKT2, which is an AKT isoform that is abundant in muscle and liver, results in a diabetic phenotype in the mouse. The relevance of this model for human disease is supported by the identification of a point mutation in AKT2 in a familial form of severe insulin resistance.

Taken together, PI3K signaling mediates different cellular responses depending on the tissue context, and defective PI3K signaling in many tissues contributes collectively to the complex metabolic defects associated with type-2 diabetes.

Future Directions

Our understanding of the diverse roles of PI3K signaling puts us in a position to manipulate this pathway therapeutically for the treatment of cancers and diabetes.

PIK3CA Oncogene

Ben Ho Park
The Sidney Kimmel Comprehensive Cancer Center, Johns Hopkins University, Baltimore, MD, USA

Synonyms

Phosphatidylinositol 3-kinase (PI3-Kinase)

Definition

PIK3CA is a human gene that regulates various cellular functions including proliferation and invasion. Because it is an ►oncogene, its activation by either gene amplification or mutation results in a cellular growth advantage contributing toward cancer formation and progression.

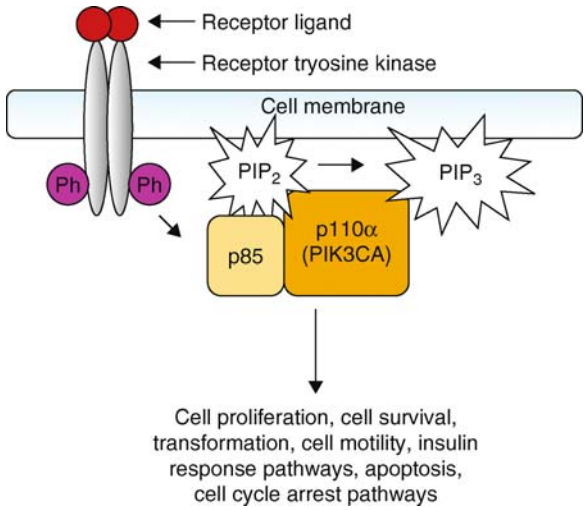
Characteristics

The PI3-Kinase pathway is one of many signaling pathways that are important for cell growth, ►transformation, adhesion, apoptosis, survival and invasion. PI3-►Kinases themselves are heterodimeric lipid kinases composed of catalytic and adaptor/regulatory subunits encoded by separate genes and alternative splicing. The PI3-Kinase enzyme family is organized under three main classes (class I, II and III) and various subgroups have been categorized based on their primary structure, substrate specificity and regulation.

The *PIK3CA* oncogene encodes for the alpha catalytic subunit and along with the p85 regulatory subunit, catalyzes the generation of the second messenger, phosphatidylinositol 3,4,5-trisphosphate (PIP_3) from phosphatidylinositol 4,5-bisphosphate (PIP_2) (Fig. 1). This action is often initiated by ligand binding and subsequent activation of receptor tyrosine kinases, with the end result of increased cell signaling as measured by phosphorylation and activation of many downstream proteins. Signaling pathways and molecules affected by PI3-Kinase activity include the ►Ras/Raf/MAP kinase pathways as well as the ►AKT pathway, all known to be involved with cellular growth and proliferation. Normally these signaling pathways are tightly regulated to ensure that proper cell growth is controlled and maintained. In the case of oncogenes, including *PIK3CA*, genetic changes such as a mutation can result in a cellular state whereby the *PIK3CA* gene product is constantly activated. Ultimately, this contributes toward uncontrolled cellular growth and other features that are the hallmarks of cancer.

Genetics

The human *PIK3CA* gene is located on chromosome 3q26.32 and is ~34 kb consisting of 20 coding exons.



PIK3CA Oncogene. Figure 1 PI3-Kinase activity. PI3-Kinase is activated upon ligand binding to a receptor tyrosine kinase (RTK) which then activates the regulatory subunit (p85) to bind the catalytic p110α subunit. This catalyzes the reaction phosphatidylinositol (PI) 4,5-bisphosphate (PIP_2) to phosphatidylinositol (PI) 3,4,5-triphosphate (PIP_3) and ultimately initiates various downstream signaling cascades affecting cell survival, apoptosis, transformation, metastasis, and invasion.

The protein contains 1068 amino acids yielding a 124 kDa size protein. The PIK3CA protein contains five known functional domains including a p85 binding domain, a Ras binding domain, a protein kinase C homology 2 domain, a helical domain and a kinase domain.

In general, two main genetic alterations can lead to oncogene activation in human malignancies. The first mechanism is gene amplification, in which a ►wild type gene is duplicated, usually involving multiple duplications, leading to increased protein production of the amplified gene. This increase in oncogenic protein continually activates downstream signaling molecules and pathways, thus driving cellular growth and transformation. For *PIK3CA*, gene amplification has been described in human cancers and ►precancerous lesions including breast cancers, ovarian cancers and thyroid adenomas. However, *PIK3CA* gene amplification appears to be a relatively uncommon event in most human malignancies. Rather, a second mechanism, somatic ►missense mutation, is the predominant method of *PIK3CA* gene activation found in most human cancers. Accordingly, the majority of *PIK3CA* mutations found in human malignancies occur in one of two domains, the helical and kinase domains. These mutations are predicted to render the kinase function of the protein as being constantly activated and experimental data has supported this supposition. *PIK3CA* mutations occur at a relatively high frequency in breast

and colorectal cancers and at lower frequency in other solid malignancies. Strikingly, in most studies of activating *PIK3CA* missense mutations, three common "hotspot" mutations have been described, E542K, E545K, H1047R, with the first two mutations occurring in exon 9 (helical domain) and the third mutation affecting exon 20 (kinase domain). These frequently occurring mutations account for 80–90% of all *PIK3CA* mutations, and lend themselves as potential targets for diagnostic and therapeutic exploitation.

Clinical Relevance

Frequently recurring "hotspot" mutations have many implications for clinical oncology. First and foremost, because these mutations are somatic, meaning they are present in the cancer cell but not in normal tissues, these *PIK3CA* mutations become obvious targets for therapeutic intervention since the "holy grail" of all cancer therapy relies upon isolating medicines capable of specifically killing cancer cells while leaving non-cancerous cells relatively unharmed. The somatic activating nature of these mutations therefore makes them perfect for this type of targeted therapy and indeed small molecule PIK3CA inhibitors are beginning to enter early phase clinical trials. Additionally, because activating "hotspot" mutations are so common in a number of different human malignancies, targeting these mutations for therapy could have a tremendous impact on the morbidity and mortality of human cancers. Second, these mutations could also be potentially useful as a more sensitive and specific means of cancer detection and/or diagnosis. For example, given newer technologies that enable the detection of single mutant molecules in blood and stool, it is tempting to speculate that genetic testing could be developed to either detect cancer cells with mutant *PIK3CA* as an adjunct to an initial screening test, or to use mutant *PIK3CA* as a molecular marker to detect metastatic disease and/or recurrent disease after treatment. Along those lines, the detection of mutant *PIK3CA* in human cancer may also lend itself as a prognostic indicator of disease recurrence, and clinical studies in a number of cancers are currently addressing this important question. Ultimately, the discovery of the *PIK3CA* oncogene as one the most mutated oncogenes in human cancers makes it one of the most important cancer causing genes to date, and places it at the forefront for targeted drug development and cancer diagnostics.

Placenta Growth Factor

Cristina Maria Failla
Laboratory of Molecular and Cell Biology, IDI-IRCCS, Rome, Italy

Synonyms
Placental growth factor; PlGF

Definition
Placenta growth factor (►PlGF) is a member of the ►vascular endothelial growth factor (VEGF) family. PlGF is a secreted, homodimeric glycoprotein, originally isolated from human placenta.

Characteristics
PlGF shares 53% of similarity in its amino acid residues with VEGF. PlGF is highly expressed in placenta, but it is also present in other normal tissues and organs, such as thyroid, trophoblasts, heart, and lung, and it is upregulated in the skin, under physiological and pathological conditions.

Human PlGF gene maps to chromosome 14q24 and encodes four isoforms generated by alternative splicing. These isoforms differ in the ability to interact with other proteins, due to the presence or not of a heparin-binding domain and of a ►neuropilin-binding motif.

It is now widely accepted that PlGF isoforms function as angiogenic growth factors through direct binding and activation of the tyrosine kinase receptor vascular endothelial growth factor receptor-1 (►VEGFR-1). PlGF uses this receptor as well as VEGF-B and VEGF, the latter showing higher affinity in VEGFR-1 binding. Even so, PlGF transmits through VEGFR-1 its own specific signal that differs from that of VEGF both in the amino acidic tyrosine residues that are phosphorylated in the receptor molecule and in the downstream effectors.

PlGF is also able to sustain VEGF actions when a small amount of VEGF is present. Different mechanisms have been proposed to explain this event. One states that binding of PlGF to VEGFR-1 leads to an intermolecular trans-phosphorylation of VEGFR-2, the main transducer of VEGF proliferation signal. Another one indicates that PlGF forms heterodimers with VEGF and these dimeric proteins directly bind and activate VEGFR-2.

Animal models give evidence that PlGF plays important functions in adult pathological ►angiogenesis, while it is redundant for the development of the embryonic vasculature. PlGF-overexpression results in significant vessel growth, with formation of enlarged, mature vessels, covered with ►mural cells. PlGF has been often associated with ►arteriogenesis. Besides acting on ►endothelial cells, PlGF is chemotactic for monocytes, and can restore early and late phases of hematopoiesis following bone marrow suppression.

The role of PlGF in cancer has been debated for a long time and its significance is not completely clear. Nevertheless, scientific data have been continuously produced, indicating that PlGF is a major factor in tumor progression. PlGF expression has been detected in various human tumors, such as meningiomas, melanoma, cervical squamous cell carcinoma, gastric, breast and lung cancer. In some cases, PlGF expression is significantly associated with tumor stage, showing constant up-regulation during tumor progression. PlGF expression is down regulated in thyroid carcinoma and cervical adeno-carcinoma. Chromosomal translocations involving the PlGF locus with consequent overexpression of PlGF have been reported in a case of hemangioendothelioma, pointing to a direct involvement of PlGF in the pathogenesis of this tumor.

PlGF produced by tumor cells contributes to tumor angiogenesis by acting in a paracrine way on the surrounding microvessels, sustaining endothelial cell proliferation, migration and differentiation. The resulting augmented vascularization promotes tumor growth.

Consistently, in experimental animal models, PlGF-deficient mice show markedly reduced angiogenesis and tumor growth, whereas mice transplanted with PlGF-overexpressing glioma cells have enhanced endothelial cell survival and tumor progression. Moreover, transgenic mice over-expressing PlGF exhibit a rapid and important enlargement of inoculated tumors due to augmented vessel area. Altogether, these data assign to PlGF a significant role in supporting tumor angiogenesis. PlGF-induced tumor vessels show a reduced cover of mural cells, indicating that PlGF is no more able to sustain maturation of the newly formed vessels in the tumor environment.

It is commonly known that after cytotoxic therapy survived tumor cells rapidly expand again. A mechanism that permits recurrence consists of re-vascularization of the tumor lesion supported by tumor-produced angiogenic factors. By stimulation of vessel growth and survival, PlGF takes part to tumor recurrence. In fact, both PlGF and its receptor VEGFR-1 are up regulated in those cancer cells that survive cytotoxic treatment.

Tumor vascularization does not exclusively rely on sprouting and enrolment of pre-existing vessels, but also depends on mobilization from the bone marrow into the blood flood and recruitment at the tumor site of ►bone marrow-derived precursor cells (BMPC). PlGF is able to augment the amount of circulating BMPC. It is not presently clear the mechanism by which PlGF mediates BMPC mobilization from the bone marrow. It has been proposed that PlGF acts through activation of ►matrix metalloproteinase-9-dependent pathways. Preliminary evidences indicate that PlGF does not recruit BMPC to the tumor site but locally up-regulates the expression of other cytokines, such as the stromal cell-derived factor-1α, able to function as BMPC chemoattractants.

The presence of a microenvironment that fosters recruitment of BMPC has been revealed also at sites of future metastasis localization. VEGFR-1-expressing BMPC are mobilized from the bone marrow and recruited to distal organs to contribute in the formation of a ►premetastatic niche. Since PlGF is a specific activator of VEGFR-1 greatly involved in BMPC mobilization, it may take part to this early step of metastasis spreading, but no definitive proof has been given to support a direct contribution of PlGF in the formation of the premetastatic niche.

Augmented vessel area nearby the primary tumor facilitates cancer cells entering into circulation and dissemination of metastases. In a transgenic mouse model over-expressing PlGF, inoculation of tumor cells gives rise to increased metastasis formation. Metastases can spread to distant organs through invasion of the vascular and/or the lymphatic system. However, PlGF has no effect on ►lymphangiogenesis, thus PlGF-induced metastatic spreading mainly depends on angiogenesis and blood vessel invasion.

Besides its role in tumor angiogenesis, the most important feature of PlGF in cancer is that PlGF can directly promote invasiveness of VEGFR-1-expressing tumor cells. Melanoma cells stimulated *in vitro* with PlGF show a higher mobility rate that is dependent on VEGFR-1 activation. In fact, cell treatment with a function-blocking antibody against VEGFR-1 inhibits melanoma cell migration. PlGF also induces leukemia cell invasion in a VEGFR-1-dependent mode. The molecular mechanisms whereby PlGF stimulates tumor-cell migration and invasion have not been fully investigated, but cell treatment with PlGF increases the secretion of active matrix metallo-proteinase-2 and -9 that can contribute to ►extracellular matrix remodeling and facilitate cell movements.

Furthermore, VEGFR-1 expression on subsets of human tumor cells raises the possibility that PlGF promotes tumor growth both by inducing angiogenesis and by directly activating an autocrine signaling on tumor cells. Under cell culture conditions, PlGF induces proliferation of human melanoma and breast carcinoma cells.

Clinical Relevance

VEGF is widely recognized as an important regulator of tumor-induced angiogenesis, and a VEGF antagonist has been approved for clinical use in cancer treatment. Nevertheless, a number of recent data indicates that inhibition of VEGF signaling alone may not be sufficient to obtain regression of the disease and that PlGF is an additional factor that should be targeted as well. At present, the role of PlGF in cancer is supported only by preclinical data and specific compounds suitable for clinical trials have not been developed. However, it should be taken into account that inhibition of PlGF activity would significantly affects not only tumor angiogenesis but also metastasis formation. As PlGF is not significantly involved in physiological angiogenesis, targeting of this growth factor would not cause severe collateral effects. Therefore, a great effort has been asked to scientific community and pharmaceutical industries to push the development of specific anti-PlGF inhibitors.

Placental Site Trophoblastic Tumor

Ie-Ming Shih
Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

PSTT

Definition

Placental site trophoblastic tumor (PSTT) is a relatively uncommon type of gestational trophoblastic neoplasm that primarily occurs in the uterus. PSTT develops from neoplastic transformation of presumable trophoblastic stem cell and assumes a differentiation toward a specific type of trophoblastic cells, called intermediate (extravillous or interstitial) trophoblastic cells that are normally located in the placental site of the endometrium during a pregnancy. Thus, the "PSTT" is named for the tumor that arises from the placental site trophoblastic cells. As compared to other human cancers, PSTT is unique because the tumor is related to fetal tissue (i.e., trophoblastic cells from a placenta) but not to the patient's tissue. Like other gestational trophoblastic tumors (epithelioid trophoblastic tumor and choriocarcinoma), PSTT is considered as a "semiallograft" tumor in patients.

Characteristics

Clinical Features

- Patients with PSTT are usually of reproductive ages (mainly from 17 to 50 years) and present with either amenorrhea or abnormal vaginal bleeding, often accompanied by uterine enlargement.
- The preceding pregnancy history can be remote and the tumor can follow an abortion, a hydatidiform moles, or a term pregnancy.
- The serum β-hCG levels in PSTT patients usually elevate but are much lower than those in choriocarcinoma (100–2,000 μ/ml in PSTT vs. >10,000 μ/ml in choriocarcinoma).
- Most (70–80%) of the PSTTs behave in a benign fashion in which the tumor is confined to the uterus and simple hysterectomy or tumor resection is the treatment of choice. For the malignant PSTTs in which the tumor has locally invaded or distantly metastasized, chemotherapy may be required in conjunction with surgery. Metastases may develop several years after the initial diagnosis.
- The behavior of PSTT is difficult to predict since it has been demonstrated that no correlation exists between clinical outcome and molecular or morphological markers.
- With the use of dose-intensive chemotherapy, imaging techniques to define disease spread, surgery for localized disease and close surveillance with serologic measurement of β-hCG levels, most patients with PSTT are curable.

Pathological Features

On gross inspection most PSTTs are well circumscribed or polypoid, projecting into the uterine cavity or predominantly involving the myometrium. Invasion frequently extends to the uterine serosa but rarely to the adnexal structures. Under a microscope, PSTT is composed of neoplastic intermediate (extravillous) trophoblastic cells with morphology similar to trophoblastic cells in a normal placental site. The large and polygonal tumor cells infiltrate deep into the myometrium and insinuate themselves between smooth muscle fibers. The cells may be present singly, in nests or masses. PSTT is characterized by extensive deposition of fibrinoid material and a unique pattern of vascular invasion – replacement of the muscular wall of an artery by trophoblastic cells and fibrinoid material deposition.

Molecular Etiology

The molecular etiology of PSTT is largely unknown because of its rarity and lack of animal models for studies.

- The trophoblastic nature (fetal origin) of PSTT has been demonstrated by molecular genetic studies showing that the tumor contains new (paternal) alleles not present in adjacent normal uterine tissue.
- PSTT is associated with abnormal expression of cell cycle regulatory genes including cyclins, cyclin-dependent kinases, and p53.
- As compared to the normal extravillous (intermediate) trophoblastic cells in the implantation site, the majority of PSTTs overexpress the activated (phosphorylated) form of mitogen activated protein kinase (MAPK). The RAS/RAF/MEK/MAPK signaling pathway participates in various cellular activities including proliferation, differentiation, apoptosis, angiogenesis, and migration. It is likely that activation of MAPK contributes to the local invasion and distant metastasis in PSTTs.

Synonyms

Plasma cell neoplasm; Solitary plasma cell myeloma; Solitary bone plasmacytoma; SBP; Solitary extramedullary/extraosseous plasmacytoma; SEP

Definition

►Plasmacytoma (►PCT) refers to a solitary, localized, malignant, monoclonal plasma cell neoplasm that grows either in bone (►solitary bone plasmacytoma: SBP) or soft tissue (►solitary extraosseous or extramedullary plasmacytoma: SEP). PCT is a rare, curable cancer. Most patients are treated with moderate-dose radiotherapy. A subset of patients requires surgical intervention. Adjuvant chemotherapy is not indicated. The likelihood of local control after treatment is high. The most common pattern of relapse is systemic, indicating progression of PCT to ►multiple myeloma (MM). This is more likely to occur after treatment for SBP compared to SEP. The importance of the diagnosis PCT rests in large measure with the potential for this malignancy to progress to MM. An excellent current review of PCT recently updated with useful clinical observations is available [1,2].

Characteristics

Epidemiology: PCT is a rare form of cancer that affects fewer than 10% of patients with plasma cell neoplasms. Plasma cell neoplasms account for 1–2% of malignancies and occur at an overall rate of ~4.5 per 100,000 people per year. PCT is more common in males, with a male-to-female ratio of ~2:1 in case of SBP and ~3:1 in case of SEP. The median age of patients with PCT is 55 years, ~15 years younger than patients with MM. SBP develops into MM in 50–60% of patients, resulting in a median overall survival time of ~10 years. Progression of SEP to MM is less frequent (~20% at 10 years after diagnosis), leading to a higher survival rate (70% at 10 years) compared to SBP.

Etiology: Although no definitive cause for PCT has been identified, it is likely that the genetic and environmental factors associated with increased risk of MM also play a role in the etiology of PCT. Genetic risk factors for MM include gender (male preponderance), race (e.g., African Americans in the U.S. exhibit twice the incidence of U.S. whites) and age (median age at diagnosis is ~70 years). Clustering of MM in certain families points to a hereditary predisposition consistent with an autosomal dominant mode of inheritance. However, the underlying tumor susceptibility alleles or "MM genes" have not yet been identified. Ionizing radiation, a well-recognized leukemogen, has long been considered the strongest environmental risk factor for MM, yet it has not been possible, thus far, to confirm radiation as a definitive cause of MM. Associations of MM with (i) occupational exposure to various metals (nickel), chemical compounds (aromatic hydrocarbons, silicone, petrochemical industries), pesticides and animal viruses (farming), (ii) protracted infections that can lead to sustained immune stimulation of B lymphocytes with antigen (*Helicobacter pylori*, human herpesvirus-8), (iii) acquired immunodeficiency syndromes that can result in reduced immune surveillance by T lymphocytes (HIV/AIDS), and (iv) autoimmune diseases, such as rheumatoid arthritis, have also been proposed, but the evidence continues to be weak.

Pathogenesis: The natural history of PCT is complex and poorly defined. SBP and SEP share many

histopathologic, genetic and biologic features, including sheets of neoplastic plasma cells that produce monoclonal immunoglobulin; recurrent chromosomal translocations that involve the immunoglobulin heavy-chain locus, *IGH*, at 14q32; dependence on the plasma cell growth, differentiation and survival factor, interleukin 6 (IL-6); and a common global gene expression profile. Nevertheless, there are also major differences of SBP and SEP that point to a different tumor precursor (cell of origin) and pathway of neoplastic development. The above-mentioned epidemiologic differences of SBP and SEP in terms of tumor progression and overall survival support this view.

Just like MM, SBP is thought to be derived from an antigen-experienced isotype-switched post-germinal center B-lymphocyte that has undergone somatic hypermutation of the expressed immunoglobulin heavy and light chain genes. The clinical observation that SBP can be an intermediate step in the evolution from ►monoclonal gammopathy of undetermined significance (MGUS) to MM underlines the view that SBP and MM share a common pathway of neoplastic cell transformation. Pathogenetic factors implicated in MM are thus likely to be also important for SBP. Factors of this sort include cytogenetic and molecular genetic alterations that result in the deregulated expression of oncogenes, such as *CCND1* (encoding cyclin D1), *FGFR3* (fibroblast growth factor receptor 3) and *WHSC1* (Wolf-Hirschhorn syndrome candidate 1; also known as *MMSET* or multiple myeloma SET domain containing protein type III). The interaction of tumor cells with the bone marrow microenvironment, which leads to the production of cytokines, such as IL-6, insulin-like growth factor 1 (IGF-1), vascular endothelial growth factor (VEGF), stromal cell-derived factor 1α (SDF-1α), tumor necrosis factor-α (TNF-α) and transforming growth factor-β (TGF-β), is also of crucial importance.

Unlike MM, SEP is believed to arise from a B lymphocyte or plasma cell that resides in the mucosa-associated lymphoid tissue of the aerodigestive tract and has performed isotype switching. Most SEP express IgA. It is possible that isotype switching occurred outside the germinal center, without T-cell help, under the influence of microbial factors from the aerodigestive tract. But this has not been demonstrated. The molecular genetics of SEP including the cellular signaling pathways that govern growth, proliferation and survival of tumor cells is less well defined than the molecular genetics of its counterpart in the bone. Likewise, the interaction of SEP with the special microenvironment of the subepithelial mucosa is less well understood than the interaction of SBP/MM with the bone marrow. As mentioned above, SEP can progress to MM, albeit less frequently than SBP. The genetic and/or epigenetic changes underlying the switch from bone-avoiding SEP to bone-seeking MM are unknown.

Clinical Features: PCT can arise in any body part. Tissue biopsy shows monoclonal plasma cell histology. Bone marrow plasma cell infiltration does not exceed 5% of nucleated cells. Peripheral blood cell count, renal function and calcium are within the reference range. Serum or urine monoclonal protein (►M protein) is absent in more than half of patients or minimal in the majority of patients in which it can be detected. Levels of immunoglobulins not involved in the M spike are preserved. A rare occurrence is multiple solitary PCT, which, at first glance, sounds like an oxymoron. Nonetheless, this form of PCT exists, without evidence of MM, in up to 5% of patients with apparent SBP or SEP.

- SBP: The most common symptom is pain at the site of the skeletal lesion, which shows predisposition for the red marrow-containing axial skeleton. Compression fractures of the thoracic and lumbar vertebral bodies (spinal disease, observed in ~50% of cases) result in severe spasms, back pain, and nerve root or spinal cord compression. The latter represents an emergency requiring immediate attention to avoid permanent neurologic damage, including paraplegia, bowel and bladder dysfunction, and chronic pain. Occasionally, patients may present with peripheral polyneuropathy or features consistent with the syndrome of ►POEMS: polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes.
- SEP: Although extraosseous tumors occur in any tissue site, 80% of SEPs develop as head-and-neck tumors in the upper aerodigestive tract, especially in the paranasal sinuses, pharynx, nasal cavity, gums and oral mucosa. Patients with tumors involving the base of the skull may present with cranial nerve palsies. In one third of cases, local lymph nodes are involved at presentation.

Imaging Studies: Skeletal survey is preferred over bone scan, which is less sensitive for detecting bone lesions. Approximately 25–50% of bone trabeculae must be destroyed for a bone defect to be visible on a plain radiograph, where SBP classically exhibits a lytic appearance with clear margins and a narrow zone of transition to healthy surrounding bone. Rare occurrences of a cyst, a trabeculated lesion resembling a giant cell tumor or an aneurysmal bone cyst, and sclerotic lesions associated with ►POEMS syndrome have been described. Computed tomography (CT) is more sensitive for evaluating the extent of bone destruction. For SPB, magnetic resonance imaging (MRI) is helpful to monitor the treatment response. In most cases of SEP with nasal cavity or maxillary sinus involvement, radiographic assessment shows local bone destruction.

Treatment: The treatment of choice for SBP is moderate-dose radiotherapy (40 Gy for spinal lesions

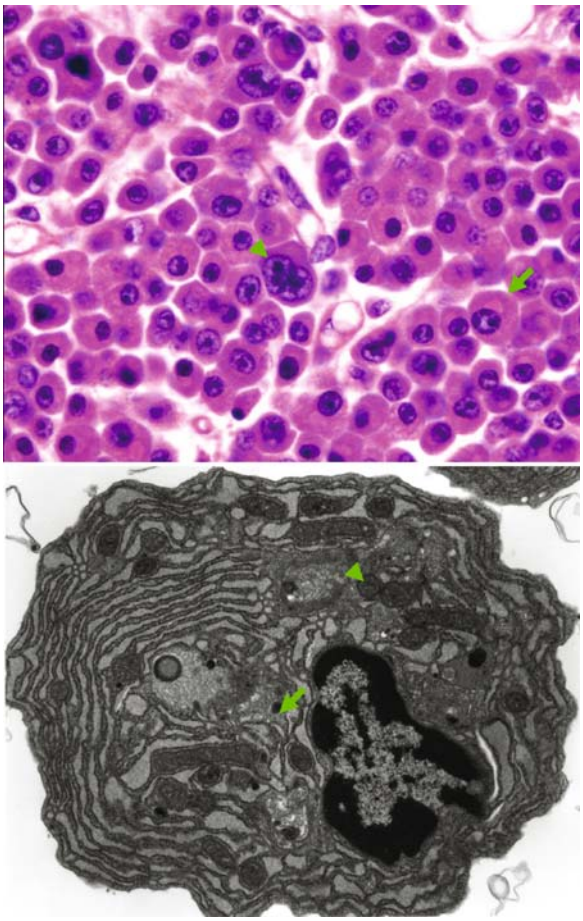
and 45–50 Gy for other bone lesions) administered once daily at 1.8–2.0 Gy per fraction in a continuous course. Virtually all patients have major symptom relief. Local tumor recurrence is ~10%. Surgery is contraindicated in the absence of structural instability or neurologic compromise. Chemotherapy using regimens proven in MM may be considered for patients not responding to radiation therapy. No role exists for adjuvant chemotherapy. In case of SEP, the accepted treatment is radiotherapy, surgery when a lesion can be completely resected, or combined surgery and radiotherapy, which may provide the best results. Chemotherapy may be considered for patients with refractory or relapsed disease. As an exception to the general rule that adjuvant chemotherapy is not indicated in PCT, this therapy may be considered for the subset of patients with positive surgical margins after resection or tumors larger than 5 cm and exhibiting high-grade histology.

Follow-up Outpatient Care: For both SBP and SEP, periodic evaluation for progression and development of MM is recommended every 6 weeks for the first 6 months, with extension of clinic appointments thereafter. Besides a complete physical examination, the following tests are recommended: complete blood cell count; complete metabolic panel with lactic dehydrogenase, calcium, phosphorus, ►C-reactive protein (CRP), and ►β2 microglobulin; sedimentation rate; serum ►protein electrophoresis with immunofixation; serum immunoglobulin quantification; urinary protein electrophoresis with immunofixation; and skeletal bone survey. Orthopedic and/or ear–nose–throat follow-up is recommended for SBP and head-and-neck SEP, respectively.

Prognosis: SBP progresses to MM in the majority of patients, with the median onset of conversion ranging from 2 to 5 years. Ten-year disease-free survival has been reported to range from 15 to 45%. Overall median survival is 10 years. In SEP, the rate of progression to MM is lower compared to SBP, ranging from 10 to 30% at 10 years after diagnosis. The 10-year overall survival rate is 70%. Thus, the prognosis of SEP is better than that of SBP.

Medical and Legal Pitfalls: Failure to diagnose spinal cord compression syndrome or impending pathologic fractures can cause irreversible neurologic damage. Inappropriate follow-up or failure to evaluate progression to MM delays institution of appropriate therapy to control the well-known systemic complications of this invariably fatal malignancy. These complications include generalized bone destruction, hypercalcemia, anemia, hyperviscosity, infections, and amyloid.

Basic Research: PCT occurs not only in human beings but also in mammals including mice (Fig. 1). The laboratory mouse is the ideal model organism for research studies on the biology and pathogenesis of PCT, because mice are prolific, easy to maintain and genetically defined. Importantly, mice are genetically manipulable using gene targeting and other methods, which afford an opportunity to accurately recapitulate genetic changes of human PCT in transgenic mice. Indeed, mouse models of human PCT are enhancing our understanding of the role of oncogenes, tumor suppressors, cytokines and environmental co-factors of oncogenesis provided by the bone marrow stroma,



Plasmacytoma. Figure 1 Histo- and cytomorphology of plasmacytoma (PCT). Shown at the top is a photomicrograph of a histological section of a mouse PCT that developed in the gut-associated lymphoid tissue of a BALB/c mouse harboring a widely expressed human interleukin-6 (IL-6) transgene. Neoplastic plasma cells are rich in cytoplasm and have a single, eccentric nucleus that contains clumped chromatin, forming in some cases the characteristic wheel spoke-like pattern (*arrow*). A large, atypical, binucleated tumor cell is located in the center (*arrowhead*). Depicted at the bottom is an electron micrograph of a neoplastic plasma cell from the same tumor. The cell nucleus (*arrow*) contains euchromatin in the center (*light grey*) and heterochromatin attached to the nuclear membrane (*black*). The abundance of rough endoplasmic reticulum (*arrowhead*) in the cytoplasm indicates that PCT cells produce copious amounts of monoclonal immunoglobulin.

inflammatory cells, and the innate and adaptive immune system. Two widely used mouse models of SBP and SEP have been developed in strains C57BL/6 and BALB/c, respectively.

Plasmin

Definition

Serine proteinase circulating in the blood stream which degrades many plasma proteins. Its most important function is the degradation of ►fibrin clots. It is secreted in its pro-form, plasminogen, which is activated by ►tissue-type plasminogen activator (tPA), urokinase-type plasminogen activator (uPA), thrombin, plasmin, and ►factor XII. Elevated levels of uPA are found in advanced breast cancer tissues.

►Proteinase-Activated Receptors

Plasminogen Activating System

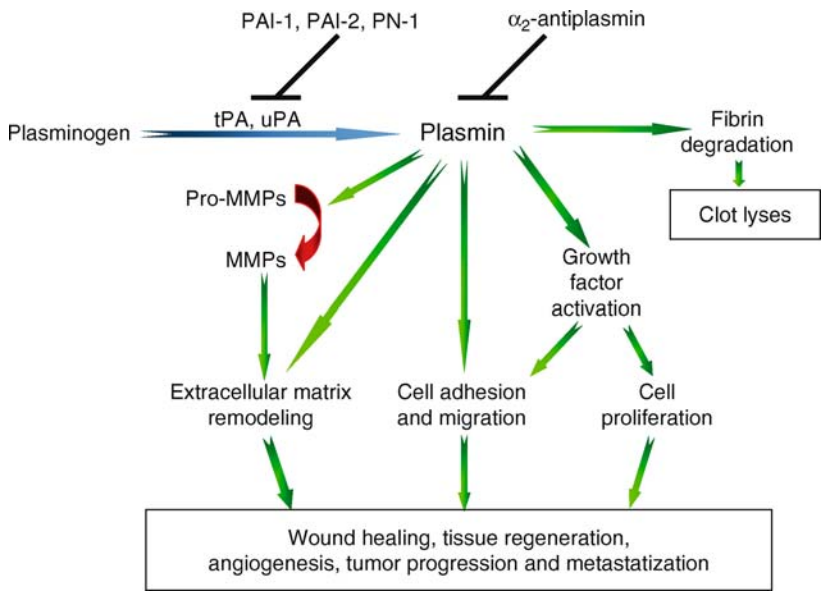
Salvatore Ulisse, Enke Baldini, Sarah Bocchini, Massimino D'Armiento
Department of Experimental Medicine, University of Rome "Sapienza", Rome, Italy

Definition

The plasminogen activating system (PAS) consists of two immunologically distinct serine proteases, the urokinase plasminogen activator (uPA) and the tissue-type plasminogen activator (tPA), their specific inhibitors, the plasminogen activator inhibitor 1 (PAI-1) and 2 (PAI-2) and the protease nexin-1 (PN-1), which belong to the serine protease inhibitor superfamily of serpins, and the glycolipid-anchored cell membrane receptor for the uPA. The two plasminogen activators convert, in the extracellular environment, the proenzyme plasminogen into the serine protease plasmin. The latter is involved in fibrin degradation during clot lysis and in a number of physiological and pathological processes requiring basement membrane (BM) and/or ►extracellular matrix (ECM) ►remodeling, such as wound healing, mammary gland development and its postlactational involution, tissue regeneration, ►angiogenesis, tumor ►progression, and metastatization (Fig. 1). Beside fibrin, in fact, plasmin may directly degrade several ECM and BM components, including laminin, vitronectin, type IV collagen, and proteoglycans, and may also activate latent ►matrix metalloproteinases (MMPs). Physiological inhibition of the plasminogen activating system may occur either at the level of plasmin by α_2-antiplasmin, or at the level of the two plasminogen activators, tPA and uPA, by PAI-1, PAI-2, and PN-1 (Fig. 1).

Characteristics

Plasminogen conversion to plasmin into the blood circulation during clot lysis is mostly due to the action of tPA, while uPA plays a major role in ECM remodeling at the tissue level. The uPA is secreted from the cells as a single chain proenzyme (pro-uPA or sc-uPA) able to bind to a specific cell membrane glycolipid-anchored receptor, the uPA receptor (uPAR) (Fig. 2). The membrane-bound pro-uPA may be converted into the active uPA, a two-chain molecule held together by a single disulfide bridge (tc-uPA), by the



Plasminogen Activating System. Figure 1 Schematic representation of the major biological processes involving the plasminogen activating system. action of different enzymes, including plasmin, cathepsin B, and kallikrein. In view of the fact that also plasminogen may bind to plasma membrane receptors, the occurrence in the same cells of both uPAR and plasminogen receptors may result in the formation of cell membrane-associated plasmin, leading to a localized pericellular ECM degradation. As mentioned, uPA activity is inhibited by PAI-1, PAI-2, and PN-1, which interact with active uPA either in solution or bound to the uPAR. In the latter case, the complex is rapidly internalized by the cells, leading to the degradation of both uPA and its inhibitor, while the uPAR is recycled to the cell membrane (Fig. 2).

The Plasminogen Activating System in Cancer Progression

An efficient ECM and BM degradation, achieved through the action of different proteolytic enzymes, is required for cancer invasion and dissemination. Several evidences, obtained using different experimental models, indicate that PAS, especially the uPA/uPAR complexes, plays a relevant role in this process. In fact, it has been demonstrated that lung ►metastasis of different ►melanoma-derived cell lines inoculated in nude mice, positively correlated with cancer cell uPA expression, and that overexpression of uPA in ►prostate cancer cells, following transfection with uPA cDNA, increased skeletal metastasis in vivo. Also, inhibition of uPA activity by low molecular weight inhibitors or antibodies, as well as inhibition of uPA or uPAR expression by antisense oligonucleotides, induced a decreased tumor growth and metastasis.

The main function of PAS, along with members of the MMPs family, was originally thought to be limited to the degradation of ECM and BM required for local diffusion and spread to distant sites of malignant cells as well as for tumor angiogenesis. However, it has become increasingly clear that PAS affects also multiple aspects of the neoplastic evolution, including tumor cell proliferation, ►adhesion and ►migration, intravasation and growth at the metastatic site (Fig. 1). In particular, uPA, directly or through the generation of plasmin,

P

promotes cell proliferation and tumor neoangiogenesis by activation or release of several growth factors, including epidermal growth factor (EGF), ►insulin-like growth factor (IGF), ►transforming growth factor-β (TGF-β), basic ►fibroblast growth factor (bFGF), hepatocyte growth factor (HGF), and ►vascular endothelial growth factor (VEGF). Moreover, uPAR, following uPA binding, may affect cell proliferation and other cellular functions by triggering intracellular signaling, leading to the activation of tyrosine and serine protein kinases (i.e., lymphocyte protein tyrosine kinase, lck; hematopoietic cell kinase, Hck; focal adhesion kinase, FAK, and mitogen-activated protein kinase, ►MAPK). Since uPAR lacks transmembrane and cytosolic domains, the activation of the intracellular signaling is realized through its interaction with at least three different transmembrane proteins, which include members of the integrins adhesion receptor superfamily, G-protein coupled receptor (GPCR), and caveolin.

The occurrence of metastasis implies the ability of malignant cells to migrate from the primary site to distant places. Cell migration initiates with the extension of the plasma membrane at the leading edge of the cell, to which corresponds an intracellular reorganization and polymerization of new actin filaments. The latter are then stabilized by the formation of new adhesions to ECM components. At the same time, at the rear or trailing edge of the cells, plasma membrane releases its binding to ECM. Thus, consecutive cycles of attachment and detachment from ECM substrates take place during cancer cell migration. Several reports demonstrated the ability of PAS to affect this process and the involved molecular mechanisms include: (i) ECM proteolysis at the leading edge of the cell allowing plasma membrane extension; (ii) ECM-cell adhesion receptor degradation causing the release of the trailing edge of the cell; (iii) activation of motogenic growth factors such as HGF, bFGF and TGF-β; and (iv) modulation of new cell adhesion to ECM. Regarding the latter, experimental evidences suggest that binding of uPA to its cognate receptor induces conformational changes in uPAR increasing its affinity for the ECM component vitronectin. The uPAR/vitronectin interaction, however, occurs only in presence of low levels of PAI-1. In fact, if the concentration of PAI-1 exceeds that of uPA, then the inhibitor will displace uPAR binding to vitronectin causing the release of the cell from the ECM. In addition, PAI-1 inhibits the binding of vitronectin to integrins receptors and reduces cell migration.

Clinical Significance of PAS Components Expression in Cancer

Consistent with their role in cancer progression and metastasis, a marked increase in the expression of uPA, uPAR, and PAI-1, with respect to normal counterpart tissues, has been observed in malignant tumors. For example, in breast cancers, the expression of uPA and uPAR has been shown to be upregulated approximately of 5- and 19-fold, respectively, compared with normal or benign tumor tissues. Similarly, in thyroid papillary carcinoma the upregulation of uPA and uPAR expression by more than fourfold, with respect to normal matched thyroid tissues, has been documented.

Different clinical studies demonstrated that high tumor tissue levels of uPA and its cognate receptor uPAR correlate with a poor prognosis in several malignancies including leukemia, breast, lung, brain, esophageal, gastric, pancreatic, colorectal, hepatocellular, endometrial, ovarian, kidney, and bladder cancers. Paradoxically, high levels of PAI-1 expression, considered the primary inhibitor of uPA, are also associated with more aggressive diseases and poor prognosis in several types of cancer. Different hypotheses have been proposed to explain these observations, including an essential role of PAI-1 in tumor angiogenesis, in cancer cells adhesion, migration, and inhibition of apoptosis.

The clinical relevance of PAS component expression is particularly evident in ►breast cancer, in which the prognostic value of uPA, uPAR, and PAI-1 cancer tissue expression has been exhaustively investigated. Indeed, the prognostic value of breast tumor tissue uPA expression was first described in 1988, when it was demonstrated that patients with breast tumors containing a high level of uPA activity had a significantly shorter disease-free interval, compared to patients with low level of tumor-associated enzyme activity. This initial observation was then confirmed in several large case studies, demonstrating that uPA is the most potent independent prognostic factor, in terms of overall survival and/or disease-free interval, described to date, with a predictive value stronger than those of patient age, tumor size, estrogen and progesterone receptors, ►HER-2/neu or ►p53 expression. High levels of PAI-1 are also associated with adverse outcome in breast cancer patients and it has been demonstrated that it represents an independent prognostic factor. Moreover, the concomitant assay of both uPA and PAI-1 possess a greater prognostic value with respect to that of each marker alone. Therefore, both uPA and PAI-1 are now candidate molecular markers for routine clinical use in patients with breast cancer.

PAS as Target for Anticancer Therapy

The involvement of PAS in cancer progression and the observation that its inhibition is devoid of toxicity, as demonstrated in uPA or uPAR-deficient mice, identify the PAS inhibition as a suitable target for anticancer therapies. The first evidence showing that uPA inhibition could be effective in preventing cancer metastasis was reported in 1983. In this study, it was demonstrated that antibodies which inhibit uPA

activity prevent metastasis from the human epidermoid carcinoma cell line Hep3 in the chick chorioallantoic membrane system. Since then, different therapeutical strategies have been designed to inhibit the uPA/uPAR function, including selective inhibitors of uPA activity, antagonist peptides and monoclonal antibodies able to prevent uPA binding to uPAR, antisense or gene therapy reducing uPAR expression and peptides that inhibit uPAR/integrins interaction, thus preventing uPAR-mediated cell signaling and adhesion. These approaches have demonstrated, in xenographic animal models, antitumor effects, including a reduction in local tumor growth and cancer dissemination. However, these new anticancer therapeutical strategies, although promising, need definitive confirmation in humans and, up-to-date, only one uPA inhibitor, the WX-UK1 (Wilex AG, Munich, Germany) entered clinical trial, the results of which are still awaited.

Platelet-Derived Growth Factor

Carl-Henrik Heldin
Ludwig Institute for Cancer Research, Uppsala, Sweden

Definition

Platelet-derived growth factor (PDGF) is a family of growth-factors with mitogenic activity for connective

tissue cells, such as fibroblasts and smooth muscle cells, as well as for certain other cell types.

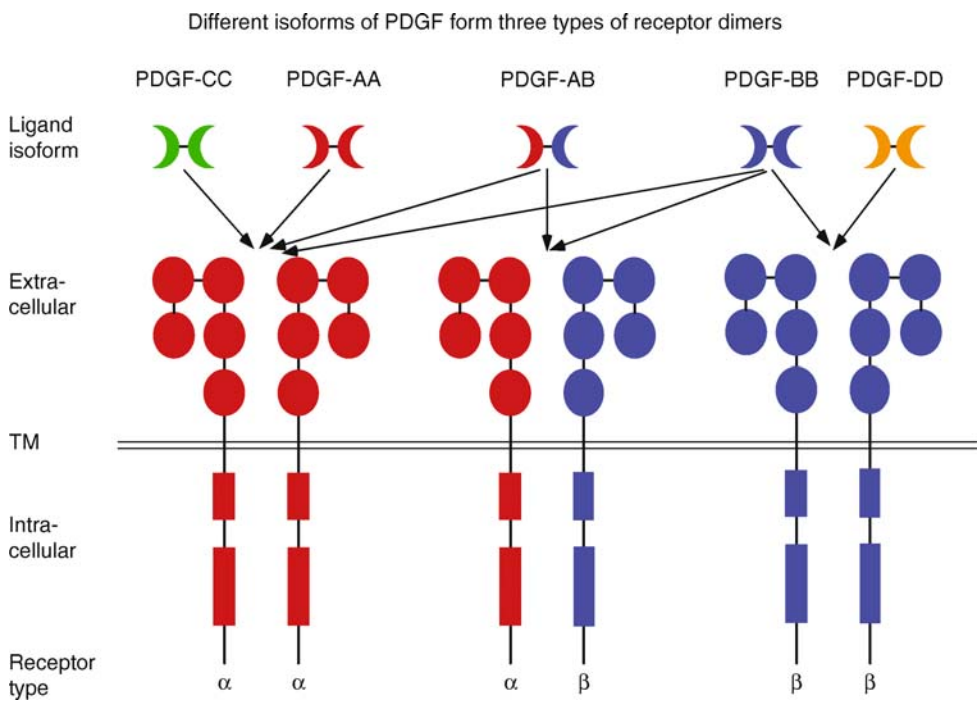
Characteristics

PDGF isoforms are disulfide-bonded homodimers of homologous A-, B-, C- and D-polypeptide chains, as well as a heterodimer PDGF-AB. PDGF A- and B-chains are proteolytically processed during secretion from the producer cell, whereas PDGF C- and D-chains are secreted as inactive precursors containing N-terminal ►CUB domains that need to be cleaved off before these isoforms can bind to receptors. The mature growth factor domain has about 100 amino acid residues with a perfect conservation of 8 cysteine residues. The two subunits in the dimers are arranged antiparallel. In addition to the two interchain disulfide bonds, each subunit contains six additional cysteine residues that are arranged in a characteristic cystine knot structure. The amino acid sequences of PDGF chains are homologous to those of vascular endothelial cell growth factors (►vascular endothelial growth factor).

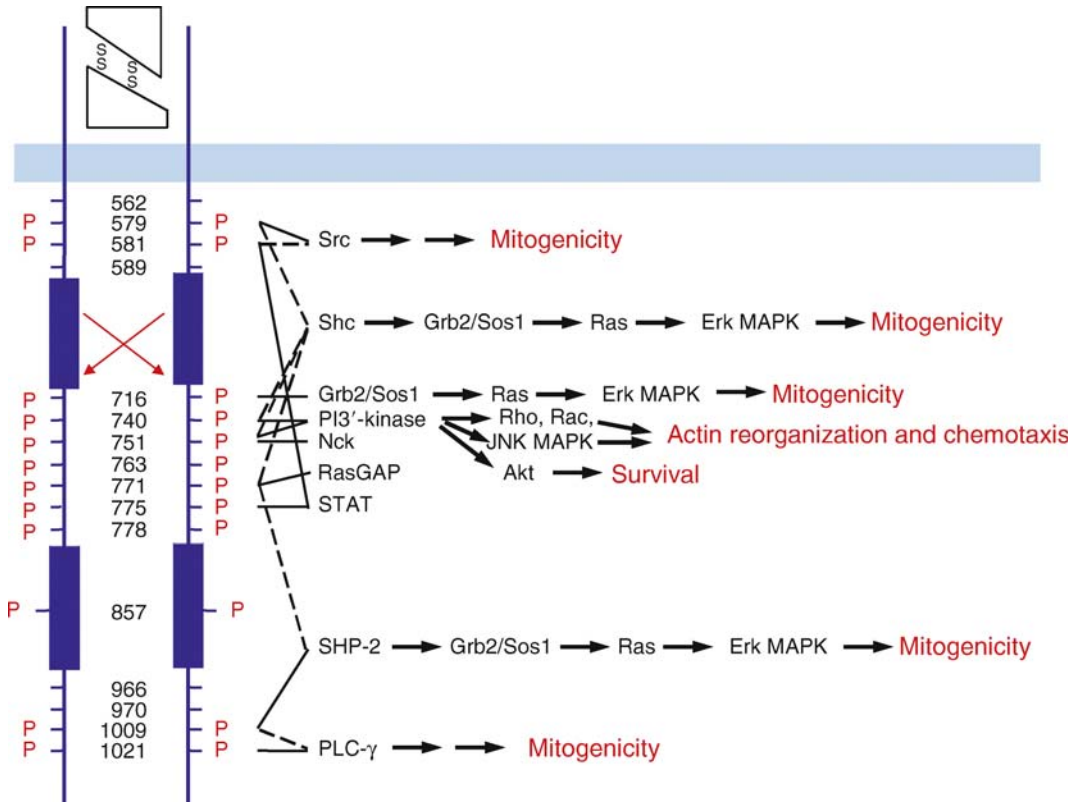
PDGF isoforms exert their cellular effects via binding to two structurally related protein tyrosine kinase receptors (►receptor tyrosine kinase), denoted α- and β-receptors. The A-, B- and C-polypeptide chains binds with high affinity to α-receptors, whereas B- and D-polypeptide chains bind to β-receptors (Fig. 1). The dimeric PDGF isoforms bind two receptor molecules simultaneously; receptor dimerization leads to juxtaposition of the kinase domains of the receptors, whereby they phosphorylate each other in *trans*. The "autophosphorylation" activates the receptor kinases and initiates intracellular ►signal transduction by recruitment of ►SH domain (SH2/SH3 domain) containing signal transduction molecules. Thereby several signal transduction pathways are initiated, ultimately leading to cell proliferation, cell migration, changes in cell morphology and inhibition of cell death (Fig. 2). Intracellular cell signaling is characterized by extensive cross-talk between different signaling pathways. Moreover, stimulatory and inhibitory pathways are often induced in parallel.

Genes

The PDGF A-, B-, C- and D-chain genes are localized on chromosomes 7, 22, 4 and 11, respectively. In all genes, the first exon encodes untranslated sequences and the signal sequence. In the A- and B-chain genes, the second and third exons encode N-terminal sequences that are removed during proteolytic processing, the fourth and fifth exons encode most of the mature parts of the proteins, and exon 7 is mainly noncoding. Exon 6 encodes C-terminal sequences that in the case of the B-chain may be removed during processing. The A-chain occurs as two different splice forms, with and without the exon 6 sequence. Since the exon 6 sequence contains a stretch of basic amino acid



Platelet-Derived Growth Factor. Figure 1 Binding of PDGF isoforms to α- and β-tyrosine kinase receptors.



Platelet-Derived Growth Factor. Figure 2 Ligand-induced dimerization of the PDGF β-receptor, followed by autophosphorylation and docking of SH2-domain-containing signaling molecules. The importance of individual signaling pathways for the effects of PDGF in cell growth, survival, migration and actin reorganization, is depicted.

residues that bind to extracellular matrix molecules, the absence or presence of the exon 6 sequence affects the localization of PDGF. In the C- and D-genes, exons 2 and 3 encode the CUB domain, exon 4 (exon 4 and 5 for the D-chain gene) encodes a linker region, and exon 5 and 6 (6 and 7 for the D-chain gene) encode the growth factor domain.

Bioactivity

Sequencing of PDGF revealed that the B-chain is almost identical to the v-Sis ►oncogene product, the transforming protein of simian sarcoma virus. Subsequent studies have shown that transformation of cells by the simian sarcoma virus occurs via autocrine stimulation involving a PDGF-like growth factor.

The demonstration that overactivity of PDGF had transforming effects prompted studies on the expression of PDGF in human tumors. PDGF was found to be commonly expressed in glioblastomas and sarcomas, tumors derived from cell types normally expressing receptors, suggesting ►autocrine stimulation of growth.

PDGF is expressed also by several cancers that are derived from cell types that do not express PDGF receptors. Such tumor-derived PDGF has been shown to be involved in a ►paracrine manner in the formation of supporting connective tissue cells that surrounds the tumor cells. PDGF stimulation of connective tissue cells in the stroma also contributes to the increased interstitial fluid pressure of tumors, which causes a decreased uptake of drugs into the tumor and precludes efficient chemotherapy of tumors. PDGF has also been shown to have an angiogenic activity (►angiogenesis), through direct effects on capillary endothelial cells, as well as indirectly through the recruitment of supporting pericytes that reinforce the walls of the newly formed vessels.

Clinical Relevance

The normal function of PDGF is to promote the development of different kinds of connective tissue cells during embryonal development. Often PDGF is produced by different epithelial cell types and acts on neighboring connective tissue cells expressing PDGF receptors. In the adult PDGF stimulates wound healing, and topically applied PDGF-BB (becaplermin) has been shown in clinical trials to increase the rate of healing of different types of wounds. PDGF also

regulates the interstitial fluid pressure in connective tissue. PDGF released from platelets may also exert a negative feed back control of platelet aggregation; binding of PDGF to α-receptors on platelets inhibits platelet aggregation.

The important function of PDGF in the development and homeostasis of connective tissue suggests that overactivity of PDGF may result in fibrotic reactions. In support of this notion, overexpression of PDGF has been shown to be involved in glomerulonephritis, liver cirrhosis, myelofibrosis and lung fibrosis. The stimulating effect of PDGF, released from platelets or secreted from macrophages, on smooth muscle cells at sites of injury to the endothelial cell layer of arteries, also contributes to the intimal hyperplasia seen in atherosclerotic reactions. In malignancies, PDGF may be involved in autocrine stimulation of tumor cell growth as well as in ►paracrine stimulation of cells in blood vessels and fibroblasts in the stromal compartment. Certain tumor types show specific perturbations in PDGF signaling pathways through mutations of genes for PDGF isoforms or PDGF receptors, including dermatofibrosarcoma protuberans (fusion of the genes for PDGF B-chain and collagen 1α1), chronic myelomonocytic leukemia and hypereosinophilic syndrome (fusion of genes for PDGF α- or β-receptor with different other genes), gastrointestinal stromal tumor (►gastrointenstinal tumor) (point mutation in the PDGF α-receptor gene), and glioblastoma (amplification of the PDGF α-receptor gene) (►brain tumor).

The involvement of PDGF in several serious disorders including malignancies makes PDGF antagonists highly warranted. Several types of such antagonists have been developed, including molecules that bind PDGF and prevent it from binding to its receptors, e.g. antibodies, soluble extracellular domains of receptors (e.g. ►STI571 or ►imatinib) or ►DNA ►aptamers, as well as low molecular weight inhibitors of the receptor kinase.

Definition

In 1844 Michele Peyrone synthesized cisplatin (*cis*-platinum(II)-diammine-dichloride, CDDP) without

being aware of its tumor-inhibiting effect. Not until the mid-1960s Barnett Rosenberg discovered the inhibition of cell division in the presence of cisplatin. Due to its outstanding effectiveness in treating numerous tumors, cisplatin became the prototype for a new class of antineoplastic substances. Meanwhile it has become one of the most frequently used cytotoxic drugs in tumor therapy. However, its use is limited due to its side effects and the development of resistance which has led to the search for new platinum complexes.

Most of the platinum complexes are uncharged *cis* configurated square-planar platinum(II) complexes that can be described by the general formula *cis*-[PtA_2 X_2], with A_2 as either two monodentate or one bidentate stable amine ligand(s) and X_2 as two monodentate or one bidentate anionic leaving ligand(s). Octahedral platinum(IV) complexes, which are now under development, can be described by the general formula *cis*-[PtA_2 X_2 Y_2] with Y_2 as monodentate anionic leaving ligands. The advantage of platinum(IV) complexes is the possibility of oral administration due to their increased stability and solubility in the gastrointestinal tract.

Characteristics

In the following paragraphs the processes taking place after the administration of ►cisplatin are described. Different characteristics of other platinum complexes are outlined in the section "Approved platinum complexes."

Mode of Action

Bioactivation

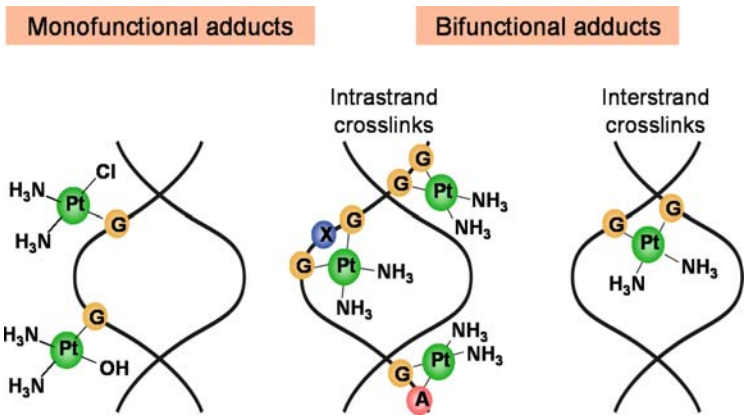
After intravenous administration a high amount of cisplatin is bound to plasma proteins and thereby inactivated. Because of the high extracellular chloride ion concentration (~100 mM), free cisplatin exhibits relatively low reactivity in the plasma. After entering the cell containing low chloride ion concentrations (~4 mM) reactive monoaqua and diaqua complexes are formed by exchange of the chloride ligands. Upon activation, cisplatin is able to form complexes with a variety of macromolecules present in the cell.

Formation of Platinum-DNA Adducts

The cytotoxic effect is mainly a consequence of the formation of platinum–DNA adducts. The primary target is the N^7 position of the purine bases due to the high nucleophilicity of the imidazole ring. Beside monoadducts, cisplatin forms bifunctional 1,2- or 1,3-intrastrand crosslinks and interstrand crosslinks (Fig. 1).

Cellular Response

1. Inhibition of DNA synthesis
   As a result of the structural change of the DNA helix binding of DNA polymerases is hampered inhibiting replication and transcription.
2. DNA repair mechanisms
   Platinum–DNA adducts are mainly repaired by ►nucleotide excision repair (NER). Due to the small substrate specificity of this repair system, it is unlikely that platinum–DNA adducts of structurally different platinum complexes are differentiated. A complete removal of the DNA damage is not possible in this way because of the limited capacity of the NER. Furthermore, adducts can be bypassed by some DNA polymerases. This translesion DNA synthesis – the so-called replicative bypass (►post replicative repair) – allows the cells to progress through the S-phase of the cell cycle.
   The ►mismatch repair (MMR) system is an important prerequisite for the cytotoxic activity of cisplatin. Base-pair mismatches are recognized and repaired by MMR proteins. The DNA strand previously synthesized is cut out and the DNA is again synthesized beyond the damaged sites entering



Platinum Complexes. Figure 1 Formation of platinum–DNA adducts.

in a vicious cycle. In the long term, these futile repair attempts lead to an induction of apoptosis. Thus, deficiency of MMR is associated with cisplatin resistance (see below).

3. Binding of HMG-proteins and transcription factors
   The disturbance of the DNA structure results in the binding of different proteins. Among them ►high mobility group box proteins– such as HMGB1 – protect platinum–DNA adducts against repair proteins by building stable bonds. Many HMG box proteins are transcription factors and partly exhibit a higher affinity for the platinated DNA than for their natural substrate. The transcription factors are intercepted by the platinum–DNA adducts, therefore the transcription is inhibited. This phenomenon is called "transcription factor hijacking."
4. Induction of ►apoptosis and necrosis
   The DNA damage caused by cisplatin triggers ►apoptosis and necrosis (Fig. 2).
   Among others, the following ways of apoptosis are being discussed:
   - The ►p53-dependent mitochondrial apoptosis with subsequent activation of ►caspase 9 and ►caspase 3
   - The ►Fas/Fas ligand (FasL)- and ►caspase-8-mediated apoptotic cascade
   - Activation of c-Abl tyrosine kinase and subsequent activation of p73 (►p53 genes family)
   - Mitogen-activated protein kinase (►MAPK) pathways

   Necrosis occurs following excessive DNA damage, which induces hyperactivation of poly(ADP-ribose) polymerase (PARP). PARP causes ATP/NAD^+ depletion leading to necrotic cell death.

Mechanisms of Resistance

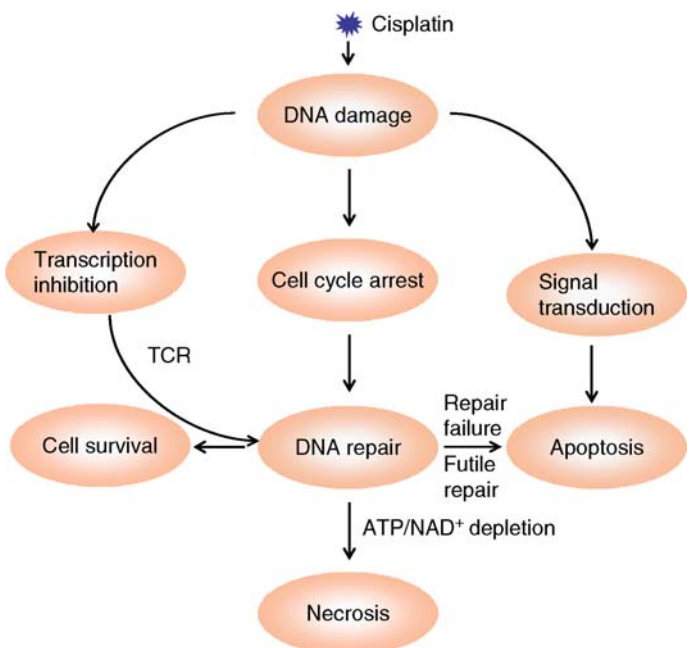
Resistance can be intrinsic or acquired by chronic drug exposure. The resistance to cisplatin is multifactorial, different resistance mechanisms may develop in parallel. Four principles of resistance mechanisms can be distinguished.

Reduced Accumulation

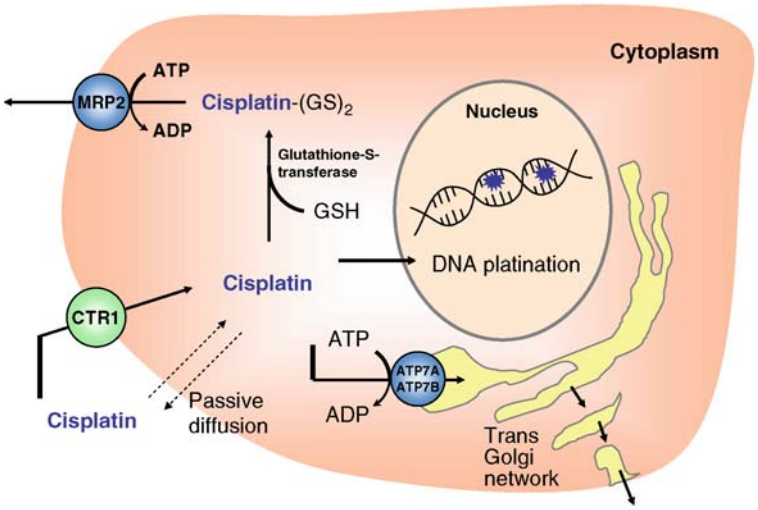
After exposure to platinum complexes, a decreased influx, an increased efflux, or a combination of both phenomena was observed. Previously, it has been assumed that platinum complexes enter the cell primarily by passive diffusion (Fig. 3). During the last decade a link between copper transporters (CTR1, ATP7A, ATP7B) and platinum influx and efflux has been discovered in numerous studies. Recent results furthermore indicate an involvement of organic cation transporters (OCT). Platinum resistance may develop by upregulation of efflux or downregulation of influx transporters.

Increased Inactivation

Platinum complexes react to a great extent with intracellular molecules that contain thiol groups, e.g.,



Platinum Complexes. Figure 2 Cell death pathways activated in response to cisplatin (modified from [5]). TCR, transcription-coupled repair.



Platinum Complexes. Figure 3 Mechanisms of cisplatin influx, efflux, and detoxification. CTR1, copper transporter 1; ATP7A, adenosine triphosphate alpha-polypeptide; ATP7B, adenosine triphosphate beta-polypeptide; MRP2, multidrug resistance protein 2.

glutathione (GSH) or metallothionein. Only a relatively small fraction of the intracellular cisplatin binds to the genomic DNA, however, more than 60% is bound to GSH. The conjugate is biologically inactive. The platinum–GSH complex can be removed from the cell by the transporter MRP2 (Fig. 3). In addition, the formation of crosslinks between platinum–DNA monoadducts and the opposite DNA strand can be prevented by reaction of the thiol-containing molecules and the monoadducts. An increased intracellular GSH production can contribute to the development of resistance.

Increased Adduct Tolerance and Failure of Apoptotic Pathways

An increase of the replicative bypass leads to an increased adduct tolerance as well as to a high mutation rate, whereby changes, which lead to subsequent development of resistance, are favored. Defects in the MMR system prevent the beginning of futile repair cycles, hence contributing to resistance.

The complex cascades of apoptosis offer a further starting point for the development of resistance. Many factors can be changed: Examples are the loss of p53 function, reduced activity of caspases, or a deregulated MAPK pathway.

Increased Repair

A general resistance mechanism is an increased repair by the NER system. The capacity of this kind of resistance mechanism seems, however, to be limited.

Approved Platinum Complexes

The chemical structures of approved platinum complexes are shown in Fig. 4.

Cisplatin

Indications. FDA labeled indications: Metastatic malignant tumor of testis, metastatic ovarian tumor and advanced transitional cell carcinoma of bladder. Furthermore one finds a broad range of non-FDA labeled indications.

Adverse Effects. Relevant and dose-limiting side effects are nephrotoxicity, ototoxicity, emesis, and neurotoxicity.

Carboplatin

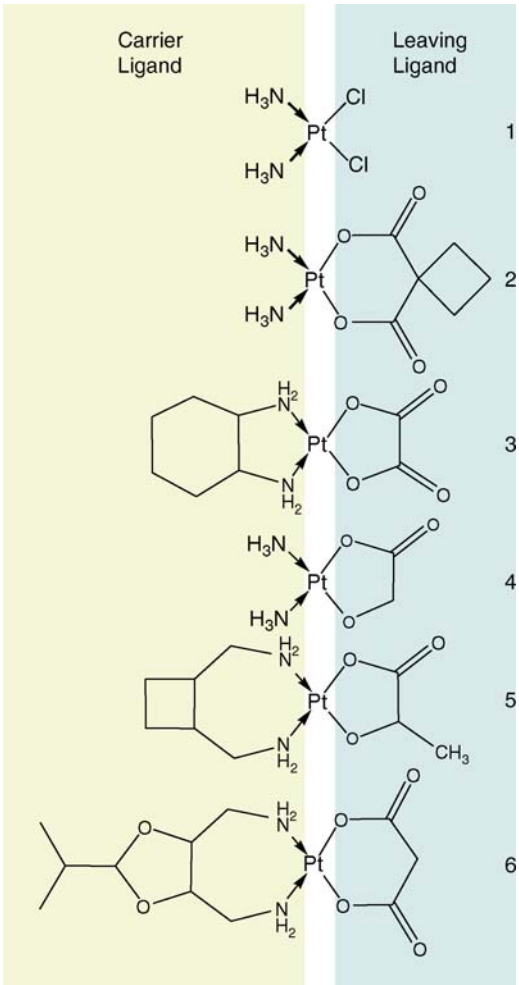
Characteristics. By the exchange of the labile chloro ligands for cyclobutan-1,1-dicarboxylate, water solubility and stability were increased compared to cisplatin, the toxicity was decreased. However, cisplatin and carboplatin show crossresistance, which points to a similar mechanism of action.

Indications. FDA labeled indication: Advanced ovarian cancer. Carboplatin is approved worldwide for the treatment of many other tumors.

Adverse Effects. The only dose-limiting side effect is myelosuppression. Among the serious side effects are an imbalance of electrolytes, a peripheral neuropathy and a less-common visual disturbance.

Oxaliplatin

Characteristics. Oxaliplatin shows another spectrum of efficacy and resistance. The oxalate ligand as the leaving group leads to a slightly reduced reactivity compared to cisplatin. The bulky 1,2-diaminocyclohexane (DACH) ligand is probably responsible for the improved water solubility as well as the changed profile of activity. Using equimolar and equitoxic concentra-



Platinum Complexes. Figure 4 Approved platinum complexes: cisplatin (1), carboplatin (2), oxaliplatin (3), nedaplatin (4), lobaplatin (5), heptaplatin (6).

tions of cisplatin and oxaliplatin, it was noted that the extent of DNA platination is substantially lower after treatment with oxaliplatin. However, the rate of single strand breaks is higher. The replicative bypass is probably disturbed by the bulky DACH ligand leading to an increased single strand break rate and enhanced cytotoxicity. An intact MMR system does not seem to be essential for the cytotoxic effect of oxaliplatin, because the DACH ligand prevents the attachment of the MMR proteins. These changes in the repair mechanisms are a possible explanation for the absence of crossresistance to cisplatin. Oxaliplatin is effective in the treatment of metastatic colon carcinoma, which exhibits intrinsic resistance to cisplatin and carboplatin.

Indications. FDA labeled indications: Colon cancer and advanced colorectal cancer.

Adverse Effects. The crucial and dose-limiting toxicity of oxaliplatin is peripheral sensory neuropathy. Myelosuppression is low. Neither ototoxicity nor nephrotoxicity has been observed.

Nedaplatin

Characteristics. The complex contains glycolic acid as leaving group. Nedaplatin exhibits a lower reactivity than cisplatin, but a higher one than carboplatin. It has a better side effect profile than cisplatin, but does not, however, show genuine advantages regarding treatment response and survival rate. Studies comparing nedaplatin with carboplatin are missing.

Indications. No FDA approval. Approved in Japan for the treatment of several tumors.

Adverse Effects. Myelosuppression, including severe thrombocytopenia, is dose-limiting. Nonhematological toxicity is reduced compared to cisplatin – except ototoxicity.

Lobaplatin

Characteristics. Lobaplatin was developed to extend the spectrum of activity of the platinum complexes. It is as active as cisplatin with absence of crossresistance. Its efficacy in cisplatin resistant tumors has to be proven in larger phase III studies.

Indications. No FDA approval. The complex has received approval in China for the treatment of different kinds of tumors.

Adverse Effects. Thrombocytopenia represents the dose-limiting toxicity.

Heptaplatin

Characteristics. Heptaplatin exhibits a more favorable adverse effect profile and a slightly reduced resistance compared to cisplatin.

Indications. No FDA approval. Heptaplatin gained approval in South Korea for the treatment of advanced gastrointestinal tumors.

Adverse Effects. Nephrotoxicity is dose-limiting.

New platinum Complexes Under Development

Platinum(IV) Complexes

These octahedral complexes exhibit some advantages compared to the square-planar Pt(II) complexes. They can be administered orally due to their increased stability and solubility in the gastrointestinal tract. Adverse effects are reduced due to their lower reactivity. New opportunities of synthesis and more possibilities of structural variations are opened. In the body they are reduced to more reactive Pt(II) complexes which form DNA adducts. In addition, there is evidence that the Pt(IV) complexes interact directly with the DNA.

Satraplatin is furthest progressed in clinical evaluation. Antitumor activity was partly determined in tumors with intrinsic and acquired resistance to cisplatin.

Sterically Hindered Platinum Complexes

The introduction of bulky substituents may lead to the reduction of detoxification and repair mechanisms.

NX473 (formerly AMD473, ZD0473), *cis*-amminedichloro(2-methylpyridine) platinum(II), was designed in order to reduce the inactivation of the complex by glutathione and other cellular thiols. In vitro activity against different human tumor cell lines, partly with intrinsic or acquired resistance to cisplatin, has been demonstrated.

Multinuclear Platinum Complexes

Two to four platinum centers with *cis*- or *trans*-configuration are connected by polyamine chains of different lengths. This approach has led to the development of highly antitumor active complex BBR3464. In clinical trials, BBR3464 was able to overcome resistance through formation of long chain interstrand crosslinks, because this type of crosslinks is not recognized by the NER system and HMG proteins.

Platinum Complexes with Bioreactive Ligands

An accumulation of the complexes in the target tissue can be achieved by the use of selective transporters or retention in the tumor tissue. Water-soluble porphyrin platinum complexes represent an example. Their accumulation in the tumor tissue is probably mediated by carrier-mediated transport with low-density lipoproteins (LDL) followed by internalization into the cell by endocytosis. The enhanced permeability and retention (EPR) effect can be used when platinum complexes are coupled to macromolecules. Synthetic (e.g., polyethylene glycol) and physiological (e.g., albumin) macromolecules are suitable for this approach.

Platinum-Refractory Testicular Germ Cell Tumors

Christian Kollmannsberger
Division of Medical Oncology, British Columbia Cancer Agency, Vancouver Cancer Centre, University of British Columbia, Vancouver, BC, Canada

Synonyms

Cisplatin-refractory germ cell tumors; Cisplatin resistant germ cell tumors; Treatment-refractory germ cell tumors

Definition

Platinum-refractory germ cell tumors (GCTs) are GCTs which no longer respond to cisplatin-based chemotherapy. *"Cisplatinum-refractory" disease* is defined as response or disease stabilization during, but disease progression within 4 weeks after cisplatin-based chemotherapy, whereas "*absolutely cisplatin-refractory" disease* refers to patients with progression during cisplatin-based treatment.

In a broader sense, multiply relapsed (≥3 recurrences) GCTs are also often referred to as treatment-refractory GCTs.

Characteristics

Today, approximately 70–80% of all patients with metastatic germ cell cancer will achieve long-term cure after standard-dose, cisplatin-based combination chemotherapy, such as PEB (cisplatin, etoposide, bleomycin) or VIP (etoposide, ifosfamide, cisplatin). Patients relapsing after cisplatin-based first-line chemotherapy have a less favorable prognosis, although 20–25% of patients are still cured with conventional second-line cisplatin-based chemotherapy. However, patients relapsing again after conventional or even high-dose salvage chemotherapy have a very poor prognosis, particularly those with cisplatin-refractory or absolutely cisplatin-refractory disease and less than 5% of these patients are long-term survivors.

The molecular basis for the exquisite chemotherapy-sensitivity and mechanisms of cisplatin resistance of malignant GCTs is poorly understood.

Mechanisms of Platinum Resistance

Despite various studies, no uniform hypothesis has been developed to explain the exquisite chemosensitivity of most GCTs as well as the chemoresistance of the minority of malignant GCT. Multiple factors on different cellular levels seem to play a role in the induction of cell death following cisplatin-based

chemotherapy, but the exact mechanisms of cisplatin resistance are still unknown.

Cisplatin is believed to kill cells through interaction with the DNA, mainly by the formation of various DNA adducts, which lead to the initiation of apoptosis. The tumour cell can escape the initiation of apoptosis on several levels: First, cisplatin can be inactivated by changes in the level of thiol-containing cell compounds such as glutathione or metallothionein or can be exported out of the cell by several export pumps, even before it reaches the DNA. Second, cisplatin-induced DNA damage can be repaired, predominantly by the so-called "nuclear excision repair (NER) pathway" prior to the activation of the apoptotic cascade; Third, the recognition of the critical DNA damage by mechanisms, which initiate apoptosis, can fail; and fourth, the execution of apoptotic cell death may be prevented by anti-apoptotic signals or by defects of apoptosis effectors.

A number of studies predominantly performed in cell lines and xenograft models, have suggested a correlation between glutathione and metallothionein levels and cisplatin resistance as well as between various export pumps, such as the ABC transporters and the lung resistance protein, and cisplatin resistance. However, validation on clinical tumour samples is generally lacking. Investigations of the role of the NER, which is thought to be the most important DNA repair mechanism for cisplatin induced damage, indicate a low capacity of GCT cells for NER. The low intrinsic capacity of the NER demonstrated in GCT cell lines has been attributed to low levels of xeroderma pigmentosum complementation group A protein (XPA) and the NER protein ERCC1. Alternatively, it has been proposed that the DNA adducts could be concealed by testis-specific high mobility group (HMG)-box proteins preventing damage detection and repair by NER factors. The finding of a low NER capacity itself and its potential clinical relevance have not been confirmed in samples from patients with GCTs, yet it is conceivable that a low NER activity contributes to the overall chemosensitivity of GCTs. A high level of wild-type p53 in GCTs has commonly been regarded as the biological explanation for GCT chemosensitivity. Two recent studies investigating the role of p53 in refractory GCT, have demonstrated that p53 mutations are rare even after treatment, that these mutations are unlikely to be the cause for chemotherapy resistance, and that the inactivation of p53 does not lead to a sensitivity change to chemotherapy in vitro. These findings suggest that induction of apoptosis in testis cancer cells can be executed even independent from p53, which questions the previously suggested important role of p53 in cisplatin resistance. A high incidence of microsatellite instability (MSI) was found in samples of patients with refractory GCT. In most refractory cases MSI was found in several loci whereas in unselected GCT only very few patients had a MSI and, most of them just in one locus. MSI in refractory GCT indicates that defects in DNA mismatch repair pathway may represent a clinically relevant resistance mechanism. Other proteins involved in the regulation of apoptosis, such as BAX, BCL-2, BCL-X_L, and others have also been investigated, but no single factor seemed to correlate with treatment response. More research is necessary to conclusively define the role for antiapoptotic regulators downstream of the initiation of apoptosis in chemotherapy resistance of GCT.

Unfortunately, most models described earlier are based predominantly on in vitro analyses of cell lines and largely lack confirmation of their relevance in clinical material.

Treatment of Patients with Cisplatin-Refractory GCTs

The treatment of patients with cisplatin-refractory disease remains a challenge due to the limited number of effective treatment options. Treatment for these patients remains largely noncurative and palliative.

Drugs with No or Minor Activity in Refractory GCTs (Table 1)

A large number of different agents have been evaluated in patients with refractory testicular cancer, mostly based on a promising preclinical activity in cell lines or xenograft models. However, the vast majority of these agents could not demonstrate any meaningful clinical activity, despite a well-received preclinical rationale and results (Table 1).

Active Agents (Table 2)

Only four chemotherapy agents, oral etoposide, paclitaxel, gemcitabine and oxaliplatin, have thus far demonstrated clinical activity in these patients. These agents were tested based on preclinical results indicating activity in germ cell cancer cell lines or tumor models as well as based on the lack of cross-resistance with cisplatin. Toxicity with all these single agent therapies is acceptable. Given as single agent therapy, all of these treatments yield response rates of approximately 20%. In all these studies single patients were long-term survivors.

Over the past years, these agents have been combined in combination chemotherapy regimens. The main objective of these studies was proof of feasibility of combination chemotherapy in these intensively pretreated patients as well as to improve the outcome for this particular patient population. Response rate and survival served as outcome measures in these trials. Achieving a high response rate in refractory patients is important since the induction of a remission may subsequently allow the resection of residual masses

Pectasides (2004)	Oxaliplatin/ irinotecan	18	0%	All patients resistant*	40% [95% CI: 17–64%]
Einhorn et al. (2007)	Paclitaxel/ gemcitabine	32	100%	n.s.	31% [95% CI: n.s.]

*All patients “resistant” defined as failure to achieve a durable complete remission to a cisplatin-based regimen and one or more of the following unfavourable prognostic features: relapse after CR or progression within 4 weeks after first-line therapy; poor or no response to prior conventional dose cisplatin/ifosfamide therapy; extragonadal primary site

**Refractory being defined as a disease progression during or within 2 months after cisplatin-based chemotherapy

n.s. = Not stated

and may thus be a chance to still achieve long-term survival in selected patients.

The first study which gave proof of the feasibility and activity of combination chemotherapy in these heavily pretreated patients was a phase II study investigating the combination of paclitaxel and gemcitabine. Twenty-one percent of patients responded and single long-term survivors were observed. A subsequent study which used paclitaxel/gemcitabine as treatment regimen after failure of salvage high-dose chemotherapy with autologous stem cell support found a response rate of 31%. Again, some long-term survivors were seen.

Two phase II studies examined the activity and toxicity of a combination consisting of oxaliplatin and gemcitabine in refractory germ cell cancer patients. These studies demonstrated again the feasibility of combination of chemotherapy in this heavily pretreated patient population. Both studies reported high response rates of 46% and 32% with a number of patients surviving long-term. These response rates are the highest published to date. Other tested combinations include paclitaxel/oxaliplatin and irinotecan-based combinations such as irinotecan/oxaliplatin or irinotecan/cisplatin. Hematological toxicity is usually the main side effect in these extensively pretreated patients.

Some trials have investigated the use of biological agents for the treatment of refractory or relapsed GCTs. None of the tested agents including suramin, an antitrypanosomal drug, all-*trans*-retinoic acid (ATRA) or thalidomide have shown activity. Novel molecular targets are also being explored now in germ cell cancer, including agents targeting the VEGF and EGF pathway. Preclinical experiments have suggested an important role for these pathways in germ cell cancers.

Salvage Surgery

Salvage surgery remains an important treatment option for chemotherapy-refractory patients, in particular for patients with limited and potentially respectable metastases.

A number of studies have investigated the role of surgery for patients with persistently elevated markers after cisplatin-based chemotherapy or patients relapsing after salvage chemotherapy (sometimes referred to as "desperation surgery"). Approximately 20–25% of patients may remain disease-free after a complete resection of all tumor manifestations. The complete resection of residual masses is the most crucial factor for success in this setting.

The complete resection of residual masses also appears to be an important step toward long-term disease free survival in cisplatin refractory patients who achieve a remission on salvage chemotherapy. Most long-term survivors in recent trials investigating novel agents had surgery subsequent to a chemotherapy response as part of their salvage treatment for refractory disease. Surgery alone or surgery after salvage chemotherapy should therefore always be considered for selected patients with cisplatin refractory disease, particularly in patients presenting with localized and potentially completely resectable recurrences or with completely resectable masses after response to salvage chemotherapy.

Platyfish-Swordtail Melanoma

►Xiphophorus

Pleckstrin Homology Domains

Definition

A region of a protein whose tertiary structure allows it to specifically bind to phosphorylated lipids. This often results in the recruitment of the proteins to the plasma membrane where they become activated. An example of such a protein is the kinase Akt. A protein region comprised of ~120 amino acids through which proteins bind to phosphoinsositides, resulting in their recruitment to the plasma membrane for participation in signal transduction pathways.

►Signal Transduction

Pleiotrophin

Evangelia Papadimitriou
Department of Pharmacy, University of Patras, Patras, Greece

Synonyms

Heparin binding growth associated molecule; HB-GAM; Heparin affin regulatory peptide; HARP; Heparin binding brain mitogen; HBBM; Heparin binding neurite promoting factor; HBNPF; Heparin binding growth factor 8; HBGF-8; Heparin binding neurotropic factor; HBNF; Osteoblast specific factor; OSF-1

Definition

Pleiotrophin (PTN) is an 18 kDa growth factor that has high affinity for heparin and together with ►midkine forms a family of structurally related heparin-binding growth factors. The two proteins share 45% homology in their amino acid sequence and ten perfectly conserved cysteine residues. They also use the same receptors and share many biological activities; the best characterized being neural development and tumor growth.

Characteristics

PTN consists of 168 amino acids that are highly conserved across different species, such as human, mouse, rat, bovine, fish, chicken, frog, and insects. The cleavage of the 32 amino acids signal peptide leads to a secreted protein, which consists of 24% of cationic residues, mainly lysines, and contains ten conserved cysteines. The 28 lysines are organized in two clusters at the NH_2- and COOH-terminal regions and the cysteines form five intrachain disulfide bonds. The tertiary structure of PTN is arranged in two β-sheet domains connected with a flexible linker. Each of the domains contains three antiparallel β-strands and possesses one ►thrombospondin type 1 (TSR-1) homology motif, implicated in its binding to heparin. The NH_2- and COOH-terminal lysine-rich regions lack a detectable structure and appear to form random coils.

PTN interacts with ►heparan sulphate ►proteoglycans (HSPGs) and other ►glycosaminoglycans (GAGs), such as ►dermatan sulphate and ►chondroitin sulphate A and can thus be found located onto the extracellular matrix and the surface of different cell types. GAGs induce PTN dimerization and enhance the mitogenic but not the neurite outgrowth activity of PTN. PTN binds ►N-syndecan, a HSPG implicated in the neurite outgrowth activity of PTN. It also binds to the ►receptor protein-tyrosine phosphatase beta/zeta (RPTPβ/ζ), which seems to be responsible for the migratory responses of neuronal, endothelial, and ►cancer cells to PTN. The more recently identified receptor for PTN is ►anaplastic lymphoma kinase (ALK), which is a transmembrane ►tyrosine kinase receptor of a 200 kDa molecular mass, expressed by many types of cancer cells. The ►signal transduction pathways used by PTN are not clearly established. It has been reported that PTN activates ►phosphatidylinositol 3-kinase (►PI3K), ►Akt, and extracellular signal-regulated kinases ½ (ERK½), although the signaling from the receptors to PI3K is not well understood. In the case of RPTPβ/ζ, it is likely that c-src is involved, which activates ►focal adhesion kinase that associates with ►PI3K and leads to activation of ERK½.

Little is still known on the regulation of PTN expression. It has been shown that PTN transcription is directly stimulated by the transcription factors ►HOXA5 and ►activator protein-1. PTN protein levels are also increased by cAMP, ►platelet derived growth factor BB and ►hypoxia.

Numerous biological activities have been attributed to PTN. The first and most prominent is stimulation of neurite outgrowth and a role in the growth and maturation of brain. PTN also induces proliferation of several types of cells, is involved in a variety of processes in bone formation, seems to play a critical role in chondrogenesis, and participates in normal spermatogenesis.

A role of PTN in human ►cancers was first suggested after purification of the growth factor from conditioned media of the highly malignant ►breast cancer cell line MDA-MB-231. Screening of various human tumor cell lines and tumor specimens of different origin revealed that PTN is expressed in many types of cancer, such as glioma, ►melanoma, meningioma, ►neuroblastoma, choriocarcinoma, ►leukemia, and cancers of ►pancreas, ►prostate, stomach, ►colon, ►breast, ►ovary, and lung. PTN receptors are also up-regulated in a plethora of tumors and are being tested as targets for anti-cancer therapy.

Regarding the biological activity of PTN in cancer, there is ample evidence that it is a tumor-promoting factor. This is supported by data showing that overexpression of PTN in human embryonic kidney cell line 293 and human adrenal carcinoma cell line SW-13 leads to autonomous growth in soft agar and formation of tumors in athymic nude mice. Moreover, the secreted PTN stimulates proliferation of fibroblasts, endothelial, and epithelial cells. PTN purified from lung cancer cell lines also stimulates the growth of fibroblasts, endothelial and SW-13 epithelial cells. In the same line, overexpression of the bovine PTN cDNA in NIH 3T3 cells results in a transformed phenotype, as judged by increased cell numbers at confluence, anchorage-independent growth, and tumor formation in nude mice.

More recently it has been shown that deletion of the tumor suppressor gene ►*PTEN* leads to up-regulation of PTN, which seems to participate in tumorigenesis caused by ►PTEN loss.

Inhibition of PTN expression in several types of cancer cells inhibits colony formation of the cells, decreases angiogenicity, and prevents tumor growth in mice. For example, human breast cancer MDA-MB-231 cells transfected with a mutant cDNA that encodes a truncated form of PTN, fail to form plaques or colonies in soft agar and are unable to form tumors in athymic nude mice. Stable transfection of human melanoma WM852 cells that express high levels of PTN mRNA, with PTN targeted ribozymes, quenches production of PTN, inhibits colony formation of the cells, and prevents tumor growth in mice. In another highly metastatic human melanoma cell line 1205Lu, transfection with PTN-targeted ribozymes decreases tumor growth and ►angiogenesis in nude mice. A replication-deficient recombinant adenovirus generated to express antisense PTN at high efficiency, induces transcripts that completely inhibit PTN protein production and decrease melanoma cell growth in soft agar and SCID mice. The down-regulation of PTN in these cells coincides with down-regulation of the cell cycle regulator cyclin E and up-regulation of the cell cycle inhibitor $p21_{WAF1/Cip1}$. PTN-targeted ribozymes have been used to deplete PTN mRNA from Colo357 ►pancreatic cancer, choriocarcinoma, and glioma cells. Reduction of PTN results in a decrease in the proliferation rate, soft agar colony formation, and tumor growth in nude mice. In human prostate LNCaP cells, antisense PTN expression decreases cell ►migration, as well as anchorage-dependent and independent growth and abrogates the stimulatory effects of ►hydrogen peroxide and ►fibroblast growth factor 2 on LNCaP cell proliferation and migration.

In contrast to a stimulating effect of PTN on tumor growth, it has also been suggested that overexpression of PTN in NIH 3T3 cells may be implicated in cellular quiescence rather than an oncogenic phenotype. In several cases, PTN has been identified as a confluence specific protein, secreted by normal cells but not cells transformed by ►ras or other ►oncogenes. High PTN expression is associated with poor vasculature in neuroblastomas, and HOXA5 that induces apoptosis of breast cancer cells and inhibits angiogenesis, directly activates PTN transcription. It has also been shown that PTN directly binds the 165-amino acid form of ►vascular endothelial growth factor ($VEGF_{165}$) leading to inhibition of $VEGF_{165}$-induced endothelial cell proliferation, migration, and tube formation on matrigel. This negative regulatory effect is attributed to both thrombospondin type I repeats of PTN, which are located in the β-sheet domains of the molecule and are responsible for the binding to $VEGF_{165}$.

Besides a direct effect of PTN on tumor cells, there is also a plethora of reports indicating a positive correlation between PTN and in vivo or in vitro angiogenesis, a key step in the progress of many tumors. Numerous in vitro studies demonstrate that PTN is involved in the control of endothelial cell migration, proliferation, and differentiation into tube-like structures. The angiogenic potential of PTN in vivo has been shown in the chicken embryo chorioallantoic membrane assay and in mice using matrigel implants. Moreover, PTN expression by monocytes/macrophages leads to downregulation of their monocytic cell markers and upregulation of endothelial cell characteristics, thus inducing the transdifferentiation of monocytes into functional endothelial cells. PTN may also serve to recruit stromal tissue and blood supply to the expanding tumor. Culture supernatants derived from a PTN transfected human adrenal carcinoma cell line (SW-13) were shown to possess mitogenic activities for fetal bovine heart endothelial cells and human umbilical vein endothelial cells (HUVEC), making PTN a candidate tumor angiogenesis factor. In the same line, PTN purified from lung cancer cell lines stimulates the proliferation of HUVEC in vitro, and ribozyme targeting of PTN mRNA, which is constitutively expressed in the human melanoma cell line 1205Lu, reduces the number of vessels in the primary tumor and the metastatic spread of these cells in athymic nude mice. PTN-transfected MCF-7 human breast carcinoma cells are mitogenic for HUVEC in vitro and strongly angiogenic in vivo, in mice xenografts and in the rabbit corneal assay. Endothelial cell functions in vitro and angiogenesis in the chicken embryo chorioallantoic membrane in vivo induced by culture medium of human ►prostate cancer LNCaP cells were also inhibited when PTN expression was diminished. Finally, in MCH66 murine mammary tumor cells, which metastasize depending only on tumor angiogenesis, PTN could be regarded as the only plausible candidate for this activity.

The identification of PTN domains responsible for its angiogenic and transforming activities is considered important and the data existing so far suggest distinct or even opposite effects for different PTN regions. The last 25 amino acids of the C-terminal region are considered important for the binding to ALK and the angiogenic effect of PTN and the last 43 amino acids of the same region enhance plasminogen activator activity and decrease the plasminogen activator inhibitor levels. An angiogenic role for the residues 65–136, as well as peptides that correspond to both the NH_2 and COOH domains of the molecule have also been suggested. Proteolysis of PTN by plasmin results in the production of five peptides with distinct activities on endothelial cell activation in vitro or angiogenesis in vivo. PTN is also a substrate for trypsin or chymotrypsin and the

hypothesis that PTN is a possible substrate for several proteolytic enzymes, which may control its angiogenic or/and tumorigenic potential, is reinforced by the presence of proteolytic forms of PTN in media from endothelial or tumor cells.

In addition to being a therapeutic target, PTN may also be an attractive circulating growth factor for prognostic monitoring. In mice, serum PTN levels increase as a function of tumor size. In humans, elevated serum PTN levels are measured in patients with pancreatic or colon cancer, but not in patients with stomach cancer. In both mice and humans, serum PTN levels drop after successful tumor removal. Elevated PTN serum levels are also measured in 30% of patients with chronic pancreatitis, a disease that frequently precedes pancreatic cancer. Moreover, PTN expression increases from 7% observed in normal tissue to 34% in inflammatory and 67% in pancreatic cancer tissues. Finally, PTN may represent a promising new diagnostic marker for ►testicular cancer with high sensitivity in early-stage disease.

In summary, PTN exhibits important biological activities in cancer and its expression or/and expression of PTN receptors in of PTN receptors at high levels may play a crucial regulatory role in many tumors of diverse origin. Clarifying the exact role of PTN in diverse tumor types could lead to the development of therapeutic tools that can be used of therapeutic tools to control tumor growth and metastasis.

Synonyms

Malignant pleural effusion; Thoracentesis; Pleurodesis

Definition

Pleural effusion is the presence of excessive fluid in the pleural cavity. The pleura is a two-sheet, serous membrane that covers chest wall, mediastinum (parietal pleura) and lungs (visceral pleura). Between parietal and visceral pleura there is a virtual space filled with a small liquid pellicle with a high daily turnover which permits sliding. Daily fluid production is about 0.01–0.02 mL kg^{-1} h^{-1} being continuously absorbed in a way that remaining the pleural fluid is about 0.1–0.2 mL kg^{-1}. Fluid movement and absorption are supported by a balance between plasmatic and pleural pressures (hydrostatic and oncotic pressures) and thoracic lymphatic drainage. Pleural effusions occur because of an upset in these mechanisms that reabsorb the fluid normally present in the pleural space.

Characteristics

Pleural effusion is a common clinical problem seen at the advanced stage of several malignant diseases and is called ►Malignant Pleural Effusion (MPE).

The physiopathology of a malignant pleural effusion includes vascular and lymphatic alterations due to a direct invasion of the pleura by a primary tumor or a metastasis. These pleural changes affect the normal reabsorptive flow of fluid from parietal to visceral pleura and can even cause an increased capillary leaking and increased fluid production.

A malignant effusion can be present whatever the direct neoplastic involvement of the pleura as a clinical consequence of a malignancy or its treatment (radio or chemotherapy, caquexia, tromboembolism, pneumonia, and others) and in these cases it is called paramalignant effusion.

An indirect increased capillary permeability, increased hydrostatic pressure, a decreased oncotic pressure, increased negative intrapleural pressure (as in cases of atelectasis), and decreased or blocked lymphatic drainage are the final organic alterations responsible by fluid overload.

The main causes of MPE are reported with different incidence rates between the literature series.

Widely, lung cancer is the most common cause of malignant pleural effusion in men. In women, breast cancer seems to be the first cause, followed by lung cancer and genital tract cancer.

Other related causes of MPE are lymphoma, gastric cancer, and mesothelioma.

In about 10% of malignant effusions no primary tumor is identified.

Table 1 shows main neoplasms related to pleural effusion.

Clinical Manifestations and Diagnosis

The most common related symptom is dyspnea. Other symptoms are cough, chest discomfort, and pain. Many patients with pleural effusions are asymptomatic, especially if a small pleural effusion is present.

Pleural Effusion. Table 1 Causes of malignant pleural effusion

Male	Female
Lung cancer	Breast cancer
Lymphoma	Female genital tract
Gastrointestinal tract	Lung cancer
Genitourinary tract	Lymphoma
Melanoma	Gastrointestinal tract
Less common tumors	Melanoma
Primary unknown	Less common tumors

Physical examination is poor in cases of small effusions or should reveal decreased chest expansion, dullness to percussion, and reduced breath sounds in cases of a larger effusion.

A simple chest radiography is the first diagnostic approach. It can confirm the presence of an effusion and other parenchymal alterations.

Small pleural effusions could not be seen in a simple chest radiogram but larger pleural effusions can cause a complete opacification of the hemithorax. Fig. 1 shows a chest radiogram with a large right pleural effusion.

When a massive pleural effusion is present there are symptoms of a tension hydrothorax with mediastinal shift, severe dyspnea, and hemodynamic instability (Fig. 2).

Pleural Effusion. Figure 1 Chest radiogram showing a large right pleural effusion due to breast cancer.

Pleural Effusion. Figure 2 CT scan disclosing massive pleural effusion with mediastinal shift and lung atelectasis.

Loculated effusions are difficult to diagnose in a simple chest radiogram because it is difficult to distinguish from other pulmonary parenchymal process such as atelectasis and consolidation.

Ultrasound and CT scan are useful diagnostic means, especially in cases of small or loculated effusions and can determine the precise site for thoracentesis.

Thoracentesis

►Thoracentesis is useful as a preliminary "looking for" diagnosis and could play a therapeutic role.

The fluid analysis permits distinguishing an exudative from a transudative effusion.

Transudative effusion is a plasma filtrate with the same characteristics and results of an elevated hydrostatic pressure or increased capillary permeability.

Exudative effusion is a rich protein fluid resulting from a local pleural inflammation or obstructed lymphatic drainage or both and it is common in neoplasm.

The fluid analysis includes the cell count (total and differential), total protein count, lactate dehydrogenase (LDH), glucose level, pH, amylase, and cytology.

Usually MPE is an exudative effusion that is characterized by serum ratio of protein greater than 0.5 (relation between pleural and plasmatic protein level); LDH ratio greater than 0.6 (relation between pleural and plasmatic LDH level), or the absolute LDH pleural level greater than 2/3 of the upper normal limit for serum level and low glucose level.

Other analyses include cholesterol, triglycerides (when a quilothorax is suspected), and ADA (adenosine deaminase), helpful to differentiate neoplastic from tuberculous effusion.

A hemorrhagic fluid is highly correlated to a malignant effusion.

The fluid analysis also permits to identify neoplastic cells and some direct and indirect tumor markers.

Some tumor markers such as ►CEA and CA 15-3 may improve the diagnostic value of cytology.

High fluid levels of CEA are seen in pulmonary squamous cell carcinoma and pulmonary adenocarcinoma. Differently, high levels of CA 15-3 are observed in breast cancer.

Chromosomal and tumor growth factors analyses are still being investigated as a worth diagnostic mean.

When an exudative effusion is present and the etiology is not clear, thoracoscopy and pleural biopsy have been described as the most rational diagnostic approaches.

Treatment

The goal of the treatment is the resolution of the effusion and its recurrence prevention.

Secondary treatment endpoints are minimizing patient's symptoms and reducing hospital stay.

Chemo and radiotherapy play a role in the treatment if the primary tumor is responsive to them and may spontaneously resolve the effusion.

Therapeutic Thoracentesis

Therapeutic thoracentesis can immediately provide relief from dyspnea and other acute symptoms, but it has an elevated recurrence rate (as high as 98–100% Fig. 3).

There is no absolute contraindication for thoracentesis. Relative contraindications are bleeding disorders, anticoagulation, and mechanical ventilation.

Complications related to thoracentesis include ►pneumothorax, hemothorax, pain, and vasovagal reaction (with bradicardia, low systemic blood pressure, and reduced conscious level) during the procedure.

Repeated thoracentesis can result in infection, tumor implantation at the site of the puncture, and adhesions between lung and chest wall.

Chest Tube Drainage

Chronic ►chest tubes have a poor indication in controlling MPE.

A low number of patients have some benefit with this technique and it is only indicated in cases of no choice of ►pleurodesis.

Patients with suspected or proven mesothelioma should receive prophylactic radiotherapy at the site of chest drainage or biopsy because about 40% of patients with malignant mesothelioma may develop tumor implant at the site of the pleural procedures.

Pleurodesis

Instillation of sclerosing agents in the pleural space causes an inflammatory process with a fusion between parietal and visceral pleura.

A successful pleurodesis provides complete lung expansion and stops the fluid collection.

Pleural Effusion. Figure 3 Thoracentesis of hemorrhagic pleural effusion.

Pleurodesis can be performed with chemical agents or mechanical abrasion of the parietal pleura.

Recently, asbestos free talc has been the most established and diffused method for the management of MPE.

It can be directly instilled in the pleural space with a chest tube or via a thoracoscopic procedure.

Pleurodesis with ►video-assisted thoracoscopic surgery (VATS) has a very high efficacy in terms of effusion control (Fig. 4).

The advantage of this method is that it offers a possibility of a uniform distribution of the talc in a direct view and high accuracy ►pleural biopsy.

Talc is usually well tolerated with few side effects. Most common ones are fever and pleuritic pain. Other described complications are acute respiratory distress syndrome (ARDS) and talc pneumonitis. These complications are rare and appear to be related with larger doses of talc (>5 g).

Other chemical agents have been described as sclerosing agents.

Bleomycin sulfate is the most used antineoplastic drug for pleurodesis. Described side effects are fever, chest pain, and nausea. The drug has a limited systemic absorption and the efficacy is about 70–80% with a high cost.

Tetracycline was frequently used in the past as a sclerosing agent with widely different results between patients' series.

Other agents as Interferons (alpha and beta) and Interleukins (IL2) have showed controversial results in the literature.

Pleural Effusion. Figure 4 One-port video-assisted thoracoscopy (VATS) for pleural biopsy and talc poudrage.

Mechanical Pleurodesis

Thoracoscopic mechanical pleurodesis has a similar effusion control rate when compared with talc pleurodesis. It has, however, more complications. The most common complications are prolonged lung deflation, bleeding, subcutaneous emphysema, and wound inflammation.

Other Treatment Options

Pleurocath is the insertion of a long-term, tunneled pleural catheter in patients with recurrent and symptomatic effusions particularly in cases of trapped lung. Pleurocath can allow the patient to lead an independent life outside the hospital. The most common complications are reaccumulation of effusion, loculations within the pleural space, empyema, and cellulitis at the catheter insertion site.

►*Surgical Pleurectomy* and ►*Decortication* are options with very high morbidity and mortality. It requires thoracotomy with frequent complications and prolonged hospital stay.

►Pleuroperitoneal shunting is an alternative for patients who have intractable symptomatic pleural effusions that have failed chemical pleurodesis or are not candidates for surgery. Shunting insertion is well tolerated in minithoracotomy or thoracoscopic procedure.

Complications related to this technique are shunt occlusion, infection, and tumor implant.

Synonyms

PLXN; Semaphorin receptors

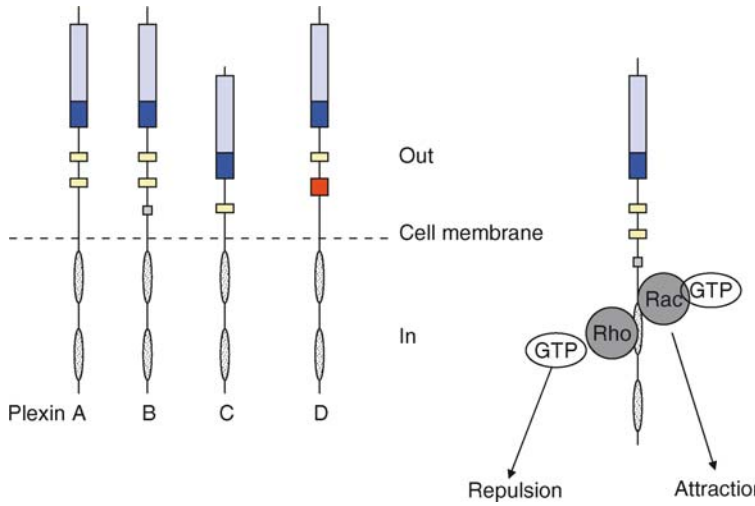
Definition

Plexins are large, transmembrane receptors with structural homology in their extracellular domains to the ►scatter factor receptor, ►c-MET. The family of plexins consists of four groups, plexin A, B, C and D, each with several subgroups. The plexins differ mostly from each other in their extracellular domains.

These ectodomains are typically composed of a ►semaphorin-like or sema domain, followed by two or three Met-related sequences (MRS). The Met related sequences of class B plexins show the highest similarity to c-Met. The intracellular parts of the plexins are highly conserved during evolution and are characterized by two conserved regions, known as the SEX-plexin (SP) domain (Fig. 1).

Characteristics

Plexin-associated molecules: Plexins are receptors for the membrane-bound ►neuropilins and semaphorins, which exist both as secreted and membrane-bound forms. Identified receptor-ligand pairs are: PLXNA1-Sema3A; PLXNA1-Sema6D, PLXNB1-Sema4D; PLXNB3-Sema5A; PLXNC1-Sema7A, PLXND1-Sema3C, and PLXND1-Sema3E. Interactions of plexins with the class 3 semaphorins are mostly mediated by the neuropilins, but exceptions to this rule exist. For example, Sema3E binds directly to PLXND1 in the absence of neuropilins. The neuropilins are also receptors for the larger variants of the angiogenic factor ►vascular endothelial growth factor-A (►VEGF-A) and binding of class 3 semaphorins to neuropilin/plexin complexes can be competed for by VEGF-A, resulting in antagonistic effects toward each other. Neuropilins are non-signaling receptors that occur in complex with VEGF receptor 2 (VEGFR2) on angiogenic ►endothelial cells and enhance binding of VEGF-A to this receptor. Since several classes of



Plexins. Figure 1 Structural domains of plexin family members: four subfamilies have been identified, plexin A–D. Blue boxes indicate sema-domains, yellow boxes represent Met-related sequence (MRS) motifs. The red box indicates an atypical MRS motif of plexin D1 which distinguishes it from the other plexin family members. Plexin B subfamily members have a potential ►furin-like proteolytic site, marked by a grey ribbon. Two intracellular conserved domains are shown as ovals. In the family of B plexins, ►RhoA and ►Rac small GTPase binding sites are activated upon semaphorin binding, resulting in repulsion (growth cone collapse) or attraction (►filopodia formation and extension) respectively.

plexins are also expressed on endothelial cells during ►angiogenesis, it is likely that multicomponent complexes of neuropilins, plexins and VEGF receptors exist. This is further supported by the finding that an association between PLXNA1 and VEGFR2 (and Off-track) is required for Sema6D signaling. Thus, it is likely that a delicate balance between semaphorins and VEGF-A provides a fine tuning mechanism to regulate angiogenesis.

Class B plexins have been found in a complex with c-Met, the receptor for hepatocyte growth factor (HGF) and Ron, the receptor for ►macrophage stimulating protein (MSP). These proteins are also known as the scatter factor receptors, and c-Met is critically involved in invasive growth (cell scattering) during development but also during tumor cell ►invasion and ►metastasis. Except for direct phosphorylation upon binding of scatter factor/HGF, c-Met is also directly activated upon binding of sema4D to a PLXNB1/c-Met complex, resulting in an invasive cell phenotype.

Taken together, most plexins exist in multicomponent receptor complexes and the outcome of activation of these complexes is determined by a concerted action of different growth factors.

Plexin Function

Initially, neuropilins and semaphorins were discovered as determinants of patterning of the central nervous system. Most work has been done on the class 3 semaphorins which act via the plexin A family as ►chemorepulsive cues during axonal growth. There are distinct similarities between development of nerves and vessels. Both display directed growth and branching morphogenesis in an orderly fashion. In this respect it is perhaps not surprising that factors that are involved in axon guidance also play a role in angiogenesis. A first indication for this came from studies, in which expression of plexin D1 was demonstrated in developing vasculature during mouse embryogenesis. A later study showed that plxnd1 was essential for angiogenesis: plxnd1 knock out mice die within one day after birth due to cardiovascular defects. Maldevelopment of the vasculature was also observed in plxnd1-loss of function mutants of zebrafish.

Evidence is emerging now that plexins play distinct roles not only during developmental angiogenesis, but also during tumor angiogenesis. At the moment an involvement in tumor biology of the B and D plexins is most clear. Therefore these two family members will be dealt with in more detail.

Plexins in Tumor Biology

Plexin D1

The occurrence of PLXND1 on developing vasculature has resulted in research towards a potential role of this family member during angiogenesis in tumor development: angiogenesis is critically involved in growth and metastasis of solid tumors, and plexin D1 is prominently expressed in angiogenic tumor blood vessels. Plexin D1 is also expressed on tumor cells in a wide variety of human tumors.

Semaphorins 3C and 3E are ligands for PLXND1. Whereas Sema3C binding to PLXND1 requires the

involvement of neuropilins, this interaction is not needed for Sema3E binding. Ssema3C seems to be involved in chemoresistance of tumor cells whereas sema3E has been identified from array analyses as a protein, implicated in tumor progression and metastasis. Because functional studies on plexin D1 during tumor development are lacking so far, it is not clear whether plexin D1 mediates these specific semaphorin effects. However, whatever its potential function in tumor biology, the presence of plexin D1 on tumor vessels and tumor cells makes it a potentially attractive target for tumor diagnosis and ►targeted drug delivery as it allows the simultaneous targeting of multiple tumor compartments.

The ►signal transduction pathways activated by plexin D1 have not yet been elucidated, but studies on other plexins suggest that active cytoskeletal rearrangements are induced upon plexin D1 activation via the small RhoGTPases. Whereas activation of the Rac RhoGTPase leads to ►lamellipodia formation and extension of cellular processes, the RhoA GTPase results in the retraction of cell processes via depolymerization of F-actin. Plexin D1 contains a consensus Rac-binding site as well as two conserved arginines that in PLXNA1 are crucial for sempahorin-mediated cellular collapse. It is not known which conditions favor Rac or RhoA activation.

B-Plexins

Another plexin that is expressed on both endothelial cells and tumor cells is plexin B1, a receptor for semaphorin 4D. It has been demonstrated that plexinB1 is present in a complex with the scatter factor receptors Met and Ron. These two tyrosine kinase receptors are implicated in the invasive growth programme of tumors. C-Met is the prototype receptor for Hepatocyte Growth Factor (HGF) and is, upon activation by this ligand, phosphorylated on two tyrosines that are docking sites for a number of signal transduction molecules such as phosphatidyl inositol 3-kinase (PI3K), SRC, GRB2, GAB1 and ►signal transducer and activator of transcription 3 (STAT3). C-Met is also associated with ►integrins, adhesion molecules that modulate cellular interactions with extracellular matrix components. C-Met is a prototype oncogene that upon constitutive activation results in malignant tumors. Constitutive activation may be the result of activating mutations, but overexpression of c-Met in itself may cause receptor oligomerization and phosphorylation.

Sema4D binding to plexin B1 in the complex also results in tyrosine phosphorylation of c-Met. Furthermore, endogenous overexpression of plexin B1 in epithelial cancers results in constitutive activation of c-Met. Thus, the B-plexins may play an important role in c-Met activation and tumorigenesis.

Unlike plexin D1, intracellular signaling from a PLXNB1/Sema4D complex has been elucidated to a large extent. Upon ligand binding, PlexinB1 interacts at its carboxyterminal domain with leukemia associated rho guanine exchange factor (LARG), an exchange factor for the small GTPase Rho. Also binding of PDZ-Rho-GEF has been demonstrated. Plexins have also been shown to activate r-RAS, resulting in down-regulation of integrin-mediated adhesion to the extracellular matrix. The resulting loss of cell adhesion is implicated in invasive growth.

In summary, plexins constitute a family of receptor proteins which occur in multicomponent complexes on the cell membrane. Evidence for an important role in tumor biology is emerging in the last years. Multiple ligands for the plexins have been identified, and intracellular signaling pathways initiated by plexin activation, results in cytoskeletal rearrangements which may lead to extension but also collapse of cellular processes, events that are indispensable for cellular migration.

Podoplanin

Andreas Wicki, Gerhard Christofori
Department of Clinical-Biological Sciences, Centre of Biomedicine, Institute of Biochemistry and Genetics, University of Basel, Basel, Switzerland

Synonyms

gp36; Human podoplanin; OTS-8, gp38, T1α2, PA2.26, RANDAM-2, Aggrus; Mouse podoplanin; E11 antigen, RTI40; Rat podoplanin

Definition

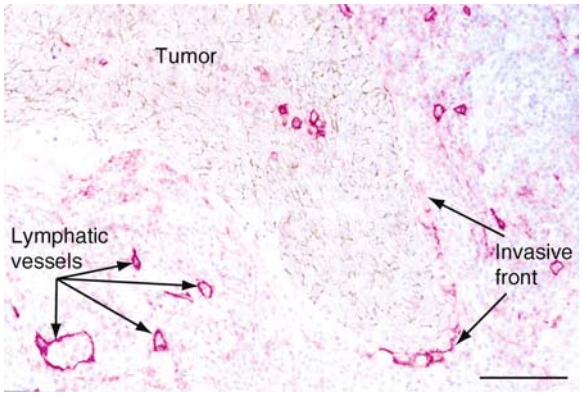
Human podoplanin is a type-1 transmembrane glycoprotein consisting of 162 amino acids, nine of which form the intracellular domain. The extracellular domain is extensively O-glycosylated. Depending on glycosylation, the molecular mass is between 36 and 45 kDa. Podoplanin is physiologically expressed in kidney podocytes, skeletal muscle, placenta, lung, heart, myofibroblasts of the breast and salivary glands, osteoblasts and mesothelial cells, and on the apical surface of alveolar type I cells. Occasionally, focal expression of podoplanin can be found in circumscribed areas of the basal layer of the human epidermis. Podoplanin is also expressed in lymphatic endothelium, but not in blood vessels. Pathological expression of podoplanin is observed in many human cancers, in particular squamous cell ►carcinomas.

Characteristics

In tumors, podoplanin is expressed by the cancer cells themselves, where it is involved in ►tumor progression. In addition, it is expressed in lymphatic endothelial cells and serves as an immunohistochemical marker for ►lymphatic vessels.

Podoplanin Expression in Human Tumors

The expression of podoplanin is upregulated in testicular carcinoma *in situ* and in many invasive human cancers, in particular squamous cell carcinomas of the skin, larynx, lung, cervix, mouth and esophagus, as well as invasive tumors of the germinal cells and the central nervous system. Podoplanin expression has also been reported in mesothelioma and several human ►sarcomas, but not in adenocarcinomas such as colorectal or prostate cancer. Podoplanin can either be selectively expressed on the ►outer edge of the tumor mass, or diffusely throughout the cancerous tissue (Fig. 1). The expression of podoplanin in a single cell layer at the tumor surface is most often observed in squamous cell carcinoma, whereas sarcomas tend to express podoplanin more diffusely. Clinical studies indicate that the expression of podoplanin in human cancer may positively correlate with tumor progression and a poor prognosis (example: malignant astrocytoma of the brain).



Podoplanin. Figure 1 Histological section of a human squamous cell carcinoma. The cells of the tumor bulk express E-cadherin (brown staining) and form an invading conus which protrudes into the surrounding tissue. Podoplanin (red staining) is expressed by cells of the invasive front and by the lymphatic endothelium (as indicated by the arrows). Size bar = 100 µm. Microphotograph courtesy of D. Kerjaschki, MUW, Vienna.

The physiological role of podoplanin remains in great parts unknown. Podoplanin-deficient mice die at birth owing to respiratory failure and exhibit a phenotype of alveolar hypoplasia, dilated malfunctioning lymphatic vessels, and lymphoedema. In addition, podoplanin has an extracellular platelet aggregation-stimulating domain and is therefore able to promote hemostasis.

Regulation

The podoplanin gene promoter is characterized by the absence of a consensus TATA and CAAT box, the presence of multiple Sp1 binding sites and a high GC-content. This promoter structure is mostly found in ubiquitously expressed or growth-related genes. In human sarcoma cell lines, the basal transcription of podoplanin is regulated by the transcription factors Sp1 and Sp3, and presumably by other, not yet identified factors. In lymphatic endothelium, podoplanin is an early responder to Prox-1, a master regulator of lymphatic vessel formation. In human carcinoma cells, upregulated expression of podoplanin is observed upon treatment of cells with EGF, FGF-2, TNF-α, or bradykinin. The expression of podoplanin is increased in mouse skin during tissue regeneration after wounding or by treatment with the carcinogen phorbol-12-myristate-13-acetate. Podoplanin expression is also induced by 12-*O*-tetradecanoylphorbol-13-acetate in

mouse osteoblastic cells and is it constitutively expressed in oncogenic Ras-transformed cells.

Podoplanin and Tumor Invasion

Podoplanin induces tumor invasion *in vitro* and *in vivo*. Transfection of podoplanin into human cancer cells usually results in increased spreading of the cells on ►fibronectin, a component of the extracellular matrix. Podoplanin also enhances cell migration and invasion through a collagen IV containing, basal membrane-like substrate. The enhanced migration is accompanied by a strong polarization of the cells. Depending on the cell of origin, podoplanin promotes collective or ►single cell invasion. During ►collective cell invasion, epithelial cancer cells remain attached to each other, since they continue to express ►E-cadherin, a cell adhesion molecule required for the formation of epithelial adherens junctions. In a transgenic mouse model of ►insulinoma, podoplanin was shown to shift the invasion pattern from single to collective cell invasion. Podoplanin also mediates single cell invasion upon loss of E-cadherin (e.g. in MDCK cells, an epithelial canine kidney cell line). Single cell invasion and loss of E-cadherin are often associated with ►epithelial-mesenchymal transition (EMT), a phenomenon that also occurs during embryogenesis, for example during neurulation or gastrulation. During both collective and single cell invasion, podoplanin promotes phosphorylation of ►ERM-proteins, in particular ezrin. Upon phosphorylation, ezrin associates with the cell membrane and re-organizes the actin cytoskeleton.

The expression of podoplanin also affects cell morphology. Stress fibers, which are often found in quiescent cells, are lost and filopodia are formed. Both cell migration and membrane motility are increased, and the formation of multiple ►microspikes of the cell membrane is induced.

Podoplanin modulates the activity of the family of ►Rho GTPases, in particular RhoA, Cdc42 and Rac. The modulation of RhoA signaling can directly translate into an increased cell movement. However, depending on the cell type, migration and invasion are induced by either up- or downregulation of distinct Rho GTPases.

Podoplanin and Metastasis

The extracellular portion of podoplanin contains a platelet-aggregation domain. Indeed, the expression of podoplanin on circulating tumor cells increases the formation of ►thrombotic cancer cell emboli, thereby increasing the efficiency of metastasis formation. In a mouse model, acetylsalicylic acid inhibits platelet aggregation, and reduces the incidence of metastasis after intravenous injection of podoplanin-expressing Chinese hamster ovary (CHO) cells. Thus, podoplanin may be involved in the transport of tumor cell-platelet clusters in the bloodstream.

Podoplanin as a Marker for Tumor-Associated Lymphatic Vessels

Podoplanin is expressed in lymphatic endothelial cells, but not in blood endothelium. Therefore, podoplanin is frequently used as a selective marker for lymphatic vessels. Together with ►Lyve-1, another lymphatic endothelium specific marker, it is employed to visualize and quantify lymphatic vessels. Tumor-associated lymphatic endothelial cells are thought to be involved in intralymphatic transport of cancer cells, and the lymphatic microvessel density is important for prognosis. For example, the density of lymphatic vessels is an independent prognostic factor for the prediction of melanoma metastasis and patient survival.

Conclusions

Podoplanin promotes tumor invasion and metastasis formation in both carcinoma and sarcoma. However, in carcinoma *in situ* and in regenerating epithelium its role has remained elusive. Alone or together with Lyve-1, podoplanin is an important marker for the assessment of lymphatic microvessel density in tumors.

POEMS Syndrome

Definition

Synonym: Crow-Fukase syndrome, Takatsuki disease or PEP syndrome; Is a rare medical syndrome named

for its main clinically recognizable features: Polyneuropathy (peripheral nerve damage), Organomegaly (abnormal enlargement of organs), Endocrinopathy (damage to hormone-producing glands)/Edema, M-protein (a monoclonal immunoglobulin produced by plasma cells) and Skin abnormalities, such as hyperpigmentation and hypertrichosis.

►Plasmacytoma

Point Mutation

Definition

Is a change on a single base of a sequence of DNA. If the mutation is placed within a sequence that codifies for a protein it may have three different outcomes. Point mutations may be silent when the substitution of a base has no effect on the sequence of the protein producing no change of the amino acid residue codified due to redundancy of the genetic code. It may also induce an alteration of the sequence of the protein. In this case, a point mutation may render either a substitution of an amino acid for a different one or generate and stop codon with a truncated protein.

Polo-Like Kinase

Definition

PLK; Are important regulators of cell cycle progression during M-phase. Named after the polo gene of Drosophila melanogaster, Plks are involved in the assembly and dynamics of the mitotic spindle apparatus and in the activation and inactivation of CDK/cyclin complexes. In mammalian cells, Plk1 protein levels increase as cells approach M phase, with the peak of phosphorylation activity reached during mitosis.

►G2/M Transition

Poly (ADP-Ribose) Polymerase

Definition

PARP; A zinc-finger DNA-binding protein which detects and signals DNA strand breaks. This protein/enzyme catalyses the synthesis of poly (ADP-ribose), from its substrate and the polymer is attached to several nuclear proteins and PARP itself. As a result, PARP converts DNA breaks into intracellular signals which activate DNA repair programs or cell death machinery.

►Inflammation
►Poly(ADP-Ribosyl)ation

Poly(ADP-Ribosyl)ation

Alexander Bürkle
Department of Biology, University of Konstanz, Konstanz, Germany

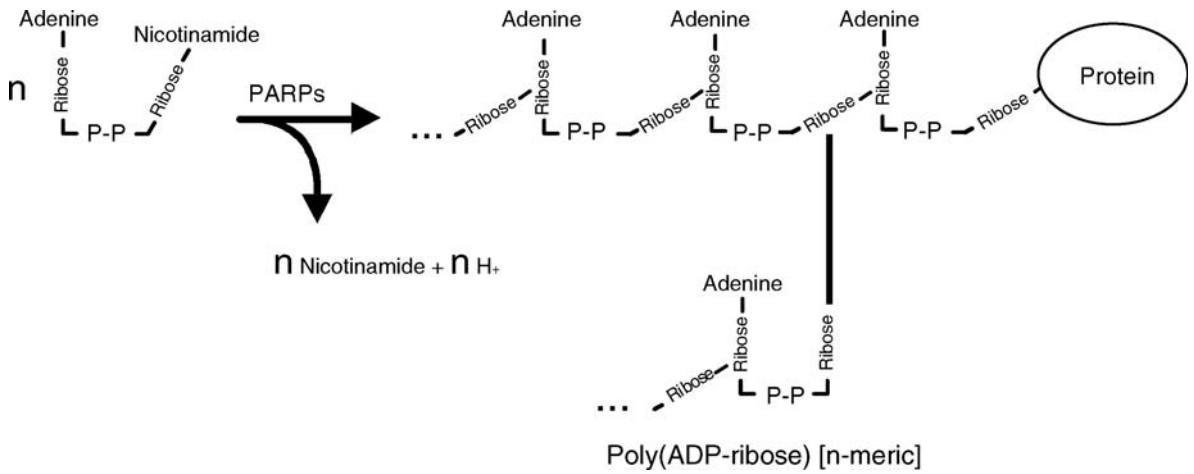
Definition

Poly(ADP-ribosyl)ation is a post-translational modification of glutamate or aspartate residues of proteins, with NAD^+ serving as precursor (Fig. 1), and represents an immediate eukaryotic cellular response to DNA damage as induced, e.g. by ionizing radiation, alkylating agents or oxidants [1–5]. Poly(ADP-ribosyl)ation is catalyzed mostly by the 113-kD enzyme ►poly (ADP-ribose) polymerase-1 (PARP-1). The *PARP1* gene (previously termed *ADPRT*) has been mapped to human chromosome 1q42. A number of additional polypeptides that are able to catalyze poly(ADP-ribosyl)ation have been identified in recent years, and sequence homology searches have revealed over a dozen different gene loci in the human genome that comprise the so-called PARP signature sequence and are now termed the *PARP* gene superfamily. The members of the PARP protein family include PARP-2, PARP-3, vPARP and tankyrases, and they collectively seem to account for up to 25% of the total cellular poly(ADP-ribose) production. The major enzyme catalyzing the catabolism of poly(ADP-ribose), by hydrolyzing the ribose-ribose linkages in the polymer, is poly(ADP-ribose) glycohydrolase (PARG). The single *PARG* locus mapped to human chromosome 10q11.23 has been shown to encode several polypeptides arising from differential splicing and displaying differential subcellular localization.

Characteristics

Catalytic Function of PARP-1 and Life Cycle of Poly(ADP-Ribose)

PARP-1 has been detected in most eukaryotes and displays a characteristic and highly conserved domain structure (which can be further broken down into subdomains). While the protein is constitutively and



Poly(ADP-Ribosyl)ation. Figure 1 Schematic representation of the structure of poly(ADP-ribose).

abundantly expressed in all proliferating and some non-proliferating cells, its catalytic activity is stimulated dramatically by DNA single-strand or double-strand breaks. Its DNA-binding domain, which is located at the amino-terminus, binds to single- or double-strand breaks in DNA via two zinc fingers. Binding of PARP-1 to broken DNA induces an immediate and dramatic activation of the catalytic centre residing in the carboxy-terminal NAD^+ -binding domain of the enzyme. PARP-1 is catalytically active as a dimer. In intact cells the enzyme itself is the major target protein ("acceptor") for covalent modification with poly(ADP-ribose). This "automodification" reaction is thought to occur mostly on a specific domain located between the DNA-binding and the NAD^+ -binding domain, respectively. However, in living cells a number of additional acceptor proteins have been identified, such as histones and ▶topoisomerases, and *in vitro* many more proteins can be modified with this polymer. The half-life of poly(ADP-ribose) is very short under conditions of DNA breakage due to its rapid degradation by PARG and other catabolic enzymes. Hence, the existence of poly(ADP-ribose) in intact cells is transient, and is restricted to the presence of DNA strand breaks. The life cycle of poly(ADP-ribose) is depicted schematically in Fig. 2.

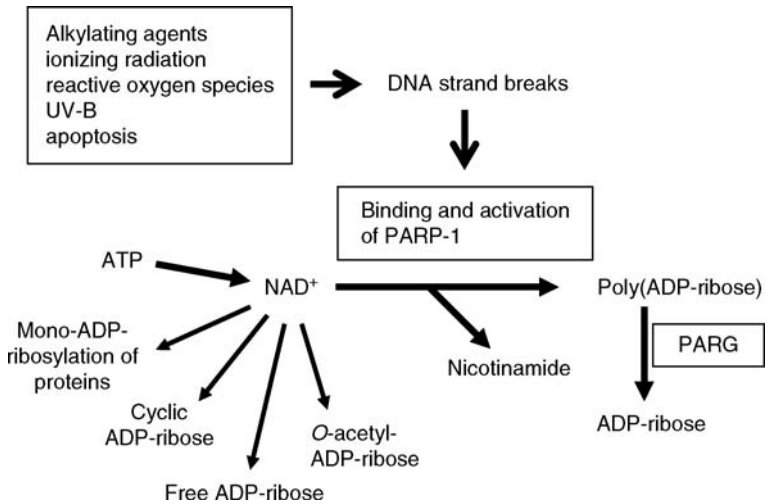
A number of molecular functions for PARP-1 and/or poly(ADP-ribose) have been proposed, and the following list is by no means exhaustive. It must be emphasized that many of the claims are based on work on subcellular systems, and the relevance for the *in vivo* situation is not known.

Molecular Functions Related with Regulation of DNA Strand Breaks and of DNA Repair

- Direct control of the activity of DNA-processing enzymes (DNA polymerases, ligases, topoisomerases etc) by their covalent modification with poly(ADP-ribose).
- Poly(ADP-ribosyl)ation of histones as a mechanism to induce localized chromatin relaxation, thus allowing access of DNA repair enzymes to the damaged site.
- Poly(ADP-ribose) as a "histone shuttle"; high-affinity non-covalent binding of (unmodified) histones to automodified PARP-1 should lead to localized chromatin relaxation, thus allowing access of DNA repair enzymes to the damaged site.
- PARP-1 as a component of a multi-protein complex carrying out DNA base-excision repair; such a protein complex would also comprise XRCC1, DNA polymerase-β and DNA ligase III. PARP-1 would detect DNA strand breaks at the original lesion site and could recruit the other partners. PARP-1 automodification might serve to regulate formation or function of such a complex.
- Physical and functional interaction of PARP-1 and poly(ADP-ribose) with the double-strand break-associated proteins DNA-dependent protein kinase (DNA-PK) and "ataxia telangiectasia mutated" (ATM).
- Locally restricted generation of ATP from poly (ADP-ribose) by pyrophosphorylytic cleavage, to be used for the DNA ligation step in DNA base excision repair.
- Signaling of DNA damage through non-covalent binding of poly(ADP-ribose) with p53, $p21^{WAF}$ etc.

Molecular Functions Related with the Maintenance of Genomic Stability

- Protection of "open" DNA strand breaks by PARP-1 binding, in order to prevent nonspecific DNA degradation and/or undesirable recombination. PARP-1 automodification might then serve to weaken the interaction with DNA, thus allowing repair activities



Poly(ADP-Ribosyl)ation. Figure 2 Life cycle of poly(ADP-ribose). PARP-1, poly(ADP-ribose) polymerase-1; PARG, poly(APD-ribose) glycohydrolase.

to proceed. It should be noted that a primary role of PARP-1 and/or poly(ADP-ribose) in DNA repair (see above) would of course indirectly contribute to the maintenance of genomic stability under conditions of genotoxic stress.

- Regulatory function of PARP-1 at the centrosome, thus preserving cellular euploidy.
- Stabilizing function of poly(ADP-ribose) at the mitotic spindle.
- Involvement of PARP family members in ►telomeres function.
- Physical interaction and functional cooperation of PARP-1 with the Werner syndrome protein (WRN).

Molecular Functions Related with DNA Replication

- PARP-1 as a component of a multi-protein DNA replication complex comprising enzymes for leading and lagging-strand DNA synthesis, some of which are potential targets for poly(ADP-ribosyl)ation (DNA polymerase-α, RPA, topoisomerase I, PCNA, DNA ligase I).
- Direct interaction between the PARP-1 DNA-binding domain and the catalytic subunit (p180) of the DNA polymerase-α-primase tetramer, independent of DNA. Thus PARP-1 might participate in a DNA damage-monitoring system, with its nick-sensor function perhaps playing a regulatory role when the progressing replication fork encounters strand breaks in the template.

Molecular Functions Related with Gene Expression

- Poly(ADP-ribosyl)ation as a regulator of chromatin compaction and DNA methylation status.
- Participation of PARP-1 in the activation of ►E2F-1 gene promoter after mitogenic stimulation of cells, leading to increased expression of both E2F-1 and DNA polymerase-α and entry into S-phase (see above, "Molecular functions related with DNA replication").
- PARP-1 as a transcriptional co-factor for B-MYB and for ►AP2 (independent of the catalytic function of PARP-1).
- PARP-1 as a cofactor for NFκB-mediated transactivation; in *Parp1*-deficient mice, the typical lipopolysaccharide-induced increases in serum levels of TNF-α, in inducible nitric oxide synthase (iNOS) expression and in nitric oxide production are lacking, and endotoxic shock does not develop.
- Silencing of RNA polymerase II-dependent transcription by PARP-1 activity in a cell-free system. Inhibition of TATA-binding protein (TBP) and the transcription factor YY1 by poly(ADP-ribosyl)ation (possible only prior to their binding to DNA).
- PARP-1 as interaction partner of transcription factors such as with retinoid X receptors (RXR), p53, Oct-1, PC1, E47, TEF-1 and DF1–4.

Molecular Functions Related with Energy Metabolism and Mitochondrial Changes

- Massive poly(ADP-ribose) synthesis leading to NAD^+ depletion and/or release of apoptosis-inducing factor (AIF) from mitochondria and consequently cell death.

Cellular Functions

Depending on the intensity of DNA damage inflicted to the cells and the cellular proliferation/differentiation status, PARP-1 has two contrasting functions:

- Cytoprotection and maintenance of genomic stability

To study the cellular function of poly(ADP-ribosyl)ation various strategies have been employed to abrogate poly(ADP-ribosyl)ation. These include competitive low-molecular weight ►PARP inhibitors, expression of a dominant negative PARP-1 version, PARP-1 antisense RNA expression, PARP-1 siRNA, or *Parp1* gene disruption in the mouse germ line. The results have consistently revealed that poly(ADP-ribosyl)ation significantly contributes to the recovery of proliferating normal and malignant cells from low-level DNA damage as induced, e.g. by alkylating agents or ionizing radiation, both *in vivo* and in cell culture. This effect has been linked mechanistically with an involvement of PARP-1 in DNA base-excision repair. Furthermore, there is clear evidence that poly(ADP-ribosyl)ation counteracts the induction of genomic instability by DNA damage, as assessed by several biological markers such as chromosomal aberrations, sister-chromatid exchange, gene amplification or mutagenesis. In addition, fibroblasts from *Parp1*-deficient mice display morphological abnormalities and reduced growth rate. These protective functions of PARP-1, as well as its role in maintaining telomere length in mice, are in line with correlative data showing an association of mammalian and human longevity with high cellular poly(ADP-ribosyl)ation capacity.

- Cell death induction

In stark contrast to the cytoprotective function mentioned above, PARP-1 overactivation may lead to cell suicide due to severe and irreversible depletion of $NAD^+$and consequently of ATP pools (Fig. 2). Whether the type of cell death induced is always necrotic or may be of the apoptotic type has not yet been clearly resolved. By comparing *Parp1*-deficient and wild-type mice and derived cells and by using competitive PARP inhibitors, such a cytotoxicity mechanism has been identified to be operative in several nonproliferating cell types. These include (i) pancreatic islet cells exposed to relevant DNA-damaging compounds (reactive oxygen species, nitric oxide metabolites, streptozotocin), (ii) neurons after regional ischemia-reperfusion damage of the brain (known to induce widespread release of reactive oxygen species and nitric oxide in the affected area, thus leading to the loss of many neurons and to brain infarct), (iii) dopaminergic neurons exposed to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP; a drug known to induce release of reactive oxygen species only in the dopaminergic neurons of the *substantia nigra*, thus leading to selective neuronal death and Parkinson syndrome). In each case it was shown that the cells from *Parp1*-deficient mice were highly protected from cell death and the animals displayed increased resistance to clinical disease. Likewise, administration of PARP inhibitors *in vivo* led to prevention of cell death in post-ischemic heart and skeletal muscle and renal tubular cells.

Recent data reveal that, apart from NAD^+ depletion, cell death by active PARP-1 can also be mediated by poly(ADP-ribose) itself. It was shown that the polymer can leave the nucleus and then trigger the release of apoptosis-inducing factor (AIF) from mitochondria. AIF, in turn, translocates to the nucleus and induces high-molecular weight DNA fragmentation and caspase-independent cell death.

It should be noted that classical ►apoptosis is associated with dramatic changes concerning the poly(ADP-ribosyl)ation system. After an initial burst of cellular poly(ADP-ribose) formation early in apoptosis, there is a well-documented proteolytic cleavage of PARP-1 into two fragments by activated caspase-3/7 during the execution phase of apoptosis, representing one of the most frequently used biochemical markers of apoptosis. This cleavage is thought to abrogate the responsiveness of PARP-1 to DNA strand breaks and thus to limit NAD^+ consumption. PARP-2 also undergoes caspase-mediated cleavage during apoptosis.

Clinical Relevance

Genetic Cancer Risk Assessment

Genetic polymorphisms and any resulting functional polymorphisms in cellular proteins involved in recognition and processing of DNA damage can be expected to contribute to the genetic risk profile of an individual with regard to the development of organ-specific cancers or cancer in general.

The active human *PARP1* gene locus on chromosome 1q42 displays several polymorphisms, such as a polymorphic dinucleotide repeat located in the promoter region and base substitutions in the coding region. Interestingly, recent publications report that the V762A polymorphism in PARP-1 leads to reduced enzymatic activity of PARP-1 and is associated with increased risk of lung, prostate and esophageal cancer. These initial observations are perfectly in line with the positive role PARP-1 activity plays in DNA repair and maintenance of genomic stability. According to this, a diminished enzyme activity based on a less active genetic variant can be expected to be limiting for the efficiency of the clearance of DNA damage and thus increase the risk of damage accumulation and genomic instability, which will act as a driving force for carcinogenesis.

Furthermore, a two-allele polymorphism in *PARP1P1*, a PARP-1-related pseudogene at 13q34, has been described. The B allele, arising from a 193-bp conserved duplicated region within the more frequent A allele, has been studied in several ethnic subpopulations, and the association of each allele with different types of cancer has been investigated. In endemic Burkitt lymphoma there was a strong association with the presence of at

least one copy of the B allele. An increased frequency of the B allele was also found in cases of multiple myeloma and prostate and colon cancer, but only among black patients. By contrast, comparisons of lung cancer cases with controls revealed significant enrichment of the B allele in Mexican-American patients only (an ethnic group with very low B allele frequency in general) and not in African Americans. Taken together this *PARP1P1* polymorphism may prove useful as a predictive factor for the risk for specific cancer types in persons from specific ethnic backgrounds. Whether or not this polymorphism has any impact on the cellular poly(ADP-ribosyl)ation status or represents just a marker for a relevant neighboring gene is unknown.

Therapy

For several decades cytotoxic tumor therapy, as delivered by the application of cytostatic drugs or ionizing radiation, has been the most frequently administered forms of cancer therapy. The sensitizing effect of PARP inhibitors in proliferating cells undergoing sublethal DNA damage has long been considered as a potentially useful mechanism to render conventional cytotoxic treatment regimens more effective at eradicating tumor cells in the body. Available data from cell culture experiments suggest that the most suitable cytotoxic agents to be combined with PARP inhibitors would be methylating agents, bleomycin and ionizing radiation, but not anti-metabolites. The first-generation inhibitors (benzamide and its derivatives), however, had significant drawbacks, particularly for the *in vivo* application, such as poor solubility, lack of potency and limited specificity of the compounds. Therefore, in recent years large numbers of novel PARP-inhibitory compounds have been synthesized and characterized, some of which proved to be at least 50-fold more effective as chemopotentiators than the reference inhibitor 3-aminobenzamide, and act in submicromolar (rather than millimolar) concentrations. Animal work revealed that combination treatment of tumors with the alkylating agent temozolomide and PARP inhibitors increases the efficacy of temozolomide. It will be interesting to see the effects of these novel compounds in clinical studies of cytotoxic tumor therapy.

Intriguingly, it was reported that tumor cells with non-functional ►BRCA1 or ►BRCA2 proteins can be sensitized to cell death by mere PARP inhibition in the absence of any DNA-damaging treatment [5]. Apparently DNA single-strand breaks arising spontaneously at rather low frequency will accumulate in under these conditions and are converted into double-strand breaks during DNA replication. As BRCA proteins are crucial for the signaling and proper repair of double-strand breaks by homologous recombination, repair is blocked and cells die as a result of the accumulating double-strand breaks. This scenario could form the basis for a highly selective future cancer chemotherapy protocol in patients with BRCA1 or BRCA2-deficient tumors, as the PARP inhibitor would kill the tumor cells, yet spare non-malignant cells as those would retain at least one functional copy of these genes.

Poly-Drug Chemotherapy

Definition

An approach to cancer therapy that utilizes the peculiar properties of the sphingolipids. Forcing a tumor to elevate its concentration of ►ceramide and gangliosides GM3 and GD3 induces their ►apoptogenic death. Simultaneously forcing the tumor to lower its concentration of proliferative sphingolipids (sphingosine-1-phosphate, ceramide-1-phosphate, glucosylceramide, and lactosylceramide) synergizes with the other procedure. Since these lipids are enzymatically interconvertible, therapy that controls only one or two of the lipids is likely to fail.

►Sphingolipid Metabolism

Polyadenylation

Definition

Step in the protein synthesis pathway in which a polyadenosine stretch is added to the 3′-end of a messenger RNA.

Polyamines

Definition

Are organic compounds, such as putrescine, spermidine, and spermine, that are growth factors in both eukaryotic and prokaryotic cells. They are synthesized in cells in pathways that are very highly regulated. The polyamines are essential for life, however in excess they can promote tumorigenesis. Biosynthesis is regulated by ►ornithine decarboxylase, and cellular export is through spermidine:spermine acetyl transferase (SSAT).

►Arginine and Cancer
►Transglutaminase-2

Polycomb

Definition

Polycomb complex modulates histone H3 by ►methylation of lysine residues, ►ubiquitination of histone H2A, and ►deacetylation of histones, and binds to the modified histones to inactivate the expression of the adjacent genes. Polycomb protein complex works as a molecular lock to suppress the gene expression to maintain the cellular homeostasis in adult cells.

Polycomb Group

Celina G. Kleer
Department of Pathology and Comprehensive Cancer Center, University of Michigan Medical School, MI, USA

Definition

The Polycomb group (PcG) is a family of proteins required for proper eukaryotic gene expression that determines ►cell fate (►Epigenetics, ►epigenetic gene silencing). They exert their role mainly by repressing gene transcription through ►epigenetic modifications on specific histone tails that are inherited through cell divisions, thus functioning as the cellular memory. They are involved in the maintenance of cell type and differentiation, and play a role in tumor development.

Characteristics

Cell differentiation depends upon keeping certain genes "on" and other genes "off" through generations. The differential gene expression patterns that define a cell type are maintained during DNA replication and at mitosis so that the daughter cells maintain the differentiated cell type of the parental cell. This is possible because cells have a ►transcriptional memory. Perturbance of the transcriptional memory can lead to severe developmental defects and to malignancy. The molecular basis of the cellular memory is controlled mainly by two groups of proteins: the Polycomb group (PcG) and the Trithorax group (TrxG).

The PcG and TrxG are chromatin associated proteins which function by activating and repressing transcription, respectively. While PcG proteins act mainly by repressing gene expression, TrxG proteins, operationally defined as antagonistic of PcG proteins, activate gene expression. Some proteins possess functions of both PcG and TrxG proteins. PcG and TrxG proteins have been well conserved throughout evolution. There are at least twenty PcG and TrxG proteins in *Drosophila*, and many have mammalian counterparts. Biochemically, they function in large protein complexes. In the following discussion we will concentrate on the PcG proteins.

Studies in *Drosophila melanogaster* have been instrumental in our understanding of proteins involved in transcriptional maintenance. The formation of *Drosophila melanogaster* relies on the expression pattern of a cluster of genes (►Homeotic genes) along the anterior-posterior axis during development. The PcG proteins maintain the correct spatial and temporal expression pattern of the homeotic genes through transcriptional repression. PcG mutants in *Drosophila* express homeotic genes outside the body segments they are normally expressed, causing marked transformations in body plan.

PcG Protein Complexes

PcG proteins function by forming two large multimeric complexes, termed Polycomb repressive complexes (PRCs). The PRC2, composed of EED, EZH1, EZH2, and SUZ12, is involved in the initiation of gene repression. The PRC1 contains multiple proteins including BMI1, HPC proteins (CBX2, CBX4, CBX7, CBX8), and RING proteins (Table 1). One of the hallmarks of transcriptionally active genes is that their nucleosomes contain acetylated histone H3. When genes are repressed, the ►histones are generally deacetylated and H3 is trimethylated on specific lysine residues (especially K9 and K27). The functional conservation between *Drosophila* and human PcG proteins in methylating histone H3 on lysine 27 has resulted in the development of a model for PcG-mediated gene silencing. In this model, at the initiation of gene repression, PRC2 associated ►histone deacetylases remove the ►acetylation of H3, and allow EZH2 to trimethylates lysine 27, and to a lesser extent lysine 9 of histone H3 ($H3K27me^3$ and $H3K9me^3$, respectively). The PRC1 can recognize the trimethylation mark through the chromo domain of the Polycomb protein, leading to the recruitment of the PRC1 maintenance complex. This interaction is proposed to target the PRC1 to specific repression sites. It should be noted that this model has not been yet confirmed in mammalian cells. The precise mechanisms by which the PcG proteins inhibit transcription are still unclear. One suggested mechanism by which the PcG proteins can block the transcription initiation machinery is though PRC1 ubiquitin E3 ligase activity of histone H2A lysine 119 (H2AK119), a modification associated with gene repression. Another suggested mechanism of PcG mediated repression is through PRC2 methyltransferase activity on lysine 26 of the linker histone H1 (H1K26). Methylated H1K26 can influence the chromatin structure. Furthermore, EZH2, a member of the PRC2 has been found to recruit DNA methyltransferases (DNMTs) to specific target genes. DNA ►hypermethylation of gene promoter regions results in transcriptional repression. By repressing specific genes, PcG proteins are involved in regulating a wide variety of fundamental cellular processes such as stem cell maintenance, cell fate, cell division, and neoplastic cell transformation.

PcG Proteins and Stem Cell Maintenance

An intriguing function of the PcG proteins is their emerging role in the maintenance of embryonic and

adult ►stem cells (►Stem cells). Stem cells have the ability to self-replicate and give rise to specialized cells, processes that require a transcriptional memory system that maintains the cell type identity from one generation of cells to another. This function is underscored by studies showing that targeted disruption of EZH2 or EED results in early embryonic lethality. Consistent with a critical role in the maintenance of stem cells, PcG proteins are able to silence genes with roles in embryonic development and genes responsible for cellular differentiation. Among these targets are homeodomain-containing transcription factors of the Dlx, Irx, Lhx and Pax gene families with functions in the early development of the neural and hematopoietic systems, and members of the Fox, Sox, Gata, and Tbx transcription factor families which not only have roles in development, but also in disease. For example, Gata3 has been found to play a role in breast cancer, with strong association with estrogen receptor expression. Furthermore, PcGs target genes in signal transduction pathways required for embryonic differentiation as well as for maintenance and proliferation of stem cells in tissues, such as transforming growth factor and fibroblast growth factor families, Hox, Notch (►NOTCH/JAGGED signaling in neoplasia), Hedgehog, and ►Wnt signaling pathways.

PcG Proteins in Human Malignancies and Their Clinical Relevance

Lack of differentiation, or anaplasia, is a hallmark of cancer which results from normal cells "forgetting" their cellular identity. Thus, it is not surprising that dysregulation of the transcriptional maintenance system can lead to malignancy. Current data suggest that altered expression of the PcG proteins may influence tumor development mainly by transcriptional repression of tumor suppressor genes and by maintaining the cells in a stem cell state. This is particularly intriguing in light of the stem cell model of carcinogenesis which proposes that human tumors contain and arise from transformed stem cells and early progenitor cells that have sustained specific genetic alterations. At least three mammalian PcG proteins, Bmi1, Rae28, and Mel18, are already implicated in the self-renewal of hematopoietic and neuronal stem cells. Although this theory is under extensive investigation and many questions need to be addressed, PcG proteins play a central role in the process of neoplastic transformation.

The first connection between PcG proteins and cancer development came from studies on Bmi1, which was found to cooperate with the proto-oncogene c-myc (►Myc oncongene) to promote the generation of B- and T-cell lymphomas and later shown to inhibit c-myc induced apoptosis through repression of the Cdkn2a locus. This tumor suppressor locus is frequently inhibited in human tumors. Further studies showed that other PcG proteins are also strongly associated with neoplastic transformation and progression. Although in human malignancies PcG proteins have primarily been found to be dysregulated in cells of hematologic origin, they play an important role in the development of carcinoma of different organs, melanoma, and neural tumors. EZH2 is overexpressed in multiple types of lymphoma and in solid tumors including carcinomas of the breast, prostate, colon, bladder, liver, and melanoma. In adenocarcinomas of the prostate gland, elevated levels of EZH2 protein are able to distinguish patients with localized prostate cancer that are more likely to experience tumor recurrence after prostatectomy. In breast tissues, overexpression of EZH2 occurs before histological evidence of malignancy and its overexpression in breast cancer is associated with larger tumors, the presence of lymph node and distant metastasis, and a worse clinical outcome. Furthermore, in breast cancers increased levels of EZH2 are associated with absent estrogen (►Estrogen receptor, estrogenic hormones and cancer) and progesterone receptors. Another PcG protein, SUZ12, is upregulated in both breast and colon cancers. The specific mechanisms leading to the overexpression of PcG genes and the events resulting in the localization of PcG proteins to different target sites await further investigations.

It is clear that the PcG proteins are overexpressed in several human malignancies, and that in carcinomas of the breast and prostate their up regulation is associated with an aggressive and metastasizing clinical course. For these reasons the use of PcG proteins as potential tissue ►biomarkers of cancer diagnosis, prognosis, and prediction to treatment response holds promise. Because PcG proteins appear to be expressed in certain cancers such as breast cancers before histological atypia, they may mark epithelium at higher risk for development of carcinoma. Importantly, given their role in malignant transformation of hematopoietic and solid human tumors, components of the PcG family may provide attractive opportunities for therapeutic intervention (►Epigenetic Therapy).

Synonyms

Polyaromatic compounds

Definition

Polycyclic aromatic hydrocarbons (PAHs) belong to the more general class of polycyclic aromatic compounds that contain two or more aromatic rings fused together in a linear or angular configuration. PAHs consist of carbon and hydrogen only. Hence, polycyclic aromatic compounds containing heteroatoms (e.g., N, S, and O) in their molecular structure would not belong to the group of PAHs in a narrow sense of the chemical nomenclature.

Characteristics

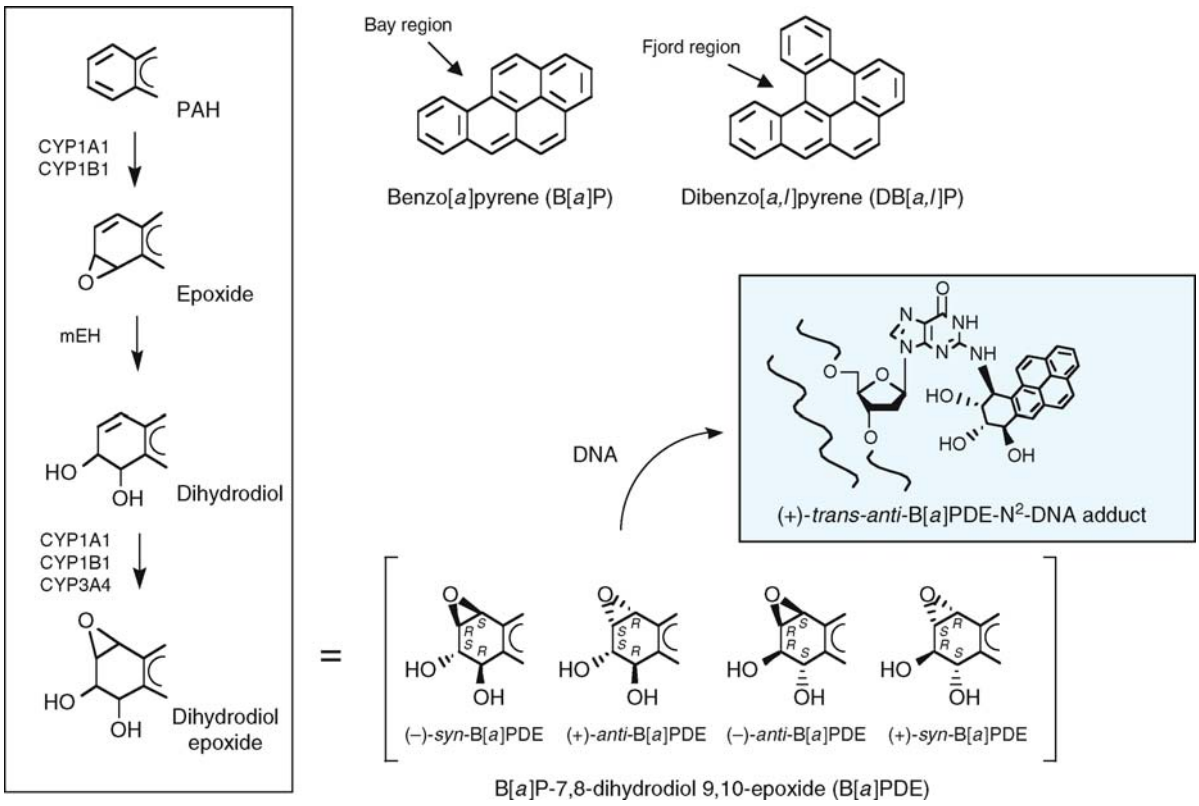
Anthropogenic Origin and Carcinogenicity

PAHs are formed during incomplete combustion processes of organic matter. Due to the abundant use of fossil energy sources, PAHs are readily detectable as ubiquitous contaminants in the environment. Humans are exposed to complex mixtures of PAHs in the atmosphere from combustion sources such as cigarette smoking, vehicle emissions, and fossil fuels, in foodstuffs from pyrolysis products such as over barbequed meat or charbroiled food. In addition, industrial and work place exposures occur through coal gasification, aluminum production, steel founding, and coal tar production. The great interest in this group of chemicals originated on the observation in animal tumor models that some member compounds possessed strong carcinogenic activity in skin, lung, breast, and other organs. Early observations of individual cancer cases occurring from occupational exposures to mixtures highly contaminated with PAHs lend support to the notion that these compounds can also act as carcinogens in man. Epidemiological data identified the occupational exposure to complex PAH-containing mixtures such as coal tar or coal tar pitches (consisting of up to 50% of PAHs with 1–2% benzo[*a*]pyrene, B[*a*]P; see Figure) as being carcinogenic to humans (IARC classification Group 1). Recent epidemiological meta-analyses confirmed that heavy exposures to mixtures of PAHs entails a substantial risk to develop cancer in lung and skin, and possibly also in the bladder (less consistent evidence), larynx, kidney, and pancreas (uncertain evidence).

No matter what kind of PAH source, humans are always exposed to mixtures of aromatic hydrocarbons with different degrees of biological activity. For instance, more than a hundred different PAHs can be detected in the air. The composition of these PAH profiles vary depending on the environmental compartment. Since there is no international agreement on which panel of individual PAHs should be analyzed and reported in order to characterize distinct emission sources, PAH lists released from different organizations may contain different compounds. Sixteen different PAHs such as pyrene, B[*a*]P, benz[*a*]anthracene, benzo-[*b*]fluoranthene, benzo[*k*]fluoranthene, indeno[1,2,3-*cd*]pyrene, dibenz[*a,h*]anthracene, and others are prioritized by the US Environmental Protection Agency. Lower molecular weight PAHs such as naphthalene, phenanthrene, anthracene, or fluoranthene are also listed due to their occurrence in environmental samples. From all hydrocarbons detectable in the human environment the most intensively studied example, B[*a*]P, has been traditionally used as an indicator for carcinogenic PAHs.

Molecular Mode of Action

PAHs can be readily absorbed from lung, skin, and gut. Rapid absorption of B[*a*]P and other PAHs from the gastrointestinal tract or from skin has been widely demonstrated in animal models, and sufficient evidence is also available for humans. On the other hand, absorption through the lungs may be affected by the size of particles at which most of the airborne PAH fraction is adsorbed. It has been shown that a considerable fraction of B[*a*]P adsorbed on soot, diesel exhaust, or carbon black particulate matter can be retained for up to weeks in the respiratory tract. The slow passage through bronchial mucosa can therefore result in very high local concentrations of these compounds directly within one of their main target tissues, the lungs. To react with cellular macromolecules, however, lipophilic and chemically inert compounds such as PAHs require enzymatic biotransformation into electrophilically reactive descendants (metabolites).



In a landmark paper from 1964, Brookes and Lawley reported on the tissue binding levels of six PAHs, i.e., naphthalene, dibenz[*a,c*]anthracene, dibenz[*a,h*]-anthracene, B[*a*]P, 3-methylcholanthrene, and 7,12-dimethylbenz[*a*]anthracene in mouse skin in vivo. The authors concluded that there is a significant positive correlation between the binding to DNA and the carcinogenic potency of these compounds. On the contrary, this correlation was not found for the binding to proteins or RNA. In more recent years it became clear that vicinal dihydrodiol epoxides of PAHs that contain the epoxy moiety in a sterically crowded bay or fjord region are the actual DNA-binding metabolites that mediate the biological effects associated with their parent structures (Figure). By direct application of these reactive descendants it has been demonstrated that their mutagenic potency correlates to the level of PAH–DNA adduct formation. Moreover, the tumor-inducing potencies of different PAHs in the lungs of strain A/J mice, another experimental tumor model, were found to correlate to the time-integrated DNA adduct levels (TIDAL) calculated as area under the curves of total dihydrodiol epoxide–DNA adduct levels during a time course of 30 days after injection. This parameter represents the total effective molecular dose delivered to target lung DNA, and it linearly correlated to the PAH doses administered. The intimate relationships between DNA binding level and mutagenicity and the TIDAL and carcinogenicity observed in mice in vivo support the notion that the DNA binding level can serve as an important biomarker for the tumor threat that may result from exposures of humans to carcinogenic PAHs. Hence PAH-DNA damage is considered to be causative and directly related to tumor formation by representing the first important step during the multistage process of PAH-induced carcinogenesis.

The PAH–DNA adduct level at a given time point is an integrated product of compound's toxicokinetic and toxicodynamic behavior, including metabolic activation and detoxification prior to covalent binding, as well as the effectiveness of the repair of those DNA lesions that have been formed. PAHs would not be carcinogenic if they were not metabolized by cytochrome P450-dependent monooxygenases (CYP enzymes) and microsomal epoxide hydrolase (mEH) through subsequent steps of epoxidation and hydrolysis (Figure). Deletion of the genes encoding the enzymes involved in this activation route (e.g., CYP1B1, mEH), or of the gene encoding the regulator protein involved in the induction of these enzymes (arylhydrocarbon receptor protein), renders mice resistant to the biological effects of potent PAHs such as B[*a*]P, 7,12-dimethylbenz[*a*]anthracene, dibenzo[*a,l*]pyrene, and others.

Metabolic activation of PAHs has been shown to be highly stereoselective. As demonstrated for a wide range of carcinogenic PAHs the initial epoxidation hydrolysis sequence produces a dihydrodiol with (*R,R*) configuration in high enantiomeric excess. Subsequent epoxidation at the vicinal double bond then predominantly generates the (*R,S*) dihydrodiol (*S,R*) epoxide with the epoxide moiety *trans* to the benzylic hydroxy group and spanning into a bay or fjord region. For B[*a*]P, all four possible stereoisomeric bay region 7,8-dihydrodiol 9,10-epoxides (B[*a*]PDE) are depicted in Figure, with (+)-*anti*-B[*a*]PDE as the major species formed during bioactivation. Depending on the activation system, very small amounts of the other isomers may also be generated. However, B[*a*]P-induced DNA damage in vitro or in vivo predominantly results from covalent interaction of (+)-*anti*-B[*a*]PDE, most of which is trapped by 2′-deoxyguanosine residues via *trans* opening of the epoxide moiety [(+)-*trans*-*anti*-B[*a*]PDE-N^2–DNA adduct; Figure]. If not repaired, this adduct causes nucleotide misincorporation at the opposite DNA strand during the next round of DNA replication, thus leading to base substitutions or frameshift mutations. In the case of B[*a*]P, recent data also suggest that poor enzymatic repair of its predominant (+)-*trans*-*anti*-B[*a*]PDE-N^2–DNA adduct is actually preceded by an insufficiently activated DNA damage checkpoint. At nontoxic doses of the dihydrodiol epoxide, a significant number of synchronized cells in vitro were found to enter the synthesis (S) phase of the cell cycle. The failure to induce a proper DNA damage arrest along with insufficient enzymatic repair increases the likelihood of transforming mutations because DNA replication continues on a damaged template via engagement of error-prone (Y-family) polymerases during translesional synthesis. Analysis of the cell cycle and the expression profiles of human epithelial cells or tumor cells of epithelial origin in culture revealed that the DNA damage arrest was insufficient even at a DNA damage level of about 180,000 *anti*-B[*a*]PDE–DNA adducts per cellular genome.

Bay or fjord region dihydrodiol epoxides of other carcinogenic PAHs were also identified as the actual metabolites that mainly mediate cellular binding to DNA and thus the genotoxic effects of their parent structures. Covalent PAH–DNA adducts are fixed as mutations if left to error-prone excision repair, misrepair, or replication errors during early S phase. Most importantly, if these fixed mutations occur in proto-oncogenes and/or tumor suppressor genes, they can contribute to the aggravation of neoplastic growth through the processes of tumor promotion and progression. Members of the oncogene family *RAS* have been found to be commonly mutated in human cancers and animal models for chemical carcinogenesis. Codon 12 (within exon 1) of *KRAS* is the most frequently affected codon in human cancers including human lung adenocarcinomas. Using human bronchial epithelial cells it was demonstrated that the first dG residue in codon 12 is a preferential binding site for the DNA-damaging dihydrodiol epoxide metabolite of B[*a*]P (at N^2). As compared with other sites, the "hotspot" character of codon 12 in target cells of chemical lung tumorigenesis results from a synergism between the preferential binding of the carcinogenic metabolite and a poor repair of those lesions that had been formed. On the other hand, binding studies of B[*a*]P at dG residues located in the DNA binding domain of the tumor suppressor *TP53* gene (exons 5, 7, and 8) have revealed that the codons and the positions within the codons affected matched between human bronchial epithelial cells exposed to *anti*-B[*a*]PDE and the *TP53* mutational hotspot pattern registered in the database of human lung cancer. This observation provided strong evidence for an etiological role of B[*a*]P in the causation of the disease.

Given the chemical complexity of most environmental matrices, it seems difficult, if not, impossible to uncover any causative relationship between certain forms of human cancer and the exposure to particular carcinogenic compounds. In addition to epidemiological hints, collective evidence from molecular toxicology and molecular epidemiology may nevertheless be able to point to the role of individual compounds (or single classes of compounds), and to extract their contribution from the overall biological response on environmental mixtures. One of the most well worked-out example is the crucial role of carcinogenic PAHs (i.e., B[*a*]P) in the etiology of human lung cancer based on their presence in cigarette smoke. Their important role in tumor initiation is supported by several lines of evidence such as (i) increased levels of PAH activating enzymes (CYP1A1 and CYP1B1) in lung cancer patients compared with controls, (ii) a correlation between pulmonary CYP1A1 levels and bulky *anti*-B[*a*]PDE–DNA adduct levels in human lung tissue from cancer patients, (iii) increased levels of *anti*-B[*a*]PDE-DNA adducts in lung tissue of smokers compared with nonsmokers, and (iv) the coincidence of mutational hotspots (G to T transversions) in *KRAS* (codon 12) or *TP53* (codons 157, 248, 273) and *anti*-B[*a*]PDE-N^2–DNA adduct hotspots as the preceding lesions found at the same sites.

Polycystic Kidney Disease

Yiqiang Cai
Section of Nephrology, Yale University School of Medicine, New Haven, CT, USA

Synonyms

Inherited human polycystic kidney disease

Definition

Polycystic kidney disease (PKD) is a common genetic disease characterized by accumulation of multiple fluid-filled cysts in each kidney and other organs. The renal cysts originate from the renal tubular epithelial cells lined by a single layer of cells that have higher rates of cellular proliferation and apoptosis, and are less differentiated than the normal tubular cells. Progression of cysts in the kidneys could ultimately cause ESRD (end-stage renal disease).

Characteristics

PKD consists of two forms: ADPKD (autosomal dominant PKD) and ARPKD (autosomal recessive PKD). ADPKD is the most common genetic disease affecting 1 in 500 to 1 in 1,000 in adults of all ethnic groups worldwide. ARPKD is far less common, affecting 1 in 6,000 to 1 in 40,000 at a far younger age, including newborns, infants and children. While kidney cysts are arise from all the segments of the nephron and collecting ducts in ADPKD, they are arise from collecting ducts in ARPKD. Extrarenal systems are affected in PKD.

Clinical Features

ADPKD

It is estimated that there are over 12.5 million affected ADPKD individuals worldwide. The development of bilateral, multiple, focal renal cysts characteristics of ADPKD lead to the clinical manifestations include abdominal mass, chronic flank or back pain, gross hematuria, urinary tract infection, and urolithiasis. Affected individuals typically present in the third and fourth decade, and ESRD usually develops in the sixth to eighth decades of life. Extrarenal cysts in ADPKD can arise from liver (~70%), pancreas (~5%), ovaries, and choroid plexus (rare). Cardiovascular abnormalities include mitral valve prolapse (~25%), mitral regurgitation, aortic insufficiency, and tricuspid regurgitation. Hypertension and left ventricular hypertrophy are common. Other extrarenal manifestations include cerebral and aortic aneurysms, cerebral dolichoectasis, and colonic diverticuli. A striking feature of ADPKD is the variability of the phenotype: the severity of the disease, the age of onset of ESRD, and the spectrum of extrarenal manifestation vary widely between affected individuals.

ARPKD

ARPKD is an important childhood nephropathy. The clinical phenotype is characterized by the combination of renal cystic disease and congenital hepatic fibrosis. Affected children often present in utero with enlarged, echogenic kidneys, as well as oligohydramnios secondary to poor urine output. Approximately up to 30–50% of affected neonates die shortly after birth as a result of severe pulmonary hypoplasia and secondary respiratory insufficiency. Those who survive the perinatal period have a 56–67% probability of survival to age 15 without ESRD and prolonged survival to age 55 has been reported. Those survivors express widely variable disease phenotypes with systemic hypertension, renal insufficiency, and portal hypertension due to portal tract fibrosis as the most common clinical features. Long-term survivors often develop sequelae of portal hypertension including esophageal varices, hepatosplenomegaly, and hypersplenism. Other clinical manifestations include growth retardation, urinary tract infection, and hyponatremia.

Molecular Basis

ADPKD is caused by mutations on a single gene of either *PKD1* or *PKD2*, while typical cases of ARPKD are resulted from mutations on *PKHD1* (polycystic kidney and hepatic disease 1) gene. Mutations have been identified throughout the gene of any among those three genes in affected PKD individuals without evidence for clustering. Both ADPKD and ARPKD might be recessive at molecular level: with two germline mutations in ARPKD or one germline mutation plus one somatic mutation caused by "second-hit" in ADPKD generating PKD phenotypes.

ADPKD

1. *PKD1*, located on chromosome 16p13.3 and responsible for ~85% of affected individuals of ADPKD, is comprised of 46 exons distributed over 52 kb of genomic DNA. The first 34 exons are duplicated several times elsewhere on chromosome

16, which has made routine mutation analysis technically difficult. *PKD1* produces a ~14 kb mRNA transcript. Polycystin-1 (PC-1), gene product of *PKD1,* is an integral membrane protein of 4302 amino acid and has molecular weigh of about 500,000 D. PC-1 contains an 11 membrane spanning domain with a ~3000 amino acid extracellular amino (NH_2)-terminus and a ~220 amino acid cytosolic carboxyl COOH-terminus. The large extracellular NH2-terminus contains domains many of which are novel and of unknown function, however, unique array of distinct protein motifs, including leucine-rich repeats flanked by cysteine-rich domains, a C-type lectin domain, a WSC domain, and 16 immunoglobin-like domains named PKD repeats, suggest PC-1 may function as a receptor since many of such motifs are involved in protein–protein or protein–carbohydrate interactions. Closer to the first transmembrane domain, there is a region of homology to the sea urchin egg jelly receptor and a consensus G-protein-coupled receptor proteolytic site (GPS site). The extracellular NH_2-terminal fragment (NTF) is cleaved at GPS site where the resulting COOH-terminal fragment (CTF) contains all the membrane spans and cytosolic tail. In addition, between the first and second transmembrane spans, there is a domain homologous to lipoxygenase (PLAT domain). The intracellular COOH-terminus contains a coiled-coil domain which mediates protein–protein interaction including the interaction with polycystin-2 (PC-2). Several potential phosphorylation sites are suggested within the COOH-terminus.

PC-1 expressed widely in vivo including kidney, brain, heart, and muscle. Subcellular expression of PC-1 is somewhat controversial as it has been detected in apical and basolateral membrane, tight junctions, adherens junctions, desmosomes, focal adhesions, and primary cilia, the key player for cystogenesis (further discussion see section "cilia and PKD"). Functions of PC-1 might be exerted through signal transduction including Wnt, JAK-STAT, AP-1, NFAT, and B-Raf/ERK-dependent pathway, ion-channel regulation, cell proliferation regulation, G-protein-coupled signaling, cellular adhesion properties, and transcription, however, precise function of PC-1 demand further investigation.

2. *PKD2*, the second gene responsible for ~15% of affected individuals of ADPKD, is located on chromosome 4 q21–23. *PKD2* gene contains 15 exons covering ~ 46 kb of genomic DNA and encodes a 5.3 kb mRNA transcript that is translated into an integral membrane protein polycystin-2 (PC-2). *PKD2* is approximately 25% homologous to a region of the *PKD1* gene. Unlike *PKD1*, *PKD2* gene is not duplicated on the chromosome. PC-2 is composed of 968 amino acids and has molecular weight of about 110,000 D. PC-2 contains six transmembrane spans and both intracellular NH_2- and COOH-termini. The transmembrane segments of PC-2 are about 50% identical to the last 6 transmembrane segments of the 11 transmembrane segments of PC-1. PC-2 is a nonselect cation channel sharing structural features with the transient receptor potential (TRP) channel family. The intracellular COOH-terminus of PC-2 contains a motif known as EF hand that can bind calcium, and an ER (endoplasmic reticulum) retention domain, deletion of which cause disruption of PC-2 localization in ER.

PC-2 is expressed widely in all tissues tested so far, including kidney, heart, brain, lung, pancreas, liver, testis, ovary, vascular smooth muscle, and intestine. At the subcellular level, located primarily in the ER, immuno-reactive PC-2 is also detected in basolateral plasma membranes, lamellopodia, mitotic spindles, in addition to the primary cilia (for further discussion see section "cilia and PKD"). PC-2 channel conducts divalent cations including calcium.

ARPKD

PKHD1, the gene responsible for ARPKD, is located on chromosome 6 p21.1-p12. *PKHD1* is very large and consists of at least 86 exons extending over 469 kb of genomic DNA on chromosome 6. The gene undergoes a complex pattern of alternative splicing to generate mRNA transcripts ranging in size from 8.5 kb to 13 kb. *PKHD1* gene is expressed in kidney with higher level and in liver and pancreas with lower level. Distribution of *PKHD1* mRNA transcript includes renal tubules, the bile ducts, blood vessels, testis, and dorsal root ganglia.

Polyductin (or Fibrocystin), encoded by *PKHD1* gene, is composed of 4074 amino acids and predicted to contain a large extracellular domain, a single transmembrane span, and a short intracellular COOH-terminus. Polyductin has molecular weigh of about 500,000 D and is expressed in cilia, cilia-associated structure basal bodies, and possibly in the plasma membrane. Functions of polyductin remain elusive.

Cilia and PKD

PKD is a human cilial disease. Cilia are microtubule-based organelles that project like antennae from the surface of almost every vertebrate cell. Ultrastructurally, cilia consist of membrane that is continuous with the cell plasma membrane but is a separate domain with unique complement of proteins and a central axoneme that is composed of microtubules. Cilia originate from the basal body, an intracellular organelle containing a pair of centrioles and surrounding matrix. There are two types of cilia: motile cilia and nonmotile primary cilia in the body. The axonemes of typical motile cilia contain nine peripheral bundles of microtubules and two central microtubules (9 + 2 pattern), whereas the axonemes of primary cilia contain nine peripheral bundles of microtubules (9 + 0 pattern). While

motile cilia move fluid past cells, nonmotile primary cilia transduce a multitude of sensory stimuli, including chemical concentrations of growth factors, hormones, odorants, and developmental morphogens, as well as osmolarity, light intensity, and fluid flow. Primary cilia have been identified in all segments of the nephron from Bowman's capsule to collecting ducts.

Abnormal structure and function of the renal primary cilium and its associated structures, i.e., centrosome and basal body, play key role in the pathogenesis of PKD. PC-1, PC-2, and polyducin are localized in primary cilia of renal epithelia. While structural disruption may be important in cystogenesis of ARPKD, dysfunction of the polycystins (PC-1 and PC-2)-functional-axis, rather than structural defect in cilia, may play a key role in cystogenesis in ADPKD.

Animal Models

Animal models for PKD have arisen through spontaneous mutations (such as *cpk, bpk, jck, kat, pcy,* and *Han:SPRD-cy*), chemical-induced mutagenesis (*jckp*), and gene-targeting approach (conventional or conditional knockout models for *Pkd1*, *Pkd2, and Pkhd1*). The pathology in these models resembles that seen in human PKD with regards to the localization, progression, and morphology of cysts, as well as involvement of the liver and pancreas. Homozygous of gene-targeting mouse models of *Pkd1, Pkd2*, and *Pkhd1* are embryonic lethal, however, an unique and most relevant mouse model that recapitulates ADPKD is the $Pkd2^{ws25}$ mouse line, which develop kidney and liver cysts postnatally. The $Pkd2^{ws25}$ allele was generated fortuitously by a targeting event that duplicated the first axon of *Pkd2*. The duplicated exon is able to undergo intragenic recombination in somatic cells at a relatively high frequency to yield either a wild-type or a mutant *Pkd2* locus. The spontaneous LOH (loss of heterozygosity) in the mouse carrying both the *Pkd2* null allele and a $Pkd2^{ws25}$ allele would result in focal cysts formation, which offer experimental evidence supporting the "two-hit" hypothesis of cysts formation in ADPKD.

Proteins encoded by genes responsible for the PKD animal models, including cystin (*cpk)*, polaris ($Tg737^{orpk}$), NPHP3 (*pcy*), Nek-8 (*jck*), Pc-1 (*Pkd1*), Pc-2 (*Pkd2*), and polyductin (*Pkhd1 and pck*), are localized in primary cilia. In addition, the proteins encoded by the *NPHP* gene family (*NPHP1–4*) and *BBS* gene family (*BBS1–8*), responsible for the nephronophthisis I–IV and Bardet–Biedl syndrome respectively, are localized in cilia or cilia-associated structure.

Nonmammalian PKD models have provided significant insights into cyst development. Most notable among these are the *Caenorhabditis elegans*, the *chlamydomonas,* and zebrafish. PKD-related genes in *C. elegans* including *lov-1* (*PKD1*), *pkd-2* (*PKD2*), *osm-5* ($Tg737^{orpk}$), *Nphp1*, and *Nphp4* are identified. Mutations in *lov-1* and *pkd-2* cause mating behavior defects associated with cilia-mediated sensory reception, whereas mutations in *osm-5* result in defects in cilia formation as seen in $Tg737^{orpk}$ mice. *Chlamydomonas* expresses many proteins that are mutated in murine and human PKD, including PC-2, polaris (IFT88), Kif3A (FLA10), and BBS proteins. Those proteins localize in flagella or cilia and their function is required for both assembly machinery such as intraflagella transport (IFT) and normal signaling activity of this organelle. In zebrafish, knock-down of zebrafish homologues such as *inv* and *Nek8* produce a distinctive renal cystic phenotype.

Therapy and Perspective

No specific treatment for PKD currently exists. Dialysis and kidney transplantation are the only effective treatments for the ESRD of PKD. Currently, therapeutic tests of V2R (Vesopressin-2 receptor) and mTOR (mammalian targets of rapamycin) inhibitors on animal models of PKD result in promising outcomes. Cyst fluid contains many hormonal activities, including antidiuretic hormone (ADH) and epidermal growth factor (EGF), as well as lipophilic substance, capable of stimulating the accumulation of cAMP (cyclic adenosine monophosphate). In the epithelial cells of distal tubules and collecting ducts, ADH activates the V2R, a $G\alpha_s$-coupled receptor linked to adenylate cyclase. PC-32160, a V2R antagonist, could prevent renal accumulation of cAMP and influences disease course in animal models of PKD including *PCK* rat (ARPKD), *pcy* mouse (adolescent nephronophthisis), $Pkd2^{ws25/-}$ (*Pkd2* gene-targeting mouse). OPC-41061, a structural analog of OPC-31260, also inhibits development of PKD in the *PCK* rats. Like OPC-31260, OPC-41061 significantly decreased renal cAMP levels, kidney weights, cyst and fibrosis volumes, mitotic and apoptotic indices. It also inhibits activation of Ras and ERK. None of those antagonists prevent development of fibropolycystic liver disease, consisting with the absence of V2R in liver.

mTOR, a key player in proliferation of activated T-lymphocytes, is a member of the phosphoinositide kinase-related kinases, and phosphorylates target protein such as S6 kinase and 4E binding protein on serine/threonine residue. Inhibition of mTOR by treatment of rapamycin was effective in reducing cyst and kidney volume in two models of recessive PKD, the $Tg737^{orpk}$ and the *bpk* mice. In addition, rapamycin was also effective in *pcy* mouse model even when started at a later time point. Reagents which have been successfully tested in different model systems are the EGFR tyrosine kinase inhibitor (Han:SPRD rat), caspase inhibitor (Han:SPRD rat), taxol (cpk mouse), methylprednisolon

(Han:SPRD rat), bicarbonate (Han:SPRD rat), and lovastin (Han:SPRD rat).

Development of renal cysts is the key phenotype of PKD. Maintenance of an intact, normal functional signaling pathway, mediated by cilia and its resident proteins polycystins, and polyductin, play a key role in preventing cyst formation. Enhanced understanding of the molecular mechanism regulating the polycysins and polyductin signaling would facilitate the intervention of effective targets which could restore the normal functional axis of polycystins and polyductin.

Polycythemia

Fulvio Della Ragione, Silverio Perrotta
Department of Biochemistry and Biophysics, Second University of Naples, Naples, Italy
Department of Pediatrics, Second University of Naples, Naples, Italy

Synonyms

Erythrocytosis

Definition

A condition in which the hemoglobin amount and the erythrocytes count are increased over the normal values.

Characteristics

The Greek term, polycythemia (literally, many cells in the blood) corresponds, in the clinical setting, to the word erythrocytosis. This condition exists when hemoglobin amount and the erythrocytes count are increased as the consequence of a build-up of the total volume of red cells.

It is possible to distinguish primary and secondary forms as well as congenital or acquired polycythemias.

Primary polycythemias show an enhanced capability of the erythroid progenitors to respond to normal levels of circulating cytokines as the consequence of genetic mutations (both germline inherited or somatically acquired) that cause an increased proliferation or a decreased apotoptosis of erythrocytes precursors. From a functional point of view, in these forms there is a dissociation between the total oxygen carrying ability (i.e. the total hemoglobin content) and the oxygen tissutal requirement or the status of oxygens-sensing pathways.

It is possible to identify forms of primary polycythemias both congenital and acquired.

The primary congenital and familial polycythemia is an autosomal dominant disorder characterized by low serum erythropoietin (Epo) levels, in vitro hypersensitivity of erythroid progenitors to Epo, normal leukocyte and platelet counts, vitamin B12 level, and bone marrow cytogenetics. A number of cases of primary congenital and familial polycythemias are due to mutations of the ►erythropoietin receptor gene. Particularly, the mutated receptors lacks C-terminal domains and show ineffectiveness of the mechanism(s) by which the receptor activation is shutted-down by inhibitory loop(s). This results in an excess of Epo stimulatory activity on erythroid precursors.

The commonest acquired form of primary erythrocytosis is the polycythemia vera (PV) also known as polycythemia rubra vera. In a frequent number of cases of PV, an excess of white blood cells and platelets, a low Epo level, and splenomegaly are also evidentiable. Thus, PV is classified as a myeloproliferative disease. This erythrocytosis rarely occurs in people younger than 20 years since it usually develops very slowly. The frequency is about 1–2 individuals affected over 100,000.

PV has been ascribed to a mutation of the gene encoding the kinase ►JAK2 (i.e. the change of the nucleotide G at the 1849 position into T that corresponds to the substitution of valine to phenylalanine at the residue 617 of the protein). About 90% of patients with PV has this mutation, but the precise percentage of them that shows the mutation in homozygosity or heterozygosity has not been definitely determined.

The JAK2 mutation results in a non synonymous amino acid substitution located in the JH2 pseudokinase auto-inhibitory domain. The change renders the enzyme constitutively active and leads to cytokine hypersensitivity, Epo-independence of erythroid precursor growth and erythrocytosis in a mouse model. Moreover, the constitutive JAK2 activation is accompanied by the enhancement of growth activating pathways (ERK) and antiapoptotic mechanisms (Akt).

Although the *JAK2*V617F mutation seems to explain some features of PV, it is becoming increasingly evident that the genetic change is not be the initial clonogenic event in PV. Indeed, the analysis of single colonies of erythroid precursors from PV patients suggests the existence of molecular changes distinct (but yet unknown) from *JAK2*V617F mutation.

In its early stages, PV usually doesn't cause any signs while as the disease progresses several symptoms might occur.

These include: headaches, weakness, dizziness (vertigo), and/or a ringing noise in the ear (tinnitus). In some cases, individuals with polycythemia vera experience itching (pruritis), especially after a hot bath. Affected individuals often have an abnormally enlarged spleen (splenomegaly) and/or liver (hepatomegaly). In some cases, patients may have associated conditions including high blood pressure (hypertension), the formation of blood clots (thrombosis), rupturing of and loss of blood (hemorrhaging) from certain blood vessels, and/or Budd-Chiari syndrome, a rare disorder characterized by obstruction (occlusion) of veins of the liver (hepatic veins).

Secondary polycythemias are characterized by a physiological responsiveness of bone marrow erythroid progenitors to cytokines and by an increased serum levels of factors driving erythropoiesis, including Epo, Insulin Growth Factor 1, cobalt, etc. Therefore, secondary polycythemias must be regarded both (i) as a normal response of bone marrow to oxygen requirements of tissues and (ii) as a mutation (germline or somatic) affecting the oxygen sensing pathway and its target (see above). In other words, in secondary polycythemias normal erythroid progenitors are stimulated by alteration in external factors.

Like primary, also secondary polycythemias might be distinguished in congenital and acquired forms.

Several congenital forms have been identified including high affinity hemoglobins due to globin gene mutations or ►bisphosphoglycerate (BPG) deficiency, congenital ►methemoglobinemia and cyanotic congenital heart or lung diseases. Particularly, cyanotic congenital heart disease represents an important cause of polycythemia in young children worldwide. In all these hereditary conditions exist a pathological low tissue oxygen tension that represents the initial event to activate mechanisms stimulating an increased erythropoietic activity.

So far, there are more than 100 mutations of hemoglobin leading to an increase in oxygen affinity and a reduction in oxygen delivery resulting in compensatory polycythemia. These mutations affect the cooperative binding between the globin subunits (α1/β2 interface) or interfere with the binding of BPG. These mutations are dominantly inherited and cause a benign polycythemia. *P*50 (partial pressure of oxygen where hemoglobin is 50% oxygenated) offers the best initial screening to detect high oxygen affinity accurately and can be estimated mathematically from venous blood gas measurements. BPG deficiency is a rare congenital red cell disorder and results from a deficiency of biphosphoglyceromutase (BPGM). BPG is present in very high concentrations in red blood cells. It binds hemoglobin and allosterically changes its configuration thereby modulating its ability to bind oxygen. A decreased BPG level shifts the oxygen dissociation curve of hemoglobin to the left (increases hemoglobin affinity for oxygen), resulting in decreased delivery of oxygen to the peripheral tissues and compensatory polycythemia. BPGM mutation should be considered in the setting of a low *P*50 and after globin gene mutations have been definitely excluded.

An important form of secondary congenital erythrocytosis, due to peculiar mutations of the von-Hippel Lindau (VHL) gene has also been recently identified.

The normal response to acute hypoxia (low oxygen pressure) includes hyperventilation, pulmonary vasoconstriction, systemic peripheral vasodilation, and tachycardia. The mechanisms by which these complex systemic responses are activated and modulated are still limited explained and, in some cases, remain elusive. Conversely, it is now clear that intracellular responses to hypoxia are coordinated by the hypoxia-inducible factor (HIF) family of transcription factors, which regulate (both directly or indirectly) the expression of numerous genes in any given cell type.

About these downstream target HIF genes, it appears important to cite *Epo*, *SLC2A1* (also known as ►*Glut-1*, encoding facilitated glucose transporter member 1 of solute carrier family 2), transferrin, transferrin receptor, vascular endothelial growth factor (VEGF) and a number of genes coding for enzymes of the anaerobic glucose metabolism. The VHL tumor suppressor protein is an essential component of the degradation pathway through which some members of HIF family are primarily regulated by oxygen pressure. Indeed, the HIF-alpha is synthesized continuously but is rapidly destroyed in the presence of O_2. Oxygen-dependent prolyl hydroxylases hydroxylate specific residues in HIF-1, increasing its affinity for VHL. The binding of VHL to hydroxylated HIF-alpha then targets the protein for destruction by the ubiquitin–proteasome pathway. Under hypoxic conditions, HIF-alpha hydroxylation is inhibited and thus there is rapid accumulation of the transcription factor and the up regulation of hypoxia-responsive genes, including Epo gene.

In the classical VHL-associated cancer syndrome, affected individuals are heterozygous for a germline VHL mutation that predisposes to specific tumors. Known clinical manifestations are confined to cancers and discrete benign lesions that arise following somatic inactivation of the second allele. However, alterations

of hypoxia-dependent pathways are limited to cancer cells and only rarely result in polycythemias.

Chuvash polycythaemia (CP) is a form of erythocytosis endemic in Chuvashia (a republic of the Russian Federation) where approximately several hundred cases are recognized among a population of about 1.5 million people. An additional cluster has been subsequently identified in Ischia island (Italy) and a number of cases in other region of world. CP patients are homozygous for 598C > T mutation in VHL gene that reduces but does not abolish HIF-alpha activity. The VHL mutation diminishes HIF-alpha degradation by pathologically upregulating HIF-alpha target genes, including Epo. CP is characterized by congenital erythrocytosis, but has yet to be extensively phenotyped. The CP is a non-benign hematological disease associated with lower peripheral blood pressures, higher estimated pulmonary artery pressures, varicose veins, vertebral hemangiomas, arterial and venous thrombosis, major bleeding episodes, cerebral vascular events and premature mortality due in part to cardiovascular and thrombotic events. Moreover, erythroid progenitors of CP patients are hypersensitive to Epo by a molecular mechanism totally obscure. This last property is, however, reminiscent of primary hereditary polycythemias, thus rendering, at least in part, uncertain the classification of CP as a primary or a secondary erythrocytosis.

Because CP is characterized by a germline mutation in the VHL gene, it has been hypothesized that homozygotes for this mutation might develop certain vascular tumors similar to those associated with the classic VHL syndrome. However, in no case, spinocerebellar hemangioblastomas, renal carcinomas, and pheochromocytomas typical of classical VHL tumor predisposition syndrome have been found, and no increased risk of cancer has been demonstrated. Through experiments conducted on CP patients, it has been demonstrated the potential role of the VHL pathway in cardiopulmonary physiology. In particular, patients with CP have an elevated basal ventilation and pulmonary vascular tone, with extremely high ventilatory, pulmonary vasoconstrictive, and heart rate responses to acute hypoxia. The abnormalities they displayed mimicked those caused by acclimatization to hypoxia at high altitude.

It has been estimated that the VHLC598T mutation arose in a single ancestor between 12,000 and 51,000 years ago. It is possible that the wide dissemination from the original founder may be associated with some survival advantages for heterozygotes carrying this mutation. Such an advantage might be related to a subtle improvement of iron metabolism, erythropoiesis, embryonic development, energy metabolism or some other yet unknown effect. An intriguing possibility is raised by the recent demonstration of a protective role for HIF-alpha in protecting against pre-eclampsia, the leading cause of maternal and fetal mortality worldwide. Another positive role of a mildly augmented hypoxic response is an improvement in the bactericidal action of neutrophils, as recently observed in HIF1alpha knock-in mice. Finally, other VHL mutations have been detected in either homozygotes or compound heterozygotes affected by secondary congenital polycythemias. It is tentative to classify these cases and Chuvash erythrocytosis as VHL-dependent polycythemias.

Although several genetic alterations responsible for secondary polycythemias have been identified, more than 50% of these erythrocytoses with normal or increased serum levels of Epo (and other cytokines), do not have a definite molecular basis. These cases include both diseases inherited with a recessive or a dominant fashion.

Secondary polycythemias due to acquired conditions include a large array of causes, all resulting in low peripheral pressure of oxygen. Among these, high altitude dwelling, chronic obstructive pulmonary disease, sleep apnea, cyanotic heart disease result in secondary polycythemia as a physiological adaptation.

In addition, kidney transplantation has polycythemia as a complication. The cause of this acquired secondary erythocytosis might be correlated to specific pharmacological treatments required during the post-transplantation period.

Polycythemia Vera

Definition

PV, synonym primary polycythemia, a condition in which there is an overproduction of red blood cells in the body as a result of an abnormality of the bone marrow.

►Erythropoietin

Polygenic

Definition
A mode of inheritance characterized by a sporadic occurrence and variable intensity of manifestation of the phenotype. It is due to the segregation in the same individual of susceptibility/resistance alleles at multiple unlinked genetic loci.

►Modifier Loci

Polygenic Diseases

Definition
Are caused by a combination of environmental factors and mutations in multiple genes; each mutation has only a small contribution to the disease susceptibility. These include most of the common chronic diseases like obesity, hypertension, Alzheimer, diabetes, arthritis, and many cancers.

►Case–Control Association Study

Polymers

Definition
Are high molecular weight molecules consisting of a repeating chain of identical base units (called monomers) connected by covalent chemical bonds. Cationic non-biodegradable polymers enhance the internalization of therapeutic molecules by cells. Biodegradable polymers are used to achieve the controlled release of therapeutic molecules.

►Non-viral Vector for Cancer Therapy

Polymorphism

Definition
Literally means existing in a variety of different shapes. Genetic polymorphism is variability at a gene locus in which the variants occur at a frequency of greater than 1%. The major histocompatibility complex is (►MHC) the most polymorphic gene cluster known in humans.

►Linkage Disequilibrium
►Personalized Cancer Medicine
►Pharmacogenomics
►MDM Genes

Polymorphonuclear Leukocyte Elastase

►Neutrophil Elastase

Polyneuropathy

Definition
Malfunction of multiple peripheral nerves.

►Peripheral Neuropathy

Polypeptide

Definition
A chain of amino acids linked by peptide bonds, in the range of 10–100 amino acids; proteins are composed of much longer sequences of amino acids and their functions are determined additionally by the 3-dimensional structure.

►Gut Peptides
►Modular Transporters

Polyphenols

Elvira de Mejia
Department of Food Science and Human Nutrition, University of Illinois, Urbana-Champaign, IL, USA

Definition
Polyphenols are plant substances possessing more than one aromatic ring bearing one or more hydroxyl

P

groups, including their ►functional derivatives, and may occur as unconjugated aglycones or as conjugated with sugars, organic acids, amino acids or lipids. Examples of polyphenols are ►epigallocatechingallate, ►genistein, ►resveratrol, quercetin, rutin. Common dietary sources rich in polyphenols include tea, soybean, berries, chocolate, wine, apple and orange juices, black beans, tomato, sweet peppers, broccoli, onion.

Characteristics

Polyphenols consist of a family of diverse compounds, which comprises chalcones (butein), dihydrochalcones (tephropurpurin), flavanones (naringenin), flavones (apigenin), dihydroflavonols (engeletin), flavonols (quercetin), flavanols (catechins), ►isoflavones (genistein), proanthocyanidins (propelargonidins), and anthocyanidins (delphinidin). Their main physiological function is as antioxidants. Therefore, a long-term consumption of a diet rich in plant foods containing polyphenols may offer some protection against chronic diseases, including ►cancer. Thus fruits, vegetables, tea, red wine and cocoa consumption have been suggested to have the capacity to reduce cancer development. ►Flavonoids may also exert other effects unrelated to their ►antioxidant capacity, for example, ►anti-inflammatory effects and inhibition of tumorigenesis. Cancer has been associated with ►oxidative stress and mechanisms involving inflammation, aberrant signaling pathways and ►gap junction intercellular communication. It is possible that the presence in the diet of compounds with the capacity to ►scavenge free radicals like polyphenols may play a role in oncogenesis. While the free radical scavenging and antioxidant properties of phenolics are well established, emerging literature reports suggest that their chemopreventive effects may also be attributed to their ability to modulate components of cell signaling pathways.

Different polyphenols have different degrees of absorption in humans, however, it is believed that isoflavones are the best absorbed even though this parameter is influenced by the matrix of the diet and enhanced by a high fat diet. Studies in humans and animals have indicated that some polyphenols can be absorbed in the small intestine (5–10%), and most of them enter the circulation as methyl, sulfate and glucuronide conjugates; of these, only a very small amount (5–10%) enter the plasma as unchanged plant polyphenols. The 90–95% ingested total polyphenols are fermented in the colon and a variable portion of these (5–50%) is absorbed mainly as conjugates of microbial metabolites. It is clear that the major part of polyphenols consumed never reach the plasma and systemic circulation so the tissues most exposed are those of the oro-gastrointestinal tract. Animal studies have shown that diets rich in polyphenols that reach the colon may protect rodents from carcinogenesis. Inside the human body, flavonoids themselves are of little or no direct antioxidant value; however, inducing phase II enzymes can help in the elimination of mutagens and ►carcinogens and may be of value in cancer prevention. Polyphenols could also induce mechanisms that help kill cancer cells and inhibit tumor invasion.

Cellular and Molecular Studies

The biological mechanisms related to the chemopreventive activities of polyphenols are believed to occur by the regulation of signaling pathways such as ►nuclear factor-kappa B, ►activator protein-1 or mitogen-activated ►protein kinases. By modulating cell signaling pathways, polyphenols activate cell death signals and induce ►apoptosis in precancerous or malignant cells resulting in the inhibition of cancer development or ►progression. However, regulation of cell signaling pathways by dietary polyphenols can also lead to cell proliferation/survival or inflammatory responses due to increased expression of several genes. Dietary polyphenols can exert their effects on these pathways separately or sequentially and in addition the occurrence of crosstalk between these pathways can also take place. Polyphenols can also behave as detoxifying enzyme inducers, modulating gene expression including induction of phase II enzymes, such as glutathione S-transferases and quinone reductase, which usually leads to protection of cells/tissues against exogenous and/or endogenous carcinogenic intermediates. Phase II gene inducers also activate ►MAPK kinases that are involved in the transcription activation of antioxidant response element-mediated reporter gene.

Genistein, an isoflavonoid with ►phytoestrogenic properties, in animal models has shown to have a very complex effect on carcinogen-induced mammary cancer and great care is required in extrapolation of this information to human ►breast cancer. Some unconjugated isoflavones from fermented soybean and ►tamoxifen promoted an additive reduction in the number of mammary tumors in rats. Isoflavonoids have biphasic effects on the proliferation of breast cancer in culture; genistein at low concentrations can stimulate the growth of estrogen receptor-positive breast cancer cells but it does not stimulate the growth of ►estrogen receptor-negative breast cancer cells. Phytoestrogen responsive genes characterized from these cells can be used to clarify the role of isoflavones in cancer prevention. Of course many other mechanisms of action have been suggested for isoflavones and in particular for genistein. An important aspect of cancer risk is the involvement of the inflammatory response thus soy isoflavones may have potentially protective benefits at sites of inflammation due to their antioxidant action and could contribute to anticancer ability because ►reactive oxygen species could initiate signal transduction through the ►mitogen activated protein kinases.

Clinical Studies

Human studies are still contradictory and not final conclusions can be drawn on the effect of polyphenols and cancer. Flavonoids may be capable of exerting antioxidant effects in humans with the possibility of direct radical scavenging, down regulation of radical production, elimination of radical precursors such as hydrogen peroxide, metal chelation, inhibition of ►xanthine oxidase and of course elevation of endogenous antioxidants. Dietary polyphenols as health promoting dietary antioxidants have a broader mechanism of action than simple radical scavenging and radical suppression.

Studies with pre and postmenopausal women administered beverages and supplements with isoflavones gave no conclusive results on breast cancer risk factors and more studies are needed to clarify the effect of isoflavones and breast cancer in women. In cultures where the intake of soy is high and consequently dietary isoflavones, breast fed infants are exposed to high levels without adverse effects and it has been observed that early exposure may even protect against cancer. Safety and efficacy of isoflavones in humans is a topic that needs further investigation.

While experimental models have suggested that flavonoids attenuated cancer risk, epidemiological studies have failed to demonstrate a clear effect for tea, although there is moderate evidence for a slightly positive or no effect of black tea consumption on colorectal cancer. Studies on cancer have been limited by sample sizes and insufficient control of confounder factors.

In addition, caution must be exerted when polyphenols bypass the gastrointestinal tract (intravenous injections) or mega doses of these compounds (purified and presented in the form of tablets or capsules) are taken due to possible adverse effects such as nephrotoxicity.

The available evidence for tea polyphenols tentatively supports their advancement into phase III clinical intervention trials aimed at the prevention of progression of prostate intraepithelial neoplasia, ►leukoplakia or premalignant cervical disease. In the case of curcumin and soya isoflavones more studies in premalignacies seem appropriate to optimize the nature and design of suitable phase III trials. There is insufficient evidence from human research as yet to claim benefits of polyphenols in relation to cancer prevention. Epidemiological data that suggest tea consumption contributes to cancer prevention do exist, however, these failed to differentiate between green, black or oolong tea. Studies of colorectal cancer suggested either a slightly positive effect or null effect.

In conclusion, further mechanistic insights are needed as well as an accurate knowledge of the concentrations of the chemopreventive agents and their metabolites occurring in humans. Only small amounts of flavonoids may be necessary to see medical benefits. In terms of safety, consistent with the expectation that dietary constituents are harmless and well tolerated, unexpected cases of severe toxicity associated with the consumption of polyphenols have been rare. Severe adverse effects have only been reported for a very limited number of cases when consuming daily gram amounts of green tea polyphenols in the form of green tea extracts or when administering high doses of quercetin intravenously in cancer patients.

Positron Emission Tomography

Andreas K. Buck, Markus Schwaiger
Department of Nuclear Medicine, Technical University of Munich, Munich, Germany

Synonyms

Hybrid positron emission tomography/computed tomography; Integrated positron emission tomography/computed tomography; Small animal positron emission tomography

Definition

Positron emission tomography (PET) is a non-invasive nuclear medical imaging modality enabling the visualization and quantification of biological processes. PET provides integral information regarding metabolic activity of the primary tumor and potential lymph node or distant organ metastases. PET can be used for cancer detection (►early detection), ►tumor staging and

restaging, assessment of response to treatment and anticancer drug development.

Characteristics

Principle of Positron Emission Tomography (PET)

PET allows non-invasive assessment of the three-dimensional distribution of a positron labeled compound within the living body. Positrons are anti-particles of electrons and originate from β+ decays of radioactive isotopes such as ^{11}C, ^{13}N, ^{15}O, ^{18}F, ^{68}Ga, ^{86}Y, or ^{124}I. During β+ decay a positron and a neutrino are emitted, both sharing a certain amount of kinetic energy. Once the positron is slowed down, a positronium consisting of a positron and an electron is created. The positronium has a very short half-life of 10^{-10} s and the masses of the positron and the electron are finally transferred into energy. This annihilation results in two gamma quants with an energy of 511 keV each. Decay events are detected by coincidence registration enabling the measurement of activity distribution in a specific transaxial section of the body. Activity distribution can be calculated from respective projections after correction for scatter, attenuation, dead time and random coincidences. Attenuation correction can be performed using a radioactive transmission source rotating around the patient. Emission and transmission scanning from scull to mid thigh usually takes 30–45 min, whole body-scans 60–90 min. The radiation dose of a standard PET examination is low with approximately 7.4 mSv and similar to spiral CT of the thorax.

Radiolabeled Biomarkers for PET Imaging Specifically Addressing Metabolic Pathways or Target Molecules

Depending on the clinical situation, various radiolabeled pharmaceuticals can be utilized for tumor imaging (Table 1). The most important biomarker for functional diagnosis of tumors is the glucose analog 2′-[^{18}F]-fluoro-2′-deoxy-D-glucose (FDG, ^{18}F-Fluorodeoxyglucose) (Fig. 1). Since conventional imaging modalities such as ►computed tomography (CT), ►magnetic resonance imaging or ultrasound detect malignant lesions because of characteristic morphological alterations, FDG-PET enables the diagnosis of malignant tumors due to an increased glucose metabolism in malignant cells. After intravenous administration, FDG is predominantly taken up by tumor cells. After enzymatic conversion of FDG to FDG-6-monophosphate by hexokinase, the metabolite can not be further metabolized resulting in an intracellular "trapping" of FDG (►metabolic trapping).

There are many other radiopharmaceuticals capable of assessing distinct pathophysiological processes (Table 1). As an example, radiolabeled nucleoside analogs such as 3′-deoxy-3′-[^{18}F]-fluorothymidine (►FLT, ^{18}F-fluorothymidine) can be used to non-invasively assess the proliferative activity of tumors. With the positron emitter ^{15}O, $H_2{}^{15}O$ can be synthetized and used for assessment of tumor blood flow. A variety of radiolabeled amino acids such as [^{11}C]-methionine (►MET, ^{11}C-methionine), [^{11}C]-leucine (LEU) or [^{18}F]-fluoro-ethyl-tyrosine (►FET, ^{18}F-fluoroethyltyrosine) can be used to evaluate transport rates of amino acids and/or protein biosynthesis. Imidazole derivatives such as [^{18}F]-misonidazole (FMISO) can be used to delineate hypoxic tissue areas of the tumor which is particularly useful for radiation treatment planning. Synthesis of phospholipids is increased in many neoplasms leading to increased uptake of [^{18}F]-choline and [^{11}C]-choline (►CHO, ^{11}C-choline). [^{68}Ga]-DOTATOC (►DOTATOC, [^{68}Ga]DOTATOC) specifically binds to somatostatin receptors and is therefore highly sensitive for detection of neuroendocrine tumors. [^{18}F]-galacto-RGD (►RGD, ^{18}F-Galacto-RGD) has a high affinity to the vitronectin receptor αvβ3 and can be used as potential surrogate marker of neoangiogenesis. These and many other radiopharmaceuticals specifically address metabolic pathways or bind to specific target structures and therefore enable molecular imaging of cancer. Specific radiotracers are especially helpful for evaluation of new drugs and early response assessment in cancer.

Clinical Applications of PET and PET/CT

The introduction of PET to clinical medicine has influenced the management of patients with cancer. In most industrialized countries, PET is now accepted as a both useful and economic diagnostic tool for characterization of indeterminate lesions, initial staging, restaging and assessment of response to therapy in a variety of cancers. Combination of a PET scanner with spiral computed tomography in a single examination (►PET/CT, Integrated positron emission tomography/computed tomography) allows integrated functional (PET) and morphologic (CT) imaging. Additionally to the results returned by individual modalities, coregistration of CT allows precise localization of PET lesions. The addition of PET to CT leads to an increase of sensitivity as well as specificity for tumor imaging. Moreover, CT data can be used for attenuation correction which leads to a significant reduction of scanning time making PET/CT more comfortable for the patient. A standard examination including the head, thorax, abdomen and pelvis can be performed within 25–30 min. Since it's introduction to clinical medicine in 2001, PET/CT represents the fastest growing imaging modality. The Centers of Medicare and Medicaid Services (CMS) approved a variety of clinical indications including staging and restaging of non-small cell ►lung cancer, esophageal (►esophageal cancer), colorectal (►colorectal cancer), breast (►breast cancer) and head and neck cancers (►oral squamous cell

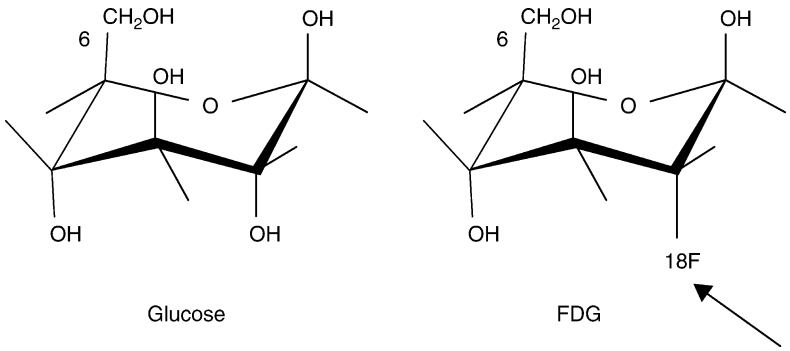
Positron Emission Tomography. Table 1 Radiopharmaceuticals (tracer) used for PET imaging (CUP, cancer of unknown primary)

Radiopharmaceutical (*under investigation)	Native molecule	Uptake mechanism in cancer	Clinical applications
18F-fluorodeoxy-glucose (FDG)	Glucose	Glucose transport/phosphorylation by hexokinase	Diagnosis, staging, restaging (e.g., cancer of the lung, breast, colon, rectum, thyroid, lymphoma melanoma, sarcoma); CUP monitoring of response to therapy (e.g., lymphoma, various cancer types including breast, GI tract, lung*)
11C-choline (CHO) 18F-fluorethylcholine (FEC) 18F-fluorocholine	Choline	Uptake by active transport and phosphorylation by choline kinase; incorporation into phospholipids (cellular membrane)	Staging, restaging (prostate cancer, bladder cancer*); therapy monitoring (prostate cancer*, bladder cancer*)
11C-acetate	Acetate	Lipid synthesis (key enzyme, fatty acid synthase, FASE)	Staging, restaging, monitoring response to therapy in a variety of cancers
68Ga-DOTATOC 68Ga-DOTATATE	Octreotide (somatostatin analog)	Binding to somatostatin receptors (predominantly SSTR-2)	Diagnosis, staging, restaging of neuroendocrine tumors, CUP (neuroendocrine)
18F-DOPA	Dihydroxy-phenylanaline	Uptake in tumors capable of DOPA decarboxylation	Diagnosis, staging, restaging of neuroendocrine and brain tumors, CUP (neuroendocrine)
18F-fluoro-ethyl-tyrosine (FET) 11C-methionine (MET)	Tyrosine Methionine	Amino acid transport, protein biosynthesis	Diagnosis, staging, restaging of brain tumors; differentiation of scar/recurrence, monitoring response in various tumor types
18F-galacto-RGD (RGD*)	Peptide containing the sequence RGD (arginine, glycine, aspartate)	Binding to integrin αvβ3 (vitronectin receptor), expressed on activated endothelial cells	Assessment of tumor angiogenesis (e.g., melanoma, sarcoma, head and neck cancer, breast cancer), monitoring response to anti-angiogenic treatment
18F-fluorothymidine (FLT*) 11C-thymidine (THY*)	Thymidine	DNA synthesis, tumor cell proliferation	Assessment of tumor proliferation (monitoring response to cytotoxic treatment in lymphoma, sarcoma, breast cancer)
18F-fluoroazamycine arabinoside (FAZA*) 18F-fluoromiso-nidazole (FMISO*)	Hypoxia markers (no biologic analog)	Passive diffusion into hypoxic cells; reactive intermediates are formed by intracellular nitroreductase and trapped within the cell	Assessment of tumor hypoxia (especially for use in tumors of the head and neck, radiation treatment planning)
11F-fluoro-17-β-estradiol (FES*)	Estradiol	Binding to estrogen receptors	Monitoring of response to antihormone treatment in breast cancer
18F-fluoride	Fluoride	Bone mineralization	Screening for bone metastases at staging or restaging

carcinoma, oral cancer), ►malignant lymphoma and ►melanoma. Monitoring response to treatment in breast cancer is also covered. Just recently, the CMS announced to provide widespread coverage of PET when respective examinations are part of prospective clinical trials.

Differentiation of Benign from Malignant Tumors and Detection of the Primary Tumor (Cancer of Unknown Primary)

Due to different glucose consumption of benign and malignant lesions, FDG-PET allows assessment of



Positron Emission Tomography. Figure 1 The glucose analog FDG (2′-[^{18}F]-fluoro-2′-deoxy-D-glucose) is the most widely used radiopharmaceutical for PET imaging. After i.v. injection, FDG is taken up by glucose transporters Glut-1 (cancer tissue, brain) and Glut-4 (skeletal muscle, heart) and is phosphorylated by hexokinase II. FDG-6-P is not a substrate for hexokinase phosphate isomerase which is the next enzyme of the glycolytic pathway. Consecutively, FDG accumulates in the cytoplasm (metabolic trapping). The figure shows the structure of the native glucose molecule (left) and the [^{18}F]-labeled analog (right).

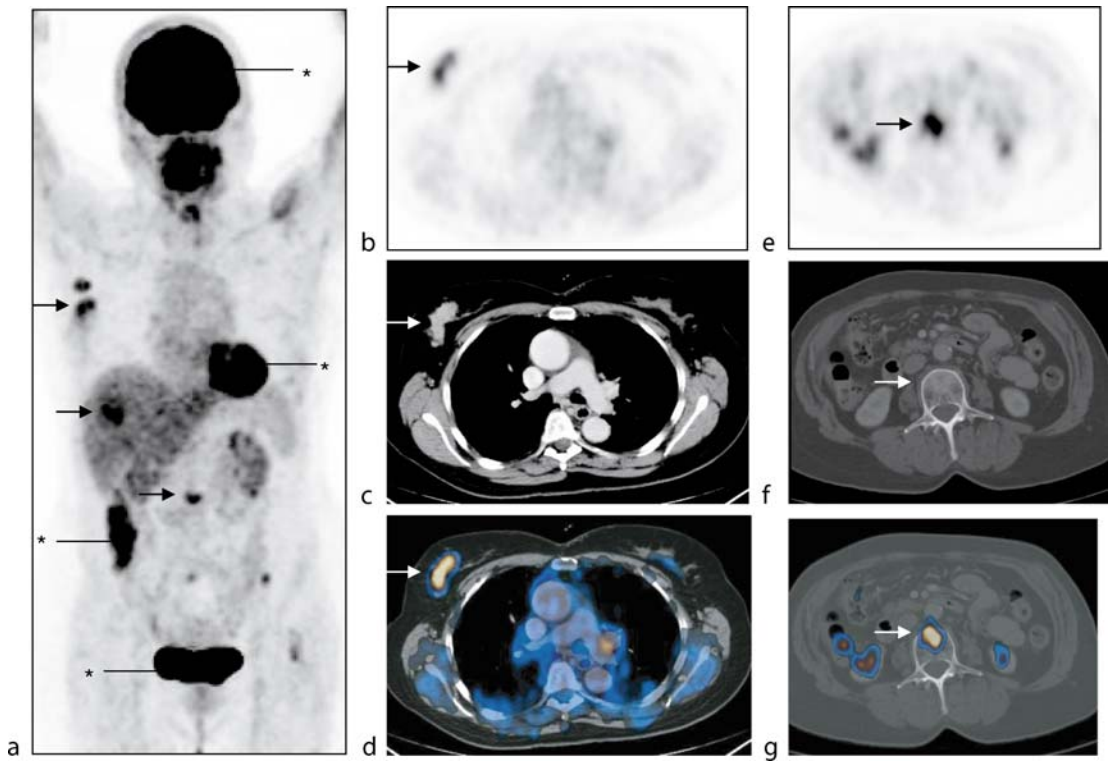
undefined tumors detected by conventional imaging modalities such as CT or MRI. Furthermore, PET sometimes allows detection of malignant lesions even when no or only minimal morphologic alterations are present. Regarding evaluation of indeterminate pulmonary nodules, prospective studies reported sensitivity values for FDG-PET between 89 and 100%, a specificity of 69–100% and an overall accuracy of 89–96%. FDG is not tumor specific leading also to non-specific tracer accumulation in benign, predominantly inflammatory lesions. However, surgery may be circumvented in patients with increased perioperative risk if the PET scan is negative. Dynamic data acquisition can further enhance the accuracy of PET imaging. In malignant lesions, a continuous increase of glucose uptake has been described, whereas benign lesions showed an increase of FDG-uptake followed by rapid efflux of FDG. Dual time point imaging or delayed PET imaging after 1 and 2 h contributes to better differentiate between benign and malignant tumors.

PET can also be used for detection of the malignant primary (►cancer of unknown primary, CUP). PET is especially useful in detecting primary tumors in the head and neck region. In case of increased cancer biomarkers (►clinical cancer biomarkers) or paraneoplastic syndromes, PET can aid in localizing the primary tumor manifestation site.

Staging of Cancer, Prognostic Potential of PET

For optimal treatment of patients with cancer, precise knowledge of the extent of the disease is crucial (tumor staging). If cancer is detected at a stage in which uncontrolled growth of tumor cells takes place but no tumor manifestations are present in distant organs, surgery is usually performed to obtain ultimate cure. However, if the tumor has already spread to distant organs, cure can usually not be achieved by surgery alone (Fig. 2). In this situation, surgery has to be replaced or supported by systemic chemo- and/or radiotherapy to entirely destroy the primary tumor and metastatic sites or to induce growth arrest in the tumor. In this context, PET has several advantages compared to conventional imaging modalities. Small tumor manifestation sites such as ►metastases in the bone, liver, lung, adrenal gland or in rare locations such as soft tissues, thyroid or (sub-) cutaneous lesions can be detected. However, micrometastases or single tumor cells can also not be detected with PET. Also, small lung metastases may appear negative at FDG-PET. In principal, staging of all tumors is possible. With the standard radiotracer FDG, PET is highly accurate for staging of non-small cell ►lung cancer, thyroid cancer, tumors of the head and neck region (►oral squamous cell carcinoma, ►oral cancer), ►colon cancer and ►esophageal cancer, ►malignant lymphoma, sarcoma (►osteosarcoma, ►Ewing sarcoma, ►chondrosarcoma), and ►melanoma. PET has been demonstrated to cause a change in patient management in 15–40% depending on the type of cancer. Some tumors present without increased glucose consumption such as prostate or neuroendocrine cancer. ^{11}C-Choline PET and ^{11}C-Choline PET/CT have been demonstrated to be highly accurate for staging and especially restaging of prostate cancer. ^{68}Ga-DOTATOC is a new PET-tracer for imaging neuroendocrine tumors. A variety of molecular probes have been evaluated to address biologic targets or metabolic pathways in vivo (Table 1). In the majority of these compounds, clinical utility remains to be determined.

The most important prognostic factor (►Prognosis, prognostic factor) is the tumor stage at initial presentation. However, risk stratification according to the



Positron Emission Tomography. Figure 2 (a) FDG-PET/CT in beast cancer (maximum intensity projection); malignoma-associated intense FDG-uptake in primary breast cancer, lymph node metastases in the axilla, liver metastases and bone metastases (arrows). (b) Transaxial PET section showing intense FDG-uptake of the primary tumor. (c) Transaxial section of helical CT indicates the anatomic correlate of primary breast cancer. (d) Fused image. (e) Transaxial PET section, high FDG-uptake in a bone metastasis of the vertebral column. (f) Transaxial section of helical CT indicates a sclerotic lesion corresponding to the PET lesion. (g) Fused image. Intense physiologic uptake of FDG in the brain, the heart, and intestines (*).

TNM-system is also subject to error, because patients with limited disease undergoing definite therapy may also develop recurrent disease. Other factors such as tumor aggressiveness or metabolic activity of tumors may aid in individual risk assessment. Several studies have correlated the intensity of FDG-uptake in the primary tumor to progression free and overall survival in various cancers. In lung cancer, intensity of FDG-uptake turned out to be an independent prognostic marker. The prognostic potential of PET has also been described for colorectal cancer, breast cancer and malignant lymphoma.

Assessment of Response to Therapy

Therapeutic efficiency of chemo- and radiotherapeutic strategies varies significantly between individual patients. Therefore, non-invasive assessment of the performance of a therapeutic protocol in an individual patient is highly desirable. With conventional imaging modalities such as CT or MRI, response (►radiological response criteria) to therapy can be detected as early as a reduction in tumor size occurs. On the contrary, PET allows assessment of response to treatment at an earlier time point before tumor shrinking can be detected by conventional imaging. In responding tumors, metabolism of tumor cells is markedly decreased due to the cytotoxic effect of the respective therapeutic regimen. Concomitantly, accumulation of FDG is reduced. This is a sign of an efficient treatment and has a high prognostic value regarding the success of further treatment. In case of a non-responding tumor, the therapeutic regimen can be altered by changing the combination of cytotoxic drugs or the radiation dose. In ►breast cancer, rapid decline of FDG-uptake already after one cycle of chemotherapy was demonstrated, whereas in non-responding tumors increasing or unchanged FDG-uptake was described. A variety of other neoplasms including ►malignant lymphoma, ►gastric cancer and ►esophageal cancer, head and neck (►oral squamous cell carcinoma, ►oral cancer) or non-small cell ►lung cancer showed rapid reduction of FDG-uptake in responding tumors. Significantly better disease-free and overall survival was described in responders compared to tumors without

significant reduction of tumoral FDG-uptake (Fig. 3). Clinical studies are needed reporting on the clinical benefit of a PET-guided change of patient management.

Restaging of Cancer, Detection of Recurrence

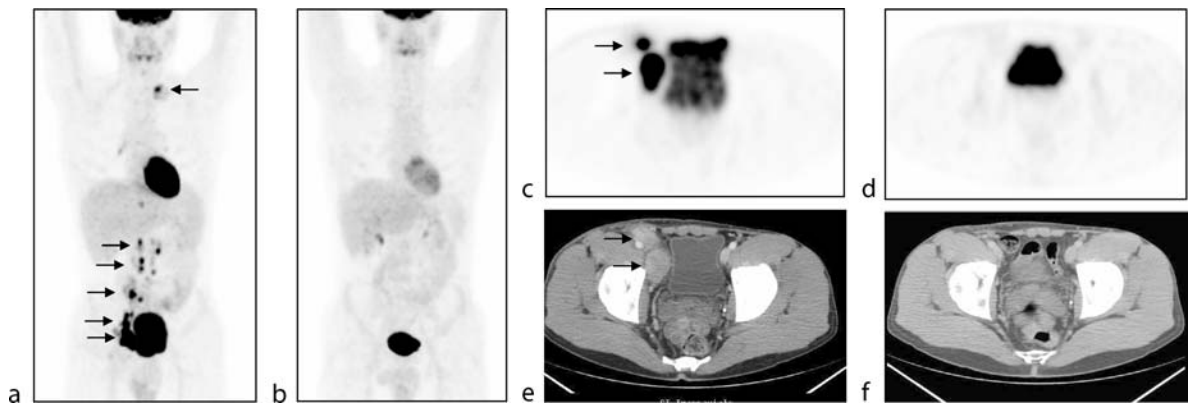
After definite surgery or chemo/radiotherapy, examinations and imaging at follow-up is important to early detect disease recurrence originating from residual tumor cells. In daily clinical practice, differentiation between scar tissue and vital tumor tissue is a frequent problem. At anatomically based imaging modalities, both are present as indeterminate tissue formation and, frequently, biopsy is needed for further clarification. Differentiation of scar tissue from vital tumor tissue is a prerequisite of PET imaging. While new onset of cancer tissue is associated with increased metabolism causing increased uptake of, e.g. FDG, scar tissue is frequently associated with reduced metabolism compared to surrounding normal tissue. PET is especially useful in the follow-up of tumor entities such as colorectal (►colorectal cancer) and ►esophageal cancer, non-small cell ►lung cancer, ►breast cancer, tumors of the head and neck (►oral squamous cell carcinoma, oral cancer), brain tumors (►malignant brain tumors), ►melanoma and ►malignant lymphoma. Restaging with PET is also approved for differentiated thyroid carcinoma with a negative ^{131}I whole-body scan and elevated tumor marker thyroglobulin.

Radiation Treatment Planning

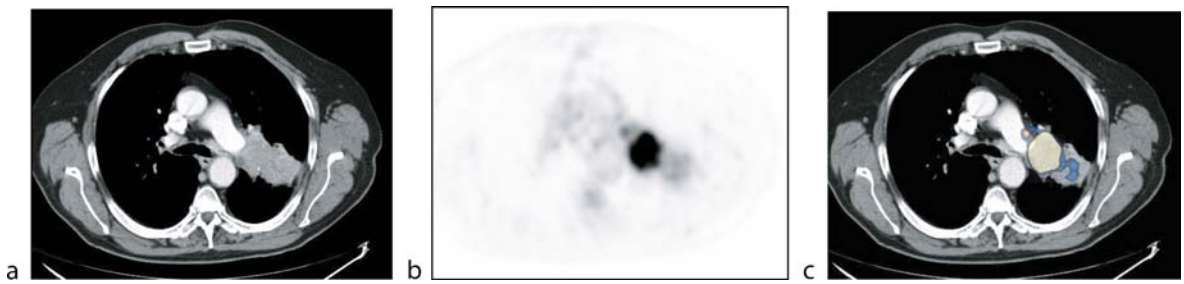
The use of metabolic information leads to biological target volumes which can have substantial impact on radiation treatment planning (►radiation oncology) by increasing or reducing the target volume. The additional identification of tumor manifestation sites which are not visible at conventional staging causes an enlargement of respective target volume. On the other hand, the radiation field can be reduced when non-malignant lesions such as atelectatic tissue can be reliably characterized as benign (Fig. 4). Consecutively, radiation dose to surrounding normal tissue can be reduced. The use of PET for radiation treatment planning leads to a change of the target volume in up to 60% of patients. This is in part related to pretherapeutic detection of distant metastases, previously unknown metastases in locoregional lymph nodes or characterization of suspicious lesions as benign. However, PET-based radiotherapy planning is not trivial. Especially the delineation of the primary tumor is subject to a relevant interobserver variability. There is a need for standardized evaluation criteria of PET allowing also the quantification of metabolic changes. The recent introduction of PET/CT hybrid scanners has lead to a reduction of errors concerning image coregistration. In several prospective studies it was shown that overall survival of patients receiving PET-guided radiation therapy was significantly longer compared to patients receiving standard treatment. Prospective randomized studies have to be performed demonstrating that the use of PET positively affects patient outcome and overall survival.

PET for Anticancer Drug Development

PET imaging has unique properties for use in anticancer drug development. Therapeutic efficiency of a novel drug can be evaluated non-invasively by assessment of specific biologic endpoints such as changes in cellular proliferation (e.g., by the use of [^{18}F]FLT), glucose utilization ([^{18}F]FDG), tissue perfusion ([^{15}O]H_2O), metabolism of amino acids ([^{18}F]FET, [^{11}C]MET),



Positron Emission Tomography. Figure 3 (a) FDG-PET for response assessment in malignant lymphoma (maximum intensity projection), intense FDG-uptake of multiple lesions of high-grade non-Hodgkin's B-cell lymphoma (arrows indicate lymphoma manifestations in the left supraclavicular region, in paraaortic, parailiac and inguinal lymph nodes. (b) Corresponding PET image of the same patient 3 weeks after completion of 8 cycles of chemotherapy with R-CHOP. No pathologic FDG-uptake in residual lymph nodes indicates complete remission of the disease and favorable outcome. (c–f) Corresponding transaxial sections of PET and CT.



Positron Emission Tomography. Figure 4 FDG-PET/CT for radiation treatment planning of nonsmall cell lung cancer. (a) Transaxial section of spiral CT shows a central tumor in the left lung which can not be discriminated from adjacent atelectatic tissue. (b) Corresponding section of FDG-PET indicates high metabolic activity of the malignant primary but anatomic landmarks are missing preventing precise tumor localization. (c) Fused PET/CT image allows exact delineation of the tumor which can be distinguished from adjacent atelectatic tissue.

or inhibition of ►angiogenesis ([^{18}F]galacto-RGD). (Over-) expression of the therapeutic target such as thymidylate synthase, VEGF receptor, ErbB2 or ►estrogen receptor status can be quantified with [^{11}C] thymidine, radiolabeled antibodies specifically binding to VEGF or ErbB2, or ^{18}F-fluoro-17-β-estradiol, respectively. Assessing biologic endpoints further provides proof of principle of the proposed mechanism of action. PET can also be utilized for in vivo-evaluation of gene expression, e.g. by the use of the substrate [^{124}I] fluoro-5-iodo-1-β-D-arabinofuranosyluracil (FIAU) for detection of Herpes simplex virus thymidine kinase type 1- or Na[^{124}I] for detection of sodium iodide symporter expression.

Generic endpoints can also be studied by PET. Drugs or biochemical probes can be labeled with positron emitters such as small molecules, proteins, or antibodies. Drugs which have been evaluated so far include ^{18}F-fluorouracil, ^{18}F-tamoxifen or ^{13}N-cisplatin. Pharmacokinetics of a drug can be investigated in tumors and normal tissues, in animal models or as part of clinical phase I (or phase II) studies. In the future, PET will be increasingly used to assess the efficiency of novel anticancer drugs.

The restoration of blood flow to an organ or tissue. After a heart attack, an immediate goal is to quickly open blocked arteries and reperfuse the heart muscles.

►Amine Oxidases

Postlabeling

Definition

32_P-postlabeling is a sensitive method for the detection and quantification of adducts to DNA. DNA is extracted in microgram quantities from tissue samples and enzymatically digested to mononucleotides. These are labeled with radioactive phosphorus (32_P) and the resulting 32_P-labeled adducts are separated from normal nucleotides by two-directional thin layer chromatography. Quantification can proceed by autoradiography, and identification is possible by co-chromatography with authentic samples.

Posttranslational Modification

Definition

PTM is the chemical modifications of proteins following their translations. After syntheses, the proteins are subjected to reversible or permanent modifications. They are one of the later steps in protein biosyntheses for many proteins. To identify the specific sites of modifications in the analysis of enzymatically digested proteins, tandem mass spectrometry with collision-induced dissociation of peptides can be used. More than 300 PTMs have been identified, such as phosphorylation, ►glycosylation, ►ubiquitination, deamidation, proteolytic processing, fatty acylation, and glycosylphosphatidylinositol lipid anchor attachment. Analysis of a protein for PTMs is very important for understanding issues such as activity, stability, interaction, and turnover.

Pre-mRNA

Definition

Precursor mRNA, an RNA that has not been processed and contains all of its introns and exons.

►pre-mRNA Splicing

Pre-mRNA Splicing

Dawn S. Chandler
Department of Pediatrics, Columbus Children's Research Institute, Center for Childhood Cancer, The Ohio State University School of Medicine, Columbus, OH, USA

Definition

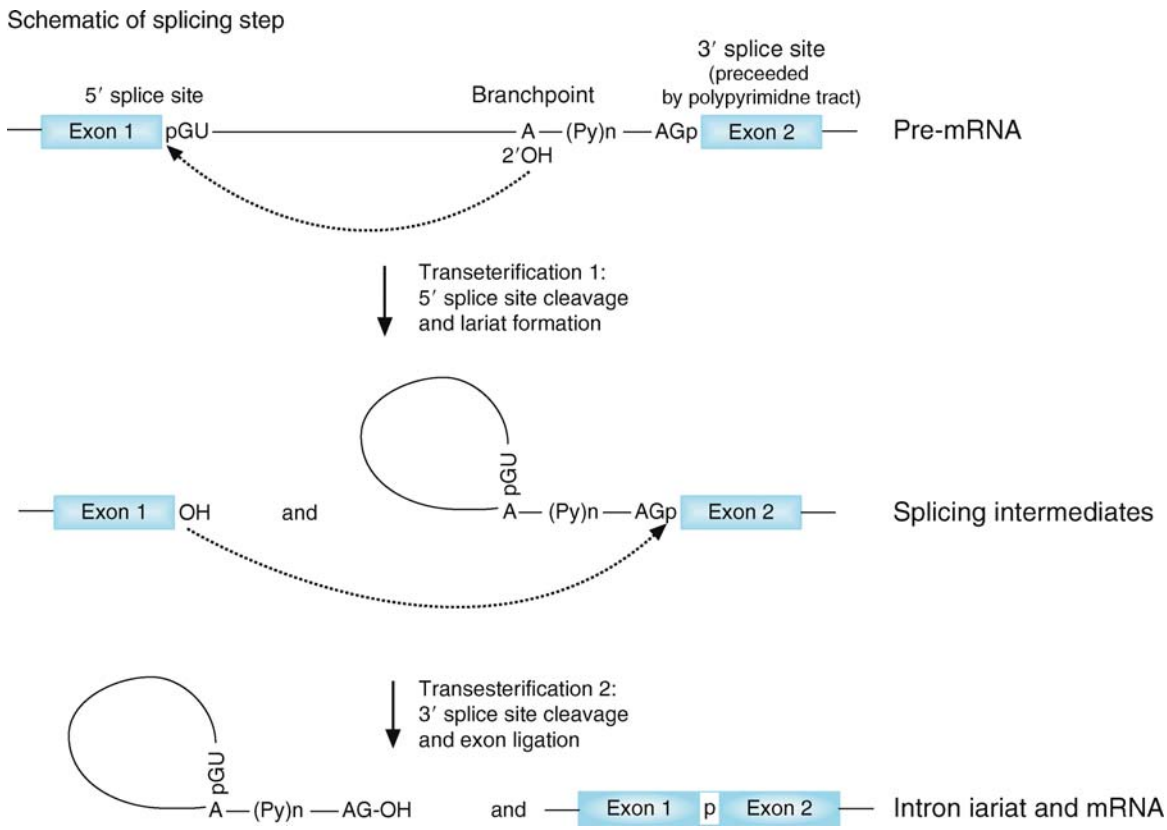
Splicing is a tightly regulated mechanism for the control of gene expression that involves the precise removal of ►introns from the precursor mRNA molecule and the subsequent ligation of the remaining ►exons.

Characteristics

Premature RNAs that are transcribed within the cell nucleus contain both coding sequences (contained within functional units called exons) and non-coding sequences that are eventually excised. Splicing is the mechanism by which the non-coding portions of the RNA (also known as introns) are removed from ►pre-mRNAs, via two cleavage-ligation reactions, each involving transesterification at a splice site phosphate (see Fig. 1). Ultimately, the two exons are ligated to generate the spliced mRNA and the excised intron is released in a lariat configuration that is eventually degraded. The splicing reaction has been well-defined and is mediated by the dynamic ordered assembly of numerous ►spliceosome components directly on the pre-mRNA. To avoid the production of nonfunctional proteins, it is essential that splicing occurs precisely and consistently as introns that are removed incorrectly or not at all can cause prematurely truncated proteins resulting from in frame stop-codons located in the intron or in proteins translated out of frame. Splicing is therefore, by necessity, an extremely accurate and specific reaction.

The way in which regulation of splicing is achieved is a complex intersection of distinct recognition sequences for binding of the splicing machinery and accessory molecules with the proteins and ►snRNP complexes that bind to these elements. Since exons are separated by introns and can be literally thousands of base-pairs away, the splicing machinery acts to recognize the splice sites and to remodel the RNA such that the splice sites are juxtaposed. In the first step of splicing the splicing components U2AF and U1snRNP bind to the 3′ and 5′ splice sites respectively. These proteins, along with accessory molecules known as ►SR proteins that help to stabilize the reaction, form the splicing commitment complex. Differential splicing regulation can be achieved by the relative concentration of these accessory molecules in the nucleus and by the expression of proteins that enhance or inhibit the splicing reaction. Subsequent steps involve the binding of the U2snRNP to the branchpoint and the U4/U5/U6 tri-snRNP complex remodeling the RNA and catalyzing the splicing reaction.

Several systems have taken advantage of the precise nature of the splicing reaction and have implemented it as a mechanism for regulation of gene expression and function. Alternative RNA splicing is the process by which mRNAs encoding several distinct proteins are produced from one single pre-mRNA sequence by use of differential splice site choices. There is a large degree of diversity in the ways that cells use alternative splicing as a mechanism for gene regulation (see Fig. 2). Exons can encode discrete functional domains and thus exons that are differentially included may dramatically alter the protein function. The inclusion or exclusion of exons may also change the reading frame of the RNA and thus regulate protein function by affecting whether or not an RNA with an intact open reading frame is produced. Because of the versatility of splicing regulation alternative splicing is prevalent in several developmental processes including muscle development, neurogenesis, meiosis, and spermatogenesis.



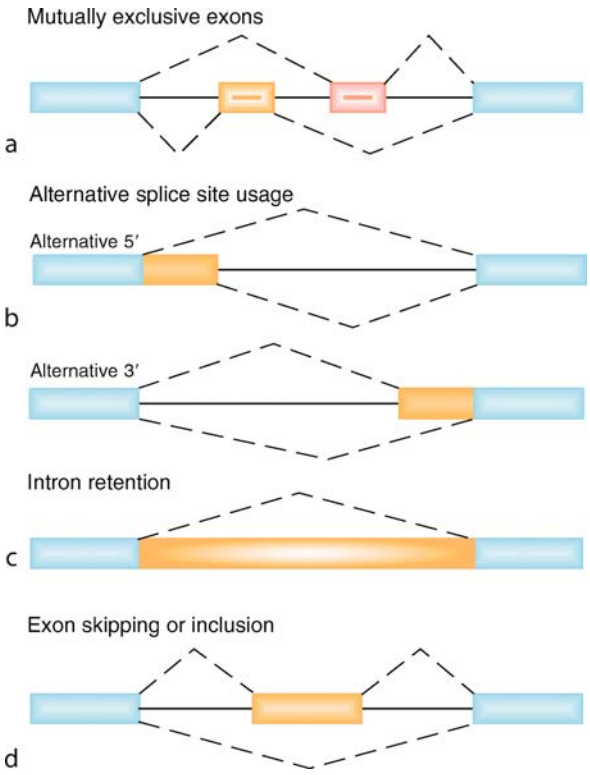
Pre-mRNA Splicing. Figure 1 The catalytic steps of pre-mRNA splicing. The required elements of the pre-mRNA are shown schematically. The exons are depicted as boxes and the intron as a line. The conserved 3′ and 5′ splice site sequences are depicted along with the relevant phosphate groups (p). The polypyrimidine tract $(Py)_n$ and the branchpoint (A) are also shown. The dashed arrows signify the hydroxl group attack of the splice site phosphate. The first transesterification reaction produces two splicing intermediates, the free 5′ exon and the intron/3′ exon in a lariat configuration. The second transesterification reaction results in the ligation of the two exons and the release of the intron lariat that is degraded. The resultant ligated exons make up the mRNA that eventually gets transcribed into protein. Figure adapted from Ref [1].

However, disruption of the developmental regulation or alteration in appropriate RNA splicing can lead to incorrect expression of alternatively or aberrantly spliced isoforms and can lead to disease.

Spliced Forms in Cancer

For each of the alternative splicing patterns there exists multiple examples that exhibit cancer specific expression. An example of each is discussed below. Mutually exclusive splicing of exons (Fig. 2a) occurs such that only one of a group of adjacent exons is included in an RNA at any one time. This type of splicing regulation is common for control of RNAs that encode proteins with defined tissue-specific functions. In the case of the c-Jun amino-terminal kinase 2 (►JNK2, ►JNK subfamily and ►cancer) that is known to phosphorylate the c-Jun protoconcgene, there is a well-defined tissue specific splicing pattern. In neuronal cells, exon 6A is included and 6B excluded, while in non-neuronal cells, 6B is included in the absence of exon 6A.

There are several examples of alternate splice site usage (Fig. 2b) for genes that are associated with cancer. The ►KLF6 tumor suppressor gene produces oncogenic variants due to alternative 5′ splice site selection. These splice variants are over-expressed in prostate cancer and seems to negatively affect the tumor suppressor activity of its normally spliced counterpart. In another example, the telomerase reverse transcriptase, TERT, utilizes alternative splicing of a 3′ splice site to generate TERT alpha. TERT is activated in most human cancers and is overexpressed in high grade astrocytic tumors. The alpha TERT isoform, that results from the use of a downstream 3′ splice site, lacks twelve amino acids and is deficient for telomerase activity. TERT alpha is furthermore suspected to cause apoptosis and thus provide cancer protection. In these



Pre-mRNA Splicing. Figure 2 Examples of possible alternative splicing patterns. Splicing choices are shown schematically with exons depicted as boxes and introns depicted as lines. A single pre-mRNA may employ multiple of these alternative choices in a combinatorial manner and thus greatly increase the diversity of proteins encoded. Figure adapted from Refs. [2] and [3].

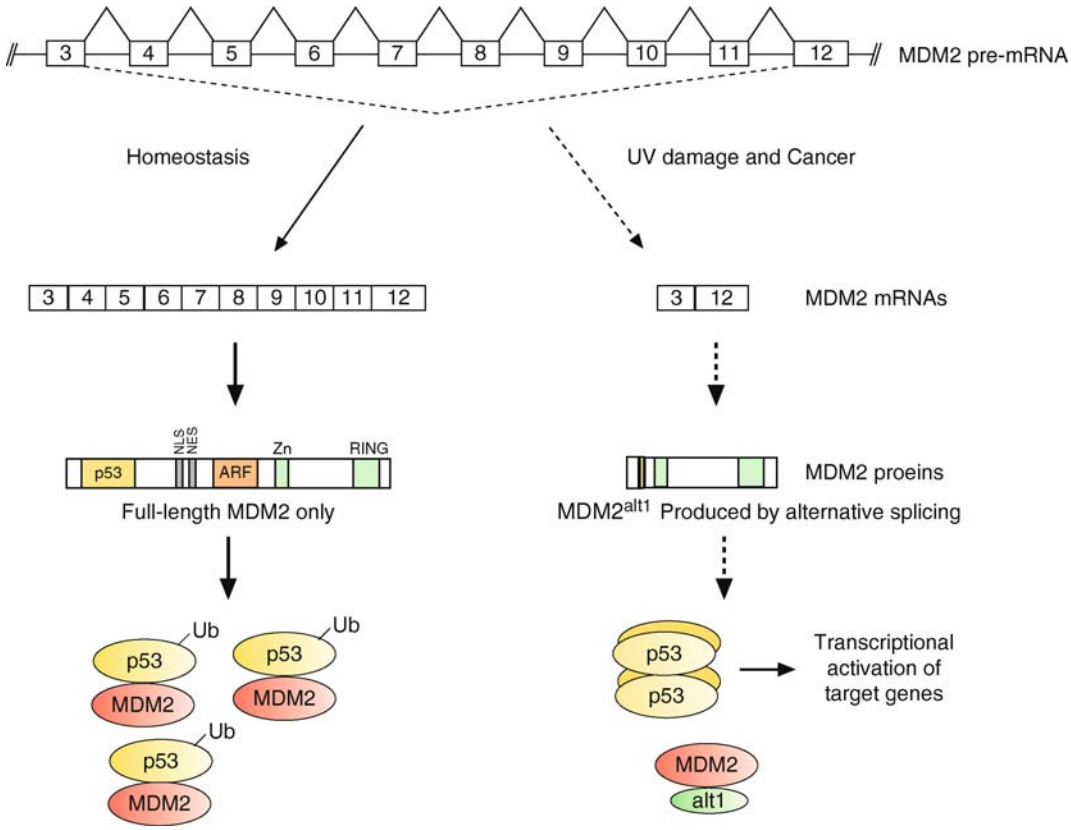
two cases of splicing regulation in cancer, the proteins that result from alternative splicing appear to have antagonistic functions to their full-length counterparts, one form promotes tumors and the other protects against cancer.

Intron retention (Fig. 2c) is yet another mechanism of regulating the splicing and thus function of genes that are involved in cancer. Intron retention occurs when the 5′ and/or 3′ splice sites are not recognized by the splicing machinery and the intron is therefore not removed from the transcript. A gene that is thought to regulate invasion and metastasis, CCK2, is altered in various cancers by retention of an intron that encodes a large intracellular loop as part of its transmembrane domain. The splice variant promotes growth via interaction with the ►Src tyrosine kinase.

The misregulation of splicing can occur via two general mechanisms. The first way is via point mutations that affect the cis-regulatory elements important for splicing control. Point mutations that create or destroy splicing signals within the RNA itself can affect splicing and are a prevalent way to destroy RNA splicing in a number of different cancers. In one example, the breast cancer susceptibility gene, ►BRCA1 (►BRCA1/BRCA2 germline mutations and ►breast cancer risk), is spliced incorrectly and the resultant truncated BRCA1 protein leads to breast cancer. In this case, a single nucleotide mutation was identified in exon 18 of BRCA1. This point mutation disrupts an ►exonic splicing enhancer (ESE) that is known to bind to the SR protein SF2/ASF. This disruption leads to the inability of exon 18 to be recognized by the splicing machinery and the exon is skipped as in Fig. 2d. The resultant mRNA is in a different reading frame than the normally spliced RNA and a truncated protein is produced. This example underscores the importance of regulatory element sequence fidelity for efficient splicing and is an important example of a cancer-causing point mutations that leads to a splicing deficiency.

The second way to express incorrect splice forms is through the altered expression or function of splicing trans-regulators. Changes in expression levels, phosphorylation state and sub-cellular localization of splicing accessory molecules are all known to be ways of regulating specific splice site choices. In the case of the ►*Mdm2* (or *Hdm2* in humans, ►MDM genes), the modulator of tumor suppressor p53 activity, splicing is regulated in normal cells as a response to stress. The resultant splice form is also an example of exon inclusion (normally) versus exon skipping (in stressed cells). As shown in Fig. 3, the internal eight exons are skipped (exons 4–11) making this an extreme example of exon skipping. Although the mechanism of MDM2 splicing regulation is still unknown, it is thought to be a result of transfactor control since this represents a normal cellular process that is reversible once the stress is removed.

The MDM2 protein derived from the alternatively spliced form has been shown to bind to the full-length MDM2 and interfere with its ability to bind to and regulate p53 (see Fig. 3). In this way, expression of MDM2alt1 facilitates upregulation of p53 activity and promotes the damage response playing an important role in tumor suppression. However, this alternatively spliced form of MDM2 is contradictorily found to be overexpressed in a number of human cancers including gliomas, rhabdomyosarcomas, breast and ovarian cancers. Although the expression of the MDM2 alternatively spliced form is predicted to suppress tumors by activating the trp53 tumor suppressor pathway, its prevalent expression in multiple tumor types has led to much speculation about a possible role of MDM2 splicing in tumor formation. One prevailing hypothesis for the role or MDM2alt in tumorigenesis is a cancer progression model in which the expression of the alternative form of MDM2



Pre-mRNA Splicing. Figure 3 Alternative splicing of MDM2. The MDM2 pre-mRNA is shown schematically; exons are depicted as boxes and introns as lines. Under normal conditions the MDM2 is spliced to include all exons and encodes the full-length protein as depicted in the left part of the figure. Under stress conditions and in certain cancers, MDM2 alternative splicing causes skipping of exons four through eleven and results in the expression of a novel MDM2 protein that lacks the p53 binding domain, the nuclear localization and export signals (NLS and NES), and the ARF binding domain (as shown in the right part of the figure). The short MDM2 protein negatively regulates its respective full-length counterpart and ultimately activates the p53 pathway. This example of regulated splicing uncovers a novel mechanism by which cellular injury can control distribution and activity of p53 within the cell and possibly lead to cancer.

initially protects the cells by activating trp53, but sustained expression of the MDM2 form and upregulated trp53 puts a selective pressure on the cells that results ultimately in mutations in the p53 gene itself or other genes in the pathway. It is these secondary mutation(s), then, that induce the cancer phenotype. This predicted model mirrors a similar situation in which perpetual ►*myc (Myc oncogene)* expression likewise induces trp53 providing cancer protection initially, but secondary mutations in genes of the trp53 pathway lead to cancer, in the end. Although experimental proof for the exact role the MDM2 alternatively spliced form plays in the initiation of cancer is lacking, the expression of alternatively spliced forms of MDM2 is clearly a marker for many different tumor types.

In summary, the expression of many alternatively spliced isoforms is associated with cancer. In many cases, the new proteins formed are ant-apoptotic or growth-promoting lending clear clues to their roles in tumor formation. In other cases, the role of the alternative forms in tumorigenesis is more elusive.

Therapeutic Intervention

Since a number of tumor specific isoforms have been identified that block apoptosis and/or promote cell growth or invasion, modification of the splicing profile in tumors is a possible therapeutic intervention point. There have been several approaches that have been successfully utilized to change splice site choices in a variety of human diseases. Low molecular weight drugs such as neomycin, aclarubicin, and sodium butyrate have been successfully utilized to promote exon inclusion. Likewise, heterologous expression of tran-acting splicing factors can alter splicing patterns of their target genes. These types of therapies must be carefully tested for non-specific effects as they have the potential

to affect the splicing of many genes in addition to the targeted disease-causing gene. This danger of non-specificity may be avoided by designing selective agents that only recognize the RNA in question. Antisense oligonucleotides and RNAi technology have been shown to be effective in recognizing specific sequences in the target RNA and successfully modulating splicing. As more becomes known about the splicing of genes and the roles of this process cancer, there is great promise for modulating gene expression by directing splice choices that encode tumor-suppressor proteins and squelch the tumor-promoting alternatively spliced isoforms.

Pre-replicative Complex

Definition

Is a complex of proteins, originally identified by in vivo footprinting, present at replication origins only during late mitosis and G1.

►Replication Licensing System

Precancerous Lesions

Definition

During the process of transformation, cells will accumulate mutations in genes in a step wise fashion. At some point, the cell may proliferate resulting in growth, but does not yet have the capacity to invade surrounding tissues. At this point the cell(s) are considered to be a benign growth or a precancerous lesion. Adenomas in colon cancer are representative of this state.

Preclinical Studies

Definition

Describe the phase of drug discovery before the first clinical studies start in man.

►ADMET Screen

Preclinical Testing

Peter Greaves
Department of Cancer Studies and Molecular Medicine, University of Leicester, Leicester, UK

Synonyms

Toxicity testing; Preclinical safety testing; Preclinical drug safety evaluation

Definitions

The process of testing potential new therapies in animal and cell-based test systems prior to their study in patients in order to assure their potential safety and efficacy.

Characteristics

It was recognized many years ago that potential medicines were often "poisons" so that some form of screening in animal models was required before new drugs could be tried in patients. For all types of medicines it has been generally agreed that these tests should take the form of both pharmacological and toxicological studies in animals to avoid patients being exposed to drugs that are excessively toxic or without evidence of potential efficacy. Added impetus has come from the Nuremberg Code that was formulated after the trials of the Nazi doctors convicted for the conduct of horrific medical experiments on prisoners. Whilst this code deals primarily with the consent of volunteers and patients, one of its articles places emphasis on the justification for any experiments in humans being based on prior information derived from animal experiments:

"*The experiment should be so designed and based on the results of animal experimentation and a knowledge of the natural history of the disease or other problem under study so that the anticipated result will justify the performance of the experiment.*"

Hence, the main concept underpinning the preclinical safety testing is the protection of volunteers and patients in the testing of new drugs. The basic paradigm for testing is similar for all drug types and falls into three main phases. Firstly, toxicity testing is often used in the discovery phase to select the least toxic candidate drug from a series of chemicals. Secondly and most importantly it is used to provide the basic safety data to permit first dosing of a novel agent to volunteers. Finally, further detailed testing using repeated dosing schedules over longer periods and specialist protocols is conducted in parallel with ongoing clinical trials to complete the preclinical safety data. This permits extended dosing of patients and supports eventual marketing of the drug (Fig.1). Although cytotoxic anticancer drugs represent a special case often needing only modest preclinical testing programmes, it needs to be kept in mind that not all drugs used in the therapy of cancer are conventional cytotoxic drugs. Some of these such as those used to manage pain, nausea or vomiting are developed in a manner similar to non anticancer drugs and consequently often have preclinical testing programme analogous to novel drugs intended for long-term use.

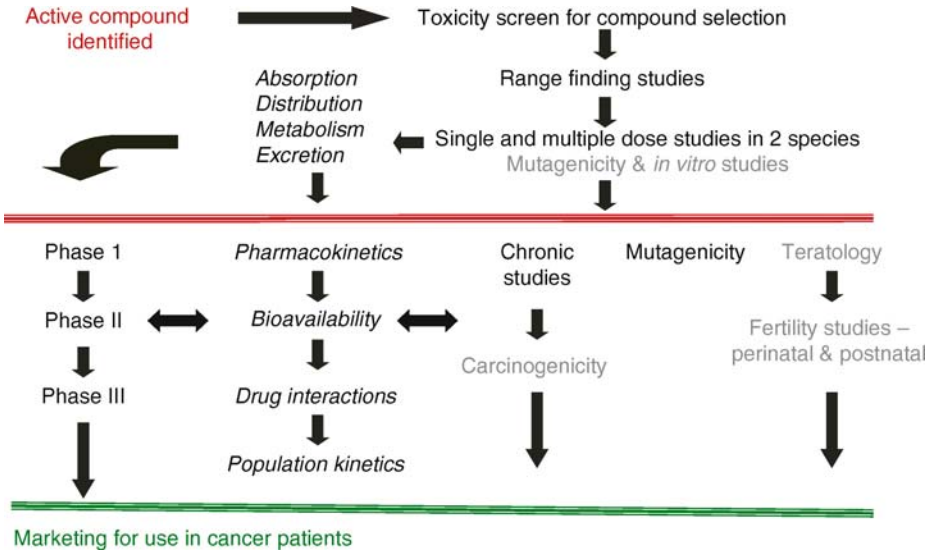
The use of preclinical safety testing is primarily screening for serious drug toxicity to permit their safe testing in humans. They are no substitute for careful study of new drugs in patients to test their ability to treat disease and for monitoring of adverse effects. Adverse effects occurring in one out of 10,000 or 100,000 patients can be devastating but would never be detected in the small number of healthy animals used in safety testing.

Discovery Phase

Basic toxicity testing has an important place in the selection of a potential new anticancer therapy, despite application of a vast array of novel approaches using molecular biology, combinatorial chemistry and bioinformatics. The activity of anticancer drugs is typically assessed using a battery of ►mouse models for different cancer types. At this stage, informal studies, so called ►screening toxicity using small numbers of rodents, often mice, might be conducted. This is often performed when series of potential drugs cause toxicity in particular organs such as the liver and kidney to enable selection of the least toxic for progression to the next phase of formal testing prior to administration to humans. Depending on the nature of the toxicity, these studies usually employ simple endpoints – clinical observation, examination of blood values and microscopic examination of important organs.

Phase I Clinical Study

Following identification of a potentially active new drug, the next major step is testing for effects in humans. However, the transition from the laboratory bench to the bedside represents a large step for which preclinical studies are crucial. At this stage, a small number of carefully planned and conducted animal toxicity and safety pharmacology experiments are performed. Typically, two laboratory animal species are used for each new drug. One of these is a rodent usually rat and the other a non rodent usually dog. These allow the precise characterization of the effects activity of the



Preclinical Testing. Figure 1 This diagram shows the place of preclinical safety studies within the context of drug discovery and development. So called screening toxicology might be conducted in rodents prior to entry into formal "single dose" and "repeat dose" toxicology studies immediately before testing in humans (red line). In parallel with the conduct of clinical phases I, II and III further testing including "chronic" (6 months or more duration) toxicity and reproductive studies are carried out prior to marketing (green line). Italics show drug kinetics and metabolism studies – performed in *both* humans and animals and enables effects in animals and humans to be correlated. Cancer drugs usually do not require the testing marked in grey print, although these are needed for drugs of other types intended for long-term use.

drug on body functions and any cellular toxicity. They provide the basis for the design, conduct and safety monitoring of clinical phase I studies of the new drug in volunteers. Whilst healthy volunteers may be studied for cancer drugs that are not cytotoxic, cytotoxic agents are usually studied in volunteer cancer patients.

The paradigm for a toxicity experiment is similar for most types of studies. Animals are dosed drug by the similar route to that intended for use in patients. This is usually done at a clinically relevant dose and usually two higher doses on a body weight or surface area basis. The minimum number of animals of each sex in each dose group is mandated in most government guidelines, notably those of the European Union, United States and Japan. These studies are conducted to an agreed international laboratory standard known as ►Good Laboratory Practice (GLP). This requires regular auditing of studies as well as inspection of laboratories by government agencies.

In all these toxicology studies the animals are monitored clinically with particular attention being paid to changes in animal behavior that could signify adverse effects on critical functions such as the nervous system. Blood pressure, heart rate and electrocardiograms are usually monitored in the dog as they are more difficult to perform in rodents that have very fast heart rates. Eyes are also carefully examined using sophisticated optical equipment similar to that employed by an ophthalmologist or optician. Blood is sampled and tested for any biochemical or hematological alterations in a similar manner to human patients, often using identical laboratory analytical apparatus. Levels of drug circulating in the body are also usually monitored in these experiments, often referred to as ►toxicokinetics.

At the end of the dosing period, or if any ill health intervenes, the animals are humanely killed using an anesthetic or barbiturate and subject to a full autopsy examination. Over 30 tissues from all the organs are taken for microscopic examination by an experienced ►toxicological pathologist. This is to check for any organ damage that could reflect danger to patients if they were to be treated with the new drug. Organs such as the liver, kidneys, ovaries and testes are particularly important, as are the lymph nodes, thymus and spleen for any deleterious effect on the immune system. Additional special studies are performed if there are findings of concern that need elucidation. As many drugs, particularly cancer drugs are locally irritant to tissues, the gastrointestinal tract is examined closely if

the oral route is employed. Likewise, injection sites are also studied microscopically if a parenteral route is used. Severe local irritancy might preclude dosing to humans or would dictate particular caution in use.

These studies are designed in a particular way for cytotoxic cancer drugs because these are liable to damage rapidly dividing cells such as those in the bone marrow and gastrointestinal tract. For these drugs it has been shown that the ►maximum tolerated dose (MTD) is often similar in mouse, rat, dog, monkey and man when compared on the basis of mg/m^2 of body surface area. Experience has shown that a safe starting dose in humans is one tenth of the MTD based on ►single dose toxicity studies. This means that a key study for cytotoxic drugs is a single dose toxicity study that has sufficient number of animals per dose to establish an MTD. These single dose studies usually have a follow up period of clinical examination of the animals for at least 14 days after dosing to exclude delayed toxic effects. Usually two animal species, one rodent and one non rodent are used to confirm the MTD. This study is required by ►government drug regulatory authorities prior to testing cytotoxic cancer drugs in cancer patient volunteers.

►Repeat dose toxicity studies are also performed with cytotoxic drugs prior to phase I clinical studies. These are designed to mirror the proposed clinical schedule with particular attention being paid to organ toxicity and reversibility of toxic effects. These are of limited duration usually 2–4 weeks or one or two cycles of treatment in two species.

However, increasingly many new anticancer drugs are not cytotoxic because they act through other mechanisms such as modulation of hormones or growth factors. These are tested in a more conventional manner similar to most other drugs intended for long-term use. Here, toxicity experiments comprise single dose studies in rodents and repeated dosing over a period of up to 1 month in two animal species. One species is a rodent, usually laboratory rat, and the other a non-rodent species, usually the beagle dog. Experiments in monkeys are avoided where possible unless the compound being studied has particular pharmacodynamic or metabolic characteristics that demand it.

Yet another variation on the basic preclinical testing scheme is used for biological products. Again the aim is to mirror the clinical treatment schedule. However, as some biological agents do not possess activity in non-primate species, monkey studies are sometimes needed to assure safety in humans. Immunogenic potential is also thoroughly investigated in specialized animal models.

At this stage determining the safety profile of a new drug is not limited to animal toxicity experiments. There are also *in vitro* ►genotoxicity studies, such as the Ames test which uses bacteria and other experiments using cells to study whether the drug can damage DNA. A standard battery of both *in vitro* and *in vivo* genotoxicity experiments is conducted prior to phase II clinical studies for conventional drugs (►Micronucleus assay).

A particularly important component of preclinical study is the investigation of absorption, distribution, metabolism and excretion of drug and their metabolites in the blood and tissues of animal species chosen for toxicity testing. This data helps interpretation of the relevance of adverse findings in animals for humans because it forms a point of comparison of drug handling between animals and humans. It also helps to validate the relevance of the data obtained in animals (►Pharmacokinetics/pharmacodynamics).

At the end of this phase of work scientists and physicians review the assembled data from all these experiments along with information from studies of drug metabolism prior to design and conduct of first studies in humans. In all cases a clear rational based on a trade-off between any potential risks with likely long-term benefit would be generated prior to the conduct of any human experiment. Moreover, there is a mandatory ethical review of the study protocol by a panel not directly involved in the human studies. The review panel would be provided with a summary of the results of the animal safety information. Government agencies in the United States and in the European Union have approval processes for all such human studies.

Phase II and III Clinical Studies

In clinical studies in patients, dosing periods are usually lengthened and more subjects are involved. These are accompanied by animal toxicology studies of longer duration and when appropriate, other specialist studies. The organization of these toxicity studies is similar to the earlier studies but the period of dosing is extended from a period of up to 1 month to period of dosing of 6 or 9 months or 1 year for most drugs. For anticancer drugs studies are usually conducted with continuous or intermittent dosing for a period equal to the duration of clinical trials although not longer than 6 months.

Further drug kinetics and metabolism studies are conducted at this stage as data from humans is available and enables comparison between species. This also serves to validate the preclinical data. Metabolites may be isolated and their toxicity studied if there is particular concern about the adverse effects of metabolites. Enzyme induction potential may also be tested in animals or *in vitro* hepatocyte test systems (Pharmacokinetics/pharmacodynamics).

Although for most drugs special experiments to examine the effects of a new drug on reproductive function and the developing foetus (►reproductive toxicity studies) are required in to be conducted in two sensitive animal species, conventionally rat and rabbit. However for most cytotoxic anticancer drugs these experiments are not usually performed.

Although *in vitro* ►genotoxicity tests are not required for anticancer drugs prior to phase I and phase II clinical trials, tests such as the Ames test which uses bacteria and other experiments using cells to study whether the drug can damage DNA are usually expected prior to clinical phase III trials and marketing applications. A full battery of *in vitro* and *in vivo* genotoxicity tests is required before phase II for more conventional drugs (Micronucleus assay).

The last preclinical experiments that are usually conducted for most drugs are the so called ►carcinogenicity studies. Although these are a requirement for most drugs that are going to be used for extended periods in patients, they are not performed for many anticancer drugs. Exceptions exist for drugs such as the selective estrogen modulating drugs such as tamoxifen that are used for extended periods and for cancer prophylaxis The studies have typically been mandated in two rodent species, mouse and rat. Again the organization of the studies is similar to those conducted previously except that the dosing period is for 2 years – most of the lifetime of a rodent (►Carcinogenesis or ►toxicological carcinogenesis). More recently, shorter studies using genetically modified, cancer-prone mice have been accepted by ►government drug regulatory agencies in place of one of these two large studies (Mouse models).

At the end of this process, the preclinical information is summarized along with information from clinical trials and manufacturing data and assembled for submission to government drug regulatory authorities to obtain marketing authorization.

Preneoplastic Changes

Definition

Are phenotypical changes in cells that follow a malignization pathway but are not yet irreversibly malignized.

Preneoplastic Lesions

Francesco Feo
Department of Biomedical Sciences, Division of Experimental Pathology and Oncology, Sassari, Italy

Definition

The development of primary tumors is often preceded, both in humans and experimental animals (mainly

rodents), by the appearance of lesions referred to as preneoplastic. These consist of genetically and phenotypically altered cells exhibiting a higher risk of malignant evolution than normal cells. These lesions generally lack one of the principal characteristics of neoplastic lesions: the capacity to grow autonomously after cessation of the stimuli that induced the lesion. Nonetheless, the distinction between preneoplastic lesions and benign neoplasias is sometimes difficult, and the terms "preneoplastic" and "premalignant" are often considered synonyms. However, benign tumors, constituted by autonomously growing cells, cannot be strictly classified as preneoplastic but only as premalignant lesions, whereas, premalignant lesions can include both preneoplastic lesions and benign tumors.

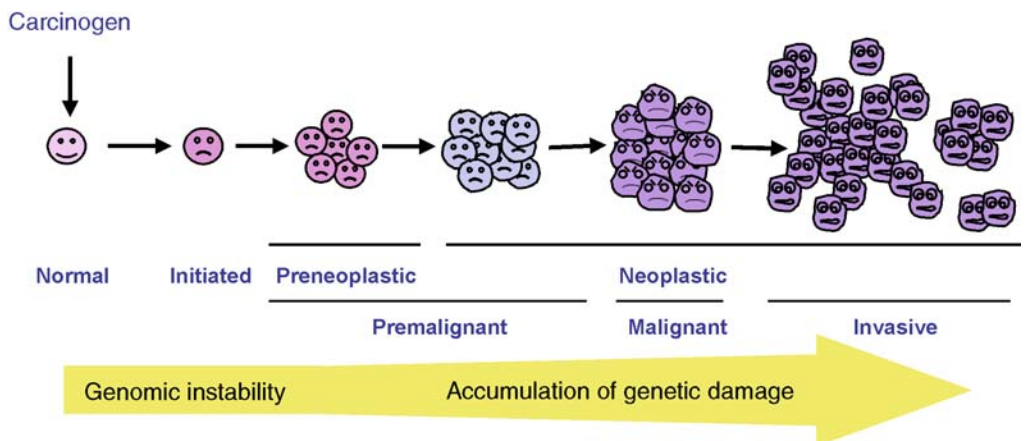
Characteristics

Tumorigenesis is considered a multistep process characterized, both in humans and rodents, by the progressive development of preneoplastic, premalignant, and malignant lesions. During this process, genomic instability occurs (►Microsatellite instability), followed by alterations in oncogenes, oncosuppressor genes, and DNA repair genes, with consequent changes in the ►signal transduction network (Fig. 1). The progressive accumulation of genetic changes generates autonomously growing premalignant and malignant lesions.

Some Experimental Models of Preneoplastic Lesions

Preneoplastic lesions have been induced in different organs, including liver, pancreas, lung, colon, skin, thyroid, mammary gland, gall bladder, prostate, in rodents treated with carcinogens and in transgenic mice. Although a close correspondence of experimental and human preneoplastic lesions does not always occur, the study of experimental lesions allowed discovery of pathogenetic mechanisms and diagnostic and prognostic markers of different tumor types. Only lesions preceding tumor development in some organs (liver, colon, lung) will be given as examples.

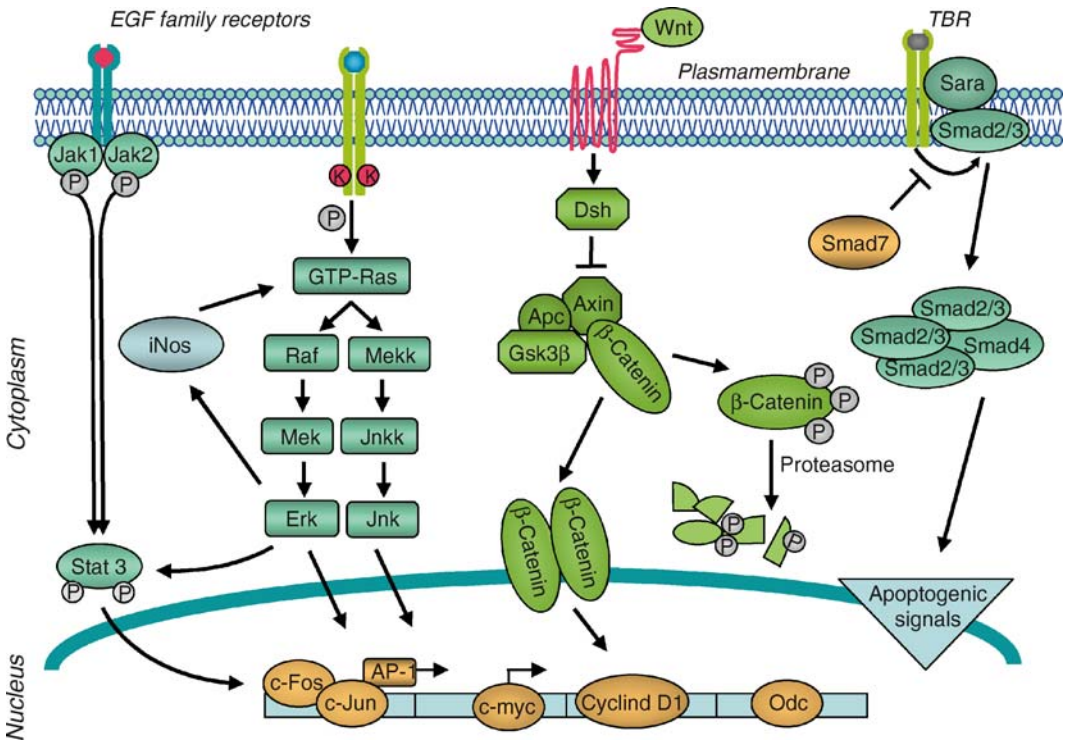
In hepatocarcinogenesis rodent models, irreversibly initiated cells by a carcinogenic stimulus can undergo clonal expansion by overresponse to the administration of promoting agents, such as phenobarbital, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, chlorinated hydrocarbons, peroxisome proliferators, for several weeks. Only few initiated cells undergo clonal expansion under promoting stimuli, probably because of irreversible change and apoptosis, giving rise to a heterogeneous population of foci of altered hepatocytes (FAH) expressing specific patterns of marker genes, such as Glutathione S-transferase (GST) 7-7, γ-Glutamyl transpeptidase, and alterations of carbohydrate metabolism defining different lineages of preneoplastic cells. When the treatment with promoters is suspended before the appearance of neoplastic lesions, early preneoplastic liver lesions partially disappear by a process called "►remodeling." GST 7-7 positive cells that acquire autonomous growth persist and further evolve to premalignant neoplastic (persistent, atypical, dysplastic) nodules and then to well-differentiated ►hepatocellular carcinomas (HCCs; ►Liver Cancer, Molecular Biology), which progress to moderately and poorly differentiated carcinomas. Other



Preneoplastic Lesions. Figure 1 Schematic representation of multistage carcinogenesis. Carcinogenesis initiation is associated with the appearance of genomic instability. Clonal expansion of initiated cells leads to the development of preneoplastic lesions carrying various genomic alterations. The accumulation of these alterations is associated with the acquisition of the capacity of autonomous growth and evolution to neoplastic lesion, which progress to moderately differentiated and poorly differentiated, invasive, carcinomas.

hepatocarcinogenesis models are based on the stable transfection of one or two cancer related genes (i.e., c-*myc*, c-*myc* plus *Tgf*-α genes) in mouse and, less frequently, rat genome, or in inactivating a gene of intact mice (knockout mice). In these models, generally the liver is dysplastic and progressively becomes adenomatous before the development of HCCs.

Alterations of several signal transduction pathways occur in rodent HCC and, at a lower extent, in preneoplastic liver lesions. They include upregulation of *EGF* receptor family, resulting in induction of the Ras-dependent activation [►Ras] of Mitogen activated protein kinases (MAPK, ►Map Kinase) and *JAK-Stat* signaling, both transducing extracellular signals resulting in phosphorylation of transcription factors targeting various genes (Fig. 2). c-Raf/MAP kinase kinase-extracellular signal-related kinases (Mek-Erk) pathway is primarily responsible for responding to cellular proliferation signals, whereas the Mitogen activated protein kinase kinase (Mekk) and c-Jun N-terminal kinases (JNK; ►JNK Subfamily and Cancer) respond to cellular stress signals and treatment with carcinogens. This leads, trough upregulation of the c-*fos* and c-*Jun* genes, to the activation of AP-1 and its targets (i.e., *Cyclin D1* gene; ►Cyclin D). As a consequence *Odc*, a c-Myc (►Myc Oncogene) target, is overexpressed and its gene product, Ornithine decarboxylase, activates polyamine synthesis required for nucleotide biosynthesis. Upregulation of c-*myc*, cyclin D1, and other Cyclins and Cyclin-dependent kinases, activates cell cycle and cell proliferation. This is favored by downregulation of cell cycle inhibitors,



Preneoplastic Lesions. Figure 2 Schematic representation of signal transduction pathways involving *Jak/Stat*, Ras/Mapk, Wnt/β-Catenin, and Tgf-β1 signaling pathways. Binding to ligands or autologous upregulation of Epidermal growth factor (EGF) family receptors causes phosphorylation of Jak1 and 2 and activation of Stat3 and formation of active GTP–Ras complex, which activates the Raf/Mek/Erk and Mekk/Jnkk/Jnk pathways. This leads to the phosphorylation of nuclear factors that, migrating into nucleus, activate numerous target genes. The inactivation of components of the complex Apc/Axin/Gsk3β/β-catenin complex, or the inhibition of Gsk3β by Dishwelled (Dsh) protein by Wnt1/Freezzled activation, suppresses β-Catenin phosphorylation and ubiquitination followed by disruption by proteasome. β-Catenin accumulation into the cytoplasm causes its nuclear translocation and activation of various target genes. Activation of Tgf-β receptor (TBR) leads to the formation of Smad2/3/Smad4 heterodimers leading to cell death by apoptosis. Overexpression of Smad7 and/or downregulation of Smad2/3 and Smad4, inhibit the TBR signaling pathway. Enhancing and inhibitory effects are indicated by pointed arrows and blunt arrows, respectively.

such as $p16^{INK4a}$ and p53, and Tgf-β/Smad signaling. Profound alteration of the Wnt/β-Catenin pathway (►Wnt Signaling), leading to inactivation of the complex Apc/Axin/Gsk3β/β-Catenin, decreases β-Catenin disruption via proteasome. Consequent nuclear translocation of β-Catenin activates various targets, including c-*myc* and cyclins. Finally, overexpression of the inducible nitric oxide synthase (iNos) contributes to activation of the MAPK cascade and the hypoxia inducible factor-1, leading to an increase in vascular endothelial growth factor (Vegf) expression and angiogenesis. The presence of these alterations in preneoplastic lesions indicates their role in early stages of hepatocarcinogenesis.

Another largely investigated model of multistep tumorigenesis is represented by chemically induced colorectal cancer (CRC; ►Colon Cancer) of rodents. Aberrant crypt foci (ACF; Colorectal Pre-malignant Lesions) identified in colonic mucosa of rodents treated with chemical carcinogens are considered preneoplastic lesions. These lesions exhibit increased expression of c-*fos*, decreased c-*myc* expression and hexosaminidase activity, and loss of transforming growth factor-α (Tgf-α), whereas mutations of *Adenomatous polyposis coli* (*Apc*; ►APC & ►β-catenin pathway) gene are absent. K-*ras* mutations occur in azoxymethane-induced ACF in rats. However, various observations strongly suggest that ACF are not preneoplastic, but only hyperplastic lesions. A subset of ACF, called "dysplastic ACF," consisting of fast-growing crypts with altered β-Catenin expression associated, in some cases, with β-Catenin mutation, are considered true CRC precursors. In colonic mucosa of rats, treated with azoxymethane, mucin depleted foci (MDF) have been described. MDF are more dysplastic and more likely to express β-Catenin than common ACF. β-Catenin accumulating crypts (BCAC) with higher cell proliferative activity than ACF significantly increase with time during colorectal carcinogenesis in rodents. The study of the molecular events in early colorectal preneoplastic lesions indicates that various mutations occur and are selected during colorectal carcinogenesis, the main selective factor being represented by those leading to a β-Catenin downregulating function.

►Lung cancer develops in a gradual and stepwise fashion. Numerous studies have addressed lung tumorigenesis in tobacco smokers. Preneoplastic lesions include focal epithelial cell ►hyperplasia, squamous metaplasia, and ►dysplasia. These lesions have been induced in rats by various carcinogens and are followed by the development of adenomas, adenocarcinomas, and squamous cell carcinomas. Exposure of rats to tobacco smoke induces dose-dependent cell proliferation and squamous metaplasia. These effects are paralleled by activation of MAPK signaling pathways and AP-1 binding to DNA (Fig. 2). This is associated with upregulation of AP-1-dependent cell cycle proteins, such as Cyclin D1 and Proliferating cell nuclear antigen (PCNA).

Human Preneoplasia

Etiologic factors of HCC include ►cirrhosis induced by hepatitis B virus (HBV) and hepatitis C virus (HCV), alcoholic cirrhosis, exposure to Aflatoxin B1, estrogenic steroids, some naturally occurring carcinogens in food, and some rare genetic syndromes (i.e., hemochromatosis, glycogenosis type I, α1 antitrypsin deficiency). About 4% of HBV infections evolve to persistent hepatitis, 30% of which can further evolve to chronic hepatitis and cirrhosis. HBV positive cirrhosis is considered a preneoplastic lesion, although the evolution to HCC has been found in only 10% of cases. Different from HBV infection, HCV-induced hepatitis becomes chronic in the majority of patients. At least 20% of them develop cirrhosis, which in most cases evolves to HCC. In these patients, as well as in individuals with alcoholic cirrhosis, the development of FAH and adenomatous nodules, correspondent to those chemically induced in rats and mice or developing in woodchucks' viral hepatitis, exhibits several molecular alterations in common with the corresponding lesions of rodent liver.

Various preneoplastic lesions have been identified in the gastroenterical tract. About 10% of patients with long-standing gastroesophageal reflux develop the Barrett esophagus, in which the distal squamous mucosal epithelium is replaced by metaplastic columnar epithelium. This lesion is preneoplastic, and the patients with Barrett esophagus develop adenocarcinomas, preceded by dysplastic lesions, with a 30–40 times increased rate over the general population. Dysplastic epithelium exhibits cell cycle deregulation, high proliferative rate, upregulation of TP53, and in more advanced stage, amplification of chromosome 4. Further evolution to carcinoma implicates deregulation of Wnt/β-Catenin pathway and c-*ERB-B2* amplification.

Preneoplastic conditions of human gastric cancer have not yet been well characterized to date. Ménétrier disease, resulting from profound hyperplasia of mucosal epithelium and glandular atrophy, rarely exhibits epithelial metaplasia, a condition that may favor the development of gastric carcinoma. Interestingly, transgenic mice overexpressing Tgf-α at gastric level, develop a syndrome similar to human Ménétrier disease. A multistep model from chronic active *Helicobacter pylori* infection through multifocal mucosal atrophy, intestinal metaplasia, dysplasia, and carcinoma has been described. During this process, complex interactions

between several bacterial, host genetic, and environmental factors determine whether *H. pylori* infected individual develop cancer. *H. pylori* infection is characterized by upregulation of various inflammation-associated genes, including chemokines, adhesion molecules, surfactant protein D and CD74 in infected stomach. Nitric oxide and reactive oxygen species, which may induce DNA damage (►DNA Damage Response; ►Repair of DNA), are overproduced. The role of these and other factors in the evolution of metaplastic and dysplastic lesions to carcinoma is still an object of study. *H. pylori* infection also predisposes to the lymphomatous transformation of the mucosa associated lymphatic tissue.

Most knowledge on multistep carcinogenesis in the gastrointestinal tract derives from colorectal tumorigenesis. Inherited syndromes, occurring in less than 10% of patients, include familial adenomatous polyposis (FAP), hamartomatous polyposis, hereditary nonpolyposis colorectal cancer (►Lynch syndrome), and common cancer family syndrome, not belonging to aforementioned syndromes, causative germline mutations of high-penetrance genes affect APC gene for familial adenomatous polyposis, LKB1, SMAD4, and *BMPR1* genes for hamartomatous polyposis, various mismatch repair genes (e.g., hMSH2, hMLH1, hPMS1, hPMS2, hMSH6) (►Mismatch Repair in Genome Stability), for Lynch syndrome I, and AXIN2, TGFβR-2, and POLD genes for Lynch-like syndromes. The homologue of human FAP, the Min mouse strain-1, carries the APC^{Min} mutation and develops intestinal neoplasms. The study of these syndromes allowed identifying early human colorectal preneoplastic lesions and the so called adenoma–carcinoma sequence, as well as the molecular alterations underlying the sequence of events leading to CRC. The morphological events include early appearance of preneoplastic ACF, followed by premalignant lesions such as adenomas and adenomatous polyps, and, finally, carcinoma development. The appearance of ACF, however, is preceded by numerous molecular events, such as germline (in the inherited syndromes) or somatic (acquired first "hit" in a "multihit" process, in sporadic cases) mutations of APC or mismatch repair genes. The mucosa harboring these mutations is at risk. Inactivation of normal alleles of tumor suppressor genes (i.e., by promoter methylation of APC, MSH2, β-Catenin) causes hyperproliferation and appearance of early preneoplastic lesions, which following K-*RAS* mutation evolve to adenomas. The loss of further suppressor genes (i.e., TP53) precedes the appearance of carcinomas whose ►progression is characterized by additional mutations of various oncogenes, chromosomal aberrations, etc.

A four to fivefold increase in the incidence of gastrointestinal tract cancer occurs in patients with Crohn disease, in which the development of carcinoma is generally preceded by dysplastic lesions of the ileum and/or colon mucosa. The pathogenesis of neoplastic transformation is unknown. Crohn disease seems to occur in predisposed individuals carrying some susceptibility loci on chromosomes 3, 7, 12 or 16. The ileum localization seems to be linked to mutations of *NOD2* and CARD15 genes. However, the relationships between these alterations and cancer development are not known. A 20–30-fold rise in CRC incidence occurs in patients with ulcerative colitis. Cancer development is preceded by premalignant multifocal dysplastic lesions exhibiting DNA instability. Genomic instability has also been documented in the colon mucosa outside of dysplastic lesions and it has been hypothesized that some deficit of DNA repair occurs in these patients.

Preneoplastic and premalignant lesions have been described for different other human tumors (Table 1). Epidemiological, clinical, and molecular characteristics of a number of these lesions are often incompletely known, but particular attention must be focused on these parameters because of their importance for prevention and early diagnosis of malignancy.

Genetic Predisposition to Neoplasia

A body of evidence shows the existence of a genetic predisposition to tumors. Strong predisposition by high penetrance mutations of oncogenes, oncosuppressor genes, and DNA repair genes, occurs for a relatively small number of the so-called hereditary tumors. Genetic predisposition to sporadic tumors depends on the inheritance of several susceptibility or resistance allelic variants, which influence (modify) the behavior of the molecular mechanisms of tumorigenesis and, hence, the phenotypic features of preneoplastic and neoplastic lesions. Several modifier genes have been mapped, but only few genes involved in genetic predisposition have been identified so far. These observations may in some way modify the definition of preneoplastic lesion. Indeed, a cell carrying polymorphic variants of cancer modifier genes responsible for increased susceptibility to malignancy, namely increased cancer risk, could be considered preneoplastic. The identification of modifier genes and the signaling pathways that they influence may lead to the discovery of early diagnostic and prognostic markers as well as therapeutic targets, which may prevent the evolution of preneoplastic cells to full malignancy.

Clinical Relevance

One of the major challenges of cancer research has been the discovery of tools for efficient prevention of malignancy. In this context, the identification of

Preneoplastic Lesions. Table 1 Preneoplastic and premalignant lesion of various human tissues

Tissue	Preneoplastic		Premalignant[a]	
	Morphology	Molecular markers	Morphology	Molecular markers
Lung	Atypical adenomatous hyperplasia; bronchial dysplasia			
Liver	FAH		Dysplastic nodules	Upregulation of MAPK, JAK-STAT *ODC*, *C-JUN*, *C-FOS*, *C-MYC*, RAS family genes, cell cycle
Pancreas	Fat or papillary mucinous hyperplasia	*HER-2*, Ki-67, $P21^{WAF1}$, *CYCLIN D1* upregulation,. *SMAD 4* underregulation	Atypical hyperplasia	*HER-2*, Ki-67, $P21^{WAF1}$, CYCLIN D1 upregulation, *SMAD 4* underregulation
Oral epithelium	Leukoplakia	LOH at 3p and 9p	Dysplastic leukoplakia	*TP53* overexpression; loss of differentiation-related keratins
Esophagus	Barrett's epithelium with metaplasia	*TP53* mutations, *CDX* mutations	Barrett's dysplasia	*TP53* mutations, *APC* LOH, $p16^{INK4a}$ hypermethylation or LOH
Stomach	Ménétrier disease with metaplasia	TGF-α overexpression		
	H. Pylori atrophic gastritis with intestinal metaplasia	Overexpression of *GASTRIN*, *COX-2*, *SURVIVIN*, *BCL-2*	Dysplastic lesions	Overexpression of Gastrin, *COX-2*, SURVIVIN, *BCL-2*
Gastrointestinal tract	Crohn disease	*NOD2* and *CARD15* mutations		
	Ulcerative colitis	*TP53* mutations, Nitric oxide overproduction	Epithelial dysplasia	*TP53* mutation, Nitric oxide overproduction
	ACF	β-catenin activation	Adenoma	β-Catenin activation, *APC* and K-*RAS* mutation, LOH at *TP53*, *SMAD2* and *4*
Urothelial	Papillary hyperplasia	LOH at 9q	Papilloma	LOH at 9q, *TP53* mutations
Vulva			VIN I and II	ei5A-1 overexpression
Uterine cervix			Dysplasia (CIN I, CIN II)	$P16^{INK4A}$ overexpression, pRb ubiquitination
Endometrium			Atypical hyperplasia	Loss of *PTEN* expression
Ovary	Metaplastic surface epithelium and inclusion glands		Atypical hyperplasia	*TP53* mutation. Loss of *BRCA1* and *2*
Breast	Hyperplastic lesions	Microsatellite instability	Atypical hyperplasia	Microsatellite instability
Thyroid	C-cell hyperplasia	Overexpression of *BCl-2* and *BCL-X*	Follicular adenoma (atypical)	Mutations of *RAS* family genes
Skin	Lentiginous melanocytic hyperplasia; Lentiginous junctional nevus		Dysplastic nevus	Overexpression of bFGF, and IL-8

[a]The definition of premalignant lesion is often based on morphologic, clinical, and epidemiologic criteria.

very early biochemical, molecular, and morphologic changes, predisposing normal cells to tumorous transformation, plays a pivotal role. In principle, tumor prevention would imply the protection of humans against tumor initiation. When this is not possible, an efficacious preventive strategy may attempt to block the evolution of initiated cells to malignancy. Of course, early identification of precancerous lesions is

a prerequisite for efficacious prevention. The recognition of these lesions (i.e., polyps, adenomas, dysplastic nevi, leukoplakias) may allow their surgical or medical treatments. The knowledge of early molecular alterations, in preneoplastic lesions, is also important to adopt chemopreventive strategies aimed at contrasting the growth and progression of early lesions to cancer and/or to block the expression of genes involved in cell transformation.

Prentice Criteria

Definition

Named after the criteria formulated by Ross Prentice in an influential 1989 article on validation of ►surrogate endpoints, were developed to ensure that rejection of the null hypothesis under the surrogate endpoint implies rejection of the null hypothesis under the true endpoint. The main criterion, sometimes called the Prentice criterion, is that the distribution of the true endpoint conditional on the surrogate endpoint does not depend on the intervention. In other words, the Prentice criterion says that, for all treatments under consideration, there is a single pathway from treatment to true endpoint that goes through the surrogate endpoint, so once the surrogate endpoint is known, no other information is needed to determine the distribution of the true endpoint.

Prenylation

Definition

Is a biochemical reaction resulting in the transfer of a farnesyl or geranylgeranyl lipid group onto a cysteine residue in characteristic carboxy-terminal motifs, giving rise to farnesylated and geranylgeranylated proteins. Such reactions are essential to the anchorage of small GTPases to cell membranes and to protein–protein interactions.

Primary Myelofibrosis

Ayalew Tefferi
Division of Hematology, Mayo Clinic College of Medicine, Rochester, MN, USA

Synonyms
Myelofibrosis with myeloid metaplasia; Chronic idiopathic myelofibrosis; agnogenic myeloid metaplasia; Idiopathic myelofibrosis

Definition

Primary myelofibrosis (PMF) is a stem cell-derived clonal myeloproliferative disorder (MPD) that is characterized clinically by anemia, marked enlargement of the spleen and liver, and severe constitutional symptoms. Peripheral blood findings include the presence of immature myeloid cells including nucleated red blood cells, immature granulocytes, and tear drop-shaped erythrocytes. The bone marrow histology exhibits reticulin and collagen fibrosis, osteosclerosis, and angiogenesis.

Characteristics

Background

The blood and bone marrow features associated with PMF are discovered either de novo (i.e. PMF) or in the setting of either polycythemia vera (post-PV MF) or essential thrombocythemia (post-ET MF). PMF is also known by many synonyms. However, the use of the term "PMF" was recently endorsed by the International Working Group for Myelofibrosis Research and Treatment (IWG-MRT).

Historical Perspective

The first description of PMF is credited to Heuck (1879). William Dameshek classified PMF as a MPD, along with chronic myeloid leukemia (CML), ET, and PV. In 1960, the Philadelphia chromosome was described in CML, which was later shown to harbor first t(9;22)(q32;q13) and subsequently the *BCR-ABL* disease-causing mutation. Accordingly, modern classification systems list PMF, PV, and ET as *BCR-ABL*-negative classic MPDs. In 1967, the Polycythemia Vera Study Group (PVSG) provided, for the first time, formal criteria for the diagnosis of PMF. Subsequently, a WHO-sponsored committee on classification of hematological malignancies revised the PVSG diagnostic criteria for PMF and reorganized the overall classification system for myeloid neoplasms.

Disease Mechanisms

In 1978, G6PD-based clonality studies established PMF as a stem cell-derived clonal myeloproliferation. In 2005, a novel gain-of-function (GOF) mutation involving the JAK2 tyrosine kinase (*JAK2*V617F) was described in ~50% of PMF patients but also in the majority of those with PV as well as ET. In 2006, another GOF mutation involving MPL (*MPL*W515L/K) was described in ~5% of patients with PMF.

*JAK2*V617F is an exon 14 *JAK2* mutation at nucleotide position 1,849 representing a G to T somatic point mutation. The mutation results in the substitution of valine to phenylalanine at codon 617. *MPL*W515L mutation represents a G to T transition at nucleotide 1,544 resulting in a tryptophan to leucine substitution at codon 515 of the transmembrane region of the MPL receptor. Both of the above mutations induce an MPD-phenotype in mice, the former a PV-like disease and the latter a PMF-like disease.

In addition to clonal myeloproliferation, PMF is characterized by bone marrow stromal aberration including collagen fibrosis, osteosclerosis, and angiogenesis. In mice, similar histological features have been induced by either systemic over-expression of thrombopoietin (TPO^{high} mice) or by megakaryocyte lineage restricted under-expression of the transcription factor GATA-1 ($GATA\text{-}1^{low}$ mice).[17] In both human PMF and experimental myelofibrosis in mice, the bone marrow stromal changes are believed to be secondary to abnormal release fibrogenic and angiogenic cytokines including transforming growth factor-β1 (TGF-β), platelet-derived growth factor (PDGF), basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), tissue inhibitors of matrix metalloproteinases, and neutrophil-derived elastase and other proteases.

Clinical and Laboratory Characteristics

The prevalence of PMF is similar in men and women (M:F = 1.6:1) and overall reported incidence figures range from 0.4 to 1.5/100,000. Median age at diagnosis is estimated between 55 and 60 years. Most, but not all, patients with PMF are symptomatic at diagnosis. The typical presentation includes anemia, marked splenomegaly, and constitutional symptoms including fatigue and night sweats. Hepatosplenomegaly in PMF is secondary to extramedullary hematopoiesis (EMH) that might also involve other organs including lymph nodes, pleura, peritoneum, and the paraspinal and epidural spaces.

The peripheral blood smear in PMF often shows leukoerythroblastosis (presence of nucleated red blood cells and immature granulocytes) and tear drop-shaped red blood cells. Other laboratory abnormalities at diagnosis include anemia, leukocytosis or leukopenia, thrombocytosis or thrombocytopenia, and increased serum levels of lactate dehydrogenase (LDH). Bone marrow examination reveals both "cellular phase" and "overtly fibrotic" stages of the disease. In both instances, the most characteristic feature is the presence of dense megakaryocyte clusters with atypical megakaryocyte morphology (cloud-like nuclear morphology) that is accompanied by increased granulocyte proliferation and reduced erythropoiesis. Additional histological features of advanced disease include new bone formation and intra-sinusoidal hematopoiesis.

Diagnosis

Bone marrow examination is essential in the diagnosis of PMF and should be accompanied by mutation screening for *BCR-ABL* in order to exclude the diagnostic possibility of CML and *JAK2*V617F in order

exclude the possibility of bone marrow fibrosis associated with non-malignant condition, lymphoid disorder, or metastatic cancer. It should be noted, however, that *JAK2*V617F can not distinguish PMF from other myeloid disorders such as MDS, ET, PV, or other MPD. Therefore, accurate diagnosis requires careful morphological evaluation. Cytogenetic abnormalities occur in approximately half of the patients with PMF at diagnosis and include del(20)(q11;q13), del(13)(q12;q22), trisomy 8, trisomy 9, del(12)(p11;p13), monosomy or long arm deletions involving chromosome 7, and partial trisomy 1q). Although none of these abnormalities are specific to PMF, the presence of either del(13)(q12;q22) or der(6)t(1;6)(q21–23;p21–23) is strongly suggestive of the specific diagnosis.

Prognosis and Treatment

Causes of death in PMF include development of blast phase PMF, which occurs in ~10% of patients during the first decade of their disease, and infections. Survival in PMF is estimated by the use of one of several prognostic scoring systems (PSSs) that rely on the presence or absence of well-established adverse prognostic features. Among the latter, the *Mayo Clinic* PSS has been reported to be superior, compared to other PSSs, in delineating both good risk and intermediate risk disease categories. The *Mayo* PSS is based on four adverse prognostic variables: hemoglobin < 10 g/dL, platelet count $<100 \times 10^9$/L, leukocyte count either $<4 \times 10^9$/L or $>30 \times 10^9$/L, and monocyte count $\geq 1 \times 10^9$/L. In the absence of any adverse feature (low-risk disease), median survival is expected to exceed 10 years. The presence of two or more adverse features (low-risk disease) predicts a median survival of <5 years.

Current management in PMF is suboptimal; erythropoietin, androgen preparations, corticosteroids, thalidomide, lenalidomide, splenectomy, and involved field irradiation of the spleen or other sites of extramedullary hematopoiesis. Treatment with either myeloablative or reduced-intensity conditioning (RIC) allogeneic stem cell transplantation (ASCT) is used for selected patients with high-risk disease. However, because ASCT is associated with relatively high incidence of regimen-associated mortality and morbidity, it is not recommended for all patients. The aforementioned Mayo PSS for PMF helps in the selection of patients suitable for ASCT.

In the asymptomatic patient with low-risk PMF, I recommend watchful waiting. The primary reason for using drug therapy in PMF is either anemia or splenomegaly. Drug options for the former include subcutaneous erythropoietin or oral drugs including androgen preparations, corticosteroids, danazol, thalidomide, and lenalidomide. The response rates from such therapy ranges from 10% to 30%. Responses last between 6 and 12 months. Single agent therapy in unselected patients with either thalidomide or lenalidomide produces 15% and 20% response rates in anemia, respectively. The addition of corticosteroids doubles the response rate with thalidomide and the presence of del(5)(q31) is associated with complete hematologic remission in the majority of patients treated with lenalidomide. The drug of choice for symptomatic splenomegaly in PMF is hydroxyurea. The drug is also used for controlling symptomatic thrombocytosis and/or leukocytosis.

Splenectomy is a strictly palliative treatment modality in PMF and does not alter the natural history of the disease. The procedure is associated with ~10% mortality and a higher incidence of morbidity that includes thrombosis, bleeding, post-splenectomy enlargement of the liver, and exacerbation of thrombocytosis/leukocytosis. Current indications for splenectomy in PMF include complications of portal hypertension including ascites and variceal bleeding, drug-refractory symptomatic splenomegaly, or very frequent red blood cell transfusions. Involved field radiotherapy provides transient relief of mechanical discomfort from hepatosplenomegaly. However, such therapy is often complicated by protracted pancytopenia and drug therapy is instead preferred. In contrast, irradiation therapy is very useful in patients with non-hepatosplenic EMH; most frequent sites include vertebral column, lungs, pleura, and peritoneum.

Both myeloablative and RIC transplant are used in advanced PMF. The experience so far with myeloablative ASCT is encouraging in very young patients (age < 45 years) but post-transplant long-term survival in older patients is less than 20%. Furthermore, the majority of survivors after ASCT experience reduced quality of life because of chronic graft versus host disease (GVHD). To date, the advantage of RIC transplant over myeloablative ASCT has not been examined in a controlled setting although single cohort studies suggest better outcome in terms of both 1-year mortality (0–33%) and morbidity (0–50% rate of acute GVHD).

Primary Pigmented Nodular Adrenocortical Disease

Definition

PPNAD; is a rare disease caused by excess production of cortisol by the adrenal glands. The adrenal glands are small glands located above each kidney and produce hormones. Hormones are chemical substances formed in one organ or part of the body that travel in the blood to other body parts where they influence how that body part works. Cortisol is one of the hormones made by the adrenals. Cortisol influences body metabolism (how the body converts small molecules to large and vice versa) and can decrease inflammation. People with PPNAD have adrenal glands that make too much cortisol or make it at inappropriate times (when the body does not need it).

Primary Sclerosing Cholangitis

Definition

PSC; Is an inflammatory disease of the bile ducts, which leads to cholestasis or blockage of bile flow. The ►inflammation of the bile ducts causes scarring and hardening (►fibrosis) that narrows the bile ducts. Because bile cannot exit, it accumulates in the liver causing damage to liver cells. Eventually, with chronic inflammation and long term cell damage, the liver develops ►cirrhosis (hardening or fibrosis) and can no longer function properly. PSC is considered to be an autoimmune disease. However, there is not universal agreement on the pathogenesis of the disease. Can develop in patients with ►inflammatory bowel disease.

►Cholangiocarcinoma
►Bile Duct Neoplasms

Primary Systemic Therapy

►Neoadjuvant Therapy

Primitive Neuroectodermal Tumor

Definition

PNET; Tumors composed of small densely packed hyperchromatic cells found in the central nervous system CNS (central PNET) or originating from soft tissue and bone (peripheral PNET). Peripheral PNET are genetically characterized by a translocation t(11;22)(q24;q12), are of neural crest origin and grouped with the ►Ewing sarcoma family of tumors. Central PNET do not show a t(11;22) translocation and exhibit divergent differentiation patterns along neuronal (e.g., cerebral ►neuroblastoma) or ependymal (e.g., ependymoblastoma) lines or are found in locations above the cerebellar tentorium (connective tissue covering the dorsal surface of the cerebellum) (e.g., pineoblastoma). Medulloblastomas are infratentorial (infra = below) central PNET.

Definition
►N- or C-Terminal Processing.

Proconvertin

Definition
►Factor VII.

Prodrug

Definition
A precursor (forerunner) of a drug. A compound that is converted within the body into its active form that has medical effects. A prodrug must undergo chemical conversion by metabolic processes before becoming an active pharmacological agent. For example, ►sulfasalazine is a prodrug. It is not active in its ingested form. It has to be broken down by bacteria in the colon into two products – 5-aminosalicylic acid (5ASA) and sulfapyridine – before becoming active as a drug. Prodrugs are useful when the active drug may be too toxic to administer systemically, the active drug is absorbed poorly by the digestive tract, or the body breaks down the active drug before it reaches its target.

►ADMET Screen
►HSV-TK/Ganciclovor-mediated Toxicity
►Xenobiotics

Progenitor Cells

Definition
These can include both stem cells and transient amplifying cells, or even cells that are well on the way to becoming differentiated.

►Adult Stem Cells

Progesterone

Definition
Is a steroid hormone involved in female menstrual cycle, pregnancy and embryogenesis. As a drug it has several indications related to its biological function.

►Fluoxetine
►Progestin

Progesterone Receptor

Definition
PR; A steroid hormone receptor that confers progesterone-responsiveness and is often co-expressed with the ►estrogen receptor (ER) in normal breast and breast cancer.

►Basal-like Breast Cancer
►Progestin

Progesterone Response Elements

Definition
PRE; Refer to a specific DNA sequence located in the promoter of ►progesterone target genes that consists on

an inverted repeat, separated by three nucleotides: AGAACAnnnTGTTCT.

Synonyms

Progesterone; Progestogen

Definition

Progesterone (4-pregnene-3,20-dione, P4) is an ►ovarian steroid hormone that plays a key role in the regulation of cell proliferation and differentiation in the female reproductive tract. Interestingly, progesterone also regulates diverse biological effects in a broad range of tissues, even of the cardiovascular and the central nervous systems, and participates in bone maintenance and regulation of thymic involution. Progesterone has also been implicated in the development and progression of ►breast cancer. Progestogen defines the category of hormone molecules (natural and synthetic) that act like progesterone in the uterus and the term progestin has been generally used to refer to both a series of synthetic hormone molecules and progesterone. We will use here the generic term progestin to refer to both progesterone and synthetic progestins.

Characteristics

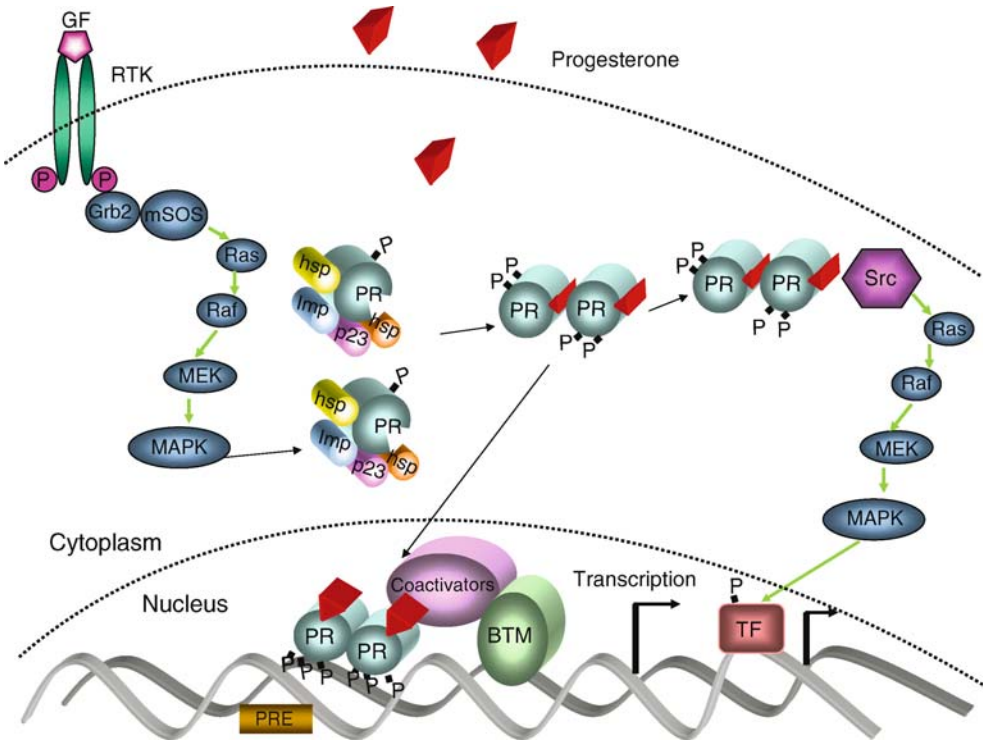
The two most studied progesterone target tissues are the uterus and the mammary gland. In the uterine epithelium progesterone antagonizes the capacity of estrogen, the other ovarian steroid, to induce cell proliferation and acts as the major differentiating hormone. These two ovarian steroid hormones are generally present jointly in physiological conditions and so are their specific receptors coexpressed in the same tissues. Notably, a series of findings have shown that estrogen and progesterone counterbalance each other's effects in target tissues. Progesterone also plays a key role in mammary gland development and function, as demonstrated, among an increasing body of evidence, by incomplete mammary gland ductal branching and failure of lobuloalveolar development in progesterone receptor (PR) knockout mice (PRKO). Interestingly, in contrast with its antagonistic effect on estrogen-driven proliferation in the uterus, in the mammary epithelium proliferation reaches its peak during the progesterone-dominant luteal phase of the human menstrual cycle, evidencing a proliferative role of progesterone in the normal breast. Accumulated findings indicate that progestins are also involved in controlling mammary gland tumorigenesis both in women and in animal models. Progestin effects in in vitro growth of breast cancer cells were found to be highly dependent on experimental culture conditions and on the presence of estrogens. Particularly, progestins were found to either support sustained growth or to induce cells to progress through one round of cell division, followed by growth arrest at the G1/S phase of the second cycle in the human breast cancer cell line T47D, the ideal model of breast cancer cell with constitutive expression of PR. A series of seminal findings evidenced that the initial pulse of progestins primes progesterone-arrested breast cancer cells for the action of secondary proliferative or differentiative ►signaling pathways. Hence, the commitment to one path or the other would be determined by cross talks between growth factor (GFs)/cytokine pathways and by progesterone/PR signaling.

Mechanisms

The biological effects of progestins are mediated by interaction with the PR, a member of the ►steroid receptor superfamily of ligand-activated nuclear transcription factors. The PR consists of two isoforms, PR-A and PR-B, expressed from a single gene by the use of alternative promoters. PR-B differs from PR-A in that PR-B contains an amino terminal extension of 128–165 aminoacids, depending on species. Both PR isoforms contain a C-terminal hormone binding domain, a DNA-binding domain, a hinge region, and two transcriptional activation function (AF) domains located at the amino terminus (AF-1) and at the ligand-binding domain (AF-2). The PR-B isoform contains a third transactivation function (AF3) within its amino terminal extension, absent in PR-A. The two PRs exhibit different transcriptional properties that depend both on the cell type and on the target gene promoter, being the PR-B a much stronger transactivator for PR target genes. On the other hand, PR-A is a more potent dominant-negative transcriptional inhibitor of PR-B and other ►steroid hormone receptors, including ►estrogen receptor (ER). Recent screens for differential regulation of gene expression by PR-A and PR-B in breast cancer revealed that although some genes are modulated by progesterone through both PR isoforms, the majority of the target genes are exclusively regulated through one or the other isoform, principally through PR-B. PR-A and PR-B ratios vary during the menstrual cycle in the uterus, indicating the physiological importance of these variations. Contrastingly, equal expression of the two PR isoforms is required for

normal development and function of the mammary gland. Different ratios of PR isoform expression have been found in several cancers. Overexpression of PR-B has been found in ovarian, endometrial, and cervical tumors. On the other hand, PR-A-rich breast tumors have poorer disease-free survival rates and exhibit resistance to ►endocrine therapy.

The classical pathway of progesterone inducible PR-mediated gene transcription has long been described. Upon progesterone binding, PR undergoes a conformational change and dissociates from a multi-protein chaperone complex, which includes ►heat shock protein (hsp) 90 and its co-chaperone p23, hsp70 and three co-chaperones: hsp40, hip (hsp70-interacting protein), and hop (hsp70-organizing protein) and ►immunophilins such as FKBP51 and FKBP52 (Fig. 1). PR then dimerizes, translocates to the nucleus, and binds to specific ►progesterone response elements (PREs) in the promoter of target genes where DNA-bound receptor recruits ►coactivators which facilitate transcription initiation through interaction with components of the basal transcription machinery (Fig. 1). Several PR coactivators have been described. Among them, well characterized has been the SRC/p160 family of proteins (NcoA/SRC1, GRIP1/SRC-2, NcoA-3/SRC3/RAC3) that binds to the AF2 region of PR. Notably, accumulating evidence indicates that coactivators not only participate in the initiation step of transcription, but also play a role in ►alternative RNA splicing, revealing another mechanism through which PR controls gene expression. Progesterone also regulates transcription of genes that lack a canonical PRE through interaction with other transcription factors, such as Sp1 and ►AP-1, at the response elements of these transcription factors. In addition to their direct transcriptional effects, rapid, extranuclear or "nongenomic" biological effects of progesterone have been described. One physiologically important process that depends on nontranscriptional effects of progesterone is the maturation of fish and amphibian oocytes, in which progesterone induces germinal vesicle breakdown, resumption of the meiotic cell cycles, and development into the mature, fertilizable egg. Assessment of the signal transduction pathways involved in this process evidenced that progesterone activates the Mos/MEK1/p42 ►mitogen-activated protein kinases (MAPK) cascade, which ultimately brings about the activation of the universal M phase trigger cdc2/►cyclin B. The receptors that mediate the nongenomic effects of progesterone remain largely unknown and have constituted a controversial issue over the years. Several findings suggested that the oocyte PR involved in nongenomic effects could be a membrane seven-pass, ►G-protein-coupled receptor, unrelated to the classical intracellular PR. Thus, progesterone can induce maturation when applied to the outer side of an oocyte. Moreover, it stimulates some aspects of maturation in enucleated oocytes and induces inhibition of adenylyl cyclase and cyclic AMP concentration. However, the recent cloning of the *Xenopus* homolog of the classical PR (X-PR) revealed that oocyte maturation could be mediated by nontranscriptional effects of the classical PR since injection of X-PR mRNA was found to accelerate progesterone-induced Mos synthesis, p42 MAPK activation, and oocyte maturation. In addition, injection of X-PR antisense oligodeoxynucleotides into oocytes inhibited progesterone-induced maturation which could be restored by overexpression of X-PR or human PR. This classical X-PR has also been found to associate with the cytosolic kinases p42 MAPK and ►phosphatidylinositol 3-kinase (PI-3K). Recently, a novel membrane progesterone receptor (mPR) gene that encodes a seven transmembrane-spaning G-protein coupled receptor was cloned from spotted sea trout ovaries and other members of this family of putative mPRs have been cloned from humans and other vertebrates. In mammalian, nongenomic effects of progestins have been described in human spermatozoa and appear to be mediated by interaction with progesterone membrane receptors. Rapid effects of progestins also include modulation of neurotransmitter receptor activity. An intense and particularly important field of investigation, for its potential therapeutic implications, lies in the nongenomic biological effects of progestins in breast cancer cells. Pioneering work demonstrated that progestin treatment of human breast cancer T47D cells activates the signal-transducing c-►Src/p21^{ras}/MAPK pathway (Fig. 1), which results in cell proliferation. This startling work has shown that progestin ability to activate c-Src/MAPK pathway depends on the presence of unliganded ERα, which is the one that activates c-Src. ERα and PR-B interaction occurs via two domains that flank a specific amino-terminal PR proline-rich sequence. On the other hand, direct interaction of the polyproline motif of PR-B with the ►SH3 domain of c-Src, which results in c-Src activation by a SH3 displacement mechanism, has been found in vitro, in human normal breast MCF-12 cells transduced with PR-B, and in T47D cells. In these two cell types, interaction is progestin-dependent. Notably, cross talk between PR/progestins and cytoplasmic signaling pathways is of a bidirectional nature, where progestins activate cytoplasmic pathways and conversely, where activation of cell signaling pathways induces ligand-independent activation of PR. It is to be noted that PR is a heavily phosphorylated protein in multiple serine residues. Though the functional role of PR phosphorylation has not been completely deciphered, increasing evidence indicates that it plays a key role in both ligand-dependent and -independent transcriptional activation of PR. Particularly, MAPK activated by ligands of the type I ►receptor tyrosine kinase family (RTKs-I/ErbBs) were



Progestin. Figure 1 Mechanisms of progesterone receptor (PR) activation. Upon progesterone binding, PR undergoes a conformational change and dissociates from a multi-protein chaperone complex, which includes heat shock protein (hsp), p23, and immunophilins (imp). PR then dimerizes and translocates to the nucleus. In it classical mechanism of action, PR binds to specific progesterone response elements (PREs) in the promoter of target genes where the DNA-bound receptor recruits coactivators. The latter facilitate transcription initiation through interaction with components of the basal transcription machinery (BTM). PR nongenomic action occurs through PR activation of cytoplasmic signaling pathways, such as c-Src/p21ras/MAPK, which results in activation of transcription factors (TFs). Shown is also a model of ligand-independet activation of PR by growth factors (GFs) that bind to receptor tyrosine kinases (RTKs), in which GF-activated MAPK induce the PR phosphorylation required for its transcriptional activity.

found to play a key role in ligand-independent activation of PR in both human and mouse breast cancer cells (Fig. 1). Convergence between growth factors/RTKs and PR signaling is directly involved in progestin-mediated proliferative effects in breast cancer cells.

Clinical Significance

Accumulating findings have clearly evidenced the involvement of progestins/PR in breast cancer development. Breast cancer is a devastating disease and is a major cause of death among women between ages of 40 and 55 in most industrialized countries. Considerable epidemiological and clinical evidence have related the cumulative and sustained exposure to ovarian steroids, estrogen and progesterone, to increased risk of developing breast cancer. Furthermore, it has been shown that PRKO mice are less susceptible to develop mammary tumors in a chemically-induced model of tumorigenesis. Strong evidence of PR implication in breast cancer etiology was also provided by the observation that postmenopausal women who undergo a combined estrogen and progestin hormone replacement therapy suffer a higher incidence of breast cancer than women who take estrogen alone. In addition, a recent study demonstrated that treatment of ►breast cancer susceptibility gene *Brca-1*-deficient mice with the ►antiprogestin RU486, prevented mammary tumorigenesis thereby highlighting the importance of a reappraisal of the therapeutic effects of targeting PR in breast cancer. At the time of diagnosis, at best only two third of tumors expressing ER and PR are responsive to endocrine therapy. Approximately 70% of all patients with ER- and PR-positive invasive breast cancers will initially benefit from ►antihormonal therapy. However, as these tumors progress, they will often acquire steroid hormone resistance. This is likely due to the fact that control over

tumor growth is undertaken by GFs that are not only able to act as mitogens for breast tumor cells, but also to transactivate steroid receptors. Clearly, understanding the molecular mechanisms of progestins action and interaction with GF signaling in breast cancer is a major question with important therapeutic implications.

197/15a (human PDCD4 variant 1); H731 (human PDCD4 variant 2, cancer-related); MA-3, TIS (mouse Pdcd4); DUG (rat Pdcd4); PDCD4/Pdcd4

Definition

PDCD4/Pdcd4 is a tumor suppressor. This protein contains two ►MA-3 domains homologous to the M1 domain of ►eIF4G and nuclear localization signals. PDCD4/Pdcd4 exhibits multiple functions such as the regulation of protein synthesis, the controls of transcription, and the induction of ►apoptosis. The human gene maps to 10q24.

Characteristics

Human *PDCD4* (*H731*) was first identified as a gene involved in the cell cycle. The human gene has also been isolated as a gene whose expression in lymphocytes was modulated by interleukins. The mouse gene (*MA-3*) was found to be upregulated during the induction of apoptosis, and the same gene (*TIS*) was downregulated by topoisomerase inhibitors such as etoposide and camptothecin. In chickens, Pdcd4 expression has been demonstrated to be controlled by the transcription factor ►myb. PDCD4/Pdcd4 is ubiquitously expressed and localized in the cytoplasm or in the nuclei, or in both, depending on the cell types and conditions. Since Pdcd4 was initially shown in 1999 to have a tumor suppressor function, the mechanisms and functions of PDCD4/Pdcd4 have gradually been elucidated.

Tumor Suppressor Activity

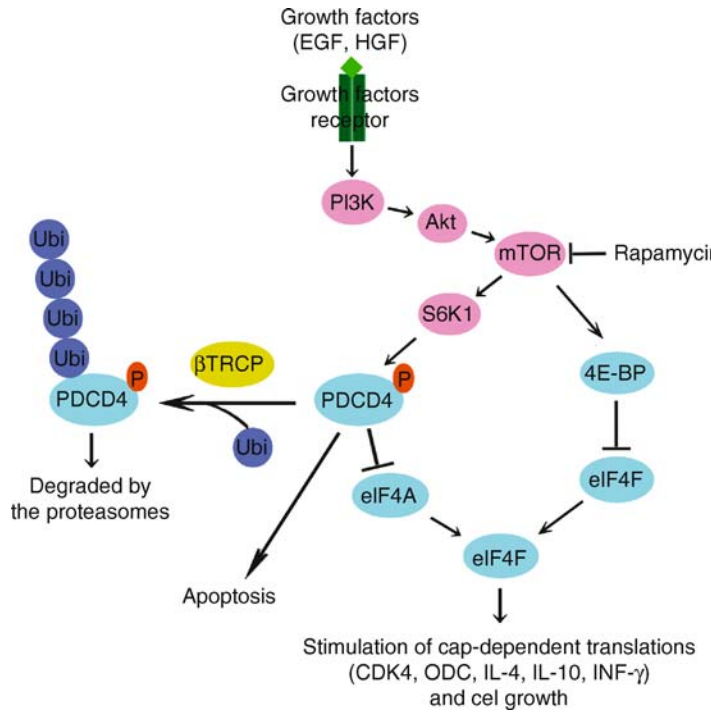
The tumor suppressor activity of Pdcd4 is considered to be well established. In the mouse JB6 epidermal cell model system, cells with high levels of Pdcd4 expression were found to be more resistant to carcinogenesis induced by 12-O-tetradecanoylphorbol-13-acetate (TPA) than cells with low levels of Pdcd4. The ectopic expression of Pdcd4 in metastatic RKO human colon carcinoma cells suppresses the ►invasion of the carcinoma cells. Transgenic mice overexpressing Pdcd4 in the epidermis (K14-Pdcd4) are resistant to ►skin carcinogenesis in response to TPA: The ►K14-Pdcd4 mouse shows significant reduction in papilloma formation, carcinoma incidence and papilloma-to-carcinoma conversion frequency. A ►Pdcd4-deficient mouse developed spontaneous lymphomas, mostly B cell lymphomas, and has a significantly reduced life span. They developed tumors around the age of 85 weeks, in comparison to p53-deficient mice, which developed tumors around the age of 12 weeks, thus indicating that Pdcd4 is a weaker repressor than p53 (►p53 Protein, biological and clinical aspects).

Control of Translation

Pdcd4/PDCD4 protein interacts with the translation initiation factors ►eIF4A and eIF4G through the MA-3 domains and thus modulates protein synthesis. Pdcd4 was shown to inhibit ►cap-dependent translation by inhibiting both the binding of eIF4A with eIF4G and the RNA-helicase activity of eIF4A. The levels of ►cycline-dependent kinase 4 (CDK4) and ornithine decarboxylase (ODC) protein, which are the candidates for Pdcd4-regulated translation as their mRNAs contain a structured 5′ untranslated region (UTR), decreased by 40 and 46%, respectively, in the ►K14-Pdcd4 transgenic mouse in comparison to their matched wild-type siblings. The PDCD4 protein was phosphorylated by ►ribosomal protein S6 kinase 1 (S6K1) at Ser67, downstream of the growth factor-induced PI3K-Akt-►mTOR signaling pathway (►AKT signal transduction pathway in oncogenesis, ►P3IK signaling), ubiquitinated by the E3 ubiquitin ligase complex $SCF^{\beta TRCP}$ (SKP1-Cull-F-box protein) and degraded by proteasomes (►Ubiquitination). The phosphorylation at Ser67 may promote the phosphorylation of Ser71 and Ser76 in the βTRCP-binding motif ($D^{70}SGRGDS^{76}$) of PDCD4 protein, which must be phosphorylated to allow recognition by βTRCP. A loss of PDCD4/Pdcd4 resulted in the modulation and increase of protein synthesis, thereby promoting cell growth that can subsequently lead to cancer (Fig. 1). The rate of protein synthesis in splenocytes derived from the Pdcd4-deficient mouse increased more than twofold in comparison to that in the cells derived from a wild-type sibling, and ~50 proteins were affected by the *PDCD4* gene mutation. Among these, three growth factors/cytokines, ►interleukine-4 (IL-4), interleukine-10 (IL-10), and interferon-γ (IFN-γ were significantly increased in the PDCD4-deficient cells, due to a posttranscriptional regulation. The PDCD4-deficient mice were significantly resistant to two models of inflammatory diseases caused by self-reactive lymphocytes: type1 diabetes induced by streptozotocin (STZ) and the experimental autoimmune encephalomyelitis (EAE) induced by the myelin oligodendrocyte glycoprotein (MOG). The PDCD4-deficient lymphocytes preferentially produce cytokines which promote oncogenesis but inhibit ►inflammation. All of these cytokines contain structured GC-rich 5′ UTRs.

Transcriptional Controls

Pdcd4 inhibits the activation of c-Jun which is a component of activator protein 1 (►AP-1) and consequently may suppress neoplastic transformation by inhibiting AP-1-dependent transcription. Pdcd4 does not directly target either c-Jun or the Jun N-terminal kinase (JNK) which activates c-Jun, but it inhibits transcription of ►MAP4K1, an upstream kinase of JNK. Therefore, Pdcd4 may contribute to the suppression of neoplastic transformation, tumor progression and invasion by the novel mechanisms of down-regulating MAP4K1-transcription, with consequent inhibition of c-Jun activation and AP-1-dependent transcriptions.



Programmed Cell Death 4. Figure 1 Controls of protein synthesis and apoptosis by PDCD4. PDCD4 inhibits ►cap-dependent protein synthesis which may stimulate carcinogenesis. The growth factor-mediated PI3K-Akt-mTOR pathway stimulates the phosphorylation and degradation of PDCD4. The loss of PDCD4 results in the increase of protein synthesis and in the suppression of PDCD4-induced apoptosis. 4E-BP, eIF4E-binding protein; βTRCP; the E3 ubiquitin ligase $SCF^{\beta TRCP}$; Ubi, ubiquitin.

Induction of Apoptosis

The Pdcd4 expression has been found upregulated upon apoptosis induction in various apoptosis-inducible mouse cell lines of thymocytes, T cells, B cells and pheochromocytoma. *PDCD4* gene expression is also upregulated in the ►transforming growth factor-β1 (TGF-β1)-induced apoptosis of human hepatoma cell lines and in the ►retinoic acid-RAR (retinoic acid receptor) signaling system-induced apoptosis of human breast cancer cells. The PDCD4 protein induces the ►apoptosis of cancer cells when the protein was over-expressed by the transfection of a PDCD4-plasmid. Upon apoptosis induction of Huh7 hepatoma cells by PDCD4 overexpression, the caspase cascade was found activated via Bax activation and mitochondria events; caspase-9, -3, and -8 were activated (►Apoptosis signaling), as in the case of TGF-β1-induced apoptosis. TGF-β1 induced the PDCD4 mRNA expression through the TGF-β1-activated Smad signaling pathway (►Smad proteins in TGF-β1 signaling). PDCD4 accumulated in the nuclei and induced the fragmentation of the nuclei in Huh7 cells induced by TGF-β1 or transfected with the PDCD4-plasmid. The PDCD4 protein amounts in the nuclei were increased in parallel to the increase in apoptotic cells, while the amount in the cytoplasm only slightly increased during the treatment of Huh7 cells with TGF-β1, thus indicating that the control mechanism of PDCD4 localization in cells may play an important role in the induction of apoptosis in Huh7 cells. In contrast to the case of Huh7 hepatoma cells, the proapoptotic molecule Bad was upregulated and the antiapoptotic ►Bcl-2 was suppressed in the lungs of K-ras null mice with pulmonary cancer exposed to aerosol containing urocanic acid-modified chitosan (UAC)/PDCD4 complexes.

Roles in Cell Differentiation

PDCD4 protein is abundantly expressed in the differentiating keratinocyte cell layers of the epidermis and its appendages, but expressed only in low levels in their germinative cell layers, in the human skin. The protein is mostly localized in the nuclei of keratinocytes. PDCD4 might contribute to the differentiation of keratinocytes inhibiting the activation of c-Jun and consequently AP-1-dependent transcriptions which would otherwise induce the cells to proliferate. Alternatively, PDCD4 might also help to activate

the proapoptotic caspase cascade that may induce cell death, during the terminal differentiation of keratinocytes.

Clinical Aspects

PDCD4 protein levels are downregulated in the human lung-, liver-, colon-, pancreas-, epidermal cell-, and glia-derived cancer tissue specimens so far tested, in comparison to corresponding normal tissues. Among these tissue samples, relatively high PDCD4 expression has thus been associated with a slower progression and a better prognosis in some lung cancers. In pancreatic cancers, this expression has been shown to correlate with the differentiation levels; high expression was observed in relatively well-differentiated tissues. In other cases, little or no correlation between the expression levels and pathological and clinical features has so far been found. However, transgenic mice preferentially expressing Pdcd4 in the epidermis, resisted skin carcinogenesis. The Pdcd4-deficient mouse exhibited an earlier development of spontaneous lymphomas, especially those of B lymphoid origin. These results indicate that the loss of PDCD4 expression may increase the risk of carcinogenesis. PDCD4 expression is modulated by various factors such as growth factors, cytokines, and vitamins. PDCD4 modulates protein synthesis. An overexpression of PDCD4 induces apoptosis of cancer cells (►Apoptosis induction for cancer therapy). Therefore, PDCD4 is expected to be a target gene for cancer prevention and therapy. The aerosol delivery of a gene carrier-PDCD4 complex may be useful for the treatment of lung cancers. High PDCD4 expression has been shown to enhance the sensitivity of cancer cells to anticancer drugs geldanamycin and ►tamoxifen using the National Cancer Institute drug-screening panel of 60 human cancer cells (NCI60).

PDCD4-deficient mice are not only sensitive to carcinogenesis of lymphocytes, but they are also resistant to inflammatory diseases such as autoimmune encephalomyelitis and diabetes. PDCD4-deficient lymphocytes preferentially produce cytokines such as IL-4, IL-10, and IFN-γ that promote oncogenesis but inhibit inflammation. Therefore, PDCD4 may also be a target gene for the therapy of inflammatory diseases.

Progression

Margot Zoeller
DKFZ, Heidelberg, Germany

Definition

Tumor progression defines the process of invasiveness which leads to settlement and growth of a tumor cell in an organ that is distant from the site of the primary tumor. Such a "secondary" tumor is called metastasis.

Characteristics

Benign tumors are defined by loss of growth control, loss of contact inhibition, a reduced requirement for growth factors, or autocrine production of growth factors. Malignant tumors, i.e., metastasizing tumors, are defined by their capacity of invasiveness. This implies that the tumor invades the surrounding tissue, the vascular system, and distant organs. The process is called the metastatic cascade and is composed of the following elements:

1. Loss of contact between the individual tumor cell and the tissue of the primary tumor
2. Penetration through the basal lamina of the primary tumor
3. Invasion of blood and/or lymphatic vessels
4. Adaptation to the blood pressure
5. Adhesion to vessel endothelia, extravasation, embedding, and growth in organs different from the primary tumor, which includes the requirement for supply with nutrients by angiogenesis

Tumor Stem Cell and Metastasis

Metastasis formation is independent of the process of oncogenesis, which is the consequence of genetic alterations within a single cell, whereas tumor progression relies on a concerted interaction with surrounding

elements, like the extracellular matrix and host cells. It is important to note that no single step in the metastatic cascade is necessarily associated with the malignant phenotype. Corresponding processes will be seen during implantation of the fertilized egg, organogenesis, stem cell maturation, and lymphocyte migration. It is therefore hypothesized that tumor progression must not necessarily be accompanied by additional genomic alterations of the transformed tumor cell. Instead, tumor progression may be initiated by inappropriate silencing or activation of (regulatory) genes. Thus, Sell and Pierce postulated in 1994 that malignant tumors arise from a blockade in stem cell differentiation. Stem cells are characterized by immortality, self renewal, differentiation into daughter cells, and migratory potential. All these features also are characteristics of metastasizing tumor cells. The transformation of stem cells into highly specialized epithelial and mesenchymal cells is guided by the transcription of selective genes and is initiated via the stem cell environment. Notably, differentiation of stem cells, including stem cells in the adult organism, is reversible. This so called ►epithelial-mesenchymal transformation (EMT) and its reversion, MET, are the fundamental principle of reorientation of transcriptional programs. A transient EMT also is central for tumor progression. It involves tumor cells and the tumor stroma. Both embryonal and metastatic EMT are initiated by identical mediators and proceed via corresponding signal transduction cascades. The theory that metastasizing tumors arise from stem cells is not in contradiction to the contribution of genetic and epigenetic alterations as essential contributors to the evolution of a malignant tumor. It only implies that stem cells in the adult organism are the target of genetic and epigenetic alterations.

Metastatic EMT is accompanied by profound changes in gene transcription. Main components are TGFβ and autocrine growth factors. Essential components of signal transduction pathways are receptor tyrosine kinases/Ras, Wnt-, Notch-, Hedgehog-, and NF-κB. *Snail*, a ►master regulator gene in the gastrulation of the zebrafish, is also a master regulator gene in the metastatic EMT. An additional important element of EMT is the downregulation of the cell–cell adhesion molecule E-cadherin that can be achieved via posttranscriptional control, somatic mutation, suppression of gene expression by hypermethylation of the promoter region, histone deacetylation, and transcriptional suppression via special E-boxes in the proximal E-cadherin promoter. An essential transcription factor of E-cadherin repression is Twist. Both Snail and Twist are central regulators of EMT, but do not influence the growth of primary tumors. Thus, these transcription factors are bona fide metastasis genes. EMT is accompanied, concomitantly with the loss of epithelial components and loss of cell polarity, with the activation of mesenchymal gene expression, like vimentin, tenascin, and matrix metalloproteinases that are required during tumor progression. The EMT process predominantly takes place at the invasive front of the primary tumor during emigration of individual tumor cells. Without question, EMT is the central element of tumor progression that does not require genetic alterations, but depends on an intimate interaction between the tumor and the tumor stroma. The assumption that the EMT process is linked to the stem cell nature of the metastasizing tumor cell is supported by the reversibility of the process.

It should be mentioned that besides of the stem cell nature of the metastasizing tumor cells, which allows these cells the activation of genetic programs via so called master regulatory genes, like glycogen synthase kinase 3 (GSK3, Snail, Slug, Twist and others), the role of the epigenom also is coming into focus. The epigenom, chromatin, associated proteins, and the pattern of covalent modification of the DNA methylation, directs the gene expression program. Tumors are characterized by significant alterations in DNA methylation. Hypo- as well as hypermethylation is observed and likely present independent processes, whereby activation of metastasis-associated genes is mostly linked to hypomethylation that contributes to chromosomal instability. Though epigenetic modifications via DNA methylation and covalent histone modifications are not yet utilized as a therapeutic tool, these can well be considered as a future therapeutic option.

The Tumor Stroma and Metastasis

Stem cell, including tumor stem cell maintenance and differentiation essentially depends on the interaction with the surrounding tissue, that can be defined as a microecosystem, that is characterized by significant changes of the system by minimal alterations of any of the individual components, i.e., the tumor cell as well as host cells and the tumor matrix are equally important parameters for tumor progression. One example for the involvement of the surrounding tissue in tumor progression provides the organ preference of metastases, the ►seed and soil theory of Paget (1889) that frequently cannot be explained mechanistically.

Besides the process of angiogenesis, where tumor cells independent of their metastatic potential require a crosstalk with the surrounding tissue, metastasizing tumor cells essentially depend on the surrounding tissue at several steps of the metastatic cascade. These are invasion of the surrounding tissue including the vasculature and the settlement and growth in a secondary organ.

Most elements of both the extracellular matrix and the basal lamina, like collagens, hyaluronic acid, and

proteoglycans, form networks that fulfill static functions by maintaining the tissue structure. However, the extracellular matrix has pores that also allow cell migration. Besides their static function, the extracellular matrix also fulfills dynamic functions by binding to cell membrane anchored receptors that possess signal transducing capacity, and by serving as a depot for growth factors. During tumor progression, the extracellular matrix can become modified to allow for invasiveness. These modifications comprise:

1. Quantitative or qualitative alterations in the components of the extracellular matrix or their cellular receptors
2. Enhanced delivery of cytokines, growth, and motility factors; these factors are frequently bound to elements of the extracellular matrix and are inactive in this form; delivery requires the degradation of the binding element, e.g., by matrix degrading enzymes
3. Regulation of gene expression in the tumor cell by contact with elements of the extracellular matrix, a process important during organogenesis; the reverse process, namely stroma induction by the tumor cell, is of particular importance for the metastatic process

Thus, it is the stroma that is responsible for changes in the composition of the extracellular matrix, for support of cell motility via matrix degrading enzymes and the liberation of bioactive fragments of the extracellular matrix and of growth factors. The changes in the tumor as compared to the normal tissue stroma are called ►desmoplasty, where activated fibroblasts, also called myofibroblasts play a central role. They are essential for EMT and become recruited by the tumor cell via TGFβ. The tumor matrix supports migration and prevents tumor cell apoptosis. The tumor matrix provides the prerequisites for the local invasiveness of tumor cells by the provision of matrix degrading enzymes, like metalloproteinases, ADAM proteinases, bone morphogenetic protein 1 (BMP-1), and serinproteases (uPA, Thrombin, and Plasmin). Notably, too, an important factor for the organ preference of metastasis is the communication between the metastasizing tumor cell and the host tissue via chemokines and their receptors that are shared between metastasizing tumor cells, circulating leukocytes and stem cells for homing in defined organs. Thus, the tumor stroma, particularly activated fibroblasts could well provide a therapeutic target. Candidate molecules are inhibitors in TGFβ- and PDGF-mediated signal transduction.

The Metastatic Cascade: Effector and Suppressor Molecules

The process of metastasis formation commences with the dissociation of the metastasizing cell from the surrounding tumor cell. The network elements involved in this dissociation are homotypic cell–cell adhesion molecules like E-cadherin, whose expression becomes strongly reduced. Thereafter, the isolated tumor cell starts to interact with the surrounding tissue. Effector molecules of the metastasizing tumor cell, which become upregulated or de novo expressed are adhesion molecules, growth factors and their receptors, chemokines and their receptors, and matrix degrading enzymes, some of which are also provided by the tumor matrix. These molecules are required for the invasive process itself that is composed of three steps:

1. Binding
2. Local proteolysis
3. Migration

Adhesion molecules that dominate the interaction of the metastasizing tumor cell with the vascular endothelial cell and the extracellular matrix are integrins, selectins, and CD44. Integrins, particularly those that interact with receptor tyrosine kinases, support internalization of the E-cadherin/β-catenin complex and, thus, reduction in homophilic tumor cell adhesion. Other integrins, particularly the α6β4 integrin contribute to tumor cell motility by its relocalization towards the migrating front of the tumor cell. The αvβ3 integrin contributes to the degradation of the extracellular matrix by associating with membrane-bound metalloproteinases and the urokinase receptor. Selectins mainly contribute to the adhesion of tumor cells to vessel endothelium. CD44 is the main receptor for hyaluronan and for several chemokines. It is of special importance in leukocyte and metastasizing tumor cell migration, and contributes to the activation of survival signals in the isolated, metastasizing tumor cell.

Local proteolysis proceeds via metastatic tumor cell–matrix interaction. Main players are metalloproteinases, the plasminogen activator system (uPA/uPAR), ADAMs, transmembrane proteins with disintegrin and metalloproteinase domains, heparanase that is also important for the settling in the metastatic organ, and molecules that regulate matrix degrading enzymes like tissue inhibitor of metalloproteinases (TIMPs) and plasminogen activator inhibitors (PAIs).

The central elements for migration of the metastasizing tumor cells are cytokines, chemokines and their receptors, as well as changes in the organization of the cytoskeleton of the metastasizing tumor cell. Reorganization of the actin cytoskeleton of the metastasizing tumor cell will be regulated mainly via Rho GTPases. It is important to note that the tumor cell can shift between mesenchymal and amoeboid migration, where the latter is independent of matrix degradation. Chemokines and their receptors are particularly important for the organ-selectivity of

metastasis formation. This has, besides others, been demonstrated for lymph node, lung, and bone marrow metastases of mammary carcinoma via CXCR4 and its ligand SDF-1 and for bone metastasis via osteopontin.

Taken together and as outlined above for the metastatic MET and its reversion, which proceeds through the reactivation of master regulator genes of developmental programs, the metastatic cascade, too, is not a consequence of genetic alterations of the contributing molecules. Instead, quantity, distribution, and posttranslational modifications become modulated.

The definition of metastasis suppressor genes is functional and based on the assumption that interference with any single step in the multistep process of the metastatic cascade should suffice for interruption. Accordingly, metastasis suppressor genes should hamper metastasis formation without having an impact on growth of the primary tumor. So far 12 metastasis suppressor genes have been identified. Most of the metastasis suppressor genes act at the step of settlement in secondary organs. The molecules frequently block essential signal transduction pathways. Yet, so far, the function of none of the metastasis suppressor genes could be fully unraveled.

In conclusion, metastasis formation is the result of a reversible activation of master regulatory genes-initiated programs of embryonic and adult stem cells. Thus, it is most likely that metastases arise from tumor stem cells. Progression through the metastatic cascade requires concerted activities of the tumor cell and the surrounding tissue, where the tumor cell influences the tumor stroma and vice versa.

Clinical Relevance

Conventional therapeutic regimen, in most instances, can cope with the primary tumor. Cancer mortality, therefore, is mainly due to the formation of metastasis. Tumor progression by silencing or activation of unaltered genes via master regulatory genes of stem cell programs supported by the interplay between the tumor stem cell and the tumor matrix will allow for the elaboration of new therapeutic, physiology-based protocols. Though research in the field of metastasis progression has most significantly progressed in the last years, (tumor) stem cell programs are just beginning to become unraveled. Also, the mutual impact of tumor and tumor stroma requires further exploration. The same accounts for epigenetic alterations in metastasizing tumor cells. Thus, there is promise for metastasis-selective therapeutics, that could not have been thought about before. Although further progress is required, highly encouraging observations in individual patients support the concept of intervention with metastasis formation by biological targeting.

Synonyms

Mammotropin; Mammotropic hormone; Luteotropin; Luteotropic hormone

Definition

Prolactin is a 23 kDa protein hormone secreted by the anterior pituitary gland in many species. Although it has many reported biological activities, prolactin's most noted effects pertain to mammary gland differentiation and promotion of lactation.

Characteristics

Pituitary Prolactin Secretion and Its Regulation

The pituitary gland is located at the base of the brain and is composed of two parts – anterior and posterior. The posterior pituitary is an extension of brain tissue from the ►hypothalamus and secretes hormones such as vasopressin, which are synthesized in the hypothalamus. The anterior pituitary arises from non-neural tissue and during embryology migrates to a position anterior to the posterior pituitary. The anterior pituitary is connected to the hypothalamus by a network of blood vessels that run with the neural "stalk" connecting the posterior pituitary to the hypothalamus. This hypophyseal-portal circulation bathes the anterior pituitary with hypothalamic factors that regulate secretion of a number of hormones; these anterior pituitary hormones include factors that control thyroid activity (TSH; thyroid stimulating hormone), adrenal gland activity (ACTH; adrenocorticotropic hormone), gonadal (ovarian or testicular) function (LH and FSH; leutinizing hormone and follicle stimulating hormone, respectively), and growth (GH; growth hormone). Additionally, prolactin is secreted by the lactotrophic cells of the anterior pituitary. ►Dopamine, produced in the hypothalamus and carried by the hypophyseal-portal circulation to the lactotrophs, inhibits the production of prolactin.

Prolactin Structure and Activation of Cellular Signaling

Human prolactin is secreted as a protein of 199 amino acids. Structurally, prolactin is comprised of four helical bundles with loops of varying length connecting these bundles. This general structure is similar to a large group of hormones and cytokines, including growth hormone, erythropoietin, leptin, and various interleukins and interferons. Prolactin interacts with the cell surface transmembrane prolactin receptor on target cells by virtue of two binding sites on prolactin that are formed three dimensionally by folding of the loops and bundles. Prolactin receptor binds prolactin in its extracellular domain and transmits signals to the inside of the cell by virtue of regulated interactions of the receptor intracellular domain with protein members of several signaling systems. The receptor encodes no enzymatic activity; rather, prolactin causes activation of the receptor-associated ►tyrosine kinase, ►JAK2 and thus stimulates pathways including the ►MAP kinase cascade and ►STAT (signal transducer and activator of transcription) 5 (►signal transducers and activators of transcription in oncogenesis; ►signal transduction). These pathways ultimately lead to changes in cellular behavior and expression of prolactin-specific genes related to prolactin's biological effects at breast and other target tissues.

Biological Effects of Prolactin

In mammals, prolactin's main effects relate to milk production. Prolactin stimulates mammary gland differentiation in pregnant females in concert with other hormones that are required for its optimal effects. Knockout studies in mice indicate that prolactin, via its receptor, exerts its role in mammary morphogenesis by regulating ductal side branching and terminal end bud regression and by directly causing lobuloalveolar development in pregnancy. Several milk protein genes are also regulated by prolactin. In humans, prolactin levels rise during pregnancy, thereby preparing the mammary gland for postpartum lactation. Initiation and maintenance of lactation are also dependent on prolactin and prolactin receptor. This function is also served by prolactin in some nonmammalian species; for example, nursing pigeons utilize prolactin to induce cropmilk in the cropsac.

In addition to its effects on mammary tissue, prolactin also affects the functions of other organs and systems. Gonadal functions are affected by prolactin both indirectly and directly. Prolactin elevation suppresses hypothalamic production of gonadotropin releasing hormone and thereby pituitary gonadotropin secretion, resulting in suppressed gonadal function. Although less profound than its reproductive functions, prolactin also exerts immunomodulatory, psychological, and osmoregulatory effects. In particular, modulation of water and electrolyte balance is an important effect in nonmammalian species such as fish and reptiles. Notably, secretion of prolactin from nonpituitary sites has become increasingly appreciated. Cell types known to produce prolactin include those found in reproductive tissue (gonads, uterus, prostate, and mammary gland itself), immune cells (B-cells, mononuclear cells, natural killer cells, and thymic epithelial cells), skin, kidney, and adrenal. The significance of this extrapituitary prolactin secretion is incompletely understood.

Disease States Related to Prolactin

Hyperprolactinemia and Prolactinoma

Normal levels of prolactin in adult humans vary and can be as high as 25 μg/l in nonpregnant females and 20 μg/l in males. As mentioned above, levels rise dramatically (roughly 10-fold) through normal pregnancy. Prolactin levels can be abnormally elevated (hyperprolactinemia) in a number of clinical circumstances. For example, certain medications

(e.g. antipsychotic agents, metoclopramide, and others) can cause hyperprolactinemia by virtue of reduction of dopamine delivery or antagonism to dopamine action at the lactotroph. Stress and chest wall stimulation can also raise prolactin, as can primary thyroid failure (by raising levels of hypothalamic thryotrophin releasing hormone, which can stimulate prolactin secretion by lactotrophs). These situations typically do not cause elevations of prolactin of sufficient magnitude to cause symptoms.

Greater degrees of hyperprolactinemia (usually more than 100 μg/l) may cause symptoms. In women, these include ►amenorrhea (with ►secondary hypogonadism), infertility, and ►galactorrhea. In men, the secondary hypogonadism of hyperprolactinemia manifests as impotence, decreased libido, and infertility. These greater degrees of hyperprolactinemia are typically caused by tumors at or in the region of the anterior pituitary/hypothalamus in the midline. Tumors that impinge upon the pituitary stalk (such as craniopharyngioma or non-lactotroph pituitary tumors) or infiltrative diseases that affect the stalk can cause hyperprolactinemia by inhibiting dopamine delivery to the lactotroph. Typically, the non-lactotrophic tumors (for example, growth hormone-, ACTH-, or non-secreting tumors) that cause this effect are non-malignant adenomas, but are large enough to exhibit suprasellar extension to the region of the stalk. By definition, these are usually macroadenomas (>1 cm in size) and they can be associated with symptoms related to the hypersecretion of the hormones originating from the tumor as well as symptoms of the intracranial mass and its extensions, such as headaches, visual field disturbance (from extension superiorly to the optic chiasm), and extraocular movement dysfunction (from extension laterally into the cavernous sinuses and impingement on the cranial nerves governing eye movement). In addition to these effects, growth hormone-secreting tumors may themselves cosecrete prolactin, suggesting somatotrophs (growth hormone-secreting cells) and lactotrophs may share common origins.

Lactotrophic tumors (prolactinomas) themselves account for the majority of pituitary tumors (roughly 40% of all pituitary adenomas) and have an estimated prevalence of 100/million population. The vast majority of prolactinomas are adenomas. Prior to the sixth decade of life, prolactinomas are much more common in women (roughly 10:1 female:male), but the distribution between the sexes is roughly equal thereafter. Most prolactinomas in women (therefore most prolactinomas in general) are microadenomas (<1 cm in size) and therefore do not themselves usually extend outside the ►sella turcica to cause mass effect symptoms. The same is not so in men, who often present with macroprolactinomas.

In distinction to other pituitary tumors that are primarily approached therapeutically with surgery or radiotherapy, prolactinomas are often treated medically with dopamine agonist drugs. These include bromocriptine and cabergoline, orally active ergot alkaloids that interact with dopamine receptors at the pituitary and elsewhere. Bromocriptine is shorter acting and typically administered more frequently than cabergoline, which is given only several times per week. Dopamine agonists are usually quite potent in reduction of hyperprolactinemia of both tumorous and nontumorous etiologies. Prolactinomas often also shrink in size in patients treated with these drugs. Surgery and radiotherapy are reserved as options for patients unresponsive to medical therapy, but are not typically as effective as dopamine agonist therapy.

Prolactin and Breast Cancer

While controversial, substantial literature suggests a role for prolactin, possibly via autocrine/paracrine effects, in human cancers, including ►breast cancer. Clinical trials with dopamine agonists to reduce circulating prolactin in women with breast cancer have not succeeded, yet epidemiologic data suggest increased serum prolactin levels correlate with breast cancer risk in postmenopausal women. Prolactin and its receptor are expressed in nearly all breast cancer samples and some studies reveal more prolactin receptor in cancerous tissue vs. normal surrounding tissue. Transgenic overexpression of prolactin results in mammary tumor formation and T47D human breast cancer xenografts in nude mice respond to PRL with increased tumor growth *in vivo*. This area of research is clearly important and may yield major insights into breast cancer biology and treatment. However, there is as yet no clear consensus on the role of prolactin in breast cancer etiology or behavior.

Proliferation

Definition

An increase in the number of cells as a result of cell growth and cell division. The expansion in numbers of a cell population.

►Sprouty

Proline

Definition

One of the common amino acids that is a single building block for peptides and proteins.

Promoter

Definition

A region upstream from a gene acting as a controlling element for the expression of that gene. It is bound by an RNA polymerase and determines the transcription start site. A constitutive promoter is permanently active in cells. A conditional or inducible promoter is only active when specific inducers (e.g. hormones) are present.

►Prostate-Specific Membrane Antigen (PSMA)

Promoter Hypermethylation

Definition

Transcriptional silencing of a gene via ►methylation of ►5′ CpG islands in a gene's ►promoter region. Promoter hypermethylation represents an epigenetic mechanism that can act as an alternative to mutations to disrupt tumor-suppressor gene function and can predispose to genetic alterations through the inactivation of DNA-repair genes.

►Epigenetic Gene Silencing

Promotion

Definition

In ►carcinogenesis, ►Tumor Promotion.

►Initiation and Promotion

β Propeller

Definition

A protein domain characterized by 4–8 blade-shaped beta sheets arranged toroidally around a central axis. Each sheet has four antiparallel β-strands.

►APAF-1 Signaling

Prophylactic Mastectomy

Definition

Removal of the non-diseased breast to reduce the risk of cancer.

►Oncoplastic Surgery

Prophylactic Vaccine Therapy

Definition

Is a form of active ►immunotherapy mediated predominantly by the humoral immune system, which causes the destruction of disease agents residing in the

body of the immunized host thereby preventing the onset of disease. Once stimulated, the immune system maintains surveillance against subsequent infection or disease development involving the targeted antigen. Prophylactic vaccines can limit the development of existing diseases as well as preventing their recurrence.

Proproteins

Definition

Are latent precursors that require proteolytic cleavage for the removal of the pro-part and for generating mature, functionally active, proteins.

2-Propylpentanoic Acid

►Valproic Acid

Prosome

Definition

►Proteasome

Prospective Study

Definition

Study type in which one or more groups (cohorts) of subjects who have not yet had the outcome event in question (e.g. cancer diagnosis) are identified and then followed forward in time. A study or clinical trial that looks forward in time, in which participants are identified and then followed over a period of time to find associations between certain factors and a particular outcome.

►Mutagen Sensitivity

Prostaglandins

Definition

Are a group of hormone-like molecules derived from arachidonic acid and mediate a wide range of physiological functions, such as control of blood pressure, contraction of smooth muscle, gastrointestinal function, pain, and inflammation. The prostaglandins together with the thromboxanes form the prostanoid class of fatty acid derivatives. ►Cyclooxygenases are responsible for prostanoid formation. The prostanoid class is a subclass of ►eicosanoids.

►Anti-Inflammatory Drugs
►Arachidonic Acid Pathway

Prostaglandins

Ido Wolf
Institute of Oncology, The Chaim Sheba Medical Center and The Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel

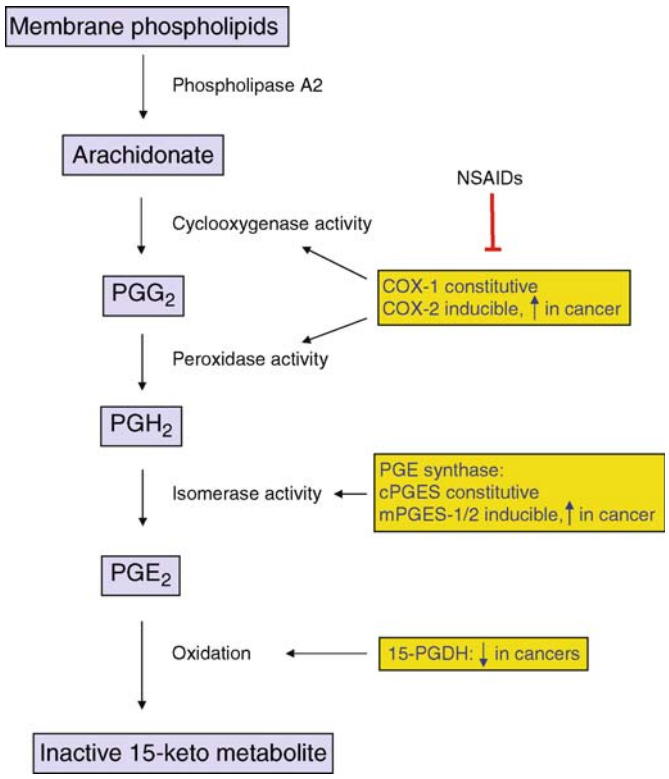
Definition

Prostaglandins are lipid compounds, which are synthesized from arachidonic acid. They are expressed in most tissues and participate in a wide array of physiologic activities, but are also involved in the pathogenesis of various malignancies. Prostaglandins levels are regulated by the balance between their metabolism, which is mainly regulated by the ►cyclooxigenase (COX) enzyme, and their degradation, which is mainly regulated by the activity of the enzyme 15-hydroxyprostaglandine dehydrogenase (15-PGDH). Following their synthesis, the prostaglandins interact with specific ►G protein coupled receptors and activate signaling pathways.

Characteristics

Biosynthesis

The first step in prostaglandin synthesis is the hydrolysis of ►arachidonic acid, by the enzyme ►phospholipase A2, from cell membrane phospholipids and the formation of free arachidonate (Fig. 1). The next two steps of prostaglandins synthesis are mediated by the COX enzymes. The cyclooxygenase activity of COX mediates the insertion of oxygen to arachidonate and the formation of prostaglandin G_2 (PGG_2), which in turn is



Prostaglandins. Figure 1 Schematic representation of PGE_2 biosynthesis.

converted to prostaglandin H_2 (PGH_2) by the peroxidase activity of COX. These COX activities are considered to be the main regulatory steps in prostaglandin synthesis. The final step of prostaglandins synthesis is the isomerization of PGH_2 into various prostaglandins, such as prostacyclin and thromboxane. This process is mediated by specific prostaglandin synthases. For example, the conversion of PGH_2 to prostaglandin E_2 (PGE_2), the major prostaglandin implicated in carcinogenesis, is mediated by PGE synthase. The prostaglandins, prostacyclin and thromboxane, are rapidly metabolized by initial oxidation into nonactive 15-keto metabolites. The first and rate-limiting step in this inactivation process is mediated by the enzyme 15-PGDH.

Regulation of Prostaglandins Synthesis and Degradation

Prostaglandin levels are determined by the balance between the expression of the rate limiting enzymes involved in their synthesis (COX) and in their degradation (15-PDGH). Two COX isoforms are currently known: COX-1 and COX-2. COX-1 is constitutively expressed in most tissues and mediates various physiologic activities, including platelets aggregation, protection of gastric mucosa, and regulation of renal blood flow. On the other hand, COX-2 is an inducible enzyme, which is undetectable in most normal tissues but is expressed in activated ►macrophages, as well as in other cells, in response to ►inflammatory cytokines, (includes tumor necrosis factor α (TNF α) and ►interleukin 1β (IL-1β)), hormones, and growth factors. The COX enzymes are the targets of the ►nonsteroidal anti-inflammatory drugs (NSAIDs). While some of these drugs inhibit both COX-1 and COX-2, others can selectively inhibit the inducible COX-2. PG synthases may also play a regulatory role in prostaglandins synthesis. For example, three PGE synthases are currently known, and while one of them, cytosolic PGE synthase (cPGES) is not inducible and is associated with COX-1 activities, another, microsomal PGE synthase-1 (mPGES-1), is inducible in response to inflammatory cytokines and mitogenic stimuli and is coupled to COX-2 activity. 15-PGDH, is a major regulator of prostaglandins levels and, similar to COX, its levels can be regulated by various stimuli, often in the opposite direction to that of COX. For example, TNF α and IL-1β simultaneously decrease 15-PGDH levels and increase COX-2 levels.

Prostaglandin Signaling Pathway

The prostaglandins have a relatively short half-life and are thought to act over short distances in either an autocrine (the same cell) or paracrine (adjacent cells)

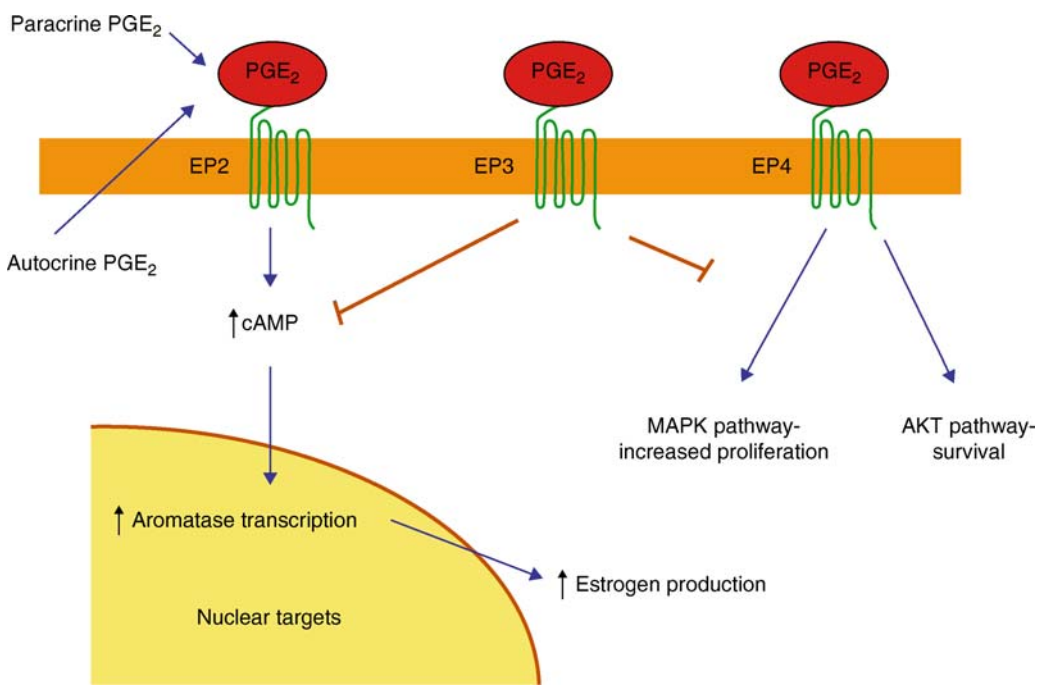
manner. Prostaglandin signaling is initiated by their binding to specific receptors, which belong to the family of seven transmembrane G protein coupled receptors. These receptors are designated according to their ligand. Thus, EP is the PGE_2 receptor and TP is the thromboxane (TXA_2) receptor. Four PGE_2 receptors, EP1, 2, 3, and 4, are currently known and differ in their downstream targets. EP1 signaling is associated with phospholipase C/inositol triphosphate pathway and elevation of intracellular calcium, EP2 and EP4 activity is associated increased cyclic AMP (cAMP), and EP3 is considered to be inhibitory and its activity is associated with decreased cAMP levels. Several downstream targets of EP activity have been identified and include the ►mitogen activated protein kinase (MAPK), ►AKT, and the ►PI3K/β-catenin pathways. A schematic representation of some of the EP activities is shown in Fig. 2.

Prostaglandin Signaling Pathway in Cancer

While early studies focused on prostaglandin levels in tumors, the cloning of the COX-1 and COX-2 enzymes during the late 1980s have shifted the interest to studies regarding their expression and activity in tumors. Recent studies investigated the role of additional components of the prostaglandin pathway (e.g., 15-PGDH, the EP receptors) in carcinogenesis.

The major prostaglandin implicated in tumorigenesis is PGE_2, which is synthesized either by the tumor or by adjacent cells. Elevated PGE_2 levels were identified in various tumors, including ►colon and ►breast cancers. PGE_2 upregulation is associated with a vast array of promalignant activities. Several signaling pathway mechanisms can be activated by PGE_2 in cancer. For example, in colorectal cancer the PGE_2 pathway can interact with the ►epidermal growth factor (EGF) pathway and activate the EGF receptor, thus leading to activation of its downstream targets, the MAPK and the AKT pathway. Activation of these pathways increases proliferation and ►invasion, inhibits ►apoptosis and promotes ►angiogenesis. In breast cancer, PGE_2 has also been shown to induce expression of tumor aromatase, which catalyzes estrogen synthesis, thus leading to upregulation of estrogen levels. As PGE_2 is a small molecule, which is rapidly metabolized, measuring its level in tumors is complicated and is not done routinely.

Ample data implicate COX-2 in carcinogenesis. COX-2 levels can be evaluated relatively easily in tumors, using either immunohistochemical staining or mRNA measurements by PCR and, importantly, COX-2 levels in tumors often correlate with PGE_2 levels. Increased amounts of COX-2 are commonly found in premalignant, as well as malignant tumors, including colorectal polyps and cancer, ►ductal carcinoma in situ and breast cancer, ►glioblastoma, ►endometrial cancer, and ►prostate cancer. Several mouse models further support the major role of COX-2



Prostaglandins. Figure 2 Schematic representation of various PGE_2 downstream pathways.

in tumor development. For example, COX-2 expression in the mammary gland was sufficient to induce cancer, while COX-2 knock-down in a mouse model of familial adenomatous polyposis reduced the number of polyps. Laboratory studies revealed that COX-2 inhibition by NSAIDs slows the growth of various cancer cells, and prevent cancer development both in vitro and in vivo. Finally, epidemiological data, as well as controlled trials, demonstrated the ability of NSAIDs, and especially of selective COX-2 inhibitors, to prevent the formation of colorectal adenomas. However, recent concerns regarding the safety of COX-2 inhibitors and the association between their use and increased incidence of cardiovascular events reduced the enthusiasm for their use as chemopreventive agents.

EP expression pattern and activities in cancer is complex and despite their pivotal role in the prostaglandin signaling, data regarding their function in carcinogenesis is limited. Different cancer models suggest a tumor promoting role for EP1, EP2, and EP4, but a tumor suppressor role for EP3. For example, in breast cancer EP1 and EP2 induce, while EP3 inhibits aromatase expression; and in different colon cancer models EP1, EP2, or EP4 has been associated with carcinogenesis. Higher EP1, EP2, and EP4 expression was noted in prostate cancer compared to normal prostate tissue, and EP1 expression was also associated with more aggressive tumor features. As the EP isoforms show specific activities and may have unique expression pattern in tumors, their targeted inhibition may serve as a novel therapeutic modality for malignant diseases. Several specific inhibitors of the EP isoforms have been developed and are now being tested in preclinical studies.

mPGES-1, the inducible isoform of PGES, has also been implicated in tumorigenesis. In several cancer models, high mPGES-1 expression was associated with increased PGE_2 levels. Moreover, high mPGES-1 levels were noted in colon, breast, lung, and ovarian cancers; and in some of these tumors were associated with more aggressive features. Laboratory data suggest that mPGES-1 inhibition downregulates PGE_2 levels and may be associated with growth inhibition. Thus, mPGES-1 may be a selective target for blocking the PGE_2 pathway. No selective mPGES-1 inhibitors are currently available.

Recent data indicate 15-PGDH, the key PGE_2 catabolic enzyme, as a tumor suppressor gene in various malignancies, including colorectal, breast, and lung cancers. Low 15-PGDH levels were identified in these tumors and upregulation of its levels in cancer cells reduced PGE_2 levels and inhibited their growth. Moreover, low 15-PGDH expression may also be associated with adverse prognostic factors. DNA methylation of the 15-PGDH promoter may play a role in its silencing in cancer.

Definition

Prostate cancer is a malignant neoplasm that arises in the male prostate gland. Most prostate cancers are adenocarcinomas (95%). About 4% have transitional cell morphology and are thought to arise from the lining of the prostatic urethra. Few have neuroendocrine morphology and are believed to arise from the neuroendocrine stem cells normally present in the prostate or from aberrant differentiation programs during cell transformation. Of the adenocarcinomas, 70% arise in the peripheral zone, 15–20% in the central

zone and 10–15% in the transition zone. These zones can sometimes be identified by transrectal ultrasonography (TRUS). Most adenocarcinomas are multifocal with synchronous involvement of multiple zones of the prostate and this may be due to clonal tumors that have spread intraprostatically or and mutiple tumor initation sites intraprostatically. In addition, multifocality may indicate a more aggressive tumor biology. The most commonly used system of classifying histiologic characteristics of prostate adenocarcinomas is the Gleason score, which is determined by the glandular architecture within the tumor at low magnification.

The predominant pattern, as well as the second most common pattern is given a grade from 1 to 5 (less malignant to more malignant). Grades are based on the extent to which the epithelium assumes a normal glandular structure. Grade 1 indicates a near normal pattern and grade 5 the absence of any glandular pattern. The sum of these two grades is referred to as the Gleason score. This scoring method was found to be superior in predicting disease outcomes when compared to using the individual grades alone. A score of 2–4 is considered low grade, 5–7 is considered moderate grade and 8–10 is considered high grade. A Gleason grade 7 can consist of 3 + 4 or 4 + 3 disease; however, a predominat grade 4 pattern tumor has a significantly worse prognosis than a predominant grade 3 pattern. High grade prostatic intraepithelial neoplasia (PIN) represents the putative precancerous end of the morphologic continum of cellular proliferations within prostatic ducts, ductules and acini. Two grades of PIN are identified (low grade and high grade), and high grade PIN may be a precursor to invasive adenocarcinoma. The continum which culminates in high grade PIN and early invasive cancer is characterized by basal cell layer disruption, basement membrane disruption, progressive loss of secretory differentiation markers, increasing nuclear and nucleolar abnormalities, increasing proliferative potential and increasing variation in DNA content (aneuploidy). Clinical studies suggest that PIN may predate carcinoma by up to 10 years or more; however, PIN need not be present for carcinoma to arise. The clinical importance of recognizing PIN is based on its strong association with carcinoma and hence its identification in prostate biopsy specimens warrants further search for concurrent invasive carcinoma. In patients with high grade PIN, the risk of cancer on subsequent biopsy is 30%. Low grade PIN should not be commented on in diagnostic pathology reports because of variability distinguishing low grade PIN and benign prostate tissue and patients diagnosed with low grade PIN on needle biopsy are at no greater risk of having carcinoma on repeated biopsy that are men with a benign biopsy finding. Atypical small acinar proliferation (ASAP) represents findings suggestive of but not diagnostic of carcinoma. The incidence of atypical needle biopsy specimens ranges from 5% to 8% and may be termed "atypical hyperplasia" or "atypical small acinar proliferation." The risk of cancer on subsequent biopsy after atypical diagnosis is 42–49%, therefore, all patients with an initial atypical diagnosis on needle biopsy should all undergo a repeat biopsy.

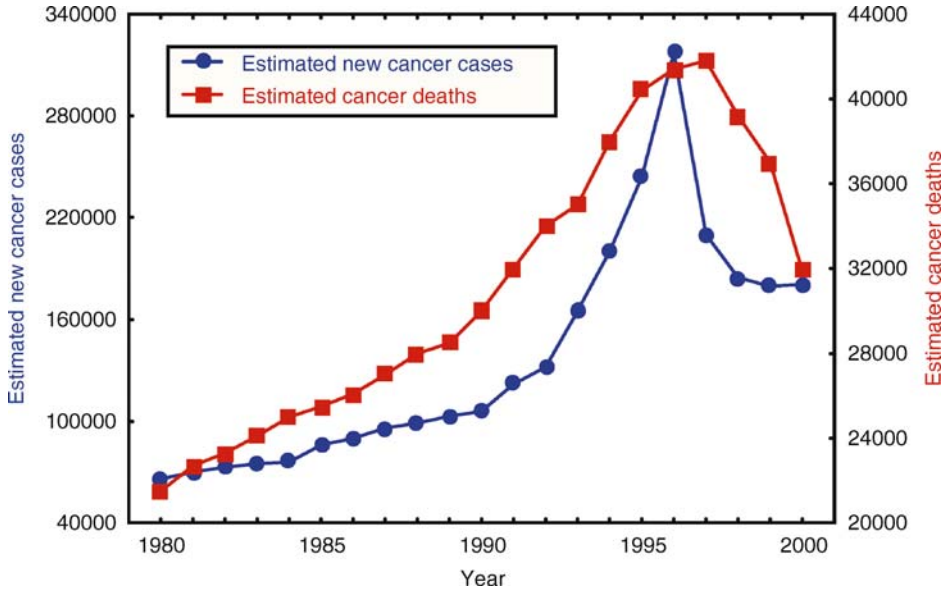
Characteristics

Clinical Epidemiology and Risk Factors

Prostate cancer is the fourth most common male malignant neoplasm worldwide. In the United States, prostate cancer incidence rates remain significantly higher in African American men than in Caucasian men. Age adjusted prostate cancer specific mortality is 2.4 times higher for African Americans than for Caucasians. Between 1989 and 1992 prostate cancer incidence rates increased dramatically, due to earlier diagnosis in men without any symptoms through the increased use of the ►prostate-specific antigen (PSA) blood test. Prostate cancer incidence rates are currently declining among all men. During 1992–1996, prostate cancer mortality rates declined significantly by 2.5% per year (Fig. 1). Prostate cancer's potential long natural clinical history is reflected in tumors found during autopsies carried out following other causes of death. The incidence of latent or autopsy cancer is much greater than cases of clinical cancer. It may reach up to 80% by age 80. Interestingly, incidence of the latent form of the disease is similar worldwide, while the incidence of clinical cancer is high in northern Europe and North America, intermediate in southern Europe, Central and South America and low in eastern Europe and Asia. In addition to changes in prostate cancer incidence and mortality since the incorporation of the PSA serum test into routine clinical practice, there has been a significant shift to more favorable stage at presentation in men with newly diagnosed prostate cancer. Nonpalpable cancers diagnosed exclusively through elevated PSA and subsequent ultrasound-guided biopsy now account for 75% of new cases. The effective treatment of prostate cancer and biologic indolence relative to life expectancy of some prostate cancers has contributed to an overall disease specific mortality of only 16%. However, given the long natural history of prostate cancer, the treatment of low stage cancers detected during the PSA era may have an effect on mortality statistics for 10 to 15 years, if ever. The Prostate, Lung, Colorectal, and Ovary (PLCO) cancer trial and the European Randomized Screening for Prostate Cancer (ERSPC) trial are two ongoing large-scale randomized trials that are designed to evaluate the effectiveness of screening for prostate cancer.

Etiology

Genetics and environment have been implicated as etiologic factors in the origin and evolution of prostate



Prostate Cancer, Clinical Oncology. Figure 1. New cancer cases and deaths in the United States of America. Data compiled from 'Cancer Statistics' issues 1980–2000 (published by the American Cancer Society).

cancer. Alteration of genes on chromosome 1 and on the X chromosome have been found in many patients with a family history of prostate cancer. In addition, genetic studies suggest that strong familial or hereditary predisposition may be responsible for up to 15% of prostate cancers. The relative risk of prostate cancer increases according to the number of affected family members and the age at which they were affected. In the US, African Americans have a higher incidence of the cancer when compared to Caucasian men, which in turn have a higher incidence than men of Asian origin. Whether tumor aggressiveness is higher in African American men is unclear. A high fat diet may lead to increased risks while a diet rich in soy protein may be protective and may account for the low incidence of clinical forms of this cancer in Asia. Hormonal causes have also been postulated since androgen influences development and maturation of the prostate and ablation causes regression of prostate cancers. Recent evidence suggests a link with an infectious agent and multiple studies have reported a significant association of prostate cancer with a history of sexually transmitted infection (Fig. 2).

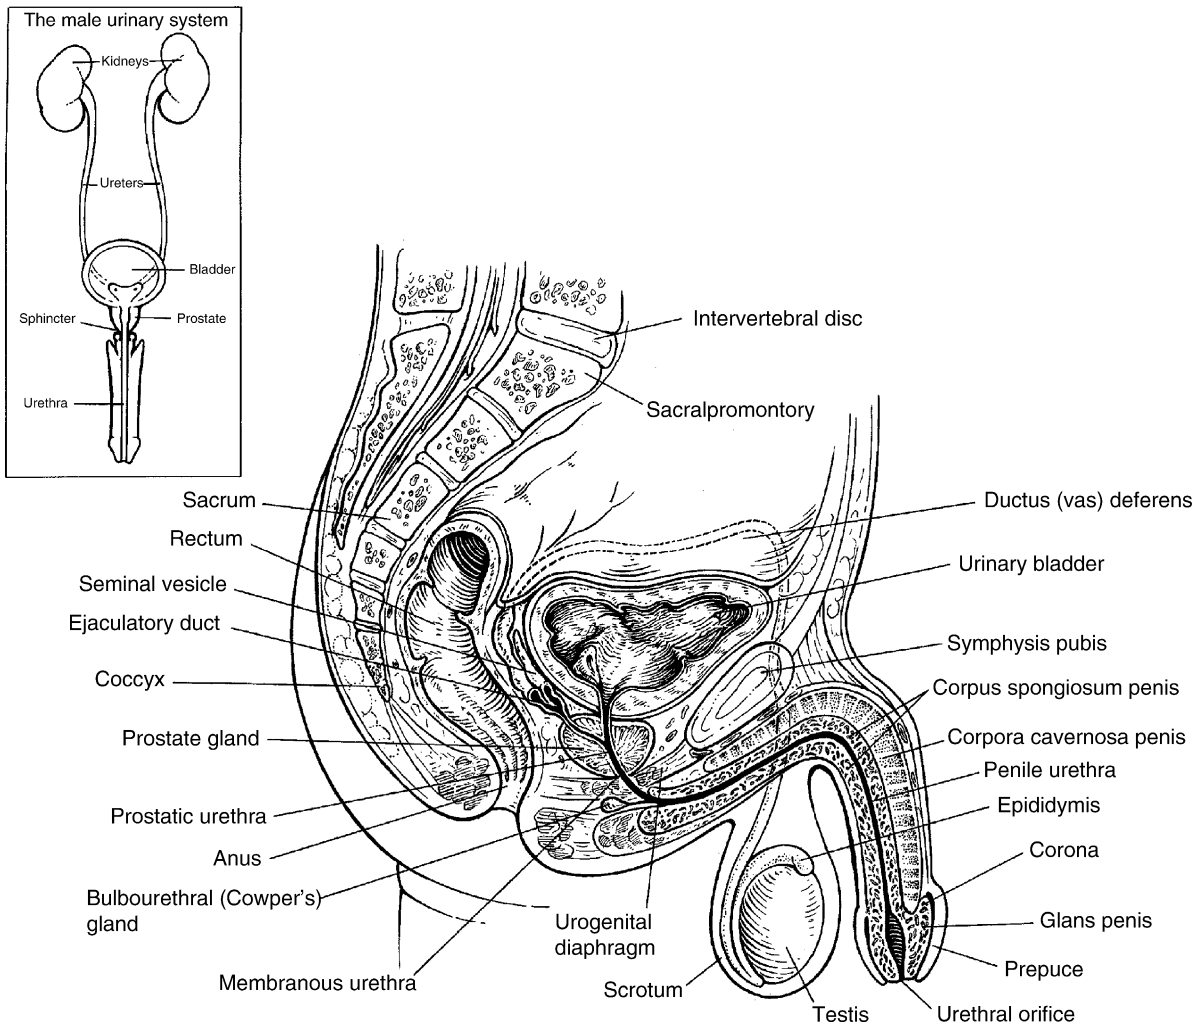
Tumor Biology and Genetics

Genetic alterations in the ►tumor suppressor genes RB1 and ►TP53 are associated with advanced metastatic or hormone refractory prostate cancer. In addition, alterations in the oncogenes ►MYC, ERBB2, and BCL2 have also been observed in advanced prostate cancer. Lack of expression of glutathione S-transferase, a protective enzyme against reactive oxygen species, and ►E-cadherin, a cell adhesion molecule, are correlated with cancer progression. Loss of p27 expression, a cell cycle regulatory inhibitor, is associated with an increased risk of biochemical failure following radical prostatectomy. Loss of PTEN, a tumor suppressor gene, is seen in advanced cancers. Vascular endothelial growth factor (VEGF), a mediator of tumor ►angiogenesis, has increased expression in metastatic tumors.

Clinical Presentation

Incidental/Screening findings:

- Elevated prostate specific antigen (PSA). The PSA threshold for that most efficiently lead to the detection of life-threatening cancer while avoiding unnecessary testing and over diagnosis is not known, but 4.0 ng/ml for men older than 50 years has been accepted by most clinicians. In addition, PSA velocity of more than 0.75 ng/ml per year is positively associated with the risk of prostate cancer over a 7 year period for men with PSA < 4.0 ng/ml. In men with a serum PSA between 4 and 10 ng/ml, using criteria of free PSA less than 25% would lead to a detection of 95% of cancers while avoiding 20% of unnecessary biopsies.
- Tissue removed at the time of transurethral resection for benign hypertrophy of the prostate (BPH).
- Abnormal digital rectal examination (DRE).
- The combination of DRE and serum PSA is the most useful first line test for assessing risk of prostate



Prostate Cancer, Clinical Oncology. Figure 2 Anatomy of the male genitourinary system.

cancer and is generally recommended for screening of populations.

Local findings:

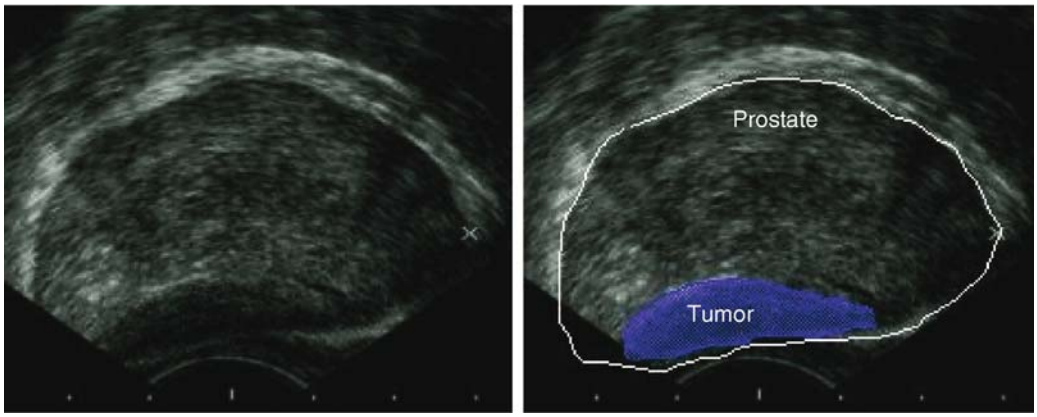
- Hematuria.
- Incontinence.
- Urinary retention due to bladder outlet obstruction with associated hydronephrosis and renal failure.

Metastatic findings:

- Weight loss and loss of appetite.
- Bone pain with or without pathologic fracture.
- Lower extremity pain and edema from nodal metastasis obstructing venous and lymphatic tributaries.
- Uremic symptoms from ureteral obstruction either due to local prostate growth or retroperitoneal adenopathy secondary to nodal metastasis.
- Neurological compromise from bony metastases to spine.
- Following in frequency after lymph nodes, bones, and lung, the next most common regions for metastatic spread include bladder, liver, and adrenal gland.

Diagnosis and Staging

Transrectal ultrasound (TRUS) is used to examine the prostate (Fig. 3) and is usually carried out in the office setting. Historically, it was believed that all cancers appear as hypoechoic (low echoes on the ultrasound, compared to normal prostate). However, more recent data indicates that such areas, even when found are not specific enough for diagnostic purposes. Therefore, a systematic approach to prostate biopsy was developed to sample most areas of the gland, irrespective of ultrasonographic abnormalities. In this approach,



Prostate Cancer, Clinical Oncology. Figure 3 Transrectal ultrasound of the prostate.

TRUS is used to guide the performance of 8–13 core needle biopsies of the prostate. The biopsies are taken from the peripheral zone and transition zone and directed laterally from the base and mid-gland bilaterally. Recently, several groups have shown extensive systematic biopsies, called "saturation biopsy," incorporating on average 22 cores improve cancer detection, especially in the setting of repeat biopsies in select patients with high suspicion of cancer. However, saturation biopsy requires local, regional or general anesthetic. In addition, the clinical signficance of these additionally detected tumors is unknown. Complications of TRUS guided biopsy include, hematospermia (9–50%), urinary tract infection (2%), and acute urinary retention (0.7%). Currently, advanced ultrasonographic techniques, including color and power Doppler TRUS using vascular contrast agents are being evaluated to selectively visualize prostate cancers based on the presence of increased tumor angiogenesis.

Once a cancer is found a staging work-up is undertaken. It includes:

- Laboratory work-up: determination of PSA (prostate specific antigen) level if not already done.
- Imaging work-up: Work-up depends on the clinical staging.

Clinical stage of primary lesion, as determined by DRE (digital rectal examination), PSA level and Gleason score of the primary lesion, as determined by TRUS guided biopsy. For example, increased clinical stage of the primary, PSA level >10 and Gleason score >7 are correlated with increased risk of extra-prostatic spread and are considered to be the key factors in determining the need for staging work-up. PSA levels <10 with low or moderate grade histology with no findings on DRE exam may proceed on to treatment. PSA levels >10 with high grade histology or DRE findings suggesting stage T3 disease should undergo staging CT scan and bone scan (Fig. 5). MRI is superior to bone scan in evaluating bone metastasis, but is so far relatively impractical for routine total body surveys. Instead it is used to determine the etiology of questionable lesions found on bone scan. Use of MRI to stage or determine the location of the local lesion is controversial. Prostate specific membrane antigen (PMSA) immunoscintigraphy with the indium-labeled immune conjugate CYT-356 (ProstaScintTM) has also been used for the detection of prostate cancer metastases, especially to the lymph nodes. The 1997 UICC/AJC TNM staging system is most commonly used (Table 1).

Management

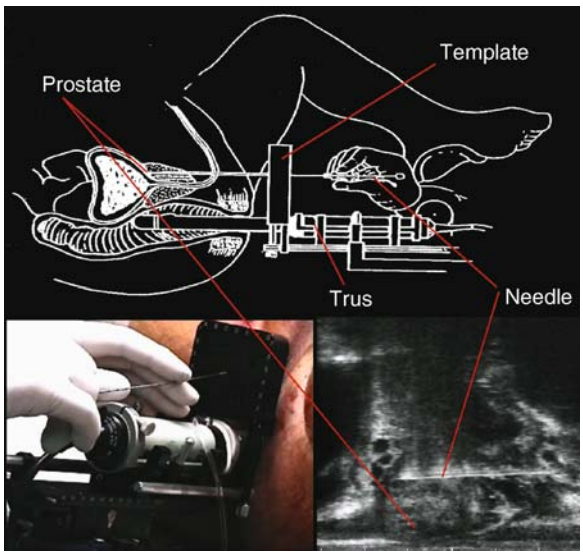
The stratification of patients to particular treatments is based on the evaluation of the patients life expectancy and the biological aggressiveness of the tumor. The biopsy grade, clinical stage PSA level and, when available, the results of imaging studies can provide such prognostic information. Treatments such as active surveillance, hormonal therapies and potentially curative therapies such as radiation and surgery are available. Treatment selection also requires a thorough analysis of the risks and benefits of each option by the patient, enabling him to have input on the therapy selection.

1. Early localized disease (T1-2N0M0): A multitude of treatment modalities are available that include active surveillance, watchful waiting, radiation therapy, and surgery.
   (a) Active surveillance is a program of regular examinations and PSA and DRE monitoring to distinguish clinically insignificant cancers from life-threatening cancers with intent to administer curative therapy. Watchful waiting is defined as delaying active treatment until patient develops symptomatic disease progression in order to limit morbidity from the disease and therapy without the goal to administer curative treatment.

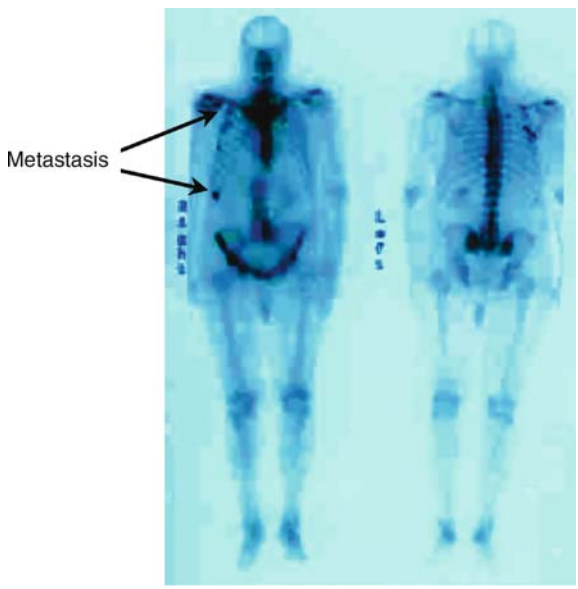
Advanced age, significant comorbidities are indications for watchful waiting. A prospective, randomized clinical trial reported that patients with clinically localized prostate cancer managed with watchful waiting have significantly higher rates of local cancer progression, metastases, and death from prostate cancer than do those treated initially with radical prostatectomy.

(b) External beam radiation treatment used with curative intent. Modalities include conventional external beam, conformal/IMRT external beam and ▶brachytherapy (Fig. 4). Randomized trials have found total androgen ablation should be combined with radiation for improved disease specific survival and increased time to recurrence in locally advanced cases. Complications from radiation include cystitis, proctitis, enteritis, impotence and urinary incontinence. Prostate cancer specific mortality can be estimated on the basis of pretreatment serum PSA, biopsy Gleason score, and clinical T category. The percentage of positive biopsies is an independent predictor of time to postoperative PSA failure after external beam radiotherapy. Nomograms have been developed that have excellent predictors for PSA failure after radiotherapy.

(c) Radical prostatectomy is removal of the prostate and seminal vesicles and pelvic lymphadenectomy. For low stage, low PSA, well-differentiated tumors the lymph node dissection may be omitted. There are currently three approaches used to remove the prostate gland: the retropubic, perineal and laparoscopic or robotic assisted retropubic approach. Laparoscopic and robotic-assisted prostatectomy are generally associated with decreased blood loss compared to the open technique. The following patient criteria are commonly used guidelines for patients to be candidates for radical prostatectomy regardless of the approach; age less than 70 years, few comorbidities, life expectancy >10 years, Gleason score $\leq$7 and PSA $\leq$10. Complications include impotence, incontinence and urethral stricture. Modifications to the classic technique to spare the neurovascular bundles has allowed improved potency and continence outcomes. Most recently, a study found that men whose PSA level increases by more than 2.0 ng/mL/year before the diagnosis of prostate cancer have an increased risk for death from prostate cancer despite undergoing radical prostatectomy. Important pathologic criteria that predict prognosis after radical prostatectomy are tumor grade, surgical margin status, presence of extracapsular disease, seminal vesicle invasion, and pelvic lymph node involvement. Nomograms have been developed that have excellent predictors for PSA failure after prostatectomy as well as adverse pathological outcomes if these tools are used pre-operatively.



Prostate Cancer, Clinical Oncology. Figure 4 Prostate brachytherapy.



Prostate Cancer, Clinical Oncology. Figure 5 Staging bone scan.

2. Locally advanced disease (T3-4N0M0): Active surveillance is an option in highly selected patients but failures usually result due to relative aggressive nature of these tumors. Radiation options as for early disease. The most common approach is external beam radiotherapy combined with androgen deprivation. If brachytherapy is used, it is often combined with external beam and androgen deprivation and

Prostate Cancer, Clinical Oncology. Table 1 The 1997 UICC/AJC TNM staging system

UICC/AJC 1997	Description
T1a	Tumor incidental histologic finding in 5% or less of tissue resected and Gleason < 7
T1b	Tumor incidental histologic finding in more than 5% of tissue resected or Gleason ≥ 7
T1c	Tumor identified by needle biopsy due to elevation of PSA; tumors found in one or both lobes by needle biopsy, but not palpable or visible by imaging
T2a	Tumor involves 1 lobe or less
T2b	Tumor involves more than 1 lobe
T3a	Unilateral extracapsular extension
T3b	Bilateral extracapsular extension
T3c	Tumor invades seminal vesicle(s)
T4a	Tumor invades bladder neck, external sphincter, and/or rectum
T4b	Tumor invades levator muscle and/or fixed to pelvic wall
N(+)	Involvement of regional lymph nodes
M(+)	Distant metastatic spread

patients receiving such multimodality radiation therapy display superior biochemical relapse free survival compared with those receiving surgery or brachytherapy alone. Surgery is usually not an option outside clinical trials and ►neoadjuvent androgen deprivation therapy before radical prostatectomy does not appear to improve cancer-specific (PSA free) or overall survival.

3. Hormonally naïve metastatic disease: Radiation therapy as described above for patients with nodal only disease. When this is accompanied by long term androgen deprivation, up to 30% of patients may have a long terms disease free interval. In patients with metastatic disease to bone, medical (►LHRH agonists ± anti-androgens) or surgical (bilateral orchiectomy) androgen ablation is the treatment of choice. Androgen ablation is associated with sexual dysfunction, osteoporosis, hot flashes, and cognitive function alterations. Serious liver toxicity is a possible side effect of all anti-androgens. Radiation therapy is used to palliate symptoms such as bone pain from metastatic deposits and neurologic symptoms secondary brain metastases or emergently in the setting of spinal cord compression (Fig. 5). Laminectomy or other orthopedic procedures can be used for pathologic fractures in the setting of bone metastases.
4. Hormonally refractory metastatic disease: Androgen ablation therapy can induce a prolonged response (several years) in most men with metastatic disease. However, in most patients the disease becomes 'androgen independent' and begins to grow despite androgen withdrawal. At this time, hormone-refractory prostate cancer is not curable. All the available forms of therapy are palliative, which means that they can be used only to slow the progression of the disease and to relieve symptoms.

Generally, for the patient who begins to fail hormonal therapy and has received combined hormonal therapy with an LHRH agonist and an antiandrogen or with an orchiectomy and an antiandrogen, antiandrogen withdrawal (stopping the antiandrogen) is undertaken. In many patients this will result in a short term decrease in serum PSA level. For patients who received LHRH agonist alone or orchiectomy alone, secondary forms of hormonal therapy may be considered, such as the addition of an antiandrogen or suppression of adrenal androgen synthesis. However, these clinical therapies are generally of limited benefit. Radiation therapy is used to help manage pain associated with the growth of bone metastases and this can be delivered via external beam therapy or osteomimetic radioisotopes (strontium-89 radionuclide) which tend to be absorbed into areas of bone remodeling such as is found in bone metastases. ►Docetaxel (Taxotere) is a cytotoxic agent and induces apoptosis of cancer cells and has become the standard treatment for hormone refractory prostate cancer. Large phase III randomized trials have demonstrated docetaxel prolongs progression free and overall survival, improves pain, and improves quality of life. Newer experimental approaches such as ►bisphosphonates, immunotherapeutics/vaccines, differentiation therapies, induction of ►apoptosis and inhibition of angiogenesis are currently in clinical trials.

Prostate-Specific Membrane Antigen

Synonyms

Glutamate carboxypeptidase II; NAALADase; folate hydrolase; PSMA

Definition

Prostate-specific membrane antigen (EC 3.4.17.21), is a 750 amino acid, 100 kDa type II transmembrane glycoprotein that is highly expressed by normal prostate and ►prostate cancer cells and by the neovasculature of many epithelial cancers. Due to this relative cancer restricted expression, PSMA-based imaging agents and PSMA-targeted therapies are under development.

Characteristics

PSMA Expression

PSMA is a type II transmembrane protein consisting of a small intracellular segment of 18 amino acids, a transmembrane domain, and an extensive extracellular domain that contains the catalytic site (Fig. 1). The extracellular domain of PSMA is highly glycosylated and ►glycosylation is required for enzymatic activity. Human PSMA was originally isolated by the laboratory of Dr. Warren Heston from a cDNA library from the androgen responsive LNCaP human prostate cancer cell line and was later found to be located on chromosome 11p11–12. The entire sequence of PSMA contains 19 exons and has a modest degree of homology to at least four other human proteins: NLDL, NLD2, transferrin receptor (TfR) 1 and 2. Both TfR1 and PSMA are internalized into endosomes via cytoplasmic YXRF and MXXXL motifs, respectively. Whereas TfR1 delivers iron-loaded transferrin cells, it is currently not known whether PSMA may internalize ligands such as polyglutamated folate (a PSMA substrate).

Immunohistochemical studies using monoclonal antibodies have demonstrated that PSMA is expressed by normal prostate epithelium and is even more highly expressed by a large proportion of prostate cancers, including metastatic prostate cancers. Low-level detection of the PSMA protein has also been seen in the duodenal mucosa and in a subset of proximal renal tubules. PSMA enzymatic activity is also present in the brain. In all other human tissues, including normal vascular endothelium, PSMA expression was not detectable by ►immunohistochemistry. The number of PSMA molecules per 10,000 actin molecules in prostate tissue is approximately 170, which is approximately 10–15-fold higher than expression in liver, kidney, and brain. As a comparison, the ratio of PSA per 10,000 actin molecules is 18,000.

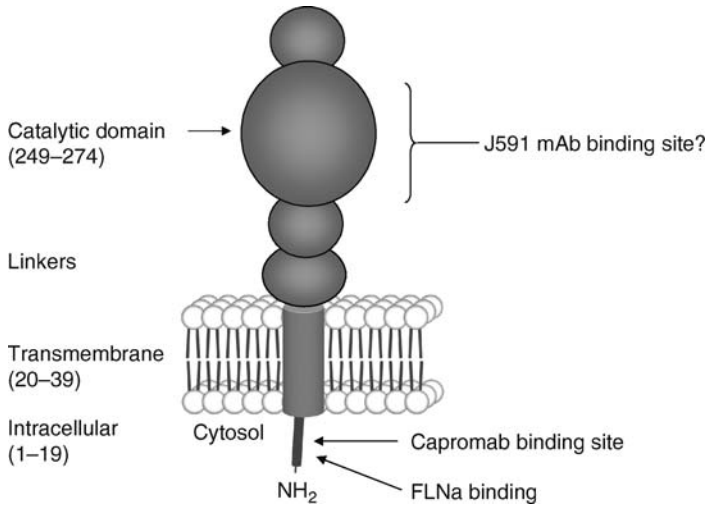
PSMA expression was also undetectable in other nonprostatic primary tumors. In multiple studies, however, PSMA expression has been detected in the neovasculature of a large number of different tumor types including breast, renal, colon, and transitional cell carcinomas. In contrast, PSMA expression was not observed in nontumor induced neovascularization associated with choroidal neovascular membrane development.

Two regulatory elements controlling PSMA expression have been characterized: the proximal 1.2 kb PSMA promoter and a PSMA enhancer located within the third intron. This PSMA enhancer is activated in a prostate specific manner and is negatively regulated by the ►androgen receptor. This negatively regulated enhancer seems to underlie findings from preclinical and clinical studies demonstrating that PSMA mRNA is upregulated upon androgen withdrawal.

The PSMA structure revealed a twofold symmetric homodimer with overall structural similarity to the transferrin receptor. Unlike the transferrin receptor, PSMA possesses an enzymatically active protease domain containing a binuclear zinc site, catalytic residues, and a proposed substrate-binding arginine patch.

Enzymatic Functions of PSMA

In addition to its role as a tumor marker and imaging target, PSMA contains a binuclear zinc site and functions as a glutamate carboxypeptidase II possessing two discrete enzymatic functions. Initially, PSMA was demonstrated to possess the hydrolytic properties of an *N*-acetylated α-linked acidic dipeptidase (NAALADase). NAALADase is a membrane hydrolase activity that is able to hydrolyze the neuropeptide *N*-acetyl-*l*-aspartyl-*l*-glutamate (NAAG) to yield the neurotransmitter glutamate and *N*-acetyl-aspartate. In addition to the NAALADase activity, PSMA also functions as a pteroyl poly-γ-glutamyl carboxypeptidase (folate hydrolase). It is able to progressively hydrolyze γ-glutamyl linkages of both poly-γ-glutamated folates and methotrexate analogs with varying length glutamate chains. Mhaka et al. demonstrated that PSMA could also hydrolyze peptides containing both α- and γ-linked acidic amino



Prostate-Specific Membrane Antigen. Figure 1 Structure of PSMA with Filamin A (FLNa), J591, and Capromab monoclonal antibody binding sites indicated.

acids. This finding has implications for exploiting the enzymatic activity of PSMA for the design of prodrugs, in which an inactive aspartyl/glutamyl peptide is selectively cleaved from the prodrug by PSMA thereby activating the drug within the vicinity of PSMA expressing cells.

The role that PSMA's NAAG or folate hydrolase activity plays in the physiology of prostate cells is presently unknown. NAAG is an inhibitor of the NMDA ionotropic receptor and an agonist of the type II metabotropic glutamate receptor subtype 3. A breakdown of the regulation of glutamatergic neurotransmission by -NAAG is implicated in schizophrenia, seizure disorders, Alzheimer's disease, Huntington's disease, and amyotrophic lateral sclerosis. Thus, inhibition of PSMA potentially confers neuroprotection both by reducing glutamate and increasing –NAAG and has been shown to provide neuroprotection in cell culture and/or animal models of ischemia, diabetic neuropathy, drug abuse, chronic pain, and amyotrophic lateral sclerosis.

Does PSMA have a Signaling Function?

PSMA's structural similarities with the transferrin receptor, its homodimeric membrane form, and its selective expression on tumor endothelial cells have raised questions whether PSMA may have a ►signal transduction functionality in addition to its carboxypeptidase activity. Inhibition of PSMA activity in cell culture or in subcutaneously implanted PSMA expressing xenografts does not lead to inhibition of growth. However, Ghosh et al. demonstrated that ectopic expression of PSMA in human prostate cancer cells reduced the invasiveness of these cells while knockdown of PSMA expression or expression of mutant PSMA lacking carboxypeptidase function increased invasiveness. Thus, this study suggested that the enzymatic activity of PSMA is somehow associated with pathways involved in promoting invasiveness.

The cytoplasmic tail of PSMA interacts with the actin binding anchor protein Filamin a (FLNa) and this association appears necessary for PSMA localization to the recycling endosomal compartment. PSMA also binds to ►caveolin-1 in human microvascular endothelial cells and undergoes internalization via a caveolae-dependent mechanism. These associations suggest a link between PSMA at the cell surface, internalization, and downstream signaling processes. ►Angiogenesis is severely impaired in PSMA-null animals and this angiogenic defect occurs at the level of endothelial cell invasion through the extracellular matrix barrier. PSMA is a principal component of a regulatory loop that modulates ►laminin-specific integrin signaling and GTPase-dependent, p21-activated kinase 1 (PAK-1) activity. PSMA inhibition, knockdown, or deficiency decreased endothelial cell invasion in vitro via ►integrin and PAK whereas inactivation of PAK increased PSMA activity. This negative regulation appeared to be mediated by the cytoskeleton as the disruption of interactions between the PSMA cytoplasmic tail and FLNa decreased PSMA activity, integrin function, and PAK activation, while the inhibition of PAK activation enhances the PSMA–FLNa interaction and increased PSMA activity. These data suggest a model whereby PSMA participates in an autoregulatory loop, in which active PSMA facilitates integrin signaling and PAK activation, leading to both productive invasion and downregulation of integrin beta(1) signaling via reduced PSMA activity. While enzymatically active PSMA appeared necessary for this signaling, the role of PSMA hydrolysis of its putative ligands was not addressed in this study.

PSMA and Imaging

In contrast to other prostate-related antigens such as PSA, prostatic acid phosphatase, and prostate secretory protein, PSMA is a type II integral membrane cell surface protein that is not secreted and, therefore, is an excellent target for monoclonal antibody (mAb)-based imaging and therapy. PSMA is constitutively internalized, but internalization is also induced by antibody binding (). Initial validation of PSMA as an in vivo mAb target has been demonstrated by imaging trials with mAb 7E11/CYT-356 (marketed as ProstaScint, Cytogen, Princeton, New Jersey) an FDA approved imaging agent. 7 However, molecular mapping indicates that mAb 7E11/CYT-356 targets an intracellular portion of the PSMA molecule not exposed on the outer cell surface. Since the 7E11/CYT-356 epitope is within the cell, the mAb does not bind viable cells.

ProstaScint has met with limited success in the clinic. ProstaScint scans are considerably less sensitive than bone scans at detecting bone disease. Since >80% of prostate cancer patients have metastatic disease in the bone, ProstaScint is not used routinely in the clinical evaluation of these patients. Thus, the only patients in whom clinically useful information is derived from a ProstaScint scan may be those in whom regional and/or systemic disease is demonstrated, and where a biopsy or other modality could confirm the findings were not a false-positive result. Given these limitations, the ProstaScint scan has not been used to any significant degree by clinicians in the work up of patients with suspected recurrent prostate cancer outside of the prostatic fossa.

The recognition that ProstaScint recognizes an internal epitope of PSMA led to the development of a series of monoclonal antibodies to extracellular epitopes of PSMA that could bind to both intact and permeabilized cells. Researchers at Cornell University, led by Dr. Neil Bander, developed four IgG mAbs (J591, J415, J533 and E99) to the extracellular domain of PSMA. These antibodies demonstrated high affinity binding to prostate cancer cells in tissue culture, on tissue sections and in animal models in vivo 9,11. Moreover, once bound, PSMA antibody complexes were shown to be rapidly internalized with intracellular accumulation of Ab, resulting in the potential internalization of toxins or isotopes conjugated to the mAb. Clinical studies using humanized antibody (HuJ591) labeled with ^{111}In, ^{90}Y and ^{177}Lu confirmed that mAb HuJ591 targeted and could image PSMA expressing human prostate cancer xenografts. Subsequently, several clinical studies have been performed evaluating efficacy of labeled humanized mAb to PSMA. ^{111}In-DOTA-huJ591 was tested in phase I trial with tumor visualization seen in both soft tissue and bone metastases. Additional phase I trials have been performed with ^{90}Y and ^{177}Lu DOTA-huJ591 conjugate and demonstrated excellent imaging capabilities with detection of >95% of bone metastases. A few PSA responses were observed in these trials. With all three radiolabeled approaches, significant nonspecific accumulation of antibody uptake was observed in the liver and kidney in all studies. In each study, the dose-limiting toxicity has been myelosuppression, particularly thrombocytopenia, which was most likely due to the long plasma half-lives of these antibodies. However, despite the theoretical advantage of targeting an extracellular PSMA epitope, a report describing initial experience with a technetium-99m-labeled J591 antibody found decidedly inferior prostate cancer imaging relative to ProstaScint.

Encouraging results were reported using 11C or 125 I radiolabeled urea derivatives that have high affinity for PSMA to image in experimental models of prostate cancer in vivo. These low molecular weight compounds offer potential advantages over antibody-based imaging that include better tissue penetration, higher specificity, and shorter half-life.

PSMA as a Therapeutic Target

The demonstration of PSMA expression by tumor vasculature, high expression in prostate cancer, and upregulation in androgen ablated patients have made PSMA an attractive therapeutic target. Current targeting strategies include ►immunotoxin conjugates, ►cancer vaccines, PSMA inhibitor–drug conjugates, and PSMA-activated prodrugs/protoxins. As described, ►radioimmunotherapy using the antiPSMA mAb coupled to radionuclides like ^{90}Y and ^{177}Lu has been tested in clinical trials. PSMA-based ►monoclonal antibody therapy using the J591 antibody coupled to maytansinoid, a highly potent microtubule depolymerizing natural product (MLN2704) has been tested clinically. This agent showed antitumor response against PSMA producing human prostate cancer xenografts and has been evaluated in a phase I trial in 23 patients. Overall, MLN2704 was well tolerated in the majority of patients and two patients had a >50% decline in PSA from baseline. Further studies with this antibody–toxin conjugate are anticipated. In addition, a number of groups have described PSMA-based vaccine strategies that range from PSMA-primed dendritic cells to injection of naked human and mouse DNA.

Since PSMA is a carboxypeptidase, a large number of PSMA inhibitors have been generated. While these inhibitors show some promise in neurologic diseases, to date no antitumor effect from direct inhibition of PSMA has been reported. However, strategies involving coupling of PSMA inhibitors or PSMA-binding moieties such as ►aptamer bioconjugates or peptides to cytotoxic agents are under exploration. Prodrug and protoxin strategies attempt to take advantage of the unique enzymatic activities of PSMA to selectively

activate cytotoxic agents within the peritumoral extracellular fluid surrounding PSMA producing cells. Unlike antibody and other PSMA-binding strategies, an advantaged of this ►targeted drug delivery approach is that drug/toxin release in the extracellular fluid is amplified by PSMA's activity. In addition, since every cell does not need to produce PSMA to be killed this approach overcomes potential resistance based on heterogeneous expression of PSMA while, at the same time, producing a substantial bystander effect. Finally, PSMA targeted cytotoxins may also function as ►vascular disrupting agents and have therapeutic potential against a variety of solid tumor types expressing PSMA in the neovasculature.

Protease Activated Receptor Family

Villares GJ, Zigler M, Bar-Eli Menashe
Department of Cancer Biology, The University of Texas, M.D. Anderson Cancer Center, Houston, TX, USA

Definition

The Protease Activated Receptors (PARs) are a group of seven transmembrane ►G protein-coupled receptors with a unique mechanism of activation. Most receptors are activated when the ligand binds to the ligand binding domain of that receptor. However, the different ►serine protease ligands that activate PAR will cleave the N-terminus of the receptor. This results in the formation of a new N-terminus peptide which acts as a tethered ligand that will now bind to the activation site of the receptor and cause irreversible activation of PAR (Fig. 1).

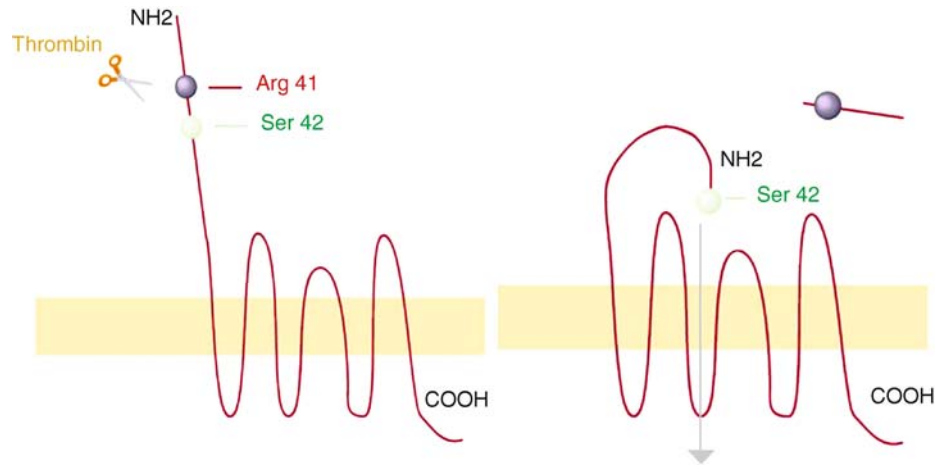
Characteristics

To date, there are four members of the PAR family that have been identified. PAR-1, PAR-3 and PAR-4 are activated by thrombin although other proteases can cleave these receptors. PAR-2 is activated by trypsin like proteases including trypsin and tryptase. Studies on PARs have been performed most extensively with PAR-1 and to a lesser degree with PAR-2. However, the role and importance of PAR-3 and PAR-4 have yet to be fully understood in cancer. Therefore, only the role of PAR-1 and PAR-2 in cancer will be discussed.

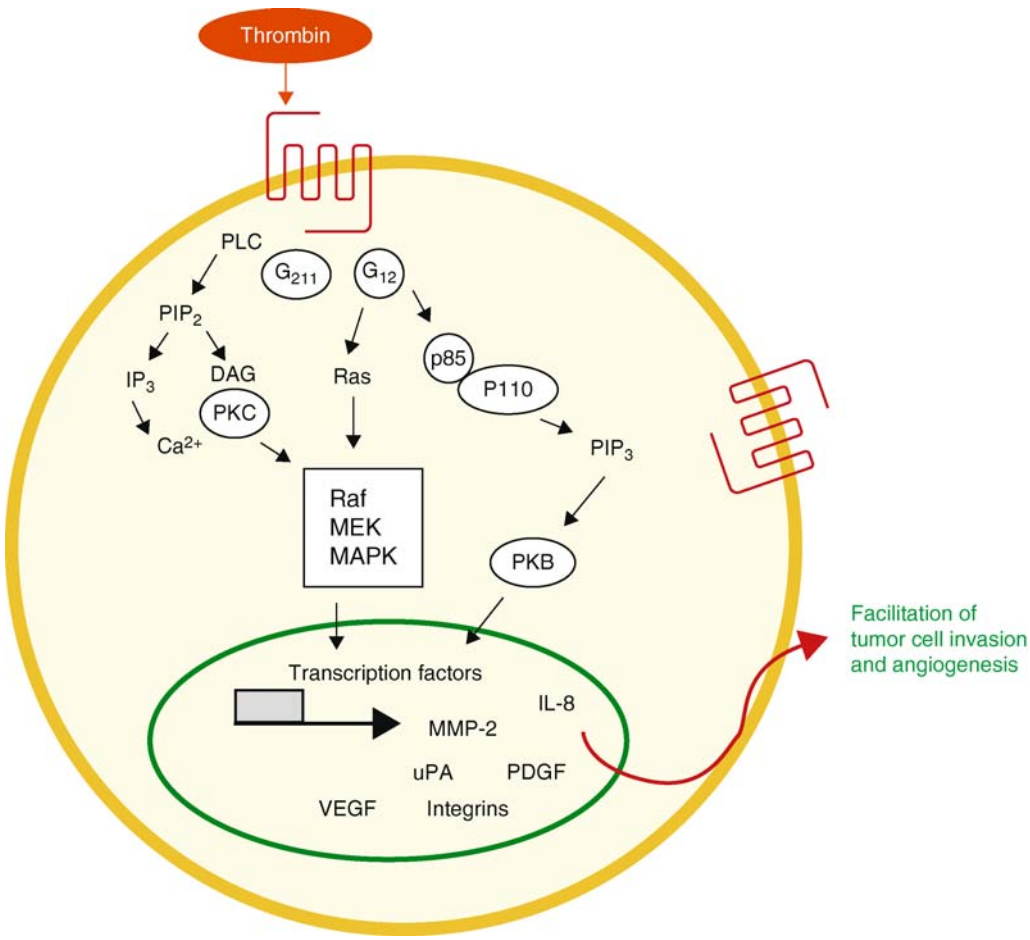
PAR-1: PAR-1, also known as the thrombin receptor, was the first family member to be discovered. It is expressed on a wide variety of cells including endothelial, epithelial, T-cells, astrocytes, neurons and platelets. It can be activated by thrombin as well as coagulation factor Xa, ►granzyme A, trypsin and ►matrix metalloprotease 1 (MMP-1) although thrombin is the most potent activator. The role of PAR-1 in platelet aggregation and degranulation has been extensively studied. In cancer, studies have shown that activation of coagulation factors, including thrombin, ►tissue factor and ►fibrinogen, is a common occurrence. In fact, activation of PAR-1 leads to induction of G proteins that trigger various downstream molecules and signal transduction pathways such as Rho kinase, phosphoinositol-3-kinase (PI3-K) and ►mitogen-activated protein kinases (MAPK), which have been shown to be involved in cell growth, tumor promotion and carcinogenesis. Activation of PAR-1 has also been implicated in secretion of many factors involved in angiogenesis and tumor cell invasion such as interleukin 8 (IL-8), vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), urokinase plasminogen activator (uPA), and MMP-2 (Fig. 2).

Therefore the thrombin receptor has been implicated in tumorigenesis and metastasis of several human cancers including melanoma, breast, prostate, pancreatic, lung and colon carcinomas among others.

PAR-2 is the second member of the PAR family to be discovered. Similar to other PAR family members, activation of PAR-2 occurs through the cleavage of the extracellular domain which forms a tethered ligand followed by downstream signaling. In contrast to other PAR family members, PAR-2 is activated mostly by trypsin which is the most potent protease, as well as by other trypsin-like proteases such as tryptase and factor Xa. PAR-2 can also be activated by PAR-1 and therefore, indirectly by thrombin. Data also suggests that the tethered ligand domain from activated PAR-1 can trans-activate PAR-2 when both receptors are present on cells in close proximity to one another as occurs on endothelial cells. This trans-activation of PAR-2 might enhance the response of cells to thrombin. In addition, tissue factor (TF) which has been found to be activated in cancer, can indirectly activate PAR-2



Protease Activated Receptor Family. Figure 1 PAR-1 is cleaved by proteases such as thrombin at Ser 41 resulting in formation of a new N-terminus pepide. This tethered ligand binds to the activation site of PAR-1 causing its activation and downstream signaling.



Protease Activated Receptor Family. Figure 2 Schematic of cell invasion and angiogenic molecules involved in tumor progression via activation of PAR-1 in melanoma cells. The tumor-promoting signals transduced by PAR-1 through G proteins upregulate molecules involved in invasion and angiogenesis, including uPA, IL-8, VEGF, PDGF, MMP-2, and integrins.

through components of the coagulation cascade. TF binds factor VIIa which can either directly activate PAR-2 or cause activation of factor X thereby mediating cleavage of PAR-2. Another manner of activation of this receptor is mediated through membrane type serine protease-1(MT-SP1), an enzyme which has been found on tissues that also express PAR-2. MT-SP1 can directly cleave PAR-2 thereby causing its activation.

PAR-2 activation induces the release of IL-6 and IL-8, granulocyte macrophage-colony stimulating factor, prostaglandins and intracellular calcium mobilization. In fact, it has been suggested that trypsin and PAR-2 act in an autocrine loop to activate signal transduction pathways, promoting cell proliferation invasion and metastasis. *In-vitro* studies have shown that activation of PAR-2 causes an induction of different signaling pathways that induce proliferation, migration, invasion and metastasis. PAR-2 also contributes to reorganization of the cytoskeleton in a different manner than PAR-1 thereby elucidating different functions of these two receptors in cell migration. PAR-2 is also involved in integrin activation by promoting integrin $\alpha_5\beta_1$ dependent cell adhesion.

PAR-2 is highly expressed in different tissues such as colon, liver, pancreas, stomach and small intestine. It is also expressed in a wide variety of cells such as endothelial cells, T cells, smooth muscle cells and surface epithelial cells. Both PAR-1 and PAR-2 are expressed in tumor cells and in the tumor microenvironment and contribute to tumorigenisis and metastasis. PAR-2 is expressed in tumors such as lung, colon, pancreas, stomach and melanoma. However, the role of PAR-2 in cancer has not been completely elucidated.

Melanoma

In human melanoma cells, thrombin acts as a growth factor and is ►mitogenic, suggesting that signaling by PAR-1 is involved in the biological response of these cells. Thrombin sources not only include systemic activation of coagulation factors seen in many cancer types but also several studies have shown that tissue factor can be expressed independent of the coagulation pathway in malignant melanoma cells thereby activating thrombin. Furthermore, fibrin deposits are formed from the cleavage of fibrinogen by thrombin. These fibrin deposits in the stromal microenvironment surrounding tumor cells may store active thrombin that is released when the clots undergo degradation.

PAR-1 has been found to be differentially expressed within human melanoma cell lines. Highly metastatic melanoma cells have over-expression of PAR-1 mRNA, while non-metastatic melanoma cells have lower levels. Over-expression of the thrombin receptor has also recently been found in clinical specimens of invasive melanoma and metastases as compared to levels found in ►common melanocytic nevi and normal skin. *In-vitro* studies have shown that when PAR-1 expression is induced in non-metastatic melanoma cells that normally have low levels of PAR-1, they acquire a more invasive and aggressive phenotype. Furthermore, there is evidence that demonstrates a physiological role for PAR-1 in the melanoma metastatic cascade where PAR-1 was the rate limiting factor in an experimental murine lung metastasis assay.

It has been recently proposed that in highly metastatic melanoma cell lines, cell migration requires activation of PAR-Z, in addition to PAR-1, and results in enhanced metastasis by promoting cell motility. *In-vivo* experiments demonstrated that PAR-2 activation by trypsin or by agonist peptide in highly metastatic melanoma cell lines have more lung metastasis as compared to those cells not exposed to these agonists.

Breast Cancer

The levels of PAR-1 expression on tumor cells directly correlates with the degree of invasiveness and therefore metastatic potential in both primary breast carcinomas and established breast cancer cell lines. The more metastatic breast cancer cell lines expressed very high levels of PAR-1, while the minimally invasive lines showed minimal expression of PAR-1. In human specimens, high grade ductal carcinoma in-situ (DCIS) showed expression of the thrombin receptor while the highest levels of PAR-1 were found in infiltrating ductal carcinoma. In contrast, undetectable levels of PAR-1 were found in low grade DCIS and normal breast tissue. *In-vitro* studies revealed increased levels of migration and invasion in a null PAR-1 breast cancer cell line transfected with PAR-1. These cells expressing PAR-1 were examined in a mouse ►xenograft model for human breast cancer which showed increased tumor growth and invasion in nude mice. Recent findings have demonstrated that MMP-1, a collagenase of the MMP family, which is found in the stromal tumor microenvironment, is an additional proteolytic activator of PAR-1 promoting invasion and tumorigenesis of breast cancer cells.

A new study on breast cancer suggests that PAR-2 has a significant role in induction of migration and invasion. In this study, an invasive breast cancer cell line transfected with PAR-2 siRNA showed a decrease in both migration and invasion comparable to cells that were transfected with PAR-1 siRNA.

Prostate Cancer

PAR-1 expression has been found in prostate cancer cell lines. Over-expression in highly invasive prostate cancer cell lines correlates with increased metastatic potential. Recently clinical specimens were analyzed for expression of PAR-1. Advanced stage prostate cancer tissue specimens had significantly higher expression of PAR-1 as compared with tissue from early stage patients. PAR-1 expression of the activated

receptor in the vasculature from benign prostatic hyperplasia (BPH) tissue was also compared with early stage and advanced stage prostate cancer specimens. BPH tissue showed very low expression of PAR-1 with the most expression being found in advanced stage prostate cancer specimens. Early stage cancer also showed positive expression of the thrombin receptor but less than advanced stage cancer. Furthermore, prostate cells from bone metastases have higher expression of PAR-1 than those from soft tissue metastasis. Bone metastasis from prostate cancer is a common feature of prostate cancer and a significant cause of morbidity. These data suggest that PAR-1 plays a pivotal role in the progression of prostate cancer.

Pancreatic Cancer

In-vitro studies have shown that pancreatic cancer cell lines express PAR-1 while no expression is seen in normal pancreatic epithelial cells. Higher levels of PAR-1 mRNA were seen in pancreatic cancer tissue samples as compared to healthy pancreas which suggests that PAR-1 could play a key role in the pathogenesis of pancreatic cancer.

PAR-2 might play a unique role in pancreatic cancer since the pancreas is a major site of production of the trypsin ►zymogen (trypsinogen) by the ►acinar cells. Studies have also proposed that it is produced by pancreatic cancer cells. It has been shown that PAR-2 is highly expressed in the pancreas and in pancreatic ductal carcinoma. *In vitro* studies suggest that trypsin might act as a stimulating growth factor in pancreatic cancer cells expressing PAR-2 thereby inducing proliferation and invasion. Examination of pancreatic cancer tissues, have shown that in tissues with infiltrative growth patterns, PAR-2 expression was higher than in tissues with expansive growth patterns. Moreover, a correlation between fibrosis, which is one of the characteristics of human pancreatic tumors that is linked to poor prognosis and high expression of PAR-2, exists in pancreatic tumors. Therefore, PAR-2 might also be involved in induction of fibrosis.

Lung Cancer

PAR-1 is highly expressed in the lung alveolar wall tissue of patients with lung adenocarcinoma when compared to those tissues without neoplastic cells. In a recent study, more than half of all specimens of non-small-cell lung cancer (NSCLC) patients also showed over expression of PAR-1. A higher and more uniform expression of the receptor was detected in aggressive tumors as compared to those with a more favorable outcome. In fact, the 3 year survival for patients expressing PAR-1 was significantly shorter than those with no expression of PAR-1. These data suggest that PAR-1 might represent a new prognostic factor in NSCLC patients.

Colon Cancer

PAR-1 has also been found to be expressed in human colon cancer cell lines and clinical specimens but is absent in epithelial cells from normal human colon. It is present in dysplastic mucosa and cancer mucosal tissues but not in the adjacent normal mucosa. *In-vitro* studies revealed that thrombin can act as a growth factor for colon cancer cells. Thrombin induces cell migration and proliferation of human colon cancer cells through PAR-1 in a similar manner seen with a PAR-1 agonist. This effect in part is due to the activation of the MAPK pathway by thrombin and its receptor.

In colorectal cancers (CRC), PAR-2 has been shown to be over expressed and its activation may promote both tumor progression and metastasis. It has been shown that in a colon carcinoma cell line, PAR-2 activation results in cell proliferation. Upon proteolysis of PAR-2 by trypsin, a signal transduction pathway is activated by the phosphorylation of MEK1/2 and ERK1/2 leading to proliferative response. This might indicate a significant role of MAPK pathway activation through PAR-2 in CRC. Furthermore, activation of PAR-2 can lead to activation of MMPs which promotes invasion and metastasis. MMP activation causes release of TGF-α which triggers activation and phosphorylation of EGFR, promoting proliferation.
